100 World Health Organization Classification of Hematologic Malignancies*

Elaine S. Jaffe

SUMMARY OF KEY POINTS

- The World Health Organization (WHO) Classification includes tumors of lymphoid, myeloid, histiocytic, and dendritic cell lineages.
- Each disease is defined as a distinct entity based on a constellation of morphological, clinical, and biological features.
- The cell of origin is the starting point of disease definition.
- Some lymphomas and leukemias can be identified by routine morphological approaches. However, for many diseases, knowledge of the immunophenotype and molecular genetics/cytogenetics plays an important role in differential diagnosis.
- The sites of presentation and involvement are an important clue to underlying biological distinctions. Extranodal lymphomas differ in many respects from their nodal counterparts.
- Many lymphoma entities display a range in cytological grade and clinical aggressiveness, making it difficult to stratify lymphomas according to clinical behavior. Several prognostic factors influence clinical outcome, including stage, international prognostic index, cytological grade, gene expression profile, secondary genetic events, and the host environment.
- The WHO classification includes four major categories of myeloid diseases, all of which are clonal stem cell disorders leading to either effective or ineffective hematopoiesis:
  - Myeloproliferative neoplasms
  - Myelodysplastic/myeloproliferative neoplasms
  - Myelodysplastic syndromes
  - Acute myeloid leukemias (AMLs)
- Among myeloid leukemias, genetic features predict behavior better than morphology alone, necessitating genetic studies for accurate diagnosis.
- AMLs, with myelodysplasia-related features, seem to represent separate pathways to leukemogenesis, with clinical implications for response to therapy.

INTRODUCTION

In recent years the discipline of hematopathology has emphasized the integration of morphology and biological markers for diagnosis. In this respect the approaches used in hematological diagnosis often have served as a model for other areas of pathology. For example, in the early 1980s detection of rearrangements of the antigen receptor genes in lymphoid cells was used to indicate both clonality and cell lineage, long before molecular diagnostic techniques became commonplace in pathology.[1] Biological approaches such as immunohistochemistry and molecular biology enhance diagnostic accuracy and play a critical role in the definition of disease entities.

Classification approaches for both lymphoid and myeloid neoplasms have undergone significant reappraisal over the past 40 years. These changes have resulted from insights gained through the application of immunological and molecular techniques, as well as better understanding of the clinical aspects of lymphoma and leukemia through advances in diagnosis, staging, and treatment.

HISTORICAL BACKGROUND

The classification of lymphomas in the past was controversial, and it had been difficult to establish an internationally accepted scheme. The earliest classification schemes were morphologically based on cytological and architectural features.[2] However, insights into the complexities of the normal immune system led to attempts to relate the lymphomas to their normal cellular counterparts. In the 1970s several European and American groups published proposals for the classification of lymphoma, and competing classification systems in use in clinical studies made it difficult to compare outcome data from different treatment centers.[3–6] The inability of the pathologists to develop consensus and agree on a common approach led to the development of the Working Formulation for the non-Hodgkin's lymphomas, following a National Cancer Institute–directed study to evaluate the six published schemes.[7]

Constructed in large measure by clinicians, the working formulation tried to stratify lymphomas according to clinical outcome on the basis of clinical trials conducted in the 1970s.[7] The low-grade, intermediate-grade, and high-grade groupings were intended to provide a clinical guide for patient management. The individual lymphoma categories were defined by morphological principles, such as growth pattern and cell size, without regard to cell lineage or stage of differentiation. Therefore, most of the diagnostic categories of the working formulation were heterogeneous. For example, "diffuse mixed small and large cell lymphoma" included a variety of both B-cell and T-cell lymphomas. It is therefore not surprising that pathologists could not use these categories reproducibly.[8]

The original intent of the working formulation proposal was to have it serve as a common language to translate among classifications, and not to serve as a freestanding classification scheme. However, because it was a convenient guide to therapy, it quickly became popular among clinicians and was adopted for use in many centers in the United States for clinical trials. In reality the working formu-

*This chapter is in the public domain.

lation was in essence the Rappaport classification[2] with updated terminology from Lukes and Collins.[3] It substituted the term "large cell" for "histiocytic" and divided the "histiocytic" lymphomas of the Rappaport scheme into two subgroups: large cell (cleaved or noncleaved) and large cell immunoblastic. This separation split the diffuse large cell lymphomas into two different treatment groups (intermediate and high grade), solely on the basis of morphological distinctions. These distinctions were not reproducible, and the clinical groupings could not be validated.

Another more basic flaw in the working formulation is that it was based on treatment outcome, not on the recognition of individual disease entities or the cell of origin for a malignant neoplasm. It lumped diseases that shared a similar cell size and median survival into single categories, even though they might be of different cellular (B- and T-cell) origins with diverse clinical features. At the time the working formulation was proposed immunophenotyping was believed to be beyond the reach of the routine pathology laboratory, and the classification was based on morphology alone.

A similar paradigm developed in the classification of acute myeloid and lymphoid leukemias. Earlier classification systems emphasized morphological approaches, although the French American and British (FAB) classification did use enzyme cytochemistry to identify cellular lineage and degree of differentiation, at least within the myeloid and monocytic neoplasms.[9] The categories of acute lymphoblastic leukemia, L1, L2, and L3 included both mature and immature lymphoid malignancies, in that L3 was largely composed of mature blastic B cells similar to the cells of Burkitt's lymphoma. L1 and L2, though both of lymphoblastic origin, correlated poorly with precursor T- or B-cell lineage.

Modern immunophenotypic and molecular approaches for characterizing lymphoid and myeloid cells are now readily available at even the community hospital level. The use of these new biological approaches has transformed our understanding of hematological neoplasia. Immunophenotypic, cytogenetic, and genotypic studies have permitted an impartial analysis of questions that were unresolved when addressed with only routinely stained sections or smears. Indeed, a broad international consensus has emerged on many topics. This consensus was embodied in the Revised European-American Classification of Lymphoid Neoplasms (REAL classification) published by the International Lymphoma Study Group (ILSG) in 1994,[10] and broadened to include myeloid and histiocytic neoplasms in the WHO classification.[11]

NEXT STEPS: FROM REVISED EUROPEAN-AMERICAN CLASSIFICATION OF LYMPHOID NEOPLASMS TO WORLD HEALTH ORGANIZATION CLASSIFICATION

The REAL classification[10] and its successor the WHO classification[11] represented a new paradigm in the classification of lymphoid neoplasms. The focus was on the identification of "real" diseases, rather than a global theoretical framework, such as survival (working formulation), or cellular differentiation (Kiel classification). The REAL classification was based on the building of consensus, recognizing that a comprehensive classification system was beyond the experience of any one individual. The 19 members of the ILSG contributed their diverse perspectives to achieve a unified point of view. In addition, the ILSG made the decision to base the classification exclusively on published data. Earlier classification systems had often been based on theoretical and untested propositions. However, to be included in the REAL classification, an entity had to be validated in at least several publications. In addition, several entities were listed as provisional, on the basis of more limited published data.

The REAL classification departed from traditional schemes by emphasizing that each disease was a distinct entity, defined by a constellation of laboratory and clinical features (i.e., morphology, immunophenotype, genetic features, clinical presentation, and course). The inclusion of clinical criteria was one of the most novel aspects of the ILSG approach. The REAL classification recognized that the site of presentation is often a signpost for underlying biological distinctions, as in extranodal lymphomas of the mucosal-associated lymphoid tissues (MALT)[12] or many forms of T-cell lymphoma.[13,14] Accurate diagnosis requires knowledge of the clinical history, because biologically distinct entities may appear cytologically similar.

The REAL classification also stressed the distinction between histological grade and clinical aggressiveness, because these concepts do not necessarily go hand in hand. For example, mantle cell lymphoma, which is composed of small to medium-sized lymphoid cells with condensed chromatin, had been considered cytologically "low grade," but in fact is one of the more aggressive lymphoma subtypes.[15,16] Similarly, among the T-cell lymphomas, angioimmunoblastic T-cell lymphoma has an aggressive clinical course, with a median survival of less than 3 years.[17] By contrast, anaplastic large cell lymphoma, despite the appearance of high histological grade, in the majority of patients has an excellent response to chemotherapy with prolonged disease-free survival.[18]

Moreover, within a given disease entity several prognostic factors influence the clinical outcome. Cytologic grade is one type of prognostic factor and is used in the stratification of follicular lymphoma. Clinical features, such as the stage or international prognostic index, also markedly affect survival and response to treatment.[19] Finally, a variety of biological factors, some of which may be secondary, affect the prognosis. These include secondary genetic events, such as mutations in p53 genes, which often lead to histological and clinical progression.[20–22] Thus, the WHO classification stresses the distinction between a *disease entity* and a *prognostic factor*.

For these reasons it is not possible to stratify lymphoma subtypes according to clinical grade, as had been attempted in the working formulation. Moreover, clinical groupings for either protocol treatment or routine clinical practice are generally not feasible. In evaluating new therapies the data for each disease must be evaluated individually. Indeed, treatment approaches for one type of lymphoid malignancy are not necessarily applicable to other diseases, even of the same cell lineage. This point is exemplified by hairy cell leukemia, a rare disease for which highly effective forms of therapy have been developed.[23,24] However, the purine analogues 2′-deoxycoformycin and 2′-chlorodeoxyadenosine have not been similarly effective in treating other B-cell leukemias and lymphomas.[25]

The REAL classification was first to emphasize the importance of molecular oncology in defining disease entities. Cancer is increasingly recognized as a genetic disease.[26] For many lymphomas there is a good correlation between the molecular pathogenesis and routine histological and immunophenotypic features. For example, the t(14;18) involving the *BCL-2* and *JH* genes is highly associated with follicular lymphoma diagnosed by routine methods. In addition, some molecular phenotypes can be recognized by immunohistochemistry, such as cyclin D1 overexpression in the diagnosis of mantle cell lymphoma, or ALK fusion protein expression in anaplastic large cell lymphoma.[27]

However, for many lymphoma subtypes, particularly the mature T-cell malignancies, the molecular pathogenesis is not known. The REAL/WHO classifications recognized limitations in our knowledge, and created "generic groupings" for those broad categories of disease that could not be resolved with existing data; these include diffuse large B-cell lymphomas and peripheral T-cell lymphomas, unspecified. Although several morphological variants had been described, evidence that these delineated distinct biological or clinical entities was lacking.

Following the publication of the REAL classification, an international study directed by Dr. James Armitage sought to determine if the REAL classification could be readily applied by a group of independent expert pathologists.[18] Other goals of the International Lym-

phoma Classification Project were: (1) to determine the role of immunophenotyping and clinical data in the diagnosis of disease entities; (2) to determine both intraobserver and interobserver reproducibility in the diagnosis of the various entities; (3) to further investigate the clinical features and/or epidemiology of the various entities; and (4) to determine if clinical groupings would be practical or useful for clinical trials or practice.

The conclusions of that study affirmed the principles of the REAL classification.[18] The use of precise disease definitions, as provided by the REAL scheme, enhanced diagnostic accuracy and reduced interobserver variability. The significance of identifying individual disease entities was confirmed by overall survival and failure-free survival data.

This study also highlighted the importance of clinical factors in predicting outcome, beyond the diagnosis alone.[19] Therefore, one must approach each disease entity individually, considering the diagnosis, the patient's risk factors, and the known idiosyncrasies of each disease with regard to treatment.

WORLD HEALTH ORGANIZATION CLASSIFICATION

Precise disease definitions have also facilitated the discovery of the molecular pathogenesis of lymphomas and leukemias. Many pathogenetic insights have followed on the heels of the identification of a disease along clinical lines (Table 100-1). Moreover, advances in therapy are best achieved when studies are conducted on a homogeneous disease entity. For example, the approaches to therapy of extranodal marginal B-cell lymphoma of MALT type differ from those of more systemic small B-cell malignancies. The ultimate goal in this model is molecularly targeted therapy, such as the use of imatinib to target the *BCR/ABL* tyrosine kinase of chronic myelogenous leukemia.[28]

In 2001 the International Agency for Research on Cancer (IARC) under the auspices of the WHO published a unified and internationally accepted classification scheme for all lymphoid, myeloid, histiocytic, and dendritic cell neoplasms (Box 100-1).[11] Part of series by the IARC, a goal is to integrate pathology and genetics to develop biologically relevant classification systems. The WHO adopted the approach of the REAL classification for the lymphoid malignancies, because this approach had been validated, and in turn applied the same principles to tumors of other hematopoietic lineages, mainly myeloid and histiocytic tumors.

Continued advances in disease definition have led to refinements in diagnostic categories. For example, "Hodgkin's-like anaplastic large cell lymphoma"[29,30] was believed upon further analysis to be resolvable into either an aggressive form of Hodgkin's disease or a rare variant of T-null anaplastic large cell lymphoma in most cases.[31] It was therefore eliminated as a category in the WHO scheme.

Table 100-1 Pathogenetic Insights Based on a Disease-Oriented Approach to Classification

Disease	Characteristic Findings
Adult T-cell leukemia/lymphoma	HTLV-1
Nasal NK/T-cell lymphoma	EBV, genetics
Anaplastic large cell lymphoma	*ALK* tyrosine kinase
Mantle cell lymphoma	*CCND1*
Lymphomatoid granulomatosis	EBV, immune dysfunction
Follicular lymphoma	*BCL2*
MALT lymphoma	*Helicobacter, MLT*
Burkitt's lymphoma	*C-MYC*
Primary effusion lymphoma	Herpesvirus-8

Molecular profiling studies are leading to better delineation of aggressive B-cell lymphomas.[32,33] For example, gene expression profiling studies identified two broad categories of diffuse large B-cell lymphoma (DLBCL); one group resembling germinal center B cells (GCBs) and a second group resembling activated peripheral blood B cells (ABCs). Furthermore, these studies are providing insights into the molecular pathways that are primarily deregulated in these tumors. For example, the ABC type of DLBCL is associated with activation of the NF-κB pathway. The host response and the tumor microenvironment have also been shown to be important in predicting outcome.[32,34] In follicular lymphoma as well the microenvironment within the neoplastic follicle seems to represent a major prognostic factor, independent of cytological grade.[35]

Additionally, stratification according to genetic and genomic profiling is beginning to have an impact on clinical practice. For example, DLBCLs of the ABC type show a significant benefit from the inclusion of rituximab in the treatment regimen, whereas DLBCLs of the GCB cell type do not.[36]

Finally, tumors that were thought to be distinct, such as classical Hodgkin's lymphoma and primary mediastinal large B-cell lymphoma have been shown through molecular approaches to share common pathways of activation and/or deregulation.[37,38] These genomic insights have also helped elucidate the nature of lymphomas that seem to bridge the gap between classical Hodgkin's lymphoma and mediastinal lymphoma, so-called gray zone lymphomas.[39] Indeed, composite, sequential, and gray zone lymphomas are observed with some regularity.[40]

The WHO classification applied the principles of the REAL classification to the classification of myeloid and histiocytic tumors, and expanded upon the classification of precursor lymphoid malignancies, the lymphoblastic lymphomas/leukemias, which had been touched upon only briefly in the REAL classification. For the acute leukemias the molecular pathogenesis is a very important determinant of clinical behavior. Unfortunately, in contrast to the lymphomas, correlations between the genetic profile, morphology, and the immuno/enzymatic phenotype are frequently absent, and for some prognostically important categories, genetic studies are essential.[41,42] Additionally, acute leukemias, being of stem cell origin, display significant lineage promiscuity at the genetic and phenotypic levels. The WHO classification for myeloid neoplasms departed from the FAB classification in several ways. For those forms of acute myeloid leukemia (AML) associated with recurrent genetic abnormalities, genetic features take precedence over morphology. However, some genetic lesions are associated with a characteristic morphological appearance.[43] For example, the detection of the inv(16) or t(16;16) usually correlates with M4 with abnormal eosinophils in the FAB approach.[44] Recurrent genetic abnormalities can be identified with classical cytogenetics, reverse transcriptase–polymerase chain reaction, or fluorescence in situ hybridization techniques.

On the basis of the observation that AML arising in the setting of myelodysplastic syndrome (MDS) is associated with some distinctive clinical and biological features, the WHO classification of 2001 distinguished two broad groups of de novo AML, with and without multilineage dysplasia.[45–47] Cases of AML with significant myelodysplastic features generally occur at an older age, respond poorly to therapy, and have high-risk cytogenetic features.[43] These criteria are modified slightly in the WHO classification of 2008, identifying AML with myelodysplasia-related features. AML arising in the setting of a MDS is distinguished from AML with multilineage dysplasia.

The WHO classification recognizes two forms of AML that occur secondary to iatrogenic therapy, with those related to alkylating agent therapy being distinguished from those associated with topoisomerase II inhibitor therapy. AML following alkylating agent therapy or radiation therapy closely resembles AML with multilineage dysplasia, and many of these patients have antecedent MDS.[48] The interval to

*These represent provisional entities or provisional subtypes of other neoplasms. They are provisional because either there is insufficient data to support their being a definite entity, significant controversies about their defining features and/or uncertainty about whether they are unique or closely related to other definite entities. Further classify according to lymphoma they resemble.

From World Health Organization: World Health Organization Classification of the Tumors of the Hematopoietic and Lymphoid Tissues. Geneva, World Health Organization, 2008 (in press).

diagnosis is generally long, and the response to therapy poor. The acute leukemias associated with topoisomerase II inhibitor therapy occur after a shorter interval, do not have associated MDS, frequently contain a prominent monocytic component, and have characteristic translocations. These patients have a response to therapy similar to other de novo cases of AML with comparable cytogenetic features.[43]

AML without recurrent cytogenetic abnormalities is subclassified according to lineage and stage of differentiation. The concept is to provide a broad framework for the classification of these disorders so as to facilitate future studies regarding the pathogenesis. Some new insights have emerged, and it is likely that future studies will further refine this broad category. For example, a significant fraction of AML without recurrent karyotypic abnormalities is found to have mutations in *NPM1*, the nucleophosmin gene.[49] These mutations are found in cases of AML across all FAB lineage-related categories.[50] It has been suggested that this category is associated with a better response to therapy. Gene expression profiling has also been used in AML with a normal karyotype to identify clinically significant prognostic groups.[51] Thus, it is clear that there will be continued inroads to better define this broad category of AML.

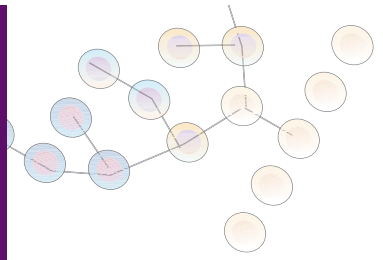
The other major categories addressed in the WHO classification of myeloid neoplasms are: (1) MDSs; (2) myeloid disorders that have features of both MDS and myeloproliferative diseases such as chronic myelomonocytic leukemia; and (3) chronic myeloproliferative disorders. The myeloproliferative and myelodysplastic diseases are clonal stem cell disorders, with or without effective hematopoiesis, respectively. The term chronic myelogenous leukemia (CML) is restricted to those cases with a *BCR/ABL* fusion gene. The diagnosis of chronic neutrophilic leukemia requires genetic evidence of a myeloid neoplasm, other than the Ph chromosome or *BCR/ABL*.

Knowing the clonal nature of MDSs and their generally poor prognosis, some have questioned the use of the term myelodysplasia and suggest that this nosology obscures the neoplastic nature of the process.[52] In the WHO classification the blast threshold for the diagnosis of AML was reduced from 30% to 20% blasts in the bone marrow or peripheral blood. Moreover, in recognition of the importance of genetic abnormalities, patients with recurring cytogenetic abnormalities are considered to have acute leukemia regardless of the blast count.[43]

There has been considerable progress in elucidating the molecular basis of myeloproliferative disorders other than CML. The *JAK2* exon 12 mutation is found in nearly all patients with polycythemia vera.[53] This mutation is also found in a substantial fraction of patients with essential thrombocythemia and primary myelofibrosis. These molecular insights have led to a recommendation that *JAK2* mutations be investigated in patients being investigated for these diagnoses. Thus, molecular diagnostic techniques are ever expanding in the arena of routine hematological diagnosis.

Finally, some new lineages have been revealed. The disease initially described as blastic natural killer (NK)-cell lymphoma has been shown not to be of NK-cell or even lymphoid derivation.[54] It repre-

sents a neoplastic expansion of immature plasmacytoid dendritic cells. This cell, which is part of the innate immune system, produces large amounts of interferon-type 1 (interferon-α). The disease is clinically more closely related to AML than either T-cell or NK-cell lymphoma, and does not respond well to lymphoma-directed therapies.[55–57] Thus, this entity will be renamed in the WHO classification of 2008, as *blastic plasmacytoid dendritic cell neoplasm*.



CONCLUSION

The WHO classification is based on the integration of traditional morphological observations with biological data related to the pathogenesis of disease. Although the ultimate aim might be to establish a genetically defined classification system in which the molecular pathogenesis of every neoplasm is known, this goal is undoubtedly some years away. However, the recognition of carefully defined disease entities should facilitate the investigation of pathogenetic mechanisms, and the development of molecularly targeted therapies. The WHO classification is a milestone, because it is the first classification system for lymphomas and leukemias universally accepted and in use on a worldwide basis. It is also a roadmap for future scientific and clinical investigations. The use of common diagnostic criteria will facilitate collaboration and synthesis of data generated from such studies.

101 Childhood Leukemia

Dario Campana and Ching-Hon Pui

SUMMARY OF KEY POINTS

Incidence

- Leukemia is the most common childhood cancer.
- The most common subtype, acute lymphoblastic leukemia (ALL), accounts for 75% to 80% of all cases of childhood leukemia, whereas acute myeloid leukemia (AML) composes approximately 20%.
- Chronic myelogenous leukemia (CML), myelodysplastic syndrome (MDS), and myeloproliferative disorders (MPDs) occur less frequently.
- Chronic lymphocytic leukemia (CLL) is extremely rare.

Etiology

- Although environmental agents, such as ionizing radiation and chemical mutagens, have been implicated in the induction of leukemia, discernible etiologic factors are lacking in almost all cases of primary leukemia.
- Acquired genetic changes are central to the development of leukemia.

Epidemiology

- Males are generally affected by leukemia slightly more often than females in all age groups except infants.
- In developed countries the incidence of ALL is highest between ages 2 and 5 years.
- The incidence of AML is relatively constant during childhood, with slight peaks in the first 2 years of life and in late adolescence.
- MDS typically occurs after 5 years of age, and juvenile myelomonocytic leukemia (JMML) occurs nearly always before 5 years of age.

Clinical Findings

- Physical signs and symptoms of thrombocytopenia and anemia are common.
- Neutropenia may lead to severe infection.
- Bone pain and arthralgia caused by leukemic infiltration is more common in ALL than AML and may be especially severe in young children.
- Common sites of extramedullary involvement in ALL include liver, spleen, thymus, and lymph nodes.
- Skin, gums, and the head and neck area are typical sites of extramedullary disease in AML.
- Infiltration of the central nervous system can be found in both ALL and AML.

Differential Diagnosis

- The acute onset of petechiae, ecchymoses, and bleeding may suggest idiopathic thrombocytopenic purpura.
- Both acute leukemia and aplastic anemia can present with pancytopenia and complications associated with bone marrow failure.
- Infectious mononucleosis and other viral infections can be confused with ALL.
- Bone pain, arthralgia, and occasionally arthritis may mimic juvenile rheumatoid arthritis, rheumatic fever, other collagen diseases, or osteomyelitis.
- Childhood ALL should also be distinguished from pediatric small round cell tumors that involve the bone marrow.

Therapy

- Patients with ALL undergo a relatively brief remission-induction phase followed by intensification (consolidation) therapy and then prolonged continuation treatment.
- All patients require treatment for subclinical central nervous system (CNS) involvement, which should be initiated early in the form of intrathecal chemotherapy.
- Most protocols for AML include remission induction and consolidation therapy; other recommended postremission therapy differs widely.
- Autologous hematopoietic stem cell transplantation is not usually recommended.
- At present, ALL with the Philadelphia chromosome or early hematologic relapse, and T-cell ALL with poor early response or hematologic relapse, are clear indications for allogeneic transplantation.
- Allogeneic transplantation seems to improve overall survival in AML, although the indications for this procedure during first remission are debated.

Prognosis

- Five-year event-free survival estimates for children with newly diagnosed ALL are now over 80%.
- Philadelphia chromosome is an unfavorable prognostic indicator, whereas hyperdiploidy with greater than 50 chromosomes and the *TEL-AML1* gene fusion are associated with a favorable outcome.
- Event-free survival for infant ALL with 11q23/*MLL* rearrangement remains only 20% to 35% and has not been improved by allogeneic transplantation.
- In AML, patients with Down syndrome or acute promyelocytic leukemia have a favorable prognosis with optimal therapy, whereas those with acute megakaryoblastic leukemia have significantly worse outcomes than others.
- Relapse less than 18 months after the end of therapy and treatment-related AML carry a dismal prognosis.
- Patients with MDS, AML arising from MDS, AML with monosomy 7, or AML with internal tandem duplication of the *FLT3* gene often have resistant disease
- Slow response to remission-induction therapy and persistent minimal residual disease are associated with a higher risk of relapse in both ALL and AML.

INTRODUCTION

Leukemia is the most common childhood cancer. Unlike leukemia in adults, childhood leukemia is acute in the vast majority of cases. The most common subtype, acute lymphoblastic (also termed lymphocytic or lymphoid) leukemia (ALL), accounts for 75% to 80% of all cases of childhood leukemia, whereas acute myeloid (also termed myelocytic, myelogenous, or nonlymphoblastic) leukemia (AML) composes approximately 20%.

Acute leukemia is a malignant proliferation and accumulation of immature lympho-hematopoietic cells. The leukemic cell population is shown to be clonal by cytogenetics, glucose 6-phosphate dehydrogenase characterization, and analysis of antigen-receptor gene rearrangements and X-linked restriction fragment-length polymorphisms.[1] Although leukemic cells generally do not proliferate as actively as their normal hematopoietic counterparts,[2] they accumulate inexorably and compete successfully with normal cells. Their inability to differentiate and their relative resistance to apoptosis may explain this phenomenon. By the time of diagnosis, leukemic cells have usually replaced normal bone marrow cells and disseminated to various extramedullary sites. Therefore, the presenting features of leukemia typically reflect the degree of bone marrow replacement and the extent of extramedullary spread.

Both ALL and AML are heterogeneous diseases that comprise different biologic subtypes. The major morphologic and immunophenotypic divisions based on lineage association and degree of maturation are subclassified by the identification of distinct, recurrent chromosomal and molecular abnormalities,[3,4] and gene expression patterns.[5–10]

Chronic myelogenous leukemia (CML), myelodysplastic syndrome (MDS), and myeloproliferative disorders (MPDs) are infrequent in children. In general, they share clinical, laboratory, and morphologic features with one of their adult counterparts.[11–13] A disorder characterized by an heterogeneous pattern of myeloproliferation, dysplasia, and hepatosplenomegaly in association with abnormal peripheral blood counts has historically been called "juvenile chronic myelogenous leukemia," "infantile monosomy 7 syndrome," and "chronic myelomonocytic leukemia" by different authors. The term juvenile myelomonocytic leukemia (JMML) is currently favored.[11,12] Only a few well-documented cases of chronic lymphocytic leukemia (CLL) have been reported in children.[14]

EPIDEMIOLOGY

Leukemia is the most common malignancy among patients less than 15 years of age. ALL is approximately five time more common than AML. Males are generally affected by leukemia slightly more often than females in all age groups, with two exceptions: boys have a risk of T-cell leukemia that is four times that of girls, and girls have a slightly higher incidence of leukemia in the first year of life (1.5 : 1 ratio).[15] Rates of ALL are comparatively higher in Northern and Western Europe, North America, and Oceania, than in Asia and Africa.[15] In developed countries the incidence of ALL is highest between ages 2 and 5 years. This age peak is accounted for largely by ALL with hyperdiploidy (>50 chromosomes) or *TEL-AML1* gene fusion.[3] The incidence of ALL is higher in the white than the black population, especially among children 2 to 5 years of age. Black children have a higher incidence of T-cell ALL and pre-B leukemia with *E2A-PBX1* fusion and are less likely to have hyperdiploid ALL with more than 50 chromosomes than white children.[16] The incidence of AML in children peaks at 2 years of age, decreases to a nadir at 9 years, then peaks again at around age 16.[17] The highest incidence of pediatric AML occurs among the Maori of New Zealand, Hawaiian Americans, and Africans in Zimbabwe.[17] In most populations of children, less than 10% of cases of AML are acute promyelocytic leukemia (APL).[17] However, this figure is approximately 25% in Latin American children[18] and about 30% in Italian children.[19] Pediatric patients with MDS are typically older at diagnosis (>5 years old) whereas JMML nearly always occurs before 5 years of age.[11,12]

Table 101-1 Congenital Disorders Associated with Increased Risk of Leukemia

Congenital Disorder	Associated Leukemia(s)
Down syndrome	ALL, AML
Ataxia-telangiectasia	ALL
Wiskott-Aldrich syndrome	AML
Bloom syndrome	ALL, AML
Fanconi anemia	AML
Kostmann's syndrome	AML
Neurofibromatosis	AML, JMML
Noonan syndrome	JMML

ALL, acute lymphoblastic (lymphocytic, lymphoid) leukemia; AML, acute myeloid (myelocytic, myelogenous, nonlymphoblastic) leukemia; JMML, juvenile myelomonocytic leukemia.

A small percentage (<5%) of cases of leukemia are associated with inherited genetic syndromes (Table 101-1). Children with Down syndrome have a 10- to 20-fold increased risk of leukemia (ALL and AML).[20,21] Furthermore, a MPD termed "transient abnormal myelopoiesis" may occur in newborns with Down syndrome.[22] This disorder spontaneously remits in almost all patients within 3 months. However, early death can occur in almost 20% of patients with high presenting leukocyte count, abnormal liver function, and failure to normalize blood count; another 20% subsequently develop AML.[22] Several other genetic disorders are associated with an increased risk of leukemia and/or MDS, including ataxia-telangiectasia, Wiscott-Aldrich syndrome, Bloom syndrome, Fanconi anemia, Kostmann's disease, Blackfan-Diamond anemia, and neurofibromatosis.[17,20,23,24] The association between leukemia and congenital immunodeficiencies, such as X-linked agammaglobulinemia and common variable immunodeficiency, is not well supported.[23]

Fraternal twins and siblings of affected children are at a 2- to 4-fold greater risk of leukemia during the first decade of life than are unrelated children.[15,25] When leukemia occurs in one identical twin, the likelihood that the other twin will develop the disease is approximately 20%. However, when leukemia is diagnosed in one twin before 1 year of age, it almost invariably develops in the other twin, typically within a few months. Molecular studies have demonstrated that intrauterine metastasis of ALL from one twin to the other, via the shared placental circulation, is responsible for the concordant leukemia.[26–28]

ETIOLOGY

Although environmental agents, such as ionizing radiation and chemical mutagens, have been implicated in the induction of leukemia, discernible etiologic factors are lacking in almost all cases of primary leukemia.[15] Association between leukemia and maternal exposure to various potential mutagens, neonatal administration of vitamin K, parental use of medications and drugs, and proximity to electromagnetic fields has not been convincingly demonstrated.[15] Although an association between increased risk of childhood ALL and exposure to high levels (0.4 μT or higher) of residential magnetic fields has been reported, this finding needs confirmation.[29,30] A recent case-control study identified a significantly increased risk of leukemia among the offspring of men employed in occupations with a risk of exposure to electromagnetic fields or radiation,[31] a finding that also warrants further studies. Because industralization, higher socioeconomic status, and social isolation are associated with an increased risk of B-lineage

ALL, Greaves hypothesized that abnormally late exposure to common infections and immune response stimulation could enhance the likelihood of leukemogenic genetic mutations, thus increasing the risk of childhood B-lineage ALL.[32] In line with this notion is the observation of occasional clustering of childhood ALL associated with rural-urban population mixing, especially in new towns.[33,34]

Infant leukemias frequently have rearrangements of the *MLL* gene, located on chromosome band 11q23.[35] *MLL* rearrangements are also common in therapy-related AML, arising after treatment with topoisomerase II inhibitors.[36] These molecular similarities raised the hypothesis that transplacental fetal exposure to substances that inhibit topoisomerase II, such as flavonoids (in food and drink), quinolone antibiotics, benzene metabolites, catechins, and estrogens, could be leukemogenic.[35,37] A case-control study found that in utero exposure to DNA-damaging drugs, herbal medicines, or pesticides was significantly associated with infant leukemia with *MLL* rearrangements.[38] Because the functional doses received via dietary and environmental exposure are much lower than those received from anticancer chemotherapy, it was postulated that affected infants or their mothers may have reduced activity of carcinogen-detoxifying enzymes due to genetic polymorphism. In this regard, deficiency of glutathione *S*-transferases (GST-M1 and GST-T1), enzymes that detoxify electrophilic metabolites by catalyzing their conjugation to glutathione, is associated with infant leukemia without *MLL* rearrangement,[35] and with ALL in black children.[39] Polymorphisms of reduced nicotinamide adenine dinucleotide phosphate : quinone oxidoreductase, an enzyme that converts benzoquinones to less toxic hydroxyl metabolites, have been associated with the development of infant and childhood ALL.[40,41] Cytochrome P-450 *CYP1A1*2A* and *NQO1*2* variant genotypes have also been linked to an increased risk of childhood ALL; children carrying both genotypes were at a particularly high risk.[42] It has also been suggested that folate pathways may play a role in susceptibility to ALL,[43] and that folate supplement may reduce the risk,[44] an intriguing finding that requires confirmation. Maternal consumption of fresh vegetables and fruits during pregnancy was associated with a decreased risk of infant leukemia, particularly *MLL*-positive, in a recent report.[45] Thus far, however, no direct gene-environment interaction has been firmly established.

PATHOGENESIS

There is strong evidence that acquired genetic changes are central to the development of leukemia. These changes affect the number (ploidy) and/or the structure of chromosomes; structural changes comprise translocations, inversions, deletions, point mutations, and amplifications. The dysregulation of genes encoding transcription factors and the resulting subversion of transcriptional pathways that regulate hematopoietic cell homeostasis, provides a mechanistic explanation for leukemogenesis.[46–48] For example, the core binding factor (CBF) family of transcription factors is disrupted by recurrent chromosomal translocations, such as those involving *TEL-AML1* in ALL and *AML1-ETO* and *CBFB-MYH11* in AML.[49,50] The encoded proteins regulate the expression of growth factors, such as interleukin-3, granulocyte-macrophage colony stimulating factor, and macrophage colony-stimulating factor receptor, as well as the T-cell receptor β enhancer and the immunoglobulin heavy chain enhancer/promoter. The function of homeobox (HOX) genes, an evolutionarily highly conserved family of transcription factors whose expression is tightly regulated during hematopoietic cell differentiation, can also be disrupted either by direct involvement in chromosomal translocations [e.g., the t(7;11), forming the *NUP98-HOXA9* fusion gene] or by the disruption of proteins believed to be their upstream regulators.[48] Among the latter, the most notable is encoded by *MLL*, a gene crucial for both embryonic development and hematopoiesis, and, as mentioned previously, is involved in translocations of the 11q23 region in both ALL and AML.[48,50] Moreover, *PBX1*, a gene involved with *E2A* in the t(1;19) typical of pre-B ALL, encodes a common partner of HOX proteins.[48] Chimeric proteins encoded by fused genes can also directly interfere with normal apoptotic pathways, as has been demonstrated in the case of the E2A-HLF protein.[48] The expression of essential molecules can be altered in the absence of detectable genetic abnormalities. For example, five different T-cell oncogenes (*HOX11*, *TAL1*, *LYL1*, *LMO1*, and *LMO2*) are often aberrantly expressed in T-lineage ALL in the absence of chromosomal abnormalities.[5]

Cell survival requirements can be altered by the dysregulated activity of tyrosine kinases, as in the case of the *BCR-ABL* gene fusion.[48] Alternatively, activating mutations in tyrosine kinase receptors for growth factors may confer a growth advantage to leukemic cells. This mechanism is exemplified by mutations of *FLT3*, which encodes a receptor tyrosine kinase expressed by immature hematopoietic cells that acts synergistically with other growth factors to stimulate proliferation of hematopoietic progenitor cells.[51] Mutant *FLT3* is detectable in both ALL and AML; these mutations typically involve small tandem duplications of amino acids that result in constitutive tyrosine kinase activity.[50,51] Activating mutations of *NOTCH1*, a gene encoding a transmembrane receptor that regulates normal T-cell development, are frequently detected in T-cell ALL.[52,53] Activating mutations of *NOTCH1* produce constitutive NOTCH1 signaling, which is sufficient to induce T-cell ALL in experimental models.[53] Constitutively active Notch1 activates the NF-κB pathway; inhibition of the pathway can restrict tumor growth in vitro and in experimental models of leukemia.[54] Gamma secretase, a multicomponent membrane-associated enzyme, is required for NOTCH1 signaling through mutant NOTCH receptors in T-cell ALL, providing an attractive target for therapeutic intervention with newly developed γ-secretase inhibitors.[53]

A recent large-scale study of DNA single-nucleotide polymorphisms analysis examined 242 cases of pediatric and identified lesions in genes encoding key regulators of B-cell differentiation in 40% of B-cell precursor ALL cases.[55] Most prominent were deletions and cryptic translocations involving the *PAX5* gene, which was altered in almost one third of cases and which would be predicted to block normal B-progenitor cell differentiation before immunoglobulin heavy chain gene rearrangement. Other mutated genes were found in concert with several of the more common translocation-induced chimeric oncogenes, such as *E2A-PBX1* and *TEL-AML1*, including the essential B-cell developmental genes *E2A*, *EBF*, *LEF1*, Ikaros, and Aiolos.

The retrospective identification of leukemia-specific fusion genes (e.g., *MLL-AF4*, *TEL-AML1*) in the neonatal blood spots of identical twins who experienced concordant leukemia has demonstrated their prenatal origin.[26,28] In cases with the t(4;11) and *MLL-AF4*, there is a high rate of concordance in identical twins (25% to 100%) and the very brief latency period after birth (a few weeks to a few months).[28] In other types of leukemia, for example those with the *TEL-AML1* fusion or T-cell phenotype, the rate of concordance is lower, the postnatal latency period is longer and is variable, and the clinical presentation and the outcome of therapy may differ widely among identical twins, suggesting that secondary postnatal molecular events are necessary for full leukemic transformation.[28] Further insights were gained from a report of a set of triplets in which the two monozygotic twins developed concordant leukemia with identical *TEL-AML1* fusion at 3 years of age, whereas the third child, who had developed from a second zygote, was free of leukemia and of the genomic sequence.[27] In addition to the fusion transcript, the identical twins had a secondary, independent deletion of the normal unrearranged *TEL* allele, suggesting a contributing postnatal event. Clone-specific antigen receptor gene rearrangements were analyzed in the neonatal blood spots of five children who were 6 months to 4 years and 8 months of age at diagnosis of B-lineage ALL and T-ALL. In all five children the clonotypic antigen receptor gene rearrangements had been present at birth. The estimated number of clonotypic cells per blood spot was in the range of 10 to 100.[56] Mori and colleagues found

the *TEL-AML1* fusion in the cord blood of about 1% of randomly selected newborns, a frequency about 100 times that of ALL with *TEL-AML1*,[57] further supporting the notion that preleukemic clones are generated in utero at a high frequency and that secondary postnatal leukemogenic events are required for a fully malignant transformation of *TEL-AML1* cells. The prevalence of leukemias with prenatal origin is not known, and not all cases develop in utero. For example, t(1;19) *E2A-PBX1* ALL seems to have a postnatal origin in most cases.[58] Although evidence for a prenatal origin of childhood ALL is solid, similar data for AML are lacking.[59]

GENERAL CLINICAL AND LABORATORY FEATURES

Physical examination of children with leukemia may reveal pallor, petechiae, ecchymoses, and mucosal bleeding. If thrombocytopenia and hyperleukocytosis are severe, there may be life-threatening bleeding (e.g., intracranial hematoma). Anemia may cause fatigue and lethargy, dyspnea, angina, and dizziness. Neutropenia may lead to severe infection. Bone pain and arthralgia caused by leukemic infiltration or, less frequently, hemorrhage is more common in ALL than AML and may be especially severe in young children. Patients may present with fever, which may be induced by infection or by pyrogenic cytokines (e.g., interleukin-1, interleukin-6, and tumor necrosis factor) released from the leukemic cells. Liver, spleen, thymus, and lymph nodes are common sites of extramedullary involvement; however, in AML, massive hepatosplenomegaly is common only in infants. Infiltration of the CNS is seen in children with ALL or AML. An anterior mediastinal (thymic) mass is typical of T-cell ALL. Painless enlargement of the scrotum can be a sign of testicular leukemia or hydrocele resulting from lymphatic obstruction. Testicular involvement is rare in AML. In patients with AML, common sites of extramedullary disease include the skin, gums, and the neck and head area. Myeloblastomas (granulocytic sarcomas, chloromas) are solid tumors composed of myeloblasts that may precede overt bone marrow involvement of AML. They typically occur in the skin, soft tissue, bones, and CNS but may develop in virtually any tissue or organ. Very rarely, acute leukemia produces no signs or symptoms and is detected during routine examination.

Anemia, neutropenia, and thrombocytopenia are common findings, and their severity reflects the degree of bone marrow replacement by leukemic cells. The presenting leukocyte count ranges from 0.1 to 1500×10^9 cells/L (median, 10 to 12×10^9/L); hyperleukocytosis ($> 100 \times 10^9$ cells/L) occurs in 15% to 18% of cases of ALL and AML. Most patients have circulating leukemic blast cells. A large leukemic cell burden is commonly accompanied by elevated serum lactate dehydrogenase activity and elevated uric acid and phosphorus concentration. Some patients with T-cell ALL present with normal red blood cell and platelet counts. In these cases the lymphoblasts in the bone marrow usually represent the leukemic phase of an extramedullary lymphoblastic lymphoma. Not infrequently, the marrow contains a significant population of nonleukemic myeloblasts, which may be difficult to distinguish morphologically from the leukemic cells.

Leukemic blast cells are identified at diagnosis in the cerebrospinal fluid (CSF) of as many as one third of children with ALL (most of whom have no neurologic symptoms) and in approximately 5% of children with AML. Traditionally, CNS leukemia is defined by the presence of at least five leukocytes per microliter of CSF and the detection of leukemic blast cells, or by the presence of cranial nerve palsy. However, the presence of any amount of leukemic cells in CSF, even from iatrogenic introduction due to a traumatic lumbar puncture, is associated with an increased risk of ALL relapse, and requires additional intrathecal therapy.[60,61]

Pancytopenia is a presenting feature in most cases of MDS.[11,12] Fetal hemoglobin is frequently slightly elevated. Most patients have no organomegaly. Extramedullary myeloid tumor may be the presenting feature of MDS, but blasts in the CSF are not seen in MDS. The bone marrow is usually normo- or hypercellular, with characteristic dysplastic features including megaloblastic erythropoiesis, bizarre small or unusual large megakaryocytes, and dysgranulopoiesis; the percentage of myeloblasts is often increased.[12] Hepatosplenomegaly and lymphadenopathy are suggestive clinical features of JMML.[11,12] Diagnostic criteria that have been suggested for patients with JMML include a peripheral monocyte count higher than 1×10^9 cells/L with more than 20% bone marrow blasts.[11,12] Other characteristic features of JMML are the consistent ability of peripheral blood and bone marrow cells to spontaneously form granulocyte-macrophage colonies in vitro, and their hypersensitivity to granulocyte-macrophage colony-stimulating factor.[11]

DIFFERENTIAL DIAGNOSIS

The acute onset of petechiae, ecchymoses, and bleeding may suggest idiopathic thrombocytopenic purpura (often associated with a recent viral infection, large platelets in blood smears, and no evidence of anemia). Both acute leukemia and aplastic anemia may present with pancytopenia and complications associated with bone marrow failure, but in aplastic anemia hepatosplenomegaly and lymphadenopathy are rare, and the skeletal changes associated with leukemia are absent.

Infectious mononucleosis and other viral infections can be confused with ALL. Detection of atypical lymphocytes or elevated viral titers aid in the diagnosis. Patients with pertussis or parapertussis may have marked lymphocytosis, but the affected cells are mature lymphocytes rather than lymphoblasts. Bone pain, arthralgia, and occasionally arthritis may mimic juvenile rheumatoid arthritis, rheumatic fever, other collagen diseases, or osteomyelitis.

Childhood ALL should also be distinguished from pediatric small round cell tumors that involve the bone marrow, including neuroblastoma, rhabdomyosarcoma, and retinoblastoma. Generally, in such cases, a primary lesion can be found by routine diagnostic studies, and disseminated tumor cells often form clumps.

MDS with a low blast count must be distinguished from aplastic anemia and other nonclonal disorders, which often requires sequential morphologic studies including bone marrow biopsies.[12,13] Myelodysplasia may also occur in a variety of disorders such as infection, drug therapy, and chronic disease. AML is the major differential diagnosis of MDS. Cases with AML-specific translocations are more appropriately classified as AML regardless of the blast count, whereas monosomy 7 as the only cytogenetic aberration is strongly suggestive of MDS.[12,13] In borderline cases (e.g., 20% to 30% blasts in bone marrow and no informative cytogenetics), it is recommended to repeat the bone marrow examination after 2 weeks. A definitive distinction between JMML and Philadelphia chromosome-positive CML requires karyotypic or molecular examination for the t(9;22)/*BCR-ABL* abnormality. These conditions must also be distinguished from "leukemoid reaction" associated with infection, cancer, or congenital heart disease in which signs and symptoms do not progress and/or resolve spontaneously.[11]

MORPHOLOGIC AND CYTOCHEMICAL ANALYSIS

Morphologic analysis of leukemic cells in smears stained with Romanowsky (Wright-Giemsa or May-Grünwald-Giemsa) stain distinguishes three subtypes of ALL (L1, L2, and L3) and eight subtypes of AML (M0–M7) as classified by the French-American-British (FAB) scheme (Fig. 101-1).[62] The term "acute myeloid leukemia" is used to designate even leukemias in which some or all cells have the morphology of monocytes (M4, M5), erythroblasts (M6), or megakaryoblasts (M7). Because of the rarity and heterogeneous nature of childhood MDS, its classification has been inconsistent, although an international consensus was achieved.[12] Analysis of a Romanowsky-stained smear cannot accurately distinguish between ALL and AML.

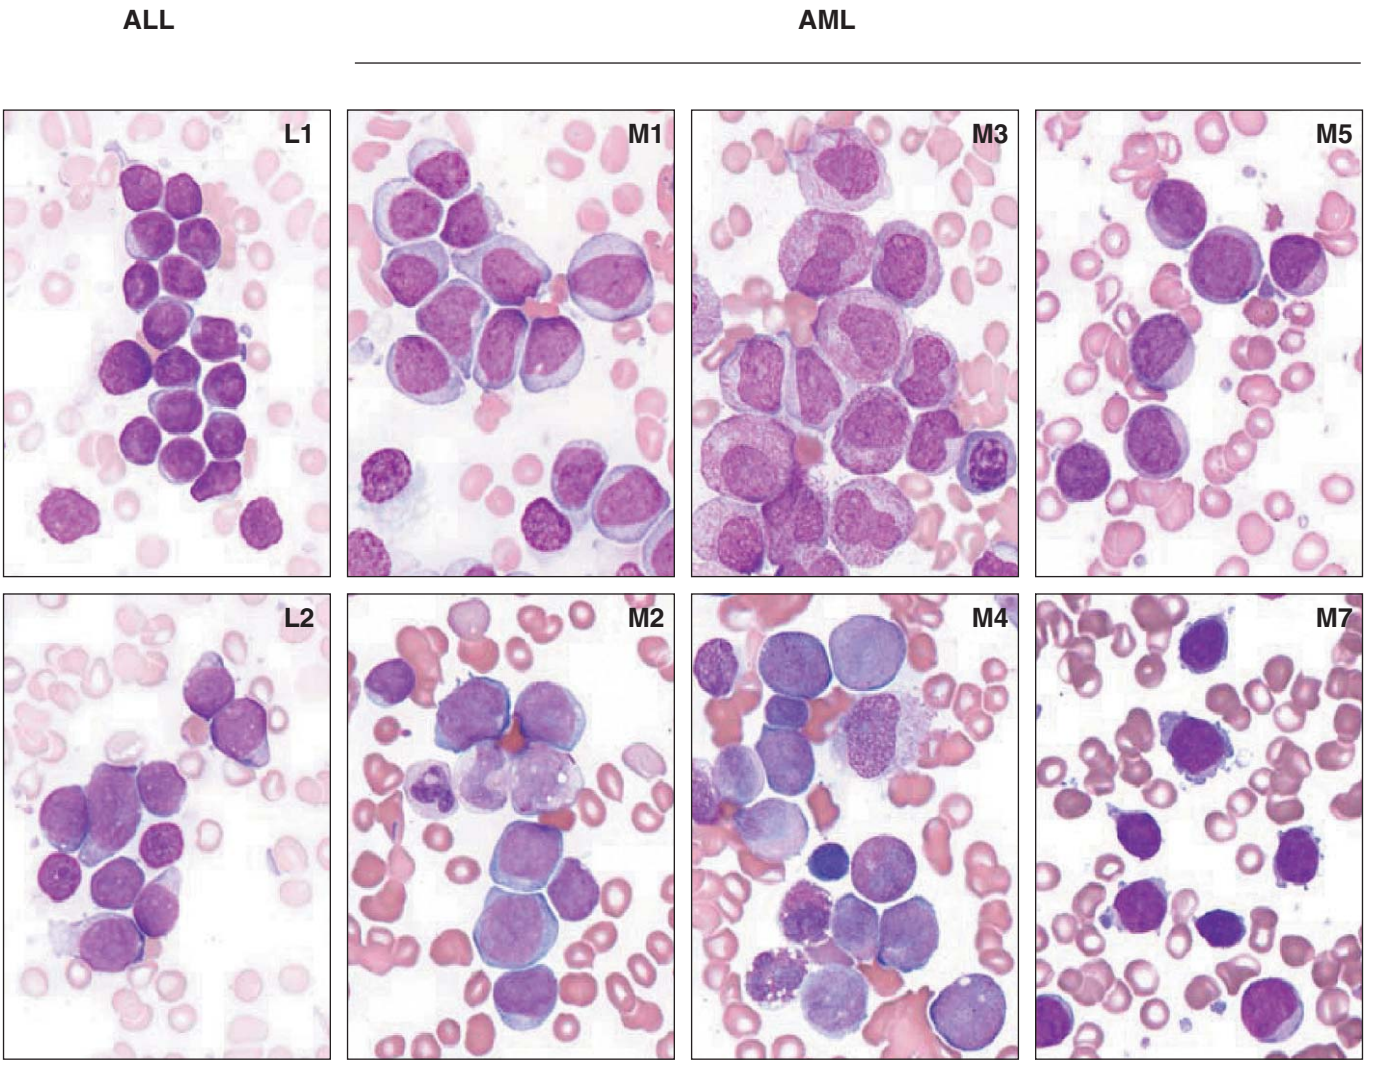

Figure 101-1 • Morphology of leukemic cells. Bone marrow smears obtained at diagnosis from children with ALL or AML were stained with Wright-Giemsa. The morphologic classification according to the French-American-British criteria is shown. (Photographs were provided by Dr. F.G. Behm, St. Jude Children's Research Hospital.)

Cytochemical stains help this distinction. Myeloperoxidase, Sudan black, and nonspecific esterases, including alpha naphthyl butyrate and alpha naphthyl acetate esterase, react with myeloid blast cells, whereas periodic acid-Schiff reagent reacts positively in over 70% of ALL cases. However, despite the traditional use of morphology and cytochemistry, contemporary classification of acute leukemias is based on subtypes that can be identified only by immunologic and molecular analyses.

The FAB group classified MDS into five subgroups: refractory anemia (RA), RA with ringed sideroblasts (RARS), RA with excess of blasts (RAEB), RAEB in transformation (RAEB-T), and chronic myelomonocytic leukemia (CMML).[63] AML was defined by the presence of 30% myeloblasts in the bone marrow. A more recent World Health Organization classification included five MDS subtypes: refractory anemia with and without ringed sideroblasts, refractory cytopenia with multilineage dysplasia, RAEB, 5q- syndrome, and MDS not otherwise categorized. The blast threshold for AML diagnosis was lowered to 20%.[11] Table 101-2 shows a classification of MDS and MPD in children, which recognizes three major diagnostic groups: JMML, myeloid leukemia of Down syndrome, and MDS occurring either de novo or as a complication of previous therapy or pre-existing bone marrow disorder (secondary MDS).[12]

Table 101-2 Classification of Pediatric Myelodysplastic and Myeloproliferative Disease

Myelodysplastic/ Myeloproliferative Disease	Down Syndrome Disease	MDS
JMML	Transient abnormal myelopoiesis	Refractory cytopenia (<2% blasts in blood and <5% blasts in marrow)
CMML (secondary to previous chemotherapy)	Myeloid leukemia of Down syndrome	RAEB (2% to 19% blasts in blood or 5% to 19% blasts in marrow)
Ph-negative CML		RAEB-T (20% to 29% blasts in blood or marrow)

CML, chronic myelogenous leukemia; CMML, chronic myelomonocytic leukemia; MDS, myelodysplastic syndrome; RAEB, refractory anemia with excess of blasts; RAEB-T, RAEB in transformation.

Proposed by Hasle et al.[12]

IMMUNOLOGIC CLASSIFICATION OF ACUTE LEUKEMIA

Acute Lymphoblastic Leukemia

Table 101-3 summarizes antigen expression patterns in ALL.

Early Pre-B Acute Lymphoblastic Leukemia

Leukemic blast cells of early pre-B ALL resemble normal marrow B-cell precursors. Immunoglobulin heavy chain genes are usually rearranged in these cells, but immunoglobulins are not detectable. The leukemic cells of early pre-B ALL always express CD19. Almost all cases have cytoplasmic CD22 and CD79α; weak surface CD22 expression is also evident in many cases.[64] CD10 and terminal deoxynucleotidyl transferase (TdT) are detectable in 90% of cases, and cells in more than 75% of cases express CD34.[64] The CD20 antigen is present on a minor proportion of blast cells in one half of cases.[64,65] In 10% to 15% of early pre-B ALL cases CD45 is very weakly expressed or undetectable; cells that have this immunophenotype are usually hyperdiploid (modal chromosome number >50).[64]

ALL with rearrangement of the *MLL* gene typically has an early pre-B ALL phenotype with distinctive features such as expression of CD15, CD65, and surface chondroitin protoglycan sulfate, and absence of CD10.[64]

Pre-B Acute Lymphoblastic Leukemia

About 25% of newly diagnosed cases of ALL have a pre-B immunophenotype consisting of accumulation of cytoplasmic immunoglobulin μ heavy chains with no detectable surface immunoglobulins.[64] Like in early pre-B ALL, cells express CD19, CD22, and CD79α. Rearrangement of immunoglobulin light chain genes is evident in some of these leukemias, but κ and λ proteins are not detectable. More than 95% of pre-B ALL express CD10 and TdT, but only two thirds express CD34.[64] In many cases of pre-B ALL, surface CD20 is absent or is weakly expressed.[64,65] ZAP-70 expression can be found in cases of B-lineage ALL, particularly those with a pre-B phenotype.[66,67]

Between 20% and 25% of pre-B ALL cases have either the t(1;19)(q23;p13) or the der(19)t(1;19)(q23;p13).[64] The antigen expression profile $CD19^+$, $CD22^+$, CD20 $^{\pm}$, $CD34^-$, $CD45^+$, cytoplasmic μ^+ is characteristic of ALL cases with the t(1;19) but is not specific to these cases.[64]

Transitional (or Late) Pre-B Acute Lymphoblastic Leukemia

Leukemic cells that express both cytoplasmic and surface immunoglobulin μ heavy chains without κ or λ light chains have been designated transitional pre-B ALL.[64] The surface μ chains on these leukemic cells are linked to pseudo light chains as well as to CD79α and CD79β. The blast cells express CD10, usually TdT, and sometimes CD34. Initial studies found this phenotype in only 1% of childhood ALL cases, but it may be more common if more sensitive reagents are used.[64] There is no chromosomal abnormality that is characteristic of this subgroup of ALL.

B-Cell Acute Lymphoblastic Leukemia

In 2% to 4% of childhood ALL cases cells express surface immunoglobulin μ heavy chains plus either κ or λ light chains. The most common type of B-cell ALL is characterized by L3 morphology according to the FAB classification. Cells express CD19, CD22, CD20, and frequently CD10 and CD23; CD34 is negative. In rare cases, TdT is expressed, or sIg is absent.[64] B-cell ALL often represents the leukemic phase of Burkitt lymphoma arising in the abdomen or the head and neck.[64] The hallmark of this subset of B-cell ALL is the presence of a reciprocal translocation of chromosome 8 with one of the chromosomes containing an immunoglobulin gene. These translocations, which include the t(8;14)(q24;q32), t(2;8)(p12;q24), and t(8;22)(q24;q11), involve rearrangement of the c-*MYC* gene.

The less common subtype of B-cell ALL is characterized by blast cells with L1 or L2 morphology. These leukemias may express TdT and CD34, and they express CD20 only weakly.[64] Extramedullary masses are not seen at presentation. The t(8;14), t(2;8), and t(8;22) are absent, as are characteristic rearrangements of the c-*MYC* gene.

T-Lineage Acute Lymphoblastic Leukemia

T-lineage ALL cells have surface CD7 and cytoplasmic CD3 (cCD3) antigens.[68,69] More than 90% of T lymphoblasts express CD2, CD5, and TdT. Surface CD1a, CD3, CD4, and CD8 are detected in fewer than 45% of cases.[64] The HLA-DR antigen is not commonly expressed, and 40% to 45% of cases are $CD10^+$ and/or $CD21^+$.[64] CD79α is also expressed in approximately one third of cases.[64]

T-lineage ALL can be divided into three stages of immunophenotypic differentiation: early ($CD7^+$, $cCD3^+$, surface $CD3^-$, $CD4^-$, and $CD8^-$), mid or common ($cCD3^+$, surface $CD3^-$, $CD4^+$, $CD8^+$, and $CD1^+$), and late (surface $CD3^+$, $CD1^-$, and either $CD4^+$ or $CD8^+$). However, as many as 25% of cases of T-lineage ALL have antigen patterns that do not conform to any of these maturation stages. Furthermore, several studies have yielded conflicting conclusions about the prognostic significance of the expression of surface CD3 and the absence of CD2, CD5, or CD10.[70–72] In a study of children with T-cell ALL at our institution, expression of CD10 was independently associated with a favorable clinical outcome.[71]

T-cell receptor (TCR) proteins are heterogeneously expressed in T-lineage ALL.[73] In approximately two thirds of cases membrane CD3 and TCR proteins are absent. In half of these cases, however, TCR proteins (TCRβ, TCRα, or both) are present in the cells' cytoplasm. Most cases with membrane CD3 and TCR chains express the αβ form of the TCR, whereas a minority express TCRγδ proteins.

Table 101-3 Immunophenotypic Subgroups of Acute Lymphoblastic Leukemia

	Antigen Expression (% of Cases Positive)										
Subtype	**CD19**	**CD22**	**CD79α**	**CD10**	**CD7**	**CD5**	**cCD3**	**clg μ**	**slg μ**	**slg κ or λ**	**Frequency (%)**
Early pre-B	100	>95*	>95	95	5	0	0	0	0	0	60–65
Pre-B	100	100*	100	>95	0	<2	0	100	0	0	20–25

Acute Myeloid Leukemia

Table 101-4 summarizes the patterns of antigen expression in AML. The leukemic cells in all myelocytic and monocytic subtypes of AML (M0 through M5) express various combinations of CD13, CD33, CD65, CD117, and myeloperoxidase (MPO).[64]

Acute Myelocytic Leukemia with Little Differentiation (M1 AML)

M1 AML cases commonly express MPO, CD13, CD33, CD34, CD65, CD117, and HLA-DR, but in variable combinations. Expression of CD4, CD11b, CD15, and CD66 is less frequent. No single antigenic profile is characteristic of M1 leukemias.

Acute Myelocytic Leukemia with Differentiation (M2 AML)

About 35% to 45% of cases of childhood M2 AML have the t(8;21)(q22;q22) translocation. Leukemic blast cells commonly express MPO, CD34, CD65, and HLA-DR, but CD13 and CD33 expression is characteristically weak and sometimes is not detectable.[64] Most cases weakly express CD19 and, less commonly, CD56.[64] By contrast, the leukemic myeloblasts of M2 AML without the t(8;21) translocation may also express MPO, CD34, CD65, and HLA-DR, but the expression of CD13 and CD33 usually exceeds that of myeloblasts that have the t(8;21) translocation. In addition, the CD19 antigen is rarely detectable, whereas T-cell–associated CD2 or CD7 is commonly present, in these cases.[64]

Acute Promyelocytic Leukemia (M3 AML)

This group of leukemias includes a microgranular variant referred to as M3v that may morphologically mimic acute monocytic leukemia. Cells of M3 and M3v AML strongly express MPO, CD13, CD33, and CD65 but usually lack HLA-DR.[64,74] Expression of CD11b and CD15 is variable, and CD4 and CD56 are seldom detected.[64] Atypical expression of CD2 is observed in 40% to 45% of cases but may be more prevalent in the M3v subtype.[64] CD34 is generally absent but may be found in some cases, usually M3v.[74] Heterogeneous expression of CD13, the existence of a single primary blast cell population, and a characteristic pattern of CD34 and CD15 expression are reportedly useful in identifying M3 AML.[75]

Acute Myelomonocytic Leukemia (M4 AML)

Blast cells of most myelomonocytic leukemias express MPO, CD4, CD11b, CD11c, CD13, CD14, CD33, CD34, CD45, CD65, and HLA-DR.[64]

A relatively uncommon variant of M4 AML, M4Eo, is associated with increased numbers of eosinophils in the bone marrow, with or without peripheral blood eosinophilia. These cases usually express the *CBFB-MYH11* chimeric gene, which is often associated with expression of CD2.[64]

Acute Monocytic Leukemia (M5 AML)

Monoblasts usually express MPO, HLA-DR, CD4, CD11b, CD11c, CD33, and CD65. The cells of some monocytic leukemias express CD117, but CD34 is rarely detected. The cells of most monocytic leukemias also express CD15, CD36, and, not infrequently, CD56. Expression of CD14 is largely restricted to cells of the monocytic lineage but is often absent in pediatric M5 cases. A variable number of monoblasts may appear to react with antibodies to CD41a and CD61 because of platelet adhesion to the cell surface or glycoprotein IIb/IIIa absorption.[64]

Acute Erythroleukemia (M6 AML) and Acute Erythroblastic Leukemia

Leukemias composed primarily of erythroid precursors are uncommon. Leukemic erythroblasts usually express CD36, CD71, and glycophorin A (GPA), and hemoglobin is detectable in late-stage erythroid precursors. Cells of the myeloid component express CD13, CD33, and MPO. M6 AML may be difficult to distinguish from M0 and M7 AML, because undifferentiated erythroblasts have few or no erythroid-associated antigens, and their antigenic and ultrastructural features may mimic those of early megakaryoblasts.[64]

Acute Megakaryoblastic Leukemia (M7 AML)

Distinguishing acute megakaryoblastic leukemia (M7 AML) from ALL, M0 and M5 AML, acute erythroblastic leukemia, and metastatic small cell tumors solely on the basis of cell morphology might be difficult. The leukemic cells of most M7 AML cases express CD41a and CD61, and those of more than half of M7 AML cases express CD42b. Most cases are positive for CD4 and CD33; CD13, CD34, CD36, CD45, and HLA-DR are infrequently detected.[64]

Acute Myeloid Leukemia without Morphologic or Cytochemical Evidence of Differentiation (M0 AML)

The term "M0" denotes minimally differentiated myeloid leukemia.[76] In general, the expression of CD3, CD79α, or TCR proteins is strongly indicative of lymphoid lineage differentiation. In the absence of these lymphoid markers and of markers associated with the megakaryocytic lineage, the expression of CD13, CD15, CD33, CD65, or MPO is evidence of myeloid lineage commitment.[64] Leukemias that are devoid of detectable MPO should be classified as M0 AML only in the absence of lineage-restricted lymphoid and megakaryocytic antigens.[64] Although the cells of most M0 cases express CD13 or CD33, some MPO^+ cases may lack these antigens.[64] The

expression of CD117 by leukemic cells is strongly suggestive of AML. Other non-lineage-restricted antigens found on M0 AML cells include CD2, CD4, CD7, CD9, CD10, CD11b, CD19, CD34, CD71, TdT, and HLA-DR.[64]

Rare Acute Leukemias

Uncommon cases of acute leukemia express an immunophenotype reminiscent of natural killer (NK) cell differentiation, and are classified as acute immature T/NK/myeloid precursor leukemia. These cases are typically express CD7, CD34, CD56, and HLA-DR.[77] Myeloid features include CD33 expression, but MPO protein is usually absent.[77] Clonal TCR delta gene rearrangements have been shown in some cases.[78]

In a very rare subset of AML, leukemic cells express markers of basophilic differentiation, have the features of differentiation into basophilic lineage, and are classified as acute basophilic leukemia. The immunophenotype is not unlike that of other AMLs, (i.e., expression of CD13 and/or CD33, CD34 and CD117). The most characteristic feature is the presence of basophilic cytoplasmic granules, which might be detectable only by ultrastructural examination.[79]

A recently recognized acute leukemia subtype is plasmacytoid dendritic cell type 2 (DC2) acute leukemia. Leukemic cells are $CD4^+$ and $CD56^+$ and lack strong expression of lymphoid and myeloid markers. Characteristic markers include expression of the interleukin-3 receptor (CD123), CD45RA, CD36, BRCA-2, BRCA-4, CD68, and HLA-DR.[80,81]

Rare cases of leukemia remain difficult to classify even after extensive morphologic and immunophenotypic analysis; these are designated acute undifferentiated (or unclassified) leukemia. Morphologically, these leukemias may resemble ALL or AML, and immunophenotyping studies show the absence of B-lympoid, T-lymphoid, myeloid, and megakaryocytic antigens.[82] The leukemic cells of true acute undifferentiated (or unclassified) leukemia lack surface and cytoplasmic antigens associated with B (CD19, CD22, and CD79α), T (CD2, CD3, CD5, and TCR proteins), myelomonocytic (MPO, CD13, CD14, CD33, CD15, and CD65), and megakaryocytic or erythrocytic (CD36, CD41a, CD42b, CD61, and GPA) lineages. Diagnostic studies should also exclude neuroblastoma, Ewing sarcoma, and other small cell tumors.

Acute Leukemias with Aberrant Lymphoid or Myeloid Antigen Expression

Immunologic and molecular studies show that many leukemias possess features characteristic of multiple hematopoietic lineages. Acute leukemias whose blast cells simultaneously demonstrate features of more than one lineage (e.g., lymphoid plus myeloid) have been termed acute mixed-lineage, hybrid, chimeric, or biphenotypic leukemias.[64] The diagnosis of B-lineage ALL should be made when leukemic cells express either cytoplasmic immunoglobulin or CD79α or CD19 plus CD22, regardless of CD13, CD15, CD33, or CD65 expression.[64] The diagnosis of T-lineage ALL should be made when leukemic cells express CD7 plus either surface or cytoplasmic CD3, regardless of myeloid antigen expression. A diagnosis of AML is rendered when leukemic cells express MPO or two or more myeloid-associated antigens, including CD13, CD15, CD33, or CD65, in the absence of the lymphoid-associated markers designated previously. An immunophenotypic diagnosis of "true" mixed-lineage leukemia should be considered when leukemic blast cells co-express MPO and CD3, MPO and immunoglobulin, or MPO and CD79α. "True" mixed-lineage leukemia should not be confused with biclonal or oligoclonal leukemias, which consist of two or more morphologically or immunophenotypically distinct leukemic cell populations. The latter types of leukemia are very rare.

Expression of myeloid antigens in ALL has no independent prognostic significance in children but is associated with molecular genetic abnormalities.[83] Atypical expression of the myeloid-associated antigen CD15 is characteristic of B-lineage ALL with *MLL* gene rearrangements. Lymphoid antigen expression in AML cells also lacks prognostic significance in children.[83]

CYTOGENETIC AND MOLECULAR CLASSIFICATION

Acute Lymphoblastic Leukemia

Figure 101-2 shows the cytogenetic groups in ALL.

Hyperdiploid Acute Lymphoblastic Leukemia

In approximately half of ALL cases, leukemic blast cells have a modal chromosomal number greater than 46. Hyperdiploidy can be identified by conventional karyotyping or by DNA content analysis with flow cytometry. In approximately 50% of hyperdiploid cases, the leukemic cells have additional structural chromosomal abnormalities, including duplication of 1q and isochromosome of 17q; however, no consistent structural abnormality has been identified. Hyperdiploid cases with a modal chromosome number of 51 to 65 represent a distinct biologic subset of B-lineage ALL with an excellent prognosis.[84–86] Leukemic lymphoblasts with this karyotype have a marked propensity to undergo apoptosis in vitro and in vivo.[87,88] In addition, they accumulate greater quantities of methotrexate and its active polyglutamate metabolites than do other leukemic lymphoblasts,[89] and they reportedly have greater sensitivity to antimetabolites in vitro.[90] These features explain the relatively small presenting tumor burden and the good prognosis of this subtype of ALL. Features that have been associated with the most favorable outcome among this subset of ALL include trisomy of chromosomes 4, 10, and 17,[91] a

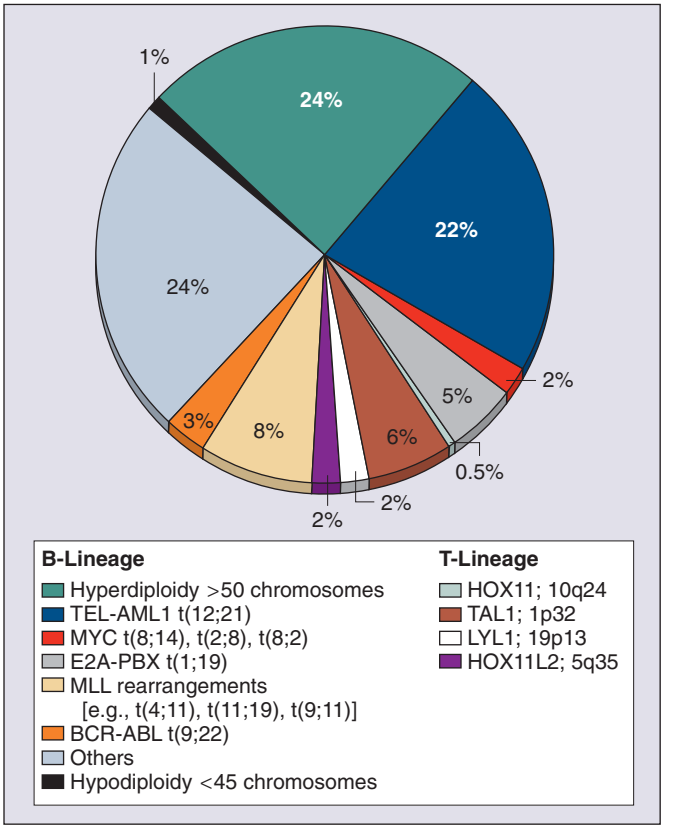

Figure 101-2 • Cytogenetic subgroups in childhood ALL.

chromosome number of 56 or more,[92] and the absence of chromosomal translocations.[93]

In contrast to the favorable prognosis of this ALL subtype, ALL cases with near-triploidy (69 to 81 chromosomes) have a response to therapy similar to that of nonhyperdiploid ALL;[94] cases with near-tetraploidy (82 to 94 chromosomes) have a high frequency of T-cell imunophenotype.[94,95] Hypodiploidy (<45 chromosomes) is found in <2% of ALL cases and is associated with a poor outcome.[96]

Acute Lymphoblastic Leukemia with E2A-PBX1 and E2A-HLF Rearrangements

The t(1;19)(q23;p13) translocation is found in 20% to 25% of pre-B ALL cases. The affected genes are those encoding the E2A transcription factor on chromosome 19 and the PBX1 homeodomain-containing transcription factor on chromosome 1.[48] The resulting E2A-PBX1 fusion protein contains the transcriptional activation domains of E2A linked to the DNA-binding domain of PBX1. Thus, the protein should inappropriately activate the transcription of genes normally regulated by PBX1. PBX1 is required for the maintenance of definitive hematopoiesis and contributes to the growth of subsets of hematopoietic progenitors.[97] Ectopic expression of the E2A-PBX1 chimeric protein in mice leads to the development of lymphomas and myeloid leukemias.[98] Some of the oncogenic potential of E2A-PBX1 could be mediated through the formation of heterocomplexes with HOX proteins. Both PBX1 and E2A-PBX1 bind to HOX proteins, and PBX1 and genes of the HOXA locus exhibit synergism in inducing leukemia in mice.[99]

Another *E2A* fusion gene is created by the t(11;17) translocation, in which *E2A* is fused to the gene that encodes hepatic leukemia factor (*HLF*).[100] HLF is a member of the bZip family of transcription factors. The E2A-HLF fusion protein contains the transcriptional activation domains of E2A linked to the DNA-binding and protein-protein interaction motifs of HLF. Thus, this chimeric protein should activate the transcription of genes normally regulated by HLF. In addition, E2A-HLF itself appears to inhibit apoptosis.[100] A zinc-finger transcriptional repressor, SLUG, which functions as an anti-apoptotic factor in normal hematopoietic progenitor cells, is aberrantly upregulated by E2A-HLF.[101]

Acute Lymphoblastic Leukemia with TEL-AML1 Rearrangements

The t(12;21) translocation forms a chimeric gene consisting of the 5′ portion of the *TEL* gene (also known as *ETV6*) and the nearly complete *AML1* gene (also known as *CBFA2*).[48] This translocation can rarely be identified by conventional cytogenetic banding techniques but can frequently be detected by fluorescence in situ hybridization. The nontranslocated *TEL* allele is frequently deleted. The *TEL-AML1* gene fusion is the most common genetic abnormality in pediatric ALL (approximately 20% of cases). In some series the *TEL-AML1* abnormality was not significantly prognostic,[102,103] whereas in others it defined a subgroup with excellent prognosis.[86,104,105] ALL cells bearing this abnormality do not show a distinctive propensity to apoptosis.[87] Reportedly, however, they have an increased in vitro sensitivity to asparaginase,[106], as well as to doxorubicin, etoposide, amsacrine, and dexamethasone.[107] Similar to T-cell ALL, blast cells with either *TEL-AML1* or *E2A-PBX1* fusion accumulate significantly lower levels of methotrexate polyglutamates than do those with other genetic abnormalities, suggesting that patients with these genotypes might benefit from an increased dose of methotrexate.[108]

The *TEL* gene belongs to the *Ets* family of transcription factors. TEL functions as a sequence-specific DNA-binding transcription regulator. It is normally widely expressed and seems to have an essential role in yolk sac angiogenesis, neuronal development, and the establishment of bone marrow hematopoiesis,[109] and is a regulator of hematopoietic stem cell survival.[110] *AML1* encodes a transcription factor that binds DNA as a heterodimer with CBFβ and is essential for the development of definitive hematopoiesis.[109] In addition, the TEL-AML1 protein represses AML1-mediated transcriptional activation through a dominant negative mechanism.[109] Retroviral transduction of murine bone marrow cells with *TEL-AML1* is associated with a higher frequency of leukemia resembling ALL.[111] Notably, the *TEL-AML1* fusion can be induced by apoptogenic stimuli in lymphoid cells.[112]

Acute Lymphoblastic Leukemia with *MLL* Gene Rearrangements

Structural alterations involving band 11q23 of chromosome 11 are the most frequent cytogenetic abnormality in infant ALL.[48] In most cases the target is a gene designated *MLL*, for mixed-lineage leukemia (also known as *HRX*, *ALL-1*, and *HTRX1*).[48] The most common 11q23 abnormality in ALL is the t(4;11), which produces a chimeric protein that contains the N-terminal portion of MLL linked in-frame to the C-terminal portion of AF-4. However, *MLL* has been reported in translocations with more than 50 partner genes in cases of leukemia. MLL is crucial for embryonic development and hematopoiesis; it normally regulates expression of HOX genes.[48] The leukemia-associated alterations in MLL directly disrupt both of these crucial activities.

The prognosis of leukemias with an *MLL* rearrangement varies according to the partner gene, age of the patient, and the treatment administered. Treatment outcome differs by age group with infants having the worst outcome,[113–115] A study found that 13 of 24 infants had breakpoints in the telomeric part of the *MLL* breakpoint cluster region, whereas 29 of 34 children and adults had breakpoints in the centromeric part of the *MLL* breakpoint cluster region, suggesting that the susceptibility of certain areas of the *MLL* breakpoint cluster region to DNA damage might vary during development and hematopoietic maturation.[116] Infant *MLL-AF4* ALL has a high prevalence of immature, nonproductive, and/or oligoclonal antigen-receptor gene rearrangements.[114,115]

A microarray analysis of gene expression in 17 cases of ALL with *MLL* rearrangement revealed several genes normally expressed in hematopoietic lineages other than lymphocytes, including *FLT3* and *LMO2*.[117] Overexpression of HOX genes, such as *HOXA9*, *HOXA5*, *HOXA4*, and *HOXC6*, was also noted. The results suggested that ALL with *MLL* rearrangement is distinct from both ALL and AML.

Acute Lymphoblastic Leukemia with BCR-ABL Rearrangements

The t(9;22)(q34;q11) rearrangement encodes a chimeric gene consisting of the 5′ portion of *BCR* fused to the 3′ portion of *ABL*.[118] In CML, breaks occur most often within the major breakpoint cluster region of *BCR* and encode a 210- kDa BCR-ABL chimeric tyrosine kinase. In ALL, breaks tend to occur in the minor breakpoint cluster regions, forming a 190-kDa BCR-ABL.[119] In each fusion protein, N-terminal sequences of ABL are replaced by BCR sequences. This alteration results in a constitutively active ABL tyrosine kinase that induces aberrant signaling and activates multiple cellular pathways.[118] Expression of either chimeric protein results in malignant transformation of hematopoietic cells and causes leukemia in murine experimental systems.[120] In mice, aggressiveness of BCR-ABL leukemias is enhanced if the activity of the Arf tumor suppressor is compromised.[121]

As a group, ALL with *BCR-ABL* fusion has been consistently associated with poor response to therapy.[122] The development of the tyrosine kinase inhibitor imatinib mesylate (Gleevec, or Glivec) has provided a way to turn off molecular mechanisms that drive leukemic cell growth in this subtype of ALL.[123] However, clinical results in patients with ALL and *BCR-ABL* show dramatic responses that are followed by the rapid development of resistance,[124] due to the outgrowth of clones with mutations in the *BCR-ABL* kinase domain.[125]

Efforts to counteract this resistance with second-generation inhibitors, such as nilotinib, dasatinib, and others are ongoing.[126–129]

Acute Lymphoblastic Leukemia with c-*MYC* Rearrangements

Most B-cell ALL cases have the t(8;14) translocation; less frequently they have the t(2;8) or the t(8;22).[64] These translocations juxtapose the c-*MYC* proto-oncogene on chromosome 8 with the *IgH*, *Igκ*, and *Igλ* loci on chromosomes 14, 2, and 22, respectively. These rearrangements dysregulate the expression of *c-MYC* (a transcription factor), resulting in altered cell proliferation and survival. Dysregulated c-MYC expression in mice, in the presence of other genetic alterations, results in B-lineage leukemia/lymphoma.[130,131]

Genetic Abnormalities in T-Cell Acute Lymphoblastic Leukemia

Genes that are dysregulated in T-cell ALL include *SCL* (*TAL-1*), *LMO1* (*TTG-1*), *LMO2* (*TTG-2*), and *HOX11*.[48,53] As a result of the t(1;14) translocation, *SCL* (a gene involved in early hematopoiesis) is inserted into the *TCRδ* locus on chromosome 14; an internal deletion in the 5′ untranslated region of SCL is found in an additional 25% of T-lineage ALL cases. This deletion juxtaposes a locus called *SIL* with the *SCL* coding region, resulting in the expression of a fused *SIL-SCL* transcript that encodes a normal SCL protein.

The t(11;14)(p15;q11) translocation inserts *LMO1* into the *TCRA/D* locus, whereas the t(11;14)(p13;q11) translocation places *LMO2* in this locus. The LMO1 and LMO2 proteins, which are then inappropriately expressed, contain two zinc-binding domains and participate in multiprotein DNA-binding complexes. LMO2, like SCL, plays an essential role in the development of primitive and definitive hematopoiesis.[132] Activation of LMO2 by retroviral insertion in its proximity has been implicated in the development of T-cell leukemia in a patient with X-linked severe combined immunodeficiency treated with gene therapy.[133]

An additional alteration found in T-cell ALL is the deletion from chromosome 9p21of the *INK4a* and *INK4b* genes, which encode the $p16^{INK4a}$ and $p15^{INK4b}$ inhibitors of the Cdk4 cyclin D-dependent kinase.[134] This locus, which is deleted in more than 50% of T-lineage cases, also encodes another cell cycle–regulatory protein, $p19^{ARF}$, which arrests cell cycle progression through p53.[135]

In a study of 59 T-lineage ALL cases, Ferrando and associates detected high expression of *HOX11* mRNA in 8, *TAL1* mRNA in 29, and *LYL1* mRNA in 13.[5] Overexpression of *LMO1* or *LMO2* was observed in most samples overexpressing *TAL1*, and high levels of *LMO2*, but not *LMO1*, were found in the $LYL1^+$ samples. Of the 59 cases, 10 did not express abnormal levels of any of the transcription factor genes studied. High levels of *LYL1* expression were associated with an undifferentiated thymocyte phenotype.[5] A highly favorable prognosis was noted for $HOX11^+$ cases. Expression of HOX11L2, a transcriptional regulator closely related to HOX11, is a frequent abnormality in childhood T-ALL.[5,136,137] The prognosis of this subset of T-ALL depends on the treatment,[138] and it was associated with poor outcome in some studies.[5,137] It has been proposed that overexpression of *HOX11*, *TAL1* and *LMO2*, frequently overexpressed in T-ALL cells that lack cytogenetic abnormalities involving the chromosomal regions that contain these genes, are due to loss of upstream down-regulatory transcriptional mechanisms.[139]

Subtypes of Acute Lymphoblastic Leukemia Identified by Global Gene Expression

In gene expression microarray analysis of 327 samples from children with ALL that used approximately 12,500 gene probes, Yeoh and coworkers identified expression patterns that distinguished B-lineage ALL from T-lineage ALL,[6] confirming the results of a smaller series.[140] Moreover, among cases of B-lineage ALL, those with hyperdiploidy (>50 chromosomes), *BCR-ABL*, *E2A-PBX1*, *TEL-AML1*, or *MLL* gene rearrangement could be clearly distinguished.[6] Interestingly, a subgroup of 14 cases had a distinct gene expression profile but showed no consistent cytogenetic abnormality.[6] In T-ALL, $HOX11^+$ cases showed increased expression of the genes associated with the early cortical thymocyte stage of differentiation, whereas the expression pattern associated with *TAL1* expression seemed to reflect the late cortical stage of thymocyte differentiation.[5]

Subsequent studies have confirmed that remarkable capacity of gene expression profiling to identify known subtypes of ALL,[8,10,117,141] as well as to identify novel patient subgroups,[5,6,8] a capability that may improve risk classification in ALL. Genome-wide expression profiling technology promises to significantly facilitate the discovery of molecules that critically influence drug resistance, as shown by studies determining gene expression changes in response to methotrexate and/or mercaptopurine,[142,143] by correlative studies based on drug sensitivity findings in vitro,[144–146] and in vivo.[147,148] By comparing gene expression profiles at diagnosis and minimal residual disease (MRD) during remission-induction therapy, we recently identified CASP8AP2, a mediator of apoptosis and glucocorticoid signaling, as a strong prognostic indicator in childhood ALL.[148]

Acute Myeloid Leukemia

Figure 101-3 shows the cytogenetic groups in AML.

Acute Promyelocytic Leukemia with t(15;17) Translocation

Acute promyelocytic leukemia (APL; M3 AML)) accounts for approximately 10% of childhood AML cases, and more than 95% of cases of APL show the presence of a t(15;17)(q22;q11) chromosomal translocation. As a result of this translocation, the retinoic acid gene (*RARA*) on chromosome 17 is fused to the *PML* gene on chromosome 15, resulting in the formation of a PML-RARα chimeric protein.[149] The translocation gives rise to two fusion transcripts: PML-RARA, which is expressed in all cases, and RARA-PML, which is expressed in approximately 80% of cases.[150] The t(15;17)(q22;q11) translocation is invariably associated with APL.

RARα is a ligand-regulated transcription factor that controls the transcription of many genes, some of which are involved in hematopoietic differentiation.[151] The normal function of RARα is linked to its formation of heterodimers with a member of the retinoid X receptors (RXRs). Its repression is mediated through the formation of a multisubunit complex consisting of RARα, RXR, the nuclear receptor-corepressors N-CoR/ silencing mediator of retinoid and thyroid receptors (SMRT) and Sin3A, and a histone deacetylase.[152] Normally,

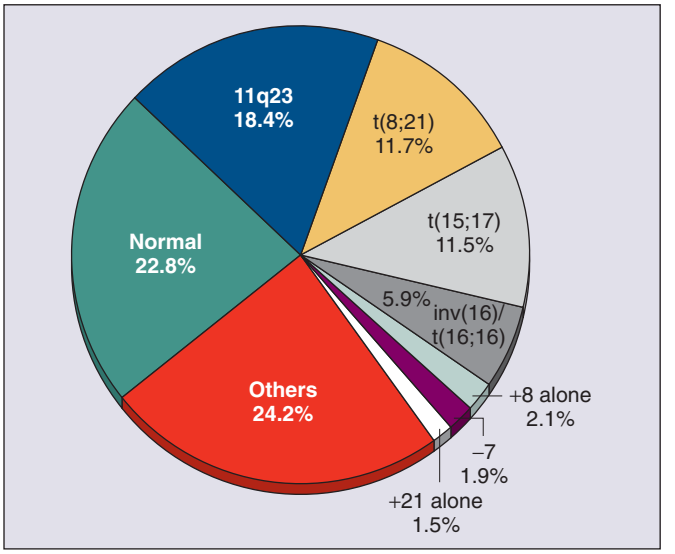

Figure 101-3 • Cytogenetic subgroups in childhood AML.

retinoic acid induces a conformational change in RARα that results in the disassembly of the complex and the recruitment of transcriptional coactivators.[151] The ubiquitous protein PML resides in nuclear organelles (nuclear bodies) conjugated to the ubiquitin-like protein SUMO1.[153] PML has been implicated in multiple cellular functions, including apoptosis, but its precise role remains undefined.[153]

The *PML-RARA* gene fusion can cause a syndrome similar to APL in transgenic mouse models.[154,155] Leukemogenic mechanisms mediated by the PML-RARα protein have been extensively studied. The RARA hormone-binding domains, dimerized by PML, has greater affinity for SMRT than the RARA/RXR heterodimers, possibly resulting in a block of myeloid differentiation and increased resistance to apoptosis.[149,156,157] In addition, PML-RARα disrupts PML nuclear bodies; the resulting redistribution of PML might interfere with the growth-regulatory activities of PML.[158] Pharmacologic doses of all-*trans* retinoic acid (ATRA) lead to conformational changes in PML-RARα that are sufficient to revert its repressor activity, allowing the recruitment of transcriptional coactivators, including CBP and p300.[159] However, mutations of the RARα binding domain may lead to resistance to ATRA.[160] Arsenic trioxide (As_2O_3), another effective treatment for APL, does not bind to RARα, but it binds to PML and induces the degradation of PML-RARα, ultimately causing apoptosis of leukemic cells.[159]

Two variants of the t(15;17) translocation have been identified: the t(5;17), which encodes an NPM-RARα fusion oncoprotein,[161] and the t(11;17), which encodes a PLZF-RARα fusion protein.[162] The latter chimeric protein forms a stable complex with nuclear corepressors and histone deacetylases and is unresponsive to either retinoic acid or ATRA. Thus, cases of AML with the t(11;17) translocation have APL morphology but are unresponsive to treatment with ATRA.

Acute Myeloid Leukemia with Alterations of the Core Binding Factor Complex

The AML1/CBFβ transcription factor complex is essential for normal hematopoiesis.[49,163] The two most common chromosomal rearrangements in de novo AML are the t(8;21) and inv(16)/t(16;16), found in approximately 12% and 6% of cases, respectively.[164] The t(8;21) translocation targets AML1, and inv(16)/t(16;16) targets CBFβ.

The t(8;21)(q22;q22) translocation is seen almost exclusively in cases of AML with FAB M2 morphology and accounts for up to 40% of these cases.[164] This translocation results in a fusion between *AML1* (also called RUNX1, core binding factor protein [CBFα], and PEBP2 alpha B) and the eight twenty-one (*ETO*) gene (also known as *MTG8*) on chromosome 8.[49] *ETO* is the mammalian homolog of the *Drosophila* gene nervy. The Nervy homology 2 (NHR2) domain in ETO mediates oligomerization and the interactions of the fusion protein with ETO itself as well as MTGR1, MTG16, and corepressor molecules mSin3A and HDAC1 and HDAC3.[165] In turn, this contributes to suppress myeloid differentiation and enhance the clonogenic potential of myeloid progenitors.[165]

Expression of AML1-ETO during murine development through a gene targeting strategy resulted in an embryonic lethal phenotype that was almost identical to that observed with the loss of AML1 or CBFβ.[166,167] Unlike AML1- or CBFβ-deficient embryos, which lack detectable hematopoietic progenitors, AML1-ETO–expressing embryos contained dysplastic multilineage hematopoietic progenitors with an abnormally high self-renewal capacity. In a conditional "knockin" mouse, AML-ETO did not block myeloid cell differentiation, nor was it sufficient to induce leukemia.[168] However, induction of cooperating mutations resulted in the development of an AML-like disease that resembled human AML1-ETO–associated leukemia.[168] AML1-ETO is degraded by treatment with histone deacetylase inhibitors,[169] providing a molecular basis for the use of this class of drugs in this type of AML.

The inv(16)(p13q22) and the variant translocation t(16;16) result in the formation of a chimeric gene consisting of the 5′ portion of *CBFB* fused to a variable length of the 3′ portion of the smooth muscle myosin heavy chain gene, *MYH11*.[50] The encoded CBFβ-MYH11 product continues to bind to AML1.[170] The genetics of the inv(16) chromosomal rearrangement suggest that the encoded product functions in a dominant manner to induce leukemia.[171] Further, CBFβ-MYH11 has been shown to directly repress AML1-mediated transcription by sequestering AML1 into inactive cytoplasmic complexes that are attached to actin-containing filamentous structures.[172]

When *CBFB-MYH11* expression was induced during murine embryogenesis, it resulted in a phenotype nearly identical to that observed with the loss of *AML1* or *CBFB*.[173] However, *CBFB-MYH11* also caused an abnormal shift of primitive erythropoietic differentiation toward immature to mid-mature cells. This result suggests that the chimeric product not only inhibits normal AML1/CBFβ activity but also provides other signals that result in abnormalities in cell growth and development. Definitive hematopoiesis can be restored in CBFβ-deficient mice by ectopic expression of *CBFβ* transgenes but not transgenes encoding *CBFB-MYH11*.[174] Transduction of *CBFβ-MYH11* into human $CD34^+$ cells leads to their abnormal proliferation.[175]

Acute Myeloid Leukemia with Alterations of *MLL*

As discussed in the ALL section, translocations involving 11q23 and the *MLL* gene result in a gain of MLL function by generating novel chimeric proteins containing the N terminus of MLL fused in-frame with one of many partner proteins of diverse function.[48] Translocations involving 11q23 are found in approximately 18% of childhood AML cases.[164] The two most common 11q23 translocations in AML, t(9;11)(p22;q23) and t(11;19)(q23;p13.3), involve *AF9* and *ENL*, respectively. Both molecules are homologous to proteins involved in RNA polymerization. When *MLL-AF9* was expressed in mice through a "knockin" strategy, mice developed AML,[176] as did mice in which hematopoietic stem cells had been transduced with *MLL-ENL*.[177] Other MLL fusions involving the forkhead transcription factors FKHRL1 and AFX[178] and the leucine zipper AF10[179] can also induce leukemia in mice when expressed in murine hematopoietic cells. It was recently shown that that enforced *MLL-AF9* expression in discrete populations of more differentiated hematopoietic progenitors can also initiate leukemia and that self-renewing cells are frequent, accounting for up to 30% of myeloid cells and express mature myeloid antigens.[180,181]

Acute Myeloid Leukemia with Other Genetic Abnormalities

Fms-like tyrosine kinase 3 (FLT3) (also known as fetal liver kinase 2 [flk2] or stem cell tyrosine kinase 1 [STK-1]) is receptor tyrosine kinase, which regulates the growth of hematopoietic cells by interacting with its ligand.[51] Internal tandem duplications (ITDs) of the *FLT3* gene have been reported in approximately 20% of adult AML and 10% to 12% of childhood AML cases.[182,183] *FLT3* ITDs result in ligand-independent hematopoietic cell growth and induce a myeloproliferative syndrome in murine models.[184] *FLT3* ITDs are associated with a poor response to chemotherapy and dismal outcome.[182,183] The incorporation of FLT3 kinase inhibitors into current treatment protocols might offer opportunities to improve outcome.[185–188] A monoclonal antibody against FLT3 with antileukemic activity has also been recently developed.[189]

Mutations of the nucleophosmin (*NPM1*) gene occur in 50% to 60% of adult AML with normal karyotype.[190] The prevalence of *NPM1* mutations is lower in childhood AML than in the adult counterpart: one study found them in 7 of 107 patients with non-M3 AML.[191] NPM1 encodes a nucleo-cytoplasmic shuttling protein mainly localized in the nucleolus, but NPM1 mutants localize aberrantly in the leukemic cells cytoplasm, thus allowing the identifica-

tion of these leukemias by immunocytochemistry.[192] It has been suggested that alterations of NPM function might lead to deregulation of p53 stability and its transcriptional activity.[193] In adult AML, *NPM1* mutations in absence of *FLT3* ITDs and the presence of a normal karyotype identify a prognostically favorable subgroup.[194] Childhood AML cases with mutated NPM1 typically have a normal karyotype and tend to occur in older patients.[191]

Down syndrome patients are highly predisposed to acute megakaryoblastic leukemia, which has a treatment outcome that is more favorable than in non-Down syndrome patients.[195,196] A characteristic feature is the presence of somatic mutations of the gene encoding transcription factor GATA1, leading to exclusive expression of a truncated form GATA1.[197,198] Leukemia blasts express both erythroid and megakaryocytic markers, suggesting transformation of an erythroid/megakaryocyte precursor of fetal origin.[197,198]

Genetic Alterations in Myelodysplastic Syndrome and Juvenile Myelomonocytic Leukemia

An abnormal karyotype is found in 60% to 70% of the children with MDS.[11–13] The numerical abnormalities dominate, with only 10% showing a translocation, a derivative, or a deletion as the sole abnormality. The most common cytogenetic abnormality in MDS and JMML is monosomy 7 or del(7q): in a series of 167 children with MDS or MPD, 53 had this abnormality.[199] Children with mutations in the neurofibromatosis gene *NF1* show a 200- to 500-fold increase in the incidence of myeloid malignancies, particularly JMML.[200] Neurofibromatosis is observed in about 15% of patients, and an additional 15% have loss-of-function mutations in *NF1*.[200] *NF1* functions as a tumor suppressor gene in myeloid leukemogenesis by negatively regulating Ras signaling, and in 15% to 30% of patients with JMML, oncogenic mutations of *RAS* have been demonstrated.[201] JMML also frequently occurs in patients with Noonan's syndrome, a congenital disorder featuring facial anomalies, short stature, and heart defects, associated with mutations of the *PTPN11* proto-oncogene, which encodes the tyrosine phosphatase SHP-2 involved in the Ras signaling pathway.[202]

Global Gene Expression Studies in Childhood Acute Myeloid Leukemia

Gene expression profiling reliably distinguishes AML from ALL.[10,140,141] A similar discrimination can also be achieved by studying microRNA expression.[203]

A study of 130 diagnostic samples of childhood AML with the Affymetrix U133A microarray identified discriminating genes for all major genetic subtypes, including t(15;17)/*PML-RARa*, t(8;21)/*AML1-ETO*, inv(16)/*CBFβ-MYH11*, *MLL* chimeric fusion genes, and cases classified as FAB-M7.[9] Interestingly, the expression signatures generated from the pediatric samples could accurately classify adult de novo AML with the same lesions. By combining data sets of 130 AML and 137 ALL it was possible to identify a gene expression signature for cases with MLL chimeric fusion genes irrespective of lineage.[9] A study of 54 pediatric AMLs with an oligonucleotide microarray containing 12,566 probe sets revealed 35 prognostic genes.[204] In a more recent study of 28 cases, expression levels of *CDKN2C*, *CRADD*, and *IGFBP-2* genes were significantly associated with treatment response.[205] These results are potentially important and warrant further studies.

CLINICAL COURSE AND PROGNOSTIC FACTORS

Relapse

Relapse is defined as the reappearance of leukemic cells at any site after remission has occurred. Most relapses occur during treatment or within the first 2 years after its completion, although ALL patients have been observed to relapse as late as 10 years after diagnosis.[206] The bone marrow is the most common site of relapse in both ALL and AML. In children with ALL, the frequency of relapse in extramedullary sites, such as the CNS and testes, has decreased to less than 5% and 2%, respectively. Leukemic relapse occasionally occurs at other sites, including the eye, ear, ovary, uterus, bone, muscle, tonsil, kidney, mediastinum, pleura, and paranasal sinus. Extramedullary relapse in children with ALL frequently presents as an "isolated" finding, but most occurrences are associated with MRD in the bone marrow.[207]

A small fraction of patients experience a recurrence of acute leukemia with an immunophenotype different from that determined at diagnosis. Often, these leukemias are secondary malignancies caused by the mutagenic effects of leukemia treatment.[36]

In some cases recurrent leukemia has genetic features that confirm its relationship to the original leukemic clone but has the phenotype of a different lineage (lineage switch). There have been reports of leukemias morphologically and immunophenotypically characterized as ALL that relapse as AML (or vice versa) while retaining the karyotypic and molecular features of the original clone.[208,209]

Bone marrow relapse, with or without extramedullary involvement, predicts a poor outcome for most patients; patients with isolated bone marrow relapse generally fare worse than those with combined bone marrow and extramedullary relapse.[17,210] In either ALL or AML, the duration of the second remission depends on the duration of the first remission.[3,17,211] In children with relapsed ALL, factors indicating an especially poor prognosis are short initial remission and T-cell immunophenotype. Other adverse factors include t(9;22) translocation, presence of circulating blast cells, or a high leukocyte count at relapse and intensive primary therapy. More recently, it has been demonstrated that the presence of MRD at the end of second remission induction is a strong adverse prognostic indicator.[212,213] Although chemotherapy may secure a prolonged second remission in children with ALL who experience late relapse (e.g., >6 months after cessation of therapy), allogeneic hematopoietic stem cell transplantation is the treatment of choice for patients who experience hematologic relapse during therapy or shortly thereafter and for those with T-cell ALL. Among patients with isolated CNS relapse, a long initial remission and a standard-risk status by National Cancer Institute-Rome criteria (i.e., age 1 to 9.9 years and leukocyte count $<50 \times 10^9$ cells/L at initial diagnosis) were independent favorable prognostic features in a recently reported study.[214] In children with relapsed AML, outcome is generally poor.[215] Relapse occurring at less than 18 months after therapy, and M5 or M7 morphology are associated with a dismal prognosis.[17,216]

Prognostic Factors in Acute Lymphoblastic Leukemia

Stringent evaluation of the risk of relapse is needed at the time of diagnosis to direct therapy so that patients are neither over- nor undertreated. Although age, leukocyte count, leukemic cell genotype, and response to early remission induction therapy are commonly used in risk classification, there is no consensus on the most useful criteria, and there is also no widely accepted system or terminology for defining risk groups. For example, patients have been classified as lower risk, intermediate risk, and higher risk by the Children's Cancer Group (CCG);[217] as standard-risk, medium-risk, or high-risk by the Berlin-Frankfurt-Münster Consortium;[218] as good-risk B-lineage, poor-risk B-lineage, or T-lineage by the Pediatric Oncology Group (POG);[219] and as standard-risk, high-risk, or very high-risk by St. Jude Children's Research Hospital.[220] Having identified a group of patients at very low risk of relapse, the Children's Oncology Group (COG) proposed a four-group classification scheme: low-risk, standard-risk, high-risk, and very high-risk.[221] In this chapter we use the St. Jude risk classification system, which is based on presenting features and on results of treatment response based on MRD assays (Fig. 101-4). It should be noted that infants younger than 12 months of age are generally treated on separate protocols.

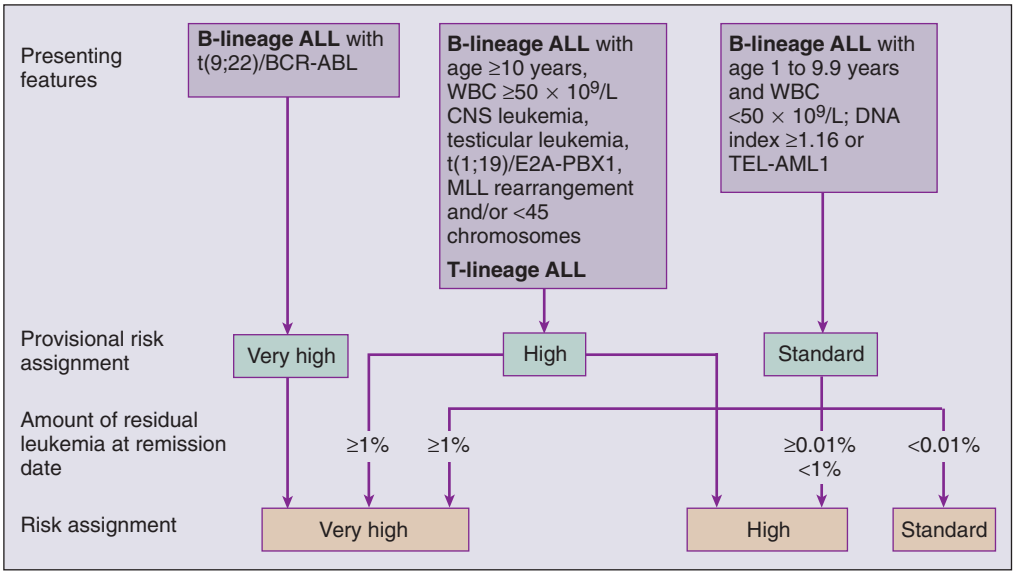

Figure 101-4 • Risk classification of childhood ALL at St. Jude Children's Research Hospital.

The type of treatment regimen remains the most important determinant of outcome. Thus, clinical and biologic variables may lose their predictive strength when treatment is changed. Presenting age and leukocyte count have generally maintained prognostic strength in B-lineage but not T-lineage ALL.[219,220,222] Even in B-lineage ALL, however, their value is limited because as many as 20% of patients who are considered at standard risk by these criteria (age 1 to 9 years with leukocyte count $<50 \times 10^9$ cells/L) may relapse, and very high-risk cases that require allogeneic hematopoietic stem cell transplantation cannot be reliably distinguished from high-risk cases by these criteria. For reasons still poorly understood, boys fare significantly worse than girls on most treatment protocols,[217–219,223–226] with rare exceptions.[227,228] In the studies of the COG, African American patients and those of Latin-American origin had a significantly worse outcome than Caucasians, after adjustment for other prognostic features.[229,230] By contrast, African Americans fared as well as Caucasians in our single-institution protocols, a finding we attributed to equal access to effective contemporary treatment for both groups of patients.[16,231]

Primary genetic abnormalities of leukemic cells influence their aggressiveness and response to therapy but are not 100% predictive of outcome. For example, as many as 15% of children with favorable genetic features (*TEL-AML1* fusion and hyperdiploidy >50 chromosomes) will eventually experience relapse, while approximately one third of those with high-risk abnormalities [the Philadelphia chromosome with *BCR-ABL* fusion or the t(4;11) translocation with *MLL-AF4* fusion] can be cured with chemotherapy alone.[3,232] It should be noted that age 1 to 9 years conferred a favorable prognosis in cases with the Philadelphia chromosome or the t(4;11) translocation, and a high leukocyte count was associated with a poor outcome in those with the former genetic feature.[113,122,221,233]

Prognostic Factors in Acute Myeloid Leukemia

Patients with APL have a relatively favorable prognosis. Patients with Down syndrome and AML often have a favorable response to therapy and require less intensive chemotherapy.[195] Age younger than 2 years and leukocyte count less than 100×10^9 cells/L were significantly associated with better outcome in some series.[234] There are also data suggesting that children younger than 10 years benefit more than older children from intensive therapies.[235] Although African American children had inferior outcome in some studies,[236] this was not the case in recent St. Jude studies.[237]

The Cancer and Leukemia Group B (CALGB) trials demonstrated that adult patients with AML and inv(16) or t(8;21) had a better outcome than patients with all other subtypes of AML and had a particularly good outcome when they were treated with multiple courses of high-dose cytarabine.[238;,239] In the United Kingdom Medical Research Council (MRC) AML10 trial, the 5-year overall survival estimates for patients with t(8;21) and inv(16) were 69% and 61%, respectively.[240] A more recent analysis of the 629 patients treated in the MRC studies confirmed that t(8;21) and inv(16) [together with t(15;17)] are independent good-risk features, and identified loss of a sex chromosome in the t(8;21) group as being associated with excellent outcome.[241] The POG reported 4-year overall survival estimates of 52% and 75% for children with similar karyotypes treated on the 8821 trial.[164] A similar result has been achieved at St. Jude, with 6-year overall survival estimates of 55% for cases with t(8;21) and 70% for cases with inv(16) treated in recent trials.[216] The French AML Intergroup demonstrated a 5-year overall survival estimate of 59% for patients with t(8;21) and suggested that the white blood cell (WBC) index (the product of the WBC count and the ratio of bone marrow blast cells) can identify prognostic subgroups of t(8;21)-positive patients.[242]

AML patients with the t(9;11) translocation also have had a favorable prognosis in some trials [243,244] but not in others.[164] In the MRC AML10 trial, patients with the t(9;11) translocation had an intermediate outcome, with a 3-year overall survival estimate of 50%,[240] whereas patients with the t(9;11) or other 11q23 abnormalities had a rather poor outcome on POG 8821 (4-year overall survival 33%).[164] Among patients treated at St. Jude for AML, those with the t(9;11) and inv(16) had a better outcome (5-year event-free survival estimate, 70% or higher) than patients in all other cytogenetic or molecular subgroups.[216] Favorable outcome of these patients is attributed to the use of epipodophyllotoxins, agents known to be effective against M5 leukemia,[245,246] and of 2-chlorodeoxyadenosine (2-CDA), which is particularly effective against M5 AML.[247] In vitro, blast cells from patients with the t(9;11) are more sensitive to cytarabine, etoposide, anthracyclines, and 2-CDA than are blast cells from other cases.[248]

Some studies have suggested that partial tandem duplications of the *MLL* gene confer a poor prognosis.[249,250] Patients with acute megakaryoblastic leukemia have significantly worse outcomes than those with other subtypes of AML.[195,251,252] At St. Jude the estimated 5-year survival for these group of patients in the absence of Down syndrome was only 10%, and no patients were cured by chemotherapy alone.[195] The outcome of treatment-related AML is also dismal, with survival rates of only 10% to 20%, despite the use of allogeneic hematopoietic cell transplantation.[253–255] Likewise, patients with MDS, AML arising from MDS, or AML with monosomy 7 often have resistant disease that is difficult to cure.[164,199,240,256]

FLT3 ITDs have been associated with a poor prognosis in both adults and children with AML.[257–262] An analysis of 91 children with ALL treated on CCG trials demonstrated an 8-year event-free survival estimate of only 7% for the 15 cases with *FLT3* ITD.[260] A multivariate analysis demonstrated that *FLT3* ITD was the most important prognostic factor in this study. Several studies have questioned the prognostic importance of *FLT3* mutations.[263–266] In an analysis of 82 adults with AML who were treated on the CALGB 9621 protocol and who had normal cytogenetics, three leukemic cell genotypes were detected: 59 cases had 2 wild-type *FLT3* alleles ($FLT3^{wt/wt}$), 15 had one wild-type and one ITD allele ($FLT3^{ITD/wt}$), and 8 had only one ITD allele ($FLT3^{ITD/-}$).[263] Overall and event-free survival were similar in patients with the $FLT3^{wt/wt}$ and $FLT3^{ITD/wt}$ genotypes. Only patients with the $FLT3^{ITD/-}$ genotype had a significantly worse outcome. Similarly, an analysis of 979 patients revealed that those with a high *FLT3* mutant to wild-type ratio had significantly shorter disease-free and overall survival, whereas those with low ratios had outcomes similar to those of patients without *FLT3* mutations.[265] Gene expression studies in samples with *FLT3* mutations identified an association between high expression of the *RUNX3* gene, low expression of the *ATRX* gene, and an inferior outcome.[267]

Prognosis of Myelodysplastic Syndrome and Juvenile Myelomonocytic Leukemia

The clinical course of children with MDS is variable. The conversion rate to AML of approximately 40% is similar to that observed in adults.[199] MDS conversion to AML may occur either with an abrupt increase in blasts or through a gradual progression.[11–13] In only approximately 15% of JMML patients the disease transforms into acute leukemia blasts crisis.[199] However, only a very small minority of patients enjoy long-term survival with a relatively indolent disease, treated with observation or low-dose chemotherapy.[11] For the majority of patients the disease course is rapid and fatal within a year. Patients with older age, a low platelet count, and high fetal hemoglobin levels fare worse. Stem cell transplantation is the only therapy that has produced sustained remissions.[11–13]

PRIMARY TREATMENT

Acute Lymphoblastic Leukemia

Overview

In the more successful contemporary clinical trials, 5-year event-free survival estimates for children with newly diagnosed ALL range from 75% to 83% (Table 101-5).[217–220,222–225,227,228,268–277] The improved cure rate of ALL can be attributed mainly to the development of more effective chemotherapeutic regimens through successive clinical trials. In patients with mature B-cell ALL, short-term (2 to 8 months) regimens of intensive chemotherapy based primarily on cyclophosphamide, methotrexate, cytarabine, and intrathecal therapy currently result in cure rates of 74% to 87%.[278–280] The development of a highly effective uricolytic agent, recombinant urate oxidase (rasburicase; Elitek, Fasurtec), promises to improve the results of treatment still further by reducing early morbidity and mortality caused by tumor lysis syndrome and acute renal failure.[281,282]

For all patients except infants, the basic approach to therapy consists of a relatively brief remission-induction phase, followed by intensification (consolidation) therapy, and then prolonged continuation treatment. All patients require treatment for subclinical leukemia of the CNS, which should be initiated early in the form of intrathecal therapy.

Remission Induction

Remission-induction regimens include a glucocorticoid (prednisone, prednisolone, or dexamethasone), vincristine, and at least a third agent (asparaginase or anthracycline). With improved supportive care and chemotherapy, the rate of complete remission now ranges from 96% to 99%.[217–220,222–225,227,228,268–276] Attempts have been made to

*Standard-risk group: children 1 to 9 years old with leukocyte count $<50 \times 10^9$ cells/L; high-risk group: all others, except infants. Differences in "overall" partly reflect the disproportion of high-risk cases referred to some institutions as compared with the others.

intensify induction therapy, especially for patients with high-risk and very high-risk ALL, on the premise that a more rapid and profound reduction of the leukemic cell burden may forestall the development of drug resistance in leukemic cells. However, several studies suggest that intensive induction therapy may not be necessary for standard-risk patients, providing that they receive postinduction intensification therapy.[217,223] Moreover, overly intensive induction therapy may lead to inferior overall outcome because of increased early morbidity and mortality.[283,284] Furthermore, we found that patients who achieved MRD^- status 14 weeks after the end of remission-induction therapy had a risk of relapse as low as that of patients who achieve this status earlier (at the end of remission induction).[285]

Most remission-induction regimens include asparaginase. However, several clinical trials using asparaginase only in the postinduction period had an excellent remission induction rate with low morbidity (especially in terms of thrombotic complications) and excellent long-term event-free survival.[223,227] A randomized trial compared the relative efficacy and toxicity of asparaginase and epidoxorubicin as a third remission-induction agent in patients with standard-risk ALL. Patients treated with asparaginase had a significantly lower rate of successful remission induction due to a higher rate of fatal infection.[283] Therefore, the use of asparaginase in remission-induction regimens is being challenged. It should also be noted that different forms of asparaginase have different pharmacokinetic profiles as well as toxicity and efficacy.[283,286] Compared with *Escherichia coli* asparaginase, *Erwinia* asparaginase was associated with inferior antileukemic response but had lower toxicity, a result now attributed to the use of inadequate doses of the latter medication.[287] In some current protocols, polyethylene glycol–conjugated asparaginase, a long-acting and less allergenic form, has replaced native *E. coli* asparaginase in initial treatment.[286] Because of the cross-reactivity of antibodies to these two forms of asparaginase, patients with allergic reactions to either preparation should be treated subsequently with *Erwinia* asparaginase.[288]

Perhaps because of its longer half-life and increased penetration into CSF,[289] dexamethasone has been used instead of prednisone or prednisolone in some induction and continuation regimens. Although this substitution yielded an improved outcome in one randomized trial,[217] it was implicated in excessive life-threatening infections and septic deaths in another study.[284] This finding underscores the importance of potential drug interactions in any complex multiagent regimen. A small randomized study showed that an increased dose of prednisone produced results comparable to those achieved with dexamethasone in the context of other intensive treatment.[290]

Intensification or Consolidation

With restoration of normal hematopoiesis, patients in remission become candidates for intensification (consolidation) therapy. There is no dispute about the importance of this phase of therapy, but there is also no consensus about the optimal regimens and their duration. Delayed intensification (or reinduction), pioneered by investigators in the Berlin-Frankfurt-Münster consortium,[269] is perhaps the most widely used regimen. It is basically a repetition of the initial induction therapy 3 months after the end of remission induction. Investigators at the CCG found that double delayed intensification beginning at week 32 of treatment improved the outcome of patients with high-risk (or so-called intermediate-risk) leukemia.[291] Interestingly, in this study additional pulses of vincristine and prednisone during continuation therapy did not improve outcome, suggesting that double delayed intensification was of benefit because of the increased dose intensity of other agents (asparaginase, anthracycline, cytarabine, and cyclophosphamide), or the timing/scheduling of the intensification regimen. Extended and stronger intensification therapy also significantly benefited patients with high-risk ALL and a slow response to initial induction therapy.[292] The benefit of double delayed intensification for high-risk ALL was recently confirmed by the Italian group AIEOP.[293] Limited data suggest that patients at standard risk do not need double delayed intensification. Hence, it seems that reinduction or delayed intensification therapy is beneficial to all patients, and double or prolonged intensification is beneficial to those with high-risk or very high-risk leukemia.

The use of different intensification regimens in various clinical trials has also led to the identification of effective treatment components for certain subtypes of leukemia. For example, improved outcome of T-lineage ALL in the clinical trials of the Dana Farber Cancer Institute (DFCI) Consortium and CCG has been credited to the intensive use of asparaginase,[227,271,294] a finding that has been corroborated by a randomized study of the POG.[295] Interestingly, in the study of the DFCI Consortium, patients who tolerated at least 26 weekly doses of asparaginase had a significantly better outcome than those who received fewer doses.[227] Intensive asparaginase treatment is also credited for a very low rate of relapse of ALL with the *TEL-AML1* fusion on the protocols of the DFCI Consortium.[227] In line with this clinical observation, leukemic blast cells with the *TEL-AML1* fusion are reportedly highly sensitive to asparaginase in vitro.[106]

Very high doses of methotrexate (5 g/m^2) seem to improve outcome in patients with T-lineage ALL.[218,221] This observation is consistent with the finding that T-lineage blast cells accumulate methotrexate polyglutamates (active metabolites of methotrexate) less avidly than do B-lineage blast cells, so that a higher serum concentration of methotrexate is needed for adequate response in T-lineage ALL.[296] Nonetheless, high-dose methotrexate also benefits patients with B-lineage ALL.[297] Although the optimal dosage of methotrexate for individual genetic subtypes remains to be determined, a dosage of 2.5 g/m^2 should be adequate for most of these patients.[298] High-dose intravenous 6-mercaptopurine has proved ineffective.[270,299,300] Consistent with this result is the finding that intravenous high-dose 6-mercaptopurine inhibited de novo purine synthesis minimally and exerted minimal antileukemic effects.[301] Similarly, high-dose cytarabine failed to improve the outcome of high-risk ALL in a randomized trial.[272]

Continuation Treatment

The most successful postremission-intensification regimens generally feature continuous therapy,[227,292] whereas high-dose pulse therapy with prolonged rest periods to recover from myelosuppression seems to be less effective.[269] Children with ALL (except those with mature B-cell leukemia) require prolonged continuation treatment. The attempt to intensify early therapy but shorten the total duration of treatment to 1 year in one study resulted in inferior overall event-free survival.[225] The general rule is to continue therapy for a total duration of 2 to 2.5 years. Many investigators prefer to extend treatment for boys to 3 years because of their generally poorer outcome,[226,302] although the benefit of this approach remains to be determined.

The combination of methotrexate administered weekly and mercaptopurine administered daily constitutes the standard "backbone" of the ALL continuation regimen. Tailoring the doses to the limits of tolerance (as indicated by low neutrophil counts) has been associated with an improved clinical outcome.[303] However, overzealous use of 6-mercaptopurine, so that neutropenia precludes further use of chemotherapy and reduces overall dose intensity, is counterproductive.[304] It is well recognized that the rare patients (1 in 300) who have an inherited deficiency of thiopurine *S*-methyltransferase have extreme sensitivity to mercaptopurine. Patients who are heterozygous for this deficiency (~10%) and have intermediate levels of enzyme activity may also require moderate dose reduction to avert side effects.[305] Identification of the genetic basis of this autosomal codominant trait has made the molecular diagnosis of these cases possible.[306] When patients show poor tolerance to methotrexate and mercaptopurine, studies can now be performed to identify and selectively reduce the dosage of the responsible agent, allowing full dosage of the other drug. In randomized trials, thioguanine (given at a daily dose of 40 mg/m^2 or more, produced superior antileukemic responses than mercaptopurine but was associated with profound thrombocy-

topenia, an increased risk of death, and an unacceptably high rate (10% to 20%) of hepatic veno-occlusive disease.[307,308] Mercaptopurine therefore remains the preferred drug, although thioguanine could still be given in short-term courses duirng the intensification phase of therapy.

The addition of intermittent pulses of vincristine and a glucocorticoid to the antimetabolite continuation regimen improves the results[309] and has been widely adopted. Dexamethasone has been substituted for prednisone during continuation therapy in many clinical trials, because of its superior clinical efficacy.[217] However, studies are needed to determine the optimal dosage and duration of dexamethasone therapy during this phase of treatment.

Prevention and Treatment of Central Nervous System Leukemia

Several factors are associated with the occurrence of leukemia in the CNS: presenting risk features, the quantity of leukemic blasts cells in the CSF, and the type of systemic as well as CNS-directed therapy. Patients with high-risk genetic features, large leukemic cell burden, T-lineage ALL, and leukemic cells in the CSF (even if iatrogenic from a traumatic lumbar puncture) are at increased risk of CNS relapse and require more intensive CNS-directed therapy.[61,277,310,311] Because of the adverse consequence of traumatic lumbar puncture at the time of diagnosis, when patients have circulating blast cells we have routinely performed this procedure under deep sedation or general anesthesia, transfused thrombocytopenic patients with platelets, and administered intrathecal chemotherapy immediately after injection of CSF. High-dose methotrexate, while useful in preventing hematologic or testicular relapse, generally has only a marginal effect on the control of CNS leukemia. However, in one study high-dose methotrexate plus intrathecal methotrexate reduced CNS relapse, although it did not affect relapse at other sites or overall surviva1.[222] Additional analyses of the method of delivery of high-dose methotrexate and folic acid rescue are needed to explain this finding. By contrast, dexamethasone was definitely shown to improve CNS control.[217,299,312] In one randomized trial, triple intrathecal therapy with methotrexate, hydrocortisone, and cytarabine was more effective than intrathecal methotrexate alone in preventing CNS relapse, but was associated with an increased frequency of bone marrow or testicular relapse.[313] One explanation for this seemingly paradoxical finding is that an "isolated" CNS relapse is in fact an early manifestation of systemic relapse, and the better CNS control secured by triple intrathecal therapy does not suppress overt relapse in other sites. If so, more effective systemic therapy is needed before the full benefit of triple intrathecal therapy can be realized.

Cranial irradiation is the most effective CNS-directed therapy but can cause substantial neurotoxicity and occasional brain tumors, prompting its replacement with intensive intrathecal and systemic chemotherapy for 80% to 95% of all patients. This approach, in combination with cranial irradiation for selected high-risk or very high-risk cases, has lowered the rate of CNS relapse to less than 5% in most studies.[227,228,269,275,292] The dose of radiation can be lowered to 12 Gy without increasing the risk of CNS relapse, provided that effective systemic chemotherapy is used.[269] In two studies that omitted cranial irradiation altogether, the cumulative risk of isolated CNS relapse was 4.2% and 3%,, and the rate of any CNS relapse (including combined CNS and hematologic relapse) was 8.3% and 6%, respectively.[224,314] Patients with a $CD10^-$ B-lineage (pro-B) leukemic phenotype, CNS 2 or CNS 3 status, and leukocyte count greater than 100×10^9 cells/L had an increased risk of CNS relapse. Because the overall 8-year event survival estimates for the two studies were only 60.7% ± 4% (SE) and 68.4 ± 1.2%, it is still unclear whether improved systemic chemotherapy can reduce the hazard of CNS relapse. It is not conclusively established whether CNS irradiation can decrease the risk of hematologic relapse.

Patients with isolated CNS relapse who did not receive cranial irradiation as initial CNS-directed therapy have a very high retrieval rate; in those who had a long initial remission before the CNS event, the long-term prognosis may even be similar to that of newly diagnosed patients.[214,315] At St. Jude, cranial irradiation is reserved for salvage therapy. Although this approach is under study, most clinical trials still specify cranial irradiation for patients at particularly high risk of CNS relapse (e.g., those with CNS 3 status or T-cell ALL with high leukocyte count).

Infant Acute Lymphoblastic Leukemia

Event-free survival estimates for infants with ALL, especially those with 11q23/*MLL* rearrangements, remain low, ranging from 20% to 45%.[35] In several recent clinical trials high-dose cytarabine, high-dose methotrexate, and intensive consolidation/reinduction therapy seemed to improve outcome.[316–320] However, these results should be viewed as preliminary because of the small numbers of patients studied and the absence of randomization. Intensive systemic and intrathecal treatment, without cranial irradiation, seem to provide adequate CNS protection, even in infants who have CNS leukemia at diagnosis.[319–321] Most investigators now treat infants as a unique subgroup with multiple drugs given at high dosages, without cranial irradiation. The role of allogeneic hematopoietic stem cell transplantation in this age group remains controversial.[113,322–324]

Pharmacokinetic and Pharmacogenomic Variables

The rate of metabolism and systemic clearance of antileukemic agents is widely variable, as is the absorption of orally administered chemotherapy. Both low systemic exposure to methotrexate and low dose intensity of 6-mercaptopurine have been associated with an inferior treatment outcome.[325,326] Importantly, concomitant administration of cytochrome P450 enzyme-inducing anticonvulsants (phenytoin, phenobarbital, carbamazepine, or a combination) significantly increases the systemic clearance rates of several antileukemic agents and is associated with lower efficacy of chemotherapy.[327] At St. Jude, anticonvulsants that are less likely to induce the activity of drug-metabolizing enzymes (e.g., gabapentin, valproic acid) are used instead. Genetic polymorphisms of several drug-metabolizing enzymes are also associated with treatment outcome. Patients who have homozygous or heterozygous deficiency of thiopurine methyltransferase, the enzyme that catalyzes the S-methylation (inactivation) of mercaptopurine, tend to have better event-free survival, probably because they receive a higher effective dose intensity of 6-mercaptopurine.[326] However, the thiopurine methyltransferase genetic polymorphism is also linked to acute dose-limiting toxicity,[328] the risk of irradiation-induced brain tumor,[329] and therapy-related acute myeloid leukemia,[253,330] in the context of antimetabolite-based therapy. Hence, therapy must be adjusted in patients who have homozygous mutant genotypes of this enzyme and in many heterozygotes. Using this approach, genetic polymorphism of this enzyme was no longer associated with clinical outcome in a recent study.[331] The null genotype (absence of both alleles) for *GSTM1* or *GSTT1* and the *GSTP1* Val_{105}/Val_{105} genes are also associated with increased treatment-related toxicity[332,333] and a lower risk of relapse,[334] perhaps because of reduced detoxification of cytotoxic chemotherapy. A tandem-repeat polymorphism within the enhancer region of the thymidylate synthase gene, a major target of methotrexate, has been associated with increased expression of the enzyme and a higher relapse hazard.[335,336] Nevertheless, the prognostic value of individual pharmacogenetic variables depends on the type of treatment.[337,338] In addition, it is likely that multiple genetic polymorphisms interact to influence treatment response.[335] Finally, the presence of additional chromosomes in leukemia cells can create discordance between germline and leukemia cell pharmacogenomic phenotypes.[339]

Acute Myeloid Leukemia

Clinical trials of therapy for AML are characterized by dose intensification of conventional therapeutic agents. Remission induction and consolidation therapy are essential components of virtually every

protocol, whereas other postremission therapy differs widely between studies.

Remission Induction

With the exception of APL, which is now treated initially with ATRA in combination with chemotherapy (generally at least an anthracycline), all cases of AML are treated with induction chemotherapy comprising cytarabine and a topoisomerase II inhibitor (anthracycline, idarubicin, doxorubicin, or mitoxantrone) with or without a third agent (etoposide or 6-thioguanine; see Table 101-5).[113,340–348] Rates of remission induction range from 74% to 91% among contemporary clinical trials.[340–350] This variation is in part due to differences in the timing of remission studies (i.e., after one, two, or multiple courses of therapy). Nonetheless, many attempts have been made to modify remission-induction therapy not only to increase the rate of remission but to improve its "quality" or "degree," which in turn can favorably affect the ultimate treatment outcome.

Modifications of remission induction include the use of additional agents or different topoisomerase II inhibitors, increased drug dosages, increased duration of drug exposure, and decreased intervals between treatment courses.[340–350] Because idarubicin has faster cellular uptake, increased cellular retention, less in vitro drug resistance, longer plasma half-life of the active metabolites, and potentially less cardiotoxicity than daunorubicin,[351] investigators of the Berlin-Frankfurt-Munster (BFM) Consortium compared the clinical efficacy of these two agents during remission induction in their AML93 study.[341,342] Idarubicin yielded a significantly lower bone marrow blast cell count on day 15 than did daunorubicin. Although long-term outcome did not differ significantly between the two randomized groups, the subset of patients who had more than 5% blast cells in the bone marrow on day 15 seemed to benefit from idarubicin. By contrast, the Australian and New Zealand CCG found daunorubicin to be as effective as idarubicin and less toxic.[340] Using an "upfront window" therapy approach, investigators at our institution demonstrated that 2-CDA given as a single agent induced remission in 45% of patients after one course and in 70.6% after two courses of treatment; 2-CDA was also particularly effective against acute monoblastic leukemia.[247] Complete remission rates of 90% and 100% were observed in two treatment arms that used two different schedules of a 2-CDA–cytarabine combination followed by two courses of daunorubicin, cytarabine, and etoposide.[348] The long-term results of this approach remain to be determined.

The CCG pursued the approach of timed-sequential therapy (i.e., intensification of therapy) by reducing the interval between two induction courses. The intensive-timing arm had a remission-induction rate comparable to that of the standard-timing arm, despite a much higher rate of early mortality (11% vs. 4%). Although the intensive-timing arm yielded a superior overall outcome, regardless of the type of postremission therapy,[343,344] this approach would not be considered acceptable in contemporary clinical trials because of its associated high rate of early toxic death. In a subsequent study, these investigators found that patients with a negative genotype (i.e., homozygous polymorphism) for glutathione *S*-transferase theta, a detoxifying enzyme, experienced greater toxicity and mortality than did patients with at least one wild-type allele.[352]

The POG has used high-dose cytarabine to intensify therapy. In the POG 8498 study, patients were randomized to receive two courses of DAT (daunorubicin, cytarabine and 6-thioguanine) or one course of DAT followed by a course of high-dose cytarabine.[353] The two treatment arms had comparable remission rates (both 85%), but patients who received high-dose cytarabine had a higher estimate of 3-year event-free survival (34% vs. 29%). In the POG 9421 study, patients were randomized to receive DAT induction at standard dose or DAT with cytarabine at a high dose. Remission rates were somewhat lower in the standard arm (87% vs. 91%), as were 3-year event-free survival estimates (34% vs. 40.4%, $P = 0.17$).[349]

The MRC used a prolonged daily exposure approach to intensify therapy. They found that prolonged treatment resulted in greater toxicity but an improved remission rate and a shorter time to remission.[354] In the MRC AML10 trial, patients randomly assigned to receive 6-thioguanine or etoposide as the third induction agent had a comparable overall outcome.[345]

In summary, intensified remission induction in general improves long-term outcome. However, vigilance in supportive care is important to reduce early mortality. Patients with Down syndrome should not receive intensified therapy, because they have more drug-sensitive disease and are more susceptible to treatment-related toxicity than the general population.[355,356]

Consolidation and Other Postremission Therapy

Without postremission therapy, relapse is nearly inevitable.[211] Although more courses of consolidation therapy are thought to be better, the optimal number is uncertain.[211] The current MRC AML12 trial is investigating whether four or five courses of consolidation therapy is better. In most clinical trials, postremission consolidation therapy lasts for 6 to 12 months in patients who do not undergo hematopoietic stem cell transplantation.

The optimal consolidation therapy has yet to be determined but generally includes high-dose cytarabine. In the BFM AML93 study, the improved outcome of high-risk cases was attributed to intensification with high-dose cytarabine and mitoxantrone.[342] This drug combination is also an integral component of the MRC AML10 trial.[345,346] The combination of high-dose cytarabine and asparaginase was credited for the improved outcome in the CCG-213 and CCG-213P studies.[357,358] Consolidation therapy with high-dose cytarabine alone also resulted in an improved outcome in the POG 8498 study.[353] In adult clinical trials, high-dose cytarabine seemed to be particularly beneficial to patients whose leukemia involved disruption of CBF.[238]

The need for continuation therapy beyond consolidation therapy is less certain. Although the BFM study group achieved excellent results with continuation therapy lasting 18 to 24 months,[341,342] other studies could not demonstrate the clinical benefit of this phase of therapy.[359,360] In fact, a randomized study by the CCG (213P) showed that 2 years of continuation treatment after intensification therapy resulted in a worse outcome than no continuation treatment.[357] In the French Leucemie Aique Myeloide Enfant (LAME) 89/91 study, low-dose continuation treatment of 18 months also resulted in worse overall survival than no continuation treatment.[344] The investigators attributed this finding to the development of drug resistance during continuation therapy, leading to a poor salvage rate. Hence, most study groups, with the exception of the BFM group, have abandoned the use of continuation therapy in AML. It should be noted that cases of APL benefit from prolonged continuation treatment with ATRA and, possibly, with 6-mercaptopurine and methotrexate.[361]

Central Nervous System-Directed Therapy

Relatively little attention has been paid to CNS-directed therapy for AML, because control of hematologic disease remains the focus of treatment. Suboptimal systemic therapy may allow hematologic relapse to precede meningeal relapse. In most clinical trials, intrathecal cytarabine with or without methotrexate and systemic high-dose cytarabine are used as CNS prophylaxis. The BFM AML87 study attempted to address whether cranial irradiation is necessary in childhood AML.[362] In that randomized study children who received cranial irradiation had longer relapse-free survival than did those receiving only intrathecal therapy, although there was only a marginal difference between the two groups in the rate of CNS relapse. The early termination of randomization in that study prevents firm conclusions; moreover, many other clinical trials have yielded similar outcomes without the use of cranial irradiation (Table 101-6). Therefore, cranial irradiation may not be necessary if systemic and intrathecal chemotherapy is adequate. Even less is known about the optimal treatment of overt CNS leukemia at presentation. In an earlier study in our institution, this factor lacked prognostic significance,[363] and a

more recent study suggested that these patients can be cured without the use of cranial irradiation.[348]

Hematopoietic Stem Cell Transplantation

The indications for transplantation should be periodically re-evaluated. At present, among children with ALL, those with the Philadelphia chromosome, early hematologic relapse, or T-cell ALL with poor early response or hematologic relapse are clearly candidates for transplantation.[3,122,364] Transplantation has not been shown to improve outcome in other types of very high-risk leukemia, including infant cases and those with *MLL* rearrangement.[113,233]

Autologous stem cell transplantation has generally been associated with a high rate of relapse in childhood ALL. Excellent results have been reported in a few small series of patients with AML,[365,366] but autologous transplantation has failed to show any survival benefit over chemotherapy in most studies.[367–369] The benefit of in vitro purging to rid autografts of residual leukemia cells remains unproven.[370] Hence, autologous transplantation is not recommended by most investigators.

Allogeneic transplantation in children with AML has been shown in most clinical trials to reduce the risk of relapse and to improve overall survival as compared with either autologous transplant or chemotherapy alone, despite a higher rate of morbidity and mortality.[211,343] However, the indications for this procedure during first remission are still debated. Investigators of the COG favor allogeneic transplantation for all patients who have a suitable donor, because this procedure yielded a superior outcome, regardless of the risk group, in their study.[343] Other investigators do not recommend allogeneic transplantation for patients at lower risk, especially in view of recent improved results with chemotherapy, and reserve this procedure for relapsed AML.[345,370] They contend that most patients with relapsed AML can be readily salvaged with hematopoietic stem cell transplantation and they should be spared the risk of unnecessary transplant-related morbidity and mortality.

Notwithstanding the controversy of allogeneic transplantation, there is general consensus that patients with very high-risk AML [monosomy 5 or 7, del(5q), 3q abnormalities, acute megakaryoblastic leukemia, or poor response to remission-induction therapy] are candidates for this procedure, perhaps even if alternative or unrelated donors are the only options.[370,371] Transplantation is also the treatment of choice for most patients with MDS. By contrast, transplantation is not recommended for patients with Down syndrome or APL in first remission, which have a favorable prognosis with current therapy.[370,371]

Treatment Sequelae

Improved supportive care reduced the rate of early death to less than 2% in the 1990s.[298] Induction therapy with prednisone, vincristine, and asparaginase may cause hyperglycemia and thrombosis. The intensified use of methotrexate and glucocorticoids has caused an increased frequency of neurotoxicity and, in older children and adults, osteonecrosis. High cumulative doses of anthracyclines can produce severe cardiomyopathy, especially in young children. Cranial irradiation causes neuropsychologic deficits, endocrine abnormalities that lead to obesity, short stature, precocious puberty, osteoporosis, and second neoplasms within the irradiated field.[372,373]

Development of therapy-related AML has been linked to the use of topoisomerase II inhibitors (teniposide and etoposide), and the risk is apparently dependent on the treatment schedule and the concomitant use of other agents (e.g., asparaginase, alkylating agents, and perhaps antimetabolites).[253] Children who receive cranial irradiation at 6 years of age or younger are most susceptible to the development of brain tumors. This risk is increased by the intensive use of antimetabolite drugs before and during cranial irradiation.[374]

MINIMAL RESIDUAL DISEASE

Rationale for Studies of Minimal Residual Disease

In vivo measurement of the cytoreductive effect of therapy can provide direct information about the combined effect of clinical and cellular variables in each patient, thereby directly measuring the effectiveness of treatment rather than predicting outcome. Sluggish or incomplete clearance of leukemic cells by remission-induction therapy as determined by morphologic examination of the bone marrow or peripheral blood is clearly associated with a poor treatment outcome.[217,218,375–377] However, conventional morphologic techniques have limited sensitivity and accuracy: in most cases, leukemic cells can be detected in bone marrow with certainty only when they constitute 5% or more of the total cell population. Methods for detecting minimal (i.e., submicroscopic) residual disease are at least 100 times as sensitive as conventional morphologic techniques and allow a more stringent definition of "remission" in patients with acute leukemia.[378] This more stringent definition is rapidly becoming the standard at many cancer centers. In addition, these methods have multiple potential applications in the clinical management of patients with leukemia (Table 101-7).

Methodological Options for Minimal Residual Disease Studies

Many methods of MRD measurement have been tested.[378,379] The most reliable methods for ALL include flow cytometric profiling of aberrant immunophenotypes, polymerase chain reaction (PCR) amplification of fusion transcripts and chromosomal breakpoints, and PCR amplification of antigen-receptor genes.[378] Only the first two can be applied to AML, because most cases lack antigen-receptor gene rearrangement. The value of another PCR target, WT-1, is being studied and awaits to be definitively proven.[380,381] *FLT3* ITDs could, in principle, be used as targets for PCR-based MRD studies in AML. However, ITDs that are detected at diagnosis are often undetectable at the time of relapse.[382,383] Because of their limited sensitivity (~1% to 5%), conventional karyotyping and fluorescence in situ hybridization cannot reliably detect submicroscopic leukemia but can occasionally be useful in clarifying the nature of morphologically suspicious blast cells.[384]

We extensively compared flow cytometric detection of aberrant immunophenotyes and PCR amplification of *IGH* genes and found them to be highly concordant.[385] Others also obtained concordant results in most samples.[386] The use of both methods in tandem allowed us to monitor MRD in virtually all patients in our recent Total XV study.[385,387] Definitive comparisons between reverse transcriptase-PCR amplification of fusion transcripts and either flow

Table 101-7 Clinical Applications of Minimal Residual Disease Studies

Time of Study	Objective
During remission induction	Measure early response to treatment.
Throughout treatment	Identify patients at a higher risk of relapse or impending clinical relapse.
Before autograft	Detect contaminating leukemic cells; evaluate the efficacy of "purging".
After allogeneic transplant	Gauge effect of withdrawal of immunosuppressive therapy and of donor lymphocyte infusions.
Testing of novel agents	Use minimal residual disease as endpoint to test efficacy.

cytometry or PCR amplification of antigen-receptor genes have not been reported.

Prognostic Value of Minimal Residual Disease in Acute Lymphoblastic Leukemia

Several prospective studies have defined the prevalence and the clinical significance of MRD at different time points during treatment of childhood ALL. In one multicenter study, MRD was measured in 178 patients by a competitive PCR assay targeting junctional sequences of *IGH* and *TCR*.[388] The presence or absence and the level of residual leukemia during the first 6 months of therapy were significantly correlated with the risk of early relapse at each of the time points studied. Patients who had 1% or more leukemic cells after the completion of induction therapy or who had 0.1% or more at later time points had a particularly high risk of relapse. Another multicenter study monitored MRD in 240 children with ALL treated on the International BFM Study Group protocols.[389] This study used PCR analysis of *IGH* genes, *TCR* genes, and *TAL1* deletions. MRD^+ patients had relapse rates 5 to 10 times the relapse rate of patients who were MRD^- at the various follow-up times. MRD levels of 1% or greater at the end of induction treatment and before consolidation treatment were associated with a very high relapse rate. Combined MRD information from the first two follow-up time points was particularly informative, allowing the identification of three different risk groups: a low-risk group comprising 43% of patients with a 3-year relapse rate of 2% (95% confidence interval, 0.05% to 12%); a high-risk group comprising 15% of patients with a relapse rate of 75% (55% to 95%); and an intermediate-risk group (43%) with a 3-year relapse rate of 23% (13% to 36%).

We used flow cytometry to prospectively study MRD in 195 children with newly diagnosed ALL enrolled in a single-institution chemotherapy program (Total XIII).[285,390,391] We found that detectable MRD (i.e., ≥0.01% leukemic mononuclear cells) at any of the time points studied (day 19 and end of remission-induction therapy and weeks 14, 32, and 56 of continuation) was significantly associated with a higher relapse rate (Fig. 101-5). Patients who had high levels of MRD at the end of the induction phase (≥1%) or at week 14 of continuation therapy (≥0.1%) had a dismal outcome. The incidence of relapse among patients with MRD at the end of the induction phase was 68% ± 16% (SE) if they remained MRD^+ through week 14 of continuation therapy, but only 7% ± 7% if MRD became undetectable. The persistence of MRD until week 32 was highly predictive of relapse: all four patients who were MRD^+ at week 32 had relapses, but only two of the eight who became MRD^- had relapses.

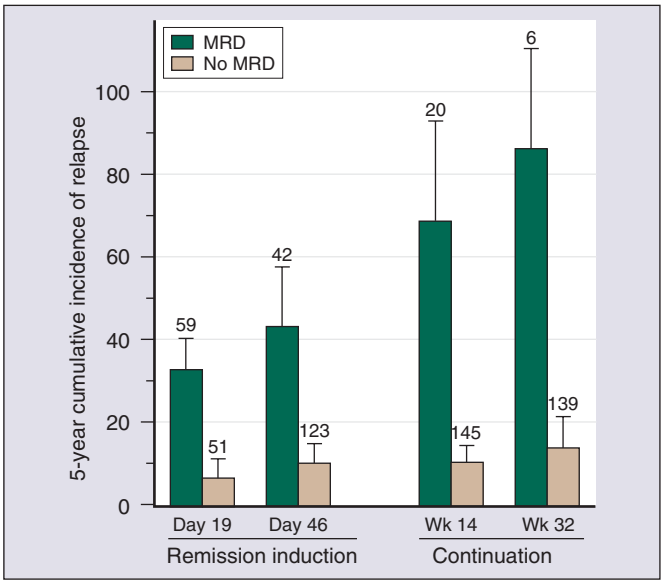

Figure 101-5 • Risk of relapse according to MRD in children with ALL. The 5-year cumulative incidence of relapse according to the results of a flow cytometric MRD assay at different times during treatment is shown.[285,391]

Of the 112 patients studied at day 19 of remission-induction therapy, 53 had achieved a profound cytoreduction (MRD < 0.01%) despite the brief duration of chemotherapy.[391] The outcome of treatment for this group of patients was outstanding: the 3-year cumulative incidence of relapse was 1.9% ± 1.9%, as compared with 28.4% ± 6.4% for MRD^+ patients. These results are consistent with those of another study in which bone marrow samples collected at day 15 of therapy from 68 children with ALL were assayed by PCR amplification of antigen-receptor genes.[392] However, the proportion of children who had the lowest levels of MRD in the two studies was different: 21% in this series, 46% in ours.

In the studies outlined previously, the prognostic value of MRD was independent of other known clinical and biologic prognosticators of outcome. In our study MRD remained a significant predictor in analyses that excluded patients at very high or very low risk of relapse by St. Jude criteria or that focused on patients at high risk of relapse by the National Cancer Institute criteria.[3,285] In the I-BFM study, MRD was also a strong predictor of outcome in children with features that indicated a medium risk.[393]

The predictive value of MRD monitoring extends to children receiving treatment for relapsed ALL.[212,213] MRD detection by PCR amplification of antigen-receptor genes before or after allogeneic bone marrow transplantation was predictive of relapse in children with ALL.[394–397]

In sum, there is strong collective evidence of an association between MRD and an increased risk of relapse of ALL. Because of their complexity, MRD assays can be performed with confidence only in a few specialized laboratories. We recently developed a simple and inexpensive flow cytometric assay that allows the study of MRD in patients with B-lineage ALL during remission-induction therapy.[398] Bone marrow normal lymphoid progenitors ($CD19^+$, $CD10^+$, and/or $CD34^+$) are exquisitely sensitive to corticosteroids and other antileukemic drugs.[398] Hence, we hypothesized that in patients with B-lineage ALL, cells with this phenotype detected early in treatment should be leukemic rather than normal. We applied the simple three-antibody assay to study MRD in bone marrow samples collected on day 19 of remission-induction therapy from 380 children with B-lineage ALL.[398] The results correlated remarkably well with those of more complex flow cytometric and molecular MRD evaluations, and provided powerful and independednt information about risk of relapse. This new assay should allow most treatment centers to identify children with ALL who have an excellent early treatment response and a high likelihood of cure.

MRD has been traditionally measured in the bone marrow, but we and others found that MRD findings in peripheral blood are completely concordant to those in bone marrow in patients with T-lineage ALL.[399,400] We also observed that peripheral blood MRD in B-lineage ALL patients was associated with a very high risk of disease recurrence.[399] Therefore, peripheral blood can be used to monitor MRD in patients with T-lineage ALL. In B-lineage ALL, the presence of MRD in peripheral blood seems to identify patients who are at a very high risk of relapse.

Minimal Residual Disease Studies in Patients with Acute Myeloid Leukemia

The lack of widely expressed molecular markers in AML cells precludes the systematic study of MRD by PCR. Antigen-receptor genes are rearranged in less than 10% of AML cases, and less than half of patients have nonrandom genetic abnormalities with fusion

transcripts suitable for molecular studies of MRD.[401] Thus, correlative studies between MRD and treatment outcome have been performed only in selected groups of patients, almost exclusively adults. In APL, PCR detection of *PML-RARA* and *RARA-PML* transcripts during remission generally predicts relapse.[402,403] Reportedly, careful quantitation of *AML1-ETO* transcripts during remission of AML with the t(8;21) translocation can help to monitor response to treatment.[404,405] Productive MRD studies have also been reported in patients with AML and inv(16)/*CBFB-MYH11*.[406–409]

Flow cytometry can be applied to study MRD in the majority of patients with AML, irrespective of their genetic leukemia subtype. In adult patients with AML, detection of MRD by flow cytometry was a strong predictor of outcome in several studies.[410–412] In a multiinstitutional study, the presence of MRD detected by flow cytometry was associated with earlier relapse in children with AML in first morphologic remission.[413] We found that 61 of 230 bone marrow samples from 46 children with AML during therapy had 0.1% or greater AML cells by flow cytometry.[414] Mean (±SE) 2-year survival estimate was 33.1 ± 19.1% for patients with 0.1% or greater AML cells after induction therapy, significantly lower than the 72.1% ± 11.5% for those with fewer than 0.1% AML cells; overt recurrence of AML within the subsequent 6 months was significantly more likely in the former group. Because of the mounting evidence of the clinical importance of MRD in AML, it has been suggested that this should be incorporated as a parameter to guide therapy.[415] Indeed, in our current AML02 protocol, MRD is used to make clinical decisions about usage of an anti-CD33 immunotoxin and eligibility for hematopoietic stem cell transplantation.

ISSUES FOR THE FUTURE

The current cure rates for ALL attest to the steady progress that has been made in treating this disease. However, cure rates for children with AML and for some patients with ALL, such as infants and those with t(9;22), remain low. Increase in cure rates will most likely require a more accurate prediction of relapse hazard and of chemotherapy resistance to maximize treatment efficacy and minimize its toxicity. MRD assays now allow the objective and sensitive assessment of treatment response in virtually all patients, and it has been incorporated into treatment protocols at our institution and in some large cooperative studies. The further simplification of MRD methods should widen the application of this powerful prognostic parameter, and extend its potential benefits to most patients, including those living in areas with poor resources.[416] A better understanding of the relation between pharmacogenomic features and responses to chemotherapy should lead to further refinement of treatment schedules and dosages.[417]

Clearly, substantial improvement in cure rates for some subsets of leukemia can only come from the development of new treatments. Several new formulations of existing agents may improve efficacy and decrease toxicity.[387,418] Novel nucleoside analogues, such as gemcitabine, clofarabine, and nelarabine, have shown promise in early reports.[418–420] Imatinib mesylate and other ABL kinase inhibitors are the paradigm of molecular therapy of leukemia.[124,126] Other novel agents include inhibitors of FLT3,[186,421] farnesyltransferase,[422] proteasome,[423] γ-secretase,[52] DNA methylation, and histone deacetylase.[424] The application of novel gene expression-based drug screening should accelerate the identification of additional effective compounds.[425]

The arsenal of antibodies for leukemia treatment is steadily increasing. Rituximab (anti-CD20), gemtuzumab ozogamicin (anti-CD33), alemtuzumab (anti-CD52), and epratuzumab (anti-CD22) have already been incorporated into some clinical trials,[418] and novel antibody derivatives and recombinant immunotoxins have also been developed for clinical use.[426] Chimeric receptors composed of single-chain variable domain of murine antibodies and human signaling molecules are a promising tool to redirect the specificity of autologous or allogeneic immune cells.[427–429] Elucidation of the mechanisms that regulate the activation of NK cells has spurred the use of haploidentical NK cells to enhance the efficacy of hematopoietic stem cell transplantation,[430,431] and to reduce leukemia cell burden.[432] Testing the effectiveness of new therapeutic approaches may necessitate nontraditional methods. It may soon be necessary to extend efficacy studies of these agents to patients who have not yet been heavily treated, and perhaps to use MRD measurement to assess tumor response.

There is mounting evidence that the bone marrow microenvironment can regulate the response of leukemic cells to chemotherapy.[433–435] We recently found that bone marrow mesenchymal cells protect ALL cells from asparaginase cytotoxicity by forming an asaparagine-rich milieu.[436] It is possible that leukemic cells that reside in microenvironmental niches become relatively insensitive to chemotherapy; if these cells have stem cell properties[181,437] they might ultimately be capable of initiating leukemia recurrence. Once the molecular mechanisms involved in the interaction between leukemic cells and their microenvironment are better understood, it may be possible to develop strategies that would alter it, thereby enhancing the antileukemic effect of chemotherapeutic agents.

102 Childhood Lymphoma

John T. Sandlund and Mihaela Onciu

SUMMARY OF KEY POINTS

Incidence

- Malignant lymphoma, which comprises both Hodgkin's lymphoma and non-Hodgkin's lymphoma (NHL), is the third most common malignancy in childhood.
- Among children younger than 15 years of age, there is a slight predominance of NHL, whereas Hodgkin's lymphoma is more frequent if children up to 18 years of age are included.
- There are approximately 500 newly diagnosed cases of pediatric NHL in the United States each year.

Etiology and Epidemiology

- NHL is more common in boys than in girls and more common in white children than in black children.
- There are geographical differences with respect to the frequency of histologic subtypes of NHL. Burkitt's lymphoma is the predominant subtype in equatorial Africa and northeast Brazil, where it is associated with Epstein-Barr virus (EBV) in the majority of cases, in contrast to the infrequent association observed in the United States and Western Europe.
- Children with immunodeficiency conditions are at increased risk of developing NHL. These include children with ataxia-telangiectasia, Wiskott-Aldrich syndrome, and X-linked lymphoproliferative syndrome. Children with acquired immunodeficiency disorders, including the acquired immunodeficiency syndrome, and those receiving immunosuppressive therapy following bone marrow or organ transplantation are also at increased risk.

Pathology and Biology

- The most common subtypes of NHL in children are Burkitt's lymphoma, lymphoblastic lymphoma, anaplastic large cell lymphoma, and diffuse large B-cell lymphoma (including the mediastinal subtype).
- Burkitt's lymphoma is a mature B-cell lymphoma of germinal center origin, characterized by a very high proliferation rate, resulting from the activation of the *c-myc* oncogene as a result of juxtaposition to one of the immunoglobulin genes, through one of three characteristic balanced chromosomal translocations [i.e., t(8;14), t(2;8), and t(8;22)].
- Lymphoblastic lymphoma is typically of precursor T-cell immunophenotype and may be associated with reciprocal translocations involving a T-cell receptor gene. Rare cases may be of precursor B-cell lineage.
- Anaplastic large cell lymphoma is a peripheral (post-thymic) T-cell lymphoma that is characterized by large anaplastic ("hallmark") cells expressing CD30 and, in the vast majority of pediatric cases, anaplastic lymphoma kinase (ALK) as a result of a balanced translocation involving the *ALK* gene [e.g., t(2;5)].
- Diffuse large B-cell lymphomas are a biologically heterogeneous category of mature B-cell lymphomas of germinal center or postgerminal center origin, composed predominantly of large cells, with a diffuse growth pattern.

Clinical Findings

- The clinical features at diagnosis are determined by primary sites of disease, which vary according to histologic subtype.
- Children with Burkitt's lymphoma usually present with an abdominal mass and associated gastrointestinal symptoms, whereas those with advanced-stage lymphoblastic lymphoma typically present with a mediastinal mass associated with a spectrum of respiratory symptoms.
- Children with large cell lymphoma or Hodgkin's lymphoma may present with disease in either the abdomen or the mediastinum.

Diagnosis and Differential Diagnosis

- Infectious processes, such as bacterial adenitis, histoplasmosis, tuberculosis, and EBV infection, can simulate lymphoma.
- A comprehensive characterization of the biologic features of tissue will help to distinguish NHL from other small round blue cell tumors, including Ewing's sarcoma, neuroblastoma and rhabdomyosarcoma.

Initial Workup and Staging

- The workup should include a history and physical examination, complete blood count, chemistry panel (including electrolytes, BUN, creatinine, uric acid, phosphorus, calcium, and lactate dehydrogenase), diagnostic imaging studies (computed tomography scan of chest, abdomen, and pelvis; nuclear imaging such as positron emission tomography or gallium scanning), and human immunodeficiency screen.
- For children with NHL, the stage is usually assigned according to the St. Jude system, whereas children with Hodgkin's lymphoma are staged by using the Ann Arbor system.

Primary Therapy

- The treatment plan is determined on the basis of histology, stage, immunophenotype, and, in some cases, clinical symptoms such as fever, weight loss, and night sweats.
- Children with advanced-stage Burkitt's lymphoma are generally treated with intensive cyclophosphamide-based regimens given over a relatively short period of time, whereas children with lymphoblastic lymphoma are generally treated with regimens derived from strategies for children with acute lymphoblastic leukemia.
- Among children with large cell lymphoma, the treatment plan varies

with respect to tumor cell immunophenotype.
- Involved-field radiation therapy has a role in certain cases of Hodgkin's lymphoma but is rarely indicated for children with NHL.

Salvage Therapy
- Children with refractory or recurrent disease are generally considered to have a poor prognosis and are therefore candidates for intensive or novel salvage treatment regimens.
- Those with chemosensitive disease are potential candidates for an intensification phase with hematopoietic stem cell rescue.

Complications
- The most concerning late effects of therapy include cardiac toxicity, infertility, and the development of a second malignancy.
- The risks for these complications are determined in part by the components of initial therapy.

Prognosis
- The most important predictors of treatment outcome for children with NHL are treatment protocol and tumor burden, as reflected by stage and serum LDH.

INTRODUCTION

Substantial clinical and laboratory advances have improved our understanding of both the pathogenesis and treatment of the malignant lymphomas of childhood and adolescence, which comprise Hodgkin's lymphoma and the non-Hodgkin's lymphomas (NHL).[1,2] These are the third most common type of cancer in children in the United States, making up approximately 15% of newly diagnosed cases in this age group each year.[3–8] Among children younger than 15 years of age, the non-Hodgkin's lymphomas account for approximately 60% of cases. However, when children up to age 18 are included, there is a slight predominance of Hodgkin's lymphoma.[7,8]

The non-Hodgkin's lymphomas of childhood are markedly different from those of adulthood.[1,9] Diffuse high-grade extranodal subtypes account for the majority of pediatric cases, whereas low- and intermediate-grade lymphomas are predominant in adults. These differences are probably due in part to age-related maturational changes in the immune system and consequently in the types of cells that are susceptible to malignant transformation.[2] The differences between adults and children in histologic subtype underlie the differing clinical features, staging, and treatment strategies in these age groups.[1]

The clinical presentation, staging, histologic subtypes, and treatment strategies in children and adults with Hodgkin's lymphoma are less dissimilar; however, some differences are worth noting.[10] Epidemiologic studies have suggested three distinct forms that depend on age: the childhood form in patients 14 years of age or younger, the young adult form (ages 15 to 34 years), and an older adult form in individuals 55 to 74 years of age.[11] Among the four histologic subtypes of Hodgkin's lymphoma described in the Rye classification system,[12] the nodular sclerosing subtype is most common in children, occurring in 40% of younger children and 70% of adolescents.[13] Mixed cellularity Hodgkin's lymphoma occurs in approximately 30% of cases and is more common in children with human immunodeficiency (HIV) infection and in those less than 10 years of age; it is frequently associated with an advanced stage (with extranodal extension) at presentation.[13] Lymphocyte-predominant Hodgkin's lymphoma accounts for approximately 10% to 15% of pediatric cases, is usually associated with localized disease at presentation and occurs more commonly in younger patients and in boys. The fourth subtype of Hodgkin's lymphoma, lymphocyte depletion, is very rare in children.[10]

Despite excellent event-free survival rates in Hodgkin's lymphoma, there are well recognized challenges related to the sequelae of therapy, which include endocrine dysfunction, chemotherapy-induced sterility, radiation-induced abnormalities in bone growth, chemotherapy-and radiation- related second cancers, and late cardiac deaths.[10] Most current studies are exploring strategies that maintain an excellent treatment result while reducing late effects. For example, a combined-modality approach with low-dose radiation and combination chemotherapy may reduce the bone growth abnormalities that are associated with high-dose extended-field radiation therapy.[10] However, as therapy is modified in an attempt to reduce the risk of late effects, the rates of event-free survival may be compromised.[14–16] For example, attempts at reducing alkylating agent-related late effects in patients with advanced-stage disease by substituting other chemotherapeutic agents have lowered event-free survival rates.[14,17] These and other issues regarding the management of Hodgkin's lymphoma will be discussed in Chapter 111. The remainder of this chapter focuses on the non-Hodgkin's lymphomas of childhood.

EPIDEMIOLOGY AND PATHOGENESIS

Non-Hodgkin's lymphomas can occur at any age in childhood but are unusual in children younger than 3 years of age; the median age at diagnosis is approximately 10 years.[1,18] There are approximately 500 new cases of pediatric NHL in the United States each year.[6,7,19] In contrast to Hodgkin's disease, which has a bimodal age distribution with peaks in early and late adulthood, the incidence of non-Hodgkin's lymphomas increases steadily with age.[7] NHL occurs almost twice as commonly in whites as in blacks and two to three times more often in boys than in girls; the explanation for these differences has yet to be elucidated.[2]

There are specific populations who are at increased risk for the development of NHL.[2,20–23] These include individuals with primary immunodeficiency syndromes,[2,22,23] including ataxia-telangiectasia, Wiskott-Aldrich syndrome, X-linked lymphoproliferative syndrome, common variable immunodeficiency, Nijmegen syndrome, and autoimmune lymphoproliferative syndrome. It is important that these syndromes be recognized so that appropriate therapy can be designed. For example, in the management of children with ataxia-telangiectasia who develop a malignancy, involved field irradiation and radiomimetics such as bleomycin should be avoided. Children with ataxia-telangiectasia are also at increased risk for the development of late-onset hemorrhagic cystitis following exposure to cyclophosphamide. Boys with X-linked lymphoproliferative syndrome are at increased risk of developing fatal infectious mononucleosis and/or B-cell lymphomas. X-linked lymphoproliferative syndrome should be considered in any boy with a high-grade B-cell lymphoma whose brother has had either fatal infectious mononucleosis or B-cell lymphoma or in any boy who has had two primary B-cell lymphomas. Children who have received immunosuppressive therapy (e.g., recipients of bone marrow or organ transplants) and those with the acquired immunodeficiency syndrome are also at a higher risk of developing NHL.[21] The overall prevalence of lymphomas among children with HIV infection is approximately 1.6%.[21] NHL is 36 times more frequent among pediatric HIV-positive hemophiliacs than in HIV-negative children with factor 8 deficiency. The majority of the HIV-associated non-Hodgkin's lymphomas have a B-cell immunophenotype with either Burkitt's or large cell morphology. Proliferative lesions of mucosa-associated lymphoid tissue, which may be either benign or malignant, have also been described in children with HIV infection.[21]Although deficient T-cell function has been implicated in these congenital and acquired immunodeficiency states, further study is required to fully clarify the mechanisms of pathogenesis.

There are well-recognized geographic differences in both the incidence and the distribution of histologic subtypes of NHL.[2,3,24] For example, the non-Hodgkin's lymphomas are very rare in Japan but are very common in equatorial Africa. More specifically, Burkitt's lymphoma accounts for approximately one half of all childhood malignancies in equatorial Africa and is the predominant NHL subtype in Northeastern Brazil and areas of the Middle East.[24] In contrast, lymphoblastic lymphomas are the predominant histologic subtype in southern India.[25] In some parts of the world, the distribution of histologic subtypes of childhood NHL has yet to be firmly established.

There are also geographic differences in the clinical and biologic features of some NHLs.[2,25,26] For example, Burkitt's lymphoma in equatorial Africa (endemic Burkitt's lymphoma) frequently involves the jaw, abdomen, orbit, paraspinal area, and central nervous system (CNS), whereas the common sites of involvement associated with Burkitt's lymphoma in the United States and Western Europe (sporadic Burkitt's lymphoma) include the abdomen, bone marrow, and nasopharynx.[2] The predominant chromosome 8 breakpoints, as well as the breakpoints within the immunoglobulin heavy chain gene (on 14q32) differ between sporadic and endemic cases.[27] In addition, sporadic cases have more complex karyotypic abnormalities than endemic cases in addition to the classic translocations, suggesting distinct mechanisms of malignant transformation.[28] The endemic cases are associated with IgM secretion, while the sporadic cases generally are not.[2] The sporadic and endemic cases also differ with respect to Epstein-Barr virus association.[26] The overlap of the lymphoma belt with the malaria belt in equatorial Africa prompted speculation that an infectious agent might be involved in lymphomagenesis. This speculation led to the discovery of the Epstein-Barr virus (EBV) and its association with African Burkitt's lymphoma.[2] Although a direct role in pathogenesis has not been demonstrated, the circumstantial evidence for its involvement is compelling. It has been suggested that as a B-cell mitogen, EBV increases the target pool of cells that are potentially susceptible to malignant transformation.[26] Supporting this hypothesis is evidence that *Rag* gene expression can be induced by EBV, theoretically increasing the likelihood of a translocation occurring in immature B-cells that are about to rearrange their immunoglobulin genes.[29] The potential role of EBNA-1 in pathogenesis has been suggested by experiments demonstrating that lymphomas develop in mice that are transgenic for EBNA-1.[30] Moreover, an identified EBNA-1 variant has been shown to be associated with the majority of Burkitt's lymphoma cases that have been studied, prompting investigators to speculate that this tumor-associated mutation alters EBNA-1 function in a way that directly or indirectly provides a growth advantage for the lymphoma cell.[31] A more direct role for EBV in lymphomagenesis is suggested by studies of the EBV positive Burkitt's lymphoma cell line, Akata, which loses its malignant phenotype with spontaneous loss of EBV; however, the malignant phenotype is regained with EBV reinfection.[32] EBV association has been reported in approximately 90% of the endemic (i.e., African) Burkitt's tumors and in approximately 15% of sporadic cases (United States and Western Europe).[2] Aberrant and disrupted expression of the EBV genome has recently been reported in cases of sporadic Burkitt's lymphoma that were EBV-negative by conventional EBNA screening.[33] This observation, coupled with the 50% rate of EBV association in Burkitt's tumors in other parts of the world (including Brazil, Russia, Argentina, and Chile), suggest a widespread role for this virus in lymphomagenesis.

PATHOLOGY AND BIOLOGY

The classification systems that are applied to pediatric NHL are similar to those used for lymphomas that occur in adults. In the National Cancer Institute Working Formulation for clinical usage, published in 1982,[9] which subclassified NHLs on the basis of their morphologic appearance and clinical aggressiveness into three grades (low, intermediate, and high), most of the childhood NHLs would be designated as high-grade lymphomas (Fig. 102-1). The Revised European-American Lymphoma (REAL) Classification[34] and the World Health Organization (WHO) Classification,[35] introduced in the mid-1990s, define the different categories of NHL as distinct clinicopathologic entities, with well-defined morphologic, immunophenotypic, and genetic features, named, where feasible, according to their postulated counterparts in the normal lymphoid system. This has led to the definition of several lymphoma subtypes within the high-grade lymphoma category previously assigned to most pediatric lymphomas. These include Burkitt's lymphoma, precursor B or T lymphoblastic lymphomas, anaplastic large cell lymphoma (ALCL), and diffuse large B-cell lymphoma (including a mediastinal or thymic subtype). Some low-grade lymphoma subtypes, including follicular center cell lymphoma and marginal zone lymphoma, may also occur in children, albeit with less frequency. The WHO classification of pediatric NHLs is summarized in Table 102-1.

Burkitt's Lymphoma

Modern classification systems[35] define Burkitt's lymphoma (BL) as a mature B-cell neoplasm with characteristic "small noncleaved cell" morphology and a high proliferation rate, resulting from *c-myc* gene translocations. BL and leukemia (classically known as acute lymphoblastic leukemia [ALL L3] in the French American British classification) form a biologic continuum. B-cell lymphomas with a similar proliferation rate and genetic features, previously termed "small noncleaved cell lymphoma, Burkitt's-like," have also been incorporated in this clinicopathologic entity as one of its morphologic variants (see later discussion).

Histologically, BL classical variant, present in endemic cases as well as in many of the sporadic cases, is characterized by a diffuse growth pattern and uniform medium-sized cells (typically equal in size to the nuclei of adjacent histiocytes), with coarsely clumped nuclear chromatin and one to three nucleoli. When observed in Wright-Giemsa-stained smears, these cells are large, with moderate amounts of deeply basophilic cytoplasm and prominent cytoplasmic vacuoles. These tumors typically contain numerous mitotic figures, and matching the high cell turnover rate, they have numerous "tingible-body" macrophages with pale cytoplasm that contain ingested apoptotic cellular debris and impart a characteristic "starry-sky appearance" on low magnification. BLs that are otherwise typical but show a greater degree of pleomorphism in nuclear size and shape and one or two large nucleoli in the neoplastic cells are classified as the atypical Burkitt's/Burkitt's-like variant. These lymphomas represent a subset of the tumors that were previously designated as "small noncleaved cell lymphoma, Burkitt's-like." This morphologic variant can be seen in sporadic cases and in immunodeficiency-associated BL. Finally, BLs with plasmacytoid differentiation (eccentric nuclei with a single central nucleolus, basophilic cytoplasm that contains abundant monotypic immunoglobulin on immunohistochemical staining) represent a third morphologic variant. This latter variant can also be seen with immunodeficiency-associated lymphoma.

The immunophenotype of BL, regardless of its morphologic variants, is that of a mature B-cell of germinal center or postgerminal center type.[35] BL cells strongly express CD19, CD20, CD22, and CD24, as well as CD10 and BCL6, and are negative for BCL2, CD5, CD23, CD34, and Tdt. The neoplastic cells also express surface immunoglobulin (typically IgM, less commonly IgA or IgG) with light chain (kappa or lambda) restriction. Staining for proliferation markers (Ki-67) highlights a growth fraction of nearly 100% in all the histologic variants. Demonstration of this high proliferation rate is required for the diagnosis of BL. Rare cases may exhibit a precursor B-cell immunophenotype associated with the characteristic Burkitt's chromosomal translocations.[36,37] These cases show morphologic and immunophenotypic features that are intermediate between those of classical BL and those of a precursor B cell. The latter

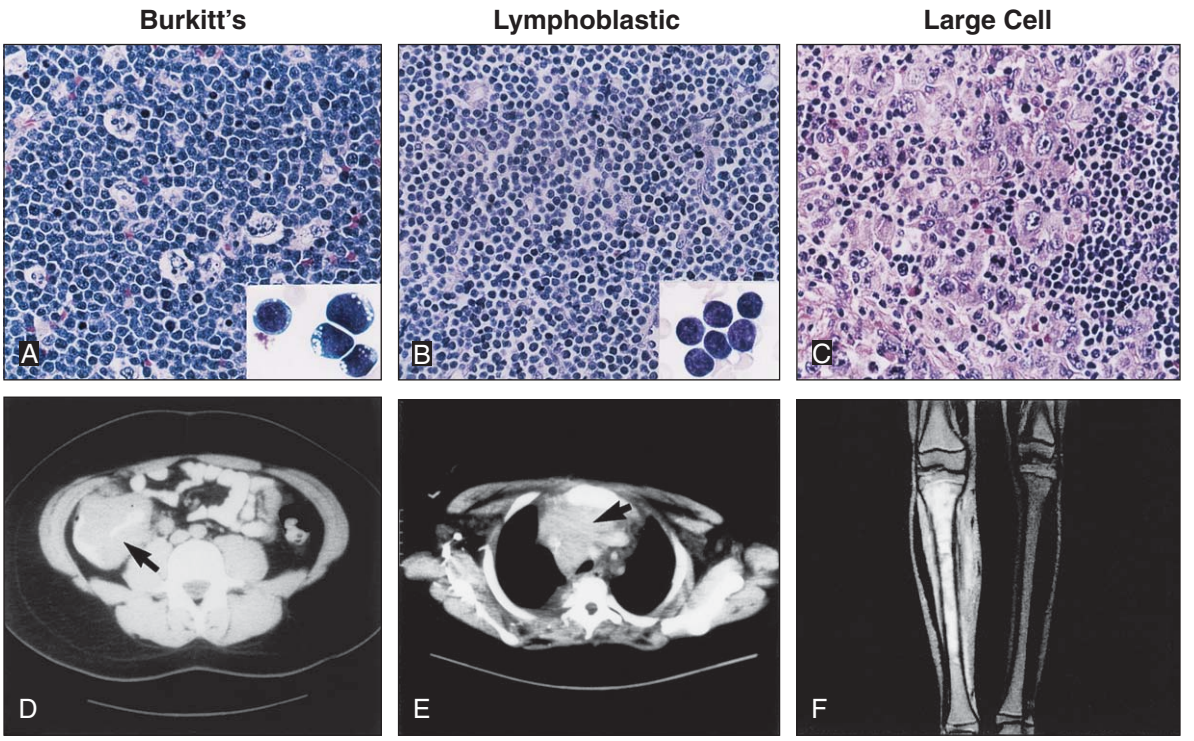

Figure 102-1 • Histologic and clinical features of non-Hodgkin's lymphoma in children. The *upper panels* show the histologic "starry sky" appearance of small noncleaved-cell (Burkitt's) lymphoma **(A),** lymphoblastic lymphoma **(B),** and the anaplastic subtype of large cell lymphoma **(C).** The inserts in panels **A** and **B** show the characteristic L3 blasts of Burkitt's tumors and the characteristic L1 blasts of lymphoblastic lymphoma, respectively. The *lower panels* show common clinical presentations of the three histologic subtypes of lymphoma: encasement of the bowel lumen by Burkitt's lymphoma on abdominal computed tomography **(D),** airway compression by lymphoblastic lymphoma on computed tomography of the anterior mediastinum **(E),** and bony destruction of the tibias by large cell lymphoma on magnetic resonance imaging **(F).**

includes expression of CD34 and Tdt and lack of surface immunoglobulin expression. Recognition of these cases as BL/leukemia typically requires integration with the cytogenetic findings.

Genetically, BL is characterized by several translocations that rearrange the *c-myc* gene on chromosome 8q24, bringing it under the controlling sequences (enhancers) for immunoglobulin heavy or light chain genes and leading to overexpression of this gene in the neoplastic B cells.[38–43] These translocations include the t(8;14)(q24;q32) translocation that is seen in 85% to 90% of the cases, which involves the *c-myc* and *IgH* gene loci, and the less common variants, t(2;8)(p11;q24) and t(8;22)(q24;q11.2), which juxtapose *c-myc* to the immunoglobulin light chain genes, *Ig kappa* (on 2p11) and *Ig lambda* (on 22q11), respectively. The breakpoints involving *c-myc* and *IgH* are highly variable and cluster in regions that are different between endemic and sporadic Burkitt's lymphoma. The *IgH* breakpoints most often involve the *VDJ* region in endemic BL and the switch region *S*μ in the sporadic cases, suggesting that the neoplastic transformation occurs at different stages of B-cell development in these two disease subtypes.[27] Similarly, the *c-myc* breakpoints appear to cluster in two different regions that correlate with the location of the *IgH* breakpoints.[44] This high variability in breakpoints leads to difficulty in generating polymerase chain reaction (PCR) assays that can detect this translocation. Long-range PCR combined with nested

Table 102-1 Pediatric Non-Hodgkin's Lymphoma According to the World Health Organization Classification

COMMON PEDIATRIC LYMPHOMAS	UNCOMMON PEDIATRIC LYMPHOMAS
B-cell lymphomas	Follicular lymphoma (grade 1, 2, or 3)
Precursor B-lymphoblastic lymphoma/leukemia	Hepatosplenic T-cell lymphoma
Burkitt's lymphoma	Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)
Diffuse large B-cell lymphoma	Mycosis fungoides
Mediastinal (thymic) large B-cell lymphoma	Subcutaneous panniculitis-like T-cell lymphoma
T-cell lymphomas	Adult T-cell leukemia/lymphoma (HTLV-1 associated leukemia/lymphoma)
Precursor T-lymphoblastic lymphoma/leukemia	Primary cutaneous CD30 positive T-cell lymphoproliferative disorders
Anaplastic large cell lymphoma	Extranodal NK/T cell lymphoma
Peripheral T-cell lymphoma, unspecified	

PCR strategies have allowed detection of the t(8;14) translocation and of the variant translocations.[45,46] Approximately 70% to 80% of the sporadic cases have additional chromosomal abnormalities, the most common of which involve chromosomes 1 (1q), 6 (6q), 13 (13q), 17, and 22.[47] Some of these alterations (such as those of chromosome 13q), appear to have a negative impact on prognosis in pediatric BL.[47]

The biology of BL has been extensively characterized. *MYC*, a widely studied oncogene, initially discovered because of its involvement in t(8;14), appears to play a central role in malignant transformation and the biologic behavior of BL.[41,42] MYC overexpression has been described in up to 50% of all human cancers,[48] occurring through both epigenetic and genetic mechanisms (which include chromosomal translocations and genomic amplifications). In BL, *MYC* is deregulated primarily by mutation/translocation and by overexpression.[49] Its oncogenic properties have been demonstrated both in vitro and in vivo by using a variety of animal models.[43,48]

MYC is a nuclear transcription factor. It is the founding member of a family of transcription factors of the BHLH-LZ (basic helix-loop-helix-leucine zipper) class. MYC operates as a heterodimeric complex with a cofactor named MAX to bind specific DNA sequences, thereby transcriptionally regulating hundreds to thousands of target genes.[50] These genes are involved in diverse programs that include cell cycle, cell growth, apoptosis, protein translation, cell adhesion, various metabolic pathways, angiogenesis, and DNA repair. MYC can promote cell proliferation through cyclins D, B1, and A and CDK4, which lead to G1 to S progression. It also inhibits differentiation, increases protein synthesis, and suppresses genes that encode cytoskeletal and cell adhesion molecules, thus contributing to neoplastic transformation. An interesting aspect of MYC biology, with major implications in neoplasia, is its role in apoptosis. MYC sensitizes cells to apoptosis; therefore, it appears that mechanisms that would block this downstream effect are necessary in the process of malignant transformation, allowing for cell proliferation to take precedence over cell death.[51] Apoptosis can be inhibited by a variety of proteins, such as BCL2, BCL-X_L, cFLIP, mTOR, Mdm2/Hdm2, Twist, Bmi1, and Cul7. Apoptosis promoters include a variety of proteins typically that are regarded as tumor suppressors, such as P53, ARF, PUMA, ATM, BAX, BID, BIM, Fas/CD95, and 4EBP1. Extensive studies of tumor cell lines and tumors arising in animal models,[48,52] as well as of primary human tumor samples, have shown that in most cases, MYC overexpression is accompanied by either the overexpression of one of the apoptosis suppressors (e.g., BCL2), or by inactivation of one of the proapoptotic factors (e.g., P53 or ARF).[53] In animal models, alterations in P53-related pathways seem to play a major role in the biology of BL. The relevance of these findings to human BL is currently under study. Limited studies performed in pediatric sporadic BL suggest that these findings could be applicable to primary tumor samples as well.[54]

Lymphoblastic Lymphoma

Modern classifications designate these neoplasms as precursor B and precursor T lymphoblastic leukemia/lymphoma, in an attempt to reflect the morphologic, immunophenotypic, genetic, and possibly biologic continuum between the lymphomatous and the leukemic presentation in these blastic tumors.[35] Indeed, at the present time, the separation between these two presentations is largely arbitrary, lymphoblastic neoplasms involving less than 25% of the marrow cellularity being treated as lymphoma with marrow involvement and those exceeding this cutoff being considered acute lymphoblastic leukemias (ALLs).[55,56]

Histologically, lymphoblastic lymphomas efface the underlying lymph node architecture totally or partially, have a diffuse growth pattern, and may occasionally show a patchy "starry sky" appearance due to the presence of interspersed phagocytic histiocytes. The malignant lymphoblasts are characteristically small to intermediate in size, with scanty basophilic cytoplasm; homogeneous, finely dispersed nuclear chromatin; and very small, inconspicuous nucleoli. A subset of cases may present with more abundant cytoplasm, vesicular cytoplasm, and prominent nucleoli. Although complex nuclear convolutions were initially described as a feature unique to T-lymphoblastic lymphomas, similar features may be seen in precursor B-cell neoplasms.

Immunophenotypically, the majority of lymphoblastic neoplasms that are designated as lymphomas (~90%) are of T lineage, while the remaining show B lineage differentiation (Table 102-2).[57–59] Very rare cases of NK cell origin have been described.[58,60,61] The antigen expression profile of lymphoblastic lymphomas is largely similar to that of their leukemic (ALL) counterparts. Most of the lymphoblastic neoplasms express markers of early lymphoid differentiation, including terminal deoxynucleotidyl transferase (Tdt), CD34, and CD10. Tdt and CD34 expression may be absent in a subset of cases, requiring careful correlation with morphology and other immunophenotypic features for the differential diagnosis with mature (peripheral) T-cell and B-cell lymphomas. T-lymphoblastic lymphomas additionally express T-lineage antigens, including CD1a, CD2, CD3, CD4, CD5, CD7, and CD8. By analogy with the stages of intrathymic T-cell differentiation, several subtypes of T-lymphoblastic neoplasms have been defined, including an early double-negative stage ($CD1a^-$, cytoplasmic $CD3^+$, $CD7^+$, variably positive for other pan-T cell antigens such as CD2 and CD5), early cortical thymic stage ($CD1a^+$, $CD2^+$, cytoplasmic $CD3^+$, often $CD4^+$, $CD8^+$, $CD5^+$, $CD7^+$, $CD21^+$), and late cortical thymic stage ($CD1a^-$, $CD2^+$, surface $CD3^+$, $CD5^+$, $CD4^+$, or $CD8^+$). The majority of T-cell lymphoblastic lymphomas correspond to a late stage of intrathymic maturation.[62,63] Gene expression profiling studies[64] have shown that different genetic lesions correlate with malignant transformation at different stages of intrathymic T-cell maturation in T-cell ALL (see later

Table 102-2 Immunophenotypic Features of the Most Common Pediatric Non-Hodgkin's Lymphomas

Type	TDT	CD20	CD79a	PAX5	sIg	cIg	CD5	CD3	CD30	CD15	ALK	BCL2

*Cytoplasmic CD3.

discussion). T lymphoblastic lymphomas are characterized by a more frequent expression of T-cell receptor αβ than γδ, as compared to T-ALL.[65] The immunophenotypic profile of true precursor B lymphoblastic lymphoma (without peripheral blood or bone marrow involvement) has been less extensively characterized, owing to the availability of paraffin-embedded tissue only, in many of the cases.[66–68] By immunohistochemistry, these neoplasms are positive for Tdt, CD34, CD10, and pan-B cell antigens (CD79a, CD22, PAX-5) and often negative for CD20, a mature B-cell antigen, as well as for immunoglobulin kappa and lambda light chains. These features, along with the morphology and clinical presentation, are helpful in the differential diagnosis with BL and diffuse large B-cell lymphoma, both mature B-cell neoplasms that are typically negative for Tdt and CD34 and strongly positive for CD20.[69–72]

Limited information is available regarding the cytogenetic abnormalities that are encountered in T-lymphoblastic lymphoma.[59] It is generally assumed that they resemble those of T-lineage ALL. Recurrent chromosomal abnormalities often include reciprocal translocations that disrupt developmentally important transcription factor genes and lead to their overexpression as a result of rearrangements to loci for T-cell receptor (TCR) genes, most commonly *TCRA* (14q11.2) and *TCRB* (7q35). For example, the *TAL1/SCL* gene (1p32) is involved in the t(1;14)(p32;q11) translocation that is present in approximately 3% of T-ALLs.[63] The *HOX11* transcription factor gene (10q24) is rearranged as part of the t(10;14)(q24;q11.2) and t(7;10)(q35;q24) translocations.[73,74] The *LMO1*(11p15) and *LMO2* (11p13) oncogenes are disrupted by t(11;14) and t(7;11), respectively.[75] Other less common translocations do not involve the *TCR* genes. For example, the t(9;17) translocation is more commonly detected in T-lineage lymphoblastic lymphoma than in precursor T-ALL[76] and is often associated with a mediastinal mass and aggressive disease course. The t(10;11)(p12;q14) translocation, leading to the *AF10-CALM* fusion gene, has been rarely reported in pediatric lymphoblastic lymphoma cases,[77,78] and limited studies suggest a poor prognostic significance.[79] The t(8;13)(p11;q11–14) translocation has been reported in rare cases of T-cell lymphoblastic lymphoma that present with eosinophilia and myeloid hyperplasia.[80–82]

Much progress has been made in recent years in understanding the biology of pediatric T-cell lymphoblastic neoplasms. Molecular studies combined with gene expression profiling have uncovered several oncogenes that appear to play important roles in malignant transformation and correlate with disease subgroups, with potential prognostic and therapeutic implications. *TAL1/SCL* shows activating mutations in up to 50% of all T-ALL,[64,83] independent of detectable translocations, and correlates with leukemias that are arrested at the late cortical stage of thymocyte maturation expressing αβ TCR and with inferior overall survival.[64] *HOX11*(*TLX1*) mutations are present in approximately 30% of all T-ALL, more commonly in adults than in children[83] and in early cortical T-ALL expressing αβ TCR, and correlate with a superior survival in limited studies.[64] *LYL1* is mutated in up to 22% of pediatric T-ALL, correlating with the double-negative early thymocyte stage of differentiation and an inferior survival.[64] The *MLL* gene is mutated in 4% to 8% of T-ALL cases, associated with maturation arrest at early thymocytes stages, expression of γδ TCR, and no impact on prognosis.[83] Certain molecular alterations may provide opportunities for therapeutic targeting. Cryptic deletions of the *INK4/ARF* locus at 9p21, leading to alterations of the p14/p16 loci, are present in up to 75% of all cases of T-ALL,[83] leading to defects in cell cycle control. Since these alterations likely lead to neoplasia through the retinoblastoma (Rb1) and p53 oncogenes, targeting the latter genes might prove to be effective in a significant proportion of T-ALL. In addition, 10% to 20% of T-ALL harbor constitutively activated tyrosine kinases (LCK, FLT3, ABL1), which might also provide targets for tyrosine kinase inhibitor drugs.[83] Finally, *NOTCH1* activating mutations are present in over 50% of T-ALL.[84] This transcription factor activates a wide variety of cellular pathways related to cell growth, using c-MYC as an essential mediator. Inhibition of these signaling pathways has been shown to inhibit cell growth in vitro in T-ALL cell lines.[85]

Anaplastic Large Cell Lymphoma

ALCL is a lymphoma of mature (peripheral) T cells, characterized by strong expression of CD30 (Ki-1)[86] and morphologically by the presence of large "hallmark" cells.[35] These lymphomas may present as systemic disease or as primary cutaneous neoplasms. A subset of the systemic lymphomas expresses the anaplastic lymphoma kinase (ALK) protein as a result of *ALK* gene rearrangements. These constitute the most common subtype of ALCL encountered in children. Only rare cases of primary cutaneous ALK-positive ALCL have been reported in both pediatric and adult patients.[87] Cases of ALK-negative primary cutaneous lymphoma have also been reported in children.[88]

ALCL was initially described as a lymphoma composed of large anaplastic cells with pleomorphic nuclei and sinusoidal lymph node involvement (hence the designation) that expressed CD30 (Ki-1).[86,89] This histologic subtype of ALCL is now designated as the common (classic) subtype. The availability of an immunohistochemical assay for ALK expression has allowed the recognition of lymphomas with very heterogeneous morphology as ALCL. Consequently, the term *ALK lymphoma* or *ALKoma* was proposed for this category of tumors to better accommodate morphologic variants that lack obvious anaplastic morphology.[90] ALCL typically involves the lymph node sinuses and interfollicular area, with subtotal effacement of the lymph node architecture. Regardless of their morphologic subtype, ALK-positive ALCLs consist of a mixture in variable proportions of large anaplastic "hallmark" cells with kidney-shaped or horseshoe-shaped nuclei and small, atypical lymphoid cells with irregular nuclear outlines, as well as inflammatory cells that may include histiocytes and plasma cells. In the common (classical) type, the hallmark cells predominate, sometimes forming cohesive clusters and sheets, while in the small cell type, these cells are sparse, and the neoplastic infiltrate consists predominantly of small lymphoid cells.[91] In the lymphohistiocytic type, the neoplastic cells may be difficult to identify within an exuberant polymorphous inflammatory background that includes histiocytes and plasma cells, is usually poor in neutrophils and eosinophils, and sometimes shows associated fibroblastic proliferation, vascular proliferation, and fibrosis.[92] Occasionally, the fibrotic component may impart a partial nodularity to the tumor. Within this infiltrate, immunohistochemical staining for CD30 or ALK will highlight large tumor cells that typically aggregate around blood vessels. In the monomorphic type, the hallmark cells may be difficult to find, with the tumor consisting predominantly of a monotonous, highly mitotic population of large immunoblastic cells. This latter variant may be associated with a "starry-sky" appearance, owing to frequent tingible-body macrophages. Rarely, ALCL may present with prominent (leukemic) peripheral blood involvement (at diagnosis or at relapse).[93–97] In such cases, the lymphoma cells that are seen on the peripheral blood smear include a mixture in variable proportions of small lymphoid cells with marked nuclear membrane irregularity ("cerebriform") and large immunoblastic cells with deeply basophilic and occasionally vacuolated cytoplasm and coarsely clumped nuclear chromatin. In most cases, there is a predominance of small cells, very similar to the cellular composition of the small cell variant. Notably, in such cases, a significant proportion of the peripheral blood leukocytosis usually consists of granulocytes that may show prominent left shift and toxic changes. These findings, combined with the clinical picture of fever, malaise, and respiratory distress, may distract from the atypical lymphoid population present. In the sarcomatoid type,[98] the tumor cells are sparse and present within an edematous stroma that contains atypical proliferating fibroblasts. In these cases, the tumor cells may have the classical morphology or a spindle cell appearance and may cluster around blood vessels. Rare histologic subtypes of ALCL include giant

cell–rich,[89] signet-ring cell,[99] neutrophil-rich,[100–102] and eosinophil-rich. The latter three have been reported only in ALK-negative ALCL.

On immunohistochemical staining, ALCL cells are characteristically positive for CD30 and ALK (in the ALK-positive cases), and usually positive for CD45 (leukocyte common antigen). In the small cell variant (including the forms with leukemic presentation), the small cells may be CD30-negative and usually show a much lower level of expression of ALK than the large "hallmark cells" that are also present within the same tumors. The majority of ALK-positive ALCL are also EMA-positive (and cytokeratin negative).[103] Many tumors express CD43. While the majority of these tumors are of T-lineage when examined at the molecular level, many of them fail to express several pan T-cell antigens as detectable by IHC, hence the apparent "null-cell phenotype." More than 50% of these lymphomas fail to express CD3, CD5, CD7, and CD45RO.[104] The majority of ALCL will express CD2 and CD4, while they are only exceptionally CD8 positive. Also, regardless of the CD4/CD8 expression status, the tumor cells are very often positive for cytotoxic T-cell antigens (e.g., TIA-1, perforin, granzyme B). Rare ALCLs also express CD56, which has been proposed as a factor of poor prognosis. Flow cytometric analysis usually shows a similar immunophenotype. In addition, 40% to 50% of the analyzed cases have been found to express antigens that are typically associated with myeloid differentiation, such as CD11b, CD13, CD15, and CD33.[105–107]

All ALK-positive ALCLs show aberrant expression of the ALK, a membrane-bound receptor tyrosine kinase that is not expressed by any normal lymphoid elements. Across normal tissues, ALK expression can be found only within the brain, in scattered neurons.[108] The aberrant ALK expression that is seen in ALCL is the result of various chromosomal translocations that juxtapose the *ALK* locus (chromosome 2p23) to other partner genes, which in turn lead to the activation and determine the subcellular localization of the ALK (as seen by immunohistochemistry). The most common translocation, present in up to 75% of ALCLs, is t(2;5)(p23;q35).[109–113] The result of this translocation is a fusion protein (p80) that includes the portion of the ALK protein with associated tyrosine kinase activity and the oligomerization domain of nucleophosmin (NPM) encoded in 5q35.[108,114,115] Normal NPM molecules dimerize and shuttle between the cytoplasm and the nucleus (nucleolus). This is why, in most ALCLs that contain the *NPM-ALK* fusion, ALK expression can be detected immunohistochemically in the nucleus and the cytoplasm. Several other translocations have been described in ALK-positive ALCL (frequency: 2% to 5%). They include t(1;2)(q21;p23) (fusion partner tropomysin 3 gene, *TPM3*),[109,116] t(2;3)(p23;q21) (fusion partner tropomyosin receptor kinase-fused gene, *TFG*), t(2;22)(p23;q11) (fusion partner clathrin heavy chain gene, *CLTCL*),[117] and inv(2)(p23;q35) (fusion partner Pur H gene, *ATIC*).[118] In all these cases, the fusion partners for ALK are proteins that dimerize (an aspect that appears to be essential for activating the kinase function of ALK) but typically localize to the cytoplasm. Therefore, in ALCLs that contain these translocations, ALK expression can be detected only in the cytoplasm. The presence of *NPM-ALK* can be explored for diagnostic purposes using PCR, RT-PCR, or fluorescence in situ hybridization. Aberrant ALK expression appears to play an essential role in tumorigenesis in ALCL.[119,120] ALK-inhibitors are currently being studied as potential therapeutic agents for this type of lymphoma.

Numerous studies have uncovered signaling pathways that are important in the biology of the ALK-positive ALCL, and especially in tumors that harbor the NPM-ALK fusion product. These pathways appear to be important in NPM-ALK-induced tumorigenesis and are attractive therapeutic targets. They include the Jak/STAT (specifically the Jak3 and STAT3 family members) and PI3Kinase/Akt pathways. Inhibition of these pathways has been shown to induce apoptosis and inhibit tumor cell growth in studies performed on lymphoma cell lines. Inhibition of the Src kinase $pp60^{src}$ and pharmacologic blockade of Hsp90 have likewise been shown to induce lymphoma cell apoptosis in vitro.[121]

Diffuse Large B-Cell Lymphoma

The WHO classification defines diffuse large B-cell lymphoma (DLBCL) as a mature B-cell neoplasm with a diffuse growth pattern, composed of large lymphoma cells (i.e., larger than the normal macrophage nuclei).[35] Several morphologic variants are accepted (all of which may be encountered in children).[122] These variants include centroblastic, immunoblastic, T-cell/histiocyte rich, and anaplastic. DLBCL may present as a de novo lymphoma or as progression of a pre-existing low-grade lymphoma. In children, de novo DLBCL is the more common occurrence. In a small percentage of cases, a pre-existing follicular lymphoma component may be identified.

DLBCL is a tumor with a diffuse growth pattern composed, in variable proportions, of several types of large lymphoma cells that include centroblasts, immunoblasts, and anaplastic cells. The predominance of one or another cell type leads to the various morphologic subtypes. Centroblasts are medium-sized to large cells with scanty cytoplasm, irregular nuclear outlines, vesicular chromatin, and several peripherally located nuclei. Immunoblasts are large cells with abundant basophilic cytoplasm, vesicular or clumped chromatin, eccentric nuclei, and single centrally located nucleoli. Anaplastic cells are similar to those seen in ALCL and include giant cells with pleomorphic nuclei or Reed-Sternberg-like morphology. In the centroblastic variant (>80% of the pediatric DLBCL),[123] the tumor consists of a polymorphous mixture of centroblasts and immunoblasts, with fewer than 90% immunoblasts. In the immunoblastic variant (<10% of the pediatric DLBCL),[123] more than 90% of the lymphoma cells are immunoblasts. In the rare anaplastic variant, frequent anaplastic cells are admixed with centroblasts and immunoblasts. Occasionally, a cohesive growth pattern may be present in the latter subtype. In T-cell/histiocyte-rich B-cell lymphoma, the bulk of the tumor consists of inflammatory cells, while the neoplastic cells (centroblasts, immunoblasts, Reed-Sternberg-like) represent less than 10% of cellularity. Rare cases of diffuse large B-cell lymphoma with plasmablastic morphology, immunohistochemical expression of ALK, and the presence of ALK fusion transcripts have been reported.[124,125]

In all subtypes of DLBCL the lymphoma cells strongly express CD45 and CD20, as well as other B-cell antigens, such as CD19, CD22, and CD24. A subset of DLBCL may express CD10, BCL-6, and BCL-2 (resembling follicle center cell lymphoma). Occasional DLBCL are positive for CD5. CD30 expression is typically present in the anaplastic subtype and may be seen in the T-cell-rich subtype. Light-chain-restricted immunoglobulin expression may be demonstrated in many cases, although a significant proportion of these lymphomas may lack immunophenotypic evidence of immunoglobulin expression. Such cases show clonal rearrangements of the immunoglobulin genes when analyzed by molecular means.[126] Some of the DLBCL may show high proliferation indices when analyzed by Ki-67 immunohistochemistry, but they typically do not exceed 90%, a feature that is helpful for the distinction from BL. The ALK-positive plasmablastic B-cell lymphomas have unique immunophenotypic features, which reflect their distinctive morphologic differentiation. They lack expression of mature B-cell antigens, such as CD20, and express weak CD79a, CD138, and abundant cytoplasmic immunoglobulin, typically IgA. They are CD30 negative in most cases.[124]

When cytogenetic studies are performed, these tumors typically show complex chromosomal abnormalities. Immunophenotypic and genetic studies, including gene expression profiling by several methodologies, have demonstrated that DLBCL is a biologically heterogeneous group of neoplasms that includes at least two major subgroups: a germinal center (GC)-like group and an activated peripheral blood B-cell (ABC)-like group.[127–129] The GC-like group is characterized by expression of CD10 and BCL-6, while negative for MUM1, contains ongoing Ig gene mutations, may show the

t(14;18) translocation, 12q12 gains, amplification of *c-rel* gene (chromosome 2p), low levels of *Blimp-1* gene mRNA expression, and a more favorable outcome. A significant number of the GC-like tumors occurring in adults also harbor the t(14;18), *IGH/BCL2* translocation. The ABC-like group lacks expression of CD10 and BCL-6 as well as ongoing Ig gene mutations, may show trisomy 3 or gains on chromosomes 3q or 18q21–22 and losses at 6q21–22, has constitutive activation of NF-κB, has high levels of *Blimp-1* mRNA expression with lack of protein expression, has aberrant IL-4 induced STAT6 signaling, and is associated with a poor prognosis.[130] Recent studies have shown that in pediatric DLBCL, the distribution and characteristics of these subgroups are different, with children showing a much higher frequency of the centroblastic variant (83% versus 75%, respectively) and of the GC-like subtype (83% versus 40% to 48%, respectively) when compared to the adult tumors and with a much lower incidence of the ABC-like subtype in this age group.[123] In addition, the t(14;18) translocation appears to be virtually absent in the pediatric GC-like DLBCL.[123] Furthermore, these disease subgroups do not appear to have an impact on prognosis in children.[123] All these insights offer interesting opportunities for differential, age-appropriate therapeutic targeting in the various disease subtypes in DLBCL.

Mediastinal (Thymic) Large B-Cell Lymphoma

Mediastinal (thymic) large B-cell lymphoma (Med-DLBCL) is a clinicopathologically and biologically distinct subtype of DLBCL that accounts for fewer than 10% of all large cell lymphomas in children.[131] It has also been designated as mediastinal clear cell lymphoma of B-cell type and mediastinal diffuse large cell lymphoma with sclerosis. It is currently thought to originate in the $CD19^{+}CD21^{-}$ B cells and asteroid B cells that reside in the thymic medulla.[132]

Histologically, Med-DLBCLs can present as any of the DLBCL variants. Approximately half of the cases can have prominent associated stromal fibrosis, adding to the difficulty in obtaining suitable diagnostic biopsy samples in many of these cases. Cytologically, the neoplastic cells may have the appearance of centroblasts or immunoblasts or may have abundant pale cytoplasm and markedly lobated, flower-like nuclear membrane outlines (so-called clear cell appearance).[35,133–138]

Immunophenotypically, Med-DLBCL shows a mature B-cell immunophenotype, with expression of CD45 and of pan-B-cell antigens, including CD19, CD20, CD79a, and PAX-5. There is typically partial and variable coexpression of CD30.[139] Some cases may express CD23. Other antigens that are expressed include BCL-2 and BCL-6.[140] The neoplastic cells are typically negative for CD10, CD21, immunoglobulin, and HLA class I and II molecules.[141]

Little conventional cytogenetic data are available, largely owing to the small tumor samples that are typically available in these patients. Alternative approaches have shown consistent gains of material on chromosome 2p (seen in approximately 25% of the cases), with amplification of *c-REL*, a gene that encodes for a transcription factor that is important in B-cell development, as well as gains of material on 9p (50% to 75% of the cases) with amplification of the *JAK2* gene, whose product is important in the JAK/STAT signaling pathway. Other alterations that have been described involve the chromosomes 6p (MHC class I locus), Xq, and 12q and the P53 gene.[132,142,143]

Biologically, Med-DLBCL has the profile of activated germinal center or postgerminal center cells. The lymphoma cells contain clonal Ig gene rearrangements with somatic mutations[126] and *BCL-6* gene mutations and express MUM1/IRF4, BCL6, and the B-cell specific transcription factors OCT-2, BOB.1, and PU.1. Overexpression of an interleukin-4-inducible gene, *FIG1* (IL-4I 1) suggests the possible oncogenic activation of signaling pathways such as IL-4/IL-13 or Janus kinase 2 (JAK2). Gene expression profiling experiments have demonstrated a close resemblance of this lymphoma with that of classical Hodgkin's lymphoma, suggesting that, at least in the mediastinal location, these neoplasms may share a common origin from a thymic B-cell. Notably, both tumors showed overexpression of genes involved in cytokine signaling pathways, such as IL-13, tumor necrosis factor, and NF-κB. These findings suggest that targeting of some of these overexpressed genes or of activated NF-κB could represent therapeutic possibilities in these tumors.[132]

Uncommon Pediatric Lymphomas

Lymphomas that occur infrequently in children and adolescents include follicle center cell lymphoma,[144] hepatosplenic lymphoma,[145] panniculitis-like T-cell lymphoma,[146] mycosis fungoides,[147–150] T/NK lymphoma, nasal-type natural killer lymphoma,[151] marginal zone lymphoma (including the extranodal MALT type),[152] and HTLV-1-associated leukemia/lymphoma.[153,154] The clinical and biologic features of these lymphomas in children are generally similar to those observed in adults; however, this conclusion is drawn from the very few reported pediatric cases.

Pediatric follicular lymphomas (FLs) appear to have a spectrum of clinicopathologic features that are distinct from those of the tumors that are seen in adults; these features are detailed next.

Because of the relatively small numbers of cases that have been reported, little is known about the genetics and biology of the follicular lymphomas that occur in children. It appears that, in addition to rare cases of classic follicular lymphomas that resemble, phenotypically and genetically, those seen in adults, children may present with a second subtype, which is in fact more common in this age group.[144,155–160] These FLs, typically limited to one site (most commonly, lymph nodes in the head and neck area or testis/epididymis) are characterized by effacement of the normal architecture by neoplastic follicles composed of large, expansile, irregular germinal centers with geographic appearance and thin or absent mantle zones. Cytologically, the germinal centers are typically composed of monotonous predominantly large centroblasts, with occasional cases showing numerous mitotic figures and a "starry-sky" appearance due to numerous tingible-body macrophages. Most of these cases have morphologically the appearance of grade 2 or grade 3 (WHO) FL, albeit without the prognostic significance that this grading would have in classical adult FL.

Immunophenotypically, the neoplastic cells express CD20, CD10, BCL-6, and, in some cases, CD43 and are typically negative for BCL-2. Staining for CD21 highlights the follicular dendritic cell meshwork that underlies the expanded neoplastic follicles.

Pediatric FL lacks, in most cases, the t(14;18) and BCL-2 rearrangements, features that distinguish it from the usual cases of adult FL. Pediatric FLs typically have clonal Ig gene rearrangements and have been found to harbor *BCL-6* gene rearrangements. Interestingly, they also lack P53 overexpression, another feature that distinguishes them from the high-grade adult-type FLs. All of these features suggest an alternative molecular pathogenesis for pediatric FL, justifying alternative therapeutic options for these patients.

CLINICAL PRESENTATION

The primary sites of involvement and the extent of disease spread determine the clinical features of NHL at presentation (see Fig. 102-1).[1,2,19]Although adults usually present with nodal disease, children with NHL usually present with extranodal disease, most frequently involving the abdomen (31% percent of cases), the mediastinum (26% of cases), or the head and neck region (29% of cases).[1] These are rapidly growing tumors associated with hematogenous disease spread, and the majority of children with NHL present with locally invasive or advanced-stage disease. Involvement of the CNS is characterized by the presence of cranial nerve palsies and/or cerebrospinal fluid pleocytosis. When the bone marrow is involved, the distinction between NHL and leukemia is somewhat arbitrary:

If more than 25% of the marrow is replaced by lymphoblasts, the patient is considered to have leukemia; if less than 25%, the patient is considered to have advanced-stage NHL with marrow involvement.

There is a striking relationship between the histologic subtype and the presenting site of disease in the lymphoblastic and Burkitt's lymphomas.[1] Among the lymphoblastic lymphomas, the typical primary site of involvement is the mediastinum and/or the head and neck region but rarely the abdomen, whereas the Burkitt's lymphomas typically present in the abdomen or head and neck region but rarely the mediastinum. In contrast to patients with lymphoblastic and Burkitt's lymphomas, children with large cell lymphomas may present with disease at almost any location. Involvement of the CNS at diagnosis is associated with both the Burkitt's and lymphoblastic histiotypes but rarely with large cell histology.[161] In contrast, spread to the bone marrow may occur in any of these three histologic subtypes.[1,162]

Primary involvement of the abdomen, as is typical of Burkitt's lymphoma, may be associated with nausea, vomiting, or abdominal pain at presentation. These tumors usually arise from the distal ileum and result in obstruction of the bowel by either intussusception or direct compression of the lumen. Other primary sites of involvement in the abdomen include the appendix and/or large bowel. Abdominal tumors may be associated with malignant ascites; involvement of kidney, liver, or lymph node; and invasion of adjacent structures, including the abdominal wall.[1,2] Involvement of the pelvis may include ureteral compression with associated hydronephrosis.

Primary involvement of the mediastinum, as is typical of advanced-stage lymphoblastic lymphoma and mediastinal large B-cell lymphoma, may be associated with respiratory symptoms ranging from mild cough to severe respiratory distress caused by direct tumor compression of the airway, requiring emergency attention (see the section on Emergency Situations).[1,2] Associated pleural effusions may further complicate the respiratory status. Compression of the superior vena cava by the tumor may obstruct venous blood return, resulting in swelling of the neck, shoulder, and face (superior vena cava syndrome); this condition may predispose the patient to the development of deep venous thromboses. In rare cases, children with mediastinal masses may also have cardiac irregularities or tamponade.[2]

Involvement of the CNS may cause symptoms resulting from increased intracranial pressure, including nausea, vomiting, headache, and vision changes; there may also be neurologic abnormalities on physical examination resulting from palsies of cranial nerves innervating the face or extraocular muscles. Involvement of the bone marrow may be associated with bone pain, pallor, neutropenia, and/or thrombocytopenia with associated bruising and bleeding. Involvement of the skin occurs in approximately 4% of children with newly diagnosed NHL. When present, it is usually associated with $CD30^+$ anaplastic large cell histology (ALCL);[163–165] however, lymphoblastic lymphomas (often non-T-cell immunophenotype) may also involve the skin.[166,167]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The differential diagnosis of NHL comprises both benign and malignant conditions. If there is no mediastinal mass and if blood counts and physical examination are within normal limits except for an isolated, painless, enlarged peripheral lymph node, a 10- to 14-day trial of antibiotics is permissible to treat presumed bacterial adenitis. Serologic and skin testing may be helpful in the diagnosis of histoplasmosis, tuberculosis, and EBV infection, which may also cause adenopathy simulating lymphoma.

The non-Hodgkin's lymphomas of childhood grow very rapidly; therefore, an expeditious diagnostic workup in consultation with a pediatric oncologist is indicated if NHL is suspected (Fig. 102-2). The diagnosis of NHL is most readily established by examination of tissue obtained by open biopsy of the involved site. A comprehensive characterization of the biologic features of the tissue, including histologic, immunophenotypic, cytogenetic, and molecular studies, will help to distinguish NHL from the small, round blue cell tumors, including Ewing's sarcoma, neuroblastoma, and rhabdomyosarcoma. When patients (such as those with large anterior mediastinal masses and associated airway compression) are too unstable to undergo anesthesia for open biopsy, the diagnosis may be established by parasternal fine-needle aspiration or biopsy with local anesthesia.[168] Among children who present with an associated pleural effusion, thoracentesis with cytologic examination of pleural fluid is usually diagnostic. For children with large abdominal Burkitt's tumors, either percutaneous aspiration of the mass or paracentesis to obtain ascitic fluid often yields diagnostic cytologic and cytogenetic findings. A bone marrow and cerebrospinal fluid examination should be performed early in the workup of a child with suspected NHL, since these studies may be diagnostic and could preclude the need for more invasive procedures.

Initial Evaluation and Staging Workup

A prompt and meticulous staging workup is imperative because treatment is determined in part by primary site and degree of disease spread. A complete history and physical examination, including documentation of the presence or absence of B symptoms by history, should be completed. Computed tomographic imaging of the chest, abdomen, and pelvis, as well as bone scans should be performed on all patients. Gallium scanning may also be helpful in selected cases, particularly in following residual masses that were gallium-positive at diagnosis.[1,2,19] Positron emission tomography is commonly used in the evaluation of adults with Hodgkin's or non-Hodgkin's lymphoma;[169] this modality is becoming more widely used in place of gallium scanning as part of the staging workup of children with non-Hodgkin's lymphoma. Bilateral posterior iliac crest aspirations and biopsies increase the chance of identifying overt marrow involvement, thus reducing the possibility of underestimating the stage of disease.[170] The bone marrow samples should be submitted for cell count and differential, flow cytometric, cytogenetic, and molecular pathologic analyses. Magnetic resonance imaging of the bone marrow has been shown to be effective in detecting occult disease is some studies;[171] however, it is not a standard component of the currently accepted pediatric NHL workup. A lumbar puncture should be performed for cytologic evaluation of the cerebrospinal fluid.

The stage of disease is usually assigned according to the St. Jude Staging System described by Murphy (Table 102-3),[56] which was developed to accommodate the noncontiguous nature of disease spread, predominant extranodal involvement, and involvement of the bone marrow and CNS that characterize the pediatric NHLs. Stages I and II are considered to be limited-stage disease, whereas stages III and IV are advanced-stage disease. The initial laboratory evaluation should include a complete blood count with differential and a chemistry panel comprising electrolytes, BUN, creatinine, LDH, calcium, phosphorus, and uric acid. An HIV screen should be performed on all patients newly diagnosed with lymphoma. Those who test positive may be at increased risk for therapy-related toxicity, including life-threatening infections. Serologic tests for EBV infection can be helpful when lymphoproliferative disease is highly suspected in the differential diagnosis; however, positive serologic results do not rule out a malignancy.

Prognostic Factors

Tumor burden at diagnosis, reflected by both the disease stage and serum LDH (lactate dehydrogenase), is an important predictor of outcome for children.[1] In one large single-institution study of childhood NHL, the treatment era, disease stage, and serum LDH level all emerged as independent and significant prognostic indicators.[1]

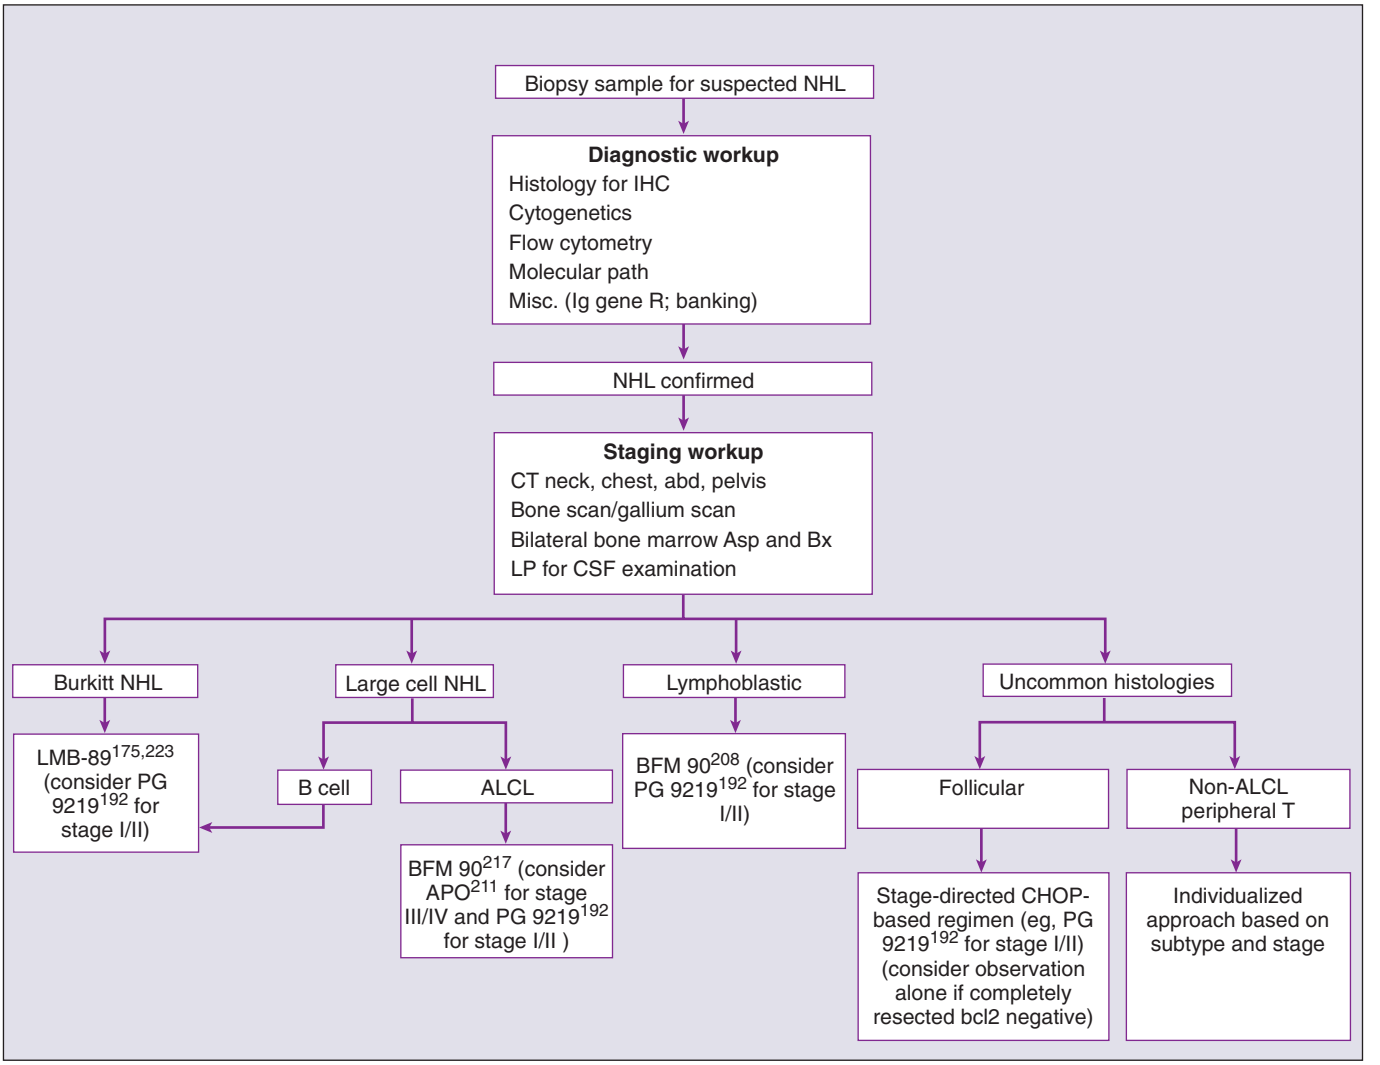

Figure 102-2 • Diagnostic workup, staging workup, and treatment approach for children not entered on current research protocols.

Serum IL-2 receptor levels, which reflect tumor burden, have also been shown to predict outcome.[172,173]

A poor early response to therapy is considered by some to confer a poorer prognosis, as has been demonstrated in children with ALL.[174] In the LMB-89 protocol, poor early response is a criterion for placement in the most intensive arm of therapy.[175] The current Children's Oncology Group study for children with advanced-stage lymphoblastic lymphoma is examining the impact of early response as determined both by diagnostic imaging and flow cytometric MRD technology.

Prognostic factors have also been identified with respect to specific histologic subtypes. For example, among adults with ALCL, ALK protein expression is a favorable prognostic factor.[176–178] In a multivariate analysis of clinical features in childhood ALCL, mediastinal, visceral (lung, liver, spleen) and skin involvement were associated with adverse risk.[179]

Primary Treatment

Treatment of the NHLs of childhood has advanced dramatically over the past 30 years through the incremental development and clinical testing of effective multiagent chemotherapeutic regimens.[1,2,19,161,180–218] In a randomized trial comparing two of the first successful regimens for treating childhood NHL (the cyclophosphamide-based COMP regimen and the multiagent LSA_2L_2 regimen designed for acute lymphoblastic leukemia), the Children's Cancer Group clearly demonstrated that children with limited-stage disease fared well regardless of histology or treatment arm assignment, while treatment outcomes for children with advanced-stage disease varied with histology and treatment arm.[186] Children with Burkitt's lymphoma had a better outcome with the COMP regimen,[186] while those with lymphoblastic NHL fared better with the LSA_2L_2 regimen.[186–188] However, among those who presented with advanced-stage large cell disease, neither treatment arm emerged as superior. In contrast to the stage- and histology-directed therapeutic approach that has been historically used in the United States, a stage- and immunophenotype-directed approach is predominant in Europe. Studies in both the United States and Europe suggest that the immunophenotype-directed approach has advantages for treating children with advanced-stage large cell NHL, a family of lymphomas whose prognoses vary with immunophenotype.[189]

Surgery and radiation therapy have minimal roles in the management of childhood NHLs.[1,2] Surgery is indicated only for diagnostic purposes and in cases in which an ileocecal mass, associated with mesenteric nodes only, can be completely resected (resulting in downstaging from III to II, which requires less intensive systemic

Table 102-3 Stages of Non-Hodgkin's Lymphoma*

STAGE I
A single tumor (extranodal) or involvement of a single anatomical area (nodal), with the exclusion of the mediastinum and abdomen
STAGE II
A single tumor (extranodal) with regional node involvement
Two or more nodal areas on the same side of the diaphragm
Two single (extranodal) tumors, with or without regional node involvement, on the same side of the diaphragm
A primary gastrointestinal tract tumor (usually in the ileocecal area), with or without involvement of associated mesenteric nodes, that is completely resectable
STAGE III
Two single tumors (extranodal) on opposite sides of the diaphragm
Two or more nodal areas above and below the diaphragm
Any primary intrathoracic tumor (mediastinal, pleural, or thymic)
Extensive primary intra-abdominal disease
Any paraspinal or epidural tumor, whether or not other sites are involved
STAGE IV
Any of the above findings with initial involvement of the central nervous system, bone marrow, or both

*Based on the classification proposed by Murphy.

therapy; see section on Staging).[219] Otherwise, aggressive debulking procedures should not be undertaken. Prospective randomized trials have demonstrated that the incorporation of involved field radiation therapy into a multiagent chemotherapy regimen does not improve outcome.[192,216] The use of radiation therapy in the management of relapse, CNS disease, and certain emergency situations will be discussed in other sections.

Initial Management

The serum chemistry values should be reviewed before chemotherapy is started. Many patients with bulky Burkitt's or lymphoblastic lymphomas present with hyperuricemia, hyperphosphatemia, and renal dysfunction due to the rapid turnover of lymphoblasts. These metabolic abnormalities are exacerbated by chemotherapy, which rapidly lyses tumor cells. Tumor lysis releases purines, potassium, and phosphorus into the bloodstream, resulting in the deposition of uric acid, xanthines, and phosphates in the renal tubules, which causes further renal dysfunction, a clinical condition termed *tumor lysis syndrome*.[2] This problem can be precluded or reduced if patients with advanced-stage disease are vigorously hydrated (3 to 4 L/m^2/day) prior to receiving chemotherapy. Alkalinization is usually necessary to maintain a urine pH of approximately 7.0. The urinary excretion of uric acid is reduced at an acidic pH, whereas the excretion of phosphorus is impaired by overalkalinization. Allopurinol, a xanthine oxidase inhibitor, has historically been helpful in the management and prevention of hyperuricemia by blocking ongoing production of uric acid. Urate oxidase, a uricolytic agent that has been used for many years in Europe, has advantages that make it a preferable alternative.[220] It results in a precipitous drop in uric acid by converting it to allantoin, precludes the need for vigorous alkalinization, and is associated with preservation of normal renal function and avoidance of dialysis in most cases. Rasburicase, a recombinant form of this drug, is also effective in reducing uric acid, has a much lower risk of associated allergic reactions, and has recently become a standard part of initial management.[221] In the rare case in which urine output is unacceptable, addition of mannitol followed by furosemide (Lasix) may be necessary.

Limited-Stage Disease

The excellent treatment results (survival rates of 85% to 95% at 5 years) that are achieved in children with limited-stage NHL have prompted an emphasis on new treatment strategies that reduce both morbidity and the risk of late sequelae (e.g., anthracycline-induced cardiomyopathy, sterility, and second malignancies) while maintaining or improving the treatment outcome.[175,183,191,192,205,222] Various approaches to reduction of treatment intensity have been investigated. The Pediatric Oncology Group performed two sequential randomized trials that examined the need for involved-field radiation therapy and maintenance chemotherapy, respectively.[192] In the first study, patients were randomly assigned to receive either chemotherapy alone (three courses of cyclophosphamide/Adriamycin/vincristine/prednisone [CHOP] followed by a 24-week continuation phase of 6-mercaptopurine and low-dose methotrexate) or chemotherapy plus involved-field radiation therapy. In the subsequent study, patients were randomly assigned to receive the three courses of CHOP with or without the 24-week continuation phase.[192] These studies demonstrated that both involved-field radiation therapy and the continuation phase of therapy could be safely eliminated without compromising outcome, with one exception. Children with limited-stage lymphoblastic lymphoma had lower event-free survival rates than did those with nonlymphoblastic histology. Even with the 24-week continuation phase, one third of the patients with lymphoblastic lymphoma developed recurrent disease. With salvage therapy, there was no reported difference in overall survival between those with lymphoblastic and nonlymphoblastic histology. The optimal management of limited-stage lymphoblastic lymphoma remains controversial. The French Society of Pediatric Oncology (SFOP) uses a more aggressive initial approach to avoid the need for retreatment.[182] Children with limited-stage lymphoblastic lymphoma are entered on the same protocol that is used for advanced-stage lymphoblastic lymphoma, and children with limited-stage nonlymphoblastic lymphoma are candidates for less-intensive regimens only if there is complete resection of disease.[175] The current Children's Oncology Group trial for lymphoblastic lymphoma is piloting an arm of ALL-derived therapy for those children who present with limited-stage disease.

Advanced-Stage Disease

Attempts to improve the treatment result in children with advanced-stage NHL have relied on further intensification of therapy. Historically, the general approach in the United States has been histology-directed, whereas in Europe, an immunophenotype-directed approach has predominated. For example, for many years, French investigators have entered patients with Burkitt's lymphoma and B-cell large cell lymphoma on the same protocol.[175,223] This approach is now widely used in the United States.

BURKITT'S LYMPHOMA. The dramatic improvements that have been achieved in the treatment of advanced-stage Burkitt's lymphoma and B-cell ALL represent one of pediatric oncology's undisputed success stories. With current therapy, which is generally cyclophosphamide-based, very intensive, and given over a relatively short period of time (4 to 8 months), at least 75% of patients are event-free survivors. Results achieved with the COMP regimen were first improved on by the incorporation of high-dose methotrexate and/or high-dose cytarabine.[190,193–196] Two studies during the same period showed that the duration of therapy for stage III patients could be shortened to 2 to 4 months without compromising patient outcome.[195,199] Further improvements in treatment outcome have been achieved over the past 8 years by further intensification of therapy (escalation of cyclophosphamide, methotrexate, and cytarabine dosages) and by the addition of new active agents, including

Table 102-4 Treatment Outcome for Advanced-Stage Burkitt's Lymphoma

Protocol	Stage	No. of Patients	Event-Free Survival Rate	Reference (First Author)
POG 8617	IV	34	4-year EFS = 79 ± 9%	Bowman[194]
	B-ALL	47	4-year EFS = 65 ± 8%	
LMB 89*	III	278	5-year EFS = 91% (95%CI: 87–94%)	Patte[175]
	IV	62	5-year EFS = 87% (95%CI: 77–93%)	
	B-ALL	102	5-year EFS = 87% (95%CI: 79–92%)	
BFM 90	III	169	6-year EFS = 86% ± 3%	Reiter[205]
	IV	24	6-year EFS = 73% ± 10%	
	B-ALL	56	6-year EFS = 74% ± 6%	

*Includes patients with B-cell large cell NHL.

etoposide and ifosfamide.[175,205,207] The LMB-89 regimen designed by the SFOP, for example, has produced one of the best results to date.[175] In this protocol, children receive high-dose methotrexate (3 g/m^2), fractionated cyclophosphamide, Adriamycin, vincristine, prednisone, and low-dose cytarabine given over approximately 5 months if marrow blast cells at diagnosis are fewer than 70%. For children with more than 70% marrow blast cells or with CNS involvement at diagnosis, therapy is intensified (methotrexate dose is escalated to 8 g/m^2, high-dose cytarabine and etoposide are incorporated, and the total duration of therapy is extended to approximately 8 months). A recently completed international trial (LMB-96) examined the safety of intensity reduction in the Group B and C arms of the LMB-89 study.[223,224] The intensity of Group B therapy was safely reduced (i.e., no escalation of cyclophosphamide in the second COPADM course, and deletion of the maintenance sequence) without compromising the excellent outcome; however, intensity of therapy of the Group C arm could not be safely reduced.

Other successful treatment strategies for advanced-stage Burkitt's lymphoma and B-cell ALL have been reported (Table 102-4). Excellent results have been achieved by the BFM (Berlin-Frankfurt-Munster) cooperative group using a regimen that incorporates high-dose methotrexate (5 g/m^2), ifosfamide, etoposide, doxorubicin, and steroids.[205] BFM trials have also examined the impact of methotrexate infusion time; they found that a 4-hour infusion time was noninferior to a 24-hour infusion for children with limited-stage disease but not for those with advanced-stage disaese.[225] Sequential National Cancer Institute studies have shown that adding etoposide, high-dose cytarabine, and ifosfamide to a regimen of cyclophosphamide, Adriamycin, vincristine, and high-dose methotrexate improved the treatment result.[207] Importantly, these more aggressive approaches have shown encouraging preliminary results in adults with the same malignancies.[226]

LYMPHOBLASTIC LYMPHOMA. Most of the successful treatment plans for children with advanced-stage lymphoblastic lymphoma are derived from therapies designed to treat children with high-risk acute lymphoblastic leukemia (Table 102-5). These regimens, which generally use multiple chemotherapy agents (up to 10 different agents) and are given over a 15- to 32-month period, result in an approximate 65% to 90% event-free survival rate at 4 to 5 years.[182,186–188,200,201,204,208] Although the multiagent nature of these regimens makes it difficult to determine the relative merit of individual components, compelling data suggest the importance of high-dose methotrexate. The French (SFOP) achieved an excellent result by incorporating courses of high-dose methotrexate into the previously studied LSA_2L_2 regimen.[182] Moreover, the BFM group has recently reported very encouraging results (a 3-year event-free survival rate of approximately 90%) of a regimen that features an intensive

Table 102-5 Treatment Outcome for Advanced-Stage Lymphoblastic Non-Hodgkin's Lymphoma

Protocol	Stage	No. of Patients	Event-Free Survival Rate	Reference (First Author)
LSA_2L_2 (modified) CCG-551	III/IV	124	5-year EFS = 64%	Anderson[186]
BFM 90	III	82	5-year EFS = 90% ± 3%	Reiter[208]
	IV	19	5-year EFS = 95% ± 5%	
X-H SJCRH	III/IV	22	4-year DFS = 73%	Dahl[200]
APO (Dana Farber)	III/IV	21	3-year DFS = 58% ± 23%	Weinstein[218]
A-COP + (POG)	III	33	3-year DFS = 54% ± 9%	Hvizdala[201]
SFOP LMT81	III	33	57-month EFS = 79% (SE: 4%)	Patte[122]
	IV/ALL	43	57-month EFS = 72% (SE: 4%)	
CCG: LSA_2L_2 (modified) vs. ADCOMP	I-IV	243	5-year EFS = 74%	Tubergen[204]
	I-IV	138	5-year EFS = 64%

	III/IV	84	4-year CCR = 78% (SE: 5%)	

high-dose methotrexate (5 g/m^2) consolidation course.[208] A subsequent study demonstrated that prophylactic cranial irradiation could be safely eliminated without compromising the excellent outcome.[227] Although definitive data are lacking, this result might reflect the higher levels of intracellular methotrexate polyglutamates that are produced in T-cell lymphoblasts by high-dose methotrexate as compared to low-dose methotrexate.[228] A current Children's Oncology Group study is examining whether high-dose methotrexate can be safely eliminated if it is replaced by extended intrathecal therapy. L-Asparaginase is also commonly used in many successful regimens. In this regard, a Pediatric Oncology Group study demonstrated a survival advantage for those who were randomized to receive additional L-asparaginase.[213] Efforts to improve the treatment result have also included the addition of new active agents (e.g., epipodophyllotoxins)[200] and the incorporation of a reinduction[208] or late intensification phase.

LARGE CELL LYMPHOMA. Historically, the biologic heterogeneity of advanced-stage large cell lymphoma coupled with quite varied treatment strategies that have been reported made it difficult to identify an optimal treatment approach (Table 102-6).[106] Histology-directed therapies in the United States, primarily CHOP-based, resulted in a 50% to 70% event-free survival rate at 3 years.[161,180,186,189,197,202,203] Although some studies have examined the feasibility of eliminating agents associated with significant late effects,[197,211] some others have examined the benefit of incorporating additional active agents (e.g., intermediate- and high-dose methotrexate, intermediate- and high-dose cytarabine, ifosfamide, and carboplatin). Pediatric Oncology Group investigators reported that children with large cell lymphoma of the B-cell immunophenotype had a better outcome than did those with a non-B-cell immunophenotype, a finding that suggested that immunophenotype-directed therapies for pediatric large cell lymphomas should be further pursued.[189] In this regard, European trials for children with large cell lymphoma have historically assigned treatment on the basis of immunophenotype (e.g., B-cell, T-cell, CD30$^+$). Currently, trials in both the United States and Europe for large cell lymphoma are being directed toward specific immunophenotypically defined categories as designated in the most recent WHO classification system. The two most common large cell types that are encountered in children are DLBCL and anaplastic large cell lymphoma (ALCL).

Diffuse Large B-Cell Lymphoma. The SFOP reported equally excellent outcomes for children with either B-cell large cell or Burkitt's lymphoma who were treated on the same B-cell regimen (i.e., LMB-89).[175] This observation was confirmed in the recently completed international collaborative LMB-96 trial, which resulted in a 4-year event-free survival rate of 92.5% for patients with DLBCL (excluding primary mediastinal disease) compared to 93.5% for those with Burkitt's lymphoma. In this trial, those with primary mediastinal disease had a somewhat inferior outcome (4-year event-free survival rate of 71.5%).[223] Other studies have also suggested that children with mediastinal B large cell lymphomas have a slightly worse outcome compared to those with DLBCL.[131,134] The anthracycline-based APO regimen was also shown to be active in children with diffuse large B-cell lymphoma (i.e., a 4-year event free survival rate of 63.8%); however, the result is somewhat inferior to that of the LMB-96 approach.[211,212]

Anaplastic Large Cell Lymphoma. The therapeutic approaches for children with CD30$^+$ ALCL are quite varied.[179,212,217] An immunophenotype-directed strategy has been used in Europe for many years. The German BFM group treated children with CD30$^+$ ALCL with a B-cell approach (Burkitt's lymphoma-like) achieving one of the best published outcomes to date (a 5-year event-free survival rate of approximately 76% for all patients).[217] The activity of a B-cell approach (NHL 9002) based on the very successful French LMB-89 B-cell protocol was studied in the United Kingdom Children's Cancer Study Group. In the NHL 9002 study, those with stage II, III and non-CNS-positive stage IV ALCL were treated with the Group B arm of the LMB-89 regimen (5-year event-free survival rate of 55%).[185] It has yet to be determined why this approach appeared to be inferior to the B-cell approach used in the BFM trials; however, it has been suggested that it might be a result of the more frequent use of alkylators in the BFM regimen. In the French (SFOP) trials, children with CD30$^+$ ALCL have been enrolled on the HM-89 and HM-91 protocols, both of which feature an initial treatment phase (one course of COP followed by two courses of COPADM) based on their very successful B-cell protocol, LMB-89.[179] The maintenance phases differed from LMB-89 as follows: The HM 89 protocol featured alternating courses of VEM (etoposide, methotrexate, and cyclophosphamide) and VAD (vincristine and doxorubicin) for a total of eight courses, and the HM-91 regimen featured alternating courses of VEBBP (vinblastine, etoposide, bleomycin, and prednisone) and Sequence 1 (vincristine, methotrexate, cyclophosphamide, and doxorubicin) for a total of eight courses. A 60% (54% to 76%) 3-year event-free survival rate was seen for all stages treated with HM-89 and HM-91; however, the 3-year event-free survival rate was only 55% for stage III and IV patients.

A histology-directed approach has historically been used in the United States to treat children with large cell lymphoma. One of the most widely used regimens is APO, which features an induction phase (doxorubicin, vincristine, prednisone, and intrathecal methotrexate) followed by sequential maintenance phases (doxorubicin, methotrexate, vincristine, prednisone, 6-mercaptopurine, and intrathecal methotrexate)[202,211,212] A randomized trial performed by the Pediatric Oncology Group examined the potential benefit of adding intermediate-dose methotrexate and high-dose cytarabine to an APO backbone and found no difference in outcome regardless of

Table 102-6 Treatment Outcome for Advanced-Stage Large Cell Non-Hodgkin's Lymphoma

Protocol	Stage	No. of Patients	Event-Free Survival Rate	Reference (First Author)
CHOP	III & IV	21	3-year EFS = 62% ± 11%	Sandlund[161]
MACOP-B	III & IV	11	3-year EFS = 55% ± 16%	Santana[180]
COMP vs. LSA_2L_2	III & IV	42	5-year EFS = 52%	
	III & IV	18	5-year EFS = 43%	Anderson[186]
APO vs. ACOP+	III & IV	62	3-year EFS = 72 ± 6%	
	III & IV	58	4-year EFS = 62 ± 7%	Laver[211]

immunophenotype.[212] A 4-year event free survival rate and overall survival rate of 71.8% and 88.1%, respectively, were reported for the 86 patients with advanced-stage disease who were enrolled on the study. Trials in Europe and the United States are building on the successful results achieved with the BFM B-cell and APO strategies, respectively. Both trials are examining the benefit of adding vinblastine, an agent that has activity as a single agent in multiply relapsed ALCL patients.[214]

RARE HISTOLOGIC SUBTYPES. The therapeutic approaches to the treatment of children with histologic subtypes that are unusual in this age group are often derived from strategies that are used in adults. Children with localized follicular lymphoma have been successfully treated with CHOP-based limited-stage therapeutic approaches; however, there have been reports of children who have remained disease-free following complete resection without adjuvant chemotherapy.[144,229,230] Children with hepatosplenic lymphomas have an aggressive disease course and often have recurrent disease even after an initial good response to aggressive therapy.[231–235] There is clearly a need for organized national trials to improve our treatment approaches to these and other infrequently encountered histologic subtypes.

Central Nervous System Prophylaxis and Treatment

The prevention of disease spread to the CNS is an important component of most successful modern treatment protocols. This generally involves both the administration of chemotherapy directly into the CSF (intrathecally by lumbar puncture or less commonly by the intraventricular route) and the administration of systemic high-dose chemotherapy (e.g., methotrexate, cytarabine). Prophylactic intrathecal therapy may be unnecessary in children who have limited-stage disease sparing the head and neck region[192] or advanced-stage large cell lymphoma sparing the bone marrow and head/neck region.[236] The benefit of cranial radiation as CNS prophylaxis remains controversial. It has been used in children with advanced-stage lymphoblastic lymphoma, but is not widely favored.[208]

Among children who present with overt CNS disease (cranial nerve palsies or cerebrospinal fluid pleocytosis), intensification of both systemic and intrathecal chemotherapy is usually indicated; except in cases of Burkitt's lymphoma, cranial radiation is also usually incorporated.

Emergency Situations

Various emergencies may arise in the management of children with NHL.[2] First, children who present with large anterior mediastinal masses associated with severe respiratory distress require immediate attention. If there is significant airway compression, deep sedation should be avoided. Chemotherapy should be started as soon as possible if the diagnostic samples have been obtained. If they have not, local radiation therapy could be the best approach, since it spares more peripheral disease for subsequent biopsy and study. Steroids might be necessary in some cases, but this therapy can alter tumor histology and preclude an accurate tissue diagnosis.

Some children with bulky Burkitt's or lymphoblastic tumors develop renal failure secondary to tumor lysis syndrome, despite appropriate prechemotherapy management. A nephrologist should be consulted immediately when renal dysfunction is first noted so that dialysis can be considered. This situation may be further complicated when a large pelvic mass creates direct ureteral compression. The placement of ureteral stents or a percutaneous nephrostomy tube can help temporarily; however, the problem is most effectively dealt with by delivery of appropriate chemotherapy.

A small percentage of children may present with epidural tumors that cause cord compression and corresponding neurologic deficits. Delivery of appropriate chemotherapy is usually all that is required; however, if there is no prompt recovery of neurologic function, a radiation therapist should be consulted about the possible need for low-dose local irradiation.[2]

Treatment Complications

As the survival of children with malignant lymphomas has improved, increased attention has been focused on treatment-related late effects.[237] The most serious treatment sequelae in survivors of childhood NHL include anthracycline-related cardiomyopathy, cyclophosphamide-related sterility, second cancers, and transfusion-related hepatitis. Attempts to reduce or eliminate these complications have included the dose reduction or elimination of both specific chemotherapeutic agents as well as involved field irradiation. Improving the process of blood product screening has also been an important area of focused research.

The design of clinical trials for pediatric NHL has been strongly influenced by the desire to avoid anthracycline-induced cardiac toxicity. Although it has been demonstrated that adults may tolerate cumulative doses of Adriamycin of 550 mg/m^2, much lower cumulative doses have been shown to have clinically significant effects on ventricular contractility in children [238] Factors that have been shown to be predictive of cardiac dysfunction include cumulative anthracycline dosage, higher anthracycline dose intensity, younger age at time of treatment, female sex, time interval since completion of therapy, and combined modality therapy that includes mediastinal irradiation.[239,240] Future trials that focus on the reduction of cumulative anthracycline dosage and the utility of cardioprotectant agents are indicated.[197]

The preservation of fertility is another important concern in the development of optimal therapeutic strategies for children with NHL. A dose-related depletion of germinal cells is associated with the use of alkylating agents such as cyclophosphamide and ifosfamide; these agents tend to be more gonadotoxic in males. Studies thus far have suggested that sterility is likely at cumulative doses of cyclophosphamide greater than 7.5 g/m^2, whereas fertility is usually maintained at cumulative dosages less than 4 g/m^2. In this regard, a number of pediatric NHL trials have attempted to eliminate or reduce the dosage of cyclophosphamide.[211]

Pediatric NHL trials have also focused on the elimination of involved field irradiation. The first of two Pediatric Oncology Group trials for limited-stage NHL demonstrated that involved field irradiation could be safely eliminated without compromising outcome.[192] A similar observation was made for children with advanced-stage disease in a St. Jude study.[216] Although involved field irradiation is not used in most current NHL trials, cranial irradiation is considered in the management of overt CNS involvement in children with lymphoblastic lymphoma. (Its use for CNS prophylaxis in children with this histologic subtype is controversial.)

Follow-up

Management of Primary Treatment Failure

Children with refractory or recurrent disease, particularly after receiving modern intensive therapy, are generally considered to have a poor prognosis. Therefore, aggressive or novel approaches are often used to treat relapse. Current approaches generally comprise multiagent salvage chemotherapy followed by an intensification phase that may include autologous or allogeneic hematopoietic stem cell transplantation (HSCT). Multiagent salvage regimens that have been studied include DHAP[180] (dexamethasone, high-dose cytarabine, and platinum), which has been shown to be active in childhood and adult recurrent large cell lymphoma, and VIPA[241] (etoposide, ifosfamide, and high-dose cytarabine), which has been shown to be active in children with relapsed Burkitt's lymphoma. Other active salvage regimens for children with refractory or recurrent malignant lymphoma include ICE[242] (ifosfamide, carboplatin, and etoposide) and MIED (high-dose methotrexate, ifosfamide, etoposide, and dexa-

methasone). Children who are found to have chemosensitive recurrent disease are usually considered for an intensification phase of chemotherapy followed by an HSCT. In a recent report, however, the benefit of HSCT in this setting was questioned.[215] Although published data on the use of HSCT in children with recurrent or refractory NHL is limited in comparison to those reported for adults, there are reported studies supporting its use.[205,243–251] For example, European cooperative group trials demonstrated that some children with Burkitt's lymphoma who had a poor early response to therapy could be successfully salvaged with high-dose chemotherapy followed by autologous HSCT.[205,246,247,249,252] Moreover, the Spanish Working Party for Bone Marrow Transplantation reported a 58% event-free survival rate following HSCT in children with either recurrent/refractory NHL or high-risk NHL in first CR.[246] The SFOP reported that 8 of 24 children with NHL who failed initial therapy were long-term disease-free survivors following HSCT.[247] In a review of 22 children at the St. Jude Children's Research Hospital, approximately 45% were survivors following intensive chemotherapy and HSCT.[251] It is difficult to make direct comparisons between the published studies of HSCT in children because they vary with respect to type of HSCT (autologous versus allogeneic), preparative regimen, numbers of patients, and histologic subtypes studied.

It appears, however, that histologic subtype should be considered in determining the type of HSCT (autologous versus allogeneic) for children with refractory or recurrent NHL. Among children with Burkitt's lymphoma, an autologous approach has been shown to be beneficial for those with a poor early response.[205,243,247] For those with disseminated recurrent Burkitt's lymphoma involving the marrow, many clinicians favor an allogeneic approach if a suitable donor can be identified. An autologous HSCT has been shown to be an effective strategy for some children with recurrent large cell lymphoma;[245,251] however, for children with recurrent lymphoblastic lymphoma, the results are less encouraging.[215]A recent study by the BFM group identified an excellent outcome using an allogeneic HSCT strategy for those with high-risk ALCL relapses.[253]

Various preparative regimens have been successfully used in the salvage of children with refractory or recurrent NHL.[205,243–251] Two of the earliest reported regimens are BACT (carmustine, cytarabine, cyclophosphamide, and thioguanine) and BEAM (carmustine, etoposide, cytarabine, and melphalan).[243,244,250] High-dose busulfan was reported as an important component of a successful French (SFOP) preparative regimen.[249] Gordon and colleagues reported the successful salvage of children with recurrent peripheral T-cell lymphoma using a preparative regimen that featured thiotepa;[245] however, it was associated with significant mucositis.

Currently, most clinicians would consider an autologous HSCT for children with chemosensitive recurrent large cell lymphoma and for those with Burkitt's lymphoma who have a poor early response. If a suitable donor is available, an allogenic HSCT approach would be considered for children with widely disseminated recurrent lymphoblastic lymphoma or Burkitt's lymphoma involving the bone marrow. An allogeneic HSCT approach may also be considered for those with high-risk recurrent ALCL. It is clear that there is a need for additional prospective clinical trials to evaluate the optimal preparative regimen and HSCT approach for children with recurrent or refractory NHL. In this regard, the European Lymphoma Bone Marrow Transplantation Registry has suggested that the potential graft-versus-lymphoma effect of allogeneic HSCT be studied.[249]

After Completion of Therapy Clinic

It is important that all children who have completed therapy for NHL be followed annually in an "after-completion-of-therapy" or late effects clinic.[254,255] The purposes of these visits are both to screen for therapy-related late effects (see section on complications of therapy) and to provide education and counseling about the medical and psychosocial issues that affect cancer survivors. These clinics also provide an opportunity for children and young adults to participate in important research initiatives that focus on cancer prevention and control, psychosocial problems, and treatment-related sequelae.

FUTURE DIRECTIONS

Despite dramatic improvements in the treatment of childhood NHL, approximately 20% to 30% of patients either do not achieve a complete remission or develop recurrent disease.[1,2,19] Treatment-related late effects that place cancer survivors at risk are of additional concern.[237] Therefore, the development of more effective and less toxic therapy remains an ongoing challenge. The identification of clinical and biologic features that are predictive of treatment failure may help in the refinement of a risk-adapted treatment approach to children with NHL.

Improvement in treatment outcome may be achieved by the incorporation of new active agents or the development of novel schedules for the delivery of currently used agents. Novel therapeutic approaches include the incorporation of immunotherapeutic approaches into multiagent chemotherapeutic regimens. In this regard, trials are under way for children with $CD20^+$ B-cell lymphomas that incorporate the anti-CD20 antibody, rituximab, an agent that has already been shown to be valuable in the treatment of some adults with $CD20^+$ B-cell lymphomas.[256,257] A phase I/II study for children with $CD30^+$ ALCL has been designed to examine the safety and efficacy of a newly developed anti-CD30 antibody.[258] Other potential therapies include the use of protein-specific cytotoxic T-lymphocytes, a strategy that has been successful in preventing and treating EBV-related post-transplantation lymphoproliferative disease.[259] Novel approaches may also include the incorporation of small molecule inhibitors, as well as antisense and anti-idiotype strategies. Molecular characterization of the chromosomal abnormalities associated with the NHLs of childhood is providing us with tools that enhance diagnosis, disease classification, and monitoring of the response to therapy (detection of minimal residual disease). A clearer understanding of molecular pathogenesis may provide insights that permit the development of therapeutic strategies that target tumor-specific molecular lesions.

103 Acute Lymphocytic Leukemia in Adults

Dieter Hoelzer and Nicola Gökbuget

SUMMARY OF KEY POINTS

Epidemiology and Etiology
- Acute lymphocytic leukemia (ALL) is more frequent in whites and in adults older than 65 years.
- Risk factors include irradiation, benzene, and leukemogenic chemotherapeutic agents.

Diagnosis
- Morphologic subtypes include L1, L2, and L3; the last is characteristic of mature B-cell (or Burkitt type) ALL.
- Subtypes of B-cell ALL include pro-B, common ALL (Expresses CD10), pre-B, and mature B-cell (Burkitt type).
- Subtype of T-cell ALL include early T-precursor, thymic (expresses CD1a and has a better prognosis), and mature T-cell (expresses CD3).

Clinical Manifestations
- Mediastinal masses occur more frequently in T-cell than in B-cell ALL.

Prognostic Factors
- Older age, high white blood cell count (on B-cell ALL but not T-cell ALL), early and mature T-cell ALL, MDR-1 expression, and Philadelphia chromosome–positive ALL are associated with a poorer prognosis.

Treatment
- Treatment phases are remission induction, consolidation, central nervous system prophylaxis, and maintenance.
- Outcome in Philadelphia chromosome–positive ALL is improved by the incorporation of imatinib.
- Allogeneic transplantation is the treatment of choice in patients with relapsed or refractory ALL who have a matched donor.
- Rituximab should be used in mature B-cell (Burkitt) ALL.

INTRODUCTION

Acute lymphocytic leukemia (ALL) is a malignant disease that is characterized by an accumulation of lymphoblasts. In the early 1980s, adult ALL was largely an incurable disease with an overall survival (OS) rate of less than 10%. After adoption of pediatric protocols the overall survival rate in adults improved to 30% to 40%. Progress has made in the tools that are used to diagnose ALL. In addition, a variety of new drugs for the treatment of ALL are now under evaluation. However, the prerequisite for comprehensive therapy of ALL requires more than ever standardization and quality control of treatment strategies. Rapid diagnosis and classification are not only important for clinical practice but also helpful in identifying prognostic factors, in defining targets for evaluation of minimal residual disease (MRD), and for creation of novel therapeutic agents.

EPIDEMIOLOGY

According to the National Cancer Institute, the age-adjusted overall incidence of ALL in the United States was 1.6 per 100,000 (1.8 in males and 1.4 in females). The incidence is higher in whites than in blacks. After an initial peak in children younger than 5 years of age (8.3 per 100,000), the incidence decreases continuously. It increases again above the age of 65 to a second peak in the age group above 85 years (2.0 per 100,000).[1]

BIOLOGIC AND MOLECULAR ASPECTS

Preferred Approach to Diagnosis

Classification of the phenotype of the blast cells in acute leukemia requires morphologic and cytochemical evaluations, immunophenotyping, cytogenetic analysis, and molecular genetic analysis. Morphology remains the means by which acute leukemia is initially detected and, together with cytochemical reactions, is the major tool in distinguishing between ALL and acute myeloid leukemia (AML; Fig. 103-1). For more precise subclassification of ALL into B or T lineages and further subtypes, immunologic techniques must be used to detect lineage-specific antigens as well as surface or intracytoplasmic molecules. These methods also offer the opportunity to identify leukemia-specific surface markers for the detection of MRD. Cytogenetic analysis is still part of the diagnostic characterization of ALL, but molecular genetic techniques for identification of particular subsets of ALL (e.g., *BCR-ABL*-positive ALL) are of greater importance. Molecular markers, particularly rearrangements of T-cell receptor genes and immunoglobulin heavy chain genes, are the most frequently used tools to evaluate MRD.

Morphology

The distribution of L1 and L2 subtypes is of minor relevance for prediction of outcome. The subtype L3, which is observed in up to 5% of adult ALL patients, should be distinguished because it is indicative of a mature B-cell ALL, which requires different treatment options, but should be confirmed by surface marker analysis. According to the World Health Organization classification, ALL is grouped together with lymphoblastic lymphoma as either precursor AB-cell or T-cell neoplasm. B-cell ALL is referred to as precursor B-lymphoblastic leukemia/lymphoma. L3-ALL is classified as Burkitt's cell leukemia together with Burkitt's lymphoma. T-ALL is grouped together with T-cell lymphoblastic lymphoma as precursor to T-lymphoblastic lymphoma/leukemia.

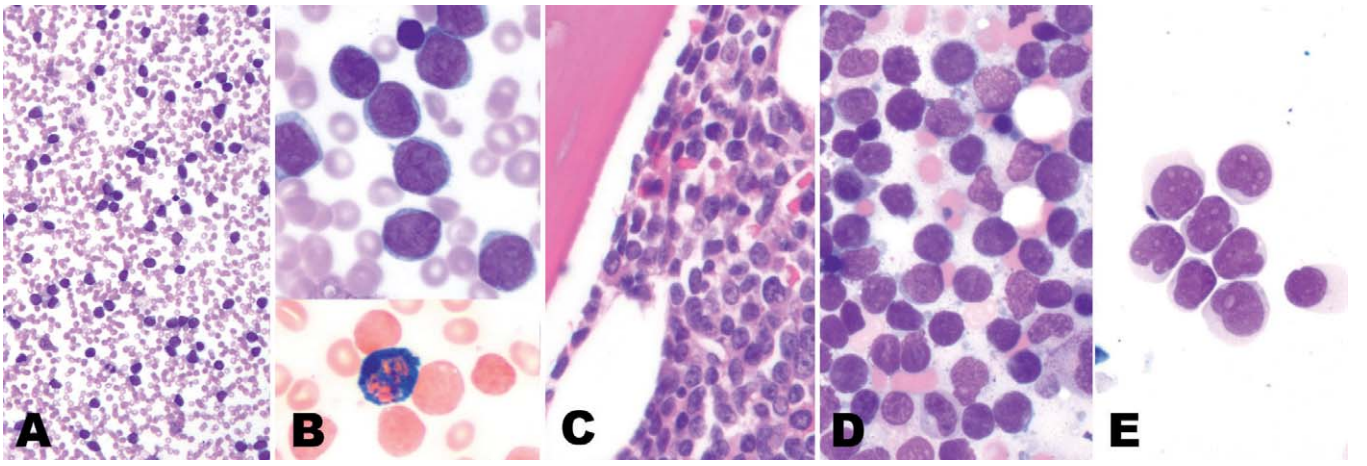

Figure 103-1 • Acute lymphoblastic leukemia: peripheral blood, bone marrow biopsy and aspirate, and cerebral spinal fluid. The illustration is from a 37-year-old male who presented with a WBC of 170 K/μL and over 90% blasts with lymphoid morphology (**A** and **B,** *top*). An initial myeloperoxidase reaction (**B,** *bottom*) showed the blasts to be negative (positive cell is a segmented neutrophil that serves as an internal control). The bone marrow was packed with blasts as seen on the biopsy and aspirated material (**C** and **D**). The blasts were immunophenotyped by flow cytometry and were shown to be precursor-B lymphoblasts with the following phenotype: CD34+, HLA-DR+, TdT+, CD19+, CD10+, cyCD79A+, cyIgM–, sIg–. Cytogenetic studies illustrated the t(9;22), and molecular analysis revealed the p190 *BCR/ABL*. A spinal tap showed a WBC count of 120/μL with a red blood cell count of 37/μL. The differential showed 80% blasts. The morphology of the blasts on the cytospin of the cerebrospinal fluid (**E**) is somewhat altered by the preparation. Note the absence of significant red blood cells in the specimen. Given the high number of blasts in the peripheral blood, a more traumatic tap would have made it difficult to distinguish between CNS disease and contamination of the cerebrospinal fluid specimen by blood. Cell Surface Marker Analysis

ALL is divided into subtypes by immunologic criteria based on the presence of specific receptors or antigens on the cell surface of leukemic blast cells. Within the B- or T-lineage ALLs, the subtypes are defined according to their stage of differentiation.

The frequency of and definition of ALL subtypes in adult and childhood ALLs are outlined in Table 103-1. In the German multicenter trials for childhood ALL (BFM) and adult ALL (GMALL), the phenotypic characteristics of 1756 children and 946 adults with ALL were analyzed prospectively. B-precursor ALL is the most frequent subtype in children and adults (85% and 70%, respectively). T-lineage ALL has a higher incidence in adults (25%). Within the B and T lineages, the more immature subtypes—pro-B ALL and early T ALL—occur more frequently in adults. The European Group for the Immunological Characterization of Acute Leukemia has proposed a unified classification of ALL immunophenotypes.[2] The use of such uniform classifications is of utmost importance to permit results in different trials to be comparable. Immunophenotypes in ALL are often associated with clinical characteristics such as disease manifestations, course of disease, and biologic markers such as cytogenetic and molecular aberrations, as illustrated in Table 103-1.

B-Lineage Acute Lymphocytic Leukemia

Pro-B ALL, also termed pre-pre-B ALL or early pre-B, lacks B-, T-, and pre-B-cell markers but expresses the human leukocyte antigen (HLA-DR), TdT, and CD19 and has rearranged immunoglobulin genes (see Table 103-1). It occurs in approximately 11% of adult ALL and 5% of childhood ALL.

Common ALL is the major immunologic subtype in childhood ALL as well as in adult ALL. It makes up more than 50% of cases of adult ALL. Common ALL is characterized by the presence of CD10 (see Table 103-1). Common ALL blast cells do not express markers that characterize relatively mature B cells, such as cytoplasmic immunoglobulins or surface membrane immunoglobulins. The blast cells are positive for CD19 and TdT.

Pre-B ALL is characterized by the expression of cytoplasmic immunoglobulins, which is absent in common ALL, but is identical to common ALL with respect to the expression of all other cell markers (see Table 103-1). Rarely, CD10 may be absent in this subtype. Pre-B ALL makes up nearly 10% and 15% of adult ALL and childhood ALL, respectively.

Mature B-cell ALL is found in approximately 4% of adult ALL patients and 3% of childhood ALL patients. The blast cells express surface antigens of mature B cells, including surface membrane immunoglobulin. CD10 may be present, as well as occasional cytoplasmic immunoglobulins (see Table 103-1).

T-Lineage Acute Lymphocytic Leukemia

Approximately 25% of adult ALL cases have blast cells with a T-cell phenotype. All cases express the T-cell antigen gp40 (CD7), and they may, according to their degree of T-cell differentiation, express other T-cell antigens (e.g., the E rosette receptor [CD2] or the cortical thymocyte antigen T6 [CD1]; see Table 103-1). A minority of T-cell ALL blast cells may also express CD10 together with T-cell antigens. In most cases of T-cell ALL, one or more of the T-cell receptor genes are rearranged. These properties make it possible to classify T-cell ALLs according to their stage of differentiation.

Early T-precursor ALL (or pre-T ALL) makes up 7% and 1% of adult ALL and childhood ALL, respectively, and shows no further differentiation markers. Thymic T-ALL (or cortical T-ALL) accounts for 13% of adult ALL and is characterized by CD1a expression. Because this subtype is associated with a better prognosis, its identification is of particular importance. Mature T-ALL forms 7% of adult ALL and shows expression of surface CD3.

Cytogenetic and Molecular Genetic Analyses

Cytogenetic abnormalities are independent prognostic variables for predicting the outcome of adult ALL.[3] In some cases, cytogenetic or molecular genetic analysis contributes to confirmation of the diagnosis, for example, the correlation between t(8;14) and mature B-ALL. In four multicenter studies, clonal chromosomal aberrations could be

Table 103-1 Immunologic Subtypes of Acute Lymphocytic Leukemia and Corresponding Cytogenetic and Molecular Markers

Subgroups	Most Important Markers	Incidence in Children (*N* = 1756)*	Incidence in Adults (*N* = 946)*	Cytogenetic/Molecular Marker†
B-Lineage	HLA-DR+, TdT+, CD19+, and/or CD79a+, and/or CD22+	85%	72%

†According to GMALL data and Armstrong and Look.[174]

detected in approximately 62% to 85% of adult ALL patients;[4–7] 15% to 38% of the cases had normal metaphases. The major cytogenetic abnormalities in ALL are clonal translocations, such as t(9;22) (20% to 30%), t(4;11) (3% to 4%), t(8;14) (5%), and t(1;19) (2% to 3%), and other structural abnormalities, such as 9p (5% to 15%), 6q (4% to 6%), and 12p aberrations (4% to 5%). If none of the structural aberrations are present, the abnormalities can be classified according to the modal chromosomal number (fewer than 46, 46 with other structural abnormalities, 47 to 50, or more than 50).

Molecular analyses, detecting gene rearrangements in ALL by the polymerase chain reaction (PCR), Southern blot analysis, or fluorescent in situ hybridization with chromosome-specific DNA probes, are useful approaches in establishing a more precise diagnosis and in defining the quality of remission, and they may also provide insights into the pathophysiology of the leukemic process (e.g., the mechanisms of leukemic cell stimulation by BCR-ABL fusion proteins). The most frequent molecular markers in ALL are BCR-ABL and ALL1-AF4.

The Ph chromosome t(9;22)(q34q11) results from a translocation involving the breakpoint cluster region of the *BCR* gene on chromosome 22 and the *ABL* gene on chromosome 9. The *BCR-ABL* gene rearrangement can be demonstrated by molecular techniques. PCR analyses revealed an incidence of 20% to 26% *BCR-ABL*-positive ALL in adults[8–10] compared with 3% in childhood ALL patients. One third of adult ALL patients with a Ph chromosome show M (major)-*BCR* rearrangements (resulting in a 210-kd protein), similar to patients with chronic myeloid leukemia, whereas two thirds have m (minor)-*BCR* rearrangements (resulting in a 190-kd protein). It is noteworthy that *BCR-ABL* is more frequently detected than is the corresponding chromosomal abnormality (t[9;22]) because of occasional difficulties in obtaining sufficient material for cytogenetic analysis.

The most frequent form of 11q23 abnormalities in ALL is t(4;11)(q21;q23). The involved gene on chromosome 11 is named *MLL* for "mixed lineage leukemia." Synonyms are *ALL-1*, *HRX*, and *HTRX1*. The *MLL* gene is fused to a gene located on chromosome 4 that is named *AF-4* (also referred to as *FEL*). The translocation is frequently detected in infant leukemia and in patients with the early pre-B subtype (CD10-negative). The overall incidence in adults is approximately 5%. Typical molecular aberrations in ALL with associated cytogenetic translocations and immunologic subtypes are summarized in Table 103-1.

The role of cytogenetic analysis has to be reevaluated critically. The most frequent cytogenetic aberrations and those with the greatest prognostic impact can also be detected by the corresponding molecular genetic aberrations, such as BCR-ABL for t(9;22) and ALL1-AF4 for t(4;11). These techniques are more reliable and have a greater sensitivity, for example, a detection level of 10^{-4} to 10^{-6}. They are therefore more useful for initial detection of the aberrations and for follow-up analysis of MRD (see later discussion).

Minimal Residual Disease

Molecular and immunologic techniques have allowed the detection of MRD, defined as leukemic cells that are undetectable by morphologic examination. MRD evaluation is most frequently based on detection of leukemia-specific constellations of surface markers by flow cytometry, fusion genes related to specific chromosomal translocations (e.g., BCR-ABL in t(9;22) by PCR), and individual rearrangements of immunoglobulin (immunoglobulin heavy chain, immunoglobulin kappa) and T-cell receptor genes (TCR-β, -γ, and -δ) by PCR and recently by real-time PCR. In ideal cases, these methods reach a sensitivity of 10^{-4}, which refers to the detection of

1 malignant cell in 10,000 normal cells. Overall, more than 90% of the ALL patients have at least one target for MRD evaluation.

ETIOLOGY

The cause of ALL remains unknown. However, a number of factors are associated with an increased risk of developing acute leukemia (ALL and AML).[11,12]

Genetic Predisposition

In epidemiologic studies, patients with some rare congenital chromosomal abnormalities have an increased risk for development of acute leukemias, including ALL. In children with leukemia (predominantly AML), there is an 18-fold higher incidence of Down syndrome than would be expected.[13] There is also an increased risk of ALL associated with inherited disorders, such as Klinefelter's syndrome, Fanconi's anemia, Bloom's syndrome, ataxia-telangiectasia, and neurofibromatosis. The impact of genetic predisposition on the pathobiology of ALL may also be inferred from reports of the simultaneous development of ALL in identical twins. Molecular analyses have demonstrated that the disease is not related to genetic predisposition but probably to the exchange of a malignant stem cell between the twins. This was demonstrated for rearrangement of the MILL gene[14] and the TEL-AML1 fusion gene.[15] Particularly in infant leukemias, prenatal molecular aberrations are probably the basis and lead after additional postpartum events to development of leukemia.

Irradiation

The incidence of acute leukemias, mainly AML but also ALL, was increased almost 20-fold in survivors of the atomic bomb explosions (>1 Gy exposure) in Japan,[16] with a peak incidence occurring 6 to 7 years after the radiation exposure. Induction of leukemia by emissions from nuclear power stations has also been raised as a possible environmental leukemogenic risk; this has never been demonstrated unequivocally. Whether radiation exposure after the Chernobyl accident led to an increased incidence of leukemia is still controversial.

Chemical

The risk for the development of ALL could also be increased after exposure to chemical agents such as benzene or other agents that are capable of producing bone marrow aplasia, including chemotherapeutic drugs. Secondary, therapy-related AMLs but also ALLs can occur after exposure to alkylating agents, such as cyclophosphamide, epipodophyllotoxins, topoisomerase II inhibitors, and, rarely, anthracyclines,[17,18] which are used for treatment of other preceding neoplasias.

Viral

There is no direct evidence that a virus causes human ALL. Indirect findings, however, suggest involvement of a virus in the pathogenesis of two lymphoid neoplasias.[19] In the endemic African type of Burkitt's lymphoma, the Epstein-Barr virus, a DNA virus of the herpes family, has been implicated as a potential causative agent.[20] The endemic infection with human T-cell leukemia virus I in Japan and the Caribbean has been shown to be an etiologic agent for adult T-cell leukemia/lymphoma.[21]

CLINICAL MANIFESTATIONS

Most adult patients initially present with clinical symptoms resulting from bone marrow failure. Physical findings such as pallor, tachycardia, weakness, and fatigue are due to anemia; petechiae or other hemorrhagic manifestations are attributable to thrombocytopenia; infectious complications are due to neutropenia. Clinical signs of leukemia related directly to infiltration of organs with leukemic blasts, such as lymphadenopathy, splenomegaly, and hepatomegaly, are present in most patients but are infrequently the problems for which the patient first seeks medical advice.

Symptoms and clinical manifestations of 938 adult ALL patients, 15 to 65 years of age, entering two consecutive German multicenter trials, are listed in Table 103-2. One third of the patients had infection or fever at presentation, and one third presented with hemorrhagic episodes. Weight loss was observed only occasionally. Approximately one half of the patients presented at diagnosis with lymphadenopathy, splenomegaly, hepatomegaly, and hilar lymph node enlargement or a thymic mass (detected on chest radiographs or computed tomography scans) in approximately 14% of patients. Most (85%) patients with mediastinal masses had T-cell ALL. Massive thymic enlargement can cause dyspnea, especially when associated with pleural effusions. Although 7% of ALL patients at presentation had central nervous system (CNS) involvement, as demonstrated by leukemic blast cells in the cerebrospinal fluid, only 4% of these initially had CNS symptoms, such as headache, vomiting, lethargy, nuchal rigidity, and cranial nerve or peripheral nerve dysfunction.

Virtually any organ can be infiltrated by ALL blast cells, and approximately one tenth of the patients had such organ involvement (see Table 103-2). Most often, a pleural effusion was observed in patients with mediastinal enlargement and T-cell ALL. Some of those patients also had a pericardial effusion. Bone or joint pain was rarely observed, in contrast to childhood ALL; bone lesions could be found in only 1% of cases. Initial involvement of the testes was very rare (<1%). Leukemic infiltration of retina, skin, tonsils, lung, or kidney was observed only occasionally, particularly in mature B-cell ALL and to a lesser extent in T-cell ALL, all of them associated with a poorer outcome.

LABORATORY EVALUATION

The peripheral blood cell values at diagnosis of the same cohort of patients are shown in Tables 103-3 through 103-5. The leukocyte count (see Table 103-3) was elevated in 59%, 14% had normal counts, and 27% had leukopenia. In 92% of the patients, leukemic blast cells were seen in the blood smear. Thus, "aleukemic" leukemias account for only a small proportion of cases of adult ALL. With automated blood counting, the diagnosis might be missed in patients with normal or decreased white blood cell counts (WBC) and with low or zero blast cells in peripheral blood. For this reason, the need for microscopic examination of blood smears in people who are suspected of having acute leukemia should be stressed. An elevated blood count (>100,000 $\times$ 10^6/L) was observed in 16% of the patients, and, occasionally, WBC counts greater than 500,000 $\times$ 10^6/L have been observed. In general, a high WBC count is found more frequently in T-cell ALL patients than in B-lineage ALL patients.

Neutrophils (see Table 103-4), less than 500 $\times$ 10^6/L, were seen in 23% of the patients, and thrombocytopenia, less than 25,000 $\times$ 10^6/L, was seen in 30% of the patients, corresponding roughly to the symptoms of infection and bleeding present at diagnosis.

Table 103-4 Peripheral Blood Counts at Time of Diagnosis of 938 Adult Acute Lymphocytic Leukemia Patients

		Patients (%)
Neutrophils ($\times 10^6$/L)	<500	23
	500–1000	14
	1000–1500	9
	>1500	54
Platelets ($\times 10^6$/L)	<25,000	30
	25,000–50,000	22
	50,000–150,000	33
	>150,000	15
Hemoglobin (g/dL)	<6	8
	6–8	20
	8–10	27
	10–12	24
	>12	21

Bone marrow aspiration or biopsy is mandatory for diagnosis of ALL. In fewer than 15% of patients, the bone marrow cannot be aspirated, and a biopsy must be performed. Dry taps are due to densely packed blast cells, fibrosis, or inadequate technique; the first two resolve after therapy. Most patients have more than 50% or even more than 90% of blast cells in the bone marrow (see Table 103-3). In fewer than 3% of cases, the blast cells constitute fewer than 50% of the nucleated marrow cells.

A lumbar puncture should be done to determine whether the CNS is involved. If there is a risk of bleeding due to a very low platelet count or of blast cell contamination due to a high leukemic blast content in the peripheral blood, lumbar puncture should be postponed. When the leukocyte count in the spinal fluid is low or the morphologic detection of blasts is inconclusive, demonstration of an immunologically defined blast cell population can confirm a diagnosis of CNS involvement.

The most frequent metabolic abnormality is an increased serum uric acid level, which occurs in approximately one half the patients; hypercalcemia was rare. Serum lactate dehydrogenase may be elevated as a result of cell destruction in patients with a large tumor mass, particularly in B-cell ALL. Owing to liver infiltration, some patients may show elevation of liver enzymes. In a small proportion of patients (see Table 103-5), the initial fibrinogen level may be less than 100 mg/dL. Disseminated intravascular coagulopathy and other disturbances of coagulation are rarely observed at diagnosis.

DIFFERENTIAL DIAGNOSIS

Difficulty is rarely experienced in establishing the diagnosis of ALL. The differentiation from lymphocytosis, lymphadenopathy, and hepatosplenomegaly due to viral infections and other acute or chronic leukemias can usually be done by lymphocyte surface markers.

Aleukemic pancytopenic ALL patients without blast cells in peripheral blood (fewer than 10%) must be distinguished from those with aplastic anemia, which may also be a preleukemic syndrome. In contrast to ALL, the bone marrow is hypocellular in aplastic anemia. In rare cases with a limited bone marrow infiltration, an arbitrary distinction between ALL and non-Hodgkin's lymphoma (NHL) is usually made according to the degree of infiltration: more or less than 25%.

In approximately 29% of the patients, blast cells coexpress myeloid surface markers such as CD13 and CD33 (>20%). Distinct subtypes of ALL are associated with a higher incidence of myeloid marker

coexpression, for example, early T-ALL, pro-B-ALL, Ph/BCR-ABL-positive ALL. These cases of ALL with myeloid marker coexpression must be differentiated from mixed or hybrid leukemias in which blast cells express lymphoid as well as myeloid antigens; they may also be termed *biphenotypic* or *bilineage* leukemias. The European Group for the Immunological Characterization of Acute Leukemia has suggested a score to unequivocally identify this rare subgroup.[2] Biphenotypic leukemias may be allocated to a treatment strategy for either for ALL or for AML and outcome seems to be poor with both approaches.

Occasionally, difficulties can occur in distinguishing Ph/BCR-ABL-positive ALL from primary lymphoid blast crisis of chronic myeloid leukemia. Sometimes final diagnosis can be made only after the initiation of treatment. In ALL patients who achieve complete clinical remission (CR), the peripheral blood count are normal values, whereas chronic myeloid leukemia cases revert to a chronic phase with a pathologic left shift.

THERAPY

Initial Evaluation and Supportive Therapy

At diagnosis, the evaluation of an adult with ALL should include a history and a careful physical examination. Speed in clinical evaluation and diagnosis is important to initiate supportive measures and to decide on appropriate therapy. Only in a few cases is the leukemic process so far advanced that immediate treatment of leukemia is necessary (e.g., in patients with symptoms that are due to a large mediastinal mass and pleural effusions or to a rapidly progressing B-cell ALL).

A few general measures should be initiated at once. Sufficient fluid intake to guarantee urine production of 100 mL/hour throughout induction therapy should be maintained to reduce the danger of uric acid formation. Parenteral fluid administration may be required when the patient's oral intake is inadequate because of nausea or difficulty in swallowing. Placement of an implantable port system is advantageous when a long period of induction therapy is anticipated or when part of the therapy will be carried out on an outpatient basis.

Patients should receive allopurinol to reduce the formation of uric acid and avoid the danger of urate nephropathy. Allopurinol blocks the enzyme xanthine oxidase, which mediates the generation of uric acid from xanthine as a product of purine catabolism. Allopurinol should be given at a dose of 300 mg/day, which may be increased to 600 mg/day if high leukocyte counts or organomegaly persists. The dose of allopurinol has to be reduced when 6-mercaptopurine is given because it potentiates the action of 6-mercaptopurine. Rasburicase is a new recombinant uratoxidase enzyme that catalyses the oxidation of uric acid to allantoin. It has been demonstrated that rasburicase can reduce high uric acid levels faster and more safely than allopurinol, thereby preventing a tumor lysis syndrome in almost all cases.[22] Therefore, it could be an alternative to allopurinol in patients with a high risk of tumor lysis syndrome.

Approximately one third of adult patients present with infection and bleeding. They are at high risk for infectious and hemorrhagic complications during the induction period because thrombocytopenia and granulocytopenia are aggravated by chemotherapy. In general, platelet transfusions should be given in response to bleeding episodes and to prevent bleeding when platelet counts fall to less than 10,000 (10^6/L) and to less than 20,000 (10^6/L) when there is a bleeding tendency or the patient is febrile. HLA-matched platelets are given to patients who become refractory to random donor platelets. The incidence of fatal hemorrhage during induction therapy has been significantly lowered by these measures.

Infection Management

The use of more intense chemotherapeutic regimens has resulted not only in improved response rates of malignancies but also in higher infection-associated morbidity and mortality. Long-term neutropenia is the most important risk factor, but CD4 lymphopenia, antibody deficiency, and immunosuppression in allogeneic stem cell transplantation (SCT) also lead to severe and lethal infections. Before the 1990s, gram-negative microorganisms were the leading cause of febrile neutropenia, but since then, gram-positive bacterial infections caused mostly by staphylococci have increased, frequently correlated to indwelling central venous access. The number of multiresistant bacteria is increasing. Invasive fungal infections are increasing in frequency, particularly mold infections.

ALL patients should receive antibacterial and antifungal prophylaxis depending on the expected duration of neutropenia. In febrile neutropenia, thorough and early diagnostic procedures are necessary. They include physical examination, microbiologic investigations, imaging procedures, and biopsies. Cultures of blood, urine, sputum, and other infected areas are mandatory. Successful treatment of febrile neutropenia is based on immediate empirical administration of broad-spectrum antibiotics.

Hematopoietic Growth Factors

The use of hematopoietic growth factors, such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) is a valuable component of supportive therapy during the treatment of ALL. There is no indication so far that these CSFs stimulate leukemic cell growth in a clinically significant manner.

Most clinical trials demonstrate that the prophylactic administration of G-CSF significantly accelerates neutrophil recovery,[23–28] and several prospective, randomized studies also show that this is associated with a substantially reduced incidence and duration of febrile neutropenia and of severe infections in ALL[24,26,27] and also reduced mortality during induction. [23,26–28]

The advantage of G-CSF administration was particularly evident in select high-risk patients receiving multiple treatment cycles,[24] whereas clinical effects appeared to be negligible in patients who are at low risk of infectious complications in one study in childhood ALL.[29] Conversely, the results of the St. Jude trial show that even in cases of acute leukemia with a greater than 40% probability of severe neutropenia, not all patients benefit from G-CSF treatment.[30] A comparison of this study with other trials[26,27] highlights the great importance of CSF scheduling. When CSFs are first given at the end of a 4-week induction chemotherapy regimen, potential benefits are limited.[30] Therefore, it is noteworthy that G-CSF may be given, even in conjunction with chemotherapy, without aggravating the myelotoxicity of these specific regimens,[25–27] and that this scheduling is an important determinant of the clinical efficacy. Alternatively, it was demonstrated that after short consolidation cycles, G-CSF application may be postponed from day 12 after high-dose cytarabine/mitoxantrone to day 17 without negative effects on duration of neutropenia.[31] Similar results were reported for consolidation therapy with the hyper-CVAD regimen.[32] A closer adherence to the dose and schedule of chemotherapeutic regimens should be theoretically possible with the use of G-CSF. So far, no trial has demonstrated a benefit of increased dose intensity made possible by G-CSF application in terms of leukemia-free survival (LFS).

G-CSF is regularly used for mobilization of stem cells in candidates for autologous stem cell transplantation. There are some hints that prophylactic application of G-CSF after intensive chemotherapy cycles or in parallel might reduce the incidence of severe mucositis. Thus, delayed application of G-CSF during induction therapy has led to an increased risk of mucositis.[32]

Chemotherapy

Chemotherapy of ALL is usually divided into several phases, beginning with remission induction. The objective of induction chemotherapy is to achieve complete remission, that is, eradication of

leukemia as determined by morphologic criteria and, more recently, also by molecular markers. Although the induction phase is usually well defined, postremission therapy can be subdivided into intensification and maintenance phases. Usually, prophylactic CNS treatment is added (Table 103-6).

Remission Induction Therapy

Exact diagnosis and management of initial complications are the prerequisites for successful induction therapy. A cautious cell reduction phase is recommended for patients with a large leukemic cell burden or a high leukocyte count (>25,000 × 10^6/L). Patients with extreme leukocytosis (>100,000 × 10^6/L) have been treated initially with leukapheresis. However, in the majority of patients, the cell count can also be reduced with steroids alone or in combination with vincristine or cyclophosphamide.

Standard induction therapy for ALL includes prednisone, vincristine, anthracyclines (mostly daunorubicin), and L-asparaginase. Other drugs, such as cyclophosphamide, cytarabine (either conventional or high dose), and mercaptopurine, are added in many protocols, sometimes called early intensification. Several new approaches are being explored in adult ALL to improve CR rates and thereby remission quality.

Steroids, mostly prednisone and prednisolone, have been administered, although dexamethasone has a higher antileukemic activity in vitro and a better penetration to the cerebrospinal fluid.[33] In pediatric trials the replacement of prednisone by dexamethasone has led to a decrease in the CNS relapse rate and improved survival.[34] The dexamethasone schedule has to be designed carefully, since continuous application of higher doses can lead to long-term complications[34] and to increased morbidity and mortality due to infections.[35]

Anthracycline dose intensity and schedule may play an important role in induction therapy of ALL.[36] The most frequently used anthracycline is daunorubicin. Many groups have replaced weekly applications by higher doses of daunorubicin (30 to 60 mg/m^2 on a 2- to 3-day schedule).[28,37,38] A particularly high CR rate (93%) was reported with intensive anthracycline therapy (270 mg/m^2 for 3 days)[38] from a single-center study, but this has not been confirmed in a larger multicenter trial.[39] Intensive anthracycline therapy may be associated with a higher mortality rate during the induction phase. Therefore, intensive supportive care and probably the use of growth factors are recommended with these protocols. Overall, it remains open whether intensified anthracyclines therapy is beneficial for all subgroups, particularly in terms of achieving a molecular remission.

Asparaginase does not affect the CR rate but improves LFS, and if not used during induction therapy, it is often included as part of the consolidation treatment. The addition of asparaginase to conventional induction therapy did not improve the CR rate in one trial in adult ALL. There was, however, a trend toward a higher LFS in patients who were treated with asparaginase.[40] Three different asparaginase preparations with significantly different half-lives are available: native *Escherichia coli* asparaginase (1.2 days), *Erwinia* asparaginase (0.65 days), and *PEG-L* asparaginase (5.7 days).[41] To reach equal efficacy, the treatment schedule has to be adapted, which is generally daily for *Erwinia* asparaginase, twice daily for *E. coli* asparaginase, and once weekly for PEG asparaginase. The importance of asparaginase pharmacokinetics is illustrated by a randomized trial in childhood ALL, in which significantly lower survival rates were achieved with *Erwinia* asparaginase compared with *E. coli* asparaginase, both given at the same schedule, which is due to underdosing of *Erwinia* asparaginase.[42] A randomized trial comparing *PEG* asparaginase with *E. coli* asparaginase in childhood ALL showed a higher earlier response rate for the latter but no difference in long-term outcome.[43] Thus, it remains open for debate whether *PEG* asparaginase is superior to Erwinia asparaginase or native *E. coli* asparaginase. During induction, asparaginase is often given concurrently with steroids in patients, inducing additional toxicities, such as coagulation disorders and hepatic dysfunction, which are not predictable. It may thereby lead to treatment delays and compromise dose intensity in individual patients.

The role of cyclophosphamide, generally administered at the beginning of induction therapy, has been evaluated in several studies. A randomized study by the Italian GIMEMA group comparing a three-drug induction regimens with and without cyclophosphamide did not show a difference in terms of CR rate (81% versus 82%).[44] However, in several nonrandomized trials, high CR rates (85% to 91%) were achieved with regimens that included cyclophosphamide pretreatment,[28,45] particularly in adult T-ALL.

High-dose treatment during induction refers particularly to high-dose cytarabine (HDAC) (1 to 3 g/m^2, usually for 12 doses) before or after the standard induction therapy. This approach has resulted in a median CR rate of 79%, which is not superior to that obtained with conventional treatment, and it remains uncertain whether and for which subgroups HDAC could be beneficial for LFS.[46] Up-front treatment before conventional chemotherapy yielded higher CR rates[37,47–49] than did treatment afterward,[45,50,51] which was, in part, related to a higher induction mortality with the latter approach. Any type of induction therapy with HDAC may lead to an increased incidence of severe neutropenias after subsequent chemotherapy cycles.

With current regimens, the remission rate in ALL is 85% to 90% (see Table 103-6) with low failure rates and a variable early mortality rate up to 11%, increasing with age. Morbidity due to extended cytopenias, for example, subsequent infections such as fungal pneumonias, can compromise further treatment and dose intensity. Options for increasing the rate of CR are limited in adult ALL. Therefore, in the future, increased molecular CR rates will be the most important goal. It may be defined as a burden of MRD below the detection limit of 10^{-4} (0.01%); the frequency of molecular CR in adult ALL ranges from 50% for Philadelphia chromosome–positive (Ph+) ALL treated with imatinib[52] to 60% for standard-risk ALL.[53]

Five percent to 15% of adult ALL patients do not achieve CR after induction therapy, compared with fewer than 3% of children with ALL. Five percent to 10% of adult ALL patients die during the induction period. Mortality during induction is age dependent; the mortality rate increases with age from less than 3% in adolescents to 20% in patients older than 60 years of age. The main cause of death in approximately two thirds of the patients is infection, often fungal infection. The remaining nonresponders may achieve a partial remission or may be refractory to standard treatment. These patients have an extremely poor prognosis and are therefore candidates for new, experimental treatment approaches and are also considered for SCT, even if they are not in complete remission.

Intensification Therapy

Consolidation therapy refers to either high-dose chemotherapy, the use of multiple new agents, or readministration of the induction regimen, also called reinduction. These measures are aimed at eliminating clinically undetectable residual leukemia after induction chemotherapy and thereby preventing relapse, as well as the emergence of drug-resistant cells.

Intensive consolidation is standard in the treatment of ALL based on pediatric studies and historic comparisons, although randomized trials often failed to demonstrate a benefit of intensification;[44,54] this is probably due to the low number of patients in whom these concepts were evaluated. Consolidation cycles in large studies are very variable, and it is impossible to evaluate their individual efficacy (see Table 103-6). Intensification schedules include teniposide, etoposide, amsacrine (*m*-AMSA), mitoxantrone, idarubicin, and HDAC or intermediate- or high-dose methotrexate (HDM). Allogeneic SCT from sibling or unrelated donors or autologous SCT is now the major approach for intensive postinduction therapy in high-risk patients (see later discussion). Before SCT, a consolidation therapy is usually delivered to achieve a CR with good remission quality. High-dose

chemotherapy has been used mainly to overcome drug resistance or to achieve therapeutic drug levels in the cerebrospinal fluid.

HIGH-DOSE CYTARABINE. Although there is considerable experience with HDAC for the consolidation treatment of ALL,[46] it still remains uncertain what dose is optimal; usually, doses ranging from 1 to 3 g/m^2 every 12 hours for 4 to 5 days are given within several combinations. HDAC has been included in several trials in adult de novo ALL as part of consolidation therapy (see Table 103-6). It seems that specific subgroups of ALL profit from HDAC treatment; thus, encouraging results are achieved for pediatric B-cell ALL. The extent HDAC to which contributes to the effects of HDM in these disease subtypes remains uncertain. Apparently, HDAC is also beneficial for adult pro-B ALL, because cure rates of 50% can be achieved.[55]

An additional argument for the use of HDAC might be its effectiveness in treating CNS leukemia. There is evidence that in ALL and NHL, higher levels of AC triphosphate can be reached with 3 g/m^2 compared with the lower dose of 1 g/m^2 AC; in addition, with the higher dose, the cerebrospinal fluid can be cleared of blast cells.[56]

HIGH-DOSE METHOTREXATE. In general, it seems that intensive application of HDM is beneficial. It has been extensively studied for the treatment of childhood ALL and to a lesser extent in treatment of adult ALL. HDM appears to be effective in preventing systemic and testicular relapses. However, in adults, dosages are probably limited to 1.5 to 2 g/m² if given as a 24-hour infusion. Otherwise, toxicities, particularly mucositis, can lead to subsequent treatment delays and decreased compliance. Toxicity, but also efficacy, is reduced with a shortened infusion time, such as 4 hours.[57] The situation might change when improved prophylaxis of mucositis, such as with keratinocyte-growth-factor, becomes available.

The effect of HDM on CNS leukemia might contribute to the favorable results that have been reported with its use. HDM at a dose of 6 g/m^2 resulted in an 80% CR rate when it was given in children with CNS relapse,[58] indicating that systemic application yields cytotoxic levels in the cerebrospinal fluid. Several studies have investigated the efficacy of HDM as consolidation (see Table 103-6). Most favorable results have been achieved in small trials with HDM as part of intensive multidrug consolidation regimens.

ASPARAGINASE. From pediatric ALL trials, there is increasing evidence that intensified application of asparaginase leads to improved overall results.[59,60] In adult ALL, this approach appears to be useful particularly in consolidation, in which less toxicity can be expected compared to induction.

Reinduction

Pediatric trials and one randomized trial in adults also underline the efficacy of repeated induction, also named reinduction or late intensification.[61]

The role of HD anthracylines and epipodophyllotoxins in consolidation remains open. Overall in adult ALL, stricter adherence to protocols during consolidation with fewer delays, dose reductions, and omission of drugs due to toxicities would be an important contribution to therapeutic progress.

Maintenance Therapy

Maintenance therapy even after intensive induction and consolidation is still standard for ALL patients. Some groups even prolong maintenance therapy beyond 2 years of total treatment. Methotrexate preferably given intravenously and mercaptopurine given orally are the backbone of maintenance regimens. The potential effects of further intensification cycles for specific subgroups of ALL remains open. It might be useful to aim for leukocyte counts below 3000/μL during maintenance[62] to achieve optimal suppression of residual disease.

Attempts to omit maintenance therapy altogether after induction and consolidation therapy have had inferior results.[63–65] On the other hand, the role of periodic cycles of intensive chemotherapy during maintenance remains to be defined.

In a large, multicenter Italian study (GIMEMA 0183), after intensive consolidation treatment, patients were randomly assigned to postconsolidation therapy with conventional maintenance therapy or to additional alternating treatment courses of different intensities.[66] In this report, there was no difference in the survival rate at 10 years between the treatment groups (27% for conventional and 28% for more intensive maintenance), which might suggest that after adequate early consolidation therapy, the intensity of the maintenance therapy has no influence on survival. However, only a few patients actually received these regimens as scheduled; adults often show poor compliance to intensive maintenance, owing to toxicities and for social reasons. Therefore, maintenance with less intensive cycles, for example, with vincristine and steroids, might be more practicable.

Currently, maintenance therapy in adult ALL is being revisited on the basis of the burden of MRD (e.g., none for MRD-negative patients), the subtype of ALL, and the use of new therapeutic options (e.g., a tyrosine kinase inhibitor for BCR-ABL-positive ALL). It is still open whether and to what extent maintenance therapy is necessary in ALL subgroups.

Prophylaxis of Central Nervous System Leukemia

Central nervous system leukemia occurs in 6% (1% to 10%) of patients with adult ALL at diagnosis, with a higher incidence in T-cell ALL (8%) and mature B-cell ALL (13%).[67] Treatment and prophylaxis of CNS leukemia may consist of intrathecal methotrexate alone or in combination with AC or prednisone, similar intraventricular therapy administered by an Ommaya reservoir, cranial irradiation, or systemic treatment with HDAC or HDM.[68]

Adult ALL patients who do not receive specific prophylactic CNS treatment have a CNS relapse rate of 30% (29% to 32%),[67] similar to that observed in children without CNS prophylaxis.[69]

With intrathecal chemotherapy alone, the rate of isolated and combined CNS relapses can be reduced to 13% (8% to 19%). Intermittent treatment during maintenance therapy improves the outcome in comparison with administration of only a few doses during induction treatment. In most adult ALL trials, additional prophylactic CNS irradiation (24 Gy) has been administered. This combined approach further reduces the CNS relapse rate to 9% (3% to 19%). There is some evidence that early irradiation after remission induction is superior to delayed irradiation during consolidation treatment.[70]

In many recent trials, combined treatment approaches have shown greater efficacy. For high-dose chemotherapy together with intrathecal therapy, the rate of CNS relapses was 7% (2% to 16%); with additional CNS irradiation, the relapse rate was 6% (1% to 13%). The efficacy of intensified CNS prophylaxis was also demonstrated in a retrospective analysis from the M.D. Anderson Cancer Center, in which the lowest CNS relapse rate (2%) was achieved in a trial with early high-dose chemotherapy and intrathecal therapy for all patients.[71]

Because the risk for CNS relapse is associated with other risk factors, such as T-cell ALL, B-cell ALL, extreme leukocytosis, high leukemia cell proliferation rate, high serum lactate dehydrogenase levels, and extramedullary organ involvement, a risk-adapted CNS prophylaxis has been suggested.[71] This approach, however, is not widely used in adults. It should be kept in mind that effective CNS prophylaxis not only reduces the risk of isolated CNS relapse but also improves general outcome. Deescalation of CNS prophylaxis should therefore be done carefully. In the future, the use of liposomal cytarabine for intrathecal therapy might help to reduce the number of intrathecal applications and thereby the risk of contamination and

could improve efficacy with the aim of replacing CNS irradiation in defined populations.

The risk of CNS relapse can also be affected by skill in the performance of the administration of intrathecal chemotherapy. Thus contamination of the CSF with blood at the initial lumbar puncture can be associated with a poor outcome. The lumbar puncture should be done by experienced physicians. Platelet transfusions should be given before in case of low platelet counts, and patients should remain in prone position after intrathecal therapy.[72]

Therapy for Relapsed and Resistant Leukemia

Patients who fail to achieve CR or those who subsequently relapse have been treated with a variety of protocols.[73,74] The repetition of regimens, including vincristine, anthracyclines, and steroids, that are similar to standard induction treatment have led to CR rates of 61% in earlier studies.[73,74] The use of single-agent HDM, HDAC, and probably the anthracycline derivatives mitoxantrone and rubidazone have resulted in a second remission in 30% of patients or fewer, whereas other agents, such as amsacrine, teniposide, and etoposide, are effective in 10% to 15% of patients.

High-dose AC has been extensively studied in relapsed adult ALL. From several small pilot studies comprising 90 patients in total, the weighted mean CR rate was 37%.[75] Higher CR rates (50% to 60%) were achieved with combination regimens that included HDAC and mitoxantrone, amsacrine, or vincristine plus steroids, again with a wide variation that may be attributed to patient selection and nonuniform intensity of pretreatment. Because HDAC is increasingly administered during frontline treatment, its efficacy following relapse might be limited. Therefore, new combinations with idarubicin (46% to 64% CR rate)[76–78] or fludarabine (67% to 83% CR rate)[79,80] have been evaluated. Median remission duration and survival rates have been reported by only a few groups but did not exceed 5 months and 16%, respectively.

HDM followed by rescue with folinic acid combined with asparaginase lead to response rates of 22% to 79% in resistant ALL in early studies.[73] This combination is no longer administered to relapsed patients but is now incorporated in several regimens for patients with de novo ALL.

The most significant predictive factor for treatment response in relapsed patients is the duration of first remission. Patients with longer previous remission (>18 months) have a higher CR rate and longer remission duration compared to those with a short previous remission (<18 months).[81,82] Therefore, decision making concerning therapy should consider the duration of first remission, age, further options, such as SCT, and other factors as summarized in Table 103-7. In patients with late relapse, a modified induction is often successful, whereas in patients with early relapse during intensive chemotherapy, new, experimental or more intensive regimens should be considered. Fortunately, at present, a variety of new drugs for ALL are being evaluated (reviewed by Pui and Jeha,[83] Thomas,[84] and Gökbuget and Hoelzer[85]).

Table 103-7 Factors for Decision Making on Therapy of Relapsed Acute Lymphocytic Leukemia Patients

- Duration of first remission: less than or greater than 18 months
- Prior therapy (drugs/cycles) not used before
- Available targets
  - Subtype: B-precursor versus T-ALL
  - Antigens: Available monoclonal antibodies
  - Molecular markers: Available kinase inhibitors
- Localization of relapse

For all chemotherapy regimens, the duration of second remission is usually short (<6 months), and the only curative approach for adult patients with relapsed or resistant ALL is SCT. The major aim of relapse treatment is the induction of a second remission with sufficient duration to permit preparation for SCT. Three large study groups have reviewed the outcome of relapsed ALL patients recently. The Medical Research Council's UK-ALL study found a 5-year survival rate of 7% in 609 patients with first relapse. Survival rates were poor in all subgroups, including younger (<20 years) versus older patients (12% versus 3%), short (<2 years) versus longer duration of first remission (11% versus 5%), and immunophenotype. One hundred twenty patients were able to receive a SCT after relapse, with survival rates of 15% for autograft, 16% for unrelated SCT, and 23% for sibling allogeneic SCT after 2 years.[86] The French group reported a rate of second remission of 44% in 421 relapsed patients with a LFS rate of 12% after 4 years. They identified transplantation during second CR and longer duration of CR (>1 year) as favorable prognostic factors.[87] The German group observed an improvement of outcome for relapsed T-ALL patients after more frequent application of experimental drugs, including nelarabine, and performance of SCT in up to 70% of the patients who achieved a second CR.[88] Thus, all attempts, including experimental drugs, should be directed toward obtaining a second remission and proceeding with SCT.

Stem Cell Transplantation

SCT has gained an increasingly important role in the treatment of patients with adult ALL. Although the majority of large prospective studies in adult ALL addressed the issue of indications for SCT in first CR, scheduling and procedures have still not been defined satisfactorily. To circumvent the problem with comparability of SCT and chemotherapy, several groups have constructed prospective trials with a "genetic" randomization offering allogeneic SCT in first complete remission (CR1) to all patients with a sibling donor. The study results certainly depend on the "conventional" treatment approach that is used in the chemotherapy arm. Some groups scheduled autologous SCT only; others included a randomized comparison of autologous SCT and chemotherapy.

The most difficult outcome parameter is the OS of the total patient cohort in a prospective trial that answers the question as to whether a SCT-based treatment concept is able to improve overall outcome. OS rates in studies with "genetic randomization" have not documented that transplant is superior to chemotherapy;[85] this could be due partly to the fact that allogeneic SCT was implemented in only 11% to 38% of the patients.[54,89–94] Even if allogeneic SCT yielded favorable results, because of its infrequent implementation, the impact on OS is too small.

Allogeneic Stem Cell Transplantation from Sibling Donors

The outcome of allogeneic SCT for patients with ALL depends on the age and remission status of the patient. The best results have been obtained in patients who were transplanted during the first remission. In a total of 1100 patients collected from published trials, the LFS rate was 50%, albeit with wide variations (21% to 66%). The relapse probability (RP) was 24%, and the transplant-related mortality (TRM) rate was 27% (Table 103-8). In more recent studies, results are improving, most probably because of a reduction in TRM.[95] According to the data of the International Bone Marrow Transplantation Registry for HLA-identical sibling SCT between 1996 and 2001, the 3-year probability of survival was 48% for ALL recipients older than 20 years of age who were transplanted during their first remission.[96]

There is evidence that graft-versus-leukemia (GvL) effects are also operational in ALL patients who receive an allograft, because several

Table 103-8 Results of Stem Cell Transplantation in Adult Acute Lymphocytic Leukemia Patients

Type of SCT	Stage	*N*	Transplant-Associated Mortality Rate (%)	Relapse Rate (%)	Leukemia-Free Survival Rate (%)
Allogeneic

*One trial.[185]

studies have shown that the RP is lower in patients with limited graft-versus-host (GvH) disease.[97–100] Age is another important prognostic factor for outcome after SCT. The LFS rate is 62% for patients below 20 years of age and 48% for those above 20 years of age.[96] Nevertheless, age limits for allogeneic matched sibling SCT have been increased continuously up to 50 to 55 years. The experience of transplant centers may also have a role. Specialized centers in the United States report LFS rates of 61% to 64% for sibling SCT in ALL in first remission.[101–103]

The LFS rate is 34% after allogeneic SCT in second remission. In advanced ALL (refractory or in relapse), allogeneic SCT results in an 18% long-term survival rate (see Table 103-8). Despite this, SCT is the treatment of choice in patients with relapsed or refractory ALL.

Matched Unrelated Donor Stem Cell Transplantation

SCT using grafts from matched unrelated donors can result in a long-term survival rate of 39% in patients with a lower RP (10%) as compared to allogeneic sibling SCT, whereas the TRM rate (47%) is higher. Both facts are probably due to more pronounced GvL and GvH effects. It should be considered, however, that matched unrelated donor (MUD) series generally include selected high-risk patients, such as patients with a high proportion of Ph/BCR-ABL-positive ALL. In the International Bone Marrow Transplantation Registry in adults older than 20 years, the 3-year probability of survival after MUD SCT in CR1 was 42%.[96] In the largest series so far, the results of MUD SCT were analyzed retrospectively in adult poor-risk ALL (mainly Ph/BCR-ABL-positive) patients with a median age of 34 years. They were particularly favorable for patients in CR1 (42% at 2 years), whereas in second or subsequent CR, the LFS rate was only 17%.[104] The RP of only 6% for patients in CR1 may be due to a more pronounced GvL effect. The high TRM rate of approximately 40%[104,105] is still the major obstacle to MUD SCT (see Table 103-8). This might be reduced by the use of different, less toxic preparative regimens, including nonmyeloablative SCT, better management of GvH disease, and improved supportive care.

Overall, the results of MUD SCT in ALL are encouraging, particularly considering that these are often patients with advanced stages of disease. There is increasing evidence that results of MUD SCT are approaching those of sibling SCT, particularly if adjusted for bias (see later discussion). MUD SCT is therefore the treatment of choice for high-risk patients in CR1, including Ph/BCR-ABL-positive ALL-and probably also other high-risk patients, if a sibling donor is not available.

In later remission or relapse, MUD SCT may lead to long-term survival rate of 27%, whereas the long-term survival rate after transplantation in relapse is only 5% (see Table 103-8).

Autologous Stem Cell Transplantation

Another attempt to overcome the limited availability of bone marrow donors is autologous SCT. The results for autologous SCT in first remission are surprisingly good, with an LFS rate of 42% and a low TRM rate (see Table 103-8). The major problem is a high RP (51%). Similar results with LFS rate of 42% in standard-risk ALL ($N = 280$) and 40% in high-risk ALL ($N = 174$) have been reported by the European Bone Marrow Transplant Group.[106] Favorable results have been achieved in a trial with autologous bone marrow transplantation or peripheral blood stem cell transplantation in adult ALL patients in first CR followed by a 2-year maintenance treatment with 6-mercaptopurine and methotrexate.[107]

The TRM rate after autologous SCT is very low (3%) and is similar to that of conventional intensification therapy. With the increasing number of MUD transplants being performed and the advantage of GvL effects, the role of autologous SCT is decreasing. However, because of the low TRM rate, this is still a reasonable approach for elderly patients and probably patients with negative MRD status in autologous bone marrow graft. Several prospective randomized trials in adult ALL showed equal outcomes for chemotherapy consolidation and autologous SCT (see later discussion).

In second remission, few patients obtain long-term survival with auto SCT (see Table 103-8). It may be considered as interim therapy before an allogeneic SCT if autologous stem cells have been collected during CR1.

Nonmyeloablative Stem Cell Transplantation

Nonmyeloablative SCT (NMSCT), a reduced-intensity conditioning regimen, is a novel approach that deserves evaluation in ALL and could lead to an extension of indications for allogeneic SCT. In contrast to conventional SCT, which mainly relies on cell kill by high-dose chemotherapy and total-body irradiation, NMSCT uses GvL effects. Immunosuppression (e.g., with purine analogs, other cytostatic drugs, or low-dose total-body irradiation) is followed by the infusion of stem cells from sibling or MUD donors with adapted immunosuppression to establish host tolerance.[108]

However, the general opinion is that GvL effects are less pronounced in ALL than in other malignancies. Nevertheless, these effects are present, as is indicated by the lower relapse rate in patients with acute or chronic GvH disease,[98–100]the lower relapse rate after MUD SCT, induction of remissions by withdrawal of GvH disease

prophylaxis, or donor lymphocyte infusions in single patients with relapsed ALL.

NMSCT is being increasingly considered as an option for elderly patients who have contraindications for conventional SCT. Initial results indicate that in CR1, stable remissions can be achieved in some patients.[109] These studies show a LFS rate of 23% for patients in all stages, with a 42% TRM rate and a 47% relapse rate (see Table 103-8). According to a European Bone Marrow Transplant Group analysis, the LFS rate in 91 adult ALL patients with a median age of 40 years was 18%, with a 24% TRM rate and a 58% relapse rate.[110] The LFS rate in both studies was considerable higher if NMSCT was performed in patients in first remission.[109,110]

Results of Umbilical Cord Blood and Haploidentical Stem Cell Transplant

The experience with umbilical cord blood transplantation in ALL mainly comes from pediatric patients. However, registry results of younger adults with acute leukemia indicate that umbilical cord blood (single or double) can be considered as an alternative donor source if available.[111]

The experience with haploidentical SCT is restricted mainly to pediatric patients, for whom it may be considered in patients without a donor and with an urgent need of SCT. In adult patients with acute leukemia, a retrospective analysis indicated that if feasible, autologous SCT is preferable to haploidentical SCT; despite a higher relapse rate, the overall outcome was slightly superior.[112] On the basis of the available experience, both approaches should be restricted to specialized centers and a later stage of disease and should be performed as part of a clinical trial.

Comparison of Different Transplantation Procedures and Transplantation versus Chemotherapy

ALLOGENEIC SIBLING AND MATCHED UNRELATED DONOR STEM CELL TRANSPLANTATION. Owing to improved supportive care, better donor selection, and extension of indications beyond very high-risk patients, the results of MUD donor SCT are similar to those of allogeneic sibling SCT. The prospective Medical Research Council/Eastern Cooperative Oncology Group study of SCT showed in 321 patients with allogenic sibling donor SCT a survival rate of 55% (standard and high-risk ALL) compared to 46% with MUD donor SCT in 67 patients with very high-risk (Ph/BCR-ABL-positive) ALL.[92] A study of nine German centers showed in CR1 a higher proportion of MUD donor SCT (60% versus 27%), and there was no difference regarding LFS rate (45% versus 42%).[113] The TRM rate for allogeneic sibling SCT ranged in prospective trials between 15% and 26%[54,89–94] and reaches 35% in MUD-SCT.[92] Several factors, such as intensity of therapy before SCT, preparative regimens, immunosuppressive therapy after SCT, and the experience and conditions at SCT centers, could play a role. However, MUD SCT appears to be a reasonable option for high-risk patients without a sibling donor.

DONOR VERSUS NO-DONOR COMPARISONS. This type of comparison represents the intent-to-treat analysis, which is an adequate approach only if a significant number of patients actually receive the assigned treatment option. Several trials did not show differences in outcome for patients with (intent to treat: allogeneic sibling SCT) or without donors (intent to treat: randomization of autologous SCT and chemotherapy).[54,94,114–116] The PETHEMA study for high-risk patients even showed a trend toward an advantage for patients without donors.[93] In contrast, several other studies demonstrated an advantage of SCT in high-risk patients.[90,91,115]

Recently, the large Eastern Cooperative Oncology Group/Medical Research Council group reported their preliminary results comparing patients with donors (allogeneic sibling SCT) to those without donors (randomized comparison of chemotherapy and autologous SCT). The special feature of this trial was the use of age (younger and older than 35 years) as a prognostic factor. Standard-risk patients were by definition younger than 35 years with WBC less than 30000/μL for B-precursor and less than 100,000/μL for T-ALL. Overall, patients with a donor had a superior OS rate (53%) compared to those without donor (45%) mainly due to a lower RP (29% versus 54%). The difference was particularly evident in standard-risk (63% versus 51% OS rate) patients but not in high-risk (39% versus 36%) patients,[117] a finding that is in contrast to all other trials. Because a younger age was the major factor for definition of standard risk, this result can be interpreted in two ways: (1) The outcome of SCT is better in younger patients, which is a well-known fact, and (2) the outcome in young standard-risk patients with a donor is not superior to that of chemotherapy in other trials. A third issue is the fact that the performance of SCT was limited (321 allogeneic sibling SCT in 1508 evaluable patients).[92] The TRM rate reached 20% even in standard-risk patients. The OS rate of 38% in this trial was similar to that in other studies.[118]

CHEMOTHERAPY OR ALLOGENEIC SIBLING STEM CELL TRANSPLANTATION VERSUS AUTOLOGOUS STEM CELL TRANSPLANTATION. In several randomized studies, no significant difference was detected in studies that compared chemotherapy and autologous SCT.[89,90,93,94] In the large randomized Eastern Cooperative Oncology Group/Medical Research Council trial, the outcome of autologous SCT was inferior (33%) to that of chemotherapy (42%) in terms of LFS rate, mainly owing to a higher RP.[117] Comparisons of allogeneic and autologous SCT have shown an inferior outcome for autologous SCT. In two trials with an intent-to-treat comparisons, the results of autologous SCT were poor (30% and 33%).[91,119]

Preferred Approach to Stem Cell Transplantation

A recently published evidence-based review emphasized that SCT offers an advantage as compared to chemotherapy in high-risk patients and in patients in second remission. The analyses also revealed the lack of prospective, controlled trials for SCT in ALL.[120] This is probably because every study design that includes SCT by definition has too many variables, such as donor availability, individual patient condition, and patient wish. Not surprisingly, a meta-analysis of seven studies[54,90,91,93,94,115,121] showed a broad variation in rates of performance of allogeneic (68% to 96%) and autologous (9% to 81%) SCT. The meta-analysis showed a correlation of outcome with compliance to allogeneic SCT. Again the OS rate for SCT was superior to that for chemotherapy, with a particular advantage in high-risk patients.[122] Therefore, the role of allogeneic SCT in standard-risk ALL remains unclear.

In ongoing trials, indications for SCT in first remission are not uniformly defined. The advantages of SCT (short treatment duration, favorable outcome in some trials) must be compared to the disadvantages (TRM, late complications, poorer quality of life). The major question is whether all patients with sibling donor should proceed to SCT or only those with specific risk factors.

When considering SCT, one has to balance the expected reduced relapse risk and the increased anticipated mortality. Also late effects are more pronounced in SCT patients, the quality of life seems to be poorer, and the risk of procedure related death is 20% to 30% compared to chemotherapy with more prolonged risks. SCT in CR1 from a sibling or unrelated donor seems to be justified in subgroups of ALL with OS rate below 40% with chemotherapy and should probably not be offered to patients with OS rate after chemotherapy above 50%. These outcomes clearly depend on the different chemotherapy regimens that are used.

Therefore, in the majority of trials, SCT indications are determined by the presence of adverse prognostic factors. The status of MRD is of increasing importance as an indication for the SCT. It remains open to further studies whether SCT is really a favorable option in patients

Table 103-9 Indications for Stem Cell Transplantation in the German Multicenter Trials for Adult Acute Lymphocytic Leukemia Patients

	Indication	Priorities*
First remission		
High risk	All patients within 3–4 months from diagnosis	1. Allogeneic sibling† 2. Allogeneic unrelated† 3. Autologous 4. NMSCT

†Matched or one mismatch.

with high MRD and whether patients with high-risk features but negative MRD status are still candidates for SCT. Allogeneic sibling and MUD SCT are considered in a similar way. Although outcome after SCT is better in younger patients, there is a trend to treat adolescents with pediatric-type intensive chemotherapy protocols and to proceed less with transplantation. For older high-risk patients and those with contraindications, nonmyeloablative SCT is a reasonable alternative, with an expected LFS rate of 34% in first CR.[110]

There is general agreement that all patients in second or later remission are candidates for SCT. Depending on donor availability and the patient's general condition, experimental procedures such as NMSCT, cord blood SCT, and haploidentical SCT may be considered.

Table 103-9 outlines the indications of SCT in the German multicenter study group for adult ALL as an example for a risk-adapted approach.

OUTCOME OF ALL SUBTYPES AND PROGNOSTIC FACTORS

Age is probably the most important prognostic factor for achievement of CR and long-term outcome.[62] Other prognostic factors are of greater importance for duration of remission and survival (Table 103-10). Appreciation of the impact of such risk factors (Table 103-11) on the results in the majority of adult ALL trials have led to the generation of risk-adapted treatment protocols (Table 103-12).

Age

Survival of patients with adult ALL decreases continuously with increasing age from 34% to 57% below 30 years to 15% to 17% above 50 years [28,44,54,118,123] also in recent studies. Some groups used age above 30 to 35 years as an indication for SCT in CR1.[91,93] This is probably counterproductive, since the outcome of SCT decreases significantly with age.[117] Increasing attention is being paid to the definition of specific treatment approaches for adult ALL patients at both ends of the age spectrum, which means adolescents on one hand and the elderly patients on the other.

Elderly Patients

The CR rate is about 50% in patients at the age of 50 to 88 years with a remission duration of 3 to 12 months and a survival rate below 10% (reviewed by Hoelzer and Gökbuget[124] and Pagano and colleagues[125]). It is difficult to define an age limit when a change in

Table 103-10 Outcome of Adult Acute Lymphocytic Leukemia Patients According to Subgroups*

Subgroup	No. of Patients	Complete Remission Rate (%)	No. of Patients	Leukemia-Free Survival Rate (%)

Table 103-11 Adverse Prognostic Factors for Remission Duration in Adult Acute Lymphocytic Leukemia Patients*

Clinical characteristics	Higher age: >50 years, >60 years	
	High white blood cell count: >30000/μL in B-lineage	
Immunophenotype	Pro-B (B-lineage, CD10–), CD10 negative pre-B-ALL	
	Early T (T-lineage, CD1a–, sCD3–)	
	Mature T (T-lineage, CD1a–, sCD3+)	
Cytogenetics/ molecular genetics	t(9;22)/BCR-ABL or t(4;11)	
	ALL1-AF4	
	New molecular markers for T-ALL	
Treatment response	Late achievement of complete remission	>3 or 4 weeks
	Minimal residual disease positivity	

*Adverse prognostic factors as they emerged from the more than 3000 adult ALL patients treated in the GMALL (German Multicenter Studies for Adult ALL) trials.

Data from Gökbuget N, Hoelzer D, Arnold R, et al: Treatment of adult ALL according to the protocols of the German Multicenter Study Group for Adult ALL (GMALL). Hemat/Oncol Clin North Am 2000;14:1307–1325.

prognosis occurs. Almost all studies use a cutoff point at the age of 55 to 65 years to determine eligibility for allogeneic HSCT. This age seems to be practical because younger patients are candidates for intensified treatment approaches, such as SCT, whereas for the older group, new strategies need to be explored, the gain in survival being carefully weighed against quality of life. Elderly patients at the age of 55 to 65 years or even older who have achieved a CR and are in good clinical condition are potential candidates for autologous SCT or NMSCT.

Several factors such as comorbidity, higher risk of complications, and increased risk of early mortality are associated with the inferior results in elderly patients. The major cause of death is infections. Therefore, the increased hematologic toxicity with prolonged severe cytopenias is of particular relevance in elderly patients. Often, it cannot be distinguished whether these are due to toxicity or to lack of response. There is the dilemma that, on one hand, the disease is more resistant in the elderly and, on the other hand, the tolerability of therapy is lower and there is a higher risk of organ toxicities, such as in the liver and heart. Altogether, comorbidities and complications lead to treatment delays, omission of single drugs, and prolonged intervals between therapy cycles, which contribute to poorer long-term results. There is also a lower incidence of favorable prognostic subtypes such as T-ALL in the elderly, whereas the incidence of unfavorable subtypes is higher.[126]

Palliative therapy is associated with a short survival[124] (Table 103-13). With the use of intensive chemotherapy protocols developed for younger patients, the CR rate in the elderly was 56%, with 23% early mortality and a median survival of 9 months. It can be assumed that only elderly patients who were in good general condition were accepted to these trials. Thomas and colleagues showed in

Table 103-12 Preferred Approach to the Treatment of Adult Acute Lymphocytic Leukemia Patients

	Low-Risk ALL	High-Risk ALL	Very High-Risk ALL	Mature B-ALL
Definition	B-lineage	B-lineage	Ph/BCR-ABL+

	Thy ALL	Early T, mature T		
Multidrug-Induction	Yes	Yes	Yes + imatinib	Short intensive cycles including HDM, fractionated C, HDAC, and other drugs
CNS prophylaxis*	Yes	Yes	Yes	Yes
Consolidation (also other combinations)	Alternating cycles (e.g., HDM, HDAC, Asparaginase reinduction)	One cycle	One cycle + imatinib	6 cycles
SCT in CR1	None	Allogeneic SCT (if matched related or unrelated donor)		None
		Autologous SCT (if no donor and negative MRD, after additional consolidation)		
Maintenance	6-MP/M + intensification for 2–2½ years			None

AC, cytosine arabinoside; ALL, acute lymphocytic leukemia; CR, complete remission; HDM, high-dose methotrexate; MRD, minimal residual disease; SCT, stem cell transplantation; Thy ALL, thymic ALL; WBC, white blood cell count.

*Intrathecal therapy with M or triple combination (M, AC, steroid) continued during maintenance therapy; additional CNS irradiation and/or high-dose chemotherapy according to subgroup.

Table 103-13 Treatment Results in Elderly Acute Lymphocytic Leukemia Patients

Approach	No. of Studies	No. of Patients	Clinical Remission Rate (%)	Early Mortality Rate (%)	Median Overall Survival
Palliative	4	94	43	24	7 months
Intensive chemotherapy	11	519	56	23	14%
Prospective studies	5	187	58	16	22%

three successive treatment periods that the remission rates of elderly patients could be improved by the adoption of specific age-adapted protocols.[127] Fortunately, there is a new trend to develop prospective trials for elderly patients in order to offer a curative option on one hand and to limit toxicity, early mortality, and duration of hospitalization on the other hand in order to maintain quality of life. With these approaches, the more favorable remission rates of 58% and survival rate of 22% have been achieved.[124]

Further improvement of results in the elderly is urgently required. Innovative strategies are based on targeted, subgroup-specific elements with the aim not to increase the typical chemotherapy associated toxicity. This includes use of the abl-kinase inhibitor imatinib for Ph+ ALL, and antibody therapy for CD20-positive ALL (rituximab). The German study group reported a remission rate of 63% in CD20-positive (Ph/BCR-ABL-negative) elderly patients and a survival rate of 54% after 1 year with a regimen combining age-adapted chemotherapy and eight doses of Rituximab before the chemotherapy cycles.[128] In elderly patients with Ph/BCR-ABL-positive ALL, the remission rate can be improved above 90% with imatinib monotherapy (see later discussion).

Adolescent Patients

In recent years, the optimal approach to treatment of adolescents has been discussed extensively. Several groups have compared the outcome of adolescents treated with adult protocols with the outcomes of those treated with pediatric protocols. Although entry criteria were quite similar, the outcome was always significantly inferior in those who participated in the adult trials (event-free survival rate: 34% to 71%) as compared to the pediatric trials (event-free survival rate: 64% to 80%).[129] The conclusion was that pediatric trials include higher doses of VCR, ASP, and HDMTX and a higher time-dose intensity. However, the poor outcomes that are associated with most adult protocols are probably also due to suboptimal approaches in these specific studies. The GMALL reported a survival rate of 64% in 417 young adults (15 to 25 years) with significant differences in outcome for subgroups ranging from 74% for standard risk to 49% for high risk and 55% for Ph+ ALL.[130] Results are superior to most of those that have been reported from adult protocols in adolescents but are still at the lower end of range for pediatric trials. Therefore, further improvement of outcome in adolescents is required.

One solution could be the extension of age limits of pediatric protocols to 25, 35, or even higher ages as is currently being attempted by several U.S. groups. It remains open to question whether a sufficient number of adults will actually be treated in these studies and whether the application of such intensive regimens will be restricted to selected patients and selected, highly experienced pediatric centers.

The other option, which is currently followed by several adult study groups, is to adopt more successful pediatric treatment elements in their protocols and to aim for a higher time and dose intensity with fewer treatment interruptions and omissions, particularly in adolescents and young adults. Interim results of such studies were reported recently. The CR rates (82% to 92%) and event-free survival rate (66% to 72%)[131–133] are promising, but considerable toxicity, such as neuropathies and thrombosis, was observed, indicating that these protocols may probably not be transferable to all adults.

White Blood Cell Count

An elevated WBC at diagnosis (>30 to 50.000/μL) is associated with a higher risk of relapse.[28,44,54,89,123] It was even considered as the most deleterious prognostic factor in B-precursor ALL, with an OS rate of 19% to 29%[118,134] whereas in T-ALL, WBC has no significant effect on outcome in a GMALL multivariate analysis.[134] The biologic reason for the highly resistant behavior of B-precursor ALL with high WBC is unclear. In the GMALL studies, these patients show a high relapse rate but also seem to have a higher mortality rate with chemotherapy and SCT.[135] In these patients, evaluation of MRD, use of experimental drugs, and SCT modalities seem to be particularly important.

Immunophenotype and Cytogenetics

The immunophenotype is an important independent prognostic variable in ALL. In ongoing trials, it is used to adjust treatment regimens accordingly (e.g., separate regimens for mature B-cell ALL). A further example for clinical application is the identification of patients for antibody therapy (e.g., anti-CD20 in CD20-positive B-lineage ALL or B-cell ALL or anti-CD52 in B- and T-lineage ALL).

T-Lineage Acute Lymphocytic Leukemia

Results of treatment of T-cell ALL have substantially improved in comparison with survival rates of 10% 20 years ago. Many groups have confirmed the superior outcome of T-lineage ALL as compared to B-lineage ALL.[118,134] There is, however, a substantial difference in outcome for the T-ALL subtypes. Thymic T-ALL, which accounts for one half of the adult T-ALL patients, has a favorable outcome with CR rates of 85% to 90% and survival rates greater than 50% at 5 years. Early T-ALL and mature T-ALL have poorer outcomes with CR rates of 70% and LFS rates of approximately 30%.[134] The biologic importance of immunophenotype was underlined by the fact that elevated expression of HOX11, HOX11L2, SIL-TAL1, and CALM-AF10 is associated with subtypes, that is, maturation states of thymocytes (reviewed by Grabher and colleagues[136]). Other groups observed inferior outcomes for early T-ALL;[137,138] coexpression of CD13, CD33, and/or CD34;[37] HOX11L2; and SIL-TAL-positive T-ALL.[138] The German group reported poor survival associated with overexpression of ERG and BAALC.[139,140] Overexpression of HOX11, which is associated with thymic T-ALL, may confer a favorable prognosis. Notch1-activating mutations with so far unclear prognostic relevance were identified in up to 50% of T-ALL cases.[136] They may be targeted by γ-secretase inhibitors. Five percent of T-ALL show the NUP214-ABL1 aberration, which may identify a target population for imatinib therapy.[141]

The addition of cyclophosphamide and AC to the usual cytostatic drugs for ALL is mainly responsible for the improved outcome in T-ALL. HDM contributed to the improvement of survival in children,[142,143] as did HDAC.[144,145] For adults, the benefit of HDM in T-cell ALL has to be confirmed in larger trials. With current treatment regimens, CR rates of more than 80% and a LFS rate above

50% can be achieved in T-ALL. New treatment approaches in adult T-ALL include purine analogs, such as nelarabine[132] and forodesine,[146] or antibody therapy (e.g., anti-CD52).

B-Lineage Acute Lymphocytic Leukemia

In common and pre-B-ALL, CR rates in adults have improved to 80% or more, but patients still relapse in most studies over a period of up to 5 to 6 years, and only one third of these patients survive. With B-precursor ALL, prognostic factors are decisive for outcome; high-risk patients with adverse prognostic features, such as high WBC (>30,000/μL), late achievement of CR (>3 to 4 weeks), and Ph/BCR-ABL-positive status (see Table 103-11) have a survival rate of 25% or less, whereas standard risk patients without any of those features have a 5-year survival rate greater than 50%.[134]

Philadelphia chromosome/BCR-ABL-positive ALL had until recently been associated with the worst prognosis in children, as well as in adults. Outcome has now improved dramatically (see later discussion).

Adults with the subtype pro-B ALL or the t(4;11) translocation have a poor prognosis, as do infant ALL patients.[147] With intensive regimens, including HDAC and mitoxantrone as consolidation therapy, the results for adults seem to be improving.[55] Pro-B-ALL patients benefit from allogeneic SCT in CR1, with survival rates of 60% in transplanted patients.[148] The adverse impact of the translocation t(4;11) seems to have changed with new treatment modalities (see earlier).

In mature B-cell ALL, CR remission rates were low (40%) a decade ago, and remission duration was short (11 months).[149] A change was brought about by innovative childhood B-cell ALL studies that significantly improved outcome, with CR rates of 80% to 94% and an LFS rate of 63% (weighted mean).[149] The drugs that were responsible for the improvement were high doses of fractionated cyclophosphamide, HDM (0.5 to 8 g/m^2), and HDAC in conjunction with the conventional drugs for remission induction in ALL, given in short cycles at frequent intervals over a period of 6 months.

The application of these childhood B-cell ALL protocols in original or modified form also brought a substantial improvement in adult patients with B-cell ALL. CR rate reached 75% (62% to 83%) and the LFS rate of 55% (20% to 71%).[149–151] Adverse outcome prognostic factors were late CR (more than two cycles of chemotherapy), high WBC (>30 × 10^9/L), and age older than 50 years. B-cell ALL has a higher incidence of CNS involvement at diagnosis and of CNS relapse. Therefore, effective measures against CNS disease, such as HDM and HDAC, as well as intrathecal therapy, are important components of treatment regimens. Maintenance treatment has been omitted. Because relapses occur almost exclusively within the first year in childhood, as well as in adult B-cell ALL studies, patients thereafter can be considered to be cured.

Further significant improvement was achieved by the addition of antibody therapy with anti-CD20 (rituximab) because more than 80% of the patients are CD20-positive. With these regimens, survival rates above 70% to 90% can be achieved in adults with mature B-ALL or Burkitt's lymphoma.[152,153]

The translocations t(8;14), t(8;2), and t(8;22) or c-myc aberrations are present in most cases of mature B-cell ALL and in Burkitt's lymphoma. They may add information in cases with uncertain diagnosis. They have lost their poor prognostic significance, however, because of the improved treatment for patients with B-cell ALL or Burkitt's lymphoma.

Treatment Response and Minimal Residual Disease

Beside age, the most relevant prognostic factor in ALL is still the achievement of CR. Further prognostic factors related to treatment response are delayed time to CR or response to prednisone therapy. A more accurate approach to assess individual response is evaluation of MRD,[62,154] since this is an independent prognostic factor that reflects primary drug resistance as well as individual completion of therapy and unknown host factors. The methods for detecting the burden of MRD have been described earlier and are summarized in Table 103-14.

Identification of High-Risk Patients as Candidates for Stem Cell Transplant or Experimental Therapy

After the start of consolidation, a high burden of MRD (>10^{-4}) at any time point is associated with a high relapse risk of 66% to 88%,[53] and the predictive value increases at later time points (months 6 to 9).[155] In the GMALL studies, patients with a high burden of MRD (>10^{-4}) after induction and first consolidation were identified as high risk and were considered candidates for SCT in CR1.[156]

Identification of Low-Risk Patients in Whom Treatment Intensity Reduction May Be Justified

This aim is more difficult to reach. An early and rapid decrease of MRD during induction is associated with a relapse risk rate of only 8%.[53] However, this course is observed in only 10% of the patients. In the GMALL studies, patients with negative MRD status after induction, which is repeatedly confirmed during first year and measured with two sensitive markers, are considered as MRD low risk.

Assessing molecular CR, thereby evaluating different induction therapies and detecting molecular relapses, are two important new items for follow-up analysis in adult ALL. Molecular response provides a more individual impression of the response and is particularly important, since nowadays, 85% to 90% of adult ALL patients achieve a cytologic CR. Even in phase II studies, molecular relapse is already an inclusion criteria. This makes sense, since patients with an increase of MRD burden above 10^{-4} after achievement of a molec-

Table 103-14 Methods for Detection of Minimal Residual Disease in Acute Lymphocytic Leukemia Patients

Method	Target	Sensitivity	Application B-Lineage ALL (%)	T-Lineage ALL (%)
Flow-Cytometry	Leukemia-specific immunophenotype	10^{-4}	~35	>90
PCR	Fusion transcripts	10^{-4}–10^{-6}	~30	~10
PCR	Ig rearrangements (IgH, IgK)	10^{-4}–10^{-6}	>90	~20

Data from Campana D, Pui C-H: Detection of minimal residual disease in acute leukemia: Methodological advances and clinical significance. Blood 1995;85:1416–1434; Beishuizen A, van Wering E, Breit TM, et al: Molecular biology of acute lymphoblastic leukemia: Implications for detection of minimal residual disease. In Hiddemann W, et al (eds): Acute Leukemias: V. Experimental Approaches and Management of Refractory Disease. Berlin, Springer-Verlag, 1996, p 460.

ular CR are at high risk of relapse (>80%), and therapeutic action should be taken.[157]

Risk Stratification According to Minimal Residual Disease

The approaches to integrate MRD analysis in prospective risk stratification of adults can be different in terms of (1) in the time points sampled, (2) the selection of patients for MRD risk stratification, (3) combination of MRD-based and conventional risk factors, and (4) the MRD-based treatment decisions. It is hardly possible to identify adult low-risk patients in whom reduction of the intensity of therapy would be justified. In the GMALL study, these patients are defined according to very strict criteria (see previous discussion) in order to omit maintenance therapy. However 20% to 30% of these patients relapsed. The major aim in MRD-based studies is therefore to identify patients who have a high risk of relapse for treatment intensification with SCT. It remains to be demonstrated that this is an effective strategy, since patients with high MRD before SCT have an increased risk of relapse and might benefit from additional conventional therapy, or even experimental therapy, to reduce tumor load. On the other hand, it has to be questioned whether patients who are candidates for SCT on the basis of conventional risk factors, including Ph+ ALL, should receive allogeneic SCT if they are MRD-negative. The best strategy remains unknown.

Evaluation of the burden of MRD has not been without problems. The technical procedure is time-consuming, expensive and requires highly specialized staff. The predictive value depends on the technical quality, such as sensitivity (10^{-4}), the number of targets (at least two for immunoglobulin or T-cell receptor rearrangements), and the frequency of evaluations (3-monthly). At least in multicenter studies, these prerequisites often cannot be fulfilled. Sensitivity of the evaluation of MRD, with the exception of BCR-ABL-based analysis, is also insufficient to evaluate the efficacy of consolidation cycles because, in most patients, MRD is below the detection limit.

Drug Resistance

MDR-1 function has been associated with a poorer prognosis.[137,158] In vitro sensitivity testing was able to identify patients who had resistance to conventional cytostatic drugs, which was associated with an inferior prognosis. More recently, it was demonstrated that in vitro resistance is associated with distinct gene expression profiles.[159] In vitro resistance testing is also increasingly used for effectiveness testing of new cytostatic drugs. In the future, a prediction of response to induction regimens might be possible in order to adapt therapy to individual susceptibility.

NEW THERAPEUTIC APPROACHES IN ADULT ALL TREATMENT WITH MONOCLONAL ANTIBODIES

ALL blast cells express a variety of specific antigens, such as CD20, CD19, CD22, CD33, and CD52, which may serve as targets for treatment with monoclonal antibodies (Table 103-15). Monoclonal antibody therapy is an attractive approach, since it is targeted, subtype specific, and, in comparison to chemotherapy, has different mechanisms of action and side effects. One prerequisite for antibody therapy might be the presence of the target antigen on at least 20% to 30% of the blast cells. Application might be most promising in combination with MRD (reviewed by Gökbuget and Hoelzer[160]).

Table 103-15 Expression of Surface Antigens on Acute Lymphocytic Leukemia Blast Cells

Subgroup	Antigen	Expression on More Than 20% of Lymphatic Blast Cells*
B-lineage	CD19	95% precursor
		94% mature
	CD20	41% precursor
		86% mature
	cyCD22	17%
T-lineage	CD25	
	CD7	99%
	CD3	33%
Both	CD52	66%–78%†
	CD33	16%

*Data from the GMALL central immunophenotyping, E. Thiel, S. Schwartz, Berlin.
†Data from Faderl S, Kantarjian HM, O'Brien S, et al: A broad exploratory trial of Campath-1H in the treatment of acute leukemias. Blood 2000;96:1397a.

Anti-CD20

Most experience exists so far with rituximab, which is a chimeric monoclonal antibody to CD20 that is expressed on normal and malignant B-lymphocytes. It exerted significant antitumor activity, and its use has led to an improvement of results in B-cell NHL. however, CD20, defined as expression on more than 20% of the blast cells, is also present on one third of B-precursor ALL blasts, particularly in elderly patients (40% to 50%), and the majority of mature B-ALL blast cells (80% to 90%).

The anti-CD20 antibody has been successfully integrated in therapy of mature B-ALL and Burkitt's lymphoma. It is now also being explored in several pilot studies for CD20-positive B-precursor ALL. In a GMALL protocol for elderly patients, Rituximab is administered prior to chemotherapy cycles starting during induction for a total of eight treatments. Also the combination of hyper-CVAD regimen with Rituximab in B-precursor ALL was feasible and a favorable outcome with CD20-positive ALL was reported (reviewed by Gökbuget and Hoelzer[161]).

Anti-CD52

The CD52 antigen is expressed by most lymphatic cells and to a higher degree in T-lymphoblasts compared with B-lymphoblasts. CD52-antibodies were first used for ex vivo T-cell depletion of allogeneic bone marrow grafts to prevent GvH disease without further GvH disease prophylaxis. The humanized antibody Campath-1H has antitumor activity in CLL, T-PLL, and other T-NHL. Several studies with anti-CD52 therapy in adults with ALL are ongoing, either during relapse or at the time of MRD. The CALGB has integrated anti-CD52 therapy as consolidation in their frontline therapy and demonstrated its feasibility in a dose-finding study. Efficacy data are not available.[162]

Additional monoclonal antibodies (B43[anti-CD19]-Genistein, B43[anti-CD19]-PAP, anti-B4-bR [anti-CD19]) have been investigated in phase I to II pilot trials in ALL. Antibodies that were developed for other diseases, such as anti-CD22 in lymphoma and anti-CD33 in AML, could be applicable in ALL because these antigens are expressed in 17% and 16% of adult ALL cases, respectively. Antibody treatment could be administered as single agents or in combination with chemotherapy, for purging, and as post-transplant therapy and might be particularly effective in low-burden disease (MRD-positive patients).

Imatinib in Ph/BCR-ABL-Positive Acute Lymphocytic Leukemia

In Ph/BCR-ABL-positive leukemia, the BCR-ABL fusion gene is causally involved in leukemogenesis and is considered to be essential for

leukemic transformation. With a selective inhibitor of the Abl tyrosine kinase (STI571, imatinib), cellular proliferation of BCR-ABL-positive chronic myeloid leukemia and ALL cells can be inhibited.

Clinical Experience with Imatinib in Advanced Ph-Positive Acute Lymphocytic Leukemia

In a multicenter phase II study, 56 patients with relapsed or refractory Ph+ ALL received imatinib at an initial daily dose of 400 mg orally, which was later increased to 600 mg; 60% of Ph+ ALL patients achieved a hematologic response. A complete hematologic remission with normalization of peripheral blood counts (absolute neutrophil count >1.5/nL, platelet count >100/nL) was noted in 19% of patients. Rapid blast cell clearance occurred within 1 week of treatment in the majority of patients. It is noteworthy that the peripheral blood response did not necessarily correspond with a bone marrow response. Median estimated time to progression for ALL patients was 2.2 months.[163] Despite the rapid development of relapse that occurs within weeks in many patients, some of these patients went on to SCT.[164] Response to imatinib therapy can be closely monitored by quantitative PCR.

Hematologic toxicity (grades III and IV) was frequent but was rarely associated with serious infectious or hemorrhagic complications. Nonhematologic toxicity attributed to imatinib consisted primarily of mild-to-moderate gastrointestinal discomfort, peripheral and facial edema, and muscle cramps and was readily manageable. No patient discontinued therapy because of nonhematologic adverse events. There were no imatinib-related deaths. Therefore, imatinib was well tolerated even in heavily pretreated patients.

Imatinib in the Treatment of Ph-Positive Acute Lymphocytic Leukemia

In younger patients, imatinib was first administered between chemotherapy cycles. However, with this approach, no molecular remissions were achieved. Therefore, studies with parallel application of chemotherapy and imatinib were started, leading to CR rates above 91% to 96% and molecular CR rates of 38% to 50%.[52,165–167] All studies reported an improved OS rate of 55% to 65% compared to 15% in studies before the imatinib era. No trial described increased toxicity compared to chemotherapy alone or negative effects on subsequent SCT.

In older patients with de novo Ph+ ALL, treatment results have been previously extremely poor with particularly high induction mortality. Therefore, induction chemotherapy was replaced by single-drug therapy with imatinib. The remission rate was 92% in an Italian trial.[168] The German study group (GMALL) conducted a randomized trial comparing dose-reduced chemotherapy and imatinib monotherapy. After induction, all patients received chemotherapy combined with imatinib. The remission rate for the imatinib arm was 93% compared to 54% with chemotherapy.[169] The survival was superior to that in previous trials without imatinib, but in both arms, the relapse rate was high, and there was no difference in outcome.

At present, a combination of chemotherapy and imatinib is the standard of the treatment of younger patients with Ph+ ALL. Patients are still referred for SCT in CR1 if possible. In elderly patients, imatinib monotherapy for induction seems reasonable, at least if a rapid response is observed. However, it remains unknown whether the high relapse rate can be decreased by a combination of imatinib with mild chemotherapy during induction or by intensification of consolidation. Furthermore, transition to the use of treatment with other tyrosine kinase inhibitors in case of molecular relapse or detection of mutations of BCR/AB2 (see later discussion) is important.

Imatinib and Allogeneic Stem Cell Transplantation in Ph-Positive Acute Lymphocytic Leukemia

It is known that MRD after SCT in Ph+ ALL is associated with a relapse probability exceeding 90%. Starting imatinib in the setting of MRD could decrease this high relapse rate. In a prospective study that was conducted by the GMALL, 27 Ph+ ALL patients received imatinib on detection of MRD after SCT. MRD became undetectable in 52% of patients after a median of 1.5 months. Each of these patients remained in remission at least for the duration of imatinib treatment. Failure to achieve MRD negativity shortly after starting imatinib predicted relapse, which occurred in 92% of these patients after a median of 3 months. LFS rate was 91% after 1 year in the molecular responders compared to 8% in the nonresponders.[170]

It remains unknown whether imatinib should be started in all patients after SCT or only in case of MRD detection. In any case, continued MRD-positivity after 2 to 3 months of imatinib identifies patients who will ultimately experience relapse and in whom additional or alternative antileukemic treatment should be initiated.

Mechanisms of Resistance to Imatinib

MRD detection often leads to early detection of molecular resistance or molecular relapse. Additional treatment can then be initiated before overt relapse occurs. Nowadays, an additional search for mutations of the tyrosine kinase domain of BCR/ABL is required, since these mutations can confer resistance to imatinib and partly to the second-generation tyrosine kinase inhibitors dasatinib and nilotinib.[171,172] Both drugs have increased efficacy in comparison to imatinib and are active in the majority of mutations, with the exception of the T315I mutation. The remission rate that is achieved with these drugs in patients who fail imatinib is approximately 30%. These second-generation drugs are currently being evaluated in patients who have relapsed, but trials for de novo Ph+ ALL are starting.

New Cytotoxic Drugs

In the past 10 years, a variety of new drugs has been developed for use in ALL (reviewed by Pui and Jeha,[83] Thomas,[84] and Gökbuget and Hoelzer[85]). Nelarabine is a purine analog that acts specifically on T-lymphoblasts, with a remission rate between 30% and 40% in relapsed T-ALL.[132,173] Treatment was generally well tolerated, although neurotoxicity occurred in some patients. At present, application of nelarabine in frontline therapy is being evaluated. BCX1777 (forodesine) is an inhibitor of the enzyme purine nucleoside phosphorylase and thereby acts similarly to purine analogs.[146] Clofarabine is a purine analog without subgroup specific effects. Other new drugs are liposomal preparations that might improve feasibility of treatment, for example, liposomal vincristine, daunorubicin, or liposomal cytarabine for intrathecal application.

FUTURE RISK STRATIFICATION AND TREATMENT CONCEPTS FOR ADULT ACUTE LYMPHOCYTIC LEUKEMIA

The treatment of adult ALL has already become more sophisticated and complicated and will be even more so in the future. Treatment strategies depend on factors that are unrelated to the disease, such as the availability of a stem cell donor, patient-related factors, disease markers, treatment response, and availability of targeted drugs. Prognostic factors and patient characteristics therefore no longer serve only as the basis for identification of candidates for SCT in CR1 but also define individualized treatment approaches, which are discussed in the following examples:

- *Subgroup-adjusted and targeted treatment*: Targeted drugs such as tyrosine kinase inhibitors, subgroup-specific purine analogs such as nelarabine, or monoclonal antibodies such as CD20 in mature B-ALL are used to increase subgroup-specific activity of treatment. These approaches have already led to significant improvement of outcome and will be refined in the future.
- *Age-adapted treatment*: In ways that are similar to subgroup-adapted treatment, therapies have to be defined for patients at both ends of the age spectrum: elderly and adolescent patients. In elderly

patients, the major focus is on effective targeted therapy with as much quality of life as possible, whereas in adolescents, the major aim is to deliver time- and dose-intensive chemotherapy based on pediatric protocols.

- *Individualized treatment*: New methods offer the option to adopt intensity and duration of therapy to individual response as measured by the presence of MRD or to add or omit specific drugs according to results of an evaluation for drug resistance.
- *New integrated risk classification*: A variety of molecular markers that have been newly detected by microarray analysis have been proposed as prognostic factors.[174] They might possibly be integrated in a conventional risk model that aims to identify patients for SCT in CR1 and might rather stimulate analysis of underlying mechanisms, drug targets, or invention of treatment adaptations.
- *Risk-adapted indications for SCT*: Indications for SCT have to be defined carefully, taking into account not only long-term results but also acute and long-term toxicities into account. At present, the majority of study groups stick to risk-adapted indications for SCT.
- *Evaluation of new cytostatic drugs*: Many of these drugs fit in subtype-adjusted, targeted therapies. Taking the number of targets and drugs into account, evidence-based priorities for clinical evaluation in relapsed ALL and for integration in frontline therapy have to be set.

Risk- and subtype-adjusted treatment strategies have led to considerable improvement in outcome in patients with mature B-ALL, T-ALL, and Ph+ ALL but less improvement in adult patients with B-precursor ALL. Future strategies will integrate a variety of additional factors, thereby resulting in a more complex, flexible, and patient-specific treatment approach.[85] Besides these sophisticated approaches, a better adherence to protocols, support of patients to improve their compliance, and documentation of compliance would be warranted in adult ALL. Treatment should be done at experienced centers, and closer cooperation between internal medicine and pediatric physicians, including cooperative studies, would be desirable.

The design of prospective trials will be challenging, since they will focus on even smaller subgroups of ALL and phase I studies with new drugs. These trials will be possible only in larger, international study groups that are able to recruit sufficient patient numbers. To enable any intergroup comparison, international efforts similar to that utilized to study childhood ALL are required to define uniform criteria for diagnostic classification, definition of subgroups, and even prognostic factors.

104 Acute Myeloid Leukemia in Adults

Frederick R. Appelbaum

SUMMARY OF KEY POINTS

Epidemiology and Etiology

- The incidence of acute myeloid leukemia (AML) in adults is 3 cases per 100,000 population per year in the United States.
- Incidence increases with age; median age at diagnosis is 60 years.
- Known causes of AML include exposure to benzene or ionizing radiation and previous chemotherapy; AML also is associated with a few uncommon inherited syndromes.

Tumor Biology

- AML is a clonal disease arising in a primitive hematopoietic progenitor cell.
- Leukemogenesis is a multistep process requiring some mutations that block differentiation and others that promote proliferation.

Diagnosis and Classification

- Diagnosis requires greater than 20% blasts of myeloid origin in marrow or peripheral blood.
- The 2002 World Health Organization (WHO) classification recognizes four categories of AML: (1) AML with recurrent genetic abnormalities; (2) AML with multilineage dysplasia; (3) AML and myelodysplastic syndrome (MDS), therapy-related; (4) AML not otherwise categorized.
- Cytogenetics is the most powerful single indicator of outcome, and cases can be defined as favorable, intermediate, or unfavorable according to cytogenetic subtype. Translocation t(15;17) is diagnostic of acute promyelocytic leukemia (APL), the M3 subtype of AML in the French-American-British (FAB) classification (see Table 104-3), which requires a very specific form of therapy.

Treatment

- Younger patients with non-M3 AML
  - *Induction*—Anthracycline plus cytarabine induces complete remission in approximately 70% of patients.
  - *Postinduction therapy*—In patients with good-risk disease, treatment with repetitive doses of cytarabine is associated with greater than 50% cure rates. In patients with intermediate-risk disease, treatment consists of either continued chemotherapy or hematopoietic cell transplantation (HCT). Patients with poor-risk disease should receive transplantation in first remission if possible.
- Older patients with non-M3 AML
  - *Induction*—Anthracyclines plus cytarabine will induce complete remission in 50% of patients.
  - *Postinduction therapy*—Continued chemotherapy may cure 15% of patients.
- Patients with APL
  - All-*trans*-retinoic acid (ATRA) should be added to the induction regimen and used as maintenance, with an expectation of cure in two thirds of patients.

INTRODUCTION

AML is the result of a genetic event or series of events occurring in an early hematopoietic precursor that both blocks differentiation and allows uncontrolled proliferation. The abnormally proliferating leukemic cells accumulate in the marrow space, eventually replacing normal marrow progenitors, with consequent diminished production of red cells, white cells, and platelets. This, in turn, leads to the common clinical manifestations of AML—namely, anemia, infection, and bleeding. As the disease progresses, leukemic blasts pour into the bloodstream, leading to the "weisses Blut" described by Virchow in 1845.[1] Eventually, the leukemic cells accumulate in the spleen, lung, brain, and other vital organs. If left untreated, AML is rapidly fatal, with most patients dying within a few months of diagnosis. With appropriate treatment, however, a substantial proportion of patients can be cured. Remarkable growth in our understanding of AML has occurred over the past decade. One of the major lessons arising from this new knowledge is the complexity of the leukemic process—a lesson that can be daunting but one that also provides multiple new targets for prevention, detection, and treatment.

EPIDEMIOLOGY AND ETIOLOGY

Incidence

Approximately 35,000 Americans were diagnosed with leukemia in 2005.[2] Of these, AML developed in 32%, chronic lymphocytic leukemia (CLL) in 26%, chronic myeloid leukemia (CML) in 15%, and acute lymphocytic leukemia (ALL) in 11%; the remaining 16% had unclassified types. The male-to-female ratio is approximately 1.3 : 1. The incidence of AML is constant during the first 30 years of life but then begins to increase almost exponentially (Fig. 104-1). The overall incidence of leukemia in the United States has remained stable over the last 30 years.[3]

Geographic Clustering

Although leukemic clusters within a given geographic area occasionally have been described, no compelling studies suggest that these represent more than chance events.

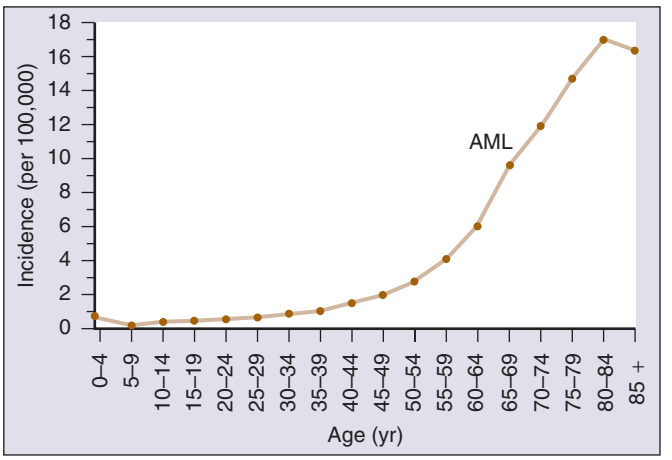

Figure 104-1 • Age-related incidence of acute myeloid leukemia (AML). The incidence is relatively stable until the age of 30 years and then increases dramatically.

Etiologic Agents and Associations

Viruses

A clear association of human T-cell leukemia virus infection with an adult form of T-cell leukemia has been recognized. No relationship between any viral infection and the development of AML, however, has been confirmed.

Carcinogens

Heavy benzene exposure is associated with the development of aplastic anemia, myelodysplasia, and AML.[4] Most studies examining the issue find a small but consistent increase in AML among cigarette smokers.[5] Survivors of the atomic bomb explosions of Hiroshima and Nagasaki in 1945 demonstrated an increased risk of all leukemias except CLL, which began as early as 1.5 years after the explosions, peaked at approximately 7 years, and returned to baseline by 1970.[6] Other evidence that ionizing radiation is leukemogenic comes from the 10-fold increased risk of AML among persons who received radiation treatment for ankylosing spondylitis in the 1930s and the 1940s.[7]

Treatment-Related Acute Myeloid Leukemia

With the increasing use of irradiation and chemotherapy to treat malignancies, the incidence of treatment-related AML has grown. It is estimated that perhaps 6% to 10% of cases of AML are treatment-related.[8] These can be grouped in several relatively distinct syndromes. AML developing after exposure to alkylating agents has a latency of 5 to 6 years, often first appears as an MDS, and frequently is associated with chromosomal abnormalities involving the long arm of chromosome 5 or 7. This association was first appreciated in the 1970s in patients who had previously received alkylating agents with or without irradiation as treatment for lymphoma.[9] Alkylating agent–induced AML has been noted in patients who received nitrogen mustard for treatment of Hodgkin's disease, in women in whom melphalan or cyclophosphamide was used to treat ovarian cancer, and in patients whose treatment for colorectal cancer included chloroethylnitrosourea.[10–15] All alkylating agents probably are leukemogenic, with risk increasing with cumulative dose.[16]

Treatment with topoisomerase II inhibitors also increases the risk for development of AML. In contrast with the leukemias seen after exposure to alkylating agents, these leukemias develop relatively rapidly (often within 2 years), generally are not preceded by a myelodysplastic phase, and frequently are associated with chromosomal rearrangements involving 11q23, the locus for *MLL* (the mixed-lineage leukemia gene), or 21q22.[17] The epipodophyllotoxins etoposide and teniposide fall in this category; with these drugs, the risk of developing secondary AML appears to be dose-related and may increase when methotrexate or cisplatin also is administered.[18,19] The anthracyclines also are topoisomerase II inhibitors, and their use—particularly when they are given with cyclophosphamide in dose-intensive regimens—has been associated with the subsequent development of AML.[20]

Patients with non-Hodgkin's lymphoma treated using autologous HCT appear to be at increased risk for the development of secondary AML, with cumulative incidence rates as high as 15% reported in some series.[21,22] Leukemias typical of previous exposure to both an alkylating agent and a topoisomerase II inhibitor have been reported. Recent registry data demonstrate that the risk of MDS or AML after autologous HCT is predicted largely by the type and intensity of chemotherapy received by the patient before transplantation. This observation raises some questions about the exact contribution of the transplantation procedure itself to the development of secondary AML.[23] Bimolane, a dioxopiperazine derivative used for the treatment of psoriasis, has been associated with the development of APL.

Not all secondary leukemias fall into the discrete categories described here. Secondary leukemias with inv16, t(9;22), and abnormalities involving 3q21 have been reported.[24] Not every leukemia developing in patients who have received radiation therapy or chemotherapy is necessarily due to that therapy. In fact, a significant elevation in risk for AML has been observed among patients with a previous malignancy treated only with surgery, suggesting a genetic or other predisposition.[25]

Ethnic Differences

APL has been reported to be more common among Hispanic populations in the Los Angeles area than in the general population.[26] A similar increased incidence has been reported in Spain.[27]

Familial Clustering

The concordance rate of leukemia in identical twins is virtually 100% if leukemia develops in one twin before the first year of life, but the rate then declines with age.[28] In a large comprehensive study of proband effects in Utah, using data from 125,000 patients with cancer, the relative risk of leukemia among first-degree relatives of probands with leukemia was 5.69, strongly suggesting that complex genetic factors may influence the development of leukemia in later life.[29] Several single-gene leukemia syndromes also have been described, including an autosomal recessive syndrome of childhood-onset myelodysplasia with monosomy 7 and a familial syndrome of erythroleukemia.[30,31] A familial syndrome of an aspirin-like platelet disorder with thrombocytopenia and propensity for the development of AML is due to germline mutations in the RUNX-1 (formerly AML-1) gene.[32] Nearly all of these autosomal dominant leukemia syndromes (with the exception of the RUNX-1 syndrome) demonstrate anticipation with declining age at onset with each generation.

Constitutional Chromosomal Abnormalities

Children with trisomy 21 (Down syndrome) have an increased risk for development of leukemia, with M7 AML seen in early childhood and ALL predominating in later years. Trisomy 8 mosaicism is a rare constitutional abnormality with features of mental retardation, multiple developmental defects, and an increased incidence of myeloid leukemias.

Genetic Syndromes Associated with Acute Myeloid Leukemia

Several DNA-repair syndromes are associated with an increased incidence of AML. *Bloom's syndrome* is a disorder of autosomal recessive inheritance resulting from mutations in the gene encoding a DNA helicase at 15q21.1 and is characterized by growth retardation, characteristic facial appearance, immunodeficiency, and, in 25% of

patients, hematologic malignancies including AML.[33] *Ataxia-telangiectasia*, inherited as an autosomal recessive trait, is due to mutations in the *ATM* gene at 11q22–23, which results in deficiencies in the G_1-S checkpoint. Features of this disorder may include progressive cerebellar ataxia, telangiectatic skin lesions, and malignancies that more often are of lymphoid than of myeloid origin.[34] *Fanconi's anemia* is a syndrome of autosomal recessive inheritance characterized by pancytopenia and a variety of developmental disorders that include skeletal abnormalities (most notably, hypoplastic thumbs) and short stature. Exposure of cells from these patients to mitomycin C or diepoxybutane results in excess chromosome breaks. In almost 50% of patients with Fanconi's anemia, myelodysplasia or AML develops by the age of 40 if death from other causes does not occur first.[35] As indicated by chromosome complementation studies, at least eight different genes can result in this syndrome.

The tumor suppressor gene syndromes *Li-Fraumeni syndrome* and *neurofibromatosis 1* are associated with an increased risk of AML, but the exact extent of increased risk is unclear. Several congenital cytopenia syndromes are associated with a definite increased risk of AML: *Blackfan-Diamond syndrome* is characterized by congenital hypoplastic anemia, growth retardation, and a definite increase in AML. *Severe congenital neutropenia*, also sometimes called *Kostmann's syndrome*, results in myelodysplasia or AML in 10% to 20% of affected persons who do not first succumb to infection.[36] *Schwachman syndrome* is a disease of autosomal recessive inheritance characterized by pancreatic insufficiency, moderate dwarfism, and a hematologic picture resembling that in Fanconi's anemia.[37]

TUMOR BIOLOGY

Pathophysiology

Clonality

AML is a clonal disorder, with all leukemic cells in a given patient descending from a common progenitor. The initial proof of the clonality of AML came from studies of the disease in females who were heterozygotic for the X-linked glucose-6-phosphate dehydrogenase (G6PD) isoenzymes. In normal heterozygotic women, because of random X chromosome inactivation, any single blood cell will express one or the other isoenzyme, and hematopoietic cells overall will be a 50–50 mix. Leukemia cells in *G6PD*-heterozygotic females, however, were found in every case to be all of one isoenzyme or the other, indicating their origin from a single precursor.[38] With the development of methods to detect X-chromosome-linked DNA polymorphisms on a broader scale, it has since become possible to assess the clonality of leukemia in virtually any female patient. Such studies have demonstrated differing patterns of clonal involvement among patients so that in some (generally younger) patients, only the frankly myeloid leukemic blasts are clonal, whereas in other (often older) patients, normal-appearing monocytes, platelets, and red cell precursors also may be of clonal origin.[39] Studies of clonality also have given the surprising result that some patients in whom treatment achieves complete remission with recovery of entirely normal-looking hematopoiesis—including loss of a leukemic chromosome marker—may still have clonal hematopoiesis, a result consistent with the hypothesis of a multistep pathogenesis for AML.[40,41]

Cell of Origin

The clonal nature of AML suggests that there is a leukemic stem cell capable of both self-renewal and proliferation. Identification of the AML stem cell is of considerable interest both for aiding in our understanding of the disease and because this cell would represent the ideal target of therapy. Recognition of cases of AML with blasts of various degrees of differentiation has given rise to two general hypotheses. In one model, progenitor cells at various levels of commitment and differentiation all are susceptible to transformation, leading to considerable heterogeneity in AML stem cells. In an alternative model, only very undifferentiated hematopoietic stem cells are capable of being transformed, but based on the particular mutations involved, some degree of further commitment and differentiation of the leukemic cell is possible. Recent studies attempting to identify the AML stem cell based on the cell's ability to transfer human leukemia to an immunodeficient (NOD-SCID) mouse are more consistent with the latter hypothesis. In human AML, when patients are tested to determine which fraction of cells is able to initiate leukemia in the NOD-SCID mouse, it is only the primitive $CD34^{++}CD38^{-}$ fraction that is able to do so, regardless of the differentiative stage of leukemic blasts.[42,43] The leukemias that subsequently develop in the animals have the same level of differentiation as for the leukemias from which the $CD34^{++}CD38^{-}$ blasts are derived, suggesting that these leukemic clones are capable of some genetically determined degree of differentiation. The $CD34^{++}CD38^{-}$ AML stem cells are at the same level of differentiation as for the normal hematopoietic stem cell capable of engrafting NOD-SCID mice and are rare cells among the leukemic mass, with a frequency of 0.2 per 10^6 to 100 per 10^6 cells. APL could represent an exception to this general model, and APL blasts do not easily engraft in NOD-SCID mice.[43]

Cell Kinetics

Available data suggest that it is the persistence rather than the speed of proliferation that leads to the outgrowth of AML. Only a small fraction of leukemic cells are in cycle at any given time, and the cell cycle duration is, in fact, longer than that of normal hematopoietic cells.[44] An unfortunate but instructive case is that of a woman with CML who, after an ablative preparative regimen, received a marrow transplant from her HLA-matched brother. Although the brother's routine pretransplantation workup was negative, the transplanted marrow was later found to contain 38% AML blasts with t(1;5). In a somewhat surprising turn of events, engraftment with normal male hematopoiesis occurred, and the patient did not show evidence of her brother's disorder until 6 months after transplantation.[45]

Marrow Failure

Although the persistent growth of the AML clone leads to marrow failure at least in part by physically crowding out normal progenitors, other mechanisms of suppression of normal marrow probably exist. Frequently, peripheral blood counts start to fall weeks or months before the appearance of leukemic blasts in the marrow, and cases of hypoplastic AML are not uncommon. The mechanisms by which suppression of normal hematopoiesis occurs are not well understood.

Molecular Pathology

The identification of recurrent chromosomal abnormalities—which can include translocations, point mutations, and gene duplications in AML—followed by the cloning of many of the involved genes has provided important insights into the pathogenesis of the disorder. The number of recurrent abnormalities so far identified is in the hundreds, a fact that would make it seem almost futile to attempt to make sense of such a wide range of abnormalities. With further investigation, however, it is becoming clear that many of these abnormalities tend to affect a limited number of transcriptional or signal transduction pathways. Of those abnormalities that have been studied extensively, most are pro-oncogenic and are not simply innocent bystanders in the leukemic process. Only a few of these abnormalities are both necessary and sufficient to cause leukemia in murine models, however—suggesting that multiple mutations are required for development of overt leukemia. A particularly useful model argues that most cases of AML have one mutation that results in differentiation blockade together with a second mutation that results in inappropriate proliferation.[46] Some of the more common and better understood molecular categories of AML are described next.

Core Binding Factor Translocations

Core binding factor (CBF) is a heterodimeric transcription factor made up of two subunits, CBFα (also known as RUNX-1 or AML-1) and CBFβ. CBF plays an important role in the transcriptional activation of a number of genes required for normal hematopoietic differentiation (Fig. 104-2). A number of leukemias are associated with translocations or mutations that involve the components of CBF.

RUNX-1/MTG8

The t(8;21) abnormality seen in approximately 8% of cases of adult AML results in the fusion of the RUNX-1 (CBFα) gene on chromosome 21 to the MTG8 (formerly ETO) gene on chromosome 8.[47] The RUNX-1/MTG8 fusion protein acts as a dominant negative inhibitor of the wild-type RUNX-1 gene, meaning that presence of the RUNX-1/MTG8 fusion protein blocks the ability of the wild-type RUNX-1 from the remaining nontranslocated chromosome to activate appropriately the transcription required for normal hematopoietic differentiation[48] (see Fig. 104-2). The RUNX-1 "knockout" mouse and the RUNX-1/MTG8 "knockin" mouse have identical phenotypes, with embryonic death at day 11.5 and a characteristic pattern of central nervous system (CNS) hemorrhage and lack of hematopoiesis. AML characterized by t(8;21) is associated with a favorable prognosis.

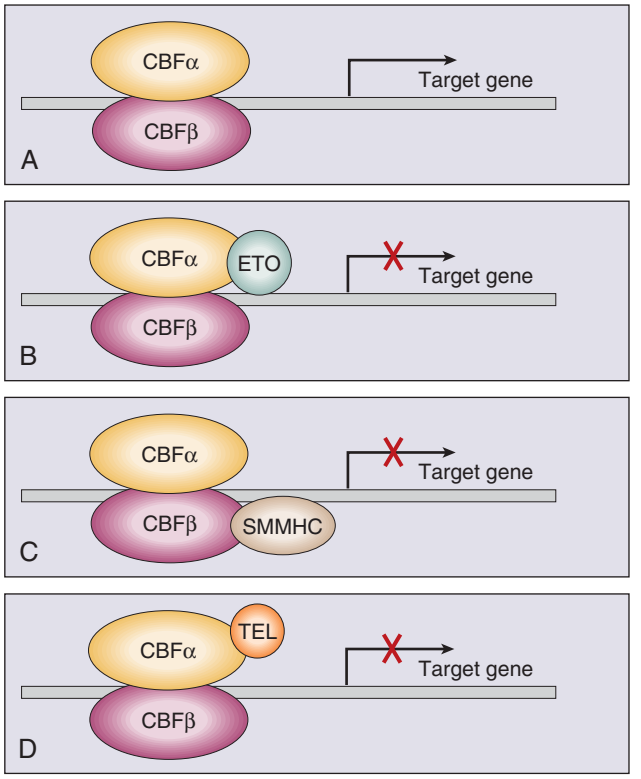

Figure 104-2 • **A,** CBFα and CBFβ form a heterodimeric transcription factor that regulates a spectrum of genes important in hematopoiesis, including those for IL-3, GM-CSF, and others. **B,** If instead of normal CBFα, the fusion product CBFα-ETO (now CBFα-MTG8) dimerizes with CBFβ, the transcription factor does not function, and target genes are not transcribed. **C,** The fusion product CBFβ-SMMHC is a dominant-negative regulator of gene transcription. **D,** Analogous to the situation with CBFα-ETO, the fusion product CBFα-TEL is a dominant-negative regulator of normal CBF function. CBF, core binding factor; GM-CSF, granulocyte macrophage colony stimulating factor; IL-3, interleukin-3.

Inv(16)

Inv(16)(p13;q22) and t(16;16)(p13;q22) both result in the fusion of the CBFβ gene at 16q22 to the smooth muscle myosin heavy chain gene (*MYH11*) at 16p13[49] (see Fig. 104-2). As in the case of t(8;21), the resultant fusion protein acts as a dominant-negative regulator of transcription. CBFβ/MYH11 knockin mice have a phenotype identical to those noted for RUNX-1 knockouts and RUNX-1/MTG8 knockins. AML with involvement of 16q22 accounts for approximately 9% of adult AML cases, is associated with a unique myelomonocytic morphology, and, like t(8;21) leukemias, carries a favorable prognosis.

TEL-RUNX-1

In up to 25% of cases of pediatric pre-B-cell ALL, a t(12;21) abnormality fusing the TEL gene with the RUNX-1 gene can be found[50] (see Fig. 104-2).The resultant fusion protein appears to function as a dominant-negative regulator of transcription. In general, this translocation is associated with a favorable prognosis in childhood ALL.

Point Mutations

Point mutations in the RUNX-1 gene occur in 3% to 5% of sporadic cases of adult AML.[51,52] In addition, as noted earlier, inherited point mutations resulting in RUNX-1 haploinsufficiency are found in families with familial platelet disorder and a high prevalence of subsequent AML.[32] The fact that AML does not always develop in these patients, or does so only after years, suggests that subsequent mutational events are required.

The mechanisms by which t(8;21), inv(16), and t(12;21) fusion proteins exert their dominant-negative effects are only now becoming understood. Recent data suggest that segments of the fusion protein recruit nuclear co-repressor (NCoR)–histone deacetylase (HD) complexes in a matter analogous to that seen in APL, as is discussed shortly. The specific pattern of transcriptional suppression probably differs for each fusion product, as suggested by the somewhat different phenotypes associated with each.

Retinoic Acid Receptor-α Gene Translocations

APL, which accounts for approximately 8% of cases of adult AML, is almost always associated with t(15;17)(q22;q11.2), a translocation that fuses the promyelocytic leukemia (*PML*) gene on chromosome 15 to the retinoic acid receptor-α (*RARα*) gene on chromosome 17. The resultant PML/RARα fusion product acts as a dominant-negative inhibitor of normal PML function and of the function of RXRα, an important heterodimeric partner of PML[53] (Fig. 104-3). PML/RARα recruits a nuclear co-repressor (NCoR) and the molecules sin3 and HD. HD deacetylates histones, a process that in turn inhibits binding of transcription factors, thereby inhibiting the expression of genes required for hematopoietic differentiation. The unique activity of ATRA in APL appears to be explained by its ability to bind to the PML/RARα fusion protein, changing its configuration and releasing the attached nuclear co-repressor (see Fig. 104-3). This then allows subsequent transcription and gene expression. Transgenic expression of the PML/RARα fusion protein in mice results in APL in a fraction of animals after a latency period of some months. The relatively long latency and incomplete penetration suggest that, as with many other leukemias, multiple mutations are required for the full development of overt APL.

A number of other translocations, including t(5;17) and t(11;17), involve the RARα gene and result in the APL phenotype. These leukemias generally are unresponsive to ATRA because clinically achievable concentrations of the drug do not result in release of the NCoR-HD complex.

C/EBPα Gene Mutations

Transcription factor CCAAT/enhancer-binding protein-α (C/EBPα) is mutated in 6% to 10% of patients with AML.[54] C/EBPα is required

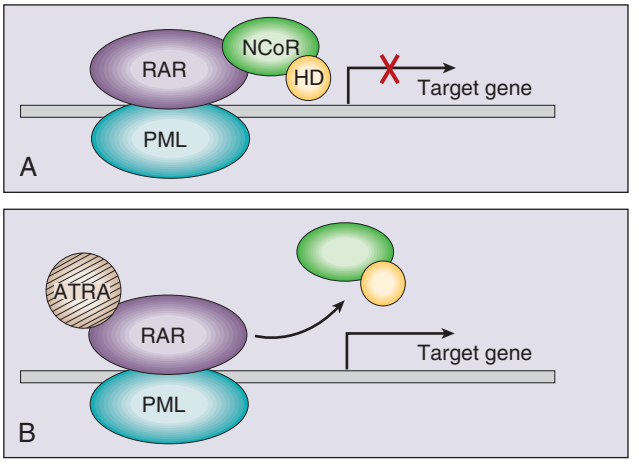

Figure 104-3 • **A,** The abnormal fusion product PML-RARα binds a nuclear co-repressor (NCoR)-histone deacetylase (HD) complex. This deacetylates histones in the region, leading to inhibition of transcription. **B,** When ATRA binds to RAR, a change in confirmation leads to release of the NCoR-HD complex, acetylation of histones, and resumption of transcription. ATRA, all-*trans*-retinoic acid; RAR-PML, retinoic acid receptor-promyelocytic leukemia protein.

for normal granulocyte differentiation, and c/ebpα-null mice lack neutrophils and eosinophils. In humans, C/EBPα gene mutations presumably result in abnormal DNA binding and loss of normal myeloid differentiation. AML cases characterized by C/EBPα gene mutations tend to demonstrate M1 or M2 morphology, with intermediate-risk cytogenetics and a favorable clinical outcome.

Mixed-Lineage Leukemia Mutations

Most nonrandom chromosomal abnormalities are associated with specific lineages or subtypes of leukemia, but abnormalities involving the mixed-lineage leukemia gene (*MLL*) located on 11q23 are exceptions, with many partner genes and many forms of hematologic malignancy including ALL, AML, and lymphoma. Altogether, translocations involving 11q23 account for approximately 7% of adult AML cases, and among these, t(9;11)(p22;q23), associated with acute monoblastic leukemia, is the most common.[55,56] The translocation fuses *MLL* with *AF9*, and leukemia invariably develops in mice with this fusion gene knockin.[57] Other *MLL* translocations seen in AML include t(6;11), t(10;11), t(11;17), and t(11;19). It also has been reported that as many as 10% of patients with AML and normal cytogenetics have tandem duplications of *MLL*.[58]

The human *MLL* gene has considerable homology with the *Drosophila* trithorax gene, a complex gene that regulates the transcription of other genes necessary for normal *Drosophila* development. The exact function of MLL in vertebrates is not entirely understood, but its structure suggests capability of minor groove DNA binding. Gene disruption experiments have shown that *MLL* positively regulates homeodomain (Hox) genes in mice and thus, like the trithorax gene, is required for normal development. Knockout mice die as embryos and demonstrate reduced hematopoiesis, suggesting that the gene has, as one of its functions, a broad effect on early hematopoiesis.[59–61] A current hypothesis is that *MML* fusion proteins result in increased expression of *HOX* genes, with increased self-renewal of affected hematopoietic progenitors.

Tyrosine Kinase Receptor Mutations

FLT1, *FLT3*, *FMS*, *KIT*, and *PDGF* are members of a family of genes encoding receptor tyrosine kinases, each with an extracellular ligand–binding domain, transmembrane and juxtamembrane domains, and an intracellular domain with tyrosine kinase activity. In general, ligand binding with the receptor causes receptor dimerization, autophosphorylation, and then subsequent phosphorylation activation of adaptive proteins (including GRB-2), which in turn activate Ras and other proteins.

FLT3 is mutated in 30% to 35% of patients with AML.[62,63] A majority of these are internal tandem duplications, but approximately one fourth of the mutations are in the form of point mutations. Both forms of mutations are activating. When inserted into murine cell lines, these mutations result in factor-independent growth.[64] Retroviral transmission of these mutations into mouse marrow is not, by itself, sufficient to cause overt AML but does lead to a myeloproliferative phenotype.[65] In clinical studies, the incidence of *FLT3* mutations in AML appears to increase with age and to be associated with high white blood cell (WBC) counts at diagnosis and poorer clinical outcome.[63,66,67] The negative impact of *FLT3* mutations apprears to increase with increasing size of the duplication and with higher allelic ratios of mutated to wild-type genes in leukemic blasts.[68,69] Clinical trials of small-molecule inhibitors of *FLT3* are ongoing.

Mutations in other receptor tyrosine kinase genes also are sometimes seen in AML. Point mutations in *FMS* have been reported in 10% to 20% of cases.[70] Point mutations, deletions, or insertions of *KIT* also have been reported in a small percentage of patients.[71] Mutations in one or another receptor tyrosine kinase are found in almost half of all AML cases.

RAS Mutations

Ras is a monomeric guanosine diphosphate-binding protein activated by various tyrosine kinases. Activation of Ras has multiple and varied effects, which, depending on the target cell and its particular state, can result in proliferation, transformation, or differentiation. *RAS* mutations have been identified in 15% to 30% of cases of AML.[72,73] In most cases, these mutations result in prevention of hydrolysis of Ras guanosine triphosphate (GTP), effectively keeping Ras in the "on" position. Thus, therapies to inhibit Ras function have been developed. To function normally, newly transcribed Ras must have a farnesyl or geranylgeranyl lipid attached, and for this reason farnesyl transferase inhibitors have been explored as therapeutic agents in AML.[74]

NPM1 Mutations

NPM1 encodes an abundant nucleolar phosphoprotein with multiple hypothesized functions. Heterozygous mutations usually involving the C-terminus at exon 12 have been detected in approximately 30% of cases of AML. Mutations in *NPM1* are seen more frequently in AML cases with monocytic differentiation, lack of CD34, normal cytogenetics, and *FLT3* mutations. Among patients with normal cytogenetics, presence of an *NPM1* mutation appears to be associated with a better prognosis, particularly among those without an *FLT3* mutation.[75,76]

Mutations Involving 5q, 7q, and 20q

AML evolving from myelodysplasia or developing from exposure to alkylating agent therapy frequently is associated with partial or complete loss of chromosomes 5, 7, and 20. The frequent loss of 5q, 7q, or 20q has led to the hypothesis that a classic tumor suppressor gene may exist in these areas. With classic tumor suppressor genes such as *RB*, when one allele is deleted, a mutation in the second results in disease. Despite considerable efforts to identify such genes, however, no classic tumor suppressor of AML in these regions has been reported.

PATHOLOGY

Histopathologic Features

The diagnosis of AML generally is made by the examination of well-prepared peripheral blood and bone marrow specimens. For more than 3 decades, the French-American-British (FAB) system was used

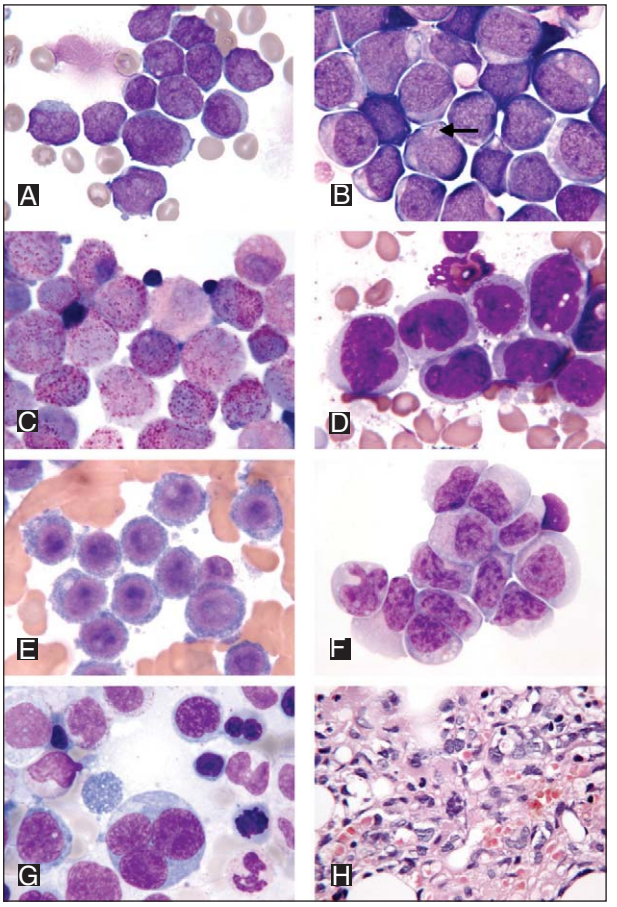

Figure 104-4 • The morphologic spectrum for the acute myeloid leukemias (AMLs) in bone marrow aspirates (**A-G**) and a marrow biopsy specimen (**H**). **A,** Acute myeloblastic leukemia with minimal (FAB AML-M0) or no (FAB AML-M1) maturation. The cells are myeloblasts with dispersed chromatin and variable amounts of agranular cytoplasm. Some display medium-sized, poorly defined nucleoli. **B,** Acute myeloblastic leukemia with maturation (FAB AML-M2). Some of the blasts contain azurophilic granules, and promyelocytes are evident. More mature neutrophils were present in other fields. Note the Auer rod *(arrow)*. **C,** Acute promyelocytic leukemia (FAB AML-M3). All of these cells are promyelocytes containing coarse cytoplasmic granules, which sometimes obscure the nuclei. **D,** Acute myelomonocytic leukemia (FAB AML-M4). Promonocytes with indented nuclei are present with myeloblasts. The dense nuclear staining is unusual. **E,** Acute monoblastic leukemia (FAB AML-M5a). These characteristic monoblasts have round nuclei with delicate chromatin and prominent nucleoli. Cytoplasm is abundant. Nonspecific esterase staining was intense *(not shown)*. **F,** Acute monocytic leukemia (FAB AML-M5b). Most of the cells in this field are promonocytes. Monoblasts and an abnormal monocyte also are present. **G,** Acute erythroid leukemia (FAB AML-M6). Dysplastic multinucleated erythroid precursors with megaloblastoid nuclei are present. **H,** Acute megakaryoblastic leukemia (FAB AML-M7). In this marrow biopsy specimen, large and small blasts and atypical megakaryocytes can be seen. FAB, French-American-British (Co-operative Group classification subtype).

to describe and classify AML, and according to this system, a finding of 30% blasts in marrow or peripheral blood was required to make the diagnosis.[77] More recently, a WHO classification suggests that a finding of 20% blasts is sufficient for this diagnosis.[78] AML blasts can be placed into the following categories on the basis of their appearance (Fig. 104-4):

- Minimally differentiated AML (FAB M0) blasts are nondescript. Without immunophenotyping, it is very difficult to identify these cells as being of myeloid origin.
- AML with differentiation (FAB M1) defines cases with sparse cytoplasmic granules, only occasional Auer rods, and positive myeloperoxidase staining.
- AML with maturation (FAB M2) is more clearly myeloid in origin, with increased cytoplasmic granules, clear myeloperoxidase positivity, and the frequent presence of Auer rods.
- APL (FAB M3) is characterized by intense cytoplasmic granulation that often obscures the nucleus. A microgranular variant exists with marked nuclear folding and only subtle cytoplasmic granulations. In both subtypes, blasts stain intensely with Sudan black or myeloperoxidase. M3 AML is invariably associated with t(15;17) or one of its variants.
- AML with myelomonocytic differentiation (FAB M4) often is characterized by dysplastic features, such as hypogranular cytoplasm and nuclear hyposegmentation. One subset associated with inv(16)(p13q22) is characterized by increased eosinophilia. In M4 AML, blasts stain positively with both myeloperoxidase and nonspecific esterase. Diagnosis of M4 AML is further strengthened by immunophenotyping demonstrating both myeloid and monocytic antigens.
- Acute monocytic leukemia (FAB M5) is characterized by blasts with folded nuclei and abundant cytoplasm that stains positively with nonspecific esterase but is myeloperoxidase-negative.
- AML (FAB M6), acute erythroid leukemia, may be associated with a variable appearance but usually is accompanied by dysplastic erythroid elements that, on occasion, can become the predominant cell type.
- The diagnosis of acute megakaryocytic leukemia (FAB M7) requires that more than 30% of blasts be of the megakaryocytic lineage. These blasts often display clumping, multinucleation, and cytoplasmic blebbing, but immunophenotyping is usually required to make the diagnosis.

Although in the past, considerable time and effort went into categorizing AML cases among these morphologic categories, morphology in fact has almost no significance once cytogenetic and (to a lesser extent) immunophenotypic information is taken into consideration.

Immunophenotype

AML cases can be categorized according to the combinations of myeloid-associated antigens displayed on the surface of the malignant blast. In undifferentiated AML cases, including FAB M0 cases, expression of CD34, CD117, and CD33 is characteristic, but the blasts tend not to express CD65s. In more mature AML types, including most cases of FAB M1 and M2, expression of CD34, CD33, CD13, and CD65s is seen. In leukemias associated with t(8;21), often with M2 morphology, an immunophenotype similar to that with other M2 AML types is present, but expression of the NK marker CD56 and the B lymphoid marker CD19 also is seen. In APLs, blasts uniquely stain strongly with CD15s and weakly with CD15. In addition, they usually do not express CD34 or HLA-DR. In acute myelomonocytic and monocytic leukemias, blasts express CD14, the prototypical monocytic antigen. Early myeloid markers, including CD34 and CD117, generally are absent. Myelomonocytic leukemias associated with inv(16) blasts frequently express the T-cell antigen, CD2. In most acute erythroid leukemias, blasts fail to express early myeloid markers (e.g., CD34) but do express CD36 and CD71 and often express blood group H antigen, the precursor to ABO. In acute megakaryocytic leukemias, blasts react with antibodies to CD41a/CD61 (GPIIb/IIIa). Mature platelets sometimes can adhere to the surface of M5 AML blasts, so that they appear as in M7 leukemias. In true M7 AML, however, expression of CD14 does not occur.

Cytogenetics

Cytogenetic analysis of human leukemias has been absolutely central to the identification of the genetic events involved in leukemogenesis.

In addition, cytogenetics has emerged as by far the single most important diagnostic factor in AML.

Conventional cytogenetics involves the staining of metaphase cells and thus requires dividing cells. Because malignant cells in the marrow are more frequent and have a higher mitotic rate, marrow, rather than peripheral blood, is the preferred source for cytogenetic analysis. Cells usually are cultured for 24 hours, with arrest by short-term incubation with colchicine; then, 20 metaphases typically are analyzed. The abnormalities detected include changes in chromosome number, gains or losses of portions of chromosomes, and reciprocal exchange of genetic material either between two or more chromosomes (translocations) or within a single chromosome (inversions).

Two other molecular techniques sometimes are used. Fluorescence in situ hybridization (FISH) techniques involve hybridization of single-stranded DNA probes to homologous single-stranded sequences in chromosomes of metaphase or interphase cells. FISH has the advantage of being able to analyze large numbers of dividing (metaphase FISH) or nondividing (interphase FISH) cells with relatively little effort. Only those abnormalities targeted by the specific probe being applied will be detected, however. Thus, FISH is very useful for monitoring the disappearance or reappearance of a specific translocation—for example, t(9;22) in CML—but is not a substitute for conventional cytogenetics for initial evaluation of AML. Polymerase chain reaction (PCR) is a method capable of amplifying selected regions of DNA through repeated cycles of DNA synthesis, denaturation, and hybridization. To use PCR analysis, the specific gene sequences to be amplified must be known. Standardized PCR assays for several of the more common fusion gene transcripts have been developed and are proving useful for monitoring minimal residual disease.

A listing of the most common cytogenetic abnormalities seen in adult AML is provided in Table 104-1. These abnormalities can be categorized according to underlying tumor biology and also prognostic significance (Fig. 104-5). Table 104-1 organizes these abnormalities according to biologic subgroups. Thus, t(8;21), t(16;21), inv(16), and t(16;16) all belong to the core binding factor leukemias. The abnormalities t(4;11), t(9;11), and del(11)(q23) constitute most of the MLL family of AML types. Leukemias involving the RARα gene include t(15;17), t(11;17), and t(5;17), whereas t(6;9) involves the fusion of the DEK and CAN genes. The EVI 1 gene is involved in inv(3) and t(3;3). Monosomy or interstitial deletions of chromosomes 5, 7, 17, and 20 are typical of AML evolving from MDS or developing after previous alkylating agent exposure. Trisomy 8 is quite common in AML and can appear as a sole abnormality or in combination with other abnormalities. By itself, trisomy 8 does not appear to influence prognosis, but when present it often is accompanied by other unfavorable risk cytogenetic abnormalities.[79] Trisomy 11, 13, and 21 also often are seen in AML.

A number of studies have analyzed the outcomes in patients with AML according to cytogenetics and have demonstrated that both complete remission rates and duration are strongly associated with pretreatment cytogenetics. In general, patients can be categorized as having a favorable, intermediate, or unfavorable cytogenetic risk status. Two of the largest prospective studies of adult AML were published by the Medical Research Council (MRC) and the Southwest Oncology Group (SWOG).[55,56] These studies concerned adults younger than 60 years of age with newly diagnosed AML treated using contemporary chemotherapy and transplantation approaches. As noted in Table 104-2, the two groups of patients reached very similar categorizations, with CBF and RARα leukemias defining the group with favorable risk status; "normal" leukemias and trisomy 8, the intermediate-risk group; and abnormalities of chromosomes 5 and 7 and complex abnormalities, the poor-risk group. Some controversy remains about whether 11q23 leukemias should be considered to reflect intermediate or unfavorable risk status. Overall, as noted in Table 104-2, 85% to 90% of favorable-risk, 75% to 80% of intermediate-risk, and 55% to 60% of poor-risk patients are predicted to achieve complete remission. Survival at 5 years also is strongly associated with risk group, with 55% to 65% of good-risk, 38% to 41% of intermediate-risk, and only 11% to 15% of poor-risk patients predicted to be alive. Recent studies suggest that patients with no cytogenetic abnormalities and therefore in the intermediate-risk category can be further categorized as having a better or worse prognosis on the basis of *NPM1* and *FLT3* mutational status, with improved outcomes seen in those with *NPM1* mutation but without mutation of *FLT3*.[75,76] As discussed later under "Primary Treatment," some of these outcomes are dependent on the particular treatment used. For example, the favorable outcomes seen in CBF leukemias may particularly depend on the use of high-dose cytarabine in the treatment regimen, whereas the use of allogeneic transplantation may overcome to some extent the impact of unfavorable risk cytogenetics.[55,80]

Table 104-1 Cytogenetic Abnormalities in Acute Myeloid Leukemia

Abnormality	Incidence (%)*
Core binding factor translocations	
t(8;21)	8
inv(16) or t(16;16)	9
Retinoic acid receptor translocations	10
t(15;17)	
Mixed-lineage leukemia translocations	
t(9;11)	2
t(10;11)	1
Other *MLL* translocations	3
Trisomies	
+8	9
+21	3
Other trisomies	6
Deletions	
–5 (5q–)	6
–7 (7q–)	8
–9 (9q–)	3
Complex†	10
Other	17
None—normal	40

*All patients with a specific abnormality are considered, whether or not an additional cytogenetic change is present. Thus, because some patients are counted twice, the total incidence is greater than 100%.

†*Complex* is defined as a clone with at least five abnormalities.

CLASSIFICATION

The FAB classification schema for AML is presented in Table 104-3.[77] This system, which has been in use for several decades, relies totally on morphology and is of only limited therapeutic or prognostic usefulness. More recently, the WHO has offered an alternative schema[78] (Table 104-4). This schema comprises the following subgroups: AML with the most common recurrent genetic abnormalities, AML types that evolve from MDS, AML types that are clearly therapy related, and AML that does not fall into any of the other three categories, for which the system resorts to a morphologic categorization similar to the previous FAB system.

CLINICAL MANIFESTATIONS

The initial clinical manifestations of AML usually are nonspecific and relate to the diminished production of normal blood cells. The onset most often is insidious over the course of several weeks to months, and it is not uncommon for a patient to be seen several times before a blood count is finally taken and the diagnosis of leukemia is suspected. Most patients complain of a brief, virus-like illness with fatigue and malaise. Some patients present with a chief complaint of easy bruising, and occasionally, a nonhealing skin wound brings the patient to a doctor's attention. Anemia is present at diagnosis in most patients, causing fatigue, pallor, headache, and, in the predisposed patient, angina. Thrombocytopenia usually is present, and when asked, approximately one third of patients note easy bruising, bleeding gums, epistaxis, or other evidence of bleeding at diagnosis. Approximately one third of patients with AML have significant infections (most often of bacterial origin) when the diagnosis is finally made.

In addition to suppressing normal blood production, leukemia can infiltrate normal organs. Diffuse bone tenderness is a finding in approximately 25% of patients. Chloromas, which are local collections of blasts, can manifest as rubbery, fast-growing, soft-tissue

Table 104-2 Impact of Cytogenetics on Complete Response and Survival in Acute Myeloid Leukemia*

Risk Status with Specific Cytogenetic Patterns	Incidence (%)		CR Rates (%)		5-Year Survival Rate (%)	
	SWOG	MRC	SWOG	MRC	SWOG	MRC
Favorable						
inv(16), t(16;16), t(8;21), t(15;17)	20	23	84	91	55	65
Intermediate						
normal, +8, +6, –y	46	66	76	86	38	41
Unfavorable						
del5q, –5, del7q, –7, complex	30	10	55	63	11	14
Unknown risk	4	—	54	—	24	—

CR, complete response; MRC, Medical Research Council; SWOG, Southwest Oncology Group.

*The SWOG study includes only adults and does not exclude secondary AML, whereas the MRC data refer to both children and adults and exclude cases of secondary AML. In the SWOG data, 11q23 is defined as unfavorable, whereas in the MRC data, 11q23 is considered intermediate risk.

Table 104-3 FAB Classification of Acute Myeloid Leukemia

Subtype	Definition
M0: acute undifferentiated leukemia	≥30% blasts
	<3% myeloperoxidase-positive
	Myeloid antigen expression
M1: AML with minimal differentiation	30% blasts
	≥3% myeloperoxidase-positive
	<10% cells mature beyond blast stage
M2: AML with differentiation	>30% blasts
	≥3% myeloperoxidase-positive
	>10% myeloid cells mature beyond blast stage
M3: acute promyelocytic leukemia	>30% blasts plus hypergranular promyelocytes
	Intense myeloperoxidase positivity
M4: acute myelomonocytic leukemia	Monocytosis
	>30% myeloblasts + monoblasts + promonocytes
	>20% myeloperoxidase-positive
	>20% nonspecific esterase-positive
M5: acute monoblastic leukemia	>30% myeloblasts + monoblasts + promonocytes
	<20% myeloperoxidase-positive
	>80% nonspecific esterase-positive
M6: acute erythroid leukemia	≥30% of nonerythroid cells are myeloblasts
	>50% erythroid elements
M7: acute megakaryocytic leukemia	>30% blasts (myeloblasts + megakaryoblasts)
	>30% megakaryocytic elements defined by immunophenotyping or electron microscopy

Table 104-4 World Health Organization Classification of Acute Myeloid Leukemia

ACUTE MYELOID LEUKEMIA WITH RECURRENT GENETIC ABNORMALITIES

Acute myeloid leukemia with t(8;21)(q22;q22), AML1/ETO

Acute myeloid leukemia with abnormal bone marrow eosinophils and inv(16)(p13q22) or t(16;16)(q13;q22), CBFβ/MYH11

Acute promyelocytic leukemia with t(15;17)(q22q12), PML/RARα and variants

Acute myeloid leukemia with 11q23 (MLL) abnormalities

ACUTE MYELOID LEUKEMIA WITH MULTILINEAGE DYSPLASIA

Following MDS or MDS/MPD

Without antecedent MDS or MDS/MPD, but with dysplasia in at least 50% of cells in two or more myeloid lineages

ACUTE MYELOID LEUKEMIA AND MYELODYSPLASTIC SYNDROMES, THERAPY-RELATED

Alkylating agent/irradiation-related type

Topoisomerase II inhibitor-related type (some may be lymphoid)

Others

ACUTE MYELOID LEUKEMIA, NOT OTHERWISE CATEGORIZED

Classify as

- Acute myeloid leukemia, minimally differentiated
- Acute myeloid leukemia without maturation
- Acute myeloid leukemia with maturation
- Acute myelomonocytic leukemia
- Acute monoblastic leukemia
- Acute erythroid leukemia (erythroid/myeloid and pure erythroleukemia)
- Acute megakaryocytic leukemia
- Acute basophilic leukemia
- Acute panmyelosis with myelofibrosis
- Myeloid sarcoma

MDS, myelodysplastic syndrome; MLL, mixed-lineage leukemia; MPD, myeloproliferative disease.
Data from ref. 78.

masses. Gingival hyperplasia due to leukemic infiltration of the gums sometimes is seen, particularly with M5 AML (Fig. 104-6). Leukemia sometimes infiltrates the skin, resulting in a raised, nonpruritic rash termed leukemia cutis (Fig. 104-7). Uncommonly, an occasional patient may present with meningeal signs or cranial neuropathies (most often affecting cranial nerve IV or VII) due to infiltration of the CNS with leukemia.

Figure 104-6 • Leukemic infiltration of the gums results in their expansion and thickening, with partial covering of the teeth.

LABORATORY MANIFESTATIONS

Peripheral blood counts are abnormal at diagnosis in virtually every case of AML. Most patients have a normochromic, normocytic anemia. Most also are thrombocytopenic, with 50% of patients having less than 50,000 platelets/mm^3 and 25% having below 20,000/mm^3. Most patients are granulocytopenic, but the total WBC count is more variable. Approximately 25% have very high WBC counts (greater than 50,000/mm^3), approximately 25% have low WBC counts (less than 5000/mm^3), and the remainder are in between. Blasts usually can be seen in peripheral blood smears.

Bone marrow examination generally reveals a hypercellular marrow containing 20% to 100% blast cells largely replacing the normal marrow. The morphologic, immunologic, and cytogenetic characteristics of AML are described in earlier sections of this chapter.

The partial thromboplastin and prothrombin times can be prolonged, and in APL, reduced fibrinogen and other evidence of disseminated intravascular coagulation (DIC) are not infrequent. Results

Figure 104-7 • Acute myeloid leukemia: M5 subtype. **A,** Multiple, raised, erythematous skin lesions caused by leukemic infiltration. **B,** Close-up view of nodular skin lesion. (From Hoffbrand AV, Pettit JE: Color Atlas of Clinical Hematology, 3rd ed. St. Louis, Mosby, 2000.)

of blood chemistry studies usually are normal, although in patients presenting with very aggressive and advanced disease, some evidence of tumor lysis syndrome at presentation is not uncommon, with hyperkalemia, hyperphosphatemia, hyperuricemia, hypocalcemia, increased lactate dehydrogenase, and renal insufficiency. This syndrome more often manifests shortly after therapy is initiated and can be rapidly fatal if it goes untreated. Occasional patients with monocytic leukemia may have tumor infiltration of the kidneys sufficient to cause renal impairment. Lumbar puncture will reveal unsuspected involvement with leukemia in approximately 2% of patients.[81]

DIFFERENTIAL DIAGNOSIS

The diagnosis of AML usually is straightforward. The distinction between AML and advanced MDS is made according to the percentage of blasts and often is arbitrary, with little clinical relevance. Distinguishing AML from ALL can virtually always be accomplished using immunophenotyping. CML in myeloid blast crisis can mimic AML, but the presence of the Philadelphia chromosome, splenomegaly, and myeloid cells at all levels of differentiation distinguish CML from AML. Other small round cell neoplasms can infiltrate the marrow, sometimes mimicking leukemia, but immunologic markers easily differentiate between the two conditions. Leukemoid reactions sometimes are seen in infections such as tuberculosis, but the proportion of blasts in the marrow in nonmalignant diseases virtually never reaches the 20% to 30% required for a diagnosis of AML. Infectious mononucleosis and other viral infections sometimes can resemble ALL but are almost never confused with AML.

PRIMARY TREATMENT

Advances in chemotherapy, HCT, and supportive care now enable many patients with AML to be cured. These therapeutic measures are complex, however, so they are best conducted at centers with appropriate experience and support services. Leukemia often is a rapidly progressive disease; accordingly specific therapy should be initiated soon after diagnosis—usually within 72 hours. Before therapy is initiated, acute hemorrhage and infection should be brought under control if at all possible. Patients should be hydrated and given allopurinol, 100 to 200 mg orally three times a day, to prevent uric acid nephropathy. Ideally, stable venous access should be established by placement of a Hickman or similar catheter. The diagnosis of leukemia causes a profound shock to the patient and family and has far-reaching implications. Thus, in addition to stabilizing the patient medically, many practitioners find it valuable to have a formalized conference at which the patient and family can be instructed about the nature of leukemia, the immediate plans for therapy, and the likely consequences of treatment.

Management of Emergencies

Any of number of treatable emergencies may require management before specific antileukemic therapy can begin. Severe bleeding from thrombocytopenia usually can be controlled with platelet transfusions. DIC typically is associated with a diagnosis of APL. This coagulopathy rapidly abates with the institution of ATRA therapy, so many of the measures used in the past to attempt control of DIC (i.e., low-dose heparin, fresh-frozen plasma, and fibrinogen) are now no longer needed. In patients with fever and granulocytopenia, blood specimens should be obtained for culture, but meanwhile, broad-spectrum antibiotic therapy should be started on an empirical basis. Very high WBC counts may constitute early evidence of tumor lysis syndrome; in such instances, the patient should be hydrated, placed on allopurinol to prevent further uric acid production, and given acetazolamide (500 mg daily) to alkalinize the urine. Patients presenting with very high WBC counts (greater than 100,000/mm^3) also are at risk for hemorrhage or microinfarctions of small vessels, presumably due to leukostasis. Lung involvement can result in pulmonary infiltrates and hypoxia; CNS leukostasis can lead to mental status changes, seizures, and sudden death. Pulmonary or CNS leukostasis represents a medical emergency requiring intravenous hydration and measures to lower the blast count immediately. Although oral hydroxyurea often is used, whether it lowers counts any faster than intravenous cyclophosphamide, daunorubicin, or cytarabine is unknown. Leukapheresis is of short-term benefit.[82] Patients with CNS symptoms should be given whole-brain irradiation emergently. Leukostasis has been associated with the expression of the adhesion molecule CD14 on malignant blasts; this may explain why the syndrome is almost never seen in lymphoid leukemias, in which this antigen is lacking.[83]

Remission Induction

General Principles

Without therapy, AML is a rapidly fatal disease; therefore, prompt initiation of antileukemic therapy is appropriate for a majority of patients. Some patients, however, may have a more smoldering variant of AML, often arising from a previous MDS. If such patients are elderly or have other serious medical problems, supportive care measures without attempts at remission induction or less intense chemotherapy designed to slow the progression of disease may be appropriate. The large majority of patients, however, should receive combination chemotherapy in an effort to eradicate the bulk of leukemic cells and allow the regrowth of normal marrow, resulting in a complete remission. Induction chemotherapy generally is given at relatively high doses and is followed by a period of significant pancytopenia before recovery of normal hematopoiesis. As discussed later on, most regimens include 3 days of an anthracycline and 7 days of cytarabine. The usual practice is to check the marrow status at day 14 after initiation of induction and then, if residual leukemic cells remain, to give a second course of therapy. Sometimes it is difficult to distinguish between residual leukemic cells and early recovery of normal hematopoiesis. In these cases, it is advisable to reassess marrow status in a few days. According to International Working Group recommendations, a morphologic complete remission (i.e., "complete response") requires less than 5% blasts with recovery of peripheral counts to an absolute neutrophil count greater than 1000 mL

and a platelet count greater than 100,000 mL.[84,85] Complete remission does not imply eradication of the disease, and with newer, more sensitive technologies, leukemic cells can sometimes be detected in patients with a morphologic complete remission. If only induction therapy is given, disease will recur in essentially every patient. In an effort to consistently define the reasons for failure of induction chemotherapy, the International Working Group suggests that patients be categorized as those with resistant leukemia, those who die from complications of aplasia, and those who die but in whom information is insufficient to determine if the cause is persistent leukemia or failure of marrow recovery.[84]

Some studies of remission induction conducted in the 1970s suggested that the reasons for treatment failure tended to differ between younger and older patients, with relatively few patients younger than 55 to 60 years of age dying of early treatment-related complications but with a much higher incidence of this problem among older persons. Accordingly, more recently, separate studies have been conducted for younger and older patients.

Remission Induction in Younger Patients

For more than 2 decades, standard induction therapy for patients with AML who are younger than 60 years of age generally has included 3 days of an anthracycline and 7 days of cytarabine. Four general questions dominated previous clinical trials of induction therapy:

1. What are the best type and dose of anthracycline?
2. What are the best dose and schedule of cytarabine?
3. Should additional chemotherapeutic agents be added?
4. Is there a role for hematopoietic growth factors?

Daunorubicin, 45 mg/m^2 for 3 days, generally has been viewed as the standard anthracycline component of therapy. Four randomized trials have compared idarubicin, 12 mg/m^2 for 3 days, with daunorubicin, 45 mg/m^2 for 3 days, both given with standard-dose cytarabine.[86–89] The complete response rates were higher with idarubicin in three of the four trials, particularly in patients younger than 50. A problem with these studies is that idarubicin and daunorubicin were not compared at equitoxic doses. For example, the degree of myelosuppression during consolidation was considerably greater with idarubicin. No prospective randomized trial has yet been completed comparing daunorubicin in a dose of 45 mg/m^2 with daunorubicin at 60 or 70 mg/m^2—doses that have been shown to be well tolerated by patients younger than 60 years. Nor have randomized trials been reported comparing idarubicin to the higher-dose daunorubicin regimens. On the other hand, sequential trials from both the Southwest Oncology Group (SWOG) and the Eastern Cooperative Oncology Group (ECOG) suggest that in patients below age 60, complete response rates are higher with higher doses of daunorubicin (i.e., 60 or 70 mg/m^2 for 3 days) than with lower doses (i.e., 45 mg/kg/m^2 for 3 days).[90–93]

Cytarabine generally is given intravenously at a dose of 100 to 200 mg/m^2 per day by bolus or by continuous infusion. Much higher doses of cytarabine are tolerable, and two prospective randomized trials compared a combination of daunorubicin and standard cytarabine with daunorubicin and cytarabine at 2 g/m^2 per day for 6 days.[91–94] In neither study was the complete response rate increased, although in the SWOG study, patients in the high-dose induction group tended to have an improved disease-free survival. The use of high-dose cytarabine is associated with more frequent and severe toxicities including more nausea, vomiting, and conjunctivitis. In an occasional patient, a disabling cerebellar toxicity may develop.

Whether the addition of a third drug to the standard daunorubicin-plus-cytarabine regimen is beneficial is uncertain. Some regimens add 6-thioguanine, but no randomized trial exists showing a benefit. The addition of etoposide was studied by the Australian Leukemia Study Group and did not increase complete response rates but seemed to prolong disease-free survival without benefiting overall survival.[95]

Because profound myelosuppression always follows administration of induction chemotherapy, a large number of trials have asked whether administration of a myeloid growth factor immediately after completion of induction chemotherapy might hasten marrow recovery, thereby preventing serious and potentially lethal infections and improving complete response rates.[96–100] In general, these studies found that administration of a myeloid growth factor after completion of induction chemotherapy accelerates subsequent myeloid recovery. In only a minority of studies, however, did this accelerated recovery result in fewer documented infections, and in only the rare study was the complete response rate or survival affected. In those studies in which addition of growth factor was assessed, the dollars saved by shorter hospitalizations with the use of these factors were approximately balanced by the cost of the agent.[101,102] Administration of hematopoietic growth factors simultaneous with chemotherapy in an effort to induce cycling of leukemia and thus sensitize cells to treatment has yielded mixed results.[103]

In summary, standard induction therapy for younger patients with AML continues to be 3 days of an anthracycline dosed at an intensity approximately equal to that of daunorubicin 60 mg/m^2 per day and 7 days of cytarabine. There is a lack of convincing evidence that alternatives in the dosing of cytarabine, inclusion of other chemotherapeutic agents, or the addition of hematopoietic growth factors consistently improves complete response rates or prolongs survival.

Despite optimal therapy, as many as 30% of younger adults fail to achieve a complete remission with initial induction therapy—some because they die of treatment complications, others because they have resistant leukemia. Allogeneic HCT can cure 15% to 20% of patients in whom initial induction attempts fail, but the logistics of identifying a donor and initiating transplantation in a timely manner for such patients often are challenging. To facilitate this process, HLA typing should be sought in all younger patients with AML and siblings shortly after diagnosis, rather than waiting until induction has failed and only a very narrow window of opportunity remains for potentially curative therapy.

Remission Induction in Older Patients

The advantages seen with more intensive anthracycline dosing—daunorubicin doses above 458 mg/m^2 for 3 days or the equivalent—generally have been restricted to younger patients. For patients older than 60 years, most experts suggest limiting the anthracycline to a dose equivalent to daunorubicin 45 mg/m^2 for 3 days, although clinical trials are under way to test more intensive dosing. As in younger patients, no clear advantage has been observed for one anthracycline over another when relatively equitoxic doses are used. A recent ECOG study compared daunorubicin with mitoxantrone or idarubicin (all given with standard-dose cytarabine) and found no advantage for any single treatment regimen.[93] As with younger patients, no evidence has been found for an advantage of high-dose cytarabine or for the addition of further chemotherapeutic agents to the induction regimen for older patients. Many of the studies of the addition of hematopoietic growth factors to AML induction have been restricted to older patients, but, as with younger patients, the advantages of the addition of growth factor appear to be limited to faster hematopoietic recovery and fewer days with neutropenic fever, but with no consistent improvement in complete response rates or overall survival.

In virtually every study conducted to date, the complete response rate drops as the age of patients increases. Although some of this effect could be due to a diminished ability of patients to tolerate therapy and to a tendency of physicians to reduce doses in older patients, even when identical doses of drugs are used and toxic deaths are censored, the incidence of remission failures increases with age. AML among older patients is much more likely to evolve from a myelodysplastic syndrome, to be accompanied by unfavorable-risk cytogenetics, and to be associated with expression of the multidrug resistance gene.[104–106] All three of these have been found to be independent risk

factors mitigating against the likelihood of achieving a complete remission. Thus, in a recent SWOG study of remission induction in patients with AML who are older than 55 years of age, the overall complete response rate with use of a standard preparative regimen was 45%. If patients had none of these three factors, their complete response rate was 81%, whereas if all three factors were present, the complete response rate was less than 15%.[104] Similar results have been reported by a group of investigators at the M.D. Anderson Cancer Center.[107]

Postremission Therapy

General Principles

If no further therapy is given after remission is achieved, all patients will inevitably relapse and do so rapidly (on average in about 4 months), demonstrating the need for further therapy.[108] Three types of postremission therapy are in general use: chemotherapy, autologous HCT, and allogeneic HCT.

Postremission Chemotherapy

Postremission chemotherapy usually consists of several cycles of combination chemotherapy given at doses similar to those used for induction. This form of therapy often is termed *consolidation* when given within a few months of induction or *late intensification* if given after a greater delay. Some trials also have explored the use of low-dose "maintenance" chemotherapy.

Most contemporary protocols include several consolidation cycles of high-dose cytarabine. The rationale for high-dose cytarabine came from studies suggesting that at higher doses, the drug is able to saturate deaminating enzymes resulting in production of higher levels of the active intracellular metabolite ARA-CTP, which in turn leads to enhanced inhibition of DNA synthesis.[109] Early phase I and II trials suggested that high-dose cytarabine regimens were tolerated and could result in complete remissions in patients with relapsed AML.[110,111] These observations led to the use of high-dose cytarabine for consolidation therapy after initial remission induction, with several phase II studies reporting sustained remissions in 30% to 40% of adults.[112,113]

Ultimately, several large randomized trials have explored the value of high-dose cytarabine for postremission therapy in adult cases of AML.[91,114] The Cancer and Leukemia Group B (CALGB) randomly assigned 596 patients in complete remission to receive four courses of cytarabine at one of three doses:

1. 100 mg/m^2/day by continuous infusion for 5 days
2. 400 mg/m^2/day by continuous infusion for 5 days
3. 3 g/m^2 as a 3-hour intravenous infusion twice daily on days 1, 3, and 5

High rates of CNS toxicity were observed among patients older than 60 years, and subsequent randomizations were limited to younger patients. At 3 years, disease-free survival rates were 21% in the 100-mg group, 25% in the 400-mg group, and 39% in the 3-g group. This trial established three or four doses of cytarabine at 3 g every 12 hours on days 1, 3, and 5 as among the most widely used consolidation regimens for younger patients with AML in first remission. Subsequent analyses have demonstrated that the advantage achieved with the highest-dose regimen was restricted to patients with favorable cytogenetics; thus, the intermediate-dose regimen may be as appropriate for patients with intermediate or unfavorable cytogenetics.[80] A SWOG trial randomized patients to receive conventional or high-dose cytarabine during both induction and consolidation.[91] The best result (52% 4-year survival rate) was seen among patients who received the high-dose cytarabine regimen, a result consistent with those of the CALGB study.

A number of other multiagent postremission chemotherapy regimens have been developed. For example, the MRC reported on a regimen that uses as consolidation a cycle of standard anthracycline plus cytarabine; a cycle of MACE combining amsacrine, conventional-dose cytarabine plus etoposide; and a cycle of high-dose cytarabine plus mitoxantrone. The reported results looked generally similar to those reported by CALGB and SWOG.[115] No large randomized trials have been conducted comparing the various more commonly used consolidation regimens. These regimens, which include repetitive cycles of high-dose therapy, generally are inappropriate for patients older than 60 years of age. Most older patients are given several cycles of combination chemotherapy at moderate dosing, such as 2 days of daunorubicin plus 5 days of conventional-dose cytarabine. Almost no data are available suggesting superiority of any particular consolidation regimen for older patients with AML.

With the increasing acceptance of short-term intensive consolidation chemotherapy as the standard for younger patients with AML, the concept of low-dose maintenance has fallen into disuse. Data from randomized trials in both younger and older patients, however, demonstrate that maintenance therapy can prolong the duration of first remission, although an impact on overall survival has not been seen.[90,116,117]

Autologous Hematopoietic Cell Transplantation

The principles underlying the concept of autologous HCT and the general technique are outlined in Chapter 32 and are not repeated here. Based on encouraging results in patients in second or subsequent remission, a number of single-center phase II trials of autologous HCT for AML in first remission were conducted and reported in the mid-1980s.[118–120] These small trials provided encouraging results, leading to wider use of the technique. Registry data describing results in hundreds of patients soon became available and suggested leukemia-free survival rates of approximately 45% at 5 years.[121] In an effort to minimize the possible impact of treatment selection bias, several large prospective randomized trials have been conducted in which adults in first remission with matched siblings have been assigned to allogeneic transplantation, whereas those without have been randomized to receive either autologous HCT or postremission chemotherapy. Relapse rates were reduced in most trials with the use of autologous transplantation compared with chemotherapy.[115,122–124] In several of these studies, autologous transplantation resulted in an improvement in disease-free survival, whereas in the others, it did not. Which patients may best benefit from autologous HCT in first remission is considered in the ensuing discussion, after the presentation of data related to studies of allogeneic transplantation.

A large number of questions exist about how best to conduct autologous HCT for AML. The most commonly used preparative regimens are combinations of busulfan plus cyclophosphamide, busulfan plus etoposide, or cyclophosphamide plus total body irradiation (TBI), but few randomized trials have been conducted.[125,126] Registry data suggest relative equivalence among regimens. Although gene-marking studies have provided unequivocal evidence that occult tumor cells in remission marrow can contribute to the risk of relapse, no comparative clinical trials have been published to confirm that the methods of ex vivo purging are of any clinical benefit.[127,128] The prospective studies that show the greatest benefit of autologous HCT used it after three or four cycles of intensive therapy, whereas the studies that showed the least benefit applied the treatment almost immediately after induction. Because these were randomized trials, effects of patient selection on lead time bias should have been minimized, suggesting that autologous transplantation is of greatest differential benefit if applied *after* consolidation therapy, rather than as a substitute for it.

Allogeneic Hematopoietic Cell Transplantation

The initial application of allogeneic HCT to treat AML was published by Thomas and colleagues[129] in 1977, when they reported on

54 patients with recurrent or refractory AML treated with TBI-containing regimens and allogeneic HCT. At the time of the report, seven of these patients were alive in remission, and a subsequent follow-up more than 13 years later showed that 6 of the 54 remained alive and disease-free.[130] In 1979, Thomas and associates[131] published the initial results of a trial of allogeneic HCT for patients in first remission, reporting for a small group of patients a 5-year disease-free survival rate in excess of 50%. Similar results were soon reported by other investigators as well.[132,133] The results reported in these small, uncontrolled, single-institution series were far superior to anything achieved at the time with conventional chemotherapy, but the potential impact of patient selection bias was unknown. Accordingly, these small, single-institution series were soon followed by a substantial number of single-institution or group trials comparing allogeneic transplantation for patients for whom donors were available with conventional chemotherapy for patients without donors. Studies published in the mid-1980s from the Royal Marsden, Seattle, UCLA, and Genoa all showed a markedly diminished risk of relapse with transplantation, a higher risk of treatment-related death with transplantation, and, in all four studies, improved disease-free survival with transplantation.[134–137]

Since the mid-1980s, of course, significant changes have occurred in both chemotherapy and the practice of allogeneic HCT, so comparisons of these techniques continue to be made. A recent meta-analysis included all studies published since 1995 that compared allogeneic HCT with chemotherapy or autologous HCT using an intention-to-treat analysis. The meta-analysis comprised 3100 subjects and demonstrated an overall survival advantage for allogeneic transplantation with a summary hazard ratio of 1.15. The survival advantage was greatest for patients with high-risk leukemia (hazard ratio, 1.39) but was lost in patients with favorable-risk cytogenetics (hazard ratio, 0.9).[138]

The general technique of allogeneic HCT is described in Chapter 32 and is not repeated here, except for the following few points specifically relevant to AML: Postremission consolidation chemotherapy before allogeneic HCT for AML in first remission does not improve outcome compared with proceeding directly to transplantation after achievement of first remission.[139] The optimal preparative regimen for transplantation of AML in first complete remission is arguable. One prospective randomized trial demonstrates superiority of cyclophosphamide plus TBI over busulfan plus cyclophosphamide.[140] A subsequent large registry study, however, found equivalence between the two approaches.[125] Although bone marrow has been the usual source of stem cells, three recent randomized trials have shown faster engraftment with the use of granulocyte colony stimulating factor (G-CSF)-mobilized peripheral blood without increasing acute graft-versus-host disease (GVHD).[141–143] In all three studies, a trend toward more chronic GVHD was observed with the use of peripheral blood, but in two of three trials, overall survival was improved with the use of peripheral blood as a source of stem cells. The combination of cyclosporine plus methotrexate is the most commonly used form of GVHD prophylaxis. Although some encouraging phase I and II studies of T-cell depletion have been published, no randomized trials have demonstrated an advantage of T-cell depletion for patients with AML in first remission.[144] Recent trials using unrelated donors have shown results approaching those achieved with fully matched siblings.

Selection of Appropriate Postremission Therapy

Postremission chemotherapy, autologous transplantation, and allogeneic transplantation all represent viable treatment options for the younger patient with AML in first remission. Opinions vary among experts, but in general, most would recommend allogeneic transplantation using a matched sibling or an unrelated donor for patients with AML and unfavorable-risk cytogenetics. For patients with favorable-risk cytogenetics, most experts would recommend consolidation chemotherapy with repetitive cycles of high-dose cytarabine. Opinions regarding management of patients with intermediate-risk cytogenetics are more varied and may be influenced by subtle risk factors such as the age of the patient, the WBC count at diagnosis, and *NPM1* and *FLT3* mutation status, with transplantation being favored for patients with higher-risk disease. The foregoing recommendations are consistent with those of the National Comprehensive Cancer Network.[145]

For patients older than 60 years of age, conventional myeloablative transplantation normally is not used, although recent studies of nonmyeloablative transplantation for patients older than 60 are showing promise.[146] The advantages of autologous transplantation seen in randomized trials were restricted to patients younger than 60. With older patients, as with all patients with AML, participation in well-designed clinical trials is appropriate and should be pursued actively.

TREATMENT OF RECURRENT ACUTE MYELOID LEUKEMIA

General Principles

Allogeneic or autologous HCT is the only therapy shown to be curative in a substantial proportion of patients with recurrent AML. For those patients who are transplantation candidates, who are found to be in early first relapse, and who have a previously identified source of stem cells, it may be appropriate to proceed directly to transplantation.[147,148] For all other patients, an initial trial of chemotherapy in an attempt to obtain a second remission is appropriate (Box 104-1).

Reinduction Chemotherapy

A number of large observational studies of reinduction chemotherapy have been published over the last 2 decades.[149–153] In general, complete response rates have ranged from 30% to 50%, and the mortality rates associated with reinduction have been 15% to 25%. Three prognostic factors have consistently been identified with an improved outcome: younger age, favorable cytogenetic risk group, and longer duration of first remission.

Box 104-1. MANAGEMENT OF NEWLY DIAGNOSED ACUTE MYELOID LEUKEMIA IN PATIENTS YOUNGER THAN 60 YEARS OF AGE

Induction

Daunorubicin, 60 mg/m^2/day for 3 days (or idarubicin, 12 mg/m^2/day for 3 days), plus cytarabine, 200 mg/m^2/day for 7 days, is the standard induction regimen.

Postremission

Favorable risk: Cytarabine, 3 g/m^2 over 3 hours every 12 hours, is given on days 1, 3, and 5 for four courses; autologous stem cells are stored if no HLA-matched sibling donor is available.

Intermediate risk: If an HLA-matched sibling is available, allogeneic transplantation is indicated. If no HLA-matched sibling is available, cytarabine, 3 g/m^2 over 3 hours, every 12 hours on days 1, 3, and 5, is given for two courses, followed by autologous transplantation.

Unfavorable risk: If an HLA-matched sibling or HLA-matched unrelated donor is available, allogeneic transplantation is performed. If no such donor is available, management is the same as for intermediate-risk disease.

HLA, human leukocyte antigen.

A limited number of randomized trials have been conducted in this group of patients. Vogler[154] found that adding etoposide to high-dose cytarabine was of no advantage, whereas Karanes[155] demonstrated a benefit of adding mitoxantrone to high-dose cytarabine. List and associates[156] conducted a randomized trial testing whether the addition of cyclosporine to a regimen of high-dose cytarabine plus infusional daunorubicin would be of benefit. This study was based on the high incidence of multidrug resistance in recurrent AML and the ability of cyclosporine at clinically achievable levels to reverse drug resistance. In this randomized trial, the investigators found a drug resistance reduced incidence of resistant leukemia with the addition of cyclosporine and a resulting improvement in both disease-free and overall survival.

Gemtuzumab ozogamicin combines a humanized anti-CD33 antibody with the potent antitumor agent calicheamicin. Gemtuzumab ozogamicin was developed on the basis of the observation that CD33 is expressed in virtually all cases of AML but not by normal hematopoietic stem cells or in nonhematopoietic tissues, and on the conclusion that by targeting CD33, a less toxic, effective therapeutic might result. Phase I studies showed saturation of CD33 antigenic sites at 9 mg/m^2 and clearing of leukemic blasts in many patients at this dose.[157] Subsequent phase II trials showed a complete response rate of 30% with less toxicity than might be expected with aggressive combination chemotherapy.[158] On the basis of this result, gemtuzumab ozogamicin was approved by the U.S. Food and Drug Administration (FDA) for the treatment of recurrent AML in older patients.

A large number of agents are in clinical trials including FLT-3 inhibitors, farnesyl transferase inhibitors, HD inhibitors, antiangiogenic agents, inducers of apoptosis, and deoxyadenosine analogs, among others.

Hematopoietic Cell Transplantation for Recurrent Disease

Approximately 30% of patients with AML who undergo transplantation of marrow from matched siblings for untreated first relapse can expect to become long-term disease-free survivors.[159–162] Autologous transplantation using marrow previously stored in first remission has resulted in a 26% 5-year disease-free survival rate.[161] These outcomes are not markedly less than what might be expected for transplantation in second remission, so for those patients in early relapse with an identified source of stem cells, immediate stem cell transplantation is a reasonable option.

A majority of patients will require reinduction, however. For those patients who achieve a second remission, have a matched sibling, and are younger than 55 years, allogeneic transplantation is the preferred form of therapy, and cure can be expected in 35% of cases.[162] Although the published experience is less extensive, similar cure rates have been reported for older patients undergoing reduced-intensity allogeneic HCT.[146] For patients without matched siblings, either autologous or matched unrelated donor transplantation should be considered. No randomized trials have been conducted comparing either approach to further chemotherapy or the two approaches to one another. In a retrospective case-control study by the European Bone Marrow Transplant Group, no statistically significant difference in disease-free survival or overall survival rate was found between autologous and matched unrelated-donor transplantation approaches.[163] Without further outcome data, the decision between autologous versus unrelated-donor transplantation for AML in second remission is difficult, but an allogeneic approach may be appropriate for younger patients with poor-risk disease characteristics (e.g., a short remission duration and unfavorable cytogenetics), whereas autologous transplantation is a good strategy for older patients with more favorable disease characteristics, including long duration of first remission.

The results of transplantation for patients in whom reinduction cannnot be achieved are less favorable, and long-term survival can be expected in only 10% to 20% of patients undergoing allogeneic transplantation for refractory AML.[164]

TREATMENT OF ACUTE PROMYELOCYTIC LEUKEMIA

APL is distinguished by both the t(15;17) translocation and a unique pattern of drug sensitivity demanding a different treatment strategy from those for other categories of AML. Specifically, APL is particularly sensitive to anthracyclines and to all-*trans*-retinoic acid (ATRA), and with appropriate use of both drugs, a high percentage of APL patients can expect to be cured[165–167] (Box 104-2).

Initial Therapy

A number of studies have been conducted in the attempt to define the best ways to incorporate high-dose anthracyclines plus ATRA into the management of newly diagnosed patients with APL. The use of ATRA as a single agent for induction results in complete response rates as high as those achieved with conventional chemotherapy regimens including anthracycline, and in improved overall survival.[168] A European APL study has since shown that concurrent administration of ATRA with the chemotherapy regimen results in an improvement in overall event-free survival (84% versus 77% at 2 years).[169] Combining chemotherapy and ATRA during induction has the added benefit of reducing the incidence of the retinoic acid syndrome (to be discussed shortly) from 25% down to less than 10%, and this is now considered standard therapy.

Consolidation chemotherapy for APL generally involves giving repeated cycles of a regimen consisting of an anthracycline and ATRA. The optimal number of cycles of consolidation is unknown.

A clear role is recognized for maintenance therapy in APL.[170] In a large North American Intergroup study, patients were randomly assigned to receive maintenance therapy with daily ATRA or to observation. Those who received ATRA had an improved disease-free survival.[168,171] Because ATRA induces enzymes that enhance its

Box 104-2. MANAGEMENT OF ACUTE PROMYELOCYTIC LEUKEMIA

Newly Diagnosed Disease

Induction

ATRA, 45 mg/m^2/day until CR is achieved, plus daunorubicin, 60 mg/m^2/day for 3 days, and cytarabine, 200 mg/m^2/day for 7 days, is the standard induction regimen.

Consolidation

Two cycles of the following regimen are given: ATRA, 45 mg/m^2/day for 7 days, and daunorubicin, 50 mg/m^2/day for 3 days.

Maintenance

ATRA, 45 mg/m^2/day for 15 days every 3 months, plus 6-MP, 100 mg/m^2/day, and MTX, 10 mg/m^2/week for 2 years, is the maintenance regimen.

Recurrent Disease

Induction

Arsenic trioxide, 0.15 mg/kg daily, is given until a second CR is achieved.

Consolidation

Autologous transplantation is indicated if PCR assay-negative stem cells are available; otherwise, allogeneic transplantation is performed if a suitable donor is available.

ATRA, all-*trans*-retinoic acid; CR, complete response; 6-MP, 6-mercaptopurine; MTX, methotrexate; PCR, polymerase chain reaction.

metabolism, many investigators have suggested that intermittent ATRA therapy may be advantageous. The European APL 93 trial randomized patients to receive intermittent ATRA, 6-mercaptopurine plus methotrexate, or a combination of intermittent ATRA plus the combination chemotherapy. The patients in the treatment group receiving maintenance ATRA plus chemotherapy had the best overall survival.[169]

With current management, the prognosis for patients with APL has improved remarkably from what it was in the 1980s. For example, in the North American Intergroup Trial, the 5-year survival rate for patients randomized to receive ATRA induction and maintenance therapies was 69%.[168,171] Both age and WBC count at diagnosis have prognostic importance, with best results seen in patients younger than 55 years and those presenting with a WBC count less than 10,000/mm^3.[172] Because of the excellent outcome with current regimens, transplantation has no generally accepted role during first remission of APL.

Treatment of Recurrent Acute Promyelocytic Leukemia

In addition to its unique sensitivity to ATRA, APL also is remarkably sensitive to treatment with arsenic trioxide, as first reported by investigators from China.[173,174] A more recent multicenter study has reported an 85% complete response rate among patients with recurrent APL using arsenic trioxide.[175] The most important forms of toxicity include prolongation of the QT interval and a syndrome essentially identical to the retinoic acid syndrome, to be discussed shortly. The QT prolongation requires careful monitoring, because two recent reports have documented sudden deaths associated with the use of arsenic trioxide.[176,177] Thus, metabolic abnormalities that also prolong the QT interval, such as hypokalemia, hypophosphatemia, and hypomagnesemia, should be corrected before therapy is initiated. Currently, reinduction with arsenic trioxide generally is considered as the initial treatment of choice for patients with APL in whom first-line therapy has failed, particularly if that failure occurred within 12 months of therapy with ATRA.

Data are limited regarding the expected duration of second remission induced with arsenic trioxide. Although some patients may remain in remission for some time if given arsenic plus chemotherapy, most experts would recommend either autologous or allogeneic HCT for patients with APL in second remission. Sanz and associates[178] presented results from the European Blood and Marrow Transplant Group for patients with APL in second remission and reported overall survival rates of 58% for allogeneic transplantation and 40% for autologous transplantation. The choice of autologous or allogeneic HCT may be influenced by the status of the autologous stem cell source. In a small but provocative study, Meloni reported on 15 patients with APL in second remission undergoing autologous transplantation. Only one of eight patients who received PCR assay-negative marrow subsequently relapsed, whereas all seven who received PCR assay-positive marrow did so.[179]

Retinoic Acid Syndrome

After therapy with ATRA, a proportion of patients with APL exhibit a syndrome manifested by fever, weight gain, respiratory distress, pulmonary infiltrates and effusions, episodic hypotension, and renal failure.[180] When ATRA is used as a single agent, this syndrome can be seen in as many as 25% of cases. Risk factors for the development of the syndrome are not obvious, but the simultaneous administration of chemotherapy during induction has seemed to diminish the risk of its development. The mortality rate for this syndrome, when first described, was about 30%, but with the recognition that the syndrome responds dramatically to the institution of dexamethasone, mortality rates have fallen to less than 5%. The observation that an identical syndrome can be seen with arsenic trioxide suggests that the syndrome probably is associated with the differentiation of APL cells and is inaccurately named.

Supportive Care

The treatment of AML is accompanied by a substantial number of complications and thus is best conducted at a center experienced in the management of these sometimes complex cases. During the granulocytopenic period after intensive induction and consolidation chemotherapy, most patients become febrile, and bacterial infections can be documented in roughly 50%. Gram-positive organisms (e.g., *Staphylococcus epidermidis*) and gram-negative enteric organisms (e.g., *Escherichia coli*, *Klebsiella/Aerobacter*) are common, but the experience can vary by medical center. Reactivation of herpes simplex infections can add to mucositis, and fungal infections can develop in patients on antibiotics. Thus, we generally recommend the following oral antimicrobial prophylactic regimen before initiation of chemotherapy: ciprofloxacin, 500 mg every 12 hours; fluconazole, 200 mg daily; and acyclovir, 800 mg every 12 hours. Patients who become febrile while neutropenic should be started on broad-spectrum antibiotics, such as monotherapy with imipenem, or a combination of an antipseudomonal penicillin and a third-generation cephalosporin. If patients are persistently febrile after 72 hours of broad-spectrum antibiotic therapy, additional antibiotics or antifungal coverage should be considered. The choice should be dictated by the unique clinical circumstances of the patient. Patients should continue on broad-spectrum antibiotics until recovery of granulocyte counts and defervescence are obtained.

In patients with APL, hemoglobin should be maintained above 8 to 10 g/dL, and platelet counts should be kept above 10,000/mm^3 in the absence of symptoms and above 20,000/mm^3 in the presence of fever or hypertension. Many patients may become candidates for HCT, so if patients are cytomegalovirus (CMV)-seronegative at the start of induction, every effort should be made to ensure that they continue to receive either CMV-seronegative or filtered blood products.

Malnutrition can be a significant problem, particularly in the older, frailer patient. Early institution of hyperalimentation should be considered if oral intake becomes inadequate.

MONITORING RESPONSE TO THERAPY

Substantial effort has been made to develop assays of leukemic burden that are more sensitive than the admittedly gross estimates afforded by morphologic examination.[181] Such assays, if sensitive, specific, and predictive of outcome, could be used to guide therapy so that, as one example, a patient in first remission could be taken to transplantation if the response to initial chemotherapy predicted a high probability of relapse, or the patient could be spared the toxicities of transplantation if the extent of response to initial therapy was so favorable as to predict a high probability of cure. Efforts to develop such assays have, to date, focused on PCR-based methods of detection of leukemia-specific translocations and multidimensional flow cytometry.

The major attraction of PCR-based assays is their high level of sensitivity and specificity. In AML, however, no universal translocations have been recognized, so separate studies, each involving only a small subset of AML cases, have been required. The most encouraging results have come from the study of APL, in which PCR-based assays for t(15;17) conducted after induction and consolidation were predictive of outcome.[182,183] The results with other translocations have been more perplexing. PCR-based assays for t(8;21) do not appear to predict relapse, and many patients show persisting positive PCR assays while remaining in complete remission for years after completing all therapy. Miyamoto and colleagues[184] studied 18 patients off therapy for 1 to 12 years, all of whom remained PCR assay-positive for the AML/ETO chimeric transcript. The positive

signal could be found in $CD34^+$ marrow cells, and analyses of the PCR assay-positive colonies demonstrated them to be clonal. These results help explain why, at present, no easy PCR-based methods are available to monitor response to therapy in most patients with AML.

An alternative approach to monitoring response to therapy is the use of multidimensional flow cytometry. This approach is not nearly as sensitive as PCR analysis, which detects 1 cell per 10^3 to 10^4. Flow cytometry does have the advantage that it is broadly applicable in virtually all cases of AML. Two different studies, one in pediatric AML and a second in adult AML, suggest that a flow-based assessment of the initial remission marrow sample adds information beyond that of routine prognostic factors regarding which patients are likely to relapse within the first several years after diagnosis.[185,186]

FUTURE DIRECTIONS IN TREATMENT

With increased understanding of the molecular events involved in the development of AML, the number of potential therapeutic targets has grown. These targets can be divided into three general categories:

1. Those that are the immediate consequences of the mutational events leading to AML
2. Those that are the adaptive changes a leukemic cell must make to stay alive given the initial mutational event
3. Those that immunologically distinguish AML cells from normal hematopoietic stem cells

The most common mutations in AML involve FLT-3, and because these mutations are activating, clinical trials are exploring the use of a number of inhibitors of FLT-3 tyrosine kinase, including CEP-701, PKC-412, SU11248, and CT53518. Ras molecules are downstream from tyrosine kinase receptors, so they themselves can be mutated in AML. Because farnesylation is required for *RAS* function, trials of several farnesyl transferase inhibitors (including R11597 and BMS214662) have been conducted. The CBF and retinoic acid receptor translocations result in recruitment of HDs, which are thought to inhibit transcription, thereby contributing to the malignant phenotype. Thus, a number of HD inhibitors (including phenylbutyrate, trichostatin, depsipeptide, and MS-275) are being studied in AML.

The mutational event or events giving rise to AML could require the cell to make other adaptive changes not required of normal cells in order to survive. Such responses might be particularly required during moments of cell stress. One example is Bcl-2, which is overexpressed in almost all AML samples compared with normal marrow and may be further overexpressed when cells are exposed to chemotherapy. Thus, agents that inhibit Bcl-2, such as Bcl-2 antisense, are being studied alone and with chemotherapy for AML.

Cell surface antigens are being increasingly explored as targets for antibody- and cellular-based therapies. As noted earlier, the anti-CD33 calicheamicin conjugate gemtuzumab ozogamicin is an active agent for the treatment of recurrent AML. Recent studies combining it with standard-dose daunorubicin and cytarabine as initial induction therapy have reported encouraging results, with 85% and 86% complete response rates, respectively, in two phase II trials.[187,188] Studies using antibodies to target radionuclides to marrow in efforts to develop improved preparative regimens for transplantation also are yielding encouraging outcomes.[189]

The markedly lower rates of disease recurrence after allogeneic transplantation compared with identical-twin transplantation have encouraged further research into the development of cell-based immunotherapies. Some of these approaches, such as the further development of nonablative allogeneic transplants, attempt to make use of polymorphic minor histocompatibility differences between donor and host. Other investigators are exploring the possibility of targeting T cells to either mutational fusion proteins, such as the RUNX-1/MTG-8 protein, or to overexpressed self-antigens, such as PR3 and WT1. This long list of therapies currently in development offer great hope that the outcomes of treatment for patients with AML will continue to improve.

105 Myelodysplastic Syndromes

James M. Foran and Mikkael A. Sekeres

SUMMARY OF KEY POINTS

Etiology

- Myelodysplastic syndromes (MDSs) are not true dysplastic disorders but rather are clonal disorders of hematopoiesis with site of transformation at a pluripotent stem cell or early myeloid progenitor cell.
- In 50% to 90% of cases associated with chromosomal abnormalities, such abnormalities often are in proximity to oncogenes—partial deletion of the long arm of chromosome 5 (5q–) and the *fms* gene, monosomy 7 (7–) and the *met* oncogene—and hematopoietic growth factor genes (5q– and genes for granulocyte macrophage colony stimulating factor [GM-CSF], interleukin-3 [IL-3], IL-5, and macrophage colony stimulating factor [M-CSF] and 7–, and the erythropoietin gene).
- These resultant genetic alterations can manifest by increased apoptosis, which explains the seemingly opposing findings of marrow hypercellularity with peripheral blood cytopenia in patients with MDS.

Epidemiology

- The therapy-related subset of MDS is secondary to previous use of alkylating agents (typically associated with monosomy 7 and 5q–), with an increasing number of cases secondary to previous use of DNA topoisomerase II-targeting agents (epipodophyllotoxins), which typically are associated with translocation involving band 11q23 or band 21q22.
- Chronic exposure to benzene (above the level set by national guidelines) is the most important environmental exposure risk.

Pathology

- The new World Health Organization (WHO) classification is a revision of the French-American-British (FAB) system and recognizes the following subtypes: refractory anemia (RA), refractory anemia with ring sideroblasts (RARS), refractory cytopenia with multilineage dysplasia (RCMD), refractory cytopenia with multilineage dysplasia and ring sideroblasts (RCMD-RS), refractory anemia with excess blasts type I and type II (RAEB I and II), 5 q– syndrome, and unclassified MDS. Refractory anemia with excess blasts in transformation was eliminated from the WHO classification. Chronic myelomonocytic leukemia (CMML) has been reclassified into a new separate category, myelodysplastic/myeloproliferative disorders, along with juvenile myelomonocytic leukemia (JMML) and atypical chronic myelogenous leukemia (aCML).

Incidence

- The incidence of MDS is approximately 4 cases per 100,000 population.
- MDS is primarily a disease of the elderly: Among persons older than 70 years of age, the incidence is 20 cases per 100,000, with only 10% to 20% of patients younger than 60, although patients in the therapy-related subset are 10 to 20 years younger.

Differential Diagnosis

- MDS often is a diagnosis of exclusion after other factors and disorders associated with cytopenia and hematopoietic dysplasia are ruled out: vitamin B_{12} or folate deficiency, recent cytotoxic therapy, heavy metal intoxication, chronic liver disease, and chronic inflammation, which includes human immunodeficiency virus (HIV) infection.

Prognosis

- Using the International Prognostic Scoring System (IPSS), patients can be categorized into distinctive subgroups with respect to both median survival and the risk for acute leukemic transformation based on four subtype-specific variables: age, percentage of bone marrow blasts, number and type of chromosomal abnormalities, and degree of cytopenia.

Primary Therapy

- Usually a "wait and watch" approach is followed, given the poor risk-benefit ratio of intensive (acute myelogenous leukemia [AML]-type) chemotherapy for a majority of patients older than 60 years, although intensive chemotherapy at the time of blast progression is appropriate and may benefit up to one half of the patients, albeit transiently. A minority of patients (those younger than 55 years) may be long-term survivors if they undergo allogeneic bone marrow transplantation. The nonmyeloablative "minitransplant" procedure may increase the upper age limit for transplantation in the future.
- Erythropoietin may reduce requirements for blood transfusion; its efficacy may be augmented by cotreatment with G-CSF.

Effective Second- or Third-Line Therapies

- No consistently effective therapies are available, but one fourth to one third of patients respond to agents such as 5-azacytidine, decitabine, thalidomide, amifostine, low-dose ara-C, and topotecan. Novel targeted therapies for MDS are in various phases of clinical trials.

INTRODUCTION

The first case of what would later be designated MDS was described in 1913 by Nageli,[1] and the first case series of 143 patients with "preleukemic leukemia" was published in 1973 by Saarni and Linman.[2] Thus, MDS can be considered a relatively recently identified medical condition. The Surveillance, Epidemiology, and End Results (SEER) Program of the National Cancer Institute and central cancer registries began formally tracking MDS only in 2001, so it can be considered an even more recently recognized form of cancer.[3,4]

Diagnosis of MDS and subsequent care of the patient require coordination among a pathologist with morphologic expertise in identifying this tricky disorder; a molecular pathologist for identifying typical abnormalities associated with MDS; a hematologist or oncologist (or both); and in some cases, a physician experienced in bone marrow transplantation. Care for the patient with a new diagnosis of MDS must include attention to baseline characteristics (such as iron and erythropoietin levels, ascertainment of potential environmental or therapy-related etiologic factors, and transfusion needs), determination of the appropriate timing of therapy initiation and the type of therapy; an understanding of indications of therapy success or failure; optimal timing of bone marrow transplantation; and attention to supportive care needs, such as transfusion requirements and the need for chelation therapy.

EPIDEMIOLOGY AND ETIOLOGY

The incidence of MDS in the United States is approximately 3.6 cases per 100,000 people in the population and may be increasing[4]; it is estimated that approximately 10,000 patients were diagnosed with MDS in the United States in 2003.[3,4] The incidence rises sharply after the age of 70 years,[4] and the median age at diagnosis is approximately 75 years. These data are consistent with reports from other Western countries (Germany, Sweden, the United Kingdom, and France).[5–8] Of interest, Japanese patients were noted to be significantly younger, with more severe cytopenias and a lower risk of transformation to acute leukemia, suggesting differences in the natural history of MDS in Eastern versus Western countries.[9] MDS is more common in men than in women.[3,4]

Although most cases of MDS are idiopathic, the risk increases significantly with age,[3–5,7] and after exposure to organic solvents including benzene[10–14]; even low-level benzene exposure has been associated with increased hematotoxicity.[15] The latter may be greater in those with specific polymorphisms in DNA repair genes[16] or NADPH : quinine oxidoreductase (*NQO1*).[14,15,17] Case-control studies confirm an increasing risk of MDS in association with family history of hematopoietic cancer, smoking, and exposure to agricultural chemicals or solvents.[18,19] Occupational or environmental exposure is significantly associated with abnormal karyotype compared with de novo MDS.[20] Rare cases of familial MDS and AML have been reported, mostly in association with loss of 5q and or 7q[21–23] or with familial platelet disorders[24]; there appears to be differential expression of genes involved in signal transduction in affected versus unaffected family members.[25] A rare G-CSF receptor polymorphism also may predispose affected persons to high-risk MDS through altered signal transduction.[26]

Previous cytotoxic chemotherapy exposure—in particular, with regimens incorporating alkylating agents or topoisomerase inhibitors including epipodophyllotoxins such as etoposide or anthracyclines—significantly increases the risk of MDS,[27–33] which also has been reported after previous exposure to fludarabine.[34,35] The risk of secondary MDS after chemotherapy may be related to genetic polymorphisms of drug-metabolizing enzymes in some patients.[36] Exposure to radiation (e.g., among radium dial painters, atomic bomb survivors, or persons residing near the site of a nuclear reactor accident)[37] or the combination of radiation therapy with chemotherapy (particularly alkylating agents) also significantly increases the risk of secondary AML and MDS.[27,29,37–41] Recent evidence suggests that specific polymorphisms in the methylene tetrahydrofolate reductase gene (involved in DNA synthesis) may predict for a higher risk of secondary MDS or AML after treatment with cyclophosphamide, particularly in patients with breast cancer.[42] The median latency period for secondary MDS or AML after exposure to alkylating agents is 5 to 10 years, and the risk appears to be dose-dependent.[40,43] In general, secondary MDS or AML after alkylating agent or radiation exposure is characterized by unbalanced translocations commonly involving chromosome 5 (particularly 5q31) or chromosome 7.[44] By contrast, secondary MDS or AML after exposure to topoisomerase inhibitors is clinically different from that following alkylating agents in several ways[45]: It is much less common; the latency period is shorter (median, approximately 2 to 4 years); it more frequently manifests with overt leukemia without a preceding MDS phase; a balanced translocation, often involving 11q23 (the *MLL* gene), is more likely; and the complete response (CR) rate is higher, although the long-term prognosis is poor.[46,47] The exception is the rare patient with t(15;17),[33,48] or with core binding factor leukemia [t(8;21) or inversion 16/t(16;16)],[49–51] in whom durable CRs may be achieved.

Additional risk factors for secondary MDS or AML include high-dose therapy and autologous stem cell transplantation (ASCT) for malignant lymphoma,[52] where the risk of MDS/AML at long-term follow-up in some series is in excess of 10%,[53,54] although the use of non-total-body irradiation (TBI)-containing regimens may diminish this somewhat.[39,53,55] Pretransplantation therapy and pre-existing cytogenetic abnormalities increase the risk of secondary MDS/AML after ASCT.[39,56,57] The risk of MDS after radioimmunotherapy (e.g., with I^{131}-tositumomab) does not appear to be significantly increased.[58] The use of G-CSF in children may increase the incidence of secondary MDS and AML,[59–61] and this has also been reported as a possible complication following dose dense breast cancer therapy.[30] MDS may also evolve from an antecedent hematologic disorder, particularly polycythemia vera after treatment with ^{32}P or busulfan.[62]

PATHOGENESIS

MDS is recognized as a malignant disease in the WHO classification and is characterized by clonal hematopoiesis, progression to acute leukemia, and a diminished survival in all subgroups.[63] The underlying cause of MDS is unknown, and no single unifying pathophysiology is recognized. Hampering our understanding of the disease, preclinical models of MDS are few, although some murine models have been developed.[64,65] A functional model of MDS molecular pathogenesis, however, is suggested by the clinical behavior of the disease—namely, the progressive transformation of a committed myeloid hematopoietic stem cell with acquisition of successive genetic abnormalities, and clonal expansion, leading to the clinical phenotype (hypercellular bone marrow with increased angiogenesis and apoptosis, abnormal cytogenetics, cytopenias and transformation to frank AML).[66–72] Gene expression profiling using complementary DNA (cDNA) microarray technology has demonstrated significant heterogeneity among patients with MDS, although the expression of subsets of genes (e.g., *DLK* gene)[73] can discriminate between different clinical and karyotypic subtypes, including predicting deletions of 5q.[74–76] In the subset of patients with 5q− syndrome, global gene expression profiling implicates a stem cell origin for the disease.[77] In patients with low-risk MDS, single-nucleotide polymorphism (SNP) analysis has demonstrated hitherto unrecognized uniparental disomy and copy number changes.[78–80] It is hoped that ongoing gene expression studies and SNP ansalysis will add further insight into occult genetic lesions and dysregulated gene expression in specific disease stages, thereby ultimately contributing to our understanding of the causes and progression of MDS.

A model of inactivation or mutation of tumor suppressor genes has been proposed, although it is clear that many of the principal tumor suppressors responsible have not yet been identified.[70] Par-

ticular attention has ben paid to the commonly deleted region on 5q.[81] Findings on recent studies in support of this model include the epigenetic suppression of the genes encoding α-catenin (*CTNNA1*)[82] and *RIL*,[83] and the observation that haploinsufficiency of *EGR1* (a candidate tumor suppressor gene encoding a transcription factor within the commonly deleted segment of 5q31) leads to myeloid disorders.[84] Upregulation of and increased protein expression of the SPARC tumor suppressor gene on 5q31-32 have been demonstrated after lenalidomide therapy and may underlie its potent effects in patients with del(5q). How these observations contribute to MDS development and progression and how they may direct treatment have not yet been determined.

Point mutations in RAS family members and p53 have been reported in MDS, albeit less commonly than in AML,[85,86] as have overexpression of EVI1[87,88] and the expression of apoptosis-related oncoproteins.[89] Mutations in *PTPN11*[90] and *L3MBTL*, a gene located on 20q12 (commonly deleted in MDS),[91] do not appear to be important in MDS pathophysiology or progression. *FLT3*-length mutations are seen in increasing frequency during MDS transformation.[86] However, constitutive activation of p38 MAPK, itself involved in cell cycle regulation, has been described in MDS and correlates with enhanced apoptosis in MDS hematopoietic progenitors. Indeed, in vitro studies suggest that inhibition of p38 MAPK leads to enhanced hematopoiesis, suggesting that this may be a therapeutic target.[92] Aberrant signaling through the Akt/mTOR pathway appears to be important for cell survival in high-risk MDS, and also may serve as a therapeutic target (e.g., with mTOR inhibition).[93]

Gene silencing through aberrant promoter methylation also appears to be important in the pathophysiology of MDS,[82,94] both early in the course of MDS (including protein kinases and some genes involved in signal transduction, such as DAP-kinase, Ras, and some SOCS-1 sites in approximately 30% of patients) and later in the disease course in genes involved in cell cycle regulation (such as *p15INK4B* in patients with RAEB).[95–99] These observations offer insight into both the development and progression of MDS and serve as the rationale for the therapeutic use of hypomethylating agents in MDS.[100]

Immune modulation appears to play a role in the pathophysiology and possibly also in the progression of MDS.[101,102] Supporting this notion is the observation of significant overlap between hypoplastic MDS and aplastic anemia.[103] An increase in B-lymphocyte apoptosis (but not in T lymphocytes) has been observed,[104] and B-cell lineage–affiliated gene expression is markedly reduced in early-stage MDS.[105] Clonal T-cell expansion is common[106] and natural killer (NK) cell function is reduced in MDS,[107] particularly in cases with higher-risk features.[108] A reduction in regulatory T cells ($CD4^+CD25highFoxp3^+$) in low-risk MDS also may contribute to the emergence of autoreactive T-cell clones.[109] Of interest, a gene expression pattern similar to that seen after interferon-γ stimulation also has been observed in MDS.[76,110] These observations serve as the rationale for immunosuppressive treatment for MDS.

It is important to emphasize that although significant clinical overlap exists between high-risk MDS (greater than 10% blasts) and AML, at least in terms of prognosis and survival with intensive therapy,[111] significant biologic differences are recognized. MDS is characterized by increased apoptosis.[71,72] Upregulation of caspases and Toll-like receptor 4 (TLR-4) expression may promote apoptosis in MDS, possibly contributing to cytopenias.[112,113] Resistance to apoptosis by $CD34^+$ cells also has been described in some subtypes of MDS (e.g., trisomy 8),[114] suggesting another mechanism for disease progression. Angiogenesis is increased in MDS, and the vascular endothelial growth factor (VEGF) may serve as an autocrine growth factor[115]; however, unlike in AML, serum VEGF levels are not prognostic in MDS.[116] Therefore, MDS must be considered a unique entity, and not merely "preleukemia".[71] It is hoped that an improved understanding of the molecular basis for MDS also will contribute to the development of more specific therapies.

CLINICAL PRESENTATION

The typical presentation of MDS is the discovery of an isolated cytopenia or abnormalities in multiple cell lines in an older patient with signs and symptoms related to hematopoietic failure (fatigue, infection, bleeding), although the diagnosis may be incidental.[66] Macrocytic anemia is typical, and other benign causes (e.g., vitamin B_{12} with or without folic acid deficiency, hypothyroidism, alcohol use, chronic liver disease) must be ruled out[117]; iron deficiency and the anemia of chronic diseases also are substantially more common causes of anemia in older adults.[118] However, in a study of elderly patients with unexplained macrocytic anemia, most had at least one molecular or cytogenetic marker of clonality suggesting "early MDS."[119] In some cases, a definitive cause for the cytopenias may not be established, and the designation "idiopathic cytopenia of undetermined significance" has been proposed in that setting; long-term follow-up and repeat BM evaluations are recommended to establish the diagnosis.[120,121] Cytogenetic studies may be particularly helpful in determining the diagnosis of MDS in the absence of clear morphologic dysplasia.[122] Studies of novel diagnostic markers to distinguish MDS from other causes of cytopenias are ongoing, such as decreased serum levels of the CXC chemokine ligands CXCL4 and CXCL7,[123] although the clinical usefulness of this approach has not yet been established. A careful transfusion history to identify use of packed red blood cells is valuable in determining the likelihood of response to antithymocyte globulin[124] and erythropoietin for anemia.[125]

Neutropenia also is a common presenting feature of MDS.[126] In addition, neutrophil dysfunction has been described,[127,128] and patients may present with pyogenic abscess in the absence of neutropenia.[129] Infection remains the most common cause of death in MDS[130] and is closely correlated with the neutrophil count; it also is a common side effect of intensive chemotherapy.[131] Therefore, infection should be treated aggressively. G-CSF has been used successfully to treat symptomatic neutropenia[132]; however, in a randomized phase III study, the use of G-CSF significantly accelerated RAEB and RAEB-t compared with supportive care, with an inferior median survival (10 versus 21 months), leading to early termination of the trial.[133] Therefore, the short-term use of G-CSF generally is restricted to those patients without an excess of blasts with a symptomatic neutropenia. Opportunistic infection also has rarely been reported in MDS (e.g., disseminated *Mycobacterium avium-intracellulare* infection),[134] presumably related to disease-related immunodeficiency.

Thrombocytopenia is increasingly recognized as a clinical problem in MDS,[135,136] although MDS uncommonly manifests with isolated thrombocytopenia.[126,137] No close association has been found between thrombocytopenia and serum thrombopoietin levels in patients with MDS.[138] Additionally, platelet dysfunction has been described in MDS.[139,140] Recent estimates suggest that bleeding contributes to death in 20% and is the sole cause of death in 10%.[135] By contrast, the 5q− syndrome may manifest with thrombocytosis, although this is uncommon[141] (see Fig. 105-3).

The cytopenias of MDS, therefore, not only are the most common finding at diagnosis but also characterize the natural history of the disease and remain the most important clinical feature of the disease. Other, less common presenting features include Sweet's syndrome,[142] Behçet's disease,[143] inflammatory arthritis and synovitis,[144,145] and rarely vasculitis,[146] Crohn's disease,[147] and other immunologic phenomena.[148] As many as 10% of MDS patients have an associated autoimmune inflammatory manifestation,[149] although it does not appear to have an impact on the prognosis or disease course.[150] MDS has rarely been diagnosed during pregnancy.[151]

LABORATORY EVALUATION

The diagnosis of MDS requires demonstration of morphologic dysplasia in the correct clinical context and also collaboration with an

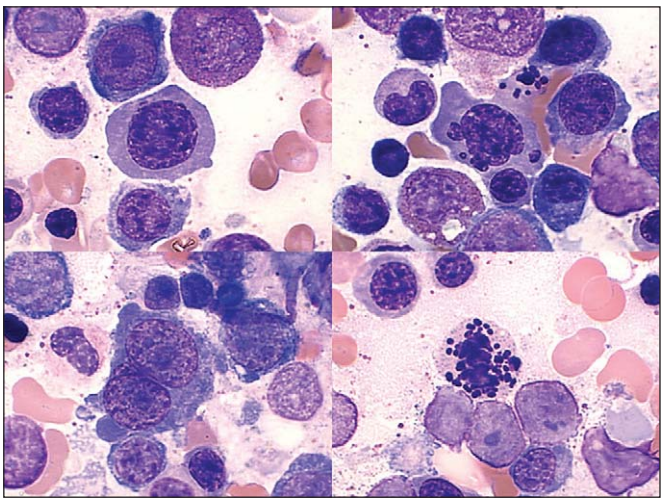

Figure 105-1 • As seen in this bone marrow aspirate, morphologic features associated with dysplastic erythropoiesis include megaloblastoid maturation *(upper left panel)*, nuclear budding and fragmentation *(upper right panel)*, multinuclearity *(lower left panel)*, and bizarre mitotic figures *(lower right panel)*. Wright-Giemsa stain, original magnification 100×. (Courtesy of Karl S. Theil, MD, Department of Clinical Pathology, Cleveland Clinic.)

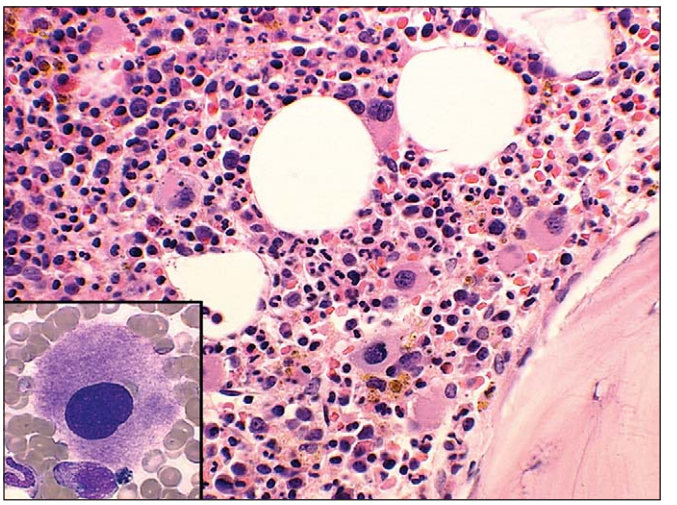

Figure 105-3 • Morphologic features associated with 5q− syndrome include hypercellular marrow containing increased megakaryocytes with abnormal hypolobulated nuclei, as seen in a bone marrow biopsy specimen. Abnormal nuclear morphology also is apparent in megakaryocytes in marrow aspirate smear *(inset)*. *Biopsy specimen*: hematoxylin-eosin stain, original magnification 40×; *aspirate*: Wright-Giemsa stain, original magnification 50×. (Courtesy of Karl S. Theil, MD, Department of Clinical Pathology, Cleveland Clinic.)

expert hematopathologist[121] (Figs. 105-1 to 105-3). MDS may not be apparent or meet diagnostic criteria at presentation in all patients, and close follow-up evaluation and repeat bone marrow examination may be required to establish the diagnosis.[120,152] MDS may in exceptional circumstances be diagnosed on the peripheral blood smear,[153] particularly in elderly or frail patients, in whom it would not alter management; however, a bone marrow aspirate usually is necessary,[154,155] and iron staining techniques should be performed in accordance with quality assurance guidelines.[152,156] Similarly, a core biopsy is helpful to support the diagnosis of MDS, including establishing cellularity, evaluating megakaryocyte dysplasia, and assessing for the presence of ALIP ("abnormal localization of immature precursors"—central clustering of immature cells, associated with poor prognosis) and fibrosis, and should be performed in all patients undergoing bone marrow aspiration.[154,155,157,158] Adverse events subsequent to bone marrow biopsy are rare.[159]

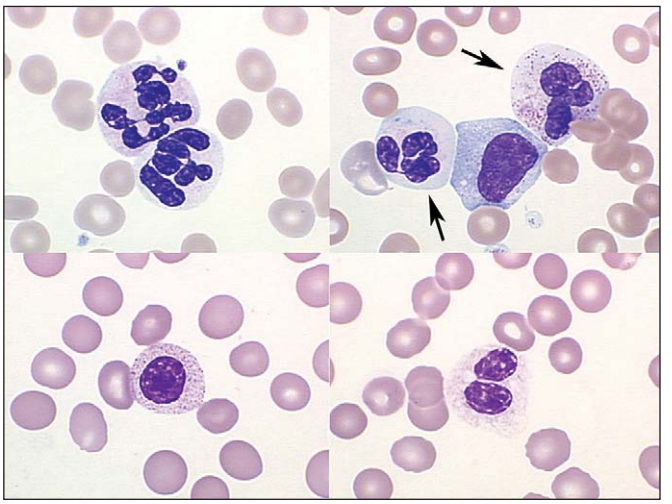

Figure 105-2 • As seen in this peripheral blood smear, morphologic features associated with dysplastic granulopoiesis include bizarre hypersegmentation *(upper left panel)*, hypogranular cytoplasm (compare neutrophils [*arrow*]; *upper right panel)*, and nuclear hyposegmentation *(lower panels)*. Acquired nuclear hyposegmentation, also known as pseudo–Pelger-Huet anomaly, ranges from complete lack of segmentation *(lower left)* to bilobed "pince-nez" nuclei *(lower right)*. Wright-Giemsa stain, original magnification 100×. (Courtesy of Karl S. Theil, MD, Department of Clinical Pathology, Cleveland Clinic.)

Cytogenetic evaluation is mandatory[126,154] and may be particularly helpful in establishing the diagnosis in patients with indeterminate morphology.[122] The role of interphase fluorescence in situ hybridization (FISH) for common abnormalities (e.g., 5q, 7q, +8, 20q, −Y, etc.) has not been established; however, it may complement standard cytogenetics.[160,161] FISH should not be performed in the place of cytogenetics but is indicated in any patient with a suspected deletion of 5q (e.g., 5q− syndrome), particularly if cytogenetic analysis has failed, or in those being considered for therapy with lenalidomide.[162] Because of the therapeutic implications (specifically, the responsiveness to imatinib), patients with CMML should be evaluated for 5q33/PDGFRβ translocation in the correct clinical setting.[163]

The diagnosis of hypoplastic MDS is difficult,[154] and this entity must be distinguished from aplastic anemia and paroxysmal nocturnal hemoglobinuria (PNH). Therefore, peripheral blood flow cytometry for CD55 and CD59 expression should be considered; the presence of a minor population of PNH-type cells in MDS may have prognostic and therapeutic implications.[164] By contrast, flow cytometric examination of the BM is controversial in MDS.[152] Flow cytometry may improve diagnostic accuracy in low-grade MDS,[165] and demonstration of aberrant antigen expression by this means may be helpful when morphologic and cytogenetic findings are indeterminate[166]; differences in enriched blast cell phenotype in MDS compared with AML have been demonstrated.[167] The import of flow in the absence of a definitive diagnosis of MDS by morphologic and cytogenetic testing is unclear, however, and consensus guidelines are being developed for the use of flow cytometry in the diagnosis of MDS.[168] Bone marrow flow cytometry studies may be helpful if concurrent T-cell large granular lymphocyte disease is suspected.[169]

Dysplasia is not specific for MDS and has been reported in the setting of regeneration following chemotherapy, hemolysis, and transplantation[155] (so-called stress dyserythropoiesis) and indeed in

the marrow of healthy subjects (typically dyserythropoiesis).[170] The presence of bone marrow dysplasia at presentation in patients with de novo AML (i.e., with no antecedent history of MDS) does not appear to have independent prognostic implications.[171–173] It is therefore important to consider other causes of cytopenias and dysplasia, some of which are potentially reversible. These include vitamin B_{12} deficiency, folate deficiency, and suspected or proven exposure to heavy metals.[152] Copper deficiency may mimic MDS[174] and is reversible with supplementation. Reversible dysplastic changes also have been noted rarely after immunosuppressive medications.[175]

A baseline reticulocyte count, iron studies (ferritin, Fe, total iron-binding capacity [TIBC]) and erythropoietin level are recommended for patients with anemia, particularly for those with lower-risk disease who may be candidates for blood transfusion and treatment with erythropoietin.[152] Baseline human leukocyte antigen (HLA) typing should be performed in any patient who is a potential candidate for allogeneic hematopoietic stem cell transplantation, and possibly for HLA-DR15 status (which may predict response)[124] before administration of antithymocyte globulin. HIV testing also should be considered in appropriate patients (see later discussion).

PATHOLOGY AND CLASSIFICATION

Minimal diagnostic criteria for MDS require morphologic abnormalities in greater than 10% of cells within a specific hematopoietic lineage[121] (see Figs. 105-1 and 105-2). Refinements in diagnostic criteria are in evolution, with future systems incorporating more refined histopathologic and immunologic determinants, along with updated cytogenetic criteria and methods of detecting cytogenetic abnormalities, such as FISH and high-resolution genomic or SNP array technology.[78,80,176,177]

French-American-British Classification

Two morphologic classification systems are commonly used to distinguish MDS subtypes. The FAB system, adopted in 1982, is a morphology-based system that was able to predict rates of survival and of transformation to AML by dividing MDS into subgroups based on the presence or absence of ringed sideroblasts, peripheral blood monocytosis, and myeloblast percentage (Table 105-1).[178] Five MDS categories are recognized in the FAB system: refractory anemia (RA); refractory anemia with ringed sideroblasts (RARS); refractory anemia with excess blasts (RAEB); refractory anemia with excess blasts in transformation(RAEB-t); and chronic myelomonocytic leukemia (CMML), an "overlap syndrome" that can include features of a myelodysplastic syndrome, a myeloproliferative disorder, or both.

Both RA and RARS are typified by a hypercellular bone marrow and dysplasia of the erythoid cell lines with or without dysgranulopoiesis or dysmegakaryopoiesis, in the setting of less than 5% bone marrow or 1% or less peripheral blood myeloblasts. RARS requires less than 15% ringed sideroblasts, in addition. A diagnosis of RAEB requires these foregoing bone marrow abnormalities, along with 5% to 20% bone marrow (or up to 4% peripheral blood) myeloblasts. If Auer rods are present in the myeloblasts, or if the myeloblast percentage in the bone marrow falls between 21% and 29% (or 5% or less in the peripheral blood), the diagnosis becomes RAEB-t. CMML is defined by a peripheral blood monocytosis with monocyte count greater than1 $\times 10^9$/L.

World Health Organization Classification

The WHO classification system was first published in 1999, and followed with detailed rationales for the differences between the FAB and WHO classifications in 2002[179,180] (Table 105-2). As with other myeloid neoplasms, the WHO system included in its classification of MDS the importance of cytogenetics and the recognition that further prognostic delineation was necessary above and beyond what the FAB system had provided.

In the WHO system, most significantly, the blast threshold for the diagnosis of AML was lowered, from 30% to 20% blasts in the blood or bone marrow, thus eliminating the nomenclature "RAEB-t" category. CMML was formally separated from the MDSs into a new category of "myelodysplastic/myeloproliferative disorders" (MDS/MPD), and a cytogenetically defined MDS subgroup, "MDS with deletion 5q," was added. This karyotype may be found in up to 29% of patients with cytogenetic abnormalities, or 10% to 15% of patients with MDS overall.[181] Finally, the WHO recognized that not everyone with MDS has a refractory *anemia*. Many have refractory thrombocytopenias, or refractory leukopenias with dysplasia predominating in other cell lineages. Thus, refractory cytopenia with multilineage dysplasia (RCMD) requires both erythroid dysplasia and dysplasia in one or more other lineages, or simply in two or more lineages.[180,182]

CYTOGENETICS

As with other hematologic malignancies, such as AML,[183–187] karyotypic abnormalities are playing a larger role in defining distinct disease subtypes of MDS, have prognostic implications, and are even refining choices in therapeutic modalities.[126,181] Incorporation of cytogenetics into morphologic classification significantly improves the prognostic stratification of patients with de novo primary MDS.[188]

Traditionally, patients with a "good-risk" karyotype include those with normal cytogenetics, del(5q), del(20q), and −Y abnormalities; those with a "poor-risk" karyotype include those with complex abnormalities and with abnormalities of chromosome 7; and those

Table 105-1 French-American-British Classification of Myelodysplastic Syndromes

MDS Subtype	Peripheral Blasts (%)	Bone Marrow Blasts (%)	Likelihood of AML Transformation	Median Survival (years)	MDS Diagnoses (%)
Refractory anemia (RA)	≤1	<5	+	4–6	10–40
Refractory anemia with ringed sideroblasts (RARS)	≤1	<5	+	7–8	10–35
Refractory anemia with excess blasts (RAEB)	<5	5–20	+++	1–2	25–30
Refractory anemia with excess blasts in transformation (RAEB-T)	≥5	21–29	++++	0–1	10–30

Table 105-2 World Health Organization Classification and Criteria for the Myelodysplastic Syndromes

MDS Subtype	Blood Findings	Bone Marrow Findings
Refractory anemia (RA)	Anemia	Erythroid dysplasia *only*
	No or rare blasts	<15% ringed sideroblasts
Refractory anemia with ringed sideroblasts (RARS)	Anemia	Erythroid dysplasia *only*
	No blasts	≥15% ringed sideroblasts
		<5% blasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Cytopenias (bi- or pancytopenia)	Dysplasia in <10% of cells in two or more myeloid cell lines
	No or rare blasts	<5% blasts in marrow
	No Auer rods	No Auer rods
	$<1 \times 10^9$/L monocytes	<15% ringed sideroblasts
Refractory cytopenia with multilineage dysplasia and ringed sideroblasts (RCMD-RS)	Cytopenias (bi- or pancytopenia)	Dysplasia in ≥10% of cells in 2 or more myeloid cell lines
	No or rare blasts	≥15% ringed sideroblasts
	No Auer rods	<5% blasts
	$<1 \times 10^9$/L monocytes	No Auer rods
Refractory anemia with excess blasts-1 (RAEB-1)	Cytopenias	Unilineage or multilineage dysplasia
	<5% blasts	5% to 9% blasts
	No Auer rods	No Auer rods
	$<1 \times 10^9$/L monocytes	
Refractory anemia with excess blasts-2 (RAEB-2)	Cytopenias	Unilineage or multilineage dysplasia
	5% to 19% blasts	10% to 19% blasts
	Auer rods ±	Auer rods ±
	$<1 \times 10^9$/L monocytes	
Myelodysplastic syndrome, unclassified (MDS-U)	Cytopenias	Unilineage dysplasia in granulocytes or megakaryocytes
	No or rare blasts	<5% blasts
	No Auer rods	No Auer rods
MDS associated with isolated del(5q)	Anemia	<5% blasts
	<5% blasts	No Auer rods
	Platelets normal or increased	Isolated del(5q)

with "intermediate-risk" karyotypes include patients with other abnormalities not defined in the other risk groups.[126] Good-risk cytogenetic subtypes are associated with a median survival period of 3 to 4 years; intermediate-risk patients survive a median of approximately 2 years; and those with poor-risk karyotypes survive less than 1 year. Some degree of overlap has been observed between karyotypes typical of MDS patients and those of older adults with AML, in whom a majority of cases probably evolved from a known, or unknown, antecedent hematologic disorder such as MDS.[126,183,185,189] Indeed, many consider the two disorders to be similar, with AML placed at a more advanced position on the disease spectrum.

Recently, the German MDS group modified this cytogenetic risk schema, on the basis of data from more than 2000 patients.[190,191] Within the good-risk group, which had a median survival period of 55.4 months in 802 patients, in addition to those abnormalities mentioned earlier, these researchers include patients with 15q–, t(15q), 12p–, +21, –X, t(1q), t(7q), t(11q), and –21, with survival periods ranging from 32 to 108 months. Note that this differs from the International Prognostic Scoring System (IPSS) cytogenetic risk schema (Table 105-3) in that t(7q), formerly a poor-risk abnormality, is now considered a good-risk factor. Patients who have complex cytogenetics with three abnormalities have been shifted into the intermediate-risk category, which is now divided into "Int-1" and "Int-2," while those with more than three abnormalities and t(5q) have been placed in the poor-risk category. This schema is undergoing further refinement and analyses and is expected to be validated using external cytogenetic data.

Deletions of chromosome 5 are worthy of special attention. Del(5q) is the most common cytogenetic abnormality, and the commonly deleted region is at 5q31-32.[192] Del(5q) is present in approximately 25% of patients with an abnormal karyotype[181] and has particular therapeutic significance because of the sensitivity to lenalidomide.[162] A subset of patients with del(5q) will have the so-called 5q– syndrome, considered separately as a unique syndrome[193] and typified by severe anemia, normal or moderately increased platelets, rare transformation to AML, and prolonged survival. The 5q– syndrome occurs more frequently in females and has characteristic bone marrow features of dysmegakaryopoiesis, with no excess in blasts (see Fig. 105-3).[180,192,193]

PROGNOSIS

A number of clinical and pathologic factors, used both in isolation and in combination, can be used to predict overall survival and risk

Table 105-3 International Prognostic Scoring System

CALCULATION OF PROGNOSTIC SCORE

	SCORE				
Feature	**0**	**0.5**	**1.0**	**1.5**	**2.0**
Bone marrow blast (%)	<5	5–10		11–20	21–29
Cytogenetics	Good	Intermediate	Poor		
Cytopenias	0 or 1	2 to 23			

ESTIMATION OF PROGNOSIS

Overall Score	IPSS Subgroup	Median Survival (years)
0	Low	5.7
0.5–1.0	Intermediate-1 (Int-1)	3.5
1.5–2.0	Intermediate-2 (Int-2)	1.2
≥2.5	High	0.4

Patients with a "good-risk" karyotype include those with normal cytogenetics, del(5q), del(20q), and -Y abnormalities; those with a "poor-risk" karyotype include those with complex abnormalities and with abnormalities of chromosome 7; and those with "intermediate" karyotypes include patients with other abnormalities not defined in the other risk groups.

IPSS, international prognostic scoring system.

of transformation to AML for an individual patient with MDS (Table 105-4).

The first, and probably most obvious, prognostic factor is the pathologic classification itself. Low-risk MDS is less likely to evolve to AML, and affected patients are more likely to live longer than those with high-risk MDS. Under the FAB classification system,[178] the low-risk MDS category includes patients with RA and RARS (in whom median survival ranges from approximately 3 to 8 years and risk of AML transformation is 10% to 35%), whereas with the WHO classification system,[180] this would include those diagnosed with RA, RARS, RCMD, RCMD-RS, MDS-U, and MDS with an isolated deletion of 5q (in whom median survival ranges from approximately 2 to 8 years and risk of AML transformation is similarly low).[126,194,195] Patients with RA and RARS enjoy a longer survival than those with RCMD and RCMD-RS, whereas those with the 5q− syndrome, or with an isolated del(5q) cytogenetic abnormality, have the best overall survival and lowest likelihood of AML transformation.[196] For patients with high-risk disease (those with an increased percentage of bone marrow myeloblasts—using the FAB system, those with RAEB, RAEB-t, and CMML subsets, whereas the WHO system would include those with RAEB-1 and -2), median survival ranges from 0.5 to 1.5 years and AML transformation is almost guaranteed, unless the patient dies from complications of MDS first.[126,194,195] These prognostic estimates worsen with increasing age and appear to be modified by lifetime transfusion amount (a greater number of transfusions translates to a worse survival)[197] and its correlate, iron overload.[198,199]

In 1997, the IPSS combined the number of cytopenias and cytogenetic information with the percentage of bone marrow blasts in developing a scoring system that accurately predicted survival and the risk of AML transformation (see Table 105-3).[126] This multivariable analysis combined data from seven international databases for patients with mostly untreated MDS (only 5% had received oral chemotherapy, and 2%, hematopoietic growth factor therapy) and was able to risk-stratify them into four distinctive subgroups: "Low" (a score of 0); "Intermediate-1" (a score of 0.5 to 1.0); "Intermediate-2" (a score of 1.5 to 2.0); and "High" (a score of 2.5 or greater; see Table 105-3). This system has further usefulness within low-risk MDS groups (scores of 0 to 1.0) when patients are analyzed by age as younger or older than 60 years, or younger or older than 70 years. The "High" risk category includes patients with IPSS scores of 1.5 or higher. Although the IPSS is criticized for being developed from data that preceded the current treatment era and as being applicable only to patients with newly diagnosed MDS, it has withstood the test of time and remains the most widely used predictive tool, determining eligibility for clinical trials and even being incorporated into the U.S. Food and Drug Administration (FDA) labeling for lenalidomide.[162] A revision of the IPSS is being developed that most likely

Table 105-4 Common Prognostic Factors for Survival in Myelodysplastic Syndrome

Characteristic	Favorable Prognostic Factor	Intermediate Prognostic Factor	Unfavorable Prognostic Factor
Morphology	*FAB subtype*:	CMML	RAEB, RAEB-t
	RA, RARS		
	WHO subtype:	RCMD, RCMD-RS, CMML-1	RAEB-1, RAEB-2, CMML-2
	del(5q), RA, RARS		
Cytogenetics	*IPSS*:	Others not in favorable or unfavorable	Chr 7 abn, complex (≥3 abn)
	del(5q), –Y, del(20q), normal

	IPSS + 15q–, t(15q), 12p–, +21, –X, t(1q), t(7q), t(11q), –21		
Clinical factors	No transfusion needs		High transfusion needs
	Normal blood counts		Pancytopenia
	Low serum ferritin (<1000)		High serum ferritin (>2000)
	Age <60 years		Age >70 years
			β_2-Microglobulin
			High Bmi-1 or WT1 expression

abn, abnormality(ies); chr, chromosome; CMML, chronic myelomonocytic leukemia; FAB, French-American-British; IPSS, International Prognostic Scoring System; RA, refractory anemia; RAEB(-t), refractory anemia with excess blasts (in transformation); RARS, refractory anemia with ringed sideroblasts.

will vary scores for degree of cytopenias (with different scores for patients with, for example, platelet counts of 90,000/mL versus 9000/mL; such patients would be scored similarly using the existing IPSS) and for lactate dehydrogenase (LDH) level and will alter the cytogenetics risk score classification.[200]

More recently, a prognostic scoring system based on the WHO classification system, termed the WHO Prognostic Scoring System (WPSS), has been developed.[194] It is based on data from a learning cohort of 467 de novo MDS patients seen by centers in Italy from 1992 to 2002 and validated using 620 de novo MDS patients from Germany, seen from 1982 to 2003. Patients were given a score based on their WHO classification, cytogenetic risk score (using the IPSS scoring scheme), and transfusion requirement. Based on this score, patients are divided into one of five risk groups—very low, low, intermediate, high, and very high. Although the WPSS is able to clearly delineate survival differences among these groups, whether it is more accurate than the IPSS, or provides any predictive advantage, is not yet clear.

In addition to the IPSS, other clinical and molecular prognostic factors predicting MDS progression, such as β_2-microglobulin[201] or Bmi-1[202] or WT1 expression,[203] have been proposed, but they have not yet been validated in multicenter prospective studies. The prognostic factors are listed in Table 105-4.

Determining if and when to treat a patient with MDS is far from straightforward. Some patients with low-risk MDS who have a mild cytopenia detected on a random laboratory test may have no symptoms and no transfusion needs; such patients can be observed without therapy for years. Other patients with high-risk MDS, multiple cytopenias, and a blast percentage just shy of the 20% required for an AML diagnosis need immediate treatment. Three decision tools are available to assist in determining the most appropriate therapy for various MDS subtypes.

The first decision tool, developed by Hellstrom-Lindberg and colleagues,[204,205] used 94 patients across three hematopoietic growth factor studies to determine predictors of response to growth factors—in their case, a combination of recombinant erythropoietin (EPO) and granulocyte colony stimulating factor (G-CSF). They found that patients with low transfusion needs (less than 2 units of packed RBCs per month) and a low baseline serum EPO level (less than 500 IU—called the "good" hematopoietic growth factor predictive group) had a 74% chance of responding to hematopoietic growth factor, whereas those with high transfusion needs (greater than or equal to 2 units of packed RBCs per month) and a high EPO level (greater than 500 IU—defining a "poor" hematopoietic growth factor predictive group) had only a 7% chance of responding. It is at this point in the disease course that tumor burden (e.g., the number of dysplastic cells or the cytokine effects from those dysplastic cells) overcomes the ability of intrinsic or extrinsic hematopoietic cell stimulatory factors to promote erythrocyte production. Patients who had a mixed picture (low transfusion needs and high EPO level, or high transfusion needs and low EPO level—the "intermediate" hematopoietic growth factor predictive group) had a 23% chance of responding to hematopoietic growth factor.

A second decision tool took this one step further. A group of Cleveland investigators took individual patient data on 799 patients with MDS treated with either hematopoietic growth factor (in 394 patients) or non-growth factor (NGF) (in 405 patients) approaches from 90 articles published over a 20-year period and applied these data to the Hellstrom-Lindberg model to determine the most appropriate initial therapy for patients with low-risk MDS (Fig. 105-4), incorporating quality of life and survival data with response rates.[206] This treatment algorithm suggests that patients with low-risk MDS who fall into a good hematopoietic growth factor predictive group (low RBC transfusion needs and low EPO levels) should receive initial treatment with hematopoietic growth factor unless NGF therapy response rates are greater than 46%. This approach maximizes survival in the "good" hematopoietic growth factor group, at 3.38 years for patients who received hematopoietic growth factor, compared with 2.57 years for patients who received NGF. Other patients with low-risk MDS (those falling into "intermediate" and "poor" hematopoietic growth factor predictive groups) probably should receive NGF therapy initially, because survival is again maximized, at 2.57 years in patients who receive NGF treatment in "intermediate" and "poor" hematopoietic growth factor groups, compared with 1.50 years and 0.91 year for patients who received hematopoietic growth factor in both groups, respectively.

In patients with high-risk MDS, a decision analysis published in 2004 determined the optimal timing to bone marrow transplantation (BMT), using data collected from the International Bone Marrow Transplant Registry (IBMTR).[207] The investigators found that patients with low-risk MDS should undergo transplantation just before transformation to AML, but not up-front. Patients with high-risk MDS, on the other hand, had the greatest survival advantage with up-front transplantation. This topic is covered later in more detail in the section on allogeneic hematopoietic stem cell transplantation (alloHSCT). These data also have been used to justify up-front

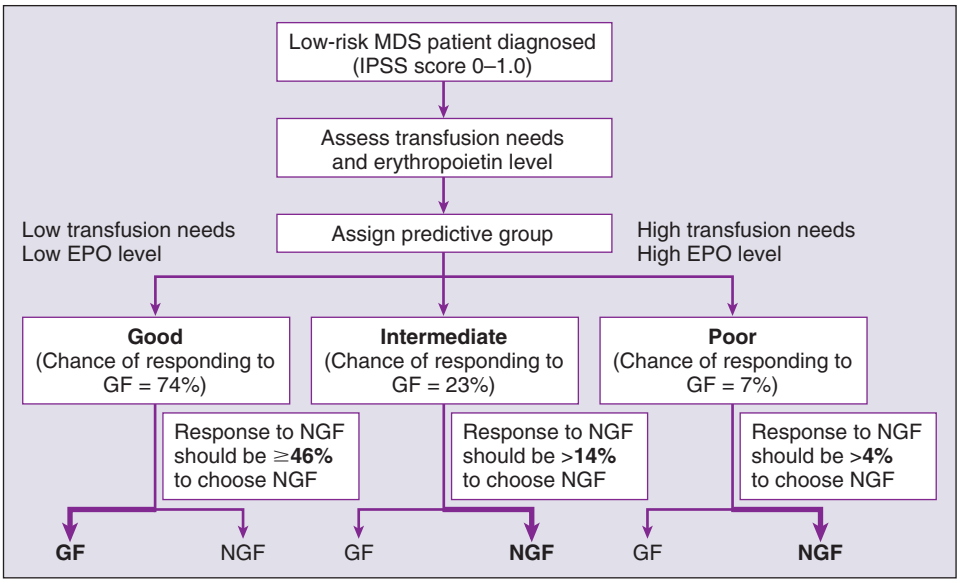

Figure 105-4 • Decision tree for treatment for patients with low-risk myelodysplastic syndrome (MDS). EPO, recombinant epoietin; GF, growth factor; IPSS, International Prognostic Scoring System; NGF, non-growth factor. (Adapted from Sekeres MA, Fu AZ, Maciejewski JP, et al: A decision analysis to determine the appropriate treatment for low-risk myelodysplastic syndromes. Cancer 2007;109:1125.)

treatment with NGF approaches, even in the absence of substantial cytopenias, in patients with high-risk MDS (as described next under "Treatment").

TREATMENT

As stated earlier, although a number of classification and prognostic systems exist for MDS, the disease commonly is divided into low-risk and high-risk subtypes. Doing so assists in providing easier prognostication and, of greater importance, in determining the most appropriate therapy or clinical trial for an individual patient. Although this section on treatment is similarly divided, it is important to recognize that the division is somewhat artificial, and the borders may not be so clearly defined for every patient. For example, MDS in a 72-year-old patient with pancytopenia, a karyotype that includes deletion of chromosome 7, and bone marrow findings of dysplasia along the erythroid cell line and only 3% blasts would be classified as Int-2 (and thus "high-risk") using the IPSS scoring system, with a median survival period of 1.2 years, but would be "low-risk" under the FAB and WHO classification systems, with predicted median survival periods of approximately 5 and 9 years, respectively. A justification could thus be made for treating this patient as either low-risk or high-risk. Additionally, these classification and prognostic systems were developed for patients with de novo disease; it is unclear whether their applicability extends to patients who have undergone treatment previously. Finally, the costs of certain therapies and the whimsy of insurance reimbursement may influence therapeutic decisions, regardless of MDS classification.

Treatment of MDS is divided into regimens using those drugs that are more appropriate for low-risk or early MDS and regimens of agents yielding higher responses in high-risk or advanced MDS. As stated previously, patients with low-risk MDS have less than 5% blasts using the FAB and WHO systems, or an IPSS score of 1.0 or lower. Patients with high-risk MDS have 5% blasts or less or an IPSS score of 1.5 or lower. Therapies directed at sustaining maximal activity of residual functioning bone marrow cells, or at immunomodulation (through abrogation of the effects of proinflammatory, proapoptotic cytokines), generally are applied to patients with early MDS, for whom treatment goals center on minimizing transfusions, restoring effective blood cell production, and maximizing quality of life.[208] Cytotoxic therapies, based on drugs that abrogate the gene-silencing effects of hypermethylation, on the other hand, are used in patients with advanced MDS, for whom treatment goals are similar to those for patients with AML: attaining a partial or complete remission, prolonging survival, and maximizing quality of life.[208,209] Therapies for low-risk and high-risk MDS are reviewed in Table 105-5.

Treatment of Low-Risk Myelodysplastic Syndromes

The goals of therapy for early MDS include improvement of hematologic parameters or decrease in transfusion needs and improvement in quality of life. Thus, if a patient with low-risk MDS has mild cytopenias not requiring transfusions and is asymptomatic, it is appropriate to monitor blood counts regularly without initiating therapy. Patients who are symptomatic, or who are on the verge of requiring a blood or platelet transfusion or have borderline or frank neutropenia, or who now require transfusions, should be started on therapy.

Growth Factors

An initial approach to attempt ameliorating cytopenias may be to initiate growth factor therapy. Patients with anemia may receive recombinant erythropoietin agents (i.e., EPO), whereas those with neutropenia may be given G-CSF or GM-CSF. At present, agents that stimulate platelet growth are not approved for the treatment of MDS by the FDA, although preliminary trials are under way testing the compound AMG531 for this purpose.

Predictive schemes to determine which patients will benefit from hematopoietic growth factor, and whether hematopoietic growth factor or NGF therapies should be initiated, have been developed and are described earlier. A number of trials have been published using EPO alone, at varying schedules and doses, or in combination with G-CSF or GM-CSF, in patients with MDS, with responses of approximately 40% in low-risk patients using International Working Group (IWG) criteria for response, and a possible advantage to combination therapy.[125,210–219] Attention has been drawn recently to the use of growth factors for treatment of a variety of malignancies, including MDS, with a possible adverse outcome in patients with solid tumors in whom hemoglobin was maintained at higher levels. For this reason, it is recommended that, in those patients responding to growth factors, hemoglobin levels be maintained in the range of 11 to 12 g/dL.

Two studies address whether or not a survival advantage is provided through the use of growth factors. The first, from a Norwegian group of investigators, examined 123 patients who received combination erythropoietin and G-CSF and compared data for these patients with those for 334 patients with untreated MDS in the IPSS/IMRAW database. No survival advantage or delay in transformation to AML was detected, although the IPSS/IMRAW database lacked information on WHO classification, transfusion needs, and baseline erythropoietin level.[220] When 121 patients from the same cohort were compared with a matched cohort of 268 patients with untreated MDS from Pavia, Italy, in whom these variables were available for matching, a survival advantage was demonstrated for treatment with hematopoietic growth factor, though still no delay in transformation to AML.[221]

The second, from the Cleveland group, reviewed 162 studies published from 1985 to 2005 that included 2592 patients with low-risk MDS treated with hematopoietic growth factor ($N = 1587$) or NGF ($N = 1005$) approaches.[222] After reclassification of patients according to IPSS scores and IWG response criteria, and adjustment for baseline differences in transfusions needs, years with MDS, previous treatments, and FAB/IPSS category, a survival advantage was found in patients in the hematopoietic growth factor treatment group at 6, 12, 18, and 24 months of follow-up. Whether this survival advantage results from diminished transfusion requirements in patients responding to growth factor, increased treatment-related morbidity in patients receiving non-growth factor, or a direct effect of growth factor on dysplastic hematopoietic precursors, is unknown.

Other novel cytokines for cytopenias (e.g., IL-3 or recombinant human IL-6) unfortunately have limited activity in MDS, along with significant toxicity.[223,224]

Immunomodulatory Agents

ANTITHYMOCYTE GLOBULIN. In at least a subset of patients with low-risk MDS, disease pathophysiology is thought to be mediated through T-cell-dependent immune destruction of hematopoietic precursors, akin to aplastic anemia. Thus, responses to immunosuppressant drugs can be seen. Four phase II studies have been reported using antithymocyte globulin with or without cyclosporine. In these studies, typical response rates occur in approximately 30% of the patients, with response rates as high as 50% seen in selected series.[225,226] Predictors of response have been reported as younger age, a brief transfusion history, and HLA DR-15 positivity, as well as treatment for hypoplastic subtypes of MDS[124]; more recently, the importance of HLA DR-15 positivity has been disputed. Cyclosporine therapy also has demonstrated clinical improvement, with decrease in cytopenias and reduced transfusion dependency in hypoplastic MDS.[227]

THALIDOMIDE. The proposed mechanism of action of thalidomide is through cytokine inhibition, receptor modulatory effects, modulation of cell adhesion to bone marrow stromal cells,

Table 105-5 Biologic and Chemotherapeutic Agents for Treatment of Low-Risk and High-Risk Myelodysplastic Syndromes

Therapeutic Agents (by Class)	Response Rate	Survival Impact	Cell Line(s) Affected	Comment(s)
Growth factors				
Erythropoietin G-CSF GM-CSF Combination GF (AMG531)	~40%	Yes, compared with no treatment and compared with non-GF therapy in retrospective studies	RBC, WBC (Plt)	With erythropoietin agents, target Hgb should be 11–12 g/dL Some evidence for synergy with combination GF Greatest effect in patients with low baseline serum erythropoietin levels and low transfusion needs (AMG531 still in clinical trials)
Immunomodulatory drugs				
ATG/CyA	~30%	None demonstrated for any drug	RBC, WBC, Plt	Most effective in younger patients with shorter disease duration; may work better in those with hypocellular marrows, HLA-DR$^+$
Thalidomide	15–20%		RBC	Dose escalation limited by peripheral neuropathies, fatigue, constipation; highly teratogenic
Lenalidomide	66% in del(5q), 26% in non-del(5q)		RBC	Pancytopenia significant in del(5q) patients, may be predictive of response; possible teratogenicity
Cytotoxic/differentiating agents				
Arsenic trioxide	~20%	None demonstrated	RBC, Plt	More effective in low-risk than high-risk patients Can cause significant cytopenias Monitoring of electrocardiogram for QTc prolongation essential
Hypomethylating agents				
5-Azacytidine Decitabine	CR in 11–16%; HI in 15–30%	Delay in transformation to AML and death for 5-aza (all MDS subtypes) and for decitabine (high-risk MDS)	RBC, WBC, Plt	Both agents most appropriately used in high-risk MDS Can cause significant cytopenias Greatest effect seen in patients who receive 4–6 cycles of treatment Both drugs equi-efficacious

ATG, antithymocyte globulin; 5-aza, 5-azacytidine; CR, complete response; CyA, cyclosporin A (cyclosporine); G-CSF, granulocyte colony stimulating factor; GM-CSF, granulocyte macrophage colony stimulating factor; Hgb, hemoglobin; HI, hematologic improvement; Plt, platelet; RBC, red blood cell; WBC, white blood cell.

cytotoxic effects, and anti-angiogenesis mechanisms of action, particularly through altering tumor necrosis factor-α (TNF-α) and VEGF activity.[228–231] Thalidomide decreases bone marrow vascularity and was the first agent of this class of small-molecule inhibitors of angiogenic cytokines to be investigated for treatment of MDS.

Four phase II studies have evaluated use of thalidomide for single-agent therapy in MDS. In the largest series, 83 patients with early and advanced MDS were enrolled, with thalidomide dose escalated from 100 mg to 400 mg per day in tolerant subjects.[232] Fifty-eight patients had early MDS, and 25 had advanced MDS. Fifteen patients (19%), 14 of whom had early MDS, showed hematologic improvement (defined as red blood cell transfusion independence or greater than 50% decrease in transfusion burden), including 10 previously transfusion-dependent patients who became transfusion-independent. Using IWG response criteria,[209] 11 patients had a major hematologic response, while 4 had a minor hematologic response (considered clinically less meaningful).

In another study of 25 transfusion-dependent patients with MDS, 5 (25%) reached transfusion independence after treatment with thalidomide.[233] One other study of 34 patients with MDS showed varied hematologic lineage improvement in 19 (56%) after treatment with thalidomide,[234] while a multicenter phase II study, presented as an abstract and conducted by the North Central Cancer Treatment Group, reported a response in only 7 of 73 patients (10%), most likely owing to high subject attrition resulting from an aggressive dose escalation scheme (from 200 to1000 mg daily).[235] Although thalidomid in general was somewhat effective, rates for toxicity-related discontinuation of the drug ranged from 12% to 40% across all of these studies, with the most common being the nonhematologic toxicities of fatigue, constipation, shortness of breath, and peripheral neuropathy, in addition to well-described hematologic toxicities. The risk for development of these side effects is dose- and time-dependent and therefore limits long-term administration—a discouraging reality, because patients who can tolerate the drug achieve hematologic response rates that approach 30%.

LENALIDOMIDE. Lenalidomide (CC-5013, Revlimid), one of only three drugs approved for the treatment of MDS, is a novel 4-amino-glutarimide analog of thalidomide. It has a mechanism of action is similar to that of thalidomide but is devoid of its neurologic effects and is 50 to 2000 times more potent.[228–231] Other in vitro studies demonstrate lenalidomide's ability to inhibit VEGF-induced clonogenic response and VEGF expression in KG1 AML cell lines, and to block VEGF-induced cell cycle recruitment and adhesion of KG1 AML cells.[236] Lenalidomide also has been shown to reduce bone marrow vascularity in subjects demonstrating clinical response during treatment.

Lenalidomide was first studied in a phase I-II trial exploring the safety and efficacy of the drug in 43 patients with MDS with transfusion-dependent or symptomatic anemia.[237] All patients either had a high endogenous erythropoietin level of greater than 500 mU/mL or had already received and not responded to recombinant erythropoietin.

Three oral dosing schedules were evaluated: 25 mg daily, 10 mg daily, and a syncopated regimen of 10 mg daily for 21 days of a 28-day cycle. Of the 43 patients enrolled, 38 had early MDS (with IPSS scores of "low" or "int-1") and 74% were transfusion-dependent, with 33 (77%) having failed previous therapy with recombinant erythropoietin. Twenty patients (46%) had clonal karyotypic abnormalities, of whom 12 had an interstitial deletion of 5q31.1 (11 in isolation and 1 with trisomy 21).

The major side effects of all dosing regimens were grade 3 or 4 neutropenia and thrombocytopenia, which occurred in a majority of subjects, and was dose-dependent, necessitating treatment interruption and dose adjustment in a majority of subjects.

Lenalidomide was effective in restoring erythropoiesis, particularly in the del(5q) subset of patients. Twenty-one patients (49%) had a major hematologic response, including 20 of 32 (63%) transfusion-dependent patients, by a median of 9 to 11.5 weeks. After a median follow-up period of 81 weeks, the median response duration had not been reached and was greater than 48 weeks. Of the 21 patients with a major hematologic response, anemia recurred in 4.

Twenty patients started the study with clonal cytogenetic abnormalities. Of these, 11 had cytogenetic responses; 10 with complete responses, including 9 with a deletion of 5q31.1 and 1 with t(1;22)(q21p11.2). Cytogenetic responses occurred only in patients who had a hematologic response. Whether cytogenetic remissions correlate with improved survival, as might be suspected, remains to be seen.

Two multicenter phase II trials of lenalidomide in MDS also have been conducted and were closed to enrollment in January 2004.[238] The first studied use of the drug with the syncopated or 10-mg daily dosing schedule in 215 transfusion-dependent patients with early ("low" or "int-1" risk) MDS, but without the del(5q) cytogenetic abnormality. The median age was 72 years, and 95 patients (44%) experienced hematologic improvement, with 56 patients (26%) achieving transfusion independence for a median of 41 weeks (range, 8 to 136 weeks). Only 9% of evaluable patients achieved a complete cytogenetic response.

The second phase II trial used the same dosing regimens in 148 transfusion-dependent patients with low-risk MDS with the 5q31.1 deletion. A total of 99 patients (67%) achieved transfusion independence, and 75% of responders experienced a cytogenetic response. Almost half of these patients had a complete cytogenetic response (44% of all patients), and approximately one third of patients achieved complete pathologic responses with resolution of cytologic dysplasia. The median duration of red blood cell transfusion independence, when these patients were combined with similar patients from the phase I-II study, was 2.2 years (range, 0.1 to 4.4 years), with no plateau to the curve—meaning that with adequate follow-up, all patients are likely to relapse. No difference was found in the rate of erythroid response according to karyotype complexity. Development of grade 3 or 4 myelosuppression was the most common adverse event, and three patients (1.5%) were suspected to have died as a result of possible therapy-associated complications of bleeding or infection. Preliminary studies indicate that treatment-related thrombocytopenia and neutropenia may correlate with achieving transfusion independence.

Lenalidomide was approved by the FDA on December 27, 2005, for the treatment of IPSS Low and Int-1 MDS in patients who harbor the del(5q) abnormality, at a dose of 10 mg daily. As with the phase I-II study, almost 80% of patients receiving this dose required a dose reduction.

Because preclinical investigations indicate that the erythropoietic effects of lenalidomide in non-del(5q) MDS are erythropoietin-dependent, the potential for additive benefit is being tested in a phase III intergroup study comparing lenalidomide monotherapy with a darbepoetin-lenalidomide combination. Lenalidomide also is being explored in the cooperative group setting as single-agent therapy for the treatment of older adults with AML associated with the del(5q) abnormality, based on the phase II MDS data showing efficacy in MDS patients with complex cytogenetics that included this specific deletion.[238] Lenalidomide in combination with the hypomethylating agent 5-azacytidine also is being studied in a multi-institution phase I trial in patients with advanced MDS.

Arsenic Trioxide

Two phase II studies have explored the use of arsenic trioxide in patients with MDS and show remarkably similar results. The first study, conducted in the United States, enrolled 76 patients, 47% with low-risk MDS and 53% with high-risk MDS.[239] Patients received arsenic trioxide at a dose of 0.25 mg/kg daily on days 1 to 5 and days 8 to 12 of a 28-day cycle. The median age of the patients was 69 years. A hematologic response, as defined by the IWG, was achieved in 20% of those who received a dose of arsenic trioxide (24% in the low-risk group). Responses took a median of 3.6 months to occur and were durable, lasting a median of 6.8 months.

In the European Union study, arsenic trioxide was administered at a dose of 0.30 mg/kg daily for the first 5 days and then at 0.25 mg/kg twice weekly for at least 15 weeks thereafter. Of 115 patients with MDS enrolled in the study, 43% had low-risk and 57% high-risk disease.[240] Responses occurred in 21% of the patients (26% in the low-risk group) at a median of 1.9 months. Toxicities were similar for both trials and included mainly hematologic complications (with grade 3 or 4 neutropenia and thrombocytopenia occurring in greater than 50% of patients). Arsenic trioxide is approved by the FDA for the treatment of relapsed acute promyelocytic leukemia and is being studied in multiple clinical trials in combination with other drugs for the treatment of MDS.

Therapies for Advanced Myelodysplastic Syndromes

Treatment goals for advanced MDS differ from those for early MDS. As the disease moves closer to leukemia, it becomes more imperative to delay transformation to leukemia and to achieve a remission.

Hypomethylating Agents

Two hypomethylating drugs have been approved by the FDA for the treatment of all MDS subtypes. Both purportedly work through a similar mechanism of action: protecting cytosine residues on tumor suppressor genes from being methylated, and thus inactivated.[241] The first agent, 5-azacytidine (Vidaza), was studied in a phase III trial in which patients were randomized to receive either the drug or supportive care.[242] Patients assigned to the supportive care group could cross over to the treatment group if their disease worsened. Patients in the treatment group received 75 mg/m^2 daily for 7 days of a 28-day cycle. Ninety-nine patients were randomly assigned to the treatment group and 92 to the supportive care group; of the latter, 49 eventually crossed over to receive active therapy. When data were analyzed using CALGB response criteria (which differ from IWG criteria most

notably in the requirement for maintenance of response for 4 rather than 8 weeks), CRs occurred in 7% of patients, partial responses (PRs) in 16%, and hematologic improvement in 37%, for an overall response rate of 60%. In a subsequent analysis of these and other CALGB data using IWG response criteria, Silverman and associates report lower response rates of 14% combined CR–PR and 30% hematologic improvement.[243] Major toxicities, as with any active agent for the treatment of MDS, included cytopenias. Patients also reported nausea and injection site-related complications.

Decitabine (Dacogen) also was studied in a phase III trial, in which 89 patients receiving this drug were compared with 81 managed with supportive care.[244] Patients received decitabine at a dose of 15 mg/m^2 every 8 hours over 3 days, with a cycle repeated every 6 weeks. Using IWG criteria, CRs occurred in 9%, PRs in 8%, and hematologic improvement in 13%, for an overall response rate of 30%. As with 5-azacytidine, major toxicities were hematologic.

In the 5-azacytidine registration study, a significant delay in transformation to AML or death was seen, but not a significant prolongation of survival among patients in the treatment group. In the decitabine trial, no significant delay in transformation to AML or death was observed, probably as a result of enrollment of different patients in each study (with more early MDS patients in the decitabine study), and of an inadequate number of cycles of decitabine. In patients with IPSS Int-2 or high-risk disease, however, an improvement in delay to AML transformation was seen. The two drugs are considered by most investigators to be clinically equivalent, and alternate dosing schedules, including once-daily dosing of decitabine over 5 days every 28-day cycle, have been explored.[245] Azacytidine was recently approved by the FDA in an intravenous dosing regimen, based on pharmacokinetic studies in 14 patients.

Intensive Therapy

It has long been recognized that intensive induction chemotherapy with AML-type regimens can induce complete remission in MDS, particularly in younger patients.[246,247] The induction death rate is high, however, and remissions typically are of short duration, particularly in patients with poor-risk cytogenetics,[248] so the long-term disease-free survival remains dismal with this strategy.[249] In general, therefore, intensive chemotherapy has been reserved for "younger" patients (i.e., younger than 65 years) with high-risk disease (specifically, greater than 5% blasts, or MDS in transformation to AML) and those with critical cytopenias (in particular, thrombocytopenia or neutropenia), or for cytoreduction before transplantation. Patients with RAEB have CR rates similar to those for patients with RAEB-t or AML and, when data are corrected for other prognostic factors (e.g., cytogenetics, age) experience similar event-free and overall survival. In combination with the poor prognosis of RAEB, this serves as the justification for administration of AML-type chemotherapy to patients with RAEB.[111]

Nevertheless, the clinical results with anthracycline-cytarabine induction therapy are similar to those seen in older patients with de novo AML, with CR rates of approximately 40% to 50%, induction mortality rates of 10% to 20%, and median duration of response of 6 to 10 months.[250–253] In some cases, recovery with lower-grade MDS (i.e., conversion of RAEB to RA—so-called partial response) has been observed, with transient clinical improvement manifested by decrease in cytopenias and reduced transfusion requirements.[248,251]

Little evidence, however, has been found for long-term disease-free survival after intensive chemotherapy. In a report from France, 10 of 99 patients selected for intensive therapy survived longer than 4 years; these patients were younger (median age, 42 years), underwent treatment soon after diagnosis, exhibited normal or favorable cytogenetics, and had RAEB-t at diagnosis.[251] Of interest, studies of X-chromosome inactivation patterns using the human androgen receptor (HUMARA) assay indicate that long-term remission after intensive chemotherapy is characterized by polyclonal hemopoiesis,[254,255] suggesting a recovery of normal hematopoiesis. A retrospective Dutch study of intensive chemotherapy for 83 "younger" MDS patients (younger than 61 years) found that the IPSS was able to predict survival for high-risk patients but not for those in intermediate-risk groups and indeed suggested an improved survival for intermediate-2-risk patients (median survival, 3.4. years).[256] For patients older than 60 years with poor-risk cytogenetics, little evidence has been found for benefit from intensive chemotherapy, with low CR rates and a short median survival of only 4 months.[248] Other chemotherapeutic drugs with apparent activity in MDS are irinotecan[257] and the anti-CD33 immunotoxin gemtuzumab ozogamicin (Mylotarg).[258,259]

In a prospective study of 184 younger patients (median age, 47 years, range, 16 to 60) receiving intensive induction chemotherapy with idarubicin, cytarabine, and etoposide followed by allogeneic or autologous transplantation, the CR rate was 54% and the induction death rate 16%, and 63 patients went on to undergo either allogeneic (N = 28) or autologous transplantation (N = 35).[253] Disease-free survival rates were similar in patients with and those without a donor (31% and 27%, respectively); of interest, a follow-up analysis showed no difference in survival based on the availability of a donor.[260] The strategy of intensive chemotherapy followed by transplantation is clearly feasible, and follow-up studies are required to determine the role of chemotherapy in patients who have an allogeneic donor (and indeed the role of autologous transplantation).

Other intensive regimens also have been employed in younger patients with MDS, including fludarabine and cytarabine in combination with idarubicin[261] or mitoxantrone,[262] with similar clinical results. The most extensive experience with intensive chemotherapy in MDS comes from the M.D. Anderson Cancer Center in Houston. In a series of successive studies, 1279 patients with AML, RAEB-t, or RAEB received intensive chemotherapy with cytarabine combined with either idarubicin (N = 322), fludarabine (N = 600), or topotecan (N = 357).[263] The CR rates were higher with idarubicin (77%), and the event-free and overall survival rates were superior with this agent (63 weeks and 70 weeks, respectively). It must be emphasized that the idarubicin regimen was not a curative therapy, but that fludarabine- and topotecan-based combinations were inferior, and the investigators themselves highlighted the need for new therapies. In a follow-up analysis focusing on the 394 newly diagnosed MDS patients with RAEB and RAEB-t who received treatment in sequential studies, the CR rate with intensive therapy was 58% and was significantly associated with karyotype, age, and the duration of antecedent hematologic disorder, but not with the IPSS score.[131] Survival was associated with cytogenetic features, age, and performance status. Of importance, after prognostic factors were accounted for, survival remained inferior with fludarabine-cytarabine combinations but was similar with idarubicin and topotecan combinations. More recently, the long-term follow-up results in 510 patients (median age, 63 years) were reported from M.D. Anderson Cancer Center. Patients with higher-risk MDS received intensive therapy.[264] The overall CR rate was 55%, with an induction mortality rate of 17% and 5-year survival rate of 8% (11% for patients younger than 65 years; 17% for patients with normal karyotype). The combination of topotecan and cytarabine was equivalent to idarubicin regimens in relation to CR and survival but was associated with a substantially lower induction death rate (6% versus 17%; P = 0.04). This experience suggests that intensive chemotherapy is appropriate for selected patients and that topotecan plus cytarabine is a reasonable alternative to idarubicin-cytarabine combinations, particularly in older patients with contraindications to anthracyclines, such as severe cardiomyopathy.

Overexpression of the multidrug resistance protein (MDR-1) gene product P-glycoprotein has been demonstrated in MDS and may contribute to chemotherapy resistance (i.e., lower CR rates and high relapse rates).[251,265–269] Efforts to target P-glycoprotein in combination with intensive chemotherapy to improve clinical outcomes have had mixed results. In a randomized French study, intravenous

quinine was administered in combination with mitoxantrone and intermediate-dose cytarabine to 131 patients with MDS.[270] No difference in the CR rate, induction deaths, or overall survival was observed between the two groups. In the subset of 42 patients in whom P-glycoprotein expression could be confirmed, however, a significantly higher CR rate (52% versus 18%; $P = 0.02$) and increased overall survival (13 versus 8 months; $P = 0.01$) were seen with use of quinine. No life-threatening toxicity was attributed to quinine, but a significant incidence of tinnitus, vertigo, hearing loss, and QT prolongation was described. Of note, the study was not stratified for P-glycoprotein expression.

In a separate study, investigators in the Eastern Cooperative Oncology Group (ECOG) treated high-risk MDS and relapsed or refractory AML in 129 patients using regimens of mitoxantrone, etoposide, and cytarabine (MEC) without or without valspodar, a more potent inhibitor of P-glycoprotein.[271] Unfortunately, CR rates and overall survival were not improved with valspodar, and indeed the CR rate was slightly lower (although the decrease was not statistically significant). Another mechanism of chemotherapy resistance in high-risk MDS is increased cytosolic expression of the high-affinity isoform of 5′-nucleotidase, which correlates with cytarabine resistance and is associated with inferior survival.[272]

Unfortunately, no comparative trials have been performed to evaluated low-intensity versus high-intensity therapy in high-risk MDS, and it is therefore difficult to estimate the impact of intensive chemotherapy.[273] Of value is a recent analysis from M.D. Anderson Cancer Center comparing outcomes with lower-intensity decitabine ($N = 115$) and intensive chemotherapy. In a retrospective comparison study in which subjects were matched for eligibility for decitabine, age, cytogenetics, and IPSS, patients receiving decitabine had a CR rate comparable to that achieved with intensive chemotherapy (43% versus 46%; $P = 0.69$) but a significantly lower 6-week mortality rate (3% versus 132 %; $P = 0.006$) and 3-month mortality rate (7% versus 23%; $P = 0.001$).[274] Similarly, overall survival was significantly better with decitabine (median survival, 22 months versus 12 months; 2-year survival rate, 47% versus 24%; $P < 0.001$) for both younger (i.e., younger than 60 years) and older patients. Therefore, with the recent availability of the methyltransferase inhibitors decitabine and 5-azacitidine, prospective studies are required to clarify the role of intensive chemotherapy in MDS.

Stem Cell Transplantation

AlloHSCT using cells from an HLA-matched donor remains the only curative therapy for MDS. Unfortunately, few randomized studies have been conducted, and comparative data on long-term outcomes with nontransplantation strategies are scarce. In addition, the use of alloHSCT has in general been restricted to younger patients because of donor availability and transplant-related mortality; this is a particularly important point, because MDS is a disease of older adults, and most MDS patients have therefore been excluded from consideration of alloHSCT because of age.

Nevertheless, alloHSCT has been extensively studied in phase II and multicenter studies and is an important treatment consideration in younger MDS patients (Table 105-6). The timing of alloHSCT in MDS remains uncertain, particularly for older patients and those with low-risk disease. Recent efforts to minimize nonrelapse transplant-related mortality with the use of reduced intensity or nonmyeloablative conditioning, as well as some improvements in donor availability, have extended the availability of alloHSCT to older patients, so that it can now be considered in selected patients aged 55 to 70 years.[275]

The benefit of alloHSCT is thought to be mediated through an allogeneic graft-versus-MDS effect, manifested by lower relapse rates after graft-versus-host disease (GVHD)[276–279] (in particular, chronic GVHD)[280]; higher relapse rates with the use of T-cell depletion[280,281]; lower relapse rate and improved disease-free survival with complete (greater than 95%) donor T-cell engraftment[282,283]; and the observation of durable remissions after donor lymphocyte infusion for post-transplantation MDS relapse.[284,285]

Sibling Donors

Many reports have been published on the toxicity and efficacy of myeloablative conditioning and alloHSCT from an HLA-matched sibling.[281,286–293] In composite, the reports suggest that greater than one third of patients are cured (29% to 40% long-term DFS). Relapse and nonrelapsed transplant-related mortality, however, remain significant problems, the latter predominantly due to the complications of GVHD. The estimated relapse rate is frustratingly high after alloHSCT (23% to 48%), and the nonrelapsed transplant-related mortality rate is approximately 37% to 50%. Therefore, although a

Table 105-6 Allogeneic Hematopoietic Stem Cell Transplantation with Myeloablative Conditioning: Clinical Results

Study	Year	No. of Patients	Median Age (years)	Donor Type	Conditioning Regimen	NRM (%)	Relapse Rate (%)	DFS Rate (%)

subset of patients may be cured, the results are inferior to those seen in patients with de novo AML, which to some extent has limited the use of alloHSCT in MDS.

Significantly higher DFS and significantly lower relapse rates have been observed in patients who undergo transplantation earlier in the course of the disease, particularly those with RA and RARS, and those who undergo transplantation within the first 6 to 12 months of diagnosis[281,289,290,294,295]; relapse rates in excess of 40% have been reported for patients with RAEB.[281,287,288,290] Improved DFS and lower nonrelapsed transplant-related mortality rates also have been observed in patients who underwent transplantation after 1989,[290,296] and with improvements in myeloablative conditioning regimens (specifically, with use of pharmacokinetically targeted busulfan dosing, and non-TBI-based regimen).[291,297–299] In addition to disease stage and FAB classification (specifically, in RAEB), the major determinants of relapse, survival, and nonrelapsed transplant-related mortality after AlloHSCT are patient age, IPSS score, and the presence of poor-risk cytogenetics, for which the relapse rate is greater than 80%.[286,288,291,296]

Another potential prognostic factor is the presence of an elevated pretransplantation serum ferritin, which in a large retrospective analysis ($N = 590$) from the Dana-Farber Cancer Institute was associated with lower DFS and overall survival rates after myeloablative alloHSCT.[300] In patients with MDS, an association between serum ferritin and a significantly higher treatment-related mortality also was observed. This finding suggests that iron overload may play an important role in alloHSCT outcome, as it does in thalassemia, and raises questions about timing of alloHSCT in heavily transfused patients, and also about the potential importance of iron chelation.

Unrelated Donors

Only a minority of MDS patients have a sibling donor, and extensive experience with the use of matched unrelated donors as a source of hematopoietic stem cells has been accumulated. In general, the reported nonrelapsed transplant-related mortality rate is higher than with sibling donors, in most series in excess of 50% (see Table 105-1), and the DFS is lower (25% to 38%).[291,301–303] Of interest, the largest published experience from the National Marrow Donor Program (NMDP; $N = 510$)[301] noted that although the nonrelapsed transplant-related mortality rate was 54% and the DFS rate only 29%, the relapse rate was relatively low at 14%, suggesting a possible augmented graft-versus-MDS effect from unrelated donors. Supporting this observation, a lower risk of MDS relapse ($P = 0.003$) and superior relapse-free survival ($P = 0.02$) also was recently demonstrated with unrelated versus sibling donors in a retrospective study from Seattle.[296]

A study from the French Society of Bone Marrow Transplantation and Cell Therapy prospectively evaluated the outcomes of 236 patients who underwent alloHSCT with myeloablative conditioning from 10/10 HLA-matched sibling ($N = 181$) or unrelated donors ($N = 55$) for standard-risk myeloid malignancy, including MDS.[304] In multivariable analysis, only CMV serostatus, donor age (older than 37 years), and the occurrence of grade II or higher acute GvHD were associated with inferior survival and with nonrelapsed transplant-related mortality, and the effect of donor type was nonsignificant. Therefore it appears that the outcomes after alloHSCT using cells from unrelated donors are similar to those with sibling donors for standard-risk patients, and in the absence of a sibling donor, a search for an unrelated donor is appropriate in patients who are considered eligible for myeloablative conditioning.

T-Cell Depletion

GVHD remains a major cause of nonrelapsed transplant-related mortality and treatment failure in MDS, and several efforts have been directed at reducing the incidence of acute and chronic GVHD through T-cell depletion.[305,306] Data from France and from the IBMTR with sibling donors demonstrated that the use of T-cell-depleted grafts was associated with lower treatment-related mortality but a higher incidence of relapse and did not have an overall effect on DFS or overall survival.[281,288] Similarly, in a randomized NMDP study with matched unrelated donors and using myeloablative conditioning, which included patients with MDS undergoing alloHSCT, the use of in vitro T-cell depletion as GVHD prophylaxis significantly lowered the incidence of acute GVHD but did not have an impact on the incidence of chronic GVHD or on survival.[280] More recently, in vivo T-cell depletion with the use of thymoglobulin[307] or alemtuzumab in reduced-intensity conditioning (RIC) regimens[295,308–310] has shown a lower incidence of acute GVHD compared with historical experience, without a clear increase in relapse. Randomized trials will be required to determine the true contribution to nonrelapsed transplant-related mortality and relapse of in vivo T-cell depletion with monoclonal antibodies in MDS.

Transplantation for Treatment-Related Myelodysplastic Syndrome

Some patients with treatment-related MDS also may benefit from alloHSCT, with a 4- or 5-year disease-free survival rate of approximately 30%, although the nonrelapsed transplant-related mortality rate appears to be substantially higher than with de novo MDS (particularly with the use of total body irradiation in the conditioning regimen).[55,311–313] A recent retrospective analysis comparing outcomes after alloHSCT for secondary MDS ($N = 257$) with those for de novo MDS ($N = 339$) found no difference in clinical outcomes, however—the only significant predictive factors being disease stage and karyotype at the time of transplantation.[296] Therefore, patients with treatment-related MDS do appear to benefit from alloHSCT.

Myeloablative Conditioning in Adults Older than 55 Years

An important point illustrated in Table 105-1 is that the studies of myeloablative conditioning and sibling or unrelated donor alloHSCT almost all have been performed in a relatively young patient population, mostly in those younger than 50 years. Some data for selected older adults (up to age 67 years) undergoing ablative alloHSCT for MDS (most with RAEB or RAEB-t)[314,315] demonstrate results similar to those achieved in younger patients (44% survival rate at follow-up evaluation). As in younger patients, the relapse-free survival rate was inversely related to cytogenetic risk classification and to IPSS risk score, as well as the use of targeted busulfan conditioning.[314]

As is evident in Table 105-1, nonrelapsed transplant-related mortality remains an important obstacle to successful alloHSCT for MDS patients and is a major cause of treatment failure. The Seattle group of investigators recently presented a Hematopoietic Cell Transplantation–Specific Comorbidity Index, which independently predicts nonrelapsed transplant-related mortality and survival after alloHSCT.[316] This is likely to be important in the design and patient selection of future alloHSCT trials in older patients with MDS.

Induction Chemotherapy before Allogeneic Hematopoietic Stem Cell Transplantation

Because RAEB is associated with inferior outcomes (increased risk of relapse, decreased survival) after alloHSCT, it has been proposed that such patients should receive induction chemotherapy before proceeding with alloHSCT, particularly those with RAEB-2 (greater than 10% blasts), or before alloHSCT with RIC regimens.[275,298,305,306] Retrospective studies do not show a clear benefit for the routine use of induction chemotherapy however,[288,317,318] and this question is being addressed in a prospective randomized trial being conducted by the European Group for Blood and Marrow Transplantation (EBMT).[305] Of interest, in a cohort of 159 patients who received intensive chemotherapy followed by either autologous or allogeneic stem cell transplantation, no difference in disease-free or overall survival was found to correlate with the availability of a sibling donor,[260] suggesting that the intensive therapy itself may improve outcome. In a

separate report, 75 patients (median age, 52 years) with high-risk AML and MDS (including patients with refractory disease) were treated prospectively with intensive cytoreduction followed immediately by RIC, alloHSCT from sibling or unrelated donors, and prophylactic donor lymphocyte transfusion. This study demonstrated remarkable clinical results in a high-risk population, with 88% CR and 40% 2-year leukemia-free survival rates.[319] It appears, therefore, that patients with refractory disease may potentially benefit from sequential cytoreduction and immediate alloHSCT, and that confirmation of chemosensitivity may not be necessary in all patients. This observation is at odds with older reports,[288] however, and these strategies are being tested prospectively in a randomized trial being run under the auspices of the EBMT.[305]

Timing of Transplantation in Myelodysplastic Syndrome: Decision Analysis

The clear dilemma in considering ablative alloHSCT for MDS patients is that although some patients may be cured, the nonrelapsed transplant-related mortality and relapse rates are high, and the best outcomes are in younger patients with early disease and without poor-risk cytogenetics.[289] In precisely this same group of patients, however, according to the IPSS, the best prognosis is observed with use of low-intensity or supportive care strategies.[126] Therefore, the patients with the most to gain from alloHSCT are also those with the most to risk in terms of survival. The obvious question, therefore, is when to consider alloHSCT, particularly for more favorable-risk patients. This has been addressed in a Markov decision model comparing outcomes in patients from sibling transplantation (Seattle and IBMTR databases) and nontransplantation (International MDS Response Assessment Workshop) registries, performed for all four IPSS risk groups and adjusted for quality of life.[320]

In that study, the strategies of immediate and delayed alloHSCT (either for MDS or at the time of leukemia transformation) were compared for their impact on overall survival. Transplantation before leukemia transformation was associated with a greater number of life years than at the time of leukemia transformation. Delayed transplantation, however, maximized overall survival for Low and Int-1 IPSS risk groups, and particularly for patients younger than 40 years. By contrast, for Int-2 and High IPSS risk groups, immediate alloHSCT maximized overall survival.[320]

Therefore, for higher-risk patients, eligible patients should undergo immediate alloHSCT, whereas for those with low-risk disease, delayed transplantation to the time of disease progression (but before leukemic transformation) is recommended, particularly for younger patients. For those with intermediate-risk disease (i.e., Int-1 under the IPSS), early transplantation should be considered on a case-by-case basis. In a retrospective analysis, the presence of significant marrow fibrosis at the time of transplantation was associated with inferior survival for patients with advanced MDS, suggesting that early alloHSCT should be considered in such cases.[321]

Reduced-Intensity Conditioning

In an effort to address excessive nonrelapsed transplant-related mortality and thereby to extend alloHSCT to older patients, several investigators have studied RIC regimens in patients with MDS[322] (Table 105-7), supplemented in some trials with donor T-cell lymphocyte infusion in the case of delayed engraftment or relapse. In general, the RIC regimens emphasize the graft-versus-MDS effect, and capitalize on the immunosuppressive effects of nucleoside analogs (predominantly fludarabine) combined with either busulfan,[277,308,309] melphalan,[295,310,323] or cyclophosphamide,[324] or the use of low-dose TBI alone or combined with fludarabine, pentostatin, or cyclophos-

phamide[278,283,325–327] to facilitate engraftment. In some series, alemtuzumab has been included in the conditioning regimen to achieve in vivo T-cell depletion, presumably minimizing the risk of acute GVHD and hence nonrelapsed transplant-related mortality.[295,308–310] The reported nonrelapsed transplant-related mortality rate with RIC regimens is substantially lower than with myeloablative conditioning (approximately 5% to 15% early nonrelapsed transplant-related mortality rates),[278,328–330] and indeed these studies have included an older patient population (median age, 52 to 63 years), including some patients older than 70 years, and unrelated donors.[278,309,330,331] Despite reduced nonrelapsed transplant-related mortality, the relapse rate appears to be significantly higher than with myeloablative conditioning[278,329,330]; this is explained, at least in part, by the inclusion of patients with more advanced disease in the RIC studies. In comparing a truly "nonablative" (fludarabine, cytarabine, idarubicin) with a reduced-intensity (fludarabine, melphalan) conditioning regimen in one center, lower nonrelapsed transplant-related mortality was noted for the former, but at the cost of inferior donor engraftment and a significantly increased risk of relapse.[332] This finding suggests that a critical minimal level of intensity may be required for successful alloHSCT. Nevertheless, the overall survival with RIC regimens is similar to that with myeloablative conditioning in younger adults, suggesting an important role in older patients. Efforts to improve the relapse rate after RIC regimens with targeted immunotherapy (e.g., ^{131}I–anti-CD45 monoclonal antibody or ^{188}RE–anti-CD66) are promising and may improve on the relapse rate without increasing nonrelapsed transplant-related mortality.[333,334] Isolated CNS relapse has been reported after RIC alloHSCT for AML/MDS,[279] and CNS prophylaxis should be considered, particularly in those with RAEB.

The feasibility of RIC alloHSCT in "older" adults (50 years of age and older) was recently evaluated in a prospective study at the M.D. Anderson Cancer Center. In that analysis, the intention was to proceed to RIC alloHSCT after achievement of a complete remission for patients with AML and high-risk MDS receiving induction treatment with intensive chemotherapy. In total, 99 of 259 patients achieved complete remission and were potentially eligible for RIC alloHSCT. Only 53, however, were evaluated for transplantation, only 26 had a donor identified, and only 14 proceeded to alloHSCT (with a sibling donor in 13 of 14 cases).[335] A clear survival advantage was found for the patients in complete remission who proceeded to RIC alloHSCT, in comparison with those in complete remission who did not receive alloHSCT. This study highlights the limitations of RIC alloHSCT in this population, particularly with regard to patient selection, and demonstrates the need for improvements in induction therapy and donor availability. Multicenter prospective trials will be required to test the impact of RIC alloHSCT in older adults with MDS.

The prognosis with relapse after RIC transplantation is very poor. The response rate to donor lymphocyte infusion is low, although rare patients may be salvaged with intensive chemotherapy and a second alloHSCT procedure.[336]

Peripheral Blood Stem Cells

Peripheral blood stem cells (PBSCs) are an attractive source of hematopoietic precursors in MDS because they are associated with faster hematologic recovery than can be achieved with bone marrow and therefore may reduce early regimen-related mortality, particularly with use of myeloablative conditioning and sibling donors.[337] In a randomized study from the Canadian BMT Group, patients with myeloid malignancy including MDS who received PBSCs experienced faster hematologic recovery without a significant increase in GVHD, and had an improved 30-month survival in comparison with bone marrow recipients (68% versus 60%; $P = 0.04$).[338] This is supported by a retrospective analysis from the EBMT, which demonstrated an increase in the incidence of chronic GVHD with PBSCs (odds ratio 1.62; 95% confidence interval [CI] 0.8 to 3.02) and an associated decrease in 2-year transplant-related mortality (relative risk [RR] 0.33, 95% CI 0.15 to 0.73; $P < 0.007$) (OR) and 2-year treatment failure (RR 0.22; 95% CI, 0.10 to 0.48; $P < 0.001$).[339] These studies suggest that PBSCs may be preferred in sibling alloHSCT for MDS, particularly in pateints with RAEB.[298] An initial retrospective experience with unrelated donor PBSCs suggested no difference in the rates of GVHD or other clinical outcomes,[340] but at long-term follow-up evaluation, an increased risk of chronic extensive GVHD was noted, with no difference in relapse rate or survival.[341] It is not known whether PBSCs are preferable to bone marrow in patients undergoing RIC alloHSCT, and longer follow-up study is required to determine long-term toxicity.[342]

Alternative Sources: Autologous, Cord Blood, and Haploidentical Transplantation

Based on more extensive experience in patients with AML[343] and the lack of an available donor in many cases of MDS, intensive chemotherapy followed by autologous bone marrow of PBSC transplantation has been evaluated in younger MDS patients.[305,344–346] Karyotypically normal autologous PBSCs can be successfully harvested in a majority of (but not all) patients with MDS[290,347,348] and the median disease-free survival period after consolidation with autologous transplantation is approximately 24 to 30 months.[290,305,345,346] Nonrelapsed transplant-related mortality is substantially lower than after allogeneic transplantation, but relapse remains a significant problem (greater than 60% relapse rate). Using a donor versus no-donor analysis, an earlier EBMT report found no clear survival advantage in autologous versus sibling allogeneic transplantation after intensive chemotherapy, calling into question the graft-versus-MDS effect.[260] More recently, however, the EBMT has performed a retrospective analysis of autologous versus unrelated donor transplantation in 593 patients with MDS and secondary AML, including those receiving autologous ($N = 290$) or unrelated donor transplantation ($N = 136$) in first CR after induction chemotherapy.[349] The nonrelapsed transplant-related mortality rate was substantially lower with autologous transplantation (17% versus 38%, respectively; $P < 0.001$), but the relapse rate was significantly higher (62% versus 24%, respectively; $P < 0.001$) and the 3-year survival rate was significantly worse (41% versus 50%; $P < 0.01$) than after unrelated donor transplantation. Autologous transplantation is therefore feasible and may be a reasonable option for selected younger patients without an available donor who achieve a CR after intensive therapy; however, allogeneic transplantation from an HLA-matched donor remains the preferred option.

Pilot results with transplantation from umbilical cord blood (UCB) in adults with MDS were initially encouraging,[350] although more recent results demonstrate a high nonrelapsed transplant-related mortality and slow engraftment.[351] UCB transplantation, therefore, remains an investigational strategy. Because of the cell dose that is required, most adults are not candidates for a single UCB transplant procedure. Recently, in order to extend access to UCB transplantation and overcome the low cell dose barrier that excludes most adults from the procedure, investigators at the University of Minnesota reported on the results of a study of myeloablative conditioning and double cord UCB transplantation using two partially HLA-matched UCB units.[352] This allows for an increased cell dose to facilitate engraftment. Engraftment rates were reported to be high, and the incidence of GVHD and nonrelapsed transplant-related mortality was low. Of interest, a syndrome of early, mixed engraftment was observed, although by day 100 after transplantation, cells from one donor predominated. Disease-related outcomes were better in patients who received their transplant while in remission. Similar results with successful engraftment also have been reported after nonmyeloablative conditioning with a double cord strategy.[353] Multicenter trials are being conducted to assess the feasibility of UCB transplantation in MDS.

It is worth noting recent encouraging experience with transplantation from haploidentical donors[354,355] that demonstrates improved nonrelapsed transplant-related mortality compared with previous experience and also disease-free survival similar to that for matched unrelated donors.[356] Prospective studies are needed to asses the impact of haploidentical donors on survival in comparison with unrelated donor transplantation, and this treatment remains investigational.

MYELODYSPLASTIC SYNDROME IN HUMAN IMMUNODEFICIDENCY VIRUS AND ACQUIRED IMMUNODEFICINECY SYNDROME

Cytopenias and dysplasia in association with a hypercellular bone marrow have long been recognized in HIV/acquired immunodeficiency syndrome (AIDS),[357,358] and the most commonly recognized abnormalities are anemia[359] and dyserythropoiesis.[360,361] The process typically is multifactorial and in some cases is related to antiretroviral therapy (e.g., with azidothymidine [AZT]).[357,362] Bone marrow findings typically are reflective of the HIV infection itself[360,363]; abnormalities are more pronounced in patients with a high HIV viral load or advanced disease,[364,365] and an increase in marrow angiogenesis also has been observed.[365,366] Treatment of MDS may reverse the changes,[367] and growth factors (e.g., erythropoietin, G-CSF) may be used to treat isolated cytopenias or to ameliorate the myelosuppressive effects of therapy in HIV-infected patients.[358,368,369]

High-grade MDS (RAEB) has been reported only rarely,[367] and in general the dysplastic changes in HIV usually are not as severe as those seen in classical MDS[370]; an excess of blasts, karyotypic abnormalities, and progression to AML all are rare.[369,371] This may be related to a reduced proliferation capacity of bone marrow progenitor cells induced directly by HIV.[372,373] Because of these differences, the term *HIV myelopathy* has been proposed to distinguish these changes from classic MDS.[361,371]

MYELODYSPLASTIC SYNDROME IN CHILDREN

MDS is rare in children,[3,5] and in most cases the clinical picture includes a related medical diagnosis (e.g., Shwachman's syndrome) or a constitutional genetic disorder such as Down's syndrome, neurofibromatosis, Fanconi's anemia, or Kostmann's syndrome.[32,60,61,374,375] Many cases are secondary to previous therapy for cancer, including both alkylating agents and etoposide,[32,376] or follow therapy with G-CSF for severe congenital neutropenia or Shwachman-Diamond syndrome[61]; in such cases, the prognosis is less favorable that with de novo disease.[32] The most common cytogenetic abnormality among children with early MDS (refractory anemia) is monosomy 7, and a hypocellular bone marrow is more common than in adults.[377] In addition to the FAB subtype, fetal hemoglobin (HbF) concentration less than 10% is a significant prognostic factor.[374,375] An associated myeloproliferative disorder is common, particularly in younger patients,[374] and transformation to acute leukemia occurs more frequently than in adults. AlloHSCT is recommended early in the course of the disease,[377] although it is not clear to what extent transplantation improves the prognosis of advanced MDS in children.[374,375]

PREVENTION

MDS is idiopathic in most cases and typically occurs in older patients (median age older than 70 years)[4]; therefore, prevention strategies for de novo MDS have not been developed. The risk of secondary MDS has been addressed through avoidance of radiation (including TBI and ^{32}P) and chemotherapy exposure[39,53,54] and prevention of benzene exposure.[11] Surveillance of blood counts in petrochemical workers has not been demonstrated to decrease MDS risk.[378] The use of nonalkylating agent regimens may lower the risk for MDS in patients with Hodgkin's lymphoma.[27] It remains to be determined whether the use of involved-field versus extended-field radiotherapy will decrease the risk of secondary MDS,[29,37,41] although early reports are encouraging.[379] The independent contribution of G-CSF to the development of MDS in patients receiving dose-dense therapy for breast cancer has not been fully elucidated,[30] and long-term follow-up studies are required to quantify the risk.

EXPERIMENTAL TREATMENTS

It is clear that present therapy is inadequate for most patients with MDS, and new treatments are urgently needed. This is especially true for older patients (who in fact comprise a majority of those with MDS), who are not candidates for intensive therapy or for alloHSCT.

Agents such as valproic acid have demonstrated histone deacetylase (HDAC) inhibition and differentiation induction of blasts in vitro and also have some single-agent clinical activity in MDS.[380] Based on preclinical studies, HDAC inhibitors have been combined with hypomethylating agents to synergistically induce differentiation (and thereby improve cytopenias).[94] Combination studies of valproic acid[381] or other targeted HDAC inhibitors[382] with 5-azacytidine have shown clinical activity, and phase III trials in comparison with 5-azacytidine alone are in progress.

Novel chemotherapeutic agents include cloretazine[383] and the nucleoside analog clofarabine, which appears to have significant activity in MDS at lower doses.[384] An oral formulation of clofarabine is being evaluated for treatment of MDS.[384] The farnesyltransferase inhibitor tipifarnib has demonstrated activity in RAEB,[385] and a recent multicenter phase II study confirmed a response rate of 32% in patients with intermediate- to high-risk MDS.[386] Other small-molecule tyrosine kinase inhibitors have been evaluated in patients with high-risk MDS, and in vivo inhibition of FLT3 phosphorylation and reduction in blasts have been reported with tandutinib.[387]

106 Myeloproliferative Disorders

Ayalew Tefferi

SUMMARY OF KEY POINTS

Incidence

- Each of the three classic *BCR-ABL*$^-$ myeloproliferative disorders (MPDs)—that is, polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF), are estimated to occur at the rate of 0.5 to 2.5 per 100,000 people per year.

Differential Diagnosis

- All three classic *BCR-ABL*$^-$ MPDs may be considered as diagnoses of exclusion, because a specific diagnostic marker is currently lacking.
- The presence of a *JAK2* mutation distinguishes PV from all other causes of polycythemia, and ET and PMF from reactive thrombocytosis or myelofibrosis, respectively.

Diagnostic Evaluation

- Evaluation of suspected PV should start with peripheral blood screening for *JAK2*V617F and serum erythropoietin (Epo) measurement.
- More than 90% of PV patients are expected to display the mutation, whereas a low serum Epo level should capture most of the *JAK2*V617F$^-$ cases, which might display other *JAK2* mutations such as an exon 12 mutation.
- Bone marrow examination remains essential in the diagnosis of ET and PMF.

Risk Stratification

- Both PV and ET display a near-normal life expectancy in the first decade of the disease. The major problem during this period is thrombosis that may occur in as many as 30% of the patients.
- A history of thrombosis or age older than 60 years is associated with a high risk of thrombosis.
- Platelet count by itself has not been significantly associated with thrombosis in either PV or ET.
- The presence of anemia, thrombocytopenia, monocytosis, either leukopenia or leukocytosis, severe constitutional symptoms, or circulating blasts are all adverse risk factors in PMF.

Treatment

- Phlebotomy remains the mainstay of therapy in PV.
- Low-risk patients (age younger than 60 years *and* no history of thrombosis) with either PV or ET have not been shown to benefit from cytoreductive therapy.
- Treatment with hydroxyurea has been shown to reduce thrombosis risk in high-risk patients with both ET and PV.
- Microvascular symptoms, including headache and erythromelalgia (painful and burning sensation of the feet or hands associated with erythema and warmth), are easily treated with low-dose aspirin, which is indicated in the absence of extreme thrombocytosis.
- Drug therapy in PMF is currently palliative, and effective agents include corticosteroids, erythropoietin (Epo), androgen preparations, thalidomide, lenalidomide, and hydroxyurea.
- Splenectomy continues to have a palliative role in PMF.
- Involved-field radiation therapy in PMF is most effective in the setting of nonhepatosplenic extramedullary hematopoiesis.
- The therapeutic value of hematopoietic stem cell transplantation in PMF is being investigated.

INTRODUCTION

The World Health Organization (WHO) classification system for hematopoietic malignancies considers four broad categories of chronic myeloid neoplasms: myelodysplastic syndrome (MDS), myeloproliferative disorders (MPDs), MDS/MPD overlap syndrome, and systemic mastocytosis (SM).[1] The WHO MPD category includes chronic myelogenous leukemia (CML), polycythemia vera (PV), essential thrombocythemia (ET), primary myelofibrosis (PMF), chronic neutrophilic leukemia, chronic eosinophilic leukemia, hypereosinophilic syndrome, and MPD unclassified. Myeloproliferative disorders unclassified refers to a clinically and histologically MPD-like phenotype that does not fulfill the standard diagnostic criteria for CML, PV, ET, PMF, chronic neutrophilic leukemia, chronic eosinophilic leukemia, or hypereosinophilic syndrome.

The WHO MDS/MPD category includes chronic myelomonocytic leukemia, juvenile myelomonocytic leukemia, atypical chronic myeloid leukemia, and "MDS/MPD, unclassifiable (MDS/MPDs unclassified)." Atypical CML is characterized by the absence of *BCR-ABL* and the presence of left-shifted granulocytosis with granulocytic dysplasia. MDS/MPDs unclassified refers to a clinical phenotype that displays histological characteristics of both MDS and MPD without fulfilling the diagnostic criteria for chronic myelomonocytic leukemia, juvenile myelomonocytic leukemia, or atypical chronic myeloid leukemia. Some place the WHO provisional entity of "refractory anemia with ringed sideroblasts associated with marked thrombocytosis" in this category of MDS/MPDs unclassified.

Table 106-1 represents an alternative semimolecular classification scheme for chronic myeloid neoplasms that uses the term "classic MPDs" to refer to the original four clinicopathologic entities (i.e.,

Table 106-1 Modern Classification of Chronic Myeloid Neoplasms

Main Categories	Subcategories	Molecular Signatures
Myelodysplastic syndrome	According to WHO classification system	
Classic myeloproliferative disorders	Chronic myeloid leukemia	100% *BCR-ABL*$^+$
	Polycythemia vera	~95% *JAK2*V617F$^+$
		~4% *JAK2* exon 12 mutations$^+$
	Essential thrombocythemia	~50% *JAK2*V617F$^+$
		~1% *MPL*W515L/K$^+$
	Primary myelofibrosis	~50% *JAK2*V617F$^+$
		~5% *MPL*W515L/K$^+$
Nonclassic myeloproliferative disorders	Chronic myelomonocytic leukemia	~3% *JAK2*V617F$^+$
	Juvenile myelomonocytic leukemia	~30% *PTPN11* mutation$^+$
		~15% *NF1* mutation$^+$
		~15% *RAS* mutation$^+$
	Chronic neutrophilic leukemia	~20% *JAK2*V617F$^+$
	Chronic eosinophilic leukemia	
	PDGFRA-rearranged	~100% *FIP1L1-PDGFRA*$^+$
	PDGFRB-rearranged	100% various *PDGFRB* translocations
	Molecularly-undefined	
	Hypereosinophilic syndrome	
	Systemic mastocytosis	
	KIT-mutated	~90% *KIT*D816V$^+$
	Molecularly undefined	
	8p11 myeloproliferative syndrome	100% various *FGFR1* translocations
	Chronic basophilic leukemia	
	Atypical chronic myeloid leukemia	~20% *JAK2*V617F$^+$
	MPD not otherwise classified (MPD-NOC) includes the WHO categories of "MPD, unclassifiable", "MDS/MPD, unclassifiable", and "RARS-T"	~20% to 50% *JAK2*V617F$^+$

MDS, myelodysplastic syndrome; MPD, myeloproliferative syndrome; MPD-NOC, MPD not otherwise classified; RARS-T, refractory anemia with ringed sideroblasts associated with marked thrombocytosis; SCLL, stem cell leukemia and lymphoma syndrome; WHO, World Health Organization.

CML, PV, ET, and PMF) in whom the term "MPDs" was first applied by William Dameshek.[2] In this operational classification system, all remaining chronic myeloid neoplasms other than MDS are assigned the term "nonclassic MPDs";[3] these include the WHO category MDS/MPD, SM, chronic neutrophilic leukemia, chronic eosinophilic leukemia, hypereosinophilic syndrome, and MPDs unclassified. The particular classification system also recognizes molecularly characterized subcategories including the platelet-derived growth factor receptor (*PDGFR*)–rearranged chronic eosinophilic leukemias, the fibroblast growth factor receptor 1–rearranged stem cell leukemia/lymphoma syndrome, and *KIT*-mutated SM. The current chapter focuses on the classic *BCR-ABL*$^-$ MPDs: PV, ET, and PMF.

POLYCYTHEMIA VERA

Vaquez and Osler are credited for the initial description of PV, as a primary erythrocythemic process, in 1892 and 1903, respectively.[4,5] Reported incidence figures in PV range from approximately 0.5 to 2.6 per 100,000 population.[6,7] A higher disease incidence has been suggested in persons of Jewish ancestry[8] as well as among parent-offspring pairs.[9] Median age at diagnosis of PV is approximately 60 years with a slight (1.2 : 1) male preponderance.[10] Approximately 7% of patients are diagnosed before age 40,[10] and there are rare cases of children affected with PV.[11]

Pathogenesis

PV is a clonal stem cell disease with trilineage myeloid involvement.[12] In addition, some studies have suggested clonal heterogeneity including clonal involvement of B lymphocytes[13] as well as polyclonal granulopoiesis in certain cases.[14] In vitro, erythroid colony formation in patients with PV does not require the addition of exogenous Epo.[15] This phenomenon is called endogenous erythroid colony growth and does not occur in either normal controls or patients with nonclonal polycythemia. In addition, erythroid progenitor cells in PV display growth factor hypersensitivity to Epo, insulin-like growth factor (IGF)-1, and other cytokines.[16,17] The consistently observed IGF-1 hypersensitivity of erythroid cells in PV has been attributed to alter-

ations in IGF-1 binding proteins.[18] However, several studies have shown that growth factor–independent or growth factor–hypersensitive colony formation is specific to neither PV nor erythroid progenitor cells.[17]

The Epo receptor gene as well as its protein are intact in PV.[19] On the other hand, several postreceptor molecular abnormalities have been reported and include increased baseline phosphorylation of the IGF-1 receptor,[20] decreased activity of SH-PTP1 (a tyrosine phosphatase),[21] increased activity of membrane-associated SH-PTP,[22] constitutive activation of STAT3,[23] upregulation of negative control elements of the cell cycle (p16/p14),[24] and abundance, in erythroid precursors, of antiapoptotic proteins (Bcl-x_L).[25] However, these observations have not been always reproducible, and none of them have been shown to be specific to PV, as opposed to other MPDs.

In 2005 a novel Janus kinase 2 (JAK2) mutation (*JAK2*V617F) was described in association with PV, ET, and PMF.[26] *JAK2*V617F occurs in approximately 95% of PV patients but also in approximately 50% of those with ET or PMF.[27–30] In addition, the mutation is found in a small proportion of patients with other myeloid neoplasms including nonclassic MPDs and MDS.[31,32] Other *JAK2* mutations (i.e., *JAK2* exon 12 mutations) were recently described in the majority of patients with *JAK2*V617F⁻ PV or "idiopathic erythrocytosis,"[33] thus raising the possibility that a *JAK2* mutation is essential for the PV phenotype. On the other hand, neither *JAK2*V617F nor *JAK2* exon 12 mutations have so far been reported in lymphoid disorders,[34–37] solid tumor,[38–40] or secondary myeloproliferation including congenital or acquired polycythemia.[41–43]

*JAK2*V617F is a G-to-T somatic mutation, at nucleotide 1849, in exon 14, resulting in the substitution of valine by phenylalanine at codon 617.[27–30] *JAK2* exon 12 mutations (F537–K539delinsL, H538QK539L, K539L, N542–E543del) include both in-frame deletions and tandem point mutations.[33] Both exon 14 and exon 12 *JAK2* mutations induce cytokine-independent/hypersensitive proliferation in Epo receptor–expressing cell lines and a PV-like phenotype in mice.[33] Whereas homozygosity for *JAK2*V617F, which results from mitotic recombination, can be demonstrated in the majority of patients with PV,[44] exon 12 *JAK2* mutations are often heterozygous.[33] The precise pathogenetic role of *JAK2* mutations in PV and related MPDs is currently under intense investigation.

Diagnosis

In clinical practice the term polycythemia is used to indicate the possible occurrence of an increased erythrocyte volume or red blood cell mass (RCM). Such a perception might be either real (*true polycythemia*) or spurious (*apparent polycythemia*; Fig. 106-1).[17] True polycythemia may represent either PV or a nonclonal increase in RCM that is often, but not always, mediated by Epo (secondary polycythemia; Fig. 106-2). Apparent polycythemia may result from either a reduction in plasma volume (relative polycythemia) or an inaccurate perception of an elevated RCM that results from not appreciating high normal values of hemoglobin/hematocrit.[45] *Inapparent polycythemia* is the converse of apparent polycythemia and indicates a true increase in RCM that is masked by a normal hemoglobin/hematocrit value secondary to a concomitant increase in plasma volume (see Fig. 106-1).[46]

In 1975 the PV study group published a set of "diagnostic criteria" that were primarily used to ensure the exclusion, to treatment protocols, of patients with secondary or apparent polycythemia.[47] These criteria required the demonstration of increased RCM by blood volume measurement using labeled erythrocytes as well as the demonstration of normal hemoglobin oxygen saturation. In 2001, the WHO published a refined diagnostic criteria for PV and related MPDs that recognized the value of both bone marrow histology and "MPD-specific" biologic parameters.[48] The recent discovery of the almost invariable association between PV and a *JAK2* mutation has led to revised WHO diagnostic criteria for PV (Table 106-2)[49] and a refined diagnostic algorithm (see Fig. 106-2),[50] both of whom incorporate *JAK2* mutation screening.

Because more than 95% of patients with PV carry the *JAK2*V617F mutation, which is absent in both secondary and apparent polycythemia, it is most effective to initiate the workup of a patient with suspected PV with peripheral blood mutation screening for *JAK2*V617F (see Fig. 106-2). Furthermore, to minimize the consequences of false-positive or false-negative molecular test results, as well as capture the few cases of PV that are *JAK2*V617F⁻, concomitant measurement of serum Epo level is recommended.[51] If the results of both tests are suggestive of PV (i.e., mutation-positive and low serum Epo), then the diagnosis is likely and bone marrow examination is encouraged but not essential for making the diagnosis. If the

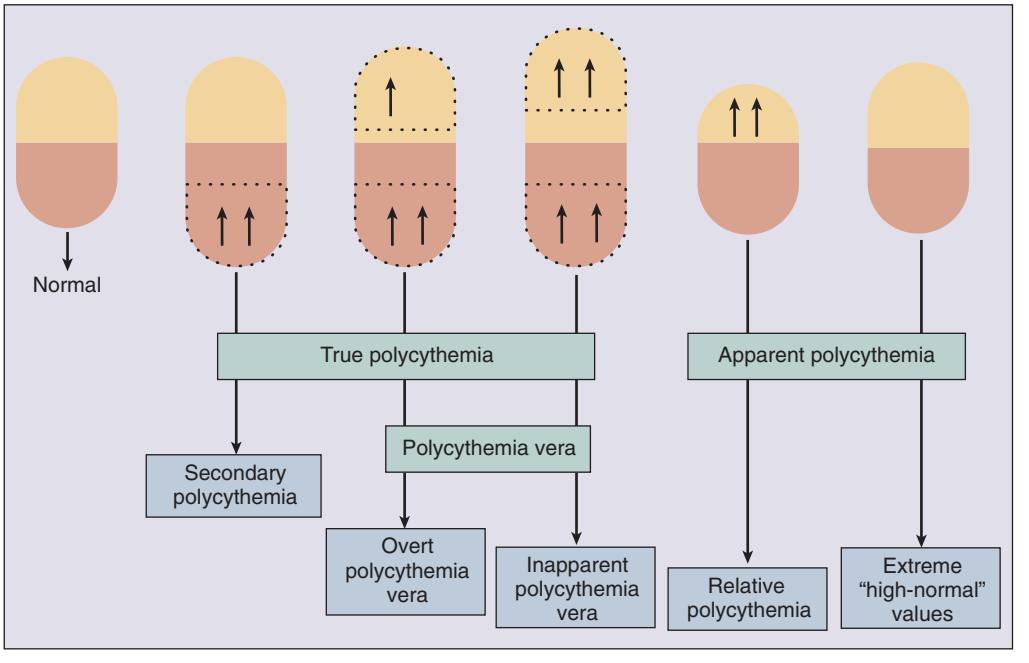

Figure 106-1 • Causes of true (associated with increased red cell mass (RCM) and apparent (not associated with increased RCM) polycythemia. Secondary polycythemia is usually mediated by endogenous erythropoietin (Epo). Erythrocytosis in polycythemia vera (PV) is Epo-independent. Patients with PV display increased plasma volume that is sometimes substantial enough to mask the underlying increased RCM by making the hematocrit appear normal (i.e., inapparent PV).

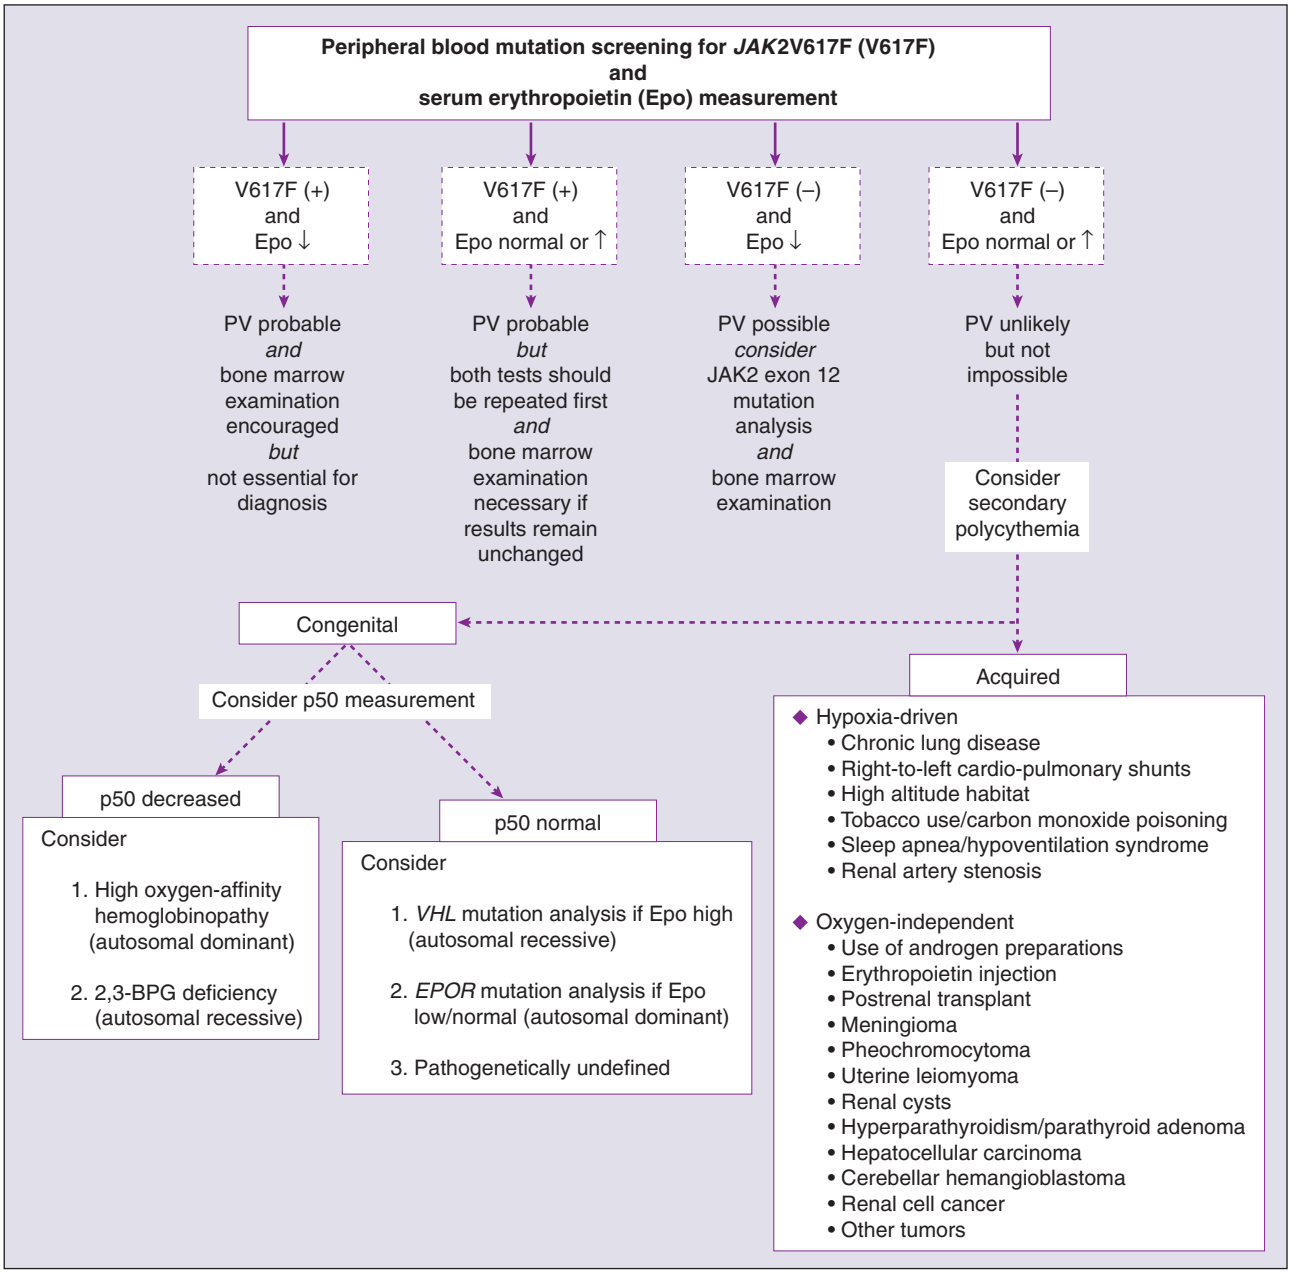

Figure 106-2 • Genetic tests-based diagnostic algorithm for the evaluation of "increased" hemoglobin. PV, polycythemia vera; p50, oxygen tension at which hemoglobin is 50% saturated; VHL, von Hippel-Lindau; EPOR, erythropoietin receptor; BPG, 2,3-bisphosphoglycerate. (Data from Tefferi A, Pardanani A: Evaluation of "increased" hemoglobin in the JAK2 mutations era: a diagnostic algorithm based on genetic tests. Mayo Clin Proc 2007;82:559–604.)

*JAK2*V617F and serum Epo test results are both not consistent with the diagnosis of PV (i.e., mutation-negative and either normal or increased Epo), then further investigation for PV is not advised unless dictated otherwise by the clinical scenario.

If there is discrepancy between the molecular test result and serum Epo level, one should first repeat both tests and then proceed with bone marrow examination if the results are unchanged (see Fig. 106-2). In a patient with acquired erythrocytosis and a subnormal serum Epo level, the possibility of exon 12 *JAK2* mutations should be entertained. In this regard it should be noted that some cases with *JAK2* exon 12 mutation–associated PV might not display overt PV-characteristic features, even at the level of bone marrow histology.[33]

When congenital polycythemia is suspected, initial laboratory testing should include measurement of the oxygen tension at which hemoglobin is 50% saturated (i.e., p50).[50] Left-shifted oxygen dissociation curve, suggested by decreased p50, suggests the presence of either high oxygen-affinity hemoglobinopathy (autosomal dominant)[52] or 2,3-bisphosphoglycerate (2,3-BPG) deficiency, usually a consequence of BPG mutase mutation (autosomal recessive).[53] If the p50 is normal, then the possibility of germline mutations of molecules that either enhance Epo effect (e.g., *EPOR* mutations)[54] or govern intracellular oxygen sensing (e.g., mutations involving the von Hippel-Lindau [*VHL*] tumor suppressor or hypoxia-inducible factor 1a [*HIF-1a*] prolyl hydroxylase genes)[55,56] should be considered (see Fig. 106-2). *VHL* mutations are usually associated with increased serum Epo level and constitute the most frequent mutations in congenital polycythemia (e.g., Chuvash polycythemia).[57] In contrast, serum Epo level is often subnormal in patients with *EPOR* mutations.[58]

Table 106-2 Revised World Health Organization Criteria for Polycythemia Vera

Diagnosis requires the presence of both major criteria and one minor criterion *or* the presence of the first major criterion together with two minor criteria.

MAJOR CRITERIA

Hemoglobin >18.5 g/dL in men, 16.5 g/dL in women, *or* other evidence of increased red cell volume*

Presence of *JAK2*V617F or other functionally similar mutation such as *JAK2* exon 12 mutation

MINOR CRITERIA

Bone marrow biopsy showing hypercellularity for age with trilineage growth (panmyelosis) with prominent erythroid, granulocytic, and megakaryocytic proliferation

Serum erythropoietin level below the reference range for normal

Endogenous erythroid colony formation in vitro

*Hemoglobin or hematocrit >99th percentile of method-specific reference range for age, sex, and altitude of residence,

or Hemoglobin >17 g/dL in men, 15 g/dL in women if associated with a documented and sustained increase of at least 2 g/dL from an individual's baseline value that cannot be attributed to correction of iron deficiency,

or Elevated red cell mass >25% above mean normal predicted value.

Data from Tefferi A, Thiele J, Orazi A, et al: Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocytopenia, and primary myelofibrosis: recommendations from an ad hoc international expert panel. Blood 2007;110:1092–1097.

Bone marrow histology, to the experienced hematopathologist, is often revealing of characteristic changes of a MPD that include hypercellularity, increased number of megakaryocytes including cluster formation, the presence of giant megakaryocytes and pleomorphism in megakaryocyte morphology, mild reticulin fibrosis, and decreased bone marrow iron stores.[59] In contrast, cytogenetic studies in PV disclose abnormalities (trisomies of chromosomes 9 and 8 and deletions of the long arms of chromosomes 13 and 20) in only 13% to 18% of patients, at diagnosis, and hence have limited diagnostic value.[60]

Treatment

The natural history of PV is characterized by a lifelong propensity for thrombohemorrhagic complications, late-onset disease transformation into post-PV myelofibrosis and/or acute myeloid leukemia (AML), and a shortened life expectancy.[61] Specific treatment has been shown to positively influence the risk of both macrovascular and microvascular complications but not that of clonal evolution to post-PV myelofibrosis or AML.

Phlebotomy is the cornerstone of therapy in PV and is the only treatment modality that has improved survival in affected patients (Box 106-1). It is reported that median survival may be as low as 2 years in the absence of such treatment.[62] Based on limited retrospective studies in PV that showed a progressive increase in the incidence of vascular occlusive episodes above a hematocrit level of 44%,[63] as well as other studies that showed suboptimal cerebral blood flow in ranges of hematocrit values between 46% and 52%,[64] the therapeutic target hematocrit level is currently set at or below 45%. Furthermore, because of the physiologic difference in hematocrit values between the two genders as well as among different races, it is reasonable, though not evidence-based, to target an even lower hematocrit level (i.e., 42%) in women and African-Americans. Although it is prudent to err on the safe side and utilize the previously mentioned hematocrit thresholds during treatment with phlebotomy, the value of aggressive phlebotomy in aspirin-treated low-risk disease, within hematocrit ranges between 40% and 55%, has been questioned by the European Collaboration on Low-dose Aspirin in Polycythemia Vera (ECLAP) Investigators.[65]

Role of Drug Therapy in Polycythemia Vera

OBSERVATIONS FROM RANDOMIZED STUDIES. In the first controlled study in PV, the PV study group randomized 431 patients to treatment with either phlebotomy alone or phlebotomy supplanted by either oral chlorambucil or intravenous radioactive phosphorus (^{32}P). The results favored treatment with phlebotomy alone with a median survival of 12.6 years as compared with 10.9 and 9.1 years for treatment with ^{32}P and chlorambucil, respectively ($P = 0.008$). The difference in survival was attributed to an increased incidence of AML in patients treated with chlorambucil or ^{32}P compared with those treated with phlebotomy alone (13.2% vs. 9.6% vs.1.5% over a period of 13–19 years).[66] Furthermore, 3.5% of the patients treated with chlorambucil developed large cell lymphoma, and the incidence of gastrointestinal and skin cancer was increased in those patients treated with either chlorambucil or ^{32}P.

In another controlled study, the European Organization for Research on Treatment of Cancer (EORTC) randomized 293 patients to treatment with either ^{32}P or oral busulfan. The results favored busulfan in terms of both first-remission duration (median, 4 years vs. 2 years) and overall survival (10-year survival rates of 70% vs. 55%; $P = 0.02$). At a median follow-up period of 8 years, there was not significant difference in the risk of leukemic transformation (2% vs. 1.4%), nonhematologic malignancy (2.8% vs. 5%), vascular complications (27% vs. 37%), or transformation into post-PV myelofibrosis (4.8% vs. 4.1%) between the busulfan and ^{32}P arms, respectively.[67]

Other randomized studies in PV have compared hydroxyurea against pipobroman (a significant difference favoring pipobroman in the incidence of transformation into post-PV myelofibrosis but no difference in survival, incidence of thrombosis, or the rate of leukemic conversion),[68] ^{32}P alone against ^{32}P plus hydroxyurea (no difference in survival, incidence of thrombosis, or risk of transformation into post-PV myelofibrosis, but ^{32}P alone was associated with significantly fewer incidences of both acute leukemia and other cancers),[69] and ^{32}P plus phlebotomy against phlebotomy plus high-dose aspirin (900 mg/day) in combination with dipyridamole (225 mg/day) (the addition of antiplatelet agents provided no benefit in terms of thrombosis prevention but increased the risk of gastrointestinal bleeding).[70] However, a more recent randomized study of PV (112 patients) using lower doses of aspirin (40 mg/day) did not show an increased bleeding diathesis.[71] Furthermore, the results of the PV study group aspirin study may have been influenced by the fact that 27% of the patients

Box 106-1. POLYCYTHEMIA VERA

- The polycythemia vera study group diagnostic criteria, including the laboratory measurement of red cell mass, are neither essential nor practical for the diagnosis of PV in routine clinical practice.
- A contemporary algorithm that is based on mutation screening for *JAK2*V617F and serum Epo measurement can be formulated for making a working diagnosis of PV.
- All patients with PV should be phlebotomized to keep the hematocrit at 45% or less at all times.
- In addition to phlebotomy, PV patients who either are older than 60 years of age or have a history of thrombosis should receive myelosuppressive treatment.
- Hydroxyurea remains the myelosuppressive treatment of choice in PV treatment, with α-IFN as a reasonable alternative treatment agent.
- There is not good evidence to implicate thrombocytosis as a prothrombotic risk factor in PV.
- The antithrombotic value of low-dose aspirin (81–325 mg/day) in PV treatment has been demonstrated in a controlled clinical trial.
- It is currently unclear whether currently used drugs in PV influence disease transformation into either myelofibrosis or acute leukemia.

randomized to the phlebotomy-aspirin-dipyridamole arm had a prior history of thrombosis compared with 13% in the other arm. This contention was confirmed by the most recent ECLAP study that showed safety as well as antithrombotic activity of low-dose aspirin in a randomized study.[72]

OBSERVATIONS FROM NONRANDOMIZED STUDIES. In a nonrandomized study by the PV study group, treatment with hydroxyurea was associated with a lower incidence of early thrombosis compared with a historical cohort treated with phlebotomy alone (6.6% vs 14% at 2 years). Similarly, the incidence of AML in patients treated with hydroxyurea, compared with a historical control treated with either chlorambucil or ^{32}P, was significantly lower (5.9% vs. 10.6% vs. 8.3%, respectively, in the first 11 years of treatment).[73] Other studies have confirmed the low incidence of AML in PV patients treated with hydroxyurea (1% to 5.6%).[74–76]

Many studies have reported on the use of pipobroman as a single agent in PV.[77,78] In one of these studies involving 163 patients, the drug was effective in more than 90% of the patients and median survival exceeded 17 years.[77] In the first 10 years, the incidences of thrombotic events, acute leukemia, post-PV myelofibrosis, and other malignancies were 16%, 5%, 4%, and 8%, respectively. Favorable outcome has also been reported in single-arm studies using oral busulfan.[79,80] In 65 busulfan-treated patients with PV followed between 1962 and 1983, overall median survival was 11.1 years and 19 years in patients whose disease was diagnosed before age 60 years.[79] Only 2 patients (3.5%) treated with busulfan alone developed acute leukemia.

Most recently, alfa interferon (α-IFN) was shown to control erythrocytosis in approximately 76% of the patients with PV receiving subcutaneous drug in doses ranging from 4.5 to 27 million units per week (usual dose is 3 million units subcutaneously three times a week).[81,82] A similar degree of benefit is appreciated in terms of reduction in spleen size or relief from intractable pruritus. Furthermore, a variable degree of *JAK2*V617F allele burden reduction was recently associated with α-IFN therapy, but the relevance in overall outcome of the disease is not known.[83] A randomized study is needed to determine if α-IFN is superior to hydroxyurea as a cytoreductive agent in PV, especially in view of its higher cost and toxicity profile. Finally, anagrelide, an oral imidazoquinazoline derivative that inhibits platelet aggregation at higher than therapeutic drug concentrations but displays a species-specific platelet-lowering effect in humans at therapeutic concentrations, controls thrombocytosis in PV.[84] However, the drug is currently not recommended in the treatment of PV, because it was associated with increased incidence of arterial thrombosis and post-ET myelofibrosis, when compared with hydroxyurea, in patients with ET.[85]

In summary, the results from single-arm studies support those of the randomized studies and show that pipobroman and busulfan are valuable treatment agents in PV and might be considered as alternatives to hydroxyurea. Pipobroman is currently not available in the United States. It is currently not clear what additional value is gained by substituting the aforementioned traditional cytoreductive agents by the newer drugs (i.e., α-IFN and anagrelide) especially in view of their unfavorable toxicity and cost profile (Table 106-3).[86]

Thrombohemorrhagic Risk Factors in Polycythemia Vera

The series of studies performed by the PV study group revealed the following: (1) a significantly higher incidence of thrombotic events, in the first 3 years, in patients treated with phlebotomy alone; (2) a lack of correlation between thrombosis and either platelet count or hematocrit value; and (3) a significant association between thrombosis risk and either age above 70 years or a prior history of thrombosis. In addition, in patients treated with phlebotomy alone, thrombosis risk was associated with an increased frequency of phlebotomy (maintenance phlebotomy of more than once every 3 months). Other studies have confirmed the detrimental effect of advanced age (>60 years) and thrombosis history in PV.[17] As such, patients who are 60 years old or older or have a history of thrombosis are considered at high risk (Table 106-4). In contrast, the degree of thrombocytosis has never been correlated with thrombosis risk. However, some patients with extreme thrombocytosis (platelet count at or above 1 million platelets/μL), carry an acquired bleeding diathesis that results from an abnormal adsorption and catabolism of large-molecular-weight von Willebrand factor.[87] The prognostic influence of extreme thrombocytosis, in the absence of acquired von Willebrand disease, is unknown. Equally uncertain is the prognostic relevance of cardiovascular risk factors.

Current Treatment Recommendations

The mainstay of therapy in PV remains phlebotomy for all patients to keep hematocrit at or below 45% in male Caucasians and the appropriate corresponding value for females and other races. However,

Table 106-3 Clinical Properties of Popular Cytoreductive Agents Used in Polycythemia Vera or Essential Thrombocythemia

Drug (class)	Hydroxyurea	Anagrelide	Alfa interferon	Phosphorus-32	Pipobroman
	Myelosuppressive	Platelet-specific	Myelosuppressive	Myelosuppressive	Myelosuppressive
Mechanism of action	Antimetabolite	Unknown	Biologic agent	Radionuclide	Alkylating agent
Pharmacology	Half-life ≅5 hr, renal excretion	Half-life ≅1.5 hr, renal excretion	Kidney is main site of metabolism	Half-life ≅14 days	Insufficient information
Starting dose	500 mg PO BID	0.5 mg PO TID	5 million units SC TIW	2.3 mCi/m^2 IV	1 mg/kg/day PO
Onset of action	≅3–5 days	≅6–10 days	1–3 weeks	4–8 weeks	≅16 days
Frequent side effects	Leukopenia, oral ulcers, anemia, hyperpigmentation, nail discoloration, xerodermia	Headache, palpitations, diarrhea, fluid retention, anemia	Flu-like syndrome, fatigue, anorexia, weight loss, lack of ambition, alopecia	Transient mild cytopenia	Nausea, abdominal pain, diarrhea
Infrequent side effects	Leg ulcers, nausea, diarrhea, alopecia, skin atrophy	Arrhythmias, lightheadedness, nausea	Confusion, depression, autoimmune thyroiditis, myalgia, arthritis	Prolonged pancytopenia in elderly patients	Leukopenia, thrombocytopenia, hemolysis
Rare side effects	Fever, cystitis, platelet oscillations	Cardiomyopathy	Pruritus, hyperlipidemia, transaminasemia	Leukemogenic	

Table 106-4 Risk Stratification in Polycythemia Vera and Essential Thrombocythemia

Low-risk	Age <60 yr *and* No history of thrombosis *and* Platelet count <1 million cells/μL
Low-risk with extreme thrombocytosis	Age <60 yr *and* No history of thrombosis *but* Platelet count ≥1 million cells/μL
High-risk	Age ≥60 yr *or* Positive history of thrombosis

in aspirin-treated patients with PV, it is not certain that a hematocrit level of 45% or below is associated with a significantly lower thrombosis risk compared to a higher hematocrit level up to 54%,[88] although the writer recommends the 45% threshold so as to err on the safe side. Additional drug therapy depends on an individual patient's risk for thrombohemorrhagic complications (see Table 106-4). In general, there is good evidence to advocate the use of cytoreductive agents in high-risk patients (Table 106-5).[66] In this regard, and based on the results of the aforementioned studies, my current choice of chemotherapy is hydroxyurea (starting dose of 500 mg twice daily) or busulfan (starting dose of 4 mg/day) in case of nontolerance to hydroxyurea. Side effects of hydroxyurea that might necessitate the use of an alternative agent include neutropenia and mucocutaneous changes such as ulcers in the mouth and lower extremities. In using busulfan, one should recognize the potential, but infrequent, toxicity to the lungs (pulmonary fibrosis)[89] and the bone marrow (aplasia).[90] Intermittent treatment with drug holidays and withholding treatment for impending cytopenia are recommended.

In the younger but high-risk patient group, some investigators are concerned about drug leukemogenicity associated with long-term treatment with either hydroxyurea or busulfan. However, there is currently not hard evidence to support the particular concern.[76] Regardless, α-IFN (starting dose of 3 million units subcutaneously three times a week) is a reasonable alternative in this instance.[81] α-IFN is also the treatment of choice in women of childbearing age (see Table 106-5) because of the theoretical risk of teratogenicity associated with the use of other cytoreductive agents.[82]

Because ^{32}P-associated leukemia in PV peaks after the first 7 years of treatment, it is reasonable to advocate the use of ^{32}P in elderly patients with issues of treatment compliance and convenience, especially if life expectancy is less than 10 years (intravenous ^{32}P at 2.3 mCi/m^2 to be repeated every 3 months if necessary).[66] The lack of evidence that correlates thrombocytosis with thrombosis in PV argues against the potential therapeutic value of anagrelide in PV.

It is currently unclear whether any specific drug therapy influences clonal evolution in PV. Under current treatment strategies, the incidences of transformation into post-PV myelofibrosis or AML, in the first decade of disease, are estimated at 10% and 5%, respectively.[66] The risk beyond the first decade increases progressively.[91]

Treatment of Non-Life-Threatening Complications in Polycythemia Vera

Additional clinical features of PV include microvascular disturbances, aquagenic pruritus, and constitutional symptoms. Microvascular disturbances in PV and related disorders are felt to represent transient inflammation-based occlusive phenomenon that is a result of interaction between clonal platelets and the endothelium of arterioles. The corresponding clinical manifestations include headache, lightheadedness, transient neurologic or ocular disturbances, tinnitus, atypical chest discomfort, paresthesias, and erythromelalgia. Aspirin produces prompt (within hours) alleviation of symptoms in the majority of patients with PV-associated microvascular disturbances.

Generalized pruritus that is often exacerbated by hot bath is a characteristic feature of PV and occurs in 48% of patients either at diagnosis or at a later stage of the disease.[92] Etiology of PV-associated pruritus remains to be determined and treatment responses to antihistamines have been both unpredictable and variable.[92] Interestingly, a recent study demonstrated a greater than 80% response rate in PV-associated pruritus treated with paroxetine, which is a selective serotonin reuptake inhibitor.[93] Other treatment modalities that have been used in PV-associated pruritus include α-IFN, psoralen photochemotherapy, and cholestyramine.[17]

ESSENTIAL THROMBOCYTHEMIA

Among the classic *BCR-ABL*$^-$ MPDs, ET is the most recently described.[94] Reported incidence figures range from 0.2 to 2.5 per 100,000 population.[8,95–97] With a median age at diagnosis of 60 years, approximately 20% of the patients with ET are diagnosed before age 40 years and in the young age group of patients, the incidence is higher in women than in men.[98,99] There are well-documented cases of ET in children, although some of the reported cases may have represented familial thrombocytosis.[100,101]

Pathogenesis

Trilineage clonal myeloproliferation has been demonstrated in the majority of patients with ET using X chromosome–linked DNA or gene product analysis.[102,103] However, X-linked clonal assays have revealed both polyclonal hematopoiesis in a substantial minority of patients with ET[104] and "monoclonal" hematopoiesis in normal elderly controls.[105] Furthermore, in some cases, the clonal process in

Table 106-5 Treatment Algorithm in Polycythemia Vera

Risk Category	Age <60 Yr	Age ≥60 Yr	Women of Childbearing Age

*Screening for acquired von Willebrand disease is encouraged before the use of aspirin in patients with extreme thrombocytosis (platelet count ≥1 million cells/μL). Use of aspirin is discouraged if ristocetin co-factor activity is <50%.

†Based on anecdotal evidence of safety.

ET was shown to include lymphocytes[13] or be restricted to megakaryocytes.[103] The clonal basis of ET was recently underlined by *JAK2*V617F mutation analysis that revealed the presence of the mutation even in those patients who feature "polyclonal" hematopoiesis by X-linked clonality studies.[104,106] However, the primary clonogenic event in ET remains undefined despite the recent descriptions of two gain-of-function mutations that occur in 50% (*JAK2*V617F)[107] and 1% (*MPL*W515L/K)[108] of patients with ET, respectively.

Other biologic features in ET include in vitro growth factor independence/hypersensitivity of both erythroid and megakaryocyte progenitor cells,[109,110] low serum Epo level,[111] altered megakaryocyte/platelet Mpl expression,[112,113] increased neutrophil PRV-1 expression,[114,115] and decreased platelet serotonin content.[116] Laboratory studies in ET have demonstrated myeloid growth factor hypersensitivity to interleukin-3 [117] as well as thrombopoietin (Tpo).[110] Growth factor independence of myeloid progenitor cells in ET and related MPDs has now been attributed to mutations involving molecules of the JAK-STAT pathway including the aforementioned *JAK2*V617F and *MPL*W515L/K. In patients with ET,[118] PV,[119] and myelofibrosis,[120] serum Tpo levels are usually normal or elevated despite an increased megakaryocyte mass. This has been attributed to the markedly decreased megakaryocyte/platelet expression of MPL, although the extent of this particular phenotypic abnormality is significantly less in ET as compared with PV or PMF.[112,113,121,122]

In addition to clonal myeloproliferation, ET is also characterized by microvascular symptoms (e.g., headaches and erythromelalgia) as well as an increased risk of both thrombosis and bleeding.[123] Pathogenesis in the former might involve abnormal thromboxane A_2 generation and small vessel–based platelet-endothelial interactions that are inhibited by aspirin therapy.[124,125] On the other hand, there is increasing information that implicates granulocytes but not platelets as the thrombogenic culprit in ET.[85,126–128] Consistent with these observations, a recent study has identified leukocytosis as an independent risk factor for thrombosis in ET.[129] Bleeding diathesis in ET is currently believed to involve an acquired von Willebrand syndrome that becomes apparent in the presence of extreme thrombocytosis.[87] The mechanism of acquired von Willebrand syndrome in ET is currently believed to involve a platelet count-dependent increased proteolysis of high-molecular-weight von Willebrand protein.[87] Other qualitative platelet defects in ET are believed to play a minor role in disease-associated hemorrhage and include defects in epinephrine-, collagen-, and adenosine diphosphate–induced platelet aggregation, decreased adenosine triphosphate secretion, and acquired storage pool deficiency that results from abnormal in vivo platelet activation.[123]

Diagnosis

Although thrombocytosis is the hallmark of ET, more than 85% of cases with thrombocytosis seen in routine clinical practice are reactive (secondary thrombocytosis) and associated with other comorbid conditions (Table 106-6).[130] The degree of thrombocytosis is a poor discriminator of ET from secondary thrombocytosis. However, the clinical scenario is often helpful in distinguishing ET from secondary thrombocytosis. In routine clinical practice it is important to exclude the contribution of either iron deficiency anemia or a hyposplenic state as possible causes of an otherwise unexplained thrombocytosis (Box 106-2). This is accomplished by the measurement of serum ferritin concentration and examination of a peripheral blood smear looking for Howell-Jolly bodies, respectively. The possibility of secondary thrombocytosis associated with an occult inflammatory or malignant process is addressed by the measurement of C-reactive protein or other acute-phase reactants.[131] In other words, an uncomplicated ET should be accompanied by a normal serum ferritin, mostly unremarkable peripheral smear, and a normal serum C-reactive protein. In general, plasma Tpo levels are not helpful in distinguishing secondary thrombocytosis from ET.[118]

Table 106-6 Causes of Thrombocytosis

SECONDARY CAUSES	
Acute	**Chronic**
Postsurgery	Iron deficiency anemia
Bleeding	Surgical or functional asplenia
Hemolysis	Metastatic cancer or lymphoma
Infections	Chronic inflammatory process
Tissue damage	Renal failure, nephrotic syndrome
Chemotherapy rebound effect	
Coronary artery bypass surgery	
PRIMARY CAUSES	
Essential thrombocythemia	
Polycythemia vera	
Primary myelofibrosis	
Chronic myeloid leukemia	
Myelodysplastic syndrome	

Unlike the case with PV, the utility of mutation screening for *JAK2*V617F for the diagnosis of ET is limited by suboptimal negative predictive value and lack of diagnostic specificity within the context of myeloid neoplasms. It should be noted that only half of patients with either ET carry *JAK2*V617F and that the presence of the mutation cannot differentiate ET from another MPD. Therefore, although peripheral blood screening for *JAK2*V617F helps in streamlining further investigation, a bone marrow biopsy is often required to help with the differential diagnosis of primary thrombocytosis. In general, the presence of *JAK2*V617F argues against the possibility of a nonclonal process such as infection or inflammation or a nonmyeloid malignancy such as lymphoma or metastatic cancer.

The typical bone marrow finding in ET consists of a mild to moderate increase in cellularity and the presence of megakaryocyte clusters that are often absent in secondary thrombocytosis (Fig. 106-3). It

Box 106-2. ESSENTIAL THROMBOCYTHEMIA

- At present, ET remains a diagnosis of exclusion. Both secondary thrombocytosis and clonal thrombocytosis associated with other chronic myeloid disorders have to be ruled out before a working diagnosis of ET is made.
- Not all patients with ET need specific therapy.
- Observation alone is a reasonable option in managing asymptomatic patients with ET who are younger than age 60 years and do not have a history of thrombosis.
- Cytoreductive therapy in ET has been shown to benefit "high-risk for thrombosis" patients.
- There is not good evidence to implicate thrombocytosis as a prothrombotic risk factor in "low-risk" patients with essential thrombocythemia.
- Although probably safe to use, the antithrombotic value of low-dose aspirin (81–325 mg/day) in ET is currently unknown.
- There is not good evidence to implicate hydroxyurea as a leukemogenic drug in ET.
- Pregnancy is not a contraindication in ET. Maternal morbidity is very low, although the first-trimester miscarriage rate is significantly higher than that of the general population.
- No specific treatment is recommended for the pregnant, or low- or indeterminate-risk patient with ET.

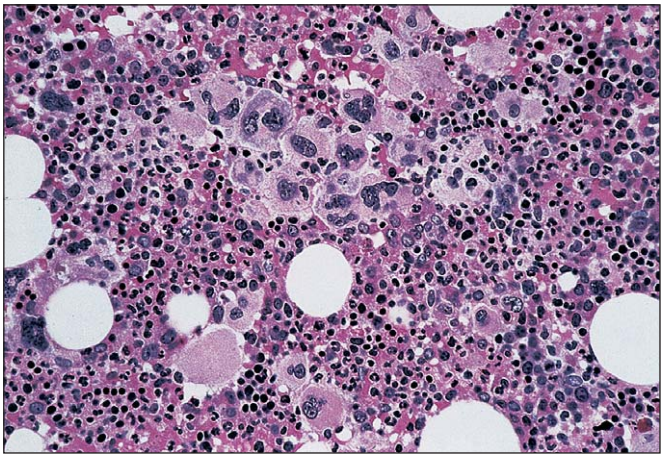

Figure 106-3 • Megakaryocyte hyperplasia and cluster formation in ET.

Table 106-7 Revised World Health Organization Criteria for Essential Thrombocythemia

Diagnosis requires meeting all four criteria.
Sustained platelet count ≥450 $\times 10^9$ platelets/L*
Bone marrow biopsy specimen showing proliferation mainly of the megakaryocytic lineage with increased numbers of enlarged, mature megakaryocytes. No significant increase or left-shift of neutrophil granulopoiesis or erythropoiesis is seen.
Not meeting WHO criteria for polycythemia vera,† primary myelofibrosis,‡ chronic myelogenous leukemia,§myelodysplastic syndrome,‖ or other myeloid neoplasm
Demonstration of *JAK2*V617F or other clonal marker, *or*, in the absence of a clonal marker, no evidence for reactive thrombocytosis¶

*During the workup period.

†Requires the failure of iron replacement therapy to increase hemoglobin level to the polycythemia vera range in the presence of decreased serum ferritin. Exclusion of polycythemia vera is based on hemoglobin and hematocrit levels and red cell mass measurement is not required.

‡Requires the absence of relevant reticulin fibrosis, collagen fibrosis, peripheral blood leukoerythroblastosis, or markedly hypercellular marrow for age accompanied by megakaryocyte morphology that is typical for primary myelofibrosis—small to large with an aberrant nuclear-to-cytoplasmic ratio and hyperchromatic, bulbous, or irregularly folded nuclei and dense clustering.

§Requires the absence of BCR-ABL.

‖Requires absence of dyserythropoiesis and dysgranulopoiesis.

¶Causes of reactive thrombocytosis include iron deficiency, splenectomy, surgery, infection, inflammation, connective tissue disease, metastatic cancer, and lymphoproliferative disorders. However, the presence of a condition associated with reactive thrombocytosis does not exclude the possibility of essential thrombocythemia if the first three criteria are met.

Data from Tefferi A, Thiele J, Orazi A, et al: Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocytopenia, and primary myelofibrosis: recommendations from an ad hoc international expert panel. Blood 2007;110:1092–1097.

should be remembered that CML and the cellular phase of PMF could both mimic ET in presentation.[132] With respect to CML, a peripheral blood or bone marrow fluorescence in situ hybridization study may be needed, in addition to cytogenetic analysis, so as to exclude the possibility of karyotypically occult CML.[133] Similarly, bone marrow histology should be carefully scrutinized for the presence of intense marrow cellularity with florid atypical megakaryocytic hyperplasia suggesting cellular phase PMF. Cytogenetic abnormalities are rare in ET (<5%) and diagnostically not helpful.[134] Taking all the preceding information into consideration, bone marrow examination remains central to the diagnosis of ET, and its importance is underlined in the newly revised WHO criteria for the diagnosis of ET (Table 106-7).

Treatment

The majority of patients with ET either are asymptomatic or suffer from non-life-threatening microvascular disturbances (headache, visual symptoms, lightheadedness, atypical chest pain, acral dysesthesia, erythromelalgia) that are effectively treated with low-dose aspirin.[135]

Approximately 20% of patients experience, usually nonfatal, thrombohemorrhagic complications, and only 5% progress into AML or post-ET myelofibrosis during the first decade of the disease.[129,136–139] Therefore, it is reasonable to expect long survival in the majority of patients with ET, especially in the absence of advanced age and leukocytosis.[139] In one study of 605 patients with ET seen at the Mayo Clinic,[139] hemoglobin level below normal (females <12 g/dL; males <13.5 g/dL) was identified as an independent risk factor for both inferior survival and leukemic transformation. Additional independent risk factors for survival included age ≥60 years, leukocyte count ≥15 $\times$ 10^9 cells/L, smoking, diabetes mellitus, and thrombosis. For leukemic transformation, platelet count ≥1000 $\times$ 10^9 platelets/L but not cytoreductive therapy was flagged as an additional independent risk factor. Presence of *JAK2*V617F did not impact either survival or leukemic transformation, and mutational frequency was similar among the different risk groups.

The relatively low incidence figures of thrombosis and hemorrhage as well as the occurrence of both short-term and long-term drug side effects are the basis for carefully selecting the patients with ET who require specific treatment. Risk stratification in ET is similar to that of PV (see Table 106-4). Table 106-8 outlines risk-adjusted treatment guideline in ET that is further elaborated in the following sections.

Antiplatelet Therapy in Essential Thrombocythemia

Unlike the case with higher doses (500 mg or higher per day), low-dose aspirin (81–325 mg/day) may not increase the bleeding diathesis of patients with ET and is currently recommended as a supplement to cytoreductive therapy in high-risk patients as well as an optional consideration in most patients with ET (see Table 106-8).[140] However, it is important to exclude the possibility of clinically significant (ristocetin co-factor activity of <50%) acquired von Willebrand

Table 106-8 Treatment Algorithm in Essential Thrombocythemia

Risk Category	Age <60 Yr	Age ≥60 Yr	Women of Childbearing Age
Low-risk	Low-dose aspirin*	Not applicable	Low-dose aspirin*

High-risk	Hydroxyurea + low-dose aspirin	Hydroxyurea + low-dose aspirin	Alfa interferon‡ + low-dose aspirin

*Not evidence-based.

†One must rule out the presence of clinically-relevant (ristocetin co-factor activity >50%) acquired von Willebrand disease before using aspirin.

‡Based on anecdotal evidence of safety.

disease before using aspirin in those patients with platelet counts above 1 million cells/μL.

Cytoreductive Therapy in Essential Thrombocythemia

The use of cytoreductive therapy to reduce the risk of thrombosis in ET is appropriate and evidence-based as long as it is applied to those patients with an increased risk for thrombosis (see Table 106-4).[128] In this instance it may be necessary to reduce the platelet count to 400,000 cells/μL or lower.[141] A less aggressive platelet control, with a cytoreductive drug, may also be indicated in patients who manifest either aspirin-resistant microvascular disturbances or symptomatic acquired von Willebrand disease.[87,142] In all other instances the decision to use a platelet-lowering agent in ET is not supported by hard data. Specifically, neither the degree of thrombocytosis nor the presence of cardiovascular risk factors has consistently been correlated with an increased thrombotic risk in ET.[135] The frequently cited association of extreme thrombocytosis and increased gastrointestinal bleeding is based on anecdotal observation and may in some instances be attributed to occult acquired von Willebrand disease. A recent retrospective study of young, low-risk ET patients with extreme thrombocytosis revealed no difference in the risk of either thrombosis or bleeding between patients receiving or not receiving cytoreductive therapy.[143]

Table 106-3 summarizes the practical pharmacologic and clinical information regarding currently used platelet count–lowering agents in ET. It is important to note that only hydroxyurea, as a treatment agent, has been shown in a prospective study to be associated with a reduced risk of thrombosis in ET.[128] Hydroxyurea was also found to be superior to anagrelide in a head-to-head comparative study of high-risk patients with ET;[85] patients treated with anagrelide displayed statistically higher incidence of arterial thrombosis and transformation into post-ET myelofibrosis. Finally, the concern regarding hydroxyurea leukemogenicity in ET is currently unsubstantiated,[139] and the indiscriminate use of new drugs that are not tested in a controlled setting is unwarranted.

Pregnancy and Essential Thrombocythemia

First-trimester spontaneous abortion rate in ET (37%) is significantly higher than the 15% rate expected in the control population and does not appear to be influenced by specific treatment.[144] Late obstetric complications as well as maternal thrombohemorrhagic events are relatively infrequent. Neither the platelet count nor treatment with aspirin seems to affect either maternal morbidity or pregnancy outcome. In fact, several studies have shown a spontaneous lowering of platelet counts during pregnancy in ET. Therefore, cytoreductive treatment is currently not recommended for low-risk women with ET that are either pregnant or wish to be pregnant. In contrast, high-risk women require cytoreductive therapy to minimize the risk of recurrent thrombosis and anecdotal evidence of safety has encouraged a preference for the use of IFN-α in case of pregnancy in such patients.[82]

PRIMARY MYELOFIBROSIS

PMF is also known as agnogenic myeloid metaplasia or chronic idiopathic myelofibrosis.[145] The disease was first described in 1879.[146] The clinical course of PMF is characterized by progressive anemia, marked hepatosplenomegaly, cachexia, development of nonhepatosplenic extramedullary hematopoiesis, and evolution into acute leukemia.[147] Similar to the situation in both PV and ET, the disease-initiating genetic lesion in PMF has not been identified, and current diagnosis is based on characteristic, but not specific, clinical and laboratory features that include bone marrow fibrosis and osteosclerosis (Table 106-9).[147]

Among the *BCR-ABL*⁻ classic MPDs, PMF is the least frequent, with an incidence figure that ranges from 0.3 to 1.5 per 100,000 population.[96,97] The median age at diagnosis is 60 years, and approximately 10% of the patients are diagnosed at age 45 years or below.[148]

Table 106-9 Revised World Health Organization Criteria for Primary Myelofibrosis

Diagnosis requires meeting all three major criteria and two minor criteria.

MAJOR CRITERIA

Presence of megakaryocyte proliferation and atypia,* usually accompanied by either reticulin and/or collagen fibrosis, *or*, in the absence of significant reticulin fibrosis, the megakaryocyte changes must be accompanied by an increased bone marrow cellularity characterized by granulocytic proliferation and often decreased erythropoiesis (i.e., prefibrotic cellular-phase disease).

Not meeting WHO criteria for polycythemia vera,† chronic myelogenous leukemia,‡ myelodysplastic syndrome,§ or other myeloid neoplasm

Demonstration of *JAK2*V617F or other clonal marker (e.g., *MPL*W515L/K), *or*, in the absence of a clonal marker, no evidence of bone marrow fibrosis due to underlying inflammatory or other neoplastic diseases‖

MINOR CRITERIA

1. Leukoerythroblastosis¶
2. Increase in serum lactate dehydrogenase level¶
3. Anemia¶
4. Palpable splenomegaly¶

*Small to large megakaryocytes with an aberrant nuclear-to-cytoplasmic ratio and hyperchromatic, bulbous, or irregularly folded nuclei and dense clustering.

†Requires the failure of iron replacement therapy to increase hemoglobin level to the polycythemia vera range in the presence of decreased serum ferritin. Exclusion of polycythemia vera is based on hemoglobin and hematocrit levels. Red cell mass measurement is not required.

‡Requires the absence of BCR-ABL.

§Requires absence of dyserythropoiesis and dysgranulopoiesis.

‖Secondary to infection, autoimmune disorder or other chronic inflammatory condition, hairy cell leukemia or other lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathies. It should be noted that patients with conditions associated with reactive myelofibrosis are not immune to primary myelofibrosis, and the diagnosis should be considered in such cases if other criteria are met.

¶Degree of abnormality could be borderline or marked.

Data from Tefferi A, Thiele J, Orazi A, et al: Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocytopenia, and primary myelofibrosis: recommendations from an ad hoc international expert panel. Blood 2007;110:1092–1097.

Children are not spared of PMF, but their clinical course may be less aggressive.[149]

Pathogenesis

In addition to clonal myeloproliferation, the bone marrow in PMF displays excess collagen fibrosis, new bone formation (osteosclerosis), and angiogenesis. These changes have been associated with alterations in both cellular and extracellular levels of various fibrogenic and angiogenic cytokines including transforming growth factor-β (TGF-β), basic fibroblast growth factor, and platelet-derived growth factor.[150] The demonstration of polyclonal fibroblast proliferation in PMF is the basis for the current assumption that the bone marrow stromal aberration in PMF is reactive[151] and mediated by the aforementioned cytokines derived from the resident clonal megakaryocytes and monocytes (Fig. 106-4).[152]

Current evidence strongly supports the stem cell origin of the clonal myeloproliferation in PMF.[153,154] However, the primary clonogenic mutation(s) has not been identified, although much attention has been given to recently described novel gain-of-function mutations involving the JAK2 tyrosine kinase (*JAK2*V617F) and Tpo receptor (*MPL*W515L/K).[30,155] *JAK2*V617F represents a G-to-T somatic mutation of *JAK2*, at nucleotide 1849, in exon 14, resulting in the substitution of valine to phenylalanine at codon 617.[30]

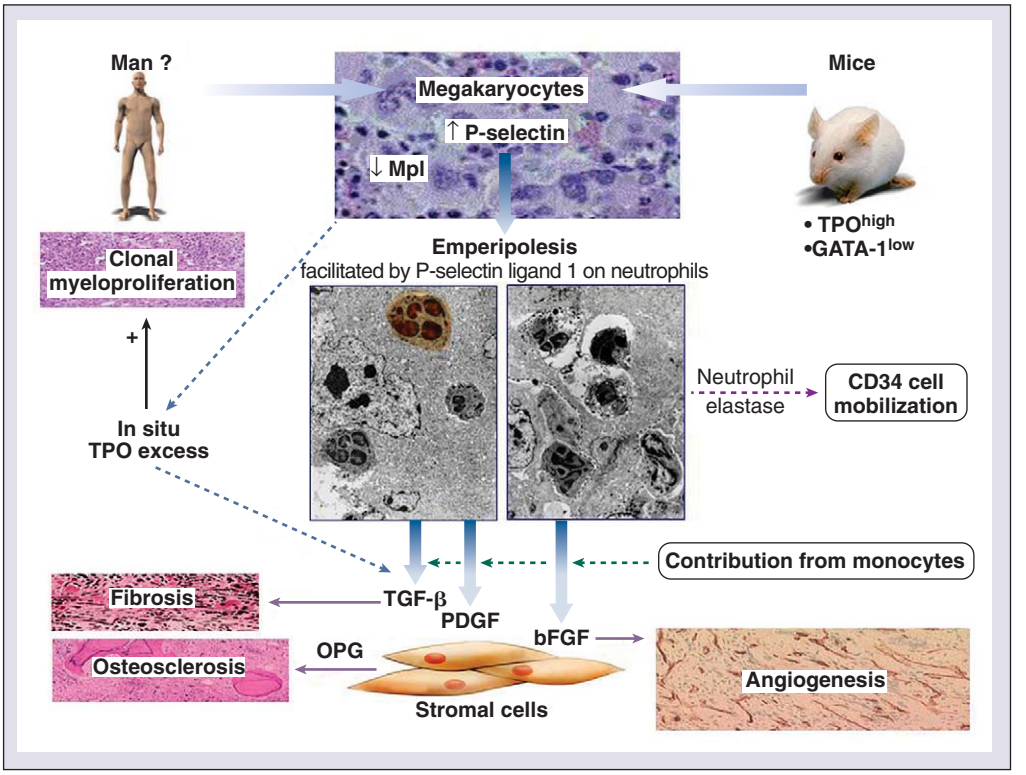

Figure 106-4 • Pathogenesis of reactive stromal changes of the bone marrow in PMF.

*MPL*W515L mutation represents a G-to-T transition at nucleotide 1544 resulting in a tryptophan-to-leucine substitution at codon 515 of the transmembrane region of the MPL receptor.[155]

*JAK2*V617F occurs not only in PMF (~50% mutational frequency) but also in ET with a similar mutational frequency and in PV where it is present in more than 90% of affected patients.[27–30] In contrast, *MPL*W515L/K seems to be specific to PMF or ET, although mutational frequency is substantially lower (~5% and 1%, respectively).[108] As mentioned before, *JAK2*V617F induces constitutive JAK-STAT activation, cytokine hypersensitivity, and/or independence in cell lines, and a PV-like disease in mice.[30,156,157] JAK-STAT is similarly hyperactivated by *MPL*W515L/K, but this mutation induces a PMF-like disease in mice.[155] In any case, about half of the patients with PMF do not display either mutation, and the precise pathogenetic role of these mutations, when they are present, remains to be clarified. Other molecular alterations in PMF include decreased expression of the tumor suppressor retinoic acid receptor-β2 gene as a result of abnormal promoter methylation[158] and reduced megakaryocyte/platelet surface expression of MPL.[122]

An animal model of PMF has been established in mice that are either chronically overexposed to Tpo[159] or carriers of a mutant *GATA-1* gene that results in reduced expression of a transcription factor that plays a role in erythroid and megakaryocyte differentiation.[160] These mice display characteristic features of PMF, including megakaryocytic hyperplasia, bone marrow fibrosis, osteosclerosis, and extramedullary hematopoiesis. The increased megakaryocyte accumulation in these experimental animals has been attributed to either a direct effect of Tpo or the lack of a negative feedback from mature elements as a result of impaired megakaryocyte differentiation, respectively. In both instances it is possible that the abnormal accumulation of megakaryocytes and their sequestered cytokines might be central to the pathogenesis of the associated stromal reaction. In this regard, the development of Tpo-induced bone marrow fibrosis in mice has been temporally associated with elevated TGF-β levels,[161] whereas it was abrogated in TGF-β-knockout experiments.[162] Similar experiments may decipher the individual roles of other cytokines, including basic fibroblast growth factor and platelet-derived growth factor, that have been implicated in PMF.[163] It is currently not clear whether the aforementioned animal models of PMF involve pathogenetic mechanisms that are operating in the human form of the disease.

Diagnosis

The typical presentation of PMF includes anemia (from ineffective erythropoiesis), marked splenomegaly (from extramedullary hematopoiesis), and a myelophthisic peripheral blood smear. Myelophthisis (the presence of nucleated red blood cells, granulocyte precursors, and teardrop-shaped erythrocytes) suggests a bone marrow infiltrative process, and the differential diagnosis includes bone marrow fibrosis, metastatic cancer, granulomatous infection, and lymphoma (Box 106-3). In PMF, peripheral blood myelophthisis is associated with

Box 106-3. MYELOFIBROSIS WITH MYELOID METAPLASIA

- The diagnosis of PMF requires input from an experienced hematopathologist, and extra caution should be taken to exclude the possibility of chronic myeloid leukemia, hairy cell leukemia, myelodysplastic syndrome with myelofibrosis, and acute myelofibrosis.
- Drug therapy in PMF is palliative and may not prolong life.
- The place of hematopoietic stem cell transplantation in the treatment of primary myelofibrosis is currently being defined, and specific decisions require input from disease experts as well as experienced transplant physicians.
- The indications for splenectomy in myelofibrosis include symptomatic portal hypertension, severe mechanical discomfort that is often associated with cachexia, and treatment-refractory anemia with heavy transfusion requirements.
- Low-dose radiation therapy is effective in the treatment of nonhepatosplenic extramedullary hematopoiesis in myelofibrosis.

bone marrow megakaryocytic hyperplasia, collagen fibrosis, osteosclerosis, and intramedullary sinusoidal hematopoiesis (Fig. 106-5). It should be noted, however, that bone marrow fibrosis may accompany not only PMF but also other hematologic and nonhematologic disorders including CML, MDS, systemic mast cell disease, eosinophilic disorders, and hairy cell leukemia (Table 106-10). Therefore, before embarking on treatment recommendations, one has to consult with an experienced hematopathologist to confirm a specific diagnosis. Extra caution should be taken not to misdiagnose CML or hairy cell leukemia as PMF. These issues are addressed and *JAK2*V617F mutation screening incorporated in the newly revised WHO diagnostic criteria for PMF (see Table 106-9).[49]

In "cellular phase" PMF the degree of bone marrow fibrosis may be minimal, but splenomegaly and myelophthisis are often present. Clonal cytogenetic abnormalities occur in approximately 50% of patients with PMF and include 13q-, 20q-, +8, +9, and abnormalities of chromosomes 1, 7, and 12.[164] None of these cytogenetic markers is specific to PMF, and they are also seen in other myeloid as well as lymphoid disorders.

Treatment

Prognostic Factors

Among the *BCR-ABL*$^-$ classic MPDs, PMF has the worst prognosis, with an approximate median survival of 5 years.[165] However, several studies have identified both clinical and laboratory parameters that are used to identify good-risk as well as high-risk patient categories.[147] The most important indicators of adverse prognosis are the presence of anemia (hemoglobin < 10 g/dL), advanced age (>64 years), hypercatabolic symptoms (weight loss, profound fatigue, night sweats, low-grade fever), leukocytosis (>30,000 cells/μL) or leukopenia (<4,000 cells/μL), circulating blasts (≥1%), high-risk cytogenetic

abnormalities (+8, 12p-), peripheral blood monocyte count of >1000 cells/μL, and platelet count of <100,000 cells/μL.[164–169] Table 106-11 outlines the three most popular prognostic scoring systems[148,166,169] that utilize the previously mentioned risk factors to construct different risk groups.[167]

Hematopoietic Stem Cell Transplantation

At present, only allogeneic hematopoietic stem cell transplantation offers a potentially curative treatment modality in myelofibrosis.[170] In a retrospective, multicenter study of 66 consecutive patients, engraftment was not a major obstacle (84% 30-day recovery of neutrophils), although it was delayed in the presence of pretransplant anemia (hemoglobin < 10 g/dL) and osteosclerosis.[171] In contrast, pretransplant splenectomy and higher doses of nucleated cells in the stem cell infusate were associated with faster engraftment. Five-year survival was 62% in patients younger than 45 years of age and 14% in those that were older. Other investigators have reported better survival figures in patients older than age 44 years,[172] and preliminary data suggest that transplant-related morbidity in older patients may be positively influenced by the use of reduced-intensity conditioning regimens.[173,174]

Nevertheless, current information does not allow definitive comments regarding the role of allogeneic hematopoietic stem cell transplantation in myelofibrosis. This author is not currently convinced that the risk of death as well as chronic graft-versus-host disease, associated with allogeneic hematopoietic stem cell transplantation, is justified in the setting of good-risk disease, even though the outcome may be better when allogeneic hematopoietic stem cell transplantation is performed during early-stage disease.[170] In the presence of Mayo PSS high-risk disease (see Table 106-11), it is reasonable to consider the particular procedure: full myeloablative conditioning in patients below 45 years of age and reduced-intensity conditioning in older patients (Table 106-12). The decision in all other instances should be individualized unless there is new information that dictates otherwise.

Conventional Drug Treatment of Anemia

Conventional drug therapy for anemia includes a combination of an androgen preparation (fluoxymesterone [halotestin], 10 mg twice daily), prednisone (0.5 mg/kg/day),[175] exogenous Epo administration (40,000 units weekly subcutaneous injections) in the presence of an endogenous Epo level of less than 100 mU/mL,[176] and danazol

Table 106-12 Current Treatment Algorithm in Primary Myelofibrosis*

Risk Stratification (Mayo Prognostic Scoring System)*	Age <45 Yr	Age 45–60 Yr	Age >60 Yr
Low-risk	Watchful waiting	Watchful waiting	Watchful waiting

†Experimental drug therapy in low-risk patients requires demonstration of safety in view of the excellent prognosis expected in such patients.

(200–800 mg/day).[177] Such therapy is not expected to alleviate splenomegaly and in some instances might result in a further increase in spleen size. Furthermore, cytoreductive treatment to control splenomegaly may be combined with Epo administration in hopes of offsetting drug-induced anemia.

Management of Splenomegaly and Other Extramedullary Hematopoiesis

Hydroxyurea is the drug of choice for controlling splenomegaly, leukocytosis, or thrombocytosis.[178] Other drugs that have been used in a similar setting include busulfan,[179] melphalan,[180] and 2-chlorodeoxyadenosine.[181] In contrast, IFN-α has limited therapeutic value in myelofibrosis.[182] Many patients with myelofibrosis experience recurrent splenic infarcts that may be associated with debilitating left upper quadrant pain that may be preceded by referred left shoulder discomfort. A computed tomography scan may but does not always show a hypodense region without contrast enhancement. Symptoms from splenic infarcts are usually managed by opiate analgesics, and drug-refractory cases may require splenectomy.

Drug-refractory anemia and symptomatic splenomegaly (portal hypertension, severe hypercatabolic symptoms) may necessitate splenectomy that often alleviates splenomegaly-associated symptoms and may also benefit approximately 25% of patients with transfusion-dependent anemia.[183] The surgical procedure is associated with an approximately 9% mortality rate, and as many as 25% of patients may experience accelerated hepatomegaly and extreme thrombocytosis/leucocytosis after splenectomy. In the presence of severe portal hypertension, which is primarily due to intrahepatic obstruction rather than increased portal flow from marked splenomegaly, portal-systemic shunt surgery may be performed concomitantly with splenectomy and has been shown to be a useful therapeutic option.[184]

In patients with mechanical splenic discomfort, splenic irradiation (100–500 cGy in 5–10 fractions) may be considered as an alternative treatment to splenectomy.[82] However, the benefit of splenic irradiation is transient (median response duration is 6 months), and the procedure is associated with more than 10% mortality rate resulting from severe and prolonged cytopenias that occur in as many as 25% of treated patients. The outcome from hepatic irradiation is even worse, and the procedure is generally not recommended.[185]

Radiation therapy is most useful in the treatment of nonhepatosplenic extramedullary hematopoiesis.[186] Symptomatic pulmonary hypertension that is not secondary to a thromboembolic process has been associated with myelofibrosis and is believed to arise from diffuse pulmonary extramedullary hematopoiesis. Diagnosis is confirmed by technetium-99 m sulfur colloid scintigraphy, which shows diffuse pulmonary uptake, and treatment with single-fraction (100 cGy) whole-lung irradiation has been shown to be effective.[187,188] Low-dose irradiation is also effective for the treatment of paraspinal/epidural extramedullary hematopoiesis (1000 cGy in 5–10 fractions), as well as extramedullary hematopoiesis resulting in pleural and peritoneal effusions (100–500 cGy in 5–10 fractions).[186,189]

Investigational Treatment

The demonstration of intense bone marrow angiogenesis in myelofibrosis prompted a series of studies using thalidomide as a therapeutic agent. When used as a single agent and at doses that average about 200 mg/day, thalidomide results in clinically relevant improvement of anemia (20%), splenomegaly (23%), and thrombocytopenia (71%).[190] However, approximately 20% of patients experience substantial thrombocytosis or leukocytosis in addition to the usual side effects of thalidomide. The use of low-dose thalidomide (50 mg/day) in combination with a tapering dose of prednisone (0.5 mg/kg/day) has been associated with a higher rate of response in both anemia (62%) and clinically relevant thrombocytopenia (75%), as well as a better toxicity profile.[191] Interestingly, some of the patients responding to thalidomide-based therapy displayed unmaintained remissions.[191] However, treatment response to thalidomide was not associated with reduced myelofibrosis or bone marrow angiogenesis, and the mechanism of action may involve other effects of thalidomide including immune modulation and tumor necrosis factor antagonism. The latter possibility is supported by another study that demonstrated a favorable response in constitutional symptoms with the use of a soluble tumor necrosis factor receptor, etanercept.[192]

Lenalidomide and pomalidomide are structurally related to thalidomide but belong to a new line of immunomodulatory drugs with a more potent antiangiogenic and anti-inflammatory activity. Among myeloid neoplasms, the most impressive treatment results with lenalidomide have been reported in del(5q)-associated MDS—45% complete cytogenetic response and an even higher rate of hematologic response.[193] In primary or post-PV/ET myelofibrosis, lenalidomide treatment was associated in approximately 20% to 30% response rate in both anemia and splenomegaly.[194] Lenalidomide response rates were higher and quality of responses most impressive in myelofibrosis patients with the del(5q) abnormality.[195] Clinical trials using pomalidomide in myelofibrosis are currently ongoing.

CONCLUSION

Table 106-12 provides a risk-based management strategy in PMF. At present it is reasonable to consider all high-risk patients (using the Mayo PSS)[167] for allogeneic stem cell transplantation if they are transplant-eligible. However, it is not unreasonable to offer such patients experimental drug therapy instead, because the mortality and morbidity associated with allogeneic transplant remains substantial. It is currently acceptable to monitor low-risk patients without specific therapeutic intervention. Management in intermediate-risk patients should be individualized and is often dictated by age and performance status. The presence of del(5q) in intermediate- or high-risk patients with myelofibrosis warrants a therapeutic trial with lenalidomide. Finally, whether or not small-molecule drugs that target JAK2 will be active as well as safe for use in patients with PMF or the related MPDs, remains to be seen.

107 Chronic Myeloid Leukemia

Hagop Kantarjian and Jorge Cortes

SUMMARY OF KEY POINTS

Incidence
- About 5000 cases per year in the United States; 15% of all leukemias
- Median age 55 to 60 years at diagnosis

Clinical Findings
- Common findings: fatigue, anemia, abdominal discomfort, splenomegaly, leukocytosis
- 30% to 50% of patients asymptomatic at diagnosis
- White blood cell count usually greater than 50×10^9 cells/L, with a left-shifted differential, basophilia, thrombocytosis

Differential Diagnosis
- Chronic myelomonocytic leukemia
- Other myeloproliferative disorders
- Leukemoid reactions

Evaluation
- History and physical examination, complete blood count with differential and platelet count, and chemistries
- Bone marrow aspiration and biopsy
- Testing for the presence of the Philadelphia (Ph) chromosome by cytogenetic analysis or for the presence of the *BCR-ABL* fusion gene by fluorescence in situ hybridization (FISH) or by reverse-transcription polymerase chain reaction

Therapy
- Hydroxyurea or imatinib mesylate initially to control leukocytosis and thrombocytosis
- Imatinib induces a complete hematologic and cytogenetic response in most patients; estimated 5-year survival rate 89%
- New tyrosine kinase inhibitors (dasatinib, nilotinib, bosutinib) active after imatinib failure
- Allogeneic stem cell transplantation may be curative but is associated with considerable morbidity and mortality

INTRODUCTION

Chronic myeloid (or myelogenous) leukemia (CML) is a clonal hematopoietic stem cell disorder. It is characterized by overproduction of myeloid cells, a result of excessive proliferation and reduced apoptosis. Clinical findings include fatigue, splenomegaly, leukocytosis, and anemia. Basophilia and thrombocytosis are common.[1–3] CML is defined by the presence of a characteristic cytogenetic abnormality, the Philadelphia (Ph) chromosome, a reciprocal balanced translocation between the long arms of chromosome 9 and 22, t(9;22)(q34;q11.2). This results in the *BCR-ABL*–associated molecular events, which are causally related to the disease pathophysiology.[4–6]

The typical course of CML is biphasic or triphasic. Most patients are diagnosed in the indolent or chronic phase. If not treated appropriately, CML progresses into the accelerated and blastic phases, which are ominously fatal. Before the discovery of imatinib mesylate, a selective Bcr-Abl tyrosine kinase inhibitor (TKI), the median survival of patients with chronic-phase CML was 3 to 4 years with hydroxyurea, and 6 to 7 years with interferon-α (IFN-α). Imatinib has resulted in a dramatic change in the prognosis of CML and is associated with an estimated 5-year survival rate of 89%. Allogeneic stem cell transplantation is curative in CML but is associated with significant mortality and with serious morbidities. As the long-term results with imatinib continue to mature positively, allogeneic stem cell transplantation, previously a frontline therapy among eligible patients, is now considered as a second-line strategy in CML after failure of TKI therapy.

INCIDENCE, EPIDEMIOLOGY, AND ETIOLOGY

CML accounts for 15% of cases of leukemia in the United States. There is a slight male preponderance (male-to-female ratio 1.6:1). Its annual incidence is about 1.5 cases per 100,000 individuals. About 5000 cases of CML are diagnosed annually. This incidence has not changed over in the past few decades, and it increases with age. The median age at diagnosis is 55 to 60 years; it is uncommon in children and adolescents; only 2.7% of CML cases are younger than 20 years.

Before imatinib therapy, the prevalence of CML was about 25,000 cases in the United States. Now that the annual mortality following imatinib therapy has been reduced to 2%, the prevalence of CML will continue to rise, reaching a plateau (in the next 20 years) at about 250,000 cases (when the annual incidence will equal the annual mortality). This will change CML from an uncommon disorder to a prevalent one.

There are no known familial associations in CML. Its risk is not increased in monozygotic twins or in relatives of patients with CML. There are no known common etiologic agents incriminated in CML. Ionizing radiation (exposure to nuclear bombs or accidents; radiation treatment of ankylosing spondylitis and cervical cancer) has increased the risk of CML. Its peak incidence is 5 to 10 years after exposure and is dose-related. The risk of CML is not increased in individuals working in the nuclear industry. Radiologists working without adequate protection (before 1940) had an increased risk of developing

chronic myeloid leukemia, but no such risk has been found in recent studies. Benzene exposure increases the risk of acute myelogenous leukemia but not of CML. CML is not a frequent secondary leukemia following treatment of other cancers with radiation and/or alkylating agents.[7–10]

PATHOGENESIS

Molecular Pathogenesis

The Ph chromosome abnormality is present in more than 90% of patients with typical CML (Fig. 107-1). It results from a balanced reciprocal translocation of genetic material between the long arms of chromosomes 9 and 22, t(9;22)(q34;q11.2). It is found in hematopoietic cells but not in other human cells. Its origin is close to the pluripotent stem cell, and it is present in erythroid, myeloid, monocytic, and megakaryocytic cells, less commonly in B lymphocytes, rarely in T lymphocytes, but not in marrow fibroblasts. The breakpoint of chromosome 9 results in translocation of the cellular oncogene *ABL1* to a region on chromosome 22 coding for the major breakpoint cluster region (*BCR*). *ABL1* is a homologue of *V-ABL*, the Abelson virus that causes leukemia in mice. This juxtaposes a 5′ portion of *BCR* to a 3′ position of *ABL1*, and produces a new hybrid oncogene, *BCR-ABL*. This codes for a novel Bcr-Abl oncoprotein of molecular weight 210 kDa ($p210^{BCR-ABL}$). The $p210^{BCR-ABL}$ oncoprotein results in uncontrolled kinase activity, which causes excessive proliferation and reduced apoptosis of CML cells,[11–13] leads to a growth advantage of CML cells over normal cells, and suppresses normal hematopoiesis. The normal stem cells, although suppressed, persist and re-emerge after effective therapy of CML.

In Ph-positive acute lymphocytic leukemia, the breakpoint in *BCR* often occurs in a more centromeric region called minor *BCR* region (mBCR). This produces a smaller *BCR* gene opposing *ABL1*, and therefore a fusion gene, messenger RNA, and Bcr-Abl oncoprotein ($p190^{BCR-ABL}$) of smaller sizes. A third rare breakpoint distal to the major *BCR* region, called μ-BCR, produces a $p230^{BCR-ABL}$ hybrid oncoprotein associated with a very indolent course of CML (see Fig. 107-1).[14]

The constitutive activation of *BCR-ABL* results in autophosphorylation and activation of downstream pathways that alter gene transcription, apoptosis, cytoskeletal organization, cytoadhesions, and degradation of inhibitory proteins. These signal transduction pathways involve RAS, mitogen-activated protein (MAP) kinases, signal transducers and activators of transcription (STAT), phosphatidylinositol 3-kinase (PI3K), MYC, and others. Many of these interactions are mediated through tyrosine phosphorylation and require binding of the *BCR-ABL* to adapter proteins such as GRB-2, CRK, CRK-like protein (CRKL) and SCR-homology containing proteins (SHC). Understanding the pathophysiology of these events could result in a successful development of targeted therapies that may synergize with imatinib to improve further the prognosis in CML.

What causes the *BCR-ABL* molecular rearrangement is unknown. Molecular techniques that amplify detection of *BCR-ABL* to 1 in 10^8 detect it in marrow cells of 25% to 30% of normal adults, in 5% of infants, but not in cord blood.[15] Because CML develops in only 1.5 of 100,000 individuals (i.e., 1 to 2 per 25,000 to 30,000 individuals who express *BCR-ABL* in their bone marrow), additional molecular events or lack of immune recognition of the clonal cells may contribute to the development of CML.

The fusion *BCR-ABL* gene and the p210 protein can be found in some patients with typical morphologic CML, in whom the t(9;22)(q34;q11.2) is not identified. These patients have a response to therapy and a survival similar to Ph^+ cases. Patients with Ph^- and $BCR\text{-}ABL^-$ CML (discussed later) constitute a different entity (atypical CML) and have a worse prognosis.[16,17] The molecular pathophysiology of CML transformation is poorly understood. Several molecular events have been associated with CML transformation, including point mutations or deletions in the p53 tumor suppression

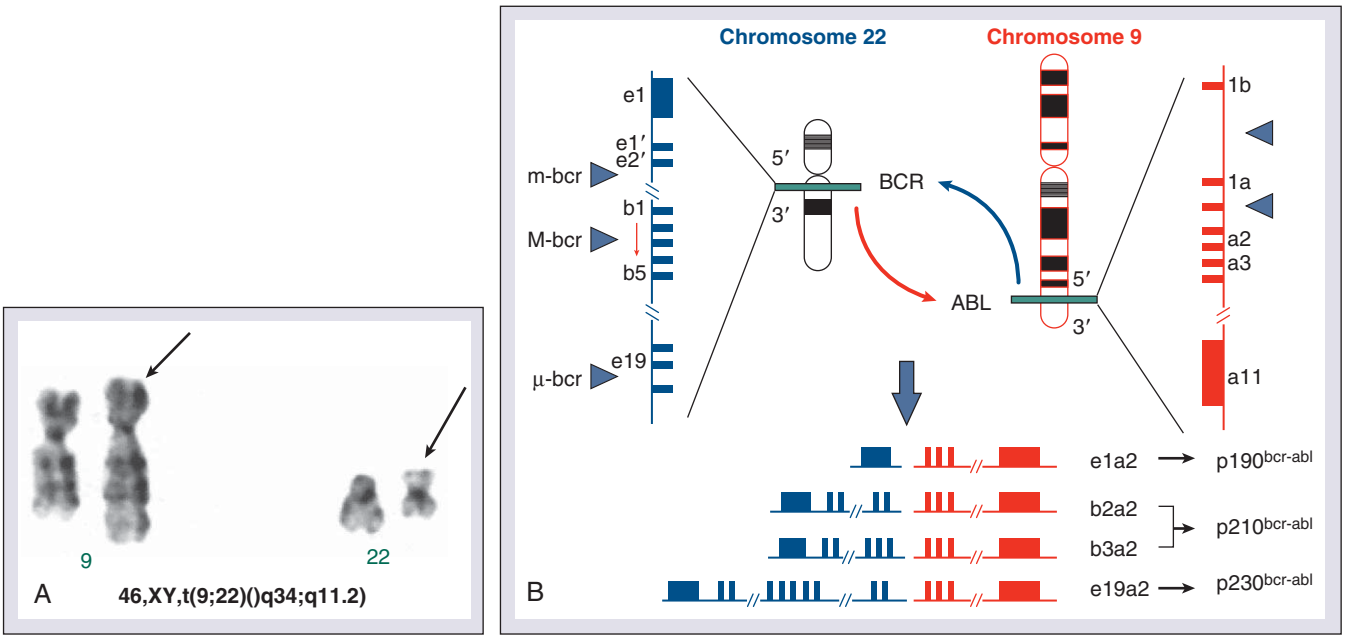

Figure 107-1 • The Philadelphia (Ph) chromosome, initially described as a minute chromosome, was later identified as a balanced reciprocal translocation between the long arms of chromosomes 9 and 22, t(9;22) (q34;q11.2). This results in the translocation of the *ABL1* gene from chromosome 9 in proximity to the breakpoint cluster region (*BCR*) on chromosome 22. Depending on the breakpoint site on chromosome 22, three resultant Bcr-Abl oncoproteins are generated: (1) $P210^{BCR-ABL}$, which occurs in the large majority of patients with Ph^+ CML; (2) $P190^{BCR-ABL}$, present in two thirds of patients with Ph^+ acute lymphocytic leukemia (the other one third have the $P210^{BCR-ABL}$ product); and (3) $P230^{BCR-ABL}$, which is found rarely (1% to 2%) in patients with an indolent course of Ph^+ CML. The three breakpoints on chromosome 22, M-Bcr (P210), m-bcr (P190), μ-bcr (P230), which correspond to the three resultant Bcr-Abl oncoproteins are shown.

gene, p35, c-*Myc* amplification, deletions in the p16 tumor suppressor gene, alteration of retinoblastoma (*Rb*) gene, and others. However the causal relation of these events to transformation is not clear.

Animal Models of Chronic Myeloid Leukemia

Experimental models have established a causal relationship between the *BCR-ABL* molecular events and the development of CML. Transgenic mice that express *BCR-ABL* developed acute leukemia. A *BCR-ABL*–expressing retrovirus used to infect murine bone marrow cells that later repopulate irradiated mice, resulted in myeloproliferative disorders, including a CML-like syndrome.[18–20] *BCR-ABL*, under the control of a tetracycline-repressible promoter, expressed in mice, resulted in a lymphoid leukemia that reversed in the presence of tetracycline,[21] attesting to the leukemic potential of *BCR-ABL* as a sole oncogenic abnormality. The recapitulation of CML-like disorders in animal models mediated by the *BCR-ABL* molecular events established them as a root cause for CML and a legitimate molecular target for therapeutic interventions with TKIs.

DISEASE MANIFESTATIONS

Chronic Phase

About 30% to 50% of patients with CML diagnosed in the United States are asymptomatic. The disease is found on routine physical examination or blood tests.

Common signs and symptoms of CML, when present, result from anemia and splenomegaly. These include fatigue, weight loss, malaise, easy satiety, and left upper quadrant fullness or pain (Table 107-1). Rare manifestations include bleeding (associated with a low platelet count and/or platelet dysfunction), thrombosis (associated with thrombocytosis and/or marked leukocytosis), gouty arthritis (from elevated uric acid levels), priapism (usually with marked leukocytosis or thrombocytosis), retinal hemorrhages, and upper gastrointestinal ulceration and bleeding (from elevated histamine levels due to basophilia). Leukostatic symptoms (dyspnea, drowsiness, loss of coordination, confusion) due to sludging in the pulmonary or cerebral vessels, are uncommon in chronic phase despite white blood cell (WBC) counts exceeding 100×10^9 cells/L.

Splenomegaly is the most consistent physical sign in CML and is detected in 50% to 60% of cases. Hepatomegaly is less common (10% to 20%). Lymphadenopathy, infiltration of skin or other tissues, is uncommon. When present, these findings may suggest accelerated or blastic phases of CML, or Ph^- CML. Headaches, bone pain, arthralgias, pain from splenic infarction, and fever are more frequent with CML transformation.

Laboratory features of untreated CML include leukocytosis with predominance of neutrophils, and a left shift extending to blast cells. Basophils and eosinophils are increased. Thrombocytosis is common; thrombocytopenia is rare and, if present, suggests a worse prognosis. Anemia (hemoglobin < 11 g/dL) is present in one third of patients. Biochemical abnormalities include a low leukocyte alkaline phosphatase score, which also occurs in some patients with agnogenic myeloid metaplasia. Serum levels of vitamin B_{12}, lactate dehydrogenase, uric acid, and lysozyme are often increased. Some patients demonstrate a cyclic oscillation of the WBC count.

The bone marrow is hypercellular with marked myeloid hyperplasia. The myeloid-to-erythroid ratio is usually 15 : 1 to 20 : 1. About 15% of patients have 5% or more blast cells in the peripheral blood or bone marrow at diagnosis. Increased reticulin fibrosis is common (30% to 40% grade 3–4 reticulin fibrosis by silver staining), but collagen fibrosis is rare at presentation.[22] Interestingly, whereas the "spent phase" of myelofibrotic CML was commonly reported in the past (with busulfan therapy) as an end-stage CML event, it has become uncommon in the eras of IFN-α and imatinib therapies. Imatinib effectively reduces myelofibrosis in CML.[23,24]

Table 107-1 Features of Patients with Newly Diagnosed Ph^+ Chronic Myelogenous Leukemia Referred to M.D. Anderson Cancer Center*

Parameter	Percentage
Age ≥60 years (median)	18 (55)
Female gender	41
Splenomegaly	37
Hepatomegaly	10
Lymphadenophathy	6
Other extramedullary disease	7
Hemoglobin <10 g/dL	13
Platelets

Accelerated and Blastic Phases

The definitions of accelerated and blastic phases of CML are shown in Table 107-2. In most patients the transformation from chronic to advanced phase is insidious, the disease becoming more difficult to control. This is referred to as the *accelerated phase*. The criteria of accelerated phase are variable. In one study, features that correlated with a median survival of 18 months or less were blast percentage equal or greater than 15%, blasts plus promyelocytes equal or greater than 30%, basophils equal or greater than 20%, and a platelet count less than 100×10^9 cells/L unrelated to therapy, and cytogenetic clonal evolution.[25] Features of accelerated-phase CML should be revisited, because some (e.g., clonal evolution more favorable, blasts >10% less favorable) have different prognostic implications from recent studies (Fig. 107-2).[26] About 5% to 10% of patients present in the accelerated phase. The accelerated phase is also associated with worsening anemia and splenomegaly, organ infiltration (liver, lymph nodes, skin, bones, or other tissues), and constitutional symptoms (aches, fever, malaise, weight loss).

Blastic-phase CML is diagnosed by the presence of 30% or more blasts in the bone marrow and/or peripheral blood, or by the presence of extramedullary blastic disease. The blastic-phase CML resembles acute leukemia. Patients may develop fever, bone aches, bleeding, infections, weight loss, and increasing splenomegaly. Approximately 70% of patients develop a myeloid or undifferentiated blastic phase and 30% a B-cell lymphoid blastic phase.[27]

Table 107-2 Definitions of the Accelerated and Blastic Phases of Chronic Myelogenous Leukemia

Criteria	M.D. Anderson Cancer Center	International Bone Marrow Transplant Registry	World Health Organization
ACCELERATED PHASE			
Percent blasts	15–29	10–29	10–19
Percent blasts + promyelocytes	≥30	≥20	NA
Percent basophils	≥20	≥20% (basophils + eosinophils)	≥20
Platelets ($\times 10^9$/L)	<100	Unresponsive ↑, persistent ↓	<100 or >1000 unresponsive
Cytogenetics	CE	CE	CE not at diagnosis
WBC	NA	Difficult to control, or doubling in <5 days	NA
Anemia	NA	Unresponsive	NA
Splenomegaly	NA	Increasing	NA
Other		Chloromas, myelofibrosis	Megakaryocyte proliferation, fibrosis
BLASTIC PHASE			
30% or more blasts; or extramedullary blastic disease, except for the WHO classification, which requires 20% or more.			

CE, clonal evolution; NA, not applicable; WBC, white blood cells.

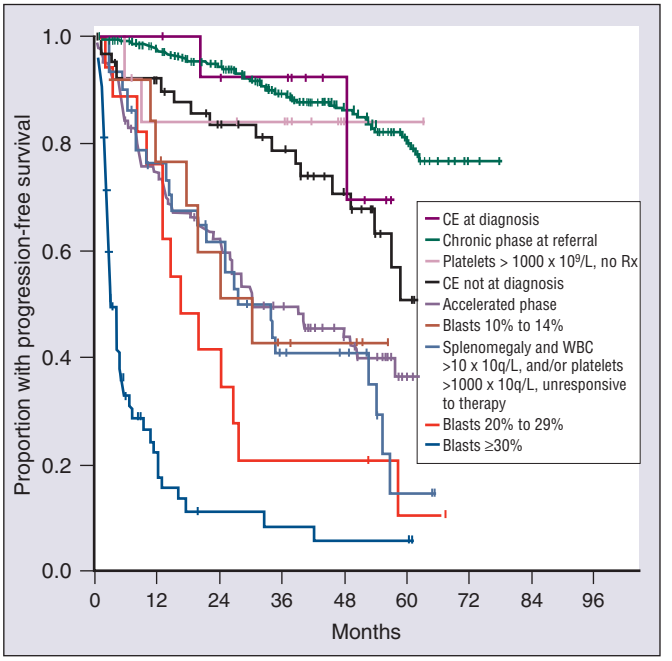

Figure 107-2 • Progression-free survival in CML by different characteristics, highlighting that clonal evolution (CE) at diagnosis is not associated with adverse prognosis. CE during the course of CML has a slight adverse prognostic impact but cannot be considered an accelerated-phase feature, because the associated estimated 4-year progression-free survival rate is 68%, similar to that of chronic phase. Similarly thrombocytosis (>1000 × 10^9 cells/L) is associated with an estimated 4-year progression-free survival rate of 84%. The estimated 4-year progression-free survival rate in accelerated phase (classical standard criteria) is 45%. The figure also highlights that whereas a blast percentage of 20% to 29% is associated with an adverse accelerated phase–like prognosis, it cannot be considered a blastic phase feature (as proposed by the World Health Organization), because it seems to be closer in outcome to accelerated than to blastic phase. Patients who present with 10% to 14% blasts have an adverse prognosis similar to accelerated phase. Therefore, the proposed new criteria of accelerated phase may exclude clonal evolution, but include patients with blast percentages above 10%.

Most patients evolve into the accelerated phase before blastic phase, but 20% of patients transit into a blastic phase without warning. Most patients in accelerated or blastic phase have additional chromosomal abnormalities, such as a double Ph, trisomy 8, or isochromosome 17. Extramedullary blastic phase of CML can occur in the lymph nodes, skin, meninges (especially in lymphoid blastic phase), bone, and other sites.

DIAGNOSIS

The diagnosis of typical CML is simple and consists of documenting, in the setting of persistent unexplained leukocytosis (or occasionally thrombocytosis), the presence of the Ph chromosome t(9;22)(q34;q11.2), by routine cytogenetics, or the corresponding *BCR-ABL* rearrangement by FISH analysis or by molecular studies.

A FISH analysis relies on the colocalization of large genomic probes specific to the *BCR* and *ABL1* genes. Comparison of simultaneous marrow and blood samples by FISH analysis shows high concordance. FISH studies may have a false-positive range of 1% to 10% depending on the probes used.

Reverse transcriptase–polymerase chain reaction (RT-PCR) amplifies the region around the junction between *BCR* and *ABL1*. It is highly sensitive for the detection of minimal residual disease. PCR testing can either be qualitative, providing information about the presence of the *BCR-ABL* transcript, or quantitative, assessing the amount of *BCR-ABL* transcripts. Qualitative PCR may be useful for diagnosis of CML; quantitative PCR is ideal for monitoring residual disease and is usually performed by real-time PCR. Simultaneous peripheral blood and marrow PCR studies show a high level of concordance. False-positive and false-negative results can happen with PCR. False-negative results may be from poor-quality RNA or failure of the reaction; false-positive results can be due to contamination. A 0.5- to 1-log coefficient of variability in some samples can occur depending on testing procedures, sample handling, and laboratory experience.[28,29]

The Ph chromosome is usually present in 100% of metaphases, often as the sole abnormality. Between 10% and 15% of patients have additional chromosomal changes (clonal evolution) involving trisomy 8, isochromosome 17, additional loss of material from the second chromosome 22 (double Ph), or others.

Eighty-five percent of patients have a typical t(9;22) translocation; 5% have variant translocations which can be simple (involving chromosome 22 and a chromosome other than chromosome 9), or complex (involving one or more chromosomes in addition to chromosomes 9 and 22). With imatinib, patients with Ph variants have response to therapy and prognosis similar to Ph^+ CML.

Diagnostic and Monitoring Procedures in Chronic Myeloid Leukemia

The improved rates of complete cytogenetic response and of molecular response with imatinib now require new techniques that measure these responses more accurately (rather than relying on evaluation of only 20 metaphases by routine cytogenetic studies), with less painful procedures (peripheral blood rather than marrow samples), and with methods that measure minimal disease below the level of detection by routine karyotypic analysis (molecular studies). FISH studies can assess rapidly disease status in 200 cells, and can be performed on blood specimens. Quantitative PCR studies usually measure the ratio of the abnormal message, *BCR-ABL*, to a normal message (e.g., *ABL*). A *BCR-ABL*/*ABL* ratio of less than 0.1% (approximately a 3-log reduction of disease from a standardized baseline) has been associated with a low risk of relapse and with favorable progression-free survival. A negative PCR analysis (undetectable *BCR-ABL* transcripts; usually a 4.5-log reduction or more) may be technique-dependent and is referred to as complete molecular response.

Monitoring response to imatinib-based therapy may use different approaches depending on the investigators' experience, patient age, whether changes of residual disease affect subsequent therapy, availability of methodologies, and other factors. In general, patients with newly diagnosed CML require an initial bone marrow analysis (to evaluate the percentage of blasts and basophils, and whether clonal evolution is present), then once a year (to detect cytogenetic abnormalities in both the Ph^+ and Ph^- cell). Some experts recommend bone marrow studies every 3 to 6 months in the first year because of the prognostic significance of the Ph^+ status from routine marrow cytogenetic studies. Practically, peripheral blood FISH studies every 3 to 4 months provide a reasonable estimate of the response profile in the first year. Once Ph^+ cells are less than 5% by FISH, the complete cytogenetic response can be confirmed by a bone marrow analysis with routine cytogenetics, and subsequent monitoring of minimal residual disease performed by peripheral blood real-time PCR studies. In a patient in stable complete cytogenetic response, real-time PCR studies may be performed every 6 months. If concerns arise regarding changes in PCR values, the study can be repeated more frequently (e.g., every 2 to 3 months). Some investigators suggest a two-fold or 0.5-log increase in transcript levels may correlate with the development of mutations or with relapse.[30–32] However, these analyses stem from individual laboratories with significant expertise and may not apply to routine practice. In general, in a patient in complete cytogenetic response, a rise of transcript levels by real-time PCR should be repeatedly confirmed before a change of therapy is considered, which may be minor (e.g., increasing the dose of imatinib), rather than drastic (e.g., allogeneic stem cell transplant).

Monitoring for mutations in the Bcr-Abl kinase domain (Abl mutations) that are associated with resistance is also an evolving concept. Assessing mutation status before therapy or in responding patients has no prognostic or therapeutic value. Mutation studies are important in patients who exhibit cytogenetic-hematologic relapse or resistance. In them, detection of a threonine-to-isoleucine mutation at codon 315 (T315I) will indicate a change of therapy to non-TKIs (e.g., allogeneic stem cell transplant, specific T315I inhibitors, combinations of chemotherapy). Particular mutations may favor the use of one TKI over others, based on preclinical studies and early clinical experience. For example, V299L and F317L mutations are less responsive to dasatinib, whereas some P-loop mutations may be less sensitive to nilotinib. Otherwise, mutation analysis at present has minimal impact on current practice in CML.[31,32]

DIFFERENTIAL DIAGNOSIS

CML can be confused with leukemoid reactions. These are usually transient, have a temporal cause (severe infection, steroids, stress), show modest rises of WBC counts up to 50×10^9 cells/L with toxic granulocytic vacuolation and Döhle bodies in the granulocytes, and a normal or increased leukocyte alkaline phosphatase level. Corticosteroids can rarely cause self-limiting extreme neutrophilia with a left shift.

CML should be differentiated from other myeloproliferative disorders or myelodysplastic syndromes like chronic myelomonocytic leukemia, proliferative myelodysplastic syndrome, agnogenic myeloid metaplasia, polycythemia rubra vera, and essential thrombocytosis. Although the clinical syndromes may overlap, cytogenetic and molecular studies demonstrating the presence of Ph or the *BCR-ABL* rearrangement clarify the diagnosis.

A difficult diagnostic situation may arise in patients with a typical morphologic picture of CML (splenomegaly, leukocytosis) but who do not have the Ph chromosome. In some, the *BCR-ABL* hybrid gene can be demonstrated by molecular studies. Patients who are Ph^- and *BCR-ABL*$^-$ often have chronic myelomonocytic leukemia. Patients may rarely have myeloid hyperplasia, with selective involvement of the neutrophil, eosinophil, or basophilic cell lineages. These are described as having chronic neutrophilic, eosinophilic, or basophilic leukemia and do not have evidence of the Ph chromosome or *BCR-ABL* fusion gene. Occasionally, patients with Ph^+ CML may present like essential thrombocytosis (marked thrombocytosis without leukocytosis). Cytogenetic studies are required in all patients with essential thrombocytosis to identify the occasional patient with Ph^+ CML and essential thrombocytosis-like presentation.

PROGNOSIS

Prognosis in CML has changed drastically over the past 5 to 10 years. Before imatinib, the median survival of patients with CML in chronic phase (85% to 90% of newly diagnosed patients) was 6 to 7 years with IFN with or without cytarabine. For candidates for allogeneic stem cell transplantation, the expected 20-year survival rate was 40% to 50% in younger patients with a matched related donor. With imatinib therapy the estimated 5-year survival rate in chronic phase is 89%.[33] With an annual mortality of 1% to 2% in the first 5 years (if this positive trend is maintained in later years), the estimated median survival may exceed 25 years (Fig. 107-3).[33–35] Thus, chronic-phase CML may have now changed to an indolent disorder in which most patients may survive normally with continued oral imatinib therapy. Imatinib therapy has also changed the prognosis in accelerated phase. The median survival has increased from 1 to 2 years before imatinib to an estimated 4-year survival rate of 60%.[36] Among patients with accelerated-phase CML who have an early cytogenetic response to imatinib, the estimated 4-year survival rate is 80%. Similarly, patients with clonal evolution as the only sign of accelerated disease have an estimated 5-year survival rate of 80%.[37] Survival in blastic phase is also better with imatinib therapy, but only modestly so (median survival improved from 3–6 months to 12–15 months). Prognosis of lymphoid blastic phase is slightly more favorable, with a response rate to anti–acute lymphoid leukemia chemotherapy and imatinib of 60%, and a median survival of 12 to 18 months.

Before imatinib, several prognostic models (Sokal, Hasford) divided patients in chronic phase into low-, intermediate-, and high-risk groups based on pretreatment adverse prognostic factors including: older age, splenomegaly, thrombocytosis, higher percentage of blasts and basophils, and presence of cytogenetic clonal evolution.[38,39] Imatinib therapy has now altered the prognostic significance of

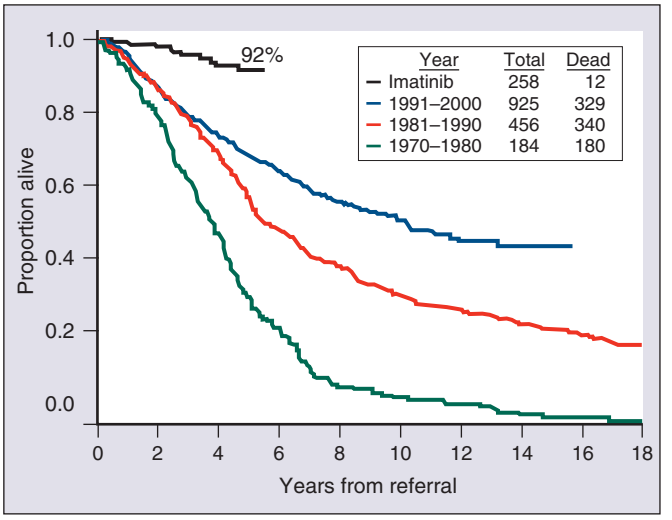

Figure 107-3 • Survival of all patients with newly diagnosed Ph+ CML in chronic phase referred to M.D. Anderson Cancer Center since 1970 (N = 1823). The estimated 6-year survival rate with recent imatinib therapy is 92%. Patients treated between 1970 and 1980 received mostly hydroxyurea-based therapy; their median survival was about 4 years. Patients treated between 1981 and 2000 received mostly interferon (IFN)-based therapy The median survival of patients treated with IFN-based therapy from 1981 to 1990 is about 6.5 years; it is about 10 years for patients treated between 1991 and 2000 because of the added benefit of sequential therapy with imatinib late in their course.

several of these factors, including deletion of derivative chromosome 9, age, and myelofibrosis.[23,24,40,41] The latter in fact resolves quite effectively with imatinib therapy.[23] Currently, the most relevant prognostic factor on imatinib therapy is the degree of cytogenetic and molecular response to initial imatinib therapy (in the first 3 to 12 months).[33,42,43] Thus, the introduction of imatinib therapy in CML will require new definitions of the accelerated phase and the adverse factors/risk models in CML.

MANAGEMENT OF CHRONIC MYELOGENOUS LEUKEMIA IN CHRONIC PHASE

In the 1980s to 1990s, the two frontline therapies in CML were IFN-α–based regimens and allogeneic stem cell transplantation. There was ongoing controversy about the best approach in newly diagnosed patients who were candidates for allogeneic stem cell transplantation. In general, allogeneic stem cell transplantation was recommended for younger patients with matched related donors, whereas older patients and those with unrelated donors (i.e., higher risk for stem cell transplantation–related mortality) were offered a trial of IFN-based therapies before considering allogeneic stem cell transplantation.[44] The maturing positive results with imatinib therapy have now convinced most investigators and patients to use imatinib as initial therapy, and to delay allogeneic stem cell transplantation to a second-line strategy after failure of imatinib and/or other TKIs.

Imatinib

The role of imatinib therapy in CML was established in a series of pivotal trials of imatinib following IFN-α failure in chronic, accelerated, and blastic phases, and later in a frontline International Randomized Study of Interferon plus cytarabine versus STI571 (IRIS trial).[33,42,45–53]

Imatinib mesylate, a 2-phenylaminopyrimidine derivative, binds to the canonical adenosine triphosphate (ATP)-binding site of the ABL kinase domain. It blocks phosphorylation of tyrosine residues on substrate protein. Blocking ATP binding inactivates the ABL kinase, because it cannot transfer phosphate to its substrate. Inhibiting phosphorylation prevents activation of signal transduction pathways that cause CML (Fig. 107-4). Imatinib inhibits several tyrosine kinases including $p210^{BCR-ABL}$, $p190^{BCR-ABL}$, v-ABL, c-ABL, c-Kit, and platelet-derived growth factor receptor (PDGF-R).

In the IRIS study 1106 patients with newly diagnosed CML were randomized to imatinib 400 mg orally daily versus IFN-α plus cytarabine. Imatinib was associated with significantly higher rates of major (Ph positivity <35%; 85% vs. 22%) and complete cytogenetic responses (74% vs. 8%), and lower rates of progression (3% vs. 20%) and transformation (1.5% vs. 7%) after 12 months of therapy.[42] An

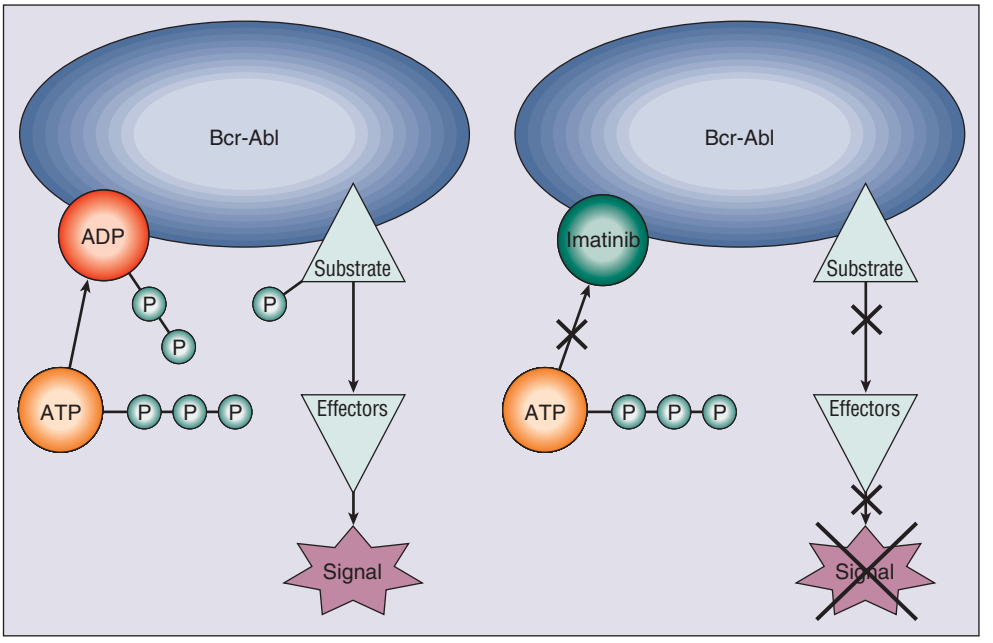

Figure 107-4 • The Bcr-Abl oncoprotein has constitutive tyrosine kinase activity compared with the tightly regulated tyrosine kinase activity of the normal ABL product. The Bcr-Abl kinase activates multiple substrates and binding partners, resulting in activation of downstream signaling pathways. This results in increased proliferation and reduced apoptosis of CML cells. By binding to the Abl kinase domain, imatinib prevents the phosphorylation of Bcr-Abl, thus interrupting the activation of the CML pathways.

update of the 5-year follow-up in the 553 patients treated with imatinib continued to show excellent results: projected complete cytogenetic response rate (single-time response) 87%; annual rate of progression to accelerated-blastic phase 4%; annual mortality rate 1% to 2%. At the 5-year follow-up time, 368 patients (67%) were still on imatinib on study. Rates of transformation and mortality seem to have been reduced in years 4 and 5 compared with the first 3 years. The estimated 5-year survival rate was 89%. The estimated 5-year survival rate excluding non-CML-related deaths was 95%.[33] Survival was also better with imatinib versus IFN + cytarabine (estimated 5-year survival rates 89% vs. 86%; $P = 0.049$). The difference was not very drastic, however, because of the crossover design of the IRIS study and the commercial availability of imatinib, both resulting in a change from IFN + cytarabine to imatinib in about 90% of patients within a median of 9 months from start of therapy. Comparison of imatinib results to historical experience with IFN therapy demonstrates more significant survival differences.[34,35]

In late chronic-phase CML after IFN-α failure, among 454 evaluable patients receiving imatinib, the cumulative complete cytogenetic response rate was 57%, and the estimated 5-year survival rate 79%.[45,46] In accelerated phase the complete cytogenetic response rate was 40%, and the estimated 4-year survival rate 60%.[49,50] In blastic phase response rates were lower and more transient, and the median survival duration only 6 to 12 months (Table 107-3).[51]

In the IRIS study, a major molecular response (3-log reduction of transcript levels) was observed in 38% of patients in the original update,[43] and in 70% of patients with longer follow-up.[48,54] Achieving a major molecular response in complete cytogenetic response at 18 months was associated with an estimated transformation-free survival and survival rates of 100% at 5 years versus 95% for complete cytogenetic response without a major molecular response ($P = 0.007$).[33] Disappearance of *BCR-ABL* was initially observed in a minority of patients (5%) but is now reported with longer term follow-ups in 30% to 50% of patients.[54,55] This rate depends on the sensitivity of the molecular test, because in general, a reduction of transcript levels by 4.5 log or more (or a *BCR-ABL/ABL* ratio of <0.003) may reach levels below detection in most molecular laboratories.[31,32]

Higher doses of imatinib 600 to 800 mg daily may overcome resistance to standard-dose imatinib in some patients.[53] In accelerated phase, high-dose imatinib was associated with higher response rates and longer survival.[49] In chronic-phase CML, imatinib 800 mg daily was also associated with higher rates of complete cytogenetic response, major and complete molecular response, and better progression-free survival rates.[48,55]

Imatinib is associated with mild-moderate side effects including nausea, vomiting, diarrhea, skin rashes, muscle cramps, bone aches, periorbital or leg edema, and weight gain. Serious but uncommon side effects (1% to 2%) include hepatic, renal, or cardiopulmonary dysfunction. These are manageable with dose reductions or treatment interruptions.[56,57] Drug-related myelosuppression occurs in 10% to 30% of patients in newly diagnosed CML. This is managed with brief treatment interruptions and/or dose modifications, or with growth factors (erythropoietin for anemia, filgrastim for neutropenia). Chromosomal abnormalities may appear in the Ph^- cells in 5% to 10% of responding patients. These include some abnormalities observed in myelodysplastic syndrome and acute myeloid leukemia such as chromosome 5 or 7 abnormalities, trisomy 8, 20q- and others. These chromosomal abnormalities are probably due to unmasking of a fragile stem cell prone to development of CML or to genetic instability. Such changes disappear spontaneously in up to 70% of cases. Evolution to a Ph^- myelodysplastic syndrome or acute myeloid leukemia is rare and probably part of the new natural course of CML.[58]

Imatinib therapy (400 mg daily) is started as soon as the diagnosis of CML is established. Allopurinol is recommended until the WBC count is less than 10×10^9 cells/L. Tumor lysis syndrome is rare, except in occasional patients in advanced-phase disease who require hydration and closer monitoring. With imatinib the WBC and platelet counts decrease in the first 2 to 4 weeks and normalize within 1 to 2 months. Complete blood counts are recommended weekly during the first month of therapy, then every 1 to 2 months. For patients with accelerated or blastic phases, complete blood counts should be performed more frequently, and as indicated clinically. Imatinib therapy should be continued indefinitely; treatment discontinuation even among patients with durable complete molecular responses (>2 years) has been associated with molecular relapse in about half.[59] High-dose imatinib (i.e., 600–800 mg daily) may be considered in CML transformation or Ph^+ acute lymphoid leukemia (in combination with chemotherapy), in patients with an unsatisfactory response to standard-dose imatinib, or with cytogenetic relapse on imatinib.

Allogeneic Stem Cell Transplantation

Allogeneic stem cell transplantation is curative in selected patients with CML. It is most effective during the chronic phase. Among patients in first chronic phase transplanted from matched siblings, the estimated 20-year survival rate is 40% to 50% (Fig. 107-5).[60] The report from the International Bone Marrow Transplant Registry (IBMTR), compiling data from over 6000 patients undergoing transplants, showed a 5-year survival rate of 60% for first chronic phase/sibling donor, but a 20-year survival rate of 40% to 45%.[60] Most of the 10% to 15% additional deaths between years 5 and 20 were due to transplant-associated complications rather than CML relapse. Chronic morbidities for stem cell transplantation include graft-versus-hose disease (GVHD), infertility, cataracts, hip necrosis, second cancers, and GVHD-associated organ damage (pulmonary, hepatic) or immune-mediated complications. Transplant-related mortality ranges from 5% to 50%, depending on several factors including patient age, whether the donor is related or unrelated, the degree of matching, and other factors such as positivity for cyto-

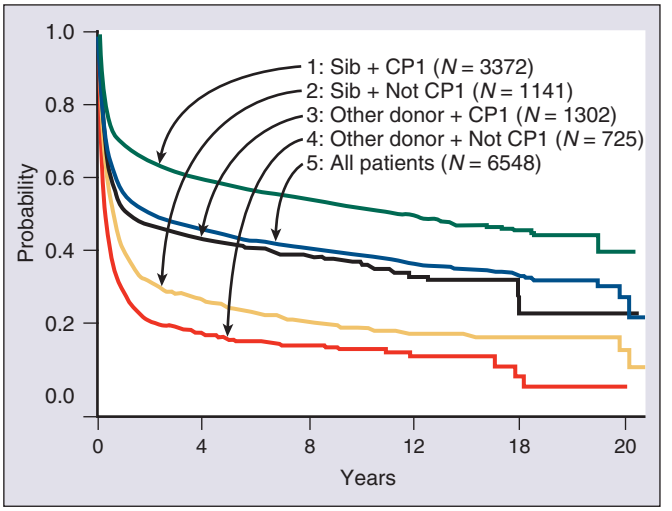

Figure 107-5 • Probability of survival of patients undergoing allogeneic stem cell transplant according to the International Bone Marrow Transplant Registry ($N = 6548$). Patients transplanted in first chronic phase (CP1) with an HLA-matched sibling (Sib) had the best outcome. Those transplanted with unrelated donors or not in CP1 had a worse outcome. The estimated 20-year survival rate of patients transplanted from a sibling donor in CP1 was 45%.

megalovirus (CMV), preparative and post-transplant regimens, and institutional expertise.[61–67] Disease-free survival rates with related allogeneic stem cell transplantation are 40% to 80% in chronic-phase CML. The disease-free survival rates are 60% to 80% among patients younger than 30 to 40 years of age and 30% to 40% in patients older than age 50 years. Disease-free survival rates range from 30% to 60% in accelerated-phase CML, and from 5% to 30% in blastic-phase CML. Patients with clonal evolution as the only accelerated-phase criterion have disease-free survival rates of 60%. Patients transplanted in second chronic phase have also favorable disease-free survival rates of about 40%.

A major limitation of allogeneic stem cell transplantation is the availability of related donors. Human leukocyte antigen (HLA)–compatible unrelated donors can be found in 50% of patients; the median time from donor search to transplant is 3 to 6 months. In general, unrelated donor stem cell transplantation is associated with higher rates of GVHD and transplant-related complications and mortality, and with lower rates of disease-free survival and survival. Results of unrelated stem cell transplantation in select centers, with molecularly matched donors and optimally managed patients, seem similar to those achieved with related donor stem cell transplantation.[62]

Nonmyeloablative preparative regimens have expanded the use of allogeneic stem cell transplantation to older patients and have reduced transplant-associated complications, organ damage, and mortality. Results in general show high degrees of engraftment, less morbidity and mortality, but perhaps higher incidences of persistent residual disease, and similar degrees of chronic GVHD.[66]

Improving Results of Allogeneic Stem Cell Transplantation

Allogeneic stem cell transplantation is safest and results are best in younger patients with an HLA-identical sibling donor. Improvement of stem cell transplantation results can be achieved through: (1) better molecular characterization of the HLA phenotype and genotype and matching of unrelated donors, (2) improved management of complications, including viral infections (CMV),[67] (3) performing stem cell transplantation before CML evolution to accelerated-blastic phases, (4) treatment of relapse after stem cell transplantation before overt disease occurs (i.e., at time of molecular relapse), and (5) safer and better conditioning regimens.[63]

Monitoring Outcome after Allogeneic Stem Cell Transplantation and Treatment of Relapse

Most CML relapses after stem cell transplantation manifest in the first 3 to 5 years. Thereafter, the relapse rate is very low but may sometimes occur even after 10 to 15 years from transplant. Patients usually exhibit molecular relapse before cytogenetic or hematologic relapse. Increasing *BCR-ABL* transcript levels usually predict for cytogenetic and hematologic relapse.[68,69]

If relapse occurs, withdrawal of immunosuppression (cyclosporine, steroids) can induce remission (especially if molecular relapse) by favoring graft-versus-leukemia effect. However, this also may exacerbate GVHD. If relapse persists, it can be managed effectively with imatinib, donor lymphocyte infusions, IFN-α, or a second stem cell transplantation.[70,71] Imatinib results in remission rates of 40% to 60% if the relapse is molecular or cytogenetic in chronic phase. It is less effective if CML relapse is hematologic or in transformation. Donor lymphocyte infusions induce durable remission rates of 60% with molecular or cytogenetic relapse, but may exacerbate GVHD (which can be fatal), and result in intense myelosuppression in 20% of patients.

MANAGEMENT OF PATIENTS WITH IMATINIB RESISTANCE

"Resistance" to imatinib therapy can be defined as failure to achieve the following endpoints: (1) complete hematologic response (CHR) after 3 months of therapy, (2) any cytogenetic response after 6 months, (3) a major cytogenetic response (Ph positivity > 35%) after 12 months, or (4) a complete cytogenetic response after 18 months. In addition, patients experiencing cytogenetic or hematologic relapse at any time on treatment are considered to have secondary resistance to imatinib.[31]

The annual resistance rate to imatinib is about 3% to 4% in the first 5 years. Resistance can be primary (mostly due to BCR-ABL–independent mechanisms; i.e., with persistent inhibition of the Bcr-Abl kinase), or secondary (after an initial response, most often due to Bcr-Abl–dependent mechanisms, i.e., with reactivation of the Bcr-Abl kinase).[31,32] Several Bcr-Abl–dependent mechanisms of imatinib resistance have been proposed including amplification of *BCR-ABL* oncogene or transcript levels, multidrug resistance-dependent pumping of imatinib out of the cell, shifts of Bcr-Abl localization in the CML cells, and mutations of the Abl kinase domain. Bcr-Abl point mutations (>40 described so far), account for about 40% to 50% of resistance. Mutations that can occur at the ATP-binding site (P-loop), at contact points with imatinib, or at other Bcr-Abl sites (catalytic domain, activating loop) can produce relative or absolute resistance to imatinib; some mutations are not relevant to resistance. Mutations with relative resistance to imatinib can be overcome with higher doses of imatinib; others do not respond to increasing the imatinib dose but respond to treatment with the more potent second-generation TKIs. A particular mutation, T315I, confers absolute resistance to imatinib and to the second-generation TKIs (i.e., dasatinib, nilotinib, bosutinib) but may be responsive to new inhibitors with different binding requirements.

Patients who develop imatinib resistance have several treatment options including allogeneic stem cell transplant, treatment with the new-generation TKIs, and others. Imatinib resistance in chronic phase is associated with an estimated 4-year survival rate of 60%. However, if progression is in accelerated or blastic phases, the prognosis is poor.[72] For patients in accelerated or blastic phase after imatinib resistance, every attempt should be made to refer them to allogeneic stem cell transplantation. If patients develop resistance to imatinib but are still in chronic phase, allogeneic stem cell transplantation is an appropriate second-line option if the patient is younger and/or has a related matched donor. In the interim, or if the patient is older and/or has an unrelated matched donor, a trial of one of the new-generation TKIs is reasonable. Subsequent therapy may be based

on the early response to that therapy. In all cases of imatinib resistance, mutational analysis is recommended to identify patients with T315I or other mutations that can be selectively nonresponsive to one of the new-generation TKIs. If a T315I mutation is identified, second-generation TKIs are not effective and the patient should be referred for allogeneic stem cell transplantation as soon as possible, and in the interim be controlled with hydroxyurea, cytarabine, combinations of standard older therapies, or investigational agents that might be effective against T315I mutations. A treatment algorithm for CML is proposed in Figure 107-6.

Dasatinib

Dasatinib (Sprycel; BMS354825) is a newly approved potent oral multitargeted kinase inhibitor of critical oncogenic kinases including Bcr-Abl, Src, C-kit, and PDGF-R. This dual Abl/Src inhibitor is 300 times more potent than imatinib in preclinical models, and is effective against all imatinib-resistant kinase domain mutations except T315I. Following the positive phase I studies of dasatinib demonstrating safety and efficacy in Ph^+ leukemias after imatinib failure,[73] pivotal phase II studies, referred to as START (Src/Abl Tyrosine kinase inhibition Activity Research Trials of dasatinib), were conducted in all phases of CML after imatinib failure and in Ph^+ acute lymphocytic leukemia. This led to the US Food and Drug Administration's approval of dasatinib for this indication in 2006. In 387 patients with chronic-phase CML after imatinib failure, dasatinib 70 mg orally twice daily produced a CHR rate of 90%, a major cytogenetic response rate of 52%, a complete cytogenetic response rate of 39%, and an estimated 10-month progression-free survival rate of 92%.[74] Response rates were higher in patients with imatinib intolerance versus resistance but were similar by whether mutations were present or absent. Results were similarly encouraging in accelerated-blastic phases and in Ph^+ acute lymphocytic leukemia (Table 107-4).[75–77] A randomized study of dasatinib 70 mg orally twice daily versus high-dose imatinib (400 mg orally twice daily) in patients with CML chronic phase after failure on imatinib 400 to 600 mg daily accrued 150 patients (2:1 randomization).[77] Dasatinib was associated with higher rates of complete cytogenetic response at 3 months (22% vs. 8%), overall major cytogenetic response (52% vs. 33%; $P = 0.02$), and overall complete cytogenetic response (40% vs. 16%, $P = 0.004$). The difference in response rates was most evident in patients with failure on imatinib 600 mg daily (major cytogenetic response rates 49% vs. 24%) but not in patients with failure on imatinib 400 mg a day (major cytogenetic response rates 58% vs. 53%). Progression-free survival was better with dasatinib (estimated 12-month rates 94% vs. 70%; $P < 0.0001$). Dasatinib was associated with higher rates of grade 3 to 4 cytopenias (55% to 59%) compared with high-dose imatinib (14% to 39%), and with pleural effusions (17% vs. 0%). In a single-institution review of the dasatinib experience, pleural effusions were observed in 48 of 138 patients (37%) treated with dasatinib. Pleural effusions were often exudates and were managed with treatment interruptions, diuretics and short courses of steroids, and resumption of dasatinib at lower dose schedules.[78] Myelosuppression was also managed with dose interruptions and reductions. A four-arm randomization study of different dasatinib dose schedules (50 mg twice daily, 100 mg single-dose daily, 70 mg twice daily, 140 mg single-dose daily) showed that a single daily dasatinib dose of 100 mg produced equivalent treatment results with fewer side effects.[79]

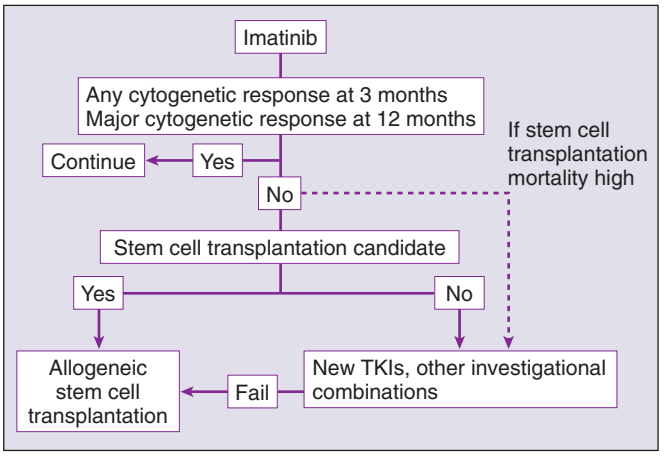

Figure 107-6 • Proposed treatment algorithm for patients with newly diagnosed CML. Patients achieving any cytogenetic response after 6 months, a major cytogenetic response after 12 months of therapy, and a complete cytogenetic response in the second year of therapy should continue on imatinib until there is evidence of resistance. High-dose imatinib could be attempted in patients with unsatisfactory response. In case of resistance, allogeneic stem cell transplantation can be considered as the next option if the transplant-related mortality is acceptable to the patient. If not, the patient can consider treatment with the new-generation tyrosine kinase inhibitors (dasatinib, nilotinib, bosutinib), or with other investigational therapies, before proceeding to allogeneic stem cell transplant.

Table 107-4 Results of Dasatinib Phase II Studies in CML and Ph^+ ALL after Imatinib Failure

		Response Rate (%)		
			Cytogenetic Response

Data extrapolated from references 74–77.

Nilotinib

Nilotinib (Tasigna, AMN107) was rationally designed by replacement of the *N*-methylpiperazine binding group of imatinib to optimize the binding affinity and selectivity for the Abl kinase. Nilotinib, a selective Bcr-Abl kinase inhibitor, was 30 times more potent than imatinib in preclinical models, and was active against all imatinib-resistant mutations except T315I. Similar to dasatinib, the phase I study with imatinib showed safety and activity after imatinib failure.[80] The pivotal phase II studies with imatinib 400 mg orally twice daily have been completed. In the phase II pivotal trial of nilotinib in 316 patients in chronic phase after imatinib failure, the CHR rate was 74%, the major cytogenetic response rate 52%, and the complete cytogenetic response rate 34%. The estimated 1-year survival rate was 95%. Side effects were modest, including grade 3 to 4 myelosuppression in 20% to 30%; no pleural effusions were observed. Response rates were similar in patients with imatinib resistance versus intolerance and in patients with or without mutations.[81]

The activity of nilotinib in CML accelerated and blastic phase after imatinib failure were also encouraging, although response rates were lower and response durations shorter (Table 107-5).[82,83] Nilotinib recently has been approved by the Food and Drug Administration (October 2007) for the treatment of CML in chronic or accelerated phases following imatinib failure.

Table 107-5 Results of Nilotinib Phase II Studies in CML and Ph$^+$ ALL after Imatinib Failure

		Response (%)		
			Cytogenetic Response	
Disease	***N***	**CHR**	**Major**	**Complete**
CML, chronic	316	74	52	34
CML, accelerated	64	17	31	17
CML, blastic	96	13	NR	NR
Ph$^+$ ALL	34	6	NR	NR

ALL, acute lymphoid leukemia; CHR, complete hematologic response; CML, chronic myeloid leukemia; NR, not reported; Ph, Philadelphia chromosome.

Data extrapolated from references 80–83.

Bosutinib

Bosutinib (SKI606) is an orally available dual Src/Abl inhibitor that is 30 to 200 times more potent than imatinib. It has minimal inhibitory activity against c-Kit and PDGF-R (therefore expected to produce less myelosuppression and pleural effusions). In a phase I/II study of 69 patients with CML treated after imatinib failure, the CHR rate among 48 patients in chronic phase was 84%, and the cytogenetic response rate 81%, (major 52%, complete 33%).[84] The median follow-up on study was short. Grade 3 to 4 toxicities were minimal, including skin rashes in 6% and thrombocytopenia in 6%. Mild to moderate diarrhea was common at the phase II dose selected of 500 mg orally daily.

Other Agents

MK0457 is an aurora kinase inhibitor with inhibitory activity against T3151 mutant CML. In a preliminary experience in patients with advanced phases of CML and T315I mutations, MK0457 showed encouraging results.[85] Other aurora kinase inhibitors with potential activity against T315I mutant CML include AT9283 and KW2449.

Other classes of agents that have shown reasonable activity against CML after imatinib failure include farnesyl transferase inhibitors (tipifarnib), decitabine, and homoharringtonine.[86–88]

SELECTION OF SEQUENTIAL THERAPIES IN PATIENTS WITH CHRONIC MYELOGENOUS LEUKEMIA

The longer term follow-up results of imatinib in newly diagnosed CML are reassuring. With its modest toxicity profile and absence of treatment-related mortality, imatinib is now frontline CML therapy in all patients regardless of age. Allogeneic stem cell transplantation is associated with mortality rates of 5% to 50% in the first year and with significant chronic morbidities including GVHD-related complications, cataracts, infertility, second cancers, and a 15% mortality between years 5 and 20 of follow-up that may be related to subtle but continuous transplant-related organ damage and some late relapses. Patients with imatinib resistance may consider allogeneic stem cell transplantation as second-line therapy if they are younger and/or have a matched related donor (i.e., expected low stem cell transplantation-related mortality). Among patients with expected high stem cell transplantation-related mortality, a trial of a second-generation kinase inhibitor may be attempted, and consideration of transplant based on the early response profile to the treatment. Patients with T315I mutations should be referred to allogeneic stem cell transplantation. Patients with imatinib resistance in accelerated or blastic phase, either de novo or after chronic phase, should also be referred to allogeneic stem cell transplantation as soon as possible regardless of their response to the second-generation TKIs (even though such attempts may debulk the transformed disease and improve the outcome after stem cell transplantation).

Old Traditional Standards of Care Revisited

Busulfan (1,4-dimethane-sulfonyl-oxybutane) is the first alkylating agent that demonstrated activity in CML. Busulfan therapy was associated with significant toxicities, including severe and prolonged myelosuppression. Busulfan should be used today only as part of some conditioning regimens in allogeneic stem cell transplantation, and must be avoided in any patients awaiting allogeneic stem cell transplantation because of the associated adverse outcome.

Hydroxyurea, a ribonucleotide reductase inhibitor, is a well-tolerated oral cytotoxic agent that can control blood counts rapidly in most patients with CML. Rare side effects include nausea, rashes, mouth ulcers, and hand or leg ulcers. Hydroxyurea is usually given at a daily dose of 1 to 10 g, depending on the degree of leukocytosis, and the dose adjusted to keep the WBC count between 2×10^9 and 10×10^9 cells/L. Hydroxyurea may be used for initial cytoreduction, as a temporary measure to control counts in between definitive therapies, or part of a combination approach with imatinib or other TKIs. It should not be used alone as a definitive treatment in CML, because it rarely suppresses Ph$^+$ cells.

IFN-α showed anti-CML activity in the 1980s and was a standard of care in CML until the discovery of imatinib. IFN-α induced CHR rates of 50% to 80% in untreated chronic-phase CML, and cytogenetic response rates of 40% to 60% (major in 10% to 40%; complete in 5% to 30%).[89] A meta-analysis of randomized studies of IFN-α versus hydroxyurea or busulfan, showed that IFN-α therapy was associated with better survival than hydroxyurea or busulfan (5-year survival rates 57% vs. 42% , $P < .00001$).[90] IFN-α has minimal activity in accelerated or blastic phases of CML. It is associated with significant side effects including flu-like symptoms, fever, chills, myalgias, fatigue, depression, neuropathy, diarrhea, memory problems, immune-mediated complications, myelosuppression, and others.[91]

Achievement of a major or complete cytogenetic response with IFN-α is associated with significantly better long-term survival.[92] Combinations of IFN-α and low-dose cytarabine improve results over IFN-α alone.[93]

New formulations of IFN-α attached to polyethylene glycol (PEG) prolong its half-life, allow weekly administration, reduce toxicities, and may also improve results (at least with a particular pegylated IFN-α2a formulation, Pegasys).[94]

MANAGEMENT OF ACCELERATED AND BLASTIC PHASES OF CHRONIC MYELOGENOUS LEUKEMIA

Imatinib, dasatinib, and nilotinib have all shown activity in CML in transformation. The single-agent activity is more encouraging and durable in accelerated phase, but less so in blastic phase.

In accelerated phase, imatinib produces a hematologic response rate of 80%, a CHR rate of 40%, a major cytogenetic response rate of 30%, and an estimated 4-year survival rate of 60%. In accelerated-phase CML after imatinib failure, dasatinib is associated with a hematologic response rate of 64%, a cytogenetic response rate of 40%, and an estimated 18-month survival rate of 70%. The second-generation TKIs probably produce better results than imatinib, either alone or in combinations.

Whereas the three TKIs have shown activity in blastic-phase CML and two of them (imatinib and dasatinib) have been approved for the indication, the results are modest, and combination modalities should be pursued. These include acute myeloid leukemia regimens

plus TKIs (e.g., idarubicin + cytarabine + imatinib) in myeloid-undifferentiated blastic phase, and acute lymphoid leukemia regimens plus TKIs (e.g., hyper-CVAD + imatinib or dasatinib) in lymphoid blastic phase.[95,96] In the latter, central nervous system prophylaxis should be included, because about 30% of patients may develop central nervous system disease. In all such instances patients should be referred to allogeneic stem cell transplant as soon as possible.

Allogeneic stem cell transplantation in accelerated phase results in 5-year disease-free survival rates of 15% to 30%. If transplant is done in a second chronic phase the results are better, with disease-free survival rates of 40% to 50%. In blastic phase, survival after allogeneic transplant is 5% to 15%.[97]

SPECIAL CONSIDERATIONS

Ph⁻ Chronic Myelogenous Leukemia

Among 10% of patients with morphologic CML without a detectable Ph chromosome, a third have the *BCR-ABL* molecular abnormality detected by FISH or PCR. These patients (Ph⁻, *BCR-ABL*⁺ CML) have similar clinical features, response to imatinib therapy, and prognosis as Ph⁺ CML. Patients who lack the *BCR-ABL* fusion gene (Ph⁻, *BCR-ABL*⁻; atypical CML according to the WHO classification) have heterogeneous conditions, including proliferative myelodysplastic syndrome, chronic myelomonocytic leukemia, or myeloproliferative disorders. They tend to be older, exhibit more often anemia, thrombocytopenia, and monocytosis, and do not show basophilia, eosinophilia, or thrombocytosis. They do not respond to imatinib therapy and have poor prognosis with a median survival of 18 to 24 months. Ph⁻ and *BCR-ABL*⁻ CML often overlaps clinically with chronic myelomonocytic leukemia. Patients die from infections and bleeding with marrow failure, or from transformation to acute leukemia (50%).

Pregnancy

If CML is diagnosed in a pregnant woman, she can be managed with leukopheresis if indicated during the first trimester of pregnancy, with hydroxyurea subsequently until delivery, then with more definitive therapy. Anecdotal reports of successful deliveries after IFN therapy during pregnancy have been reported; however, IFN is antiangiogenic and may have adverse affects on the fetus that are not evident with reports including only few patients. If a woman becomes pregnant while on imatinib therapy, the drug should be discontinued. Partners of men on imatinib have delivered normal babies. However, the numbers are too small to make definitive conclusions.[98]

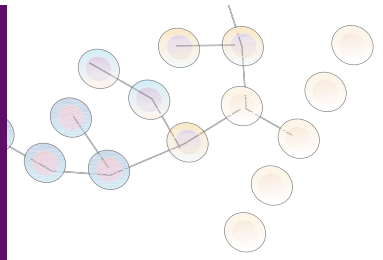
Other Considerations

Severe thrombocytosis not responding to imatinib or other TKIs may be controlled with the addition of hydroxyurea, anagrelide, or other chemotherapeutic agents (thio-TEPA, 6 mercaptopurine).

Splenectomy or splenic irradiation is rarely used in current management of CML. A rare indication for splenectomy is disease progression and painful, massive splenomegaly with hypersplenism; splenectomy may provide temporary benefit. Splenic irradiation should be avoided because of its transient effects and the resultant adhesions, which make subsequent splenectomy risky.

Leukapheresis is also rarely indicated for control of severe symptomatic leukocytosis during the first trimester of pregnancy, or for leukostasis-induced complications such as priapism. The latter can also be managed surgically through decompression of the penile vein or with brief local irradiation.

FUTURE DIRECTIONS



Targeted therapy with TKIs has significantly improved prognosis in CML, particularly for patients in chronic phase. Emergence of resistance in a minority of patients with newly diagnosed CML suggests the complex interactions in CML pathophysiology and the need to improve therapy. Long-term therapy with imatinib is expensive and presents a socioeconomic issue. Current and future studies are exploring the role of the new TKIs (dasatinib, nilotinib, bosutinib) as frontline therapy in CML to reduce or prevent emergence of resistance due to mutations or other mechanisms. Combinations of TKIs with each other (simultaneous, sequential), or with other active agents that may target the downstream events, should also be explored. These include inhibitors of pathways involving Raf, farnesylation, mTOR, JAK/STAT, MEK/MAPK, PI3K/AKT, or others. Combinations of TKIs with such classical anticancer agents as hydroxyurea, cytarabine, homoharringtonine, and others are in progress. Vaccine strategies in the setting of minimal residual disease may eradicate dormant resistant clones and provide a potential for long-term event-free survival or cure without the need for indefinite therapy.[99,100]

108 Chronic Lymphoid Leukemias

Michael R. Grever, Leslie A. Andritsos, and Gerard Lozanski

SUMMARY OF KEY POINTS

Epidemiology

- Chronic lymphocytic leukemia (CLL) is one of the most common forms of adult leukemia. Although there is an increased incidence after age 65, approximately 30% of the patients are younger than this age.
- Approximately 5% to 10% of patients with CLL have other family members with this disease. The familial form of CLL has a similar clinical course to the spontaneous form of the disease.

Clinical Features

- CLL often presents as an asymptomatic finding associated with a peripheral blood monoclonal population of neoplastic cells with a characteristic immunophenotye (CD5-positive, CD19-positive, CD23-positive, CD79b-negative, FMC7-negative, and dim expression of CD20). Flow cytometric demonstration of the characteristic monoclonal population of cells can establish the diagnosis. A bone marrow aspirate and biopsy are not necessarily required at diagnosis but are extremely useful before therapy is initiated.
- Multiple predictive biomarkers for estimating the time from diagnosis until treatment exist and include IgV gene mutational status, ZAP-70 protein expression, and CD38-positive antigen expression on leukemic cells. Cytogenetic abnormalities are quite common (e.g., more than 80% of patients have abnormalities detectable by fluorescence in situ hybridization (FISH)) and predict survival. Some predictive information with FISH can also identify patients who are projected to have a shorter duration of response to chemotherapy (i.e., del 17p).
- Clinical complications of the disease include autoimmunity, enhanced risk of infection, increased risk of secondary malignancies, and progression to a high-grade lymphoid malignancy.

Management

- Prevention is a key element for physicians following patients with this disease. Early intervention for infection and screening for other secondary malignancies (e.g., skin cancers, gastrointestinal cancers, and other solid tumors) are essential. Careful monitoring of the patient with a quarterly hemogram and a physical examination are important.
- Specific therapy for CLL is initiated when bone marrow failure appears imminent (e.g., anemia or thrombocytopenia is detected on quarterly routine hemograms), there is progressive symptomatic lymphadenopathy or splenomegaly, or there are systemic symptoms (e.g., progressive fatigue, night sweats, weight loss). Standard chemotherapy usually entails a purine nucleoside analog with rituximab. Participation in ongoing clinical trials in an effort to improve combination chemotherapy is highly recommended for all patients who need therapy. Consideration of stem cell transplantation is an alternative for those who are progressing despite frontline therapy or are participating in an organized clinical trial because of adverse prognostic parameters. Suspicion of high-grade lymphoma transformation requires more innovative therapy on a clinical trial if possible.
- Autoimmune complications (e.g., autoimmune hemolysis or thrombocytopenia) should be treated with effective immunosuppressive therapy prior to initiating cytotoxic agents to treat the CLL.

Establishing the Correct Diagnosis

- Establishing the exact diagnosis for the lymphoid leukemia is essential for selecting the optimal therapeutic approach. Alternative diagnoses such as mantle cell lymphoma, splenic marginal zone lymphoma, prolymphocytic leukemia, and hairy cell leukemia (or a variant) may be erroneously reported as CLL. Hematopathology review is therefore essential for diagnostic confirmation. Furthermore, an enormous amount of data has accrued that predicts the outcome for specific subsets of patients with CLL, and in contrast to previous decades, it is essential to distinguish among the various forms of chronic lymphoid leukemia.

INTRODUCTION

Chronic lymphocytic leukemia (CLL) is the most common form of adult leukemia in the Western hemisphere. The clinical course of this malignant disease is quite variable, and the complications that are associated with this entity are diverse. Enormous research efforts have been expended over the four decades since Dameshek described CLL as an accumulative disease of immunologically incompetent lymphocytes in 1967.[1] Historically, this disease has been described as a lymphoproliferative process. Dameshek wisely suggested that an additional defect in the leukemic cells' ability to undergo apoptosis results in an accumulation of malignant cells. Recent advances in the understanding of the pathogenesis of CLL have confirmed that both historical descriptions have validity, but that the complexity of malignant clonal expansion and progression requires more explanation.

CLL is a neoplastic disorder of CD5-positive B cells that is affected by genetic, molecular, and microenvironmental factors that might ultimately result in a fatal outcome. Recently, observations have indicated that two basic forms of this disease exist. These originate from events in B-cell development surrounding the mutational status of the immunoglobulin variable gene region (IgV).[2] In normal B-cell development, the IgV gene undergoes a specific rearrangement that provides for diversity of immunoglobulin protein synthesis in response to antigenic stimulation. Normal B cells traffic from the bone marrow to the germinal centers of lymph nodes, where IgV gene rearrangement occurs. In CLL, there are two groups of patients with diverse clinical outcomes that are separated by the mutational status of this IgV gene. Patients who have a mutated IgV gene detected in their leukemic cells have a favorable clinical course. In contrast, patients with an unmutated IgV gene in their leukemic cells have a more aggressive clinical course.[3]

In addition to these important clinical consequences related to the normal process of rearrangement of the IgV gene, there have been a host of additional molecular observations that are associated with the prognosis of this disease. Patients with an overexpression of CD38 on their leukemic cells also have an aggressive clinical course.[4] The genetic profiling of leukemic cells identified that the expression of ZAP-70, a protein tyrosine kinase that is normally found only in T cells, represents another marker for aggressive clinical disease when detected in leukemic B cells.[5,6]

Genetic abnormalities in leukemic cells from patients with CLL have been detected in approximately 50% of patients by standard cytogenetics. The majority of findings that have been identified by fluorescence in situ hybridization (FISH) analyses show that approximately 80% of patients with CLL will have a detectable abnormal clone, and many have multiple or complex clonal cytogenetic abnormalities.[7,8] The observations of clonal evolution coupled with new discoveries in gene expression patterns present a picture of a complex series of events that result in a multiplicity of clinical outcomes. The recent demonstration that microRNA molecules within the leukemic cells might control gene expression (e.g., TCL-1), that these entities can induce a CLL-like disease in mice, and that they might be associated with progression of disease in humans provides further insight into the expanding list of molecular features that affect outcomes.[9,10]

Finally, the importance of signal transduction at the cellular level in promoting either cell death or survival is increasingly appreciated. Signals from the microenvironment might tip the balance in favor of leukemic cell survival via upregulation of antiapoptotic proteins (e.g., BCL-2, survivin, and MCL-1).[11,12] In vivo studies have confirmed that this disease is truly proliferative even in its early clinical stages. Patients with an elevated growth fraction can have more rapid clinical disease progression. Therefore, the novel description of the disease entity 40 years ago by Dameshek was correct in stating that this disease is an accumulative disorder but underestimated the complexity of the modulating genetic, molecular, and microenvironmental factors that can result in rapid or indolent clinical progression. In caring for patients with CLL, it is important to understand and appropriately utilize this new knowledge for assessment of patient prognosis in order to provide guidance for optimal disease management.

EPIDEMIOLOGY

While CLL is the most common form of adult leukemia in the United States and Europe, it has a low incidence in Asia. In Asian immigrants to the United States, there is no increase in the frequency of this form of leukemia. The median age at diagnosis of CLL is 72 years of age; however, the Surveillance Epidemiology and End Results (SEER) database indicates that about 30% of patients are younger than 64 years of age at diagnosis.[13] Therefore, this is not a disease that solely afflicts the older aged patient. While the median age at death was 78 years of age, many features of the disease need to be considered in estimating the risks for death from this disease. The incidence in the general population does increase dramatically with age. People over the age of 65 had an incidence of approximately 20.6 per 100,000, while those under this age had had an incidence of 1.3 per 100,000. CLL is more common in males than in females. In 2006, the SEER database predicted that 10,020 new cases would be identified. This would include 6280 men and 3740 women. In 2000, the age-adjusted incidence of males and females was estimated at 4.7 and 2.4 per 100,000, respectively. CLL is slightly more common in whites than in blacks. In the United States in 2000, the age-adjusted incidence in whites and blacks was 3.7 and 2.5 per 100,000, respectively.[14] Some investigators believe that these figures are too conservative and that as many as 21,000 new cases per year in the United States might be more accurate.

PATHOGENESIS

A definitive cause for CLL has not yet been identified. The possibility of a genetic predisposition appears strong, considering the population differences between Asia, North America, Europe, and Australia. In addition, families with an increased incidence of CLL have been identified, and it is estimated that approximately 5% to 10% of patients with CLL have a family history of this disease.[15] There does appear to be a phenomenon of anticipation in the familial form of this disease, in which family pedigrees demonstrate onset of disease at a younger age with subsequent generations.[16] A large Italian study involving 1449 patients with CLL showed that 181 of these patients (12.5%) reported having one or more relatives with a hematologic malignancy, of which 6% were CLL.[17] Overall, the patients with the familial form of the disease had a prognosis that was similar to the prognosis of those with a spontaneous diagnosis with respect to requirement for therapy and survival. Preliminary data from Raval and colleagues implicate specific genes (e.g., death-associated protein kinase 1) in the development of CLL.[18]

Although there has been no linkage of CLL to irradiation, some association has been noted between pesticide exposure and farming with development of CLL.[19,20] Recently, exposure to Agent Orange during the Vietnam era was linked to an increase in this disease.[21]

CLINICAL FEATURES AND INVESTIGATION

CLL is a neoplastic disease involving a malignant transformation of a B-cell precursor cell. This event occurs in a common lymphocyte precursor cell. The common lymphocyte precursor cell undergoes the neoplastic transformation with an expansion of a clonal population of cells that have a characteristic immunophenotype (CD5-positive, CD19-positive, CD23-positive). There are other characteristic immunophenotypic antigens that are also expressed (e.g., CD20-expression is dim), and these cells can be identified by flow cytometry of the circulating peripheral blood.[22] These cells infiltrate all organs including lymph nodes, bone marrow, spleen, and liver. The pattern of lymph node invasion is characteristic of a small cell lymphocytic lymphoma. The bone marrow will show an infiltration of more than 30% cells of monoclonal lymphoid origin. Morphologically, these cells appear as small, mature-appearing lymphocytes with dense chromatin structure. The pattern of lymphocyte infiltration in the bone marrow ranges from interstitial or nodular to diffuse involvement. The pattern of involvement has prognostic significance, diffuse infiltration being associated with an inferior prognosis.[23] The microenvironments in both the lymph nodes and bone marrow are felt to contribute to the progression of the malignant disease. Ultimately, the leukemic cells will displace many of the normal cellular elements within the bone marrow, leading to peripheral blood cytopenias.

The cells of this disease have been characterized as restricted in G_0 and therefore are predominantly a clonal population of nondividing malignant cells. However, recent in vivo studies utilizing deute-

Table 108-1 Initial Investigation and Pretreatment Evaluation

INITIAL INVESTIGATION
Complete blood count with differential
Review of peripheral smear
Complete metabolic panel with LDH
Peripheral blood immunophenotyping
Serum protein electrophoresis
Quantitative immunoglobulins
Beta-2 microglobulin
Chromosome analysis of peripheral blood with interphase cytogenetics for 17p, 11q, and 13q, as well as translocation 11;14 to rule out mantle cell lymphoma
IgV mutation testing, CD38, and Zap-70*
PRETREATMENT PLANNING
Complete blood count with differential
Complete metabolic panel with LDH to evaluate renal function
Viral serologies (e.g., hepatitis, CMV)
Bone marrow aspirate and biopsy with flow cytometry
CT scan of the neck, chest, abdomen, and pelvis
Consideration for PET scan if transformation to large cell lymphoma is suspected

*Since no clinical intervention is currently based on these prognostic indicators, these studies should be carefully considered by the clinican and extensively discussed with the patient prior to ordering.

rium-labeled water have shown a highly proliferative compartment to the circulating leukemic cells that can be identified in patients even at the earliest stages of the disease. Although there are differences between patients with respect to the size of the proliferative component, patients who have a percentage of new cells in excess of 0.3% of the total leukemic cell mass per day have a more aggressive clinical course.[24]

The observation that many of the leukemic cells are nondividing has prompted studies of duration of cell survival. Indeed, there are many factors that contribute to prolonged cell survival. In particular, antiapoptotic proteins (e.g., BCL-2 and MCL-1) are expressed in CLL cells, and these result in the accumulation of large numbers of long-lived leukemic cells. This process is aided by the presence of protective cells in the marrow and lymph node microenviroments that upregulate antiapoptotic proteins and protect cells from the effects of chemotherapy.[25,26]

The criteria for diagnosis of CLL include documentation that a peripheral lymphocytosis exists (absolute lymphocyte count > 5000), demonstration of a monoclonal population of malignant B cells characterized by light chain restriction, and a specific immunophenotype in the peripheral blood. Flow cytometry is essential in demonstrating a clonal population of lymphocytes that coexpress CD5-positive, CD19-positive, and CD23-positive; are CD79b-negative and FMC7-negative; and are weakly positive for surface immunoglobulin. CLL cells weakly express CD20 antigen. The peripheral blood smear shows small mononuclear cells with a dense chromatin structure. There should be fewer than 11% prolymphocytes, and it is important also to evaluate the morphology of both the red blood cells and the platelets. A bone marrow aspirate and biopsy are not required to establish the diagnosis of CLL, as definitive flow cytometry may be performed on the peripheral blood. However, these studies are usually required prior to initiating therapy (Table 108-1). It is important to note that there are other lymphoid malignancies that coexpress CD5, and it is therefore essential to confirm the diagnosis of CLL and to exclude the possibility of an alternative diagnosis. Table 108-2 lists the diagnostic features of CLL along with those of other lymphoid malignancies that should be considered in the differential diagnosis. Mantle cell lymphoma (MCL) in particular

Table 108-2 Differential Immunophenotype of Chronic Lymphoid Leukemias

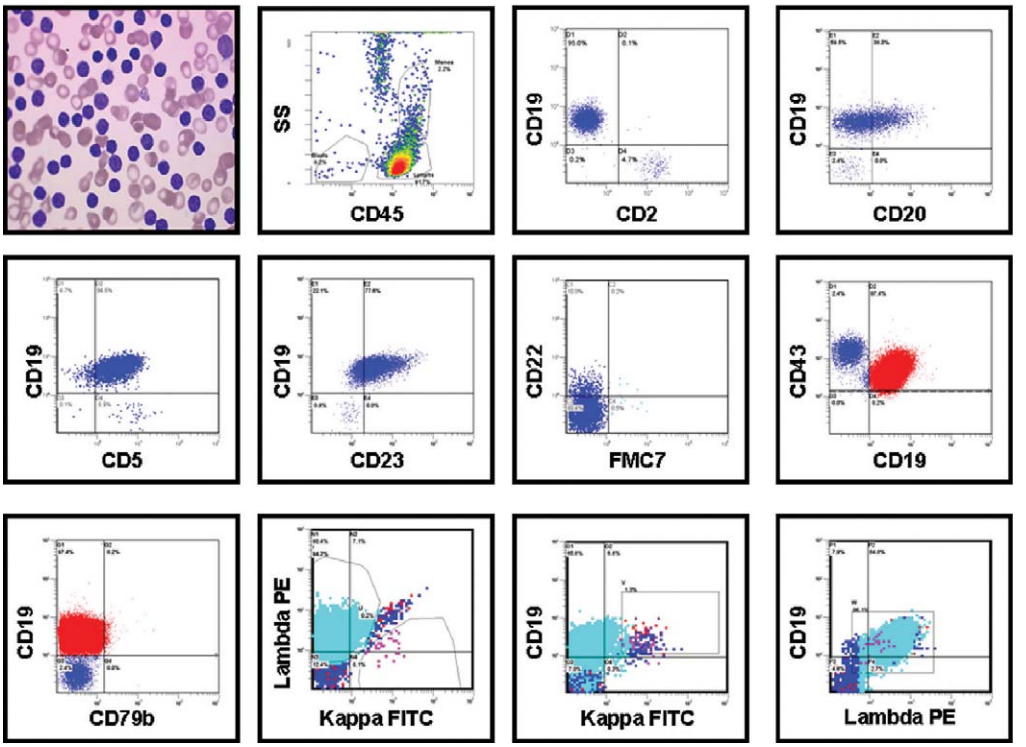

Figure 108-1 • Classic immunophenotypic profile for chronic lymphocytic leukemia/small lymphocytic lymphoma.

may present with a hematologic picture that is similar to that of CLL. However, the prognosis and therapeutic approach for MCL would be completely distinct from those for CLL. Patients with MCL have a shorter interval to disease progression, and the overall survival is markedly diminished when compared with that of CLL. A CLL scoring system has been established that assigns specific points for the respective antigen expression on the malignant cells as determined by flow cytometry.[27] In addition to this scoring system, many centers perform testing for overexpression of cyclin D_1, which is associated with specific cytogenetic evidence that confirms a diagnosis of MCL. Patients with MCL can be identified with FISH probes showing the t(11;14) translocation (Fig. 108-1).

Morphologic evaluation of the leukemic cells on the peripheral blood smear will be important for recognizing another aggressive form of chronic lymphoid leukemia that can masquerade as CLL. Prolymphocytic leukemia will often present with a marked peripheral blood lymphocytosis associated with malignant cells that have a very prominent large central nucleolus (Fig. 108-2). In patients with de

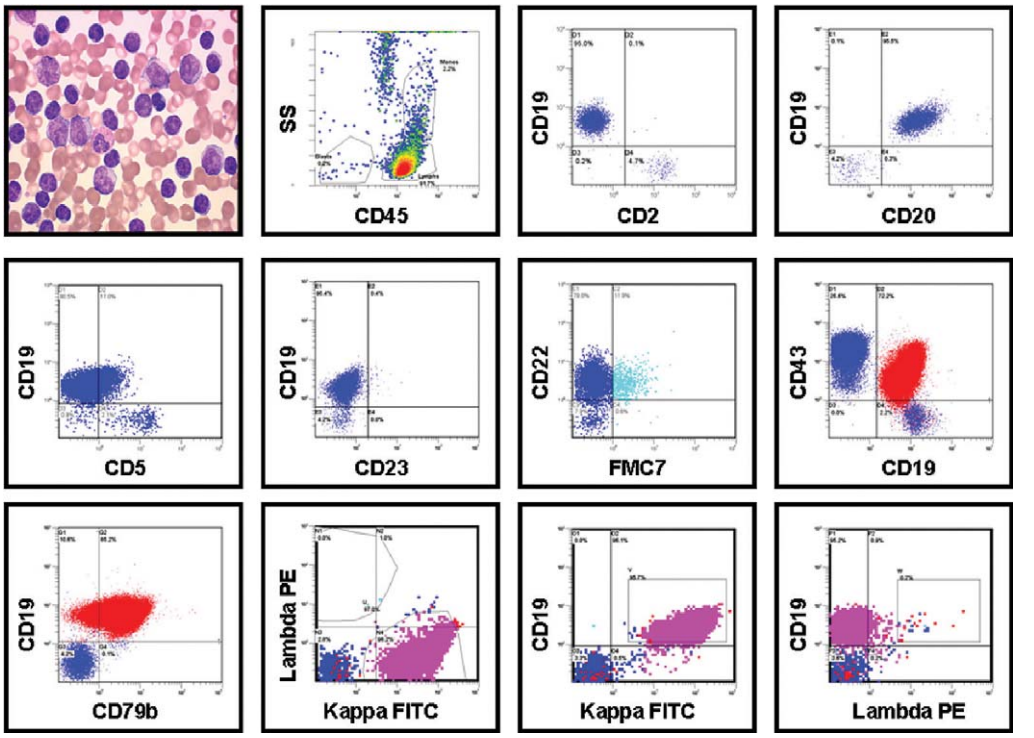

Figure 108-2 • Typical immunophenotypic profile for chronic lymphocytic leukemia (CLL) in transformation to prolymphocytic leukemia (PLL).

novo common lymphocyte precursor cell, more than 55% of the peripheral lymphoid cells will be prolymphocytes. These patients frequently have marked splenomegaly with very little lymphadenopathy. The clinical course is much more aggressive than that of CLL, and the response to standard chemotherapy is suboptimal.[28–30] The de novo form of prolymphocytic leukemia is distinctly different from the prolymphocytic transformation of standard CLL. The immunophenotypic data will help in making these subtle differential comparisons.

Enormous progress has been made over the past decade in defining molecular parameters that will predict the clinical course of CLL, but most important is the task of establishing the basic diagnosis. In fact, as therapy improves for the specific subsets of chronic lymphoid leukemia, it becomes paramount that the correct diagnosis and prognostic profile are established for individual patients.

CLINICAL STAGING: HIGHLY RELIABLE PREDICTORS THAT HAVE WITHSTOOD THE TEST OF TIME

In 1975, Rai and colleagues published a clinical staging system that predicted the overall survival of patients with CLL based on data derived from a physical examination and a hemogram.[31] In Europe, Binet and colleagues popularized another system that conveniently conveys the same basic prognostic prediction regarding survival.[32] These systems have been utilized for more than a quarter of a century in clinical investigation of CLL. In addition to providing a prognostic estimate for the individual patient, the use of these respective systems enabled investigators to compare patient characteristics between clinical trials. While these staging systems are very useful and convenient, there are limitations. In 1986, Rai simplified his five-stage system to three stages: low-risk, intermediate-risk, and high-risk disease. Both systems are useful but primarily define the prognosis at the time of diagnosis. Neither system permits a modification of prognosis as the disease progresses. Table 108-3 provides a description of the Rai staging system.

CLINICAL AND MOLECULAR PROGNOSTIC STUDIES

Over the past 10 years, molecular parameters have been identified within the leukemic cells that predict disease progression. Several investigators have independently shown that CLL can be divided prognostically into two independent subsets: those with IgV gene mutation and those that are unmutated.[2,33] Patients with unmutated IgV gene have a significantly shorter survival than do patients with more extensive IgV gene mutation. The patients with aggressive disease often have a shorter time from diagnosis to requiring therapy for CLL. In addition, the unmutated group of patients tends to have the associated cytogenetic abnormalities that predict shorter time to disease progression following therapy.[34,35] Flow cytometric studies have demonstrated that overexpression of the CD38 antigen on CLL cells defines two similar groups, of which patients who have a higher percentage of leukemic cells with overexpression of CD38 have a worse prognosis.[33,36–38] CD38 is a transmembrane glycoprotein that is widely expressed on a range of cell types. In normal mature B cells, its expression is confined to the germinal center of secondary lymphoid follicles. There has been extensive discussion that overexpression of this membrane protein is associated with a relative lack of IgV mutation and thus is associated with a worse clinical prognosis in CLL. Several studies have classified those patients with more than 7% positive CD38 cells as being at risk for aggressive disease, and others have used the cutoff of 30% positive cells for identifying patients with a worse prognosis.[4] In general, it is much easier to establish the percentage of CD38-positive cells by flow cytometry than by sequencing the B-cell receptor heavy chain to determine whether there is a substantial mutation (>2%) from germline. The application of this flow cytometric assessment of risk is more generally available than attempting to determine whether the patient is in the "unmutated" or the "mutated" form of this disease.

ZAP-70 is a 70-kd tyrosine kinase that normally is required for T-cell receptor signaling. It is expressed in normal T cells and NK cells but not in normal circulating B cells. In addition to the other predictive molecular prognostic parameters, there have been numerous studies showing that the expression of ZAP-70 in circulating leukemic cells from patients with CLL is associated with shorter overall and progression-free survival.[5,6] Several studies have confirmed that patients with expression of ZAP-70 in more than 20% of their leukemic cells will require therapy earlier than will patients who are negative for this protein.[39] However, this testing is difficult to validate, as the reproducibility of the assay varies between laboratories. Therefore, it is not offered by all reference laboratories.

While standard cytogenetics in CLL had been severely limited by banding techniques in cells that were basically trapped in G_0, the growing use of FISH probes to examine leukemic cells in interphase has been remarkably rewarding. We now appreciate that at least 80% to 85% of patients with CLL will have a cytogenetic abnormality that can be defined by FISH.[40] Of patients with an abnormality that is identified by this technique, most will have one abnormality (~50%). Approximately 25% will develop a second abnormality, and another 25% will ultimately have a complex cytogenetic pattern as defined by three or more abnormalities. Patients with a complex karyotype will have a more aggressive clinical course.[41] Dohner and colleagues have defined a hierarchical classification system as defined in Table 108-4 that provides very useful information regarding prognosis in this disease. There is a clear separation in survival curves for each of these cytogenetics subsets.[41]

In an Intergroup Study in the United States, a prospective randomized clinical trial carefully examined the impact of these parameters on the response to therapy. Previously untreated patients with CLL were randomized to receive their initial therapy as either fludarabine alone or fludarabine combined with cyclophosphamide. This

Table 108-3 Stage at Presentation and Outcome of Chronic Lymphoid Leukemia

Rai Stage	Clinical Features	Percent of Cases	Survival
Low risk	Lymphocyte count $> 5 \times 10^9$/L	30	≥10 years
Intermediate risk	Enlarged LN or organomegaly	60	6 years
High risk	Hb < 11 g/dL or Plt $< 100 \times 10^9$/L	10	2 years

Table 108-4 Effect of Cytogenetic Abnormalities on Time to Treatment and Survival

Abnormality	Time to Treatment (months)	Overall Median Survival (months)
17p deletion	9	32

Trisomy 12	33	114
Normal	49	111
13q deletion	92	133

Data from Dohner, et al.[41]

study had initially been designed in 1997, and the major correlative project was to examine the importance of flow cytometry with detailed immunophenotyping, FISH cytogenetics, immunoglobulin gene rearrangement with an assessment of mutational status, ZAP-70 protein expression, and quantitative analysis of bcl-2 antiapoptotic proteins, p53 mutational status, and other molecular parameters on outcome. A total of 278 patients were enrolled in this Intergroup Study (E2997). Treatment outcomes were disappointing, with low complete remission rate being observed with fludarabine alone (4.6%). Patients who received the combined therapy with fludarabine and cyclophosphamide had a statistically higher complete remission rate (23.4%; $P < 0.013$). Furthermore, the progression-free survival (PFS) with the combined therapy arm of the study was markedly longer: 31.6 months compared to 19.2 months ($P < 0.0001$). The clinical factors that were associated with a better response outcome on this study were interesting: the treatment arm assigned (i.e., combined therapy being better than monotherapy) and the Rai stage (0 or 1) at the time of registration ($P < 0.0001$). In addition, PFS was associated with time from diagnosis until treatment (more than 3 years being better), and the presence of splenomegaly at study entry was associated with a shorter PFS. The extensive correlative laboratory studies showed that FISH cytogenetics were able to identify the patients who were predicted to have a significantly shorter PFS (i.e., those with a del 17p or del 11q23), but the other biomarkers did not predict response to chemotherapy or PFS.[42]

The conclusions from many studies remain that IgV mutational status, ZAP-70 expression, and quantitation of CD38 enable prediction of the overall aggressiveness of the disease in identifying patients with the shorter time from diagnosis until therapy is required. The hope remains that these biomarkers will define the specific groups of patients who would be better served by investigational therapy than by standard treatment. This extensive work of the U.S. Intergroup Study defined the relative contribution of many laboratory parameters in evaluating the overall prognosis for these patients. Some of these parameters will identify the patients who are likely to require therapy earlier than the average. FISH will define the group of patients who are likely to have a shorter PFS with standard chemotherapy and, it is hoped, will assist with risk stratification for future clinical trials attempting to improve on current therapeutic strategies.

Table 108-1 lists a summary of recommended laboratory studies for the initial diagnosis of CLL and prognostic information for treatment planning. The diagnosis can be established by reviewing the peripheral blood smear and documenting that a monoclonal population of neoplastic cells has the characteristic immunophenotypic markers by flow cytometry. A bone marrow aspirate and biopsy are not necessarily needed at the time of diagnosis in an asymptomatic patient. However, the bone marrow aspirate and biopsy become potentially very useful in patients who have anemia, thrombocytopenia, or symptoms of progressive disease.

DIFFERENTIAL DIAGNOSIS

The importance of establishing the correct diagnosis of the specific subtype of chronic lymphoid leukemia cannot be overstated. Patient prognosis and anticipation of the clinical events to follow rest heavily on the accuracy of the diagnosis and staging. Decisions regarding therapeutic intervention for an individual patient rely heavily on risk-adapted biomarkers and the natural history associated with the many forms of these diseases. While a careful review of the morphologic features of the circulating leukemic cells on the peripheral blood smear may be helpful, the modern use of flow cytometry for establishing the immunophenotypic profile is crucial. Furthermore, incorporation of interphase FISH cytogenetics and standard cytogenetics studies assists in further refinement of the disease and its potential response to therapy.

The initial task involves establishing the presence of a monoclonal population of leukemic cells and then further refining the nature of the antigens that are expressed on these cells (as outlined in Table 108-2). The FISH probes will confirm and refine the final decisions for diagnostic classification (see Fig. 108-1). These steps are essential in planning patient management. Although these diseases cannot be cured by currently available pharmacologic agents, the increasing number of patients who are achieving durable remissions has resulted in specific therapies for individual diseases.

The clinical features of presentation can also be helpful in defining the disease process. For example, patients who present with anemia and thrombocytopenia associated with a monoclonal population of B cells in the peripheral blood might have one of many forms of chronic lymphocytic leukemia. Therapy for CLL differs from therapy for CLL/prolymphocytic leukemia, and they both differ from therapy for prolymphocytic leukemia. Patients who present with a low-grade indolent form of chronic lymphoid leukemia with splenomegaly might have either hairy cell leukemia or marginal zone lymphoma. The therapeutic approach to the two diseases is currently very divergent.

Patients who present with severe pancytopenia and a markedly hypocellular bone marrow might actually have a very treatable form of hairy cell leukemia (and not aplastic anemia). Yet the clue might reside in the close examination of the peripheral blood with either morphology or flow cytometry. The outcome for the patient is markedly different depending on the exact underlying diagnosis. While not common, this diagnostic dilemma is encountered in patients with hairy cell leukemia who have a hypocellular marrow with minimal to no splenomegaly. Recognizing the even rarer patient with the variant of hairy cell leukemia might require differentiation from other proliferative forms of chronic lymphoid leukemia. The effort in establishing the correct diagnosis will be justified in selecting the correct therapeutic strategy.

Complications of Chronic Lymphocytic Leukemia from Fatigue to Dysfunctional Immunity and Infection

The diagnosis of CLL is often made in asymptomatic individuals. The most common symptoms associated with early-stage disease are fatigue and occasional lymph node enlargement. Infection represents a frequent cause of morbidity and mortality. Multiple features of this disease contribute to the risks for viral, bacterial, and opportunistic infections.[43] Many patients develop neutropenia either as a consequence of bone marrow infiltration with leukemia or as a consequence of therapy for the disease. Progressive hypogammaglobulinemia develops in approximately 60% of the patients.[44] Abnormalities of complement function as well as intrinsic defects in T cells provide additional factors leading to an excessive risk of infection. T-cell defects are present before chemotherapy but are profoundly and negatively affected following the use of purine nucleoside analogs. The resultant T-cell reductions following fludarabine or pentostatin may persist for a year (or more) after completion of chemotherapy. The increasing use of alemtuzumab for treating either minimal residual disease or drug-resistant leukemia further aggravates the T-cell impairment.[45]

The most common sites for infection involve the respiratory tract, particularly sinopulmonary infections. Skin infections and soft-tissue infections can also occur. Reactivation of herpes zoster must be treated promptly in these immune-compromised patients to avoid excessive morbidity and generalized zoster. *Pneumocystis jiroveci* (formerly *P. carinii*) may develop in patients who have had treatment with both purine nucleoside analogs and additional immunosuppressive therapy (e.g., steroids). Fungal infections may also develop in patients who have received chemotherapy plus additional immunosuppressive therapy. The use of purine nucleoside analogs and monoclonal antibodies to treat the leukemia results in a long-lasting

profound depletion of mature B cells, T lymphocytes, natural killer cells, and monocytes.[46] Consequently, the spectrum of infectious agents for these patients has changed from simple common bacteria to now include opportunistic agents resulting from these profound immune effector cell defects: *P. jiroveci*, Listeria, mycobacteria, cytomegalovirus (CMV), herpesviruses, and Candida.

The risks associated with serious infection markedly increase in patients with advanced disease that is refractory to purine nucleoside analogs. The median survival in patients who are refractory to fludarabine is 13 months.[47] Infection constitutes the major cause of death in this patient population; consequently, prompt attention to a febrile illness is necessary. Appropriate cultures should be secured, and then a decision should be made to cover the most likely source of infection. Considering the many immune defects that accompany this disease, patients with CLL should be treated promptly for symptoms of infection.

In select high-risk patient populations, prophylactic therapy and monitoring for specific infections are warranted.[48] Patients who are receiving combined purine nucleoside analog therapy and other immunosuppressive therapy are often treated prophylactically with trimethoprim-sulfamethoxazole for *P. jiroveci* and with agents to prevent herpetic infection. In patients who subsequently receive alemtuzumab, careful monitoring for reactivation of CMV is necessary.[45] While a recent publication indicated that younger patients might not require prevention for opportunistic infections following therapy of leukemia, the majority of patients with this disease are not young. In addition, consideration should be given to screen for hepatitis or latent tuberculosis in patients who are likely to require combined immunosuppressive chemotherapy plus monoclonal antibody therapy.

Immune Dysfunctional Paradox: Severe Immunodeficiency and Autoimmunity

Autoimmune phenomena present a challenge in management. While patients may present with autoimmune complications of this disease when their leukemic burden is quite low, the decision to treat requires specific attention to the dysfunctional immune system. Barcellini and colleagues recently cataloged the immune complications found in a large number of patients with CLL.[49] This review included both a retrospective and a prospective analysis of 194 cases of autoimmune complications resulting from CLL. Autoimmune hemolytic anemia represented the most frequent complication (129 cases, or 66%). While 89% of these episodes involved a warm IgG antibody, 11% of the patients had a cold hemagglutinin (IgM anti-C) producing the anemia. Autoimmune thrombocytopenia accounted for 35 cases (16%) of the immune complications associated with CLL. They found 30 additional autoimmune complications that did not involve destruction of a hematologic target. For example, bullous pemphigus affected nine of these patients, and Hashimoto's thyroiditis complicated the course for eight patients.

Follow-up data were available for approximately 116 patients who had been identified as having an autoimmune complication associated with their CLL. Recovery was observed in 65% of the patients with autoimmune hemolysis. In addition, 54% of patients with autoimmune destruction of platelets and about 40% of those with other forms of autoimmunity recovered. Unfortunately, 42% of the cases of refractory autoimmune hemolysis were fatal. Paraneoplastic pemphigus associated with this disease may also be fatal, associated with progressive involvement of the oropharynx or as a result of excessive immunosuppression.[50,51] Simply embarking on standard therapy for treating bulk disease in the patient with autoimmune complications of CLL might be quite ineffective in adequately controlling the immune destruction of normal cellular elements. Therefore, careful attention to effective immunosuppressive therapy should be the primary initial objective in dealing with these autoimmune complications of CLL.

COMPLICATIONS OF PROGRESSIVE DISEASE OR HIGH-GRADE TRANSFORMATION

Patients with CLL frequently develop anemia, thrombocytopenia, and neutropenia from progressive infiltration of the bone marrow. Furthermore, enlargement of the spleen can result in pancytopenia from sequestration of cellular elements. Ideally, the therapy of CLL should be initiated before these hematologic parameters have reached dangerously low levels. In following the National Cancer Institute (NCI) guidelines, therapy should be started for progressive anemia (i.e., hemoglobin < 10 g/dL) or severe thrombocytopenia.[52] The least accurate hematologic parameter for deciding on therapy would be the absolute granulocyte count. As the total lymphocyte count increases, the accuracy of determining the absolute granulocyte count decreases.

In deciding on treatment for CLL, a bone marrow examination (both aspirate and biopsy) is appropriate to understand the mechanism for the lowered counts. For example, diffuse infiltration of the bone marrow might explain the presence and the mechanism of either anemia or thrombocytopenia. However, it is essential to be alert to increased platelet destruction as evidenced by persistence of either adequate or increased numbers of megakaryocytes within the bone marrow despite a lowered platelet count. In reviewing the bone marrow, it is important to evaluate the red blood cell precursors to avoid overlooking pure red cell aplasia or the presence of giant pronormoblasts that could signal a concomitant parvoviral infection.[53] A full understanding of the mechanism for bone marrow failure will enable selection of appropriate therapy. For example, patients with anemia and a pure red cell aplasia associated with a parvoviral infection may deteriorate with cytotoxic chemotherapy. The treatment of choice would include initial intravenous immunoglobulin to attempt to eradicate the parvoviral infection before considering other additional therapy. Identification of other unrelated disorders that could contribute to the anemia or thrombocytopenia is equally important. Decreased iron stores or megaloblastic features may signal yet another underlying explanation for decreased production of cellular elements. All of these possibilities reflect the necessity for careful consideration of the basic workup for each patient rather than simply attributing the decrease in blood counts to progression of the CLL.

In addition to progressive leukemic infiltration of the bone marrow, the bulk of the disease may increase, resulting in enlargement of lymph nodes or the spleen. Enlarging lymph nodes or splenomegaly can produce symptoms that require treatment. Progressive increases in the absolute peripheral lymphocyte count can also eventually mandate initiation of therapy. While patients might tolerate circulating absolute lymphocyte counts in the 200,000 range without symptoms, some patients will experience vascular compromise if these counts exceed 300,000/μL. There is enormous variability in how well patients tolerate high lymphocyte counts, but the NCI guidelines caution that rapid doubling of leukemic cells over less than 6 to 12 months usually heralds the need for therapy.

Enlargement of an isolated lymph node area or the development of systemic symptoms including weight loss, fever, and night sweats may indicate transformation to a high-grade lymphoma (e.g., Richter's syndrome).[54] If this is suspected, a biopsy of the suspect lymph node can provide histologic evidence of large cell lymphoma transformation that would require more aggressive therapy, as illustrated in Figures 108-3 and 108-4. Patients with standard CLL may also progress into a prolymphocytic transformation as the pace of the disease increases. This transformation may be suspected if more than 11% but fewer than 55% of the circulating peripheral blood leukemic cells have large single nucleoli. This stage of the disease is not as responsive to standard therapy for CLL and might require consideration of more aggressive intervention if appropriate for the patient.[29,30] The transformation to the more aggressive malignancy may be a consequence either of the underlying compromised immunosurveillance

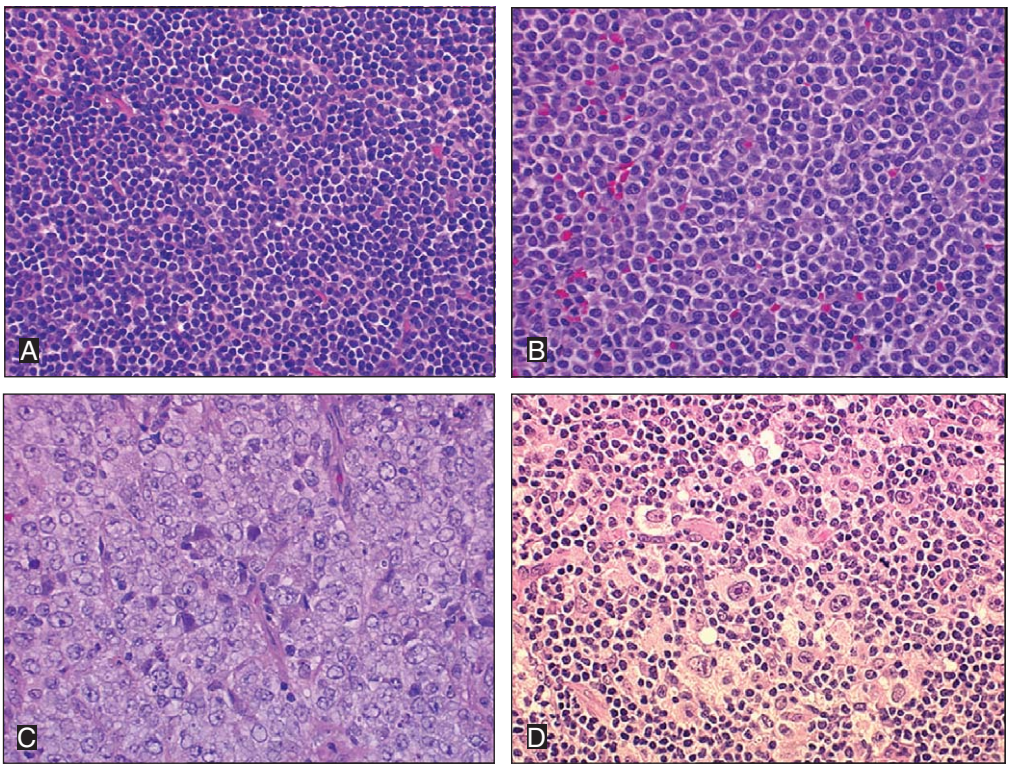

Figure 108-3 • Lymph node sections demonstrating chronic lymphocytic leukemia with transformation. **A,** Small lymphocytic lymphoma (SLL). **B,** SLL with prolymphocytic transformation. **C,** SLL with large cell transformation. **D** SLL with large cell transformation and Reed-Sternberg Hodgkin-like cells.

or as a result of the therapy for the leukemia. Epstein-Barr virus infection has also been implicated in this transformation process for a limited number of patients with Richter's transformation.[55–57]

Although the actual cause of these high-grade malignant transformations has been debated, cases have been documented to show the same clonal features both within the initial leukemia and in the high-grade malignant cells. Furthermore, other cases clearly show that a separate clonal disease process has occurred in the aggressive malignant tissue. The rate of high-grade malignant transformation may vary from 1% to 10% of patients with CLL over an extended period of time from the initial diagnosis.

The spectrum of malignant lymphoid diseases that have been associated with the aggressive transformation process in CLL include large cell lymphoma, Hodgkin's disease, prolymphocytic leukemia,

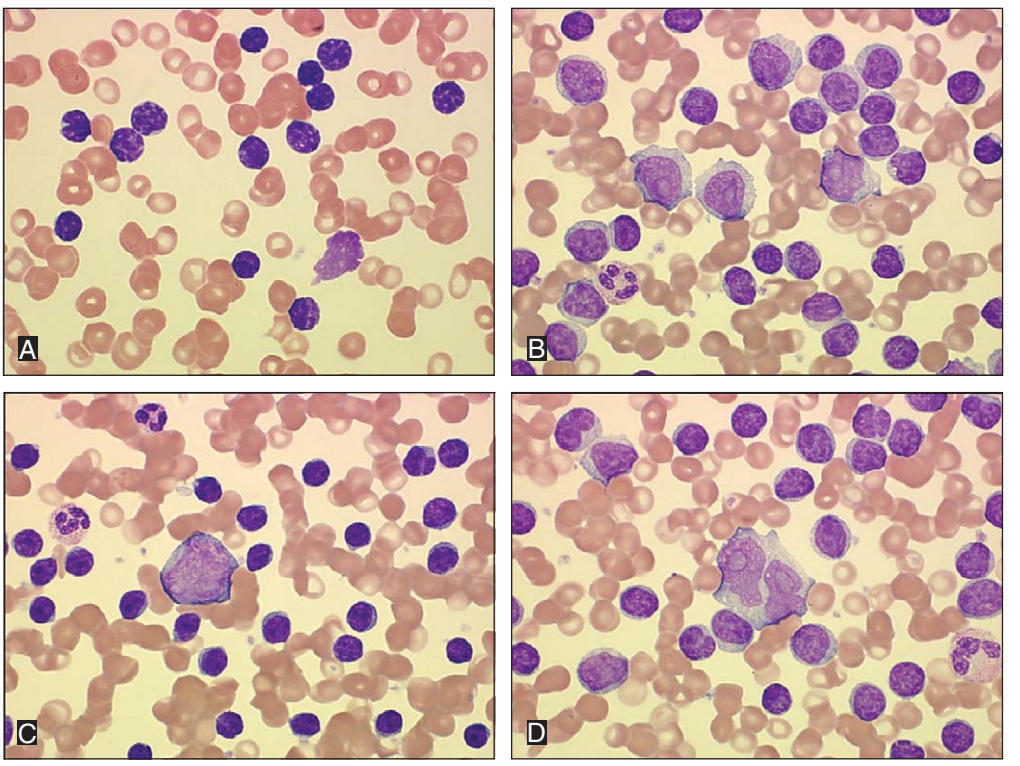

Figure 108-4 • Peripheral blood morphology demonstrating CLL with transformation. High magnification (100×) of Wright-Giemsa-stained blood smears representing **A,** chronic lymphocytic leukemia (CLL), **B,** CLL with prolymphocytic transformation, **C,** CLL with large cell transformation, and **D,** CLL with large cell transformation and circulating Reed-Sternberg-like cells.

multiple myeloma, and, rarely, acute lymphoblastic leukemia. Patients may complain of progressive "B" symptoms, including night sweats, fever, and unintentional weight loss. They may have abdominal pain or discomfort associated with progressive adenopathy or splenomegaly. Laboratory features may include progressive anemia, thrombocytopenia, and a rapidly rising absolute lymphocyte count. Patients frequently have an associated increase in lactate dehydrogenase or develop a progressively increasing paraprotein. Approximately 40% of CLL patients with high-grade transformation may develop extranodal malignant lymphoid infiltrates in diverse locations (e.g., pleura, central nervous system, oropharynx, skin, lung, bone, or gastrointestinal tract).

Patients with malignant transformation of the large cell lymphoma variety have a poor prognosis, with reduced response rates to standard chemotherapy. Allogeneic stem cell transplantation is being explored in this setting, but the current overall survival is less than 6 months, warranting enrollment of patients into well-organized clinical trials.[58] Patients with alternative forms of lymphoid malignancy are treated with the therapy that best targets the disease type of transformation (e.g., ABVD regimen for those who have developed a transformation resembling Hodgkin's disease).

SECONDARY MALIGNANCIES

The SEER database has estimated the risk of patients with CLL developing a secondary malignancy to be 20%. Others have suggested that there is a threefold increase in comparison to age-matched control patients. The Veterans Administration estimated that 14.4% of patients with CLL had another nonlymphoid malignancy and that the second malignancy is a common cause of death.[59] The most frequent types of solid tumors include lung cancer, gastrointestinal carcinomas, melanomas, and other skin cancers.[60] Consequently, it is advisable to screen patients for these entities to ensure early detection.

Patients with CLL have also been rarely reported to have concomitant myelodysplasia, myeloproliferative disorders, or even myeloid leukemia.[61,62] Patients who have been treated with extensive alkylating agents are potentially at increased risk for therapy-induced acute myeloid leukemia.[63] There has been concern that purine nucleoside analogs in conjunction with alkylating agents may further increase this risk. Treatment-induced leukemia is usually preceded by a period of myelodysplasia.

PATIENT MANAGEMENT

The NCI has defined general principles for initiating therapy for CLL.[52] Once the diagnosis has been established, it is quite important to have an extensive discussion with the patient and family to define a course of action (Box 108-1). Patients who realize that they have an incurable malignancy frequently are anxious to initiate treatment. For asymptomatic patients with low-stage disease, it is important to explain that careful follow-up is an appropriate alternative to treat-

Box 108-1. MANAGEMENT OF CHRONIC LYMPHOCYTIC LEUKEMIA

Most patients with CLL ultimately require therapy. Because this is an incurable form of leukemia, the decision regarding therapy is judiciously made on the basis of symptoms or signs of anemia or thrombocytopenia. Adequate counseling of the patient to pursue an approach of watchful waiting requires extensive explanation. Patients must be informed that current therapeutic agents can further compromise the immune system and cause profound myelosuppression. Therefore, the decision to treat must be balanced with careful consideration of the risks of therapeutic intervention.

The current therapy based on a purine nucleoside analog (e.g., fludarabine) alone or in combination with another single agent (e.g., cyclophosphamide or rituximab) may result in a complete remission in approximately 5% to 25% of patients. Although earlier reports suggested higher complete remission rates (particularly in comparison to chlorambucil), the latest multi-institutional studies are reporting complete remissions in this range. The highest complete remission rates have been reported with triple drug therapy. Additional patients may achieve symptomatic improvement with a less than complete remission. In the context of a well-designed clinical trial, it may be appropriate to attempt to achieve eradication of minimal residual disease. However, in standard practice, there are not sufficient data to recommend continued therapy beyond 6 months for the purpose of minimal residual disease eradication in light of the potential infectious complications.

A standard course of fludarabine would be 25 mg/m^2/day intravenously on days 1 through 5 every 28 days. Each course may be repeated up to four to six cycles if there is evidence of improvement and no excessive toxicity is observed. Alternative regimens may incorporate either rituximab, cyclophosphamide, or both agents. Pentostatin is another purine nucleoside analog that has been approved for refractory hairy cell leukemia. In clinical trials, the combination of pentostatin, rituximab, and cyclophosphamide has been reportedly effective and well tolerated. However, it is important to understand that this use is not currently FDA approved for CLL.

In patients who relapse, repeat therapy may be useful if the initial response to a specific regimen was adequate and the response lasted for more than 1 year. The repeated use of fludarabine-based regimens can have a serious impact on bone marrow reserve. Consequently, patients should not be routinely exposed to repeated cycles of this agent without confirming that an objective response was demonstrated with adequate patient tolerance, including a follow-up bone marrow biopsy to confirm sufficient marrow reserve. While alemtuzumab has also been useful in patients who have failed to respond to fludarabine, this agent does not produce responses in those with bulky disease. Furthermore, alemtuzumab may produce excessive immunosuppression. Patients on this agent should receive prophylaxis to prevent infectious complications commonly encountered in the heavily immunosuppressed patients and should be monitored for reactivation of CMV antigenemia with institution of pre-emptive therapy to prevent CMV disease.

In patients with an autoimmune complication of CLL, the process must be controlled with optimal immunosuppressive therapy prior to initiating standard cytotoxic therapy. In patients with autoimmune hemolytic anemia or autoimmune thrombocytopenia, prednisone at 1 mg/kg/day is appropriate until the process is controlled. At this point, a careful taper is pursued. Modifications may be required including the addition of steroid-sparing agents (e.g., cyclosporine) in select cases. In all patients, consideration for prophylaxis against opportunistic infection should be incorporated with the administration of immunosuppressive therapy (e.g., against *Pneumocystis jiroveci* and herpes simplex virus/varicella-zoster virus).

Patients with resistant disease deserve consideration for an experimental approach. Some patients may enroll in stem cell transplant protocols with a matched related or unrelated donor. Reduced-intensity stem cell transplantation has been increasingly explored. In addition, novel therapeutic agents (e.g., flavopiridol) have induced durable responses in heavily treated patients, including those with high-risk cytogenetic features. In general, all patients with CLL should be encouraged to participate in clinical research in an effort to improve the ultimate clinical outcome of this incurable disease.

ment and what changes in symptoms or disease activity would prompt therapy. Inappropriate early intervention can increase the risks of immunosuppression without a long-term clinical benefit.

Current recommendations for initiating therapy include development of symptomatic disease with bulky lymphadenopathy, symptomatic organomegaly, or constitutional symptoms. Other indications for treatment may include development of either anemia or thrombocytopenia, rapid doubling of the absolute lymphocyte count (i.e., in less than 6 to 12 months), or an absolute lymphocyte count at which complications of tumor lysis or vascular compromise may be expected (e.g., >300,000/μL). The absolute value associated with leukostasis due to lymphocytosis is variable; some patients are able to tolerate higher values, and others develop symptoms of vascular compromise at lower levels.

Before initiating a course of cytoreductive therapy, it is essential to have a full understanding of the disease process. For example, there are many potential causes for either anemia and/or thrombocytopenia in patients with CLL. Consequently, there is a strong indication for obtaining a bone marrow aspirate and biopsy before starting on a therapeutic course. It is essential to evaluate the pattern of CLL infiltration into the bone marrow space. A careful assessment of red blood cell mass, numbers of megakaryocytes, and maturation of the granulocyte series will provide clues if there is a concomitant component of destruction as well as decreased production contributing to the reason for cytopenias. Careful evaluation of the iron stores and a search for other evidence of nutritional deficiency are important before starting on cytoreductive therapy. Patients with myelodysplasia in addition to infiltration of the bone marrow space by CLL will not always tolerate standard doses of cytotoxic chemotherapy. Finally, patients with more than one cause for anemia need to have a careful assessment of the etiology of bone marrow failure before simply treating the leukemia.

In patients who have progressive lymphadenopathy or splenomegaly, there may be value in documenting the extent of disease by imaging studies of the chest and abdomen. However, while this may be helpful in documenting a response to therapy it is not absolutely required as part of the clinical staging of CLL. There is an ongoing discussion of the necessity for computed tomography scans in staging these patients. In a patient who is suspected as having a malignant transformation to an aggressive lymphoma, a positron emission tomography scan may be helpful in directing the biopsy for confirmation of this complication.[64]

A thorough understanding of comorbid medical conditions in these patients is essential to optimal management. A careful assessment of renal and cardiac function may affect the selection of chemotherapeutic regimen. Dose modifications for either chemotherapy or immunotherapy or other agents that are used to treat complications of this disease require an understanding of these laboratory parameters. For instance, knowing whether a patient has diabetes could have an impact on whether or not steroids are included as part of the therapeutic plan.

As was noted previously, patients with CLL have altered immunity. Treatment with currently available therapies such as the purine analogs, rituximab, and alemtuzumab may significantly impair infectious immunity and increase susceptibility to viral reactivation and opportunistic infections. Prior exposure to tuberculosis or hepatitis may increase the risks associated with administration of some immunosuppressive agents that are used to treat this disease. It is recommended that hepatitis and CMV serologies are assessed prior to initiating therapy, as a positive result may affect the choice of treatment. Prophylactic antimicrobial therapy for prevention of herpes simplex virus/varicella-zoster virus and *P. jiroveci* is utilized during purine nucleoside analog therapy in a large proportion of patients and is particularly recommended for older patients, those with a history of varicella-zoster virus reactivation, or patients who have received prior therapy. Monitoring for CMV is required during treatment with alemtuzumab, and pre-emptive therapy is utilized to prevent CMV infection, which in some patients may be fatal. Careful attention to the entire medical history is imperative.

In patients who have developed an autoimmune complication of their underlying CLL, the plan should initially be directed at stabilizing that process before embarking on standard cytoreductive therapy. Patients with autoimmune hemolytic anemia or autoimmune thrombocytopenia are initially started on prednisone (e.g., 1 mg/kg/day) until the destructive process is controlled. At that time, the prednisone is cautiously and gradually tapered with close monitoring of the autoimmune process. In those patients who fail to respond to high-dose prednisone or are unable to tolerate this agent, cyclosporine or other immunosuppressive agents may be helpful and steroid-sparing. In selected patients, splenectomy affords an option to control either red blood cell or platelet destruction.

Assessment of the risks associated with initial therapy may dictate that the first course of therapy be delivered in an inpatient setting, depending on the age and medical condition of the patient. Patients who have a high peripheral absolute lymphocyte count can develop acute decompensation if confronted with tumor lysis following chemotherapy. Consequently, allopurinol is used for the first course of therapy. Patients might also experience respiratory decompensation and a cytokine release syndrome following the rapid administration of rituximab. Therefore, a graded approach to administration of the initial dose of this monoclonal antibody is required.[65] Preparation with diphenhydramine, acetominophen, and possibly steroids might be necessary for the initial course of therapy.

Selection of Chemoimmunotherapy for Chronic Lymphocytic Leukemia

In the development of a careful therapeutic plan, it will be important to select the optimal agents and schedule of administration. Until recently, the standard of care in the United States had been the use of alkylating agents either alone or with prednisone. Some investigators in Europe successfully utilized combined chemotherapy (CHOP or CAP), and in the United States, investigators have utilized COP or EPOCH regimens for treating CLL.[66] Chlorambucil had been the mainstay of oral chemotherapy for this disease in the community-based practice of medicine.[67,68]

In the early 1980s, Grever introduced the purine nucleoside analogs for patients with advanced and resistant disease.[69] The overall responses to either pentostatin or fludarabine were compromised because many of the patients had substantial prior therapy. However, pentostatin was capable of inducing a complete remission in even very heavily pretreated patients. Up to 10% of heavily pretreated patients could achieve a complete remission with single-agent fludarabine. Subsequent studies by M.D. Anderson using fludarabine in untreated patients found that up to 30% achieved a complete remission.[70] Combination studies over the past 10 years have shown that fludarabine is most effective when combined with another agent (either rituximab, cyclophosphamide, or both).

A prospective randomized Intergroup Study reported by Rai and colleagues showed that single-agent fludarabine was superior to chlorambucil for inducing a complete response and a durable remission.[68] Two additional randomized studies confirmed the benefit of fludarabine over standard therapy.[71,72] Although fludarabine is primarily approved for relapsed disease by the FDA, the off-label use of this agent as frontline therapy is common practice. There are continued efforts to improve the responses by combining fludarabine with other effective agents in this disease. Byrd and colleagues reported a prospective randomized trial in which patients were assigned either to fludarabine administered either simultaneously or sequentially with rituximab (i.e., the fludarabine was administered first, and the rituximab was delivered after the courses of purine analog were completed). There was a statistically significant improvement with the simultaneous administration of the two agents.[73]

Patients who have been treated with the combination of fludarabine and cyclophosphamide have been reported to have a complete remission rate in the 40% to 50% range with a median PFS of 33 to 44 months following achievement of response.[74–76] Most recently, the M.D. Anderson group reported the results of their trial, which included fludarabine, cyclophosphamide, and rituximab (FCR).[77] In previously untreated patients, complete response rates of 70% were reported, many patients being free of microscopic residual disease by flow cytometry and polymerase chain reaction. The median age of this group was 58 years. In this study, 33% of the patients were reported to have Rai stage III or IV disease.[78] While these results are currently the best reported response rates to date, there have not been as yet many confirmatory studies from other institutions. This regimen was felt to be well tolerated, but in older patients, myelosuppression with advanced stages of disease could be prolonged. There is one study from Tam and colleagues that followed the same FCR regimen.[79] In their report, 12 patients with CLL received this regimen as initial therapy for their CLL/SLL. Eight patients (67%) achieved a complete remission, and three additional patients achieved a nodular partial response. Patients with previously untreated disease were found to have the longest PFS. The median age of the patients in this small trial was similar to that in the M.D. Anderson report.

In another recently reported triple agent combination utilizing pentostatin, cyclophosphamide, and rituximab (PCR), the complete remission rate in previously untreated patients was 41%.[80] This regimen was equally effective in patients who were younger or older than 70 years of age. Patients who achieved a complete remission had a median duration of remission of 35.6 months. In contrast to the M.D. Anderson report with FCR, the median age of patients on this trial was 63 years (range: 38 to 80 years). Furthermore, 53% of patients had Rai stages III and IV disease. This study presented many of the molecular characteristics confirming that the patient population was indeed high-risk; 71% were unmutated for IgV, 34% were CD38-positive and ZAP-70-positive, and 36% had high-risk cytogenetics by FISH analysis. The regimen was well tolerated with no evidence of excessive morbidity. In contrast, the M.D. Anderson FCR regimen was associated with substantial myelosuppression, and 58 (26%) could not complete the intended six courses of FCR owing to persistent cytopenias. The study from Kay and colleagues involved two institutions, which may more closely reflect the community experience.[80] The differences between ages and stages of disease in the PCR study and FCR study make direct comparisons difficult. It is to be hoped that additional studies will be reported to confirm the encouraging complete remission rate observed with FCR at M.D. Anderson. Additional time will also enable an accurate estimate of response duration, which, on the basis of available data, appears longer than that reported with the PCR regimen. The German Cooperative Study Group for CLL currently has a multi-institutional study in progress that has randomized patients to fludarabine and cyclophosphamide versus FCR. In addition, it is hoped that a U.S. Intergroup trial will soon be launched that will prospectively compare the optimal regimens in a multi-institutional setting with comparably high-risk patients on each of the respective arms.

Alemtuzumab is a monoclonal antibody directed at human CD52, which is expressed on most mononuclear cells, including CLL cells. Alemtuzumab is currently FDA approved for treatment of fludarabine-refractory CLL and is associated with overall response rates up to 80% in untreated patients and up to 40% in previously treated patients.[81–83] Complete remissions may be achieved in a small percentage of patients. Alemtuzumab is particularly effective in patients with T-cell prolymphocytic leukemia and in B-cell CLL with deletions of 17p.[84,85] Its effectiveness is limited in patients with bulky lymphadenopathy, particularly those with lymph node areas greater than 5 cm in diameter. It should be noted that alemtuzumab is associated with severe myelosuppression as well as profound dysfunction of cellular immunity, necessitating antimicrobial prophylaxis during and after therapy as well as surveillance for CMV reactivation.[45]

Minimal residual disease status is defined as achievement of a complete remission by NCI-WG criteria but with persistent disease detectable on four-color flow cytometry. Improved outcomes in patients who achieve complete remissions without detectable minimal residual disease have led some researchers to investigate the potential benefit of therapy aimed at eradication of minimal residual disease following standard therapy. One study in which alemtuzumab was used to eradicate minimal residual disease found a statistically significant treatment-free interval and overall survival in patients achieving negative minimal residual disease status.[86] However, the high percentage of toxicities in terms of infections raises questions about the risk-benefit ratio of this approach. Furthermore, conclusions of superiority of one approach over another must be cautiously applied. Analysis of patient outcome after achieving negative minimal residual disease can be validly assessed by using a specific fixed landmark following therapy.[87] It is exciting that achievement of negative minimal residual disease status might have an impact on patient outcome, including survival, but study design is important in coming to these conclusions.[88] Future studies using agents that are less likely to cause severe immunosuppression could lead to improved outcomes with less toxicity. At the present time, eradication of minimal residual disease with alemtuzumab is recommended only in the context of a clinical trial.

Many ongoing studies are also exploring the value of eliminating residual microscopic disease with other agents, including the novel cyclin-dependent kinase inhibitor flavopiridol, which is one of the most active agents in patients with heavy exposure to other cytoreductive therapy.[89,90] This agent does not appear to significantly increase the risk of opportunistic infection.[91] Consequently, studies are under way to evaluate the contribution of this agent to patients with microscopic residual disease in hopes of enhancing the quality and number of complete remissions that are achieved with standard cytoreductive therapies.

In Figure 108-5, an algorithm is presented that suggests the current therapeutic options for patients with CLL who require initial

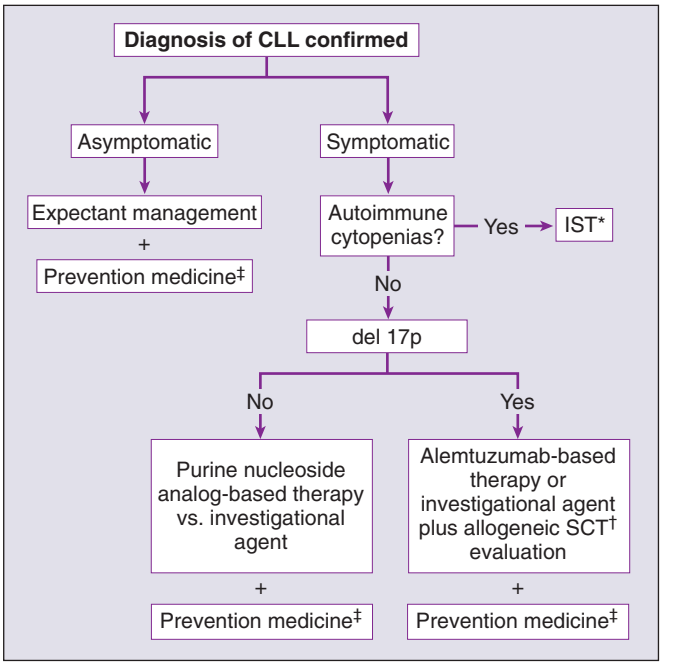

Figure 108-5 • Chronic lymphocytic leukemia initial treatment algorithm. *Immunosuppressive therapy, followed by standard therapy if indicated. †Allogenic stem cell transplantation if indicated. ‡Cancer screening, immunization, and management of infectious complications. Alemtuzumab is ineffective for bulky disease.

Table 108-5 Allogeneic Stem Cell Transplantation Using Reduced Intensity Conditioning Regimens in Chronic Lymphoid Leukemia*

Center	*N*	Median Age	Regimen	aGVHD (%)	cGVHD (%)	TRM (%)	EFS (%)	OS (%)
Germany 2003	30	53	FluBuATG	56	75	15	67 at 2 y	72 at 2 y
Spain 2005	30	53	FluMel	40	76	22	72 at 6 y	70 at 6 y
Britain 2006	41	54	Alemtuzumab based	41	33	26	45 at 2 y	51 at 2 y

aGVHD, acute graft-versus-host disease; cGVHD, chronic graft-versus-host disease; EFS, event-free survival; OS, overall survival; TRM, treatment-related mortality.
*The majority of these patients were heavily pretreated, and these results reflect outcomes from both related and unrelated donor transplants.

therapy. In addition, patients who relapse following their initial therapy require consideration. If the initial relapse or progressive disease requiring therapy develops in less than a year following the first regimen, then an alternative therapeutic plan should be considered. In patients who have a long-standing initial response and then relapse, consideration for utilizing a similar regimen may be reasonable. The long-term effects of multiple cycles of fludarabine (particularly in combination with an alkylating agent) raise concern about the impact on the bone marrow reserve as well as the potential for developing myelodysplasia.

Stem Cell Transplantation for Chronic Lymphocytic Leukemia

Both autologous and allogeneic hematopoietic stem cell transplantation have been studied for the treatment of CLL. Clinical trials of high-dose chemotherapy with autologous stem cell support have shown high rates of complete responses and, in some cases, improved overall survival when compared with standard chemotherapy even in high-risk patients.[92] However, despite these encouraging responses, there has been no plateau in the survival curve, indicating the lack of curative potential with this therapy. In addition, the treatment-related mortality may be as high as 10% and there is an additional increased risk of late development of myelodysplastic syndrome post-transplantation.[93] Patients who fail to achieve minimal residual disease status are likely to relapse early, and further relapses are usually heralded by loss of minimal residual disease status. Autologous stem cell collection may be hampered by prior therapy with purine nucleoside analogs, which additionally might limit the application of this therapy.[94]

Considering that CLL is currently incurable with either standard or high-dose chemoimmunotherapy, there is hope that allogeneic stem cell transplantation might have substantial benefit for high-risk patients. A graft-versus-leukemia effect has been demonstrated by the effectiveness of donor leukocyte infusions to induce remissions in patients who relapse post-transplantation and by a plateau in the survival curve in long-term follow-up of these patients.[95,96] Increasing agreement regarding allogeneic transplant eligibility criteria has facilitated the identification of patients who should be considered for this potentially curative approach.[97] As improvements in treatment-related mortality using reduced-intensity conditioning regimens have extended the eligibility for allogeneic transplantation to older patients and those with comorbid illnesses, eligibility criteria have expanded in recent years. These criteria will vary by transplant center, but certainly, younger patients who have drug-resistant or relapsed disease should be aggressively evaluated for nonmyeloablative allogeneic stem cell transplantation. A consensus regarding who should be considered might include younger patients with nonresponsive or early relapsing disease (within 12 months), patients who relapse within 24 months following therapy with a purine-based regimen, and patients with cytogenetic abnormalities predicting a shorter PFS following intensive chemoimmunotherapy.[8,88,98] The high success with engraftment, comparatively low treatment-related mortality, reasonable rates of acute and chronic graft-versus-host disease, and overall disease control have been encouraging. A review of recent studies using reduced-intensity conditioning regimens is summarized in Table 108-5.[47,99–101] Importantly, with improvements in the treatment and prophylaxis of graft-versus-host disease, there are decreasing differences in adverse outcomes between related and unrelated donor allogeneic transplant recipients; therefore, the lack of a sibling donor should not be considered a barrier to transplantation. As extensive prior therapy and advanced disease are associated with diminished disease-free survival post-transplantation, identification of potential patients should be pursued before the candidate has deteriorated. Considering the increased incidence of clonal lymphocytosis in relatives of patients with CLL, caution should be employed in screening a potential donor.

The decision regarding the use of a myeloablative conditioning regimen versus a reduced-intensity conditioning regimen is based on patient status at the time of transplantation. Younger patients without comorbid illnesses who have poorly controlled disease might benefit from myeloablative conditioning. Conversely, inferior outcomes have been demonstrated from using reduced-intensity conditioning in patients with extensive previous treatment, dense infiltration of the bone marrow with leukemic cells, and poor nodal disease control. Prospective randomized studies comparing the two treatment modalities are not available; however, one situation in which myeloablative conditioning has been shown to be clearly superior is in Richter's transformation, with a proportion of patients achieving long-term disease control but no patients surviving using reduced-intensity conditioning or conventional chemoimmunotherapy.[102]

As the role for allogeneic transplantation in CLL becomes more clearly defined and experience widens, further advances in prevention and treatment of graft-versus-host disease, management of relapse post-transplantation, and optimal donor selection will no doubt expand its application. Patients who are being offered an opportunity for stem cell transplantation should be vigorously persuaded to participate in ongoing active clinical research protocols.

OTHER B-CELL CHRONIC LEUKEMIAS

The use of immunophenotype analysis is critically important in understanding the variety of chronic lymphoid leukemias as depicted in Table 108-2 and Figures 108-3 through 108-6.

Prolymphocytic Leukemia

Galton described the distinct clinical entity of de novo prolymphocytic leukemia as a lymphoproliferative disorder with a more aggressive clinical course than CLL, occurring in older patients, and with

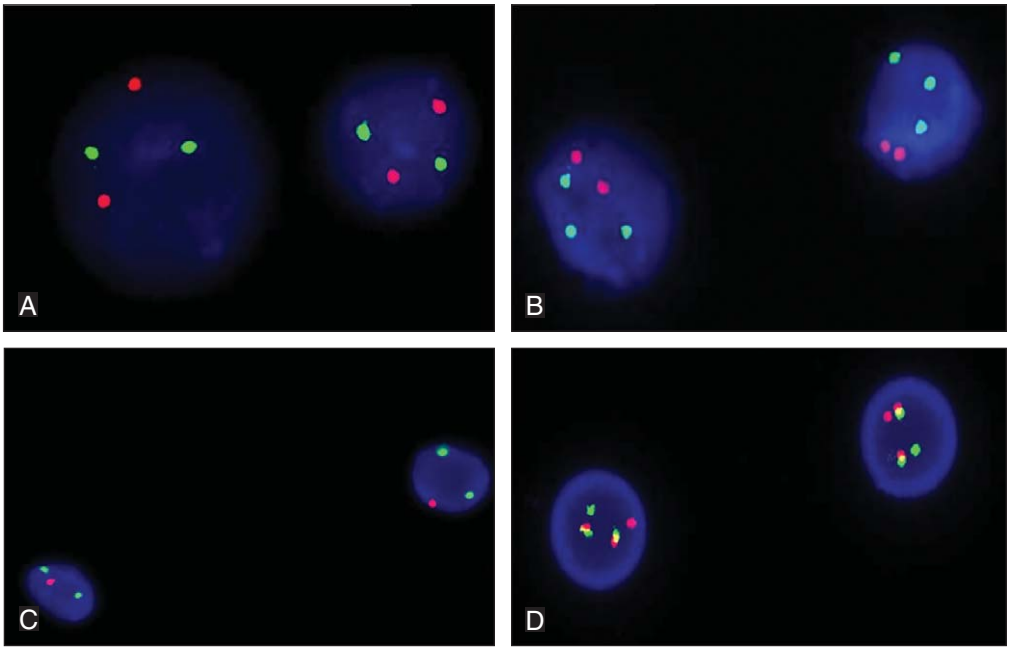

Figure 108-6 • Examples of fluorescence in situ hybridization (FISH) panels: **A,** Normal signal for 11q23-ATM locus (*green*) and 17p13-p53 locus (*red*). **B,** Trisomy of chromosome 12 (*green centromeric probe*) and normal signal for 13q14 (*red*). **C,** Deletion of 17p13-p53 locus (*red*) and normal signal for 11q23–ATM locus (*green*). **D,** Fusion signal (*yellow*) for 11q13-Bcl-1 locus (*red*) and 14q32-IgH locus (*green*) c/w translocation t(11;14)(q13;q32) Bcl-l-IgH. **D,** represents malignant cells from mantle cell lymphoma.

a high peripheral lymphocyte count with a predominance of prolymphocytes.[103] The cells have a distinct large nucleolus and represent more than 55% of the circulating neoplastic cells. Patients with prolymphocytic leukemia frequently have enlarged spleens without impressive lymphadenopathy.[29] The immunophenotypic profile differs both from that of CLL itself and that of the prolymphocytic transformation of CLL (CLL/prolymphocytic leukemia; shown in Fig. 108-2). Accurate recognition of this entity is important because the response to standard therapy for CLL is suboptimal.[83] Although several case studies show patient responses to purine nucleoside analogs, the projected median survival for this disease is shorter than that with CLL.

Hairy Cell Leukemia

In 1958, Bouroncle and colleagues described the clinical features of hairy cell leukemia (HCL).[104] This entity is discussed in Chapter 109.

Additional Lymphomas with Circulating Neoplastic Cells That Can Be Confused with Chronic Lymphocytic Leukemia

Mantle cell lymphoma (MCL) may present with a circulating neoplastic cell that morphologically can be confused with CLL. However, the distinctive immunophenotypic profile and the diagnostic cytogenetics that are characteristic of the t(11:14) demonstrable by FISH or the expression of cyclin D1 will enable this entity to be recognized (shown in Fig. 108-6). Considering the more aggressive clinical course of MCL and the requirement of different chemotherapy, this diagnostic distinction is critically important. Concern for recognizing this early in the course of the disease has prognostic and therapeutic implications and has been the underlying reason for recommending that FISH and immunophenotypic analysis include the appropriate markers and probes for this purpose.

Marginal Zone Lymphoma

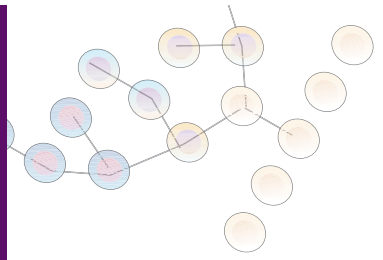
Marginal zone lymphoma may also present with circulating lymphoid neoplastic cells, making the distinction from CLL important. This entity may be indolent, but diagnostically and prognostically, it is different from CLL.[105–110] Patients with marginal zone lymphoma have been reported to respond to either splenectomy or rituximab, depending on the extent of bone marrow involvement and cytopenias.[102]

Lymphoplasmacytic Lymphoma

Patients with this indolent B-cell malignancy may present with features resembling both CLL and Waldenström's macroglobulinemia. The neoplastic cell morphologically resembles a plasmacytic lymphocyte. Immunophenotypically, the distinction can be made with respect to this entity as described in Table 108-2.

Chronic T-Cell Leukemias

Finally, a host of chronic T-cell leukemias and lymphomas are important to recognize in establishing the differential diagnosis. Patients with cutaneous T-cell lymphoma often have circulating abnormal lymphoid cells that can be distinguished immunophenotypically as being of T-cell origin. Most of these patients have a history of recurrent skin manifestations of the underlying disease. Patients with cutaneous T-cell lymphoma eventually progress to have more extensive lymphadenopathy and increasing complications with infection as a result of impaired immune function.[108]



Patients with T-prolymphocytic leukemia present with very high lymphoid counts, splenomegaly, progressive lymphadenopathy, and bone marrow failure. These patients are older and less responsive to standard chemotherapy. Alemtuzumab has been reported to provide some therapeutic response, but there is a clear need for experimental approaches to improve on the therapy of this disease.[85,109,110]

109 Hairy Cell Leukemia

Martin S. Tallman, Anaadriana Zakarija, and LoAnn C. Peterson

SUMMARY OF KEY POINTS

- Hairy cell leukemia (HCL) is an uncommon clonal B-cell lymphoproliferative disorder.
- Physical findings generally are confined to splenomegaly.
- The purine analogs are the therapeutic agents of choice today.
- Most patients who receive treatment with cladribine or pentostatin enjoy prolonged survival.
- BL22, an immunoconjugate of an anti-CD22 antibody linked to a truncated *Pseudomonas* exotoxin A, is a novel agent that has been very effective in the management of relapsed and refractory HCL.

INTRODUCTION

HCL is a rare chronic B-cell lymphoproliferative disorder with unique morphologic features and an excellent prognosis. Bouroncle described 26 patients in 1958 with what then was called "leukemic reticuloendotheliosis" and are credited with the initial description of HCL as a distinct clinical entity.[1] The disease is characterized by splenomegaly, pancytopenia, and infiltration of the bone marrow with lymphocytes that have irregular cytoplasmic projections when identified in the peripheral blood.[2,3] Although the origin of the malignant cell was unclear for some time, immunoglobulin gene rearrangements confirm that the disease is a clonal B-cell malignancy.[4–6] The pattern of expression of B cell-associated surface antigens (described later on) reflects a degree of differentiation between the mature B cell of chronic lymphocytic leukemia and the plasma cell of multiple myeloma.[7,8] A majority of patients have few symptoms at the time of diagnosis. Occasionally, however, patients present with life-threatening pancytopenia, symptomatic splenomegaly, serious infections, or constitutional signs and symptoms justifying treatment, or such problems may develop later in the disease course.[9,10]

Treatment strategies have evolved relatively rapidly during the last 50 years. Splenectomy was the first effective treatment described and remained the therapeutic modality of choice for many years. Although the mechanism of benefit is not clear, removing the spleen leads to normalization of the peripheral blood counts in approximately one half of all patients.[11–14] Interferon-α induces a high overall response rate; however, most responses are partial.[14–21] The most remarkable progress has occurred with the introduction of the two purine analogs, 2′-deoxycoformycin (2′-DCF; i.e., pentostatin)[22–33] and 2-chlorodeoxyadenosine (2-CdA; i.e., cladribine).[24,34–44] Most patients with both previously treated and untreated HCL achieve durable complete remission (i.e., CR) with either of these agents. With use of molecular techniques, however, minimal residual disease (MRD) can be identified in most if not all patients, suggesting that most patients are not actually cured of their disease. Nevertheless, with either purine analog, a majority of patients enjoy prolonged periods of progression-free and overall survival.

EPIDEMIOLOGY

Relatively little is known about the epidemiology of HCL, partly because of its rarity. In the United States, HCL represents 2% of adult leukemias, with only approximately 600 to 800 new cases diagnosed each year.[45,46] Although anecdotal reports of familial HCL have been published, no clear genetic predisposition has been recognized.[47–53] The median age at diagnosis is 52 years, and for unclear reasons, the disease occurs in men more often than in women, with a sex ratio of approximately 4 : 1.[54] Although reported incidence rates are similar in the United States and Great Britain,[45,46] classic HCL is rare in Japan, where a distinct variant form has been described.[55–57]

ETIOLOGY AND PATHOGENESIS

The etiology of HCL has not been determined. An association with exposure to benzene,[58,59] organophosphorus insecticides,[60] or other solvents[61] has been suggested but has not been confirmed.[62] Exposure to radiation,[63] agricultural chemicals,[59] or wood dust[46] and a previous history of infectious mononucleosis[61] also have been suggested as potential associations. Among a majority of patients, however, no such exposures can be identified. Cyclin D1, an important cell cycle regulator, may play a role in the molecular pathogenesis of HCL. Overexpression of the cyclin D1 protein has been described in HCL patients.[64,65] Unlike in mantle cell lymphoma, 11q13 rearrangements are not detected in most patients with HCL, suggesting other mechanisms of gene deregulation.[65]

The hairy cell may be derived from the memory B cell because the genome-wide expression profile is close to that of post-germinal center B cells.[66] Evidence suggests that hairy cells may come from B cells of the splenic marginal zone because hairy cells have a splenic expression signature that reflects tissue components, such as the marginal zone, that are not well represented in lymph node tissue.[67] However, expansion of the red pulp of the spleen, so characteristic of HCL, is in contrast with expansion of the white pulp, which involves the splenic marginal zone. Hairy cells express Bcl-2, an universal inhibitor of apoptosis.[68] Survival of hairy cells may be

further promoted by overexpression of FLT3, which activates the phosphatidylinositol-3 kinase (PI3K) pathway that activates anti-apoptotic signals.[66,69] Hairy cells produce basic fibroblast growth factor (bFGF) and overexpress bFGF tyrosine kinase receptor,[66,70] which can activate the PI3K-Akt cascade.[71]

The characteristic appearance of the hairy cells is due to expression of β-actin, which is polymerized to F-actin, located in the cortical cytoskeleton, in the peripheral part of the cell, that serves to support the hair-like projections.[66] The actual hair-like projections probably are due to increased expression of pp52, a leukocyte-specific intracellular phosphoprotein, that binds to F-actin.[72,73]

CLINICAL PRESENTATION

HCL should always be considered in the differential diagnosis for a middle-aged man presenting with splenomegaly and pancytopenia. Circulating hairy cells usually are present in the peripheral blood, but they may be difficult to detect. The initial evaluation should include a history and physical examination, a complete blood count with differential count, review of the peripheral blood smear, measurement of routine serum electrolytes, blood urea nitrogen and creatinine determination, assay of hepatic transaminases, bone marrow aspiration and core biopsy, and immunophenotyping by flow cytometry of peripheral blood or bone marrow aspirate.

At the time of diagnosis, most patients have symptoms attributable to anemia, neutropenia, thrombocytopenia, or splenomegaly. Approximately 25% of patients present with fatigue or weakness and 25% with infection; another 25% come to medical attention because of incidental discovery of splenomegaly or an abnormal peripheral blood count.[54]

Most patients are relatively well at the time of diagnosis. The most common and invariably the only physical finding is splenomegaly, occurring in approximately 80% of patients.[3,54] The spleen is palpable 5 cm below the left costal margin in approximately 60% of patients. Hepatomegaly occurs in approximately 20% of patients. Unlike in many other chronic lymphoproliferative disorders, peripheral adenopathy is uncommon at diagnosis, with less than 10% of patients presenting with peripheral nodes larger than 2 cm. Although adenopathy is not common at diagnosis, internal adenopathy may develop after a prolonged disease course[74,75] and is present in 75% of patients at autopsy.[76] The characteristic distribution in HCL probably is due to expression of the integrin receptor, $\alpha_4\beta_1$, by the hairy cells and its interaction with the vascular cell adhesion molecule-1 (VCAM-1) found on splenic and hepatic endothelia and in bone marrow and splenic stroma.[77]

Patients with HCL are susceptible to both gram-positive and gram-negative bacterial infections.[78] In addition, susceptibility to atypical mycobacterial infections,[79] particularly those due to *Mycobacterium kansasii*, as well as to invasive fungal infections, also has been documented.[78] Other opportunistic infections that have been reported include legionnaires' disease,[80] toxoplasmosis,[81] and *Listeria monocytogenes* infection.[82] The milieu specific for this increased susceptibility to infections comprises granulocytopenia, monocytopenia, poor granulocyte reserve and abnormal mobilization,[83] T-cell dysfunction,[84] and decreased numbers of dendritic cells and antigen-presenting cells.[85]

Rarely, patients with HCL may have associated systemic immunologic disorders,[86] including scleroderma and polymyositis[87] and polyarteritis nodosa.[88] HCL has been associated with other cutaneous lesions such as erythematous maculopapules[89] and pyoderma gangrenosum.[90,91] An associated coagulopathy manifested by factor VIII antibodies has been reported.[92] Osseous involvement also has been described, primarily lytic lesions in the axial skeleton, usually the proximal femur.[93,94] Rarely, osteolytic lesions may be associated with paraproteinemia.[95] A rare case of HCL occurring with systemic mast cell disease has been reported.[96]

LABORATORY EVALUATION

Pancytopenia is present in approximately 50% of patients with HCL at diagnosis; most other patients present with suppression of one or two cell lines.[3,54] Most patients with HCL present with leukopenia, although 10% to 20% of patients exhibit a "leukemic phase" with a white blood cell count above 10,000 to 20,000/μL. Monocytopenia is a characteristic but often overlooked finding.[1,3,54] Other laboratory findings include abnormal hepatic transaminase levels (19%), azotemia (27%), and hypergammaglobulinemia (18%), which rarely is monoclonal.[3,95,97] Unlike in chronic lymphocytic leukemia, hypogammaglobulinemia is uncommon.

Hairy cells can be identified in Wright's-stained blood smears from almost all patients with HCL, although the number of circulating hairy cells usually is low. Bone marrow often is inaspirable, resulting in a "dry tap." When aspiration is successful, however, hairy cells morphologically similar to those in the blood can be found.

The morphologic features of hairy cells are distinctive (Fig. 109-1). The neoplastic cells are approximately one to two times the size of a small lymphocyte. The nuclei are round, oval, indented, or monocytoid; rarely, they appear convoluted.[98] The nuclei are located in a central or eccentric position. The chromatin pattern is net-like in appearance, and nucleoli are indistinct or absent. The amount of cytoplasm varies, ranging from scant to abundant; a pale blue-gray color is characteristic. The cytoplasmic borders are irregular and exhibit fine, hair-like projections or ruffled borders. Occasionally, cytoplasmic granules are present. Rarely the cytoplasm exhibits basophilia, or rod-shaped inclusions that correspond to ribosomal lamellar complexes, observed on ultrastructural examination in approximately 40% of cases.[99]

Examination of the bone marrow core biopsy specimen is critical in the diagnosis of HCL because of its characteristic histopathologic appearance[100–103] (Figs. 109-2 and 109-3). The bone marrow usually is hypercellular in most patients, but this finding may be variable. Hairy cell infiltration may be diffuse, patchy or interstitial, or a combination of these patterns. In patients with *diffuse* involvement, large areas of the bone marrow are replaced by hairy cells, with complete effacement of marrow in some patients. With *patchy* infiltration, small subtle clusters of hairy cells are present focally or scattered throughout the bone marrow. Unlike in lymphomas, the hairy cells do not form well-defined, discrete aggregates; instead, they merge

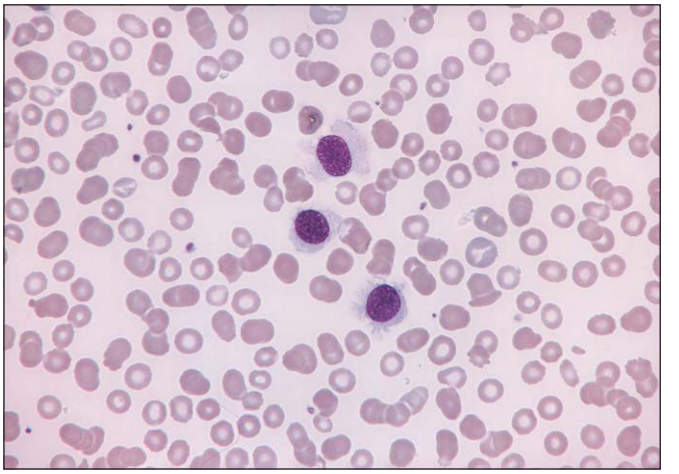

Figure 109-1 • Peripheral blood smear from a patient with hairy cell leukemia. This case was unusual in that the patient presented with leukocytosis. The hemoglobin and platelet count were reduced. The nuclei of the hairy cells are eccentrically located and exhibit a reticular chromatin. The cytoplasm is abundant, and the cytoplasmic borders are irregular, with fine, hairlike projections. (Wright-Giemsa stain.)

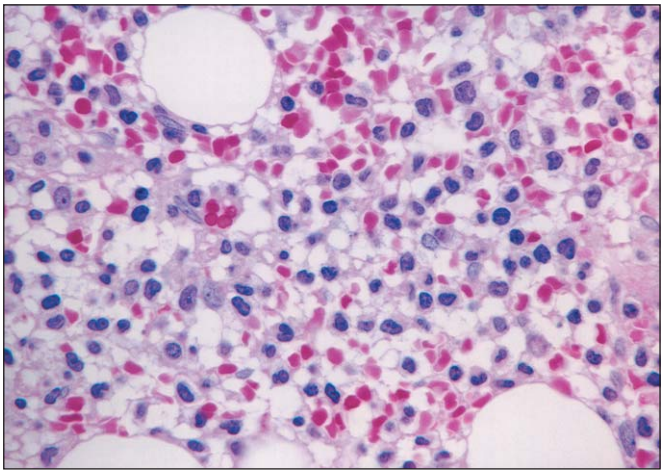

Figure 109-2 • Bone marrow trephine biopsy section from a patient with hairy cell leukemia. The bone marrow is hypercellular with a diffuse infiltration by hairy cells. The hairy cell nuclei are widely spaced, separated from each other by a pale, lightly eosinophilic cytoplasm. Many extravasated red blood cells are present between the hairy cells. (Hematoxylin and eosin stain.)

subtly with the surrounding residual hematopoietic tissue. In the *interstitial* pattern of involvement, variable numbers of hairy cells infiltrate between normal hematopoietic cells and fat, with preservation of the overall bone marrow architecture. Hairy cell nuclei in biopsy sections are round, oval, or indented and widely separated from each other by abundant clear or lightly eosinophilic cytoplasm; rarely, the cells are convoluted or spindle shaped. The nuclear chromatin is lightly condensed, nucleoli are inconspicuous, and mitotic figures are rare or absent. Extravasated red blood cells often are seen, and blood lakes, similar to those observed in the spleen, also may be observed. Reticulin stains of the bone marrow trephine biopsy specimen in HCL show a moderate to marked increase in reticulin fibers.

Normal hematopoietic cells usually are decreased in HCL; the number of granulocytes typically is more severely reduced than are erythroid precursors and megakaryocytes. In approximately 10% to 20% of patients with HCL, the bone marrow is hypocellular. The hypocellularity may be severe,[104] with a marrow appearance resembling that in aplastic anemia.

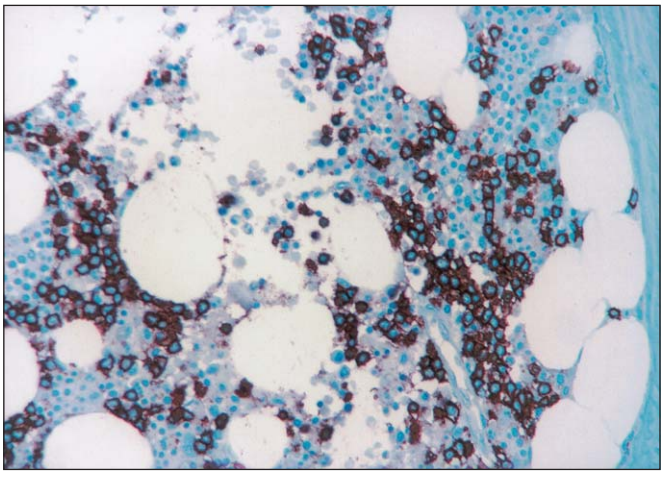

Figure 109-3 • Within the patchy infiltration of hairy cells seen on this biopsy section, the cells are accentuated by immunostaining for the B-cell antigen CD20. Residual hematopoietic precursors are negative for CD20. (Immunohistochemical stain for CD20.)

Historically, cytochemical demonstration of tartrate-resistant acid phosphatase (TRAP) activity has been used to confirm the diagnosis of HCL.[105] TRAP-positive cells are found in most cases of HCL at diagnosis, although the percentage of positive cells varies greatly among patients. A positive TRAP stain in conjunction with characteristic histopathology is essentially diagnostic of HCL. Today, however, the routine use of immunophenotyping by flow cytometry for the diagnosis of chronic lymphoproliferative disorders has made reliance on the TRAP stain less important.

Flow cytometric immunophenotyping is an essential part of the diagnostic evaluation, both to identify the characteristic immunophenotypic profile of HCL and to distinguish it from other chronic B-cell and T-cell lymphoproliferative disorders. Because hairy cells exhibit distinctive light scatter characteristics and immunophenotype, they can be identified even when present in very low levels (less than 1% of lymphocytes) in either the peripheral blood or bone marrow aspirate.[106] This property is useful not only at the time of diagnosis but also after therapy to assess for residual disease.[107]

Hairy cells show bright CD45 expression with increased forward and side scatter resembling that of large lymphocytes or monocytes. They exhibit a mature B-cell phenotype and express one or more heavy chains and monotypic light chains. The numbers of cases with expression of kappa or of lambda light chains are approximately equal. Surface immunoglobulin is of moderate to bright intensity. Hairy cells strongly express pan-B-cell antigens, including CD19, CD20, CD22, and CD79b. They usually are negative-staining for CD5, CD10, and CD23. They strongly express CD11c, CD25, and FMC7. CD103, an antigen expressed on mucosal T cells and some activated T cells, is expressed in a majority of cases of HCL.[106,108] Approximately 35% of patients have a variant immunophenotype, but the hairy cells from such patients have the characteristic morphologic features of classic hairy cells, and these patients have the same excellent response to treatment with purine analogs.[109] Several B cell-associated antibodies, including CD20, CD79a, and DBA.44, react with hairy cells in fixed, routinely processed tissue sections. Although these antibodies are not specific for HCL, they are useful in documenting the B-cell nature of the infiltrate and highlighting the extent of bone marrow infiltration at the time of diagnosis and after therapy.[110–113]

Splenic involvement in HCL is characterized by diffuse infiltration of the red pulp cords and sinuses, with atrophy or replacement of the white pulp. Blood-filled sinuses, lined by hairy cells, often are present but are not pathognomonic for HCL; they have been referred to as "pseudosinuses."[114] The liver shows both sinusoidal and portal infiltration by hairy cells. Involved lymph nodes commonly exhibit partial effacement, with hairy cells infiltrating the paracortex and medulla in a leukemic pattern. The leukemic cells often surround residual lymphoid follicles and extend through the capsule.

Clonal cytogenetic abnormalities are present in approximately two thirds of patients with HCL. Karyotype analysis is rarely required or useful to establish the diagnosis, however. The most frequently involved chromosomes include chromosomes 1, 2, 5, 6, 11, 14, 19, and 20. In particular, chromosome 5 is altered in 40% of patients, most commonly as trisomy 5, pericentric inversions, or interstitial deletions involving band 5q13.[115–117]

DIFFERENTIAL DIAGNOSIS

Considerations in the differential diagnosis for HCL include other chronic B-cell lymphoproliferative disorders associated with splenomegaly, including prolymphocytic leukemia, splenic marginal zone lymphoma, and hairy cell variant (Table 109-1). Patients with prolymphocytic leukemia typically present with splenomegaly, but this disorder usually can be distinguished from HCL by the marked leukocytosis, the characteristic morphologic appearance of the prolymphocytes, and an immunophenotypic profile different from that for HCL.[118–121] Splenic marginal zone lymphoma exhibits some

Table 109-1 Differential Diagnosis for Hairy Cell Leukemia

Chronic lymphocytic leukemia
Low-grade lymphoma
Agnogenic myeloid metaplasia
Systemic mastocytosis

clinical and morphologic features similar to those of HCL, but in contrast, the bone marrow infiltrates are sharply demarcated from the surrounding normal tissue, and intrasinusoidal infiltration often is prominent. In addition, the immunophenotypic profile differs from that for HCL, including negative staining for CD103.[122–125] Hairy cell variant exhibits morphologic features that are intermediate between those of HCL and prolymphocytic leukemia. Unlike HCL, hairy cell variant is associated with prominent leukocytosis, lack of monocytopenia, and absence of CD25 expression.[126–130] Finally, infiltrates of systemic mastocytosis in the bone marrow may resemble those seen in HCL. Immunohistochemistry studies, however, show the mast cells, unlike hairy cells, to be negative for B-cell antigens and positive for tryptase.[131]

TREATMENT

Indications

Hairy cell leukemia almost always has an indolent course, with some patients surviving 10 years without need for therapy.[132] In a majority of patients, however, progressive disease eventually leads to complications resulting from anemia, bleeding, splenomegaly, or recurrent infections. Therapy is indicated when the patient has significant cytopenias; symptomatic organomegaly or adenopathy; repeated infections or constitutional signs and symptoms such as fever, night sweats, or fatigue. Persistent blood counts showing an absolute neutrophil count (ANC) less than 1000/μL, a hemoglobin less than 11.0 g/dL, or a platelet count below 100,000/μL are guidelines that can serve as indications for therapy.

Role of Splenectomy

Splenectomy was the first effective therapy for HCL and remained the initial treatment of choice until approximately 2 decades ago.[11–14] After splenectomy, counts for all three cell lines return to normal in approximately 40% to 70% of patients.[13,133] This response is maintained for a median of 20 months in approximately two thirds of patients, and the overall 5-year survival rate is approximately 70%.[133] No correlation has been found between spleen size and response to splenectomy. Splenectomy may have a possible role in an occasional patient to establish the diagnosis, in rare cases of splenic rupture, or in patients with life-threatening thrombocytopenia or a significant bleeding diathesis, because emergency splenectomy can lead to a rapid rise in the platelet count. Except in these very unusual circumstances, however, little, if any, role for splenectomy is recognized since the introduction of the purine analogs.

Chemotherapeutic Approaches

Cytotoxic chemotherapy was given for the treatment of HCL before the advent of more effective therapies in the early 1980s. A variety of agents, including anthracyclines,[134] alkylating agents (chlorambucil),[135] and high-dose methotrexate,[136] demonstrate activity. Combination chemotherapy, such as the CHOP regimen (cyclophosphamide, hydroxyldaunoribicin, Oncovin [vincristine sulfate], prednisone), produces long-lasting normalization of peripheral blood counts.[137] In one report in the literature of successful syngeneic (identical twin) bone marrow transplantation, the patient remained free of disease at least 15 years later.[138] Although HCL is sensitive to chemotherapy, significant myelosuppression and toxicity are associated with use of this modality. Therefore, conventional chemotherapy is now a therapy of only historical interest.

Interferon

Interferon was first reported in 1984 to be an effective therapy for patients with HCL[15]; since then, many large studies have confirmed its activity.[15–21] The precise mechanism of action of interferon is not known, but its activity may be attributable to a decrease in the production of cytokines such as granulocyte colony stimulating factor, granulocyte macrophage colony stimulating factor, interleukin-3, and interleukin-6, perhaps related to the characteristic monocytopenia associated with interferon treatment.[139] Studies suggest that interferon-α results in apoptotic death of hairy cells, mediated by tumor necrosis factor-α.[140] Despite a high overall response rate of 75% to 90%, most patients achieve only partial remission (i.e., they have a partial response [PR], defined as normalization of all peripheral blood counts).[18,19] Interferon commonly is administered subcutaneously at a dose of 2 million international units/m^2 three times a week for 12 to 18 months. During the first 2 months of treatment, the white blood cell count and hemoglobin often decrease, occasionally precipitating transfusion. The platelets normalize earliest in responding patients, followed by the hemoglobin and the white blood cell count. An ANC greater than 1500/μL is achieved after a median of 5 months of therapy. The most common manifestations of toxicity include flu-like symptoms, anorexia and fatigue, nausea and vomiting, diarrhea, dry skin, peripheral neuropathies, and central nervous system dysfunction, usually manifested as depression or memory loss. Elevated hepatic transaminases are the most common laboratory abnormality, other than myelosuppression. The median failure-free survival period after discontinuing interferon ranges from 6 to 25 months in different series.[18–20,141] Patients with more than 30% hairy cells in the marrow or a platelet count less than 160,000/μL at the end of treatment have a higher risk of early relapse.[18–20] In addition, patients who express the CD5 antigen appear to respond poorly to interferon.[142] Patients can be maintained on long-term interferon at a dose of 3 million units subcutaneously given three times a week with minimal toxicity. Sixty percent of patients have sustained their initial response for a median of 5 years, 9% discontinued therapy early because of unexpected neurologic toxicity, and only 13% stopped therapy because of progressive disease.[21] Although treatment of HCL with interferon is effective, complete responses (CRs) are uncommon, and failure-free survival usually is short after discontinuation of treatment. Furthermore, the purine analogs have completely supplanted interferon for the treatment of newly diagnosed HCL.

Purine Analog Therapy

As early as the 1960s, Giblett and colleagues observed that 30% of children with severe combined immunodeficiency syndrome lacked the enzyme adenosine deaminase (ADA).[143] It appeared that the accumulation of the triphosphorylated form of deoxyadenosine was responsible for lymphocyte depletion.[144] Therefore, the deliberate inhibition of ADA was recognized as a potentially useful antileukemic strategy. The methods to accomplish this therapeutic effect included the development of agents to bind irreversibly to ADA or to resist the action of the enzyme. These agents affect both dividing and nondividing cells.[145] After purine analog therapy, accumulation of deoxyadenosine triphosphates leads to DNA strand breaks and inhibition of DNA repair, which ultimately results in cell apoptosis.

Pentostatin (2′–Deoxycoformycin)

Pentostatin, or 2′-DCF, was the first agent to induce a significant number of CRs in HCL.[22,146] This drug binds to ADA, resulting in irreversible inhibition of the enzyme,[147] which is found in all lymphoid cells and is important in purine metabolism. In most studies, CR is defined by disappearance of hairy cells in the blood and bone marrow, complete normalization of peripheral counts (hemoglobin concentration greater than 120 g/L, platelet count greater than 100,000/μL, and ANC greater than 1500/μL), and resolution of splenomegaly and lymphadenopathy. A partial remission (i.e., PR) requires normalization of blood counts, greater than 50% reduction in hairy cells in the bone marrow, and greater than 50% reduction in splenomegaly.

A number of studies demonstrate the efficacy of 2′-DCF in patients with HCL (Table 109-2).[23–33] A large prospective, randomized study showed that the CR rate and relapse-free survival rate are significantly better with 2′-DCF than with interferon.[31] Various dosing schedules have been reported in early studies, but the current dose is 4 mg/m^2 given by intravenous infusion every 2 weeks until maximum response. The median number of cycles required by patients until best response has been from 6 to 12 cycles.[24,27,29,33] In one of the earlier studies conducted by the Eastern Cooperative Oncology Group, most patients achieved maximal response within the first 6 months.[27] Therapy is relatively well tolerated; neutropenia, fever, and infections are the most frequent toxicities.[25,27,32] One of the largest published series providing long-term evaluation was reported by the Southwest Oncology Group.[25] A total of 241 patients received 2′-DCF on a phase III trial comparing interferon and 2′-DCF; 154 were randomized to receive 2′-DCF initially, with crossover of 87 additional patients from the interferon group after it failed to produce improvement. Seventy-two percent of patients achieved a CR with 2′-DCF. Long-term survival was not statistically different based on initial treatment; in both groups overall survival was 90% at 5 years, and 81% at 10 years (Fig. 109-4). With longer follow-up, 2′-DCF does not appear to be curative in all patients. Studies with follow-up periods longer than 5 years after treatment report relapses in 15% to 48% of patients.[23–25,30]

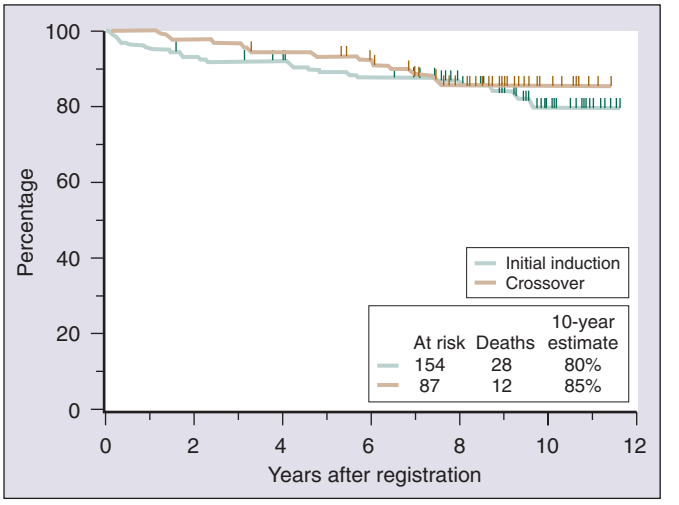

Figure 109-4 • Overall survival of 241 patients with HCL treated with 2′-deoxycoformycin (2′-DCF), stratified by treatment up front or after failure on interferon. (Data from Flinn IW, Kopecky KJ, Foucar MK, et al: Long-term follow-up of remission duration, mortality, and second malignancies in hairy cell leukemia patients treated with pentostatin. Blood 2000;96:2981.)

Cladribine (2-Chlorodeoxyadenosine)

Cladribine, or 2-CdA is a purine analog that is resistant to the action of ADA. This agent accumulates in the lymphoid cells, possibly because they are rich in the enzyme deoxycytidine kinase.[144] This enzyme phosphorylates 2-CdA to the active 5′-triphosphate form, creating a deoxynucleotide that cannot readily exit the cell. This compound inhibits ribonucleotide reductase, which results in decreased synthesis of deoxynucleotides. Both DNA synthesis and repair are impaired.

2-CdA was first reported to be effective in HCL by Piro and colleagues in 1990.[34] Twelve patients were given a single cycle of 2-CdA at a dose of 0.1 mg/kg per day by continuous infusion for 7 days; a CR was obtained in 11 of the 12 patients within 8 weeks of treatment. A number of subsequent studies have shown similar remarkable efficacy (Table 109-3).[24,34–44] Clear orders for use of the 7-day infusion pump are critical because poor response to therapy has been attributed to underdosing of drug when 1 day's dose was administered over 7 days.[148] Excellent results with alternative dosing schedules and routes of administration have been reported (Table 109-4).[149–152] In the study conducted by Von Rohr and colleagues,

*2-CdA dose: 0.1 mg/kg/d × 7 days by continuous infusion.

2-CdA was administered as a subcutaneous bolus injection of 0.14 mg/kg per day for 5 days to 62 patients.[152] The results were similar to those of previous studies, with 76% of patients achieving a CR and an overall response rate of 97%. Robak and colleagues conducted a prospective randomized trial comparing a standard 5-day schedule with a 6-week schedule, which had been reported to be potentially less toxic.[153,154] These investigators observed similar CR rates, overall response rates, and progression-free- and overall survival rates, with no less toxicity.[154] (Fig. 109-5).

The most common toxicities associated with 2-CdA treatment are neutropenia and fever. Investigators at the Scripps Clinic reported results for the largest collection of patients with HCL treated with 2-CdA. Of 349 patients who received a single cycle of 2-CdA, 87% had grade 3 or 4 neutropenia, 42% had a neutropenic fever, but only 13% had documented infections, none of which were opportunistic infections.[38] Most of the fevers seen with administration of 2CdA do not appear to represent infection but may be due to release of cytokines. Owing to the high incidence of neutropenic fever, these investigators conducted a prospective trial examining the effect of filgrastim in 35 patients receiving 2-CdA.[155] Filgrastim was administered on days 3 through 1, and again after completion of 2-CdA therapy until the ANC was over 2000/μL on two consecutive days. When compared with historical controls, patients in the filgrastim treatment group more rapidly achieved an ANC greater than 1000/μL, in 9 days versus 22 days. The incidence of fever and need for hospital admission, however, did not differ between the two groups. Therefore, the routine use of prophylactic filgrastim is not indicated in this setting. Such a strategy may be useful in the rare patient who presents with a life-threatening infection and requires therapy with a purine analog.

Although response rates are very high with 2-CdA, they are not sustained in all patients. The experience with 2-CdA is similar to that with 2′-DCF in that relapses have appeared with longer follow-up (see Table 109-3). In a report from the Scripps Clinic, after a median follow-up period of 108 months, 37% of patients relapsed, with a median time to relapse of 42 months.[39] Initial PR is associated with a shorter duration of remission (Fig. 109-6A and B). The response to re-treatment remains very good. Of the patients who relapsed, 79% received re-treatment with 2-CdA; the overall response rate was 92%, including 75% with a complete remission.[39] One retrospective study has suggested that durability of response is greater with 2′-DCF than with 2-CdA: At 45 months of follow-up for each, relapse rates were 9.7% and 29%, respectively.[24] To date, no randomized trials of the two agents have been conducted to resolve this issue. Thus far,

Table 109-4 Alternate Schedules of 2-Chlorodeoxyadenosine Therapy for Treatment of Hairy Cell Leukemia

Study	Dosing	Route of Administration	Response(s)
Juliusson et al[149]	3.4 mg/m^2/d × 7 days	Subcutaneous injection	*CR*: 75% after 1 cycle, 85% after 2 cycles

Blood 2007;109:3672.)

no plateau has been reached with either agent, and relapses continue to occur after initial treatment.

Immunosuppression with Purine Analogs

Treatment with both 2′-DCF and 2-CdA results in prolonged immunosuppression.[41,156–158] A decrease in the total lymphocyte count occurs with 2′-DCF, with a greater reduction in T cells than in B cells or natural killer cells.[157] The levels of $CD4^+$ and $CD8^+$ cells decrease to fewer than 200 cells/μL for at least 6 months after 2′-DCF treatment is discontinued. In a series of 15 patients with HCL treated with 2′-DCF with long follow-up, the median time to recovery of $CD4^+$ lymphocyte counts to normal was 54 months.[158] Treatment with 2-CdA induces similar suppression of $CD4^+$ cell counts.[35] The median time to recovery of $CD4^+$ cell counts to normal after completion of 2-CdA therapy was 40 months. Treatment with 2-CdA affects one distinct subset of $CD4^+$ T cells. The $CD4^+/CD45RA^+$ subset is significantly reduced for up to 5 years; the $CD4^+/CD45RO^+$ T cells, which secrete cytokines and enhance B cell function, are not suppressed.[159] In addition, recovery of CD8 and NK cells is more rapid; they normalize within 3 months of treatment with 2-CdA.[160] This finding may explain why opportunistic infections, other than an occasional case of herpes zoster, are surprisingly uncommon.[33,38,41,159]

PROGNOSIS

Before the routine introduction of interferon therapy, survival at 4 years was reported to be 68%.[161] With the use of purine analogs, durable remissions are obtained, and even after relapse, retreatment with a purine analog results in good responses. The 5-year survival rates are greater than 85%.[24,25,29,33,38,39] Flinn and colleagues reported long-term results for 241 patients with HCL treated with 2′-DCF; the overall survival rate was 90% at 5 years and 81% at 10 years (see Fig. 109-4).[25] The leading causes of death were second malignancies and infection. Only 2 of 40 deaths in this series were attributable to HCL.

A series of 209 patients with HCL treated with 2-CdA at the Scripps Clinic have been followed for at least 7 years.[39] The overall survival rate at 9 years is 97% (see Fig. 109-6A). At least three other long-term follow-up studies of 2′-DCF or 2-CdA have been published.[162–164] After a median follow-up period of 8.5 years, Jehn and coworkers reported a relapse rate of 39%, but the overall survival rate at 12 years was 79%.[162] At Northwestern University, among 86 patients, the overall survival rate at 12 years was 87%.[163] After a median follow-up period of 9.7 years, 36% of patients had relapsed. Else and colleagues reported a study with one of the longest follow-ups of patients who received a purine analog, 2-CdA in 34 patients and 2′-DCF in 185, with a median follow-up period of 12.5 years.[164] Although an earlier report from the same group of investigators suggested a lower relapse rate associated with use of 2′-DCF, in this more

recent report, the response, relapse, and overall survival rates at 10 years were similar.

OTHER CONSIDERATIONS IN MANAGEMENT

Evaluation of Minimal Residual Disease

The remarkable activity of the purine analogs has led to the examination of post-treatment bone marrow biopsy specimens to detect MRD in patients otherwise in complete remission. Immunohistochemistry studies using anti-CD20, DBA.44, and anti-CD45RO antibodies in paraffin-embedded biopsy specimens have been used most frequently.[109–112,165–167] Newer techniques for MRD detection include flow cytometric immunophenotyping and consensus primer polymerase chain reaction (PCR) assay.[107] Depending on the criteria used, 13% to 51% of patients in apparent complete remission have evidence of MRD[109–111,168] (Fig. 109-7). In one study, no statistically significant difference in incidence of MRD was found between patients receiving 2′-DCF and those given 2-CdA.[168] The presence of MRD appears to predict relapse.[111,167] In one study evaluating MRD in 66 patients, 50% of those with MRD relapsed, whereas only 6% of patients without MRD relapsed.[168] Two trials have suggested that administration of the anti-CD20 monoclonal antibody rituximab after 2-CdA therapy is effective in eradicating MRD.[169,170]

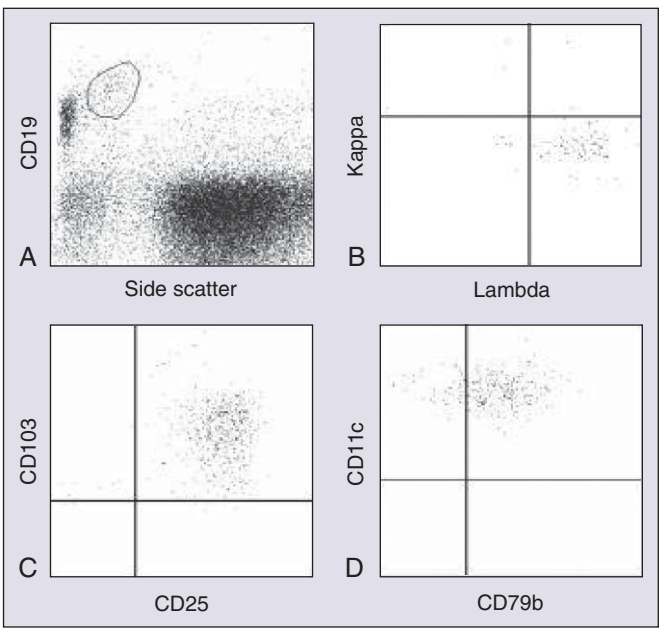

Figure 109-7 • Representative example of flow cytometric detection of hairy cell leukemia, comprising 0.2% of a peripheral blood sample. **A,** Distribution of CD19 staining versus side-scattered light intensity. The *circled* population represents the hairy cell population. Note the increased side-scattered light intensity that is characteristic of hairy cell leukemia. **B,** Distribution of kappa versus lambda staining for this hairy cell population, showing that it is lambda positive and kappa negative, which is indicative of its clonal nature. **C,** Distribution of CD25 versus CD103. **D,** Distribution of CD79b versus CD11c. These histograms demonstrate the characteristic CD19-, CD103-, CD11c-, and CD25-positive staining in hairy cell leukemia. (Data from Robak T, Jamroziak K, Gora-Tybor J, et al: Cladribine in a weekly versus daily schedule for untreated active hairy cell leukemia: final report from the Polish Adult Leukemia Group (PALG) of a prospective, randomized, multicenter trial. Blood 2007;109:3672–3675.)

Whether such a strategy prolongs overall survival, however, is not clear.

Treatment of Relapse

Relapse often is detected on bone marrow biopsy alone, and immediate retreatment is not necessary. In a study by Kraut and colleagues, relapse was detected at a median of 30 months from achievement of remission with 2′-DCF, but retreatment was initiated at a median of 60 months after first remission.[30] Retreatment with purine analogs resulted in complete remission in five of seven patients. Patients with an initial response to 2-CdA also respond well to retreatment with a purine analog. In the Scripps Clinic series, 76 of 207 patients relapsed, and 79% received retreatment with 2-CdA. The overall response rate was 92%, including 75% with a CR.[39] The median duration of the second response was 35 months, which is comparable with the 42-month duration of first response. Responses continue to be seen even with a third cycle of 2-CdA in 80% of patients receiving retreatment. In patients who relapse after purine analog therapy, re-treatment may be with either 2-CdA or 2′-DCF. Alternative agents for treatment of relapsed or treatment-refractory disease include BL22 and rituximab (see "New Therapies").

Risk of Second Malignancies

An association has been noted between HCL and second malignancies, although such a relationship is difficult to determine with certainty. Malignancies that have been observed in patients with HCL include melanoma, prostate cancer, gastrointestinal cancers, non-Hodgkin's lymphoma, and nonmelanomatous skin cancers. It is not clear whether HCL itself increases risk or whether the type of therapy may play a role. Kampmeier and colleagues reported a significantly increased incidence of second malignancies in patients with HCL treated with interferon.[171] The British Columbia Cancer Agency reported data from a 20-year follow-up study of 117 patients; a second malignancy developed in 31%; 30% of these malignancies were diagnosed before the diagnosis of HCL.[172] The risk was elevated regardless of the type of therapy. This association has not been uniformly observed, however.[173,174] Investigators at the M.D. Anderson Cancer Center reported no excess of second malignancies among 350 patients who received either interferon, 2-CdA, or 2′-DCF.[175] The immunosuppression due to the purine analogs may play a role in the increased malignancy incidence, but the evidence is not clear. Long-term follow-up studies of patients with HCL treated with 2′-DCF have not demonstrated a statistically significant increased risk of second malignancies.[23,25] Other studies have suggested that treatment with 2-CdA is associated with an increased cancer risk.[38,39,176] In a review of the Scripps Clinic experience with 349 patients, 8% of patients had a second malignancy that developed at a median time of 62 months after the diagnosis of HCL, and 21 months after treatment with 2-CdA.[38] Of note, 11% of the patients in this study had a diagnosis of malignancy before the diagnosis of HCL. It is not clear, therefore, that therapy increases risk; HCL itself may be associated with an inherent predisposition to malignancy.

New Therapies

The anti-CD-20 monoclonal antibody rituximab has been tested in patients with HCL refractory to other treatments.[177,178] In their series of 11 patients with HCL treated with rituximab, Hagberg and colleagues reported an overall response rate of 64% (Table 109-5).[179] The median duration of response in this group was 14 months. The largest published report describes 24 patients who received four weekly doses of rituximab.[180] All of the patients had relapsed after prior treatment with 2-CdA, and the median time since treatment was 73 months. Thirteen percent of patients had a CR and 13% had a PR, for an overall response rate of 26%. One third of responders

Table 109-5 Antibody and Immunoconjugate Therapy in Treatment of Hairy Cell Leukemia

relapsed after a median follow-up period of 14.6 months. It appears that rituximab has activity in some patients with HCL. Thomas and colleagues[181] used this agent to treat relapsed or refractory disease in 15 patients and observed an overall response rate of 60%.

CD-25, also known as Tac, is the α subunit of the IL2R and is expressed in 80% of patients with HCL.[182] LMB-2, anti-Tac(Fv)-PE38, is an immunotoxin that contains the variable heavy domain of anti-Tac fused to the amino terminus of a 38-kD truncated form of the *Pseudomonas* exotoxin.[183] Tac has demonstrated some efficacy in patients with $CD25^+$ hematologic malignancies. After binding to CD25, the compound is internalized, leading to apoptosis and cell death. Of four patients with HCL refractory to standard therapies, including 2-CDA and interferon regimens, all demonstrated a response to LMB-2, with one CR.[183] LMB-2 is well tolerated and appears to have no hematologic toxicity. Larger studies need to be conducted to better determine the safety and efficacy of this agent.

Another promising immunotoxin under investigation is BL22, a recombinant immunotoxin containing anti-CD22 monoclonal antibody and PE38, the *Pseudomonas* exotoxin. CD22 is expressed by normal B cells and B-cell leukemias and lymphomas, including HCL, but is not found on stem cells.[184] Kreitman and colleagues recently updated their original study[185] and presented the results for 23 patients with HCL treated with BL22.[186] The overall response rate was 83%, with 65% of patients attaining a CR. Of the complete responders, only one had MRD as determined by immunohistochemistry studies of bone marrow, and none had MRD when peripheral blood was tested by PCR analysis. Arons and colleagues showed that patient-specific relative quantitative (RQ) PCR assay was the most sensitive test to detect MRD in HCL, compared with immunophenotyping by flow cytometry and consensus PCR analysis.[187] The median follow-up period was 12 months, and of the four patients who relapsed, retreatment resulted in a CR in three. This therapy appears to be well tolerated, although a reversible hemolytic-uremic syndrome developed in two patients. No other hematologic toxicity or decrease in T-cell count was observed.[185] BL22 is the first therapeutic agent since the purine analogs to effect a high CR rate.

These new therapies are effective in patients with HCL that is resistant or refractory to the purine analogs and therefore constitute another treatment option. The durability of effect remains to be determined in larger studies with longer follow-up.

HA22 is a new immunoconjugate, which differs from BL22 by two amino acids, that improves the binding of the agent to CD22 by a factor of 14.[188] Such increased affinity results in better cytotoxicity against B-cell lines, as well as against cells isolated from patients with HCL and chronic lymphocytic leukemia.[189] Clinical trials with this new agent are under way.

Increased angiogenesis has been reported in patients with HCL.[190–192] Microvessel density is higher in the marrow of patients with active HCL than in normal control subjects. Treatment with both interferon-α and 2-CdA is associated with a decrease in microvessel density.[190–192] These observations suggest a potential role for antiangiogenesis agents.

General Principles of Management

Box 109-1 presents the recommended approach to management of HCL. Figure 109-8 summarizes the treatment strategies developed at Northwestern University.

Box 109-1. APPROACH TO THE MANAGEMENT OF HAIRY CELL LEUKEMIA

For patients with newly diagnosed HCL who require treatment (as indicated by absolute neutrophil count less than 1000/μL, hemoglobin less than 11.0 g/dL, and platelet count less than 100,000/μL; symptomatic organomegaly; or repeated infections), we administer 2-chlorodeoxyadenosine (2-CdA) 0.1 mg/kg per day by continuous intravenous infusion for 7 days as an outpatient procedure by portable pump using a midline percutaneous intravenous central catheter (PICC; see Fig. 109-8). Other schedules may be equally effective. If fever with temperatures of 100.5° F or higher develops while the patient is neutropenic, blood and urine cultures and chest radiography are performed, and a broad-spectrum oral antibiotic such as ciprofloxacin 750 mg given orally twice daily is administered. If cultures are sterile at 24 to 48 hours, an anti-inflammatory agent such as naproxen 250 mg given orally twice daily is added for 2 to 4 days; 2-CdA is not discontinued. Hematopoietic growth factors are not routinely given after treatment. The platelet count usually normalizes first (platelets are the first cell line to recover), typically within 2 to 4 weeks, followed by the white blood cell count and finally the hemoglobin concentration. The bone marrow examination is repeated at 3 months to assess remission status. We currently do not administer a second cycle of 2-CdA for patients with minimal residual disease (MRD). If the repeat bone marrow at 3 months shows evidence of MRD by either routine morphology or histochemistry, if the peripheral blood counts are normal, follow-up without further therapy is indicated. Rituximab may be considered.

For patients with relapsed HCL previously treated with either splenectomy, interferon, or pentostatin (2′-deoxycoformin [2′-DCF]), we administer a repeat cycle of 2-CdA, as described. For patients who relapse after a single cycle of 2-CdA, we give a second cycle of 2-CdA. For patients with relapsed HCL previously treated with at least two prior cycles of 2-CdA, we prefer BL22 if available. If BL22 is not available, use of rituximab may be a consideration. Alternatives include 2′-DCF, 4 mg/m^2 given intravenously every 2 weeks for 3 to 6 months, and interferon, 2×10^6 units/m^2 three times per week for 12 to 18 months.

110 Multiple Myeloma and Related Disorders

S. Vincent Rajkumar and Angela Dispenzieri

SUMMARY OF KEY POINTS

Multiple Myeloma

Introduction

- Multiple myeloma accounts for approximately 10% of hematologic malignancies. Almost 20,000 new cases are estimated to occur in the United States in 2007.
- Almost all patients are thought to evolve from an asymptomatic premalignant stage termed monoclonal gammopathy of undetermined significance (MGUS).

Diagnosis

- The most common presenting symptoms are fatigue and bone pain.
- Osteolytic bone lesions and/or compression fractures are the hallmark of the disease.
- Hypercalcemia is found in one fourth of patients; the serum creatinine is elevated in almost one half of patients.
- Diagnosis requires 10% or more plasma cells in the bone marrow, M protein in the serum, and/or urine and evidence of end-organ damage (hypercalcemia, renal insufficiency, anemia, or bone lesions) secondary to the underlying plasma cell disorder.
- Monoclonal (M) proteins can be detected by serum protein electrophoresis and immunofixation in 93% of patients; Addition of urine protein electrophoresis and urine immunofixation or the serum free light-chain assay will increase sensitivity to 97% or higher.

Prognosis

- The International Staging System divides patients into three distinct stages and prognostic groups based on the β_2-microglobulin and albumin levels in the serum.
- The presence of any one of the following indicates high-risk myeloma: deletion 13 or hypdiploidy on metaphase cytogenetic studies, deletion 17p- or immunoglobulin heavy-chain translocations t(4;14) or t(14;16), or plasma cell labeling index of 3% or higher.

Treatment

- Newly diagnosed patients are categorized into standard-risk and high-risk myeloma on the basis of specific prognostic factors.
- Initial therapy for patients with standard-risk disease is dependent on eligibility for autologous stem cell transplantation (ASCT).
- Patients who are eligible for ASCT are treated with nonalkylating-agent-containing regimens as initial therapy, such as thalidomide-dexamethasone or lenalidomide-dexamethasone. They can then pursue early or delayed ASCT. If early ASCT is used, a second ASCT is considered in patients who do not achieve a very good partial response or better with the first ASCT. If delayed ASCT is used, the initial induction is continued until plateau or progression at reduced doses.
- For patients who are not eligible for ASCT, the current standard is melphalan, prednisone, and thalidomide (MPT); however, if such patients are unable to tolerate (or have access to) thalidomide, melphalan plus prednisone remains a reasonable alternative.
- Patients with high-risk myeloma are candidates for novel therapy, since outcome is poor even with tandem ASCT. Considerations include bortezomib-containing initial therapy, routine maintenance therapy if ASCT is utilized, MPT in elderly patients, and consideration of allogeneic approaches in selected patients.
- Options for relapsed disease include thalidomide, lenalidomide, bortezomib, alkylating agents, anthracyclines, and corticosteroids alone or in combination.

Monoclonal Gammopathy of Undetermined Significance

- Monoclonal gammopathy of undetermined significance (MGUS) is an asymptomatic, premalignant, clonal plasma cell proliferative disorder defined by the presence of a serum M protein level less than 3 g/dL; bone marrow plasma cells less than 10%; and absence of anemia, hypercalcemia, lytic bone lesions, or renal failure that can be attributed to the plasma cell proliferative disorder.
- MGUS is present in approximately 3% of the general population 50 years of age and older.
- Patients with three adverse risk factors, namely, an abnormal serum free light-chain ratio, non-IgG MGUS, and a high-serum M protein level (≥15 g/L), have a risk of progression at 20 years of 58% (high-risk MGUS) compared to 37% in patients in with any two of these risk factors present (high-intermediate-risk MGUS), 21% in patients with one risk factor present (low-intermediate risk MGUS), and 5% when none of the risk factors were present (low-risk MGUS).
- The current standard of care for MGUS is observation alone, without therapy.

Smoldering Multiple Myeloma

- Smoldering multiple myeloma is defined by the presence of a serum IgG or IgA M protein level of 3 g/dL or greater and/or bone marrow plasma cells 10% or more, and absence of anemia, hypercalcemia, lytic bone lesions, or renal failure that can be attributed to the plasma cell proliferative disorder.
- The risk of progression to myeloma or related malignancy is much higher in smoldering multiple myeloma than in

MGUS: 10% to 20% per year versus 1% per year, respectively.
- The standard of care is observation alone until evidence of progression to myeloma.

Waldenström's Macroglobulinemia

- Waldenström's macroglobulinemia is a clonal IgM monoclonal protein that secretes lymphoid/plasma cell disorder, which currently also includes the entity that was previously referred to as lymphoplasmacytic lymphoma.
- Median survival is approximately 5 years.
- There are four options for initial therapy: rituximab, purine nucleoside analogs, alkylators, and combination chemotherapy. Unfortunately, there are no randomized data to determine the best option; therapy is typically decided on the basis of the age of the patient and the aggressiveness of the presentation.
- Options that have been listed for initial therapy can also be tried at the time of relapse. The same initial therapy can be tried again at relapse if there was an adequate interval between cessation of therapy and relapse. Other options for relapsed or refractory disease include stem cell transplantation, interferon-α, thalidomide, and bortezomib.
- Plasmapheresis is indicated for the treatment of hyperviscosity syndrome.

Systemic Immunoglobulin Light-Chain Amyloidosis

- Amyloid is a fibrillar proteinaceous material that is detected with congo-red staining based on a characteristic apple-green birefringence under polarized light.
- It consists of rigid, linear, nonbranching fibrils, 7.5 to 10 nm in width, aggregated in a β-pleated sheet conformation. There are several distinct types of amyloidosis; they are classified on the basis of the protein composition of the amyloid material.
- AL (immunoglobulin light-chain) amyloidosis refers to the type of amyloidosis that is derived from the variable portion of a monoclonal light chain. It should be suspected when patients with the appropriate clinical syndrome, such as nephrotic syndrome, axonal neuropathy, or restrictive cardiomyopathy, display evidence of a plasma cell proliferative disorder such as a serum or urine monoclonal protein.
- Patients are offered ASCT if eligible. Patients who are not eligible for stem cell transplantation (poor performance status, major comorbidities, three or more organs involved, and advanced cardiac amyloidosis) are treated with melphalan plus high-dose dexamethasone.
- Thalidomide (or lenalidomide) plus dexamethasone are second-line treatment options for patients with systemic AL amyloidosis.

Solitary Plasmacytoma

- Solitary plasmacytomas may be confined to bone (solitary bone plasmacytoma) or may occur in extramedullary sites (extramedullary plasmacytoma).
- Patients with solitary plasmacytoma are at risk for progression to multiple myeloma.
- Treatment consists of radiation in the range of 40 to 50 Gy to the involved site.
- The disease-free survival rate at 10 years ranges from 25% to 50%.

MULTIPLE MYELOMA

Introduction

Definition

The diagnosis of active myeloma requires 10% or more plasma cells on bone marrow examination (or biopsy proven plasmacytoma), M protein in the serum and/or urine (except in patients with true non-secretory myeloma), and evidence of end-organ damage (hypercalcemia, renal insufficiency, anemia, or bone lesions) secondary to the underlying plasma cell disorder (Table 110-1). Multiple myeloma accounts for approximately 10% of hematologic malignancies.[1,2] Almost all patients are thought to evolve from an asymptomatic premalignant stage termed *monoclonal gammopathy of undetermined significance* (MGUS). MGUS is present in over 3% of the population above the age of 50 years and progresses to myeloma or related malignancy at a rate of 1% per year.[3,4] In some patients, an intermediate asymptomatic but more advanced premalignant stage referred to as *smoldering multiple myeloma* can be recognized clinically.

Epidemiology

The annual incidence, age-adjusted to the 2000 U.S. population, is 4.3 per 100,000.[5] Almost 20,000 new cases and 11,000 new deaths are estimated to occur in the United States in 2007.[6] Multiple myeloma is twice as common in African Americans as in Caucasians and slightly more common in males than in females. The median age at diagnosis is 66 years,[7] and only 2% of patients are younger than 40 years of age.

Pathogenesis

Transition from Normal Plasma Cell to Monoclonal Gammopathy of Undetermined Significance

ANTIGENIC STIMULATION AND IMMUNOSUPPRESSION. MGUS is the precursor lesion from which almost all cases of myeloma are thought to evolve. MGUS is characterized by evidence of genomic instability on molecular genetic testing. The trigger for this genomic instability is not well understood, but current evidence suggests that in many cases, antigenic stimulation might be a key factor (Fig. 110-1). Unlike normal plasma cells, human myeloma cell lines and primary myeloma cells express a broad range of Toll-like receptors (TLRs). TLRs are normally expressed by B lymphocytes and are essential for these cells to recognize infectious agents and pathogen-associated molecular patterns, which then initiate the host-defense response.[8–10] The aberrant expression of TLRs by plasma cells may enable them to respond to TLR-specific ligands, resulting in an abnormal and perhaps sustained response to infection. It has been shown that TLR-specific ligands cause increased myeloma cell proliferation, survival, and resistance to dexamethasone-induced apoptosis. These effects are mediated in part by autocrine interleukin-6 (IL-6) production.[8,9]

IL-6 is a major growth factor for plasma cells,[11] and there is overexpression of CD126 IL-6 receptor α-chain) in MGUS compared to normal plasma cells.[12,13] Thus, abnormal TLR expression and/or overexpression of IL-6 receptors in plasma cells may be early, initiating events that lead to an abnormal response to infection and act as sustained, autocrine IL-6-dependent, proliferative triggers for plasma

Table 110-1 Mayo Clinic Diagnostic Criteria for Selected Clonal Plasma Cell Disorders

Disorder	Disease Definition	References
Monoclonal gammopathy of undetermined significance (MGUS)	Serum monoclonal protein < 3 g/dL, bone marrow plasma cells < 10%, and absence of end-organ damage such as lytic bone lesions, anemia, hypercalcemia, or renal failure that can be attributed to a plasma cell proliferative disorder.	International Myeloma Working Group,[180] Rajkumar et al.[181]
Smoldering multiple myeloma (also referred to as asymptomatic multiple myeloma)	Serum monoclonal protein (IgG or IgA) ≥ 3 g/dL and/or bone marrow plasma cells ≥ 10%, absence of end-organ damage such as lytic bone lesions, anemia, hypercalcemia, or renal failure that can be attributed to a plasma cell proliferative disorder.	International Myeloma Working Group,[180] Rajkumar et al.[181]
Multiple myeloma	Bone marrow plasma cells ≥ 10%, presence of serum and/or urinary monoclonal protein (except in patients with true nonsecretory multiple myeloma), plus evidence of lytic bone lesions, anemia, hypercalcemia, or renal failure that can be attributed to the underlying plasma cell proliferative disorder.	Rajkumar et al.,[2] International Myeloma Working Group,[180] Rajkumar et al.[181]
Waldenström's macroglobulinemia	IgM monoclonal gammopathy (regardless of the size of the M protein) with >10% bone marrow lymphoplasmacytic infiltration (usually intertrabecular) by small lymphocytes that exhibit plasmacytoid or plasma cell differentiation and a typical immunophenotype (e.g., surface IgM+, CD5+/–, CD10–, CD19+, CD20+, CD23–) that satisfactorily excludes other lymphoproliferative disorders, including chronic lymphocytic leukemia and mantle cell lymphoma. *Note*: IgM MGUS is defined as serum IgM monoclonal protein < 3 g/dL, bone marrow lymphoplasmacytic infiltration < 10%, and no evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly. Smoldering Waldenström's macroglobulinemia (also referred to as indolent or asymptomatic Waldenström's macroglobulinemia) is defined as serum IgM monoclonal protein ≥ 3 g/dL and/or bone marrow lymphoplasmacytic infiltration ≥ 10%, and no evidence of end-organ damage such as anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that that can be attributed to a plasma cell proliferative disorder.	Kyle et al.,[3] Owen et al.,[197] Baldini et al.,[198] Gobbi et al.,[199] Kyle et al.[200]
Solitary plasmacytoma	Biopsy-proven solitary lesion of bone or soft tissue with evidence of clonal plasma cells, normal bone marrow with no evidence of clonal plasma cells, normal skeletal survey and MRI of spine and pelvis, and absence of end-organ damage such as anemia, hypercalcemia, renal failure or additional lytic bone lesions that can be attributed to a plasma cell proliferative disorder	International Myeloma Working Group,[180] Dimopoulos et al.[182]
Systemic AL amyloidosis	Presence of an amyloid-related systemic syndrome (such as renal, liver, heart, gastrointestinal tract, or peripheral nerve involvement) with positive amyloid staining by congo red in any tissue (e.g., fat aspirate, bone marrow, or organ biopsy), plus evidence that amyloid is light-chain related established by direct examination of the amyloid (immunoperoxidase staining, direct sequencing, etc), plus evidence of a monoclonal plasma cell proliferative disorder (serum or urine M protein, abnormal free light chain ratio, or clonal plasma cells in the bone marrow). *Note*: Approximately 2–3% of patients with AL amyloidosis will not meet the requirement for evidence of a monoclonal plasma cell disorder listed above; the diagnosis of AL amyloidosis must be made with caution in these patients.	Kyle and Rajkumar[171]
POEMS syndrome	Presence of a monoclonal plasma cell disorder, peripheral neuropathy, and at least one of the following seven features: osteosclerotic myeloma, Castleman's disease, organomegaly, endocrinopathy (excluding diabetes mellitus or hypothyroidism), edema, typical skin changes, and papilledema. *Note*: Not every patient who meets the above criteria will have POEMS syndrome; the features should have a temporal relationship to each other and no other attributable cause. The absence of either osteosclerotic myeloma or Castleman's disease should make the diagnosis suspect. Elevations in plasma or serum levels of vascular endothelial growth factor and thrombocytosis are common features of the syndrome and are helpful when the diagnosis is difficult.	Dispenzieri[259]

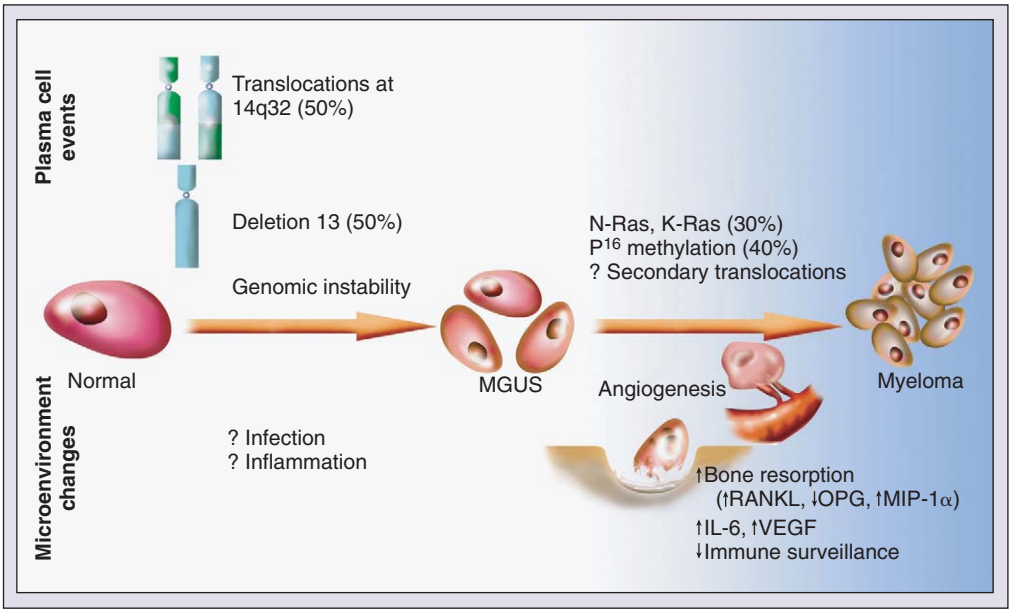

Figure 110-1 • Pathogenesis of myeloma. IL-6, interleukin-6; MGUS, monoclonal gammopathy of undetermined significance; MIP-1α, macrophage inflammatory protein-1α; OPG, osteoprotegerin; RANKL, receptor activator of nuclear factor-κB ligand; VEGF, vascular endothelial growth factor.

cells. During this process, plasma cells may acquire one of the various cytogenetic alterations (described in the following sections) that result in a limited clonal plasma cell proliferative process, namely, MGUS.

Immunosuppression either by promoting evasion of tumor surveillance or by promoting antigenic stimulation may also contribute to the initiation of monoclonal gammopathies. Monoclonal proteins have been reported in the context of immunosuppressive states such as bone marrow/stem cell transplantation, organ transplantation, and human immunodeficiency virus infection.[14–17] Patients undergoing renal transplantation develop monoclonal proteins dependent on the level of immunosuppression that they are subjected to.[17]

CYTOGENETIC CHANGES. Over 90% of MGUS is associated with cytogenetic changes that are possibly precipitated by infection or immune dysregulation as discussed previously, likely during immunoglobulin heavy-chain (IgH) switch recombination or somatic hypermutation.[18]

Approximately 50% of patients with MGUS have primary translocations in the clonal plasma cells involving the IgH locus on chromosome 14q32 (IgH translocated MGUS/smoldering multiple myeloma; see Fig. 110-1).[1,18] The most common partner chromosome loci and genes dysregulated in these translocations are 11q13 (CCND1 [cyclin D1 gene]), 4p16.3 (FGFR-3 and MMSET), 6p21 (CCND3 [cyclin D3 gene]), 16q23 (c-maf), and 20q11 (mafB; Table 110-2).[19–21] It is likely that these translocations play an important pathogenetic role in the resultant limited clonal proliferation that is clinically manifested as MGUS.

Approximately 45% of MGUS is associated with hyperdiploidy, usually of the odd-numbered chromosomes with the exception of 13; the origin of the remaining 5% or fewer of MGUS is not clear.[18,22–27] These categories of MGUS that lack evidence of IgH translocations are referred to as IgH nontranslocated MGUS.

Deletion of chromosome 13, a major prognostic factor in multiple myeloma, is seen in up to 50% of patients with MGUS by interphase fluorescent in situ hybridization; hence, the presence of this abnormality cannot be used to differentiate MGUS from multiple myeloma.[21]

Progression of Monoclonal Gammopathy of Undetermined Significance to Malignancy

The constant rate of progression of MGUS to myeloma, macroglobulinemia, or related malignancy in a recent epidemiologic study over a period spanning 30 to 35 years strongly suggests a simple, random, two-hit genetic model of malignancy.[3] The risk of progression is similar regardless of the known duration of antecedent MGUS, suggesting that the second hit that is responsible for progression is a random event, not cumulative damage.

The specific second hit that initiates the cascade of events associated with progression is unknown. Several abnormalities have been detected with progression in both the plasma cell and its microenvironment that likely play a role in the progression of MGUS, but little is known about the sequence of events (see Fig. 110-1). Ras mutations, p16 methylation, abnormalities involving the myc family of oncogenes, secondary translocations, and p53 mutations have all been identified in clonal plasma cells in association with progression to the symptomatic stage.[19] It is possible that the

Table 110-2 Cytogenetic Classification of Monoclonal Gammopathy of Undetermined Significance

Cytogenetic Abnormality	Approximate Percentage of MGUS	Gene(s)/Chromosomes Dysregulated by Translocation
IGH TRANSLOCATED MGUS (50%)		
t(11;14)(q13;q32)	25%	CCND1 (cyclin D1)
t(4;14)(p16;q32)	15%	FGFR-3 and MMSET
t(14;16)(q32;q23)	5%	C-MAF
t(6;14)(p21;q32)	3%	CCND3 (cyclin D3)
t(14;20)(q32;q11)	2%	MAFB
IGH NONTRANSLOCATED MGUS (50%)		
Hyperdiploid MGUS	45%	Recurrent trisomies involving odd-numbered chromosomes with the exception of chromosomes 1, 13, and 21
Unknown	<5%	

MGUS, monoclonal gammopathy of undetermined significance.

second hit that is responsible for disease progression is different in IgH translocated MGUS versus IgH nontranslocated MGUS and even within the various subtypes of IgH translocated MGUS, depending on the partner chromosome involved. For example, amplification of chromosome 1q21 been noted in over 40% of patients with smoldering multiple myeloma and myeloma compared to 0% in MGUS,[28] suggesting that such amplification (e.g., by trisomy 1) might play a role in progression, perhaps in IgH nontranslocated MGUS.

The bone marrow microenvironment undergoes marked changes with progression, including induction of angiogenesis,[29] suppression of cell-mediated immunity,[30] and paracrine loops involving cytokines such as IL-6 and vascular endothelial growth factor.[31] As in solid tumors, the transition from MGUS to multiple myeloma may involve an angiogenic switch. In solitary plasmacytoma, which can be considered to be analogous to localized stage I solid tumor, induction of angiogenesis at the time of diagnosis has been shown to be a predictor of progression to myeloma, suggesting a pathogenetic role for the process in disease progression.[32] Furthermore, there is a gradual increase in degree of bone marrow angiogenesis along the disease spectrum from MGUS to smoldering multiple myeloma to symptomatic myeloma.[29] In one study, approximately 60% of myeloma bone marrow plasma samples stimulated angiogenesis in an in vitro angiogenesis assay, compared to 0% of smoldering multiple myeloma and 7% of MGUS ($P < 0.001$).[33] Increased angiogenesis in myeloma is correlated with disease activity, bone marrow plasma cell involvement, and plasma cell proliferative capacity.

The increased angiogenesis seen in myeloma may be related to expression of proangiogenic cytokines.[34] However, no significant difference is seen in expression of vascular endothelial growth factor, basic fibroblast growth factor, or their receptors between MGUS, smoldering multiple myeloma and myeloma. Loss of angiogenesis inhibitory activity has been noted with disease progression from MGUS to multiple myeloma, which could in part account for the increase in angiogenesis that occurs in myeloma.[33,35] In an in vitro human angiogenesis assay, 63% of MGUS bone marrow plasma samples inhibited angiogenesis, compared to smoldering multiple myeloma (43%) and myeloma (4%; $P < 0.001$).

The formation of new blood vessels may contribute to disease progression by ensuring an adequate tumor nutrient supply as well as by paracrine stimulation of tumor growth. The role of angiogenesis in myeloma has triggered an interest in antiangiogenic therapy for the disease. Studies show that while increased microvessel density in myeloma might not regress following conventional dose or high-dose chemotherapy, regression has been noted in responders with thalidomide, an agent that has known antiangiogenic properties.[36] Clinical trials have been initiated to test the hypothesis that therapy with antiangiogenic agents might inhibit angiogenesis and delay progression in smoldering multiple myeloma.

Pathogenesis of Bone Lesions

Progression of MGUS to myeloma is characterized by the development of bone lesions. Lytic bone lesions in myeloma are caused by an imbalance between the activity of osteoclasts and osteoblasts. There is an increase in receptor activator of nuclear factor κB ligand expression by osteoblasts (and possibly plasma cells) accompanied by a reduction in the level of its decoy receptor, osteoprotegerin.[37,38] This leads to an increase in the receptor activator of nuclear factor κB ligand/osteoprotegerin ratio, which causes osteoclast activation and bone resorption. In addition, increased levels of macrophage inflammatory protein-1a (MIP-1a), IL-3, and IL-6 produced by marrow stromal cells contribute to the overactivity of osteoclasts.

At the same time, increased levels of IL-3, IL-7, and dickkopf 1 (DKK1) inhibit osteoblast differentiation in myeloma. Myeloma cells express DKK1, and increased expression of DKK1 by these cells has been associated with presence of focal bone lesions in myeloma.[39] The combination of osteoclast activation and inhibition of osteoblast differentiation is thought to be the mechanism behind the development of osteolytic lesions in myeloma.

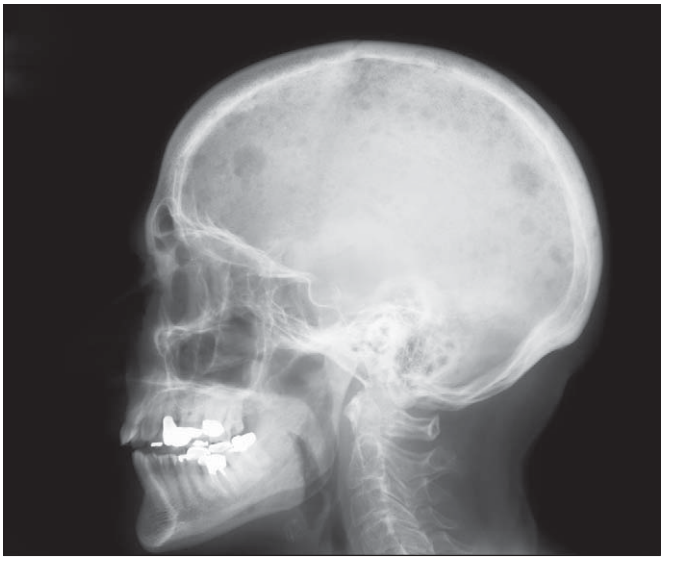

Figure 110-2 • Osteolytic lesions in the skull on plain radiograph in a patient with myeloma.

Clinical Features

The most common presenting symptoms of myeloma are fatigue and bone pain.[7] Osteolytic bone lesions and/or compression fractures that can be detected on routine radiographs, magnetic resonance imaging (MRI), or computed tomographic (CT) scans are the hallmark of the disease and cause significant morbidity (Figs. 110-2 through 110-4). Bone pain may present as an area of persistent pain or migratory bone pain, often in the lower back and pelvis. Pain may be sudden in onset when associated with a pathologic fracture and is often precipitated by movement. Extramedullary expansion of bone lesions may cause nerve root or spinal cord compression. Anemia occurs in 70% of patients at diagnosis and is the primary cause of fatigue. Hypercalcemia is found in one fourth of patients, and the serum creatinine is elevated in almost one half of patients.

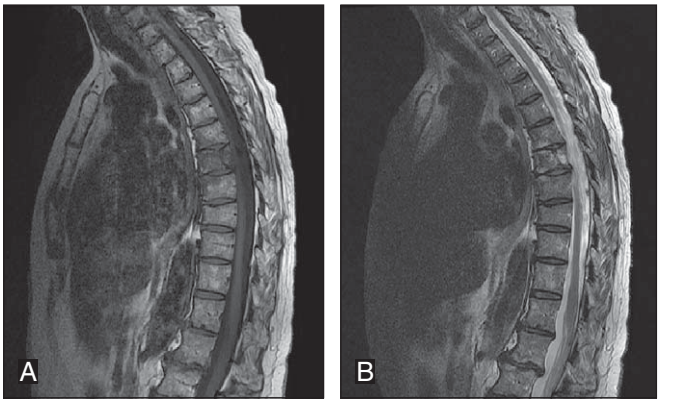

Figure 110-3 • Magnetic resonance imaging of the spine in a patient with myeloma showing marrow edema of T11 and L1 to L3 vertebral bodies. Marrow signal intensity is diffusely heterogeneous, consistent with patient's known clinical diagnosis of multiple myeloma.

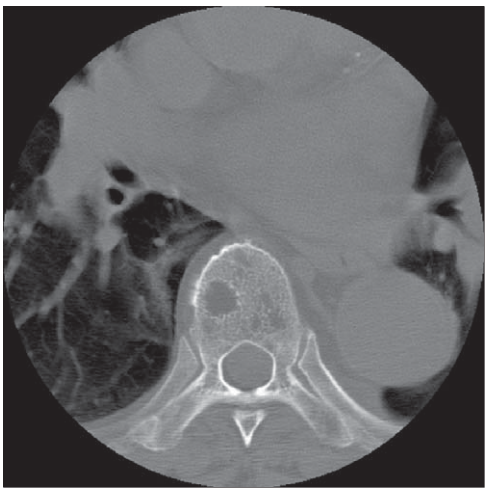

Figure 110-4 • Computed tomographic scan of a vertebral body showing osteolytic bone lesions in a patient with myeloma.

Investigation

A complete blood count, urinalysis, and serum creatinine, calcium, β_2-microglobulin, albumin, c-reactive protein, and lactate dehydrogenase levels are needed for diagnosis, prognosis, and staging. In addition, patients require tests to identify and quantitate monoclonal proteins, bone disease, and bone marrow involvement. Specialized tests are also performed on the bone marrow for risk stratification.

Identification of Monoclonal Proteins

Myeloma is characterized by the presence of monoclonal immunoglobulins in the serum and/or urine. Monoclonal immunoglobulins are commonly referred to as monoclonal proteins, M proteins, or paraproteins. The presence of M proteins is indicative of a clonal plasma cell proliferative disorder such as myeloma, MGUS, or Waldenström's macroglobulinemia. Additional tests are required to distinguish between the various plasma cell disorders.

M proteins can be detected by serum protein electrophoresis (SPEP) in 82% of patients with myeloma and by serum immunofixation in 93%.[7] Up to 20% of patients with myeloma lack heavy-chain expression in the M protein and are considered to have light-chain myeloma. The M protein in these patients is always detected in the urine but can be absent in the serum even by immunofixation, making it imperative that protein electrophoresis and immunofixation are always done on both the serum and the urine in all patients in whom myeloma is suspected. Addition of urine protein electrophoresis (UPEP) and urine immunofixation will increase the sensitivity of detecting M proteins in patients with myeloma to 97%. Most (60%) of the remaining patients who are negative for M protein on serum and urine electrophoresis and immunofixation studies will have evidence of clonal paraproteins on the serum free light-chain assay. Currently, only 1% to 2% of patients with myeloma will have no detectable M on any of these tests; these patients have true nonsecretory myeloma.

SERUM PROTEIN ELECTROPHORESIS AND IMMUNOFIXATION. Agarose gel SPEP and immunofixation are the preferred methods of detection of serum M proteins (Fig. 110-5). M proteins appear as a localized band on SPEP.[40] After recognition of a localized band that is suggestive of an M protein on SPEP, immu-

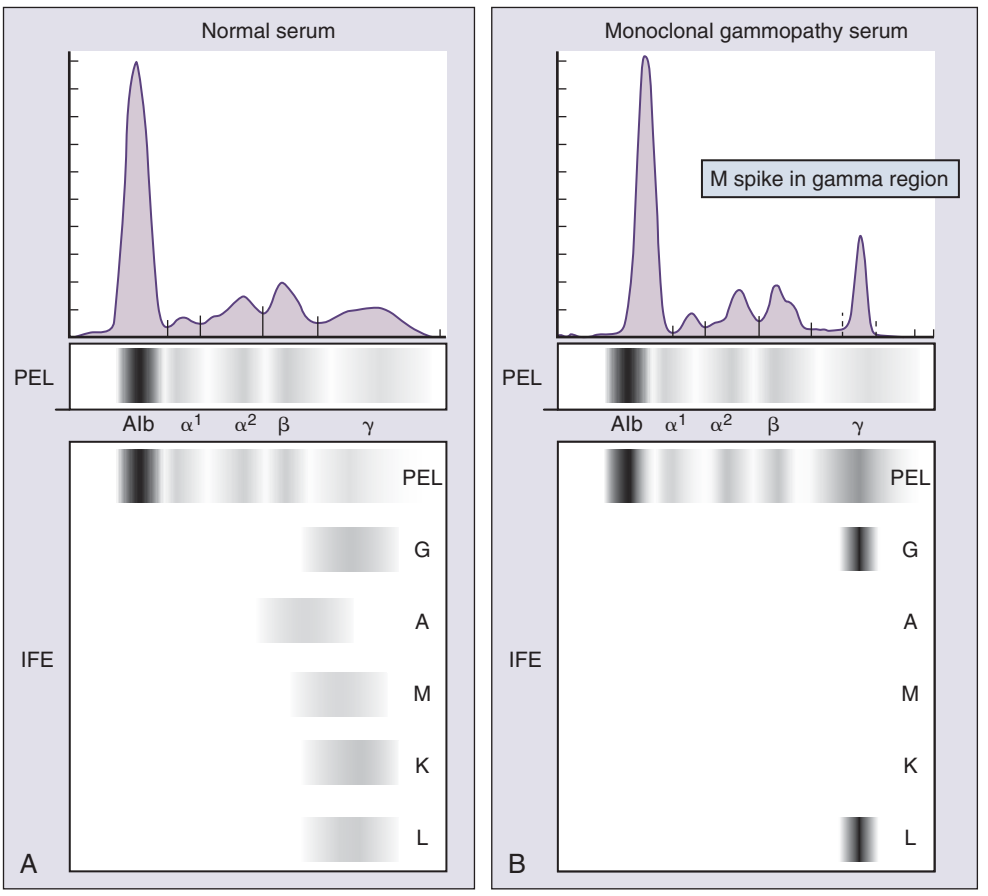

Figure 110-5 • **A,** Serum protein electrophoresis (PEL) and immunofixation (IFE) showing a normal pattern with no evidence of monoclonal protein. **B,** PEL showing a monoclonal (M) protein in the gamma region, which is IgG lambda on IFE.

nofixation is necessary for confirmation and to determine the heavy- and light-chain class of the M protein. In addition, immunofixation is more sensitive than SPEP and allows detection of smaller amounts of M protein and should therefore be performed whenever myeloma, amyloidosis, macroglobulinemia, or a related disorder is suspected. The size of the M protein is measured by using the SPEP; small M proteins that are not apparent on SPEP but are apparent only on immunofixation are considered unmeasurable.

QUANTITATIVE IMMUNOGLOBULIN STUDIES. Quantitation of serum immunoglobulins is performed with a rate nephelometer in patients in whom M proteins are detected. It is an added parameter that can be followed particularly in patients with myeloma and macroglobulinemia, in which at times the M protein size estimated on SPEP can be unreliable (e.g., small beta migrating proteins and IgA/IgM proteins that tend to polymerize)

URINE PROTEIN ELECTROPHORESIS AND IMMUNOFIXATION. Typically, screening for suspected monoclonal gammopathies has included UPEP and immunofixation in addition to the serum studies that were discussed earlier, since a subset of patients with myeloma and amyloidosis may have an M protein that is restricted to the urine and absent on serum studies. In such patients, the diagnosis of plasma cell dyscrasia would be missed if urine studies were not performed. A 24-hour urine specimen is required for UPEP and immunofixation. Urine M protein levels are measured on UPEP and are used in monitoring disease progression and response to therapy.

SERUM-FREE LIGHT-CHAIN ASSAY. Measurement of the serum free light-chain assay (Freelite, The Binding Site Limited, Birmingham, U.K.) has recently been introduced into clinical practice.[41] This automated nephelometric assay allows quantitation of free kappa and lambda chains (i.e., light chains that are not bound to intact immunoglobulin) secreted by plasma cells. An abnormal kappa/lambda free light-chain ratio indicates an excess of one light-chain type versus the other and is interpreted as a surrogate for clonal expansion based on extensive testing in normal volunteers, and patients with myeloma, amyloidosis and renal dysfunction.[41,42] The assay is performed on automated chemistry analyzers, is widely available, and is commonly used to monitor patients with oligosecretory or nonsecretory myeloma and primary amyloidosis, as well as patients with the light-chain-only form of myeloma.[42–44]

The normal serum free kappa level is 3.3 to 19.4 mg/L, and the normal free lambda level is 5.7 to 26.3 mg/L.[45] The normal ratio for free light-chain kappa/lambda is 0.26 to 1.65. The normal reference range in the free light-chain assay reflects a higher serum level of free lambda light chains than would be expected given the usual kappa/lambda ratio of 2 for intact immunoglobulins. This occurs because the renal excretion of free kappa (which exists usually in a monomeric state) is much faster than that of free lambda (which is usually in a dimeric state).[41,42] Patients with a kappa/lambda free light-chain ratio less than 0.26 are typically defined as having monoclonal lambda free light chain, and those with ratios greater than 1.65 are defined as having a monoclonal kappa free light chain. If the free light-chain ratio is greater than 1.65, kappa is considered to be the "involved" free light chain, and lambda is considered to be the "uninvolved" free light chain, and vice versa if the ratio is less than 0.26.

In a recent study, 428 patients with a monoclonal gammopathy and urine M protein at initial diagnosis of plasma cell dyscrasia who had also undergone serum immunofixation and serum free light-chain quantitation within 30 days of diagnosis were studied.[46] The results of SPEP, serum immunofixation, serum free light-chain, UPEP, and urine immunofixation were then analyzed to determine whether all patients could be accurately identified as having a monoclonal plasma cell disorder had the urine studies not been done. All three serum studies were normal in only two patients (0.5% of the cohort), indicating that urine studies can be eliminated in screening for the presence of monoclonal plasma cell disorders by using the serum free light-chain assay in combination with the SPEP and immunofixation. However, urine studies are required if a monoclonal process is identified, since it helps in monitoring disease progression and response to therapy over time.

Identification of Bone Disease

Plain radiographic examination of all bones, including long bones (skeletal survey), is the preferred method of detecting lytic bone lesions in myeloma. Conventional x-rays show skeletal abnormalities in almost 80% of patients with myeloma; often, these lesions have a characteristic punched-out appearance. Osteoporosis and/or fractures are also detected by conventional radiography. Occasionally, osteosclerotic lesions can occur. CT and MRI scans are more sensitive than is conventional radiography in detecting bone disease. Among asymptomatic multiple myeloma patients with normal x-rays, up to 50% have tumor-related abnormalities on MRI of the lower spine. CT and/or MRI studies are indicated when symptomatic areas show no abnormality on routine radiographs. There routine use in assessing extent of bone disease in addition to skeletal radiographs is unclear.

Fluorodeoxyglucose positron emission tomography has shown promise in the evaluation of bone disease and in staging of myeloma (Fig. 110-6). However, the routine use of this method and its specific role in management need further investigation. The role of bone mineral density studies in myeloma and the use of these studies in identifying patients who are at risk for pathologic fractures and prophylactic bisphosphonate therapy also remains unresolved.

Bone Marrow Studies

Unilateral bone marrow aspiration and biopsy are indicated in all patients with myeloma. By definition, all patients with myeloma should have 10% or more clonal bone marrow plasma cells. If a lower extent of involvement is detected, either one is dealing with an erroneous diagnosis or there is a sampling error due to patchy marrow involvement, in which case a repeat marrow biopsy is indicated. Occasionally an entity called "multiple" solitary plasmacytomas has been described in which there are clearly multiple plasmacytomas on clinical and radiographic examination but marrow involvement is either minimal or absent. The monoclonal (or, more accurately, monotypic) nature of bone marrow plasma cells is established by the demonstration of an abnormal kappa/lambda ratio by immunohistochemistry or flow cytometry. On flow cytometry, plasma cells in

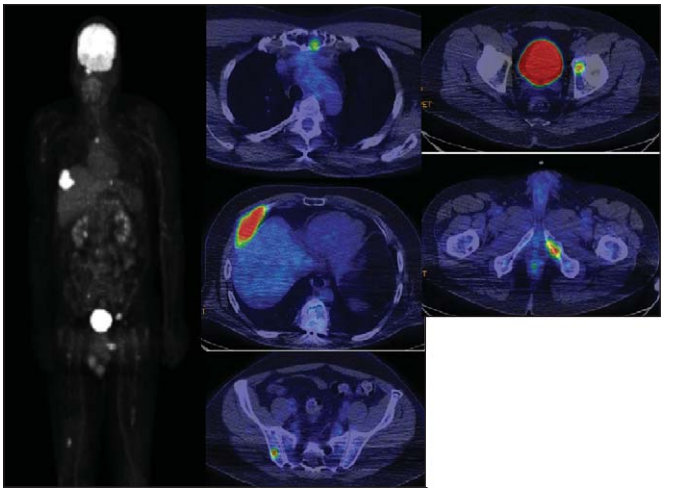

Figure 110-6 • Fluorodeoxyglucose positron emission tomography imaging of bone lesions in a patient with myeloma showing lesions in the sternum, right rib, right ilium, left hip, and left ischium.

multiple myeloma typically stain positive for CD38, CD56, and CD138 and are usually negative for surface immunoglobulin and CD19. Up to 20% stain positively for CD20. Morphologically, the presence of immature blast-like plasma cells (plasmablastic morphology) carries an adverse prognosis.

Given their impact on prognosis (see "Prognosis"), bone marrow samples should be studied by conventional karyotyping studies and/or fluorescent in situ hybridization studies to detect specific abnormalities such as t4;14, t14;16, and 17p-. The bone marrow plasma cell labeling index should be performed, if available.

Differential Diagnosis

In patients with evidence of M proteins, the main differential diagnosis is between myeloma, MGUS, smoldering myeloma, macroglobulinemia, and primary amyloidosis. These disorders are distinguished from each other by using the criteria listed in Table 110-1. In patients with marrow plasmacytosis, monoclonal plasma cell disorders are differentiated from polyclonal reactive plasmacytosis that occurs in conditions such as autoimmune diseases, metastatic carcinoma, chronic liver disease, acquired immunodeficiency syndrome, or chronic infection based on kappa/lambda staining. In monoclonal plasma cell disorders, plasma cells express either kappa or lambda, resulting in a markedly abnormal kappa:lambda ratio. In contrast both kappa-staining plasma cells and lambda-staining plasma cells (usually in a kappa:lambda ratio of 2 : 1) are seen in disorders in which there is reactive plasmacytosis.

Bone lesions in a patient with MGUS due to an unrelated metastatic carcinoma may be mistaken for multiple myeloma. The presence of a small M protein and fewer than 10% plasma cells in the bone marrow makes metastatic carcinoma with an unrelated MGUS more likely. If there is any doubt, a biopsy of one of the lytic lesions is needed.

Table 110-3 Prognostic Factors in Myeloma

MAJOR INDEPENDENT PROGNOSTIC FACTORS

- Performance status
- Stage (International Staging System)
  - Stage I (serum β_2-microglobulin < 3.5 mg/L and albumin ≥ 3.5 g/dL; median survival: 62 months)
  - Stage II (not fitting stage I or II; median survival: 44 months)
  - Stage III (serum β_2-microglobulin ≥ 5.5 mg/L; median survival: 29 months)
- Cytogenetic changes
  - Abnormal cytogenetics by karyotyping (especially deletion 13 or hypodiploidy)
  - Translocations t(4;14) or t(14;16) on fluorescent in situ hybridization
  - Deletion 17p on fluorescent in situ hybridization
- Serum lactate dehydrogenase
- Plasmablastic morphology
- Bone marrow plasma cell labeling index

OTHER PROGNOSTIC MARKERS

- Advanced age
- Stage (Dure-Salmon stage)
- C-reactive protein
- Serum creatinine
- Platelet count
- Increased circulating plasma cells by flow cytometry or immunofluorescence

Prognosis

Stage

Historically, although median survival has been approximately 3 years,[7] some patients can live longer than 10 years.[47–50] Survival depends on disease stage, and since 1975, the Durie-Salmon staging system has been used to stratify patients with multiple myeloma.[51] However, this staging system has limitations, especially in the categorization of bone lesions.[52,53] Recently, Greipp and colleagues developed the new International Staging System (ISS), a collaborative effort by investigators from 17 institutions worldwide and data on 11,171 patients.[54] The ISS overcomes the limitations of the Durie-Salmon staging and divides patients into three distinct stages and prognostic groups based solely on the β_2-microglobulin and albumin levels in the serum (Table 110-3).

Prognostic Factors

Once a patient has been staged using the ISS, several additional independent prognostic factors are used to further help predict outcome in myeloma (see Table 110-3).[18,52,55–57] In general, a combination of two or more of the independent prognostic factors provides adequate information to estimate prognosis. Facon and colleagues have shown that patients undergoing stem cell transplantation (SCT) can be grouped into three clear prognostic categories using two prognostic factors; median survival was 25 months if patients had a high β_2-microglobulin level and deletion of chromosome 13 by fluorescent in situ hybridization.[58] Patients with only one abnormal factor had a median survival of 47 months, while survival was in excess of 111 months in patients in whom both factors were normal.

Age, hemoglobin concentration, creatinine, calcium, albumin, immunoglobulin class subtype, and extent of bone marrow involvement have also demonstrated prognostic value.[52,55,57] However, they have limited predictive value once the ISS and the independent prognostic factors discussed earlier are known.[59,60] Newer risk factors such as angiogenesis shed light on biology, but clinical utility is unclear.

Risk Stratification

The specific prognostic factors that are used to stratify patients at the Mayo Clinic into high-risk and standard-risk myeloma to guide therapeutic strategy are deletion 13 or hyperdiploidy on metaphase cytogenetic studies, deletion 17p- or immunoglobulin heavy-chain (IgH) translocations t(4;14) or t(14;16), or a plasma cell labeling index of 3% or higher (Table 110-4). The presence of any one or more of the preceding high-risk factors classifies a patient as having high-risk multiple myeloma. The median survival of high-risk multiple myeloma is only 2 to 3 years even with tandem SCT, compared to over 6 to 7 years in patients with average-risk multiple myeloma.[2]

Management

The median survival of symptomatic myeloma is 3 to 4 years. For decades, the mainstay of therapy had been oral chemotherapy with melphalan and prednisone (MP). High-dose therapy with autologous stem cell transplantation (ASCT) prolongs survival compared to conventional chemotherapy and is now routinely incorporated into the treatment strategy either early in the disease course or at the time of relapse in eligible patients. More recently, thalidomide,[61] bortezomib,[62,63] and lenalidomide,[64,65] have emerged as effective agents in the treatment of myeloma.

There is no evidence that early treatment of patients with asymptomatic (smoldering) multiple myeloma prolongs survival compared to therapy at the time of symptoms. However, clinical trials are ongoing to determine whether newer agents can delay progression.

Table 110-4 Mayo Clinic Criteria for High-Risk Multiple Myeloma

High-Risk Characteristic	Percentage of Newly Diagnosed Patients with the Abnormality (%)[7,18,266]
Conventional cytogenetics	
Deletion of chromosome 13 (monosomy)	14
Hypodiploidy	9
Either hypodiploidy or deletion 13	17
Fluorescent in situ hybridization	
t(4;14)	15
t(14:16)	5
17p-	10
Plasma cell labeling index studies: PCLI ≥ 3%	6
Any one of the above high-risk abnormalities	25%–30%

Initial therapy depends on eligibility for SCT and risk stratification. Eligibility for SCT is determined by age, performance status, and coexisting comorbidities. Risk stratification is based on presence or absence of high-risk factors (see Table 110-4)[66] The approach to treatment of symptomatic newly diagnosed multiple myeloma at Mayo Clinic is outlined in Figure 110-7A and B. Table 110-5 lists the most common regimens used in the treatment of newly diagnosed myeloma. Response to therapy is assessed by using the International Myeloma Working Group Uniform Response Criteria (Table 110-6).[67]

Initial Therapy in Standard-Risk Patients Who Are Eligible for Transplantation

It is important to avoid protracted melphalan-based therapy in patients with newly diagnosed myeloma who are considered eligible for ASCT, since the therapy can interfere with adequate stem cell mobilization, regardless of whether an early or delayed transplant is contemplated. Typically, patients are treated with approximately four cycles of induction therapy prior to stem cell harvest. This includes patients who are transplant candidates but who wish to reserve ASCT as a delayed option for relapsed or refractory disease. Such patients can resume induction therapy following stem cell collection until a plateau phase is reached, reserving ASCT for relapse.

The combination of vincristine, doxorubicin, and dexamethasone (VAD) was used for many years as pretransplant induction therapy for patients who were considered candidates for ASCT. However, VAD requires an intravenous indwelling catheter, which predisposes patients to catheter-related sepsis and thrombosis. Moreover, the neurotoxicity of vincristine can limit the future use of thalidomide and bortezomib, both of which also have neurotoxic potential. Most of the activity of VAD is from the high-dose dexamethasone component. Recently, Cavo and colleagues, in a matched case-control study of 200 patients, demonstrated that response rates with VAD were significantly lower than those with thalidomide-dexamethasone (Thal/Dex): 76% versus 52%, respectively.[68] Preliminary results from

Table 110-5 Selected Regimens for the Treatment of Newly Diagnosed Multiple Myeloma

Regimen	Usual Dosing Schedule*
Melphalan-prednisone (MP) (7-day schedule)[1]	Melphalan 8–10 mg oral days 1–7
	Prednisone 60 mg/day oral days 1–7
	Repeated every 6 weeks until plateau
Melphalan-prednisone (MP) (4-day schedule)[84]	Melphalan 0.25 mg/kg (9 mg/m^2) oral days 1–4
	Prednisone 2 mg/kg oral days 1–4
	Repeated every 4–6 weeks until plateau
Thalidomide-dexamethasone (Thal/Dex)[70]	Thalidomide 200 mg oral days 1–28
	Dexamethasone 40 mg oral days 1, 8, 15, 22
	Repeated every 4 weeks × 4 cycles as pretransplant induction therapy or continued until plateau or progression if used as primary therapy
Lenalidomide-dexamethasone (Rev/low-dose Dex)[78]	Lenalidomide 25 mg oral days 1–21 every 28 days
	Dexamethasone 40 mg oral days 1, 8, 15, 22 every 28 days
	Repeated every 4 weeks × 4 cycles as pretransplant induction therapy; or continued until plateau or progression if used as primary therapy
Bortezomib-dexamethasone (Vel/Dex)[81]	Bortezomib 1.3 mg/m^2 intravenous days 1, 4, 8, 11
	Dexamethasone 40 mg oral days 1–4, 9–12
	Reduce dexamethasone to days 1–4 after first 2 cycles
	Repeated every 3 weeks × 4 cycles as pretransplant induction therapy
Melphalan-prednisone-thalidomide (MPT)[84]	Melphalan 0.25 mg/kg oral days 1–4
	Prednisone 2 mg/kg oral days 1–4
	Thalidomide 100–200 mg oral days 1–28
	Repeated every 6 weeks × 12 cycles
Melphalan-prednisone-bortezomib (MPV)[110]	Melphalan 9 mg/m^2 oral days 1–4
	Prednisone 60 mg/m^2 oral days 1–4
	Bortezomib 1.3 mg/m^2 intravenous days 1, 4, 8, 11, 22, 25, 29, 32
	Repeated every 42 days × 4 cycles followed by maintenance therapy as given below:
	Melphalan 9 mg/m^2 oral days 1–4
	Prednisone 60 mg/m^2 oral days 1–4
	Bortezomib 1.3 mg/m^2 intravenous days 1, 8, 15, 22
	Repeated every 35 days × 5 cycles
Melphalan-prednisone-lenalidomide (MPR)	Melphalan 0.18 mg/kg oral days 1–4
	Prednisone 2 mg/kg oral days 1–4
	Lenalidomide 10 mg oral days 1–28
	Repeated every 4–6 weeks × 9 cycles
Bortezomib-thalidomide-dexamethasone (VTD)[267]	Bortezomib 1.3 mg/m^2 intravenous days 1, 4, 8, 11
	Thalidomide 100–200 mg oral days 1–21
	Dexamethasone 20 mg/m^2 oral days 1–4, 9–12, 17–20
	Reduce dexamethasone to days 1–4 after first two cycles
	Repeated every 4 weeks × 4 cycles as pretransplant induction therapy

*Starting and subsequent doses need to be adjusted for performance status, renal function, blood counts, and other toxicities.

Table 110-6 Response Criteria for Multiple Myeloma

Response Subcategory	Response Criteria
Complete response (CR)	• Negative immunofixation on the serum and urine *and* • Disappearance of any soft tissue plasmacytomas *and* • <5% plasma cells in bone marrow
Stringent complete response (sCR)	CR as defined above *plus* • Normal free light chain ratio *and* • Absence of clonal cells in bone marrow by immunohistochemistry or immunofluorescence
Very good partial response (VGPR)	• Serum and urine M component detectable by immunofixation but not on electrophoresis *or* • ≥90% or greater reduction in serum M component plus urine M component <100 mg per 24 hours
Partial response (PR)	• ≥50% reduction of serum M protein and reduction in 24-hour urinary M protein by ≥90% or to <200 mg per 24 hours • If the serum and urine M protein are unmeasurable, a ≥50% decrease in the difference between involved and uninvolved free light chain levels is required in place of the M protein criteria • If serum and urine M protein are unmeasurable and serum free light assay is also unmeasurable, ≥50% reduction in bone marrow plasma cells is required in place of M protein, provided that the baseline percentage was ≥30% • In addition to the above criteria, if present at baseline, a ≥50% reduction in the size of soft tissue plasmacytomas is also required
Stable disease (SD)	• Not meeting criteria for CR, VGPR, PR, or progressive disease
Progressive disease (PD)	Increase of 25% from lowest response value in • Serum M component (absolute increase must be ≥0.5 g/dL) *and/or* • Urine M component (absolute increase must be ≥200 mg/24 hours) *and/or* • Only in patients without measurable serum and urine M protein levels: the difference between involved and uninvolved free light chain levels (absolute increase must be >10 mg/dL) • Bone marrow plasma cell percentage (absolute percentage must be 10%) • Definite development of new bone lesions or soft tissue plasmacytomas or definite increase in the size of existing bone lesions or soft-tissue plasmacytomas • Development of hypercalcemia (corrected serum calcium >11.5 mg/dL) that can be attributed solely to the plasma cell proliferative disorder

All response categories (CR, sCR, VGPR, PR) require two consecutive assessments made at any time before the institution of any new therapy; complete and PR and SD categories also require no known evidence of progressive or new bone lesions if radiographic studies were performed. Radiographic studies are not required to satisfy these response requirements. Bone marrow assessments need not be confirmed.

Data from reference 67.

a randomized trial from France confirm these findings.[69] As a result, VAD is no longer recommended as initial therapy.

Dexamethasone alone has also been used as induction therapy. It is typically used at a dose of 40 mg orally on days 1 to 4, 9 to 12, and 17 to 20 every 4 to 5 weeks. Objective response rates are approximately 45%,[70] significantly lower than those of newer induction regimens. In randomized trials, the early mortality rate associated with dexamethasone is over 10% in the first 4 months of therapy, reflecting the toxicity and ineffectiveness of this regimen. Consequently, single-agent dexamethasone is also no longer recommended as initial therapy.

The main choices for initial therapy are Thal/Dex, bortezomib-based regimens, and lenalidomide-dexamethasone (Rev/Dex). All of these regimens act rapidly and are associated with high response rates. Thal/Dex and Rev/Dex have the added advantage of being orally administered. Thal/Dex and Rev/Dex are associated with an increased risk of deep vein thrombosis (DVT), necessitating routine thromboprophylaxis.

THALIDOMIDE-DEXAMETHASONE. The finding of increased angiogenesis in myeloma and recognition of the antiangiogenic properties of thalidomide led to the first clinical trial with the agent. This trial demonstrated a response rate of 25% in heavily pretreated patients with relapsed or refractory disease.[61] Since then, several studies have confirmed response rates of 25% to 35% in relapsed and refractory myeloma, with a median response duration of approximately 1 year. Thalidomide is usually given orally in a dose of 100 to 200 mg daily. After a response has been achieved, the dose is adjusted to the lowest dose that can achieve and maintain a response, in order to minimize long-term toxicity. Response rates in relapsed disease are about 50% with thalidomide plus corticosteroids and over 65% with a three-drug combination of thalidomide, corticosteroids, and alkylators.

In the last few years, Thal/Dex has emerged as the most commonly used induction regimen for the treatment of newly diagnosed myeloma in the United States. The use of Thal/Dex was initially based on three phase II clinical trials.[71–73] Response rates with Thal/Dex range from 64% to 76% in these studies, comparable to or better than those obtained with infusional VAD.

The Eastern Cooperative Oncology Group (ECOG) recently reported the results of a randomized trial comparing Thal/Dex to dexamethasone (Table 110-7).[70] Two hundred seven patients were studied. The best response within four cycles of therapy was significantly higher with Thal/Dex than with dexamethasone alone: 63% versus 41%, respectively ($P = 0.0017$). Adjusted response rates allowing for the use of serum M protein values alone in patients in whom

Table 110-7 Results of Major Randomized Trials Using New Active Agents for Multiple Myeloma

Trial	Study Regimens	Disease Stage	No. of Patients	Primary Results	Major Toxicity
E1A00[70]	Thalidomide plus dexamethasone (Thal/Dex) versus dexamethasone alone (Dex)	Newly diagnosed myeloma	202	Superior response rate with Thal/Dex compared to Dex, 58% versus 42%, respectively ($P = 0.02$). Grade 3 nonhematologic toxicity higher with Thal/Dex compared to Dex, 68% versus 43%, respectively.	Deep vein thrombosis (DVT) occurred in 18% of patients in the Thal/Dex arm within first 4 months of therapy, indicating need for routine prophylactic anticoagulation while using this regimen; DVT was seen in 3% of patients treated with Dex.
MM003[74]	Thalidomide plus dexamethasone (Thal/Dex) versus placebo plus dexamethasone (Dex)	Newly diagnosed myeloma	202	Superior response rate with Thal/Dex compared to Dex, 58% versus 42%, respectively ($P = 0.02$). Superior time to progression. Grade III nonhematologic toxicity higher with Thal/Dex compared to Dex: 68% versus 43%, respectively.	DVT occurred in 18% of patients in the Thal/Dex arm within first 4 months of therapy, indicating need for routine prophylactic anticoagulation while using this regimen; DVT was seen in 3% of patients treated with Dex.
Italian[83]	Melphalan-prednisone (6 cycles) versus melphalan, prednisone, thalidomide (MPT) (6 cycles with maintenance thalidomide)	Newly diagnosed myeloma	200	Superior response rate with MPT compared to MP, 76% versus 48%, respectively; event free survival at 24 months was 54% versus 27%, respectively ($P < 0.001$).	No significant differences in overall survival seen so far. DVT occurred in 19% of patients in the MPT arm compared to 2% in the MP arm, indicating need for routine prophylactic anticoagulation while using MPT.
IFM 99-06[84]	Melphalan-prednisone (MP) (12 cycles) versus melphalan, prednisone, thalidomide (MPT) (12 cycles) versus intermediate-dose melphalan × 2 courses with stem cell support (Mel 100)	Newly diagnosed myeloma	200	Superior response rates, PFS (17 versus 30 versus 19 months) and OS (30 versus not reached versus 39 months) in MPT arm.	Accrual restricted to patients 65–75 years of age. DVT occurred in 6%, 9%, and 4% of patients treated with MP, MPT, and Mel 100, respectively.
E4A03	Lenalidomide plus standard-dose dexamethasone versus lenalidomide plus low-dose dexamethasone in relapsed myeloma	Newly diagnosed myeloma	445	Superior survival at 4 months postinduction therapy with lenalidomide plus low-dose dexamethasone compared to lenalidomide plus standard-dose dexamethasone, 0.5% versus 5%, respectively ($P <$ 0.001).	
IFM 99-02[82]	Bortezomib-dexamethasone versus vincristine, doxorubicin, dexamethasone (VAD)	Newly diagnosed myeloma	222 (interim analysis)		Additional chemotherapy with doxorubicin, cyclophosphamide, cisplatin, and etoposide were also studied in this trial.
IFM 99-02[115]	No therapy versus pamidronate versus pamidronate plus thalidomide as maintenance therapy following tandem autologous stem cell transplantation	Posttandem auto transplant	597	Event-free survival rate at 3 years was 36%, 37%, and 52%, with no maintenance, pamidronate and pamidronate plus thalidomide, respectively ($P < 0.01$). Corresponding 4-year overall survival was 77%, 74%, and 87%, respectively ($P < 0.04$).	In this trial, 597 low-risk patients (lack of concomitant B2M>3 and deletion 13 by fluorescent in situ hybridization) who were treated with induction chemotherapy with the VAD (vincristine, doxorubicin, and dexamethasone) regimen followed by tandem autologous transplantation were randomized to maintenance therapy.

Table 110-7 Results of Major Randomized Trials Using New Active Agents for Multiple Myeloma—cont'd

Trial	Study Regimens	Disease Stage	No. of Patients	Primary Results	Major Toxicity
APEX[63]	Bortezomib versus dexamethasone for relapsed refractory myeloma	Relapsed myeloma	669	Median time to progression 5.7 months with bortezomib compared to 3.6 months with dexamethasone alone ($P <$ 0.001).	
010 Trial[145]	Lenalidomide plus dexamethasone versus placebo plus dexamethasone in relapsed myeloma	Relapsed myeloma	351	Superior time to progression with lenalidomide plus dexamethasone compared to placebo plus dexamethasone, 13 months versus 5 months, respectively ($P < 0.001$).	Thrombosis risk: 8.5% versus 4.5%.
009 Trial[76]	Lenalidomide plus dexamethasone versus placebo plus dexamethasone in relapsed myeloma	Relapsed myeloma	354	Superior time to progression with lenalidomide plus dexamethasone compared to placebo plus dexamethasone, >11 months versus 5 months, respectively, ($P < 0.001$). Superior overall survival: not reached versus 24 months.	Thrombosis risk: 15% versus 30%.

a measurable urine protein at baseline was unavailable at follow-up were 72% with Thal/Dex versus 50% with dexamethasone alone. Stem cell harvest was successful in 90% of patients in each arm. DVT was more frequent with Thal/Dex (17% versus 3%). Overall, grade III or higher nonhematologic toxicities were seen in 67% of patients within four cycles with Thal/Dex and 43% with dexamethasone alone ($P < 0.001$). Early mortality (first 4 months) was 7% with Thal/Dex and 11% with dexamethasone alone. On the basis of this trial, the U.S. Food and Drug Administration (FDA) has granted accelerated approval for Thal/Dex for the treatment of newly diagnosed myeloma.

Preliminary results are available from a separate randomized, double-blind, placebo-controlled study comparing Thal/Dex versus dexamethasone alone as primary therapy in 470 patients with newly diagnosed myeloma.[74] Among 470 patients enrolled, the response rate was significantly higher with Thal/Dex than with placebo/Dex: 59% versus 42%, respectively ($P < 0.001$). Time to progression (TTP) was also significantly superior with Thal/Dex ($P < 0.001$). As in the ECOG trial, DVT and other grade III to IV events were more frequent with Thal/Dex.

The incidence of DVT is 1% to 3% in patients receiving thalidomide alone but rises to approximately 15% to 20% in patients receiving thalidomide in combination with dexamethasone and over 25% in patients receiving the agent in combination with other cytotoxic chemotherapeutic agents, particularly doxorubicin. Patients who are receiving thalidomide in combination with high-dose steroids or chemotherapy need routine thromboprophylaxis with coumadin (target INR 2 to 3) or low-molecular-weight heparin (equivalent of enoxaparin 40 mg once daily). Aspirin can be used instead in patients who are receiving only low doses of dexamethasone (40 mg once a week or lower) or prednisone in combination with thalidomide, provided that no concomitant erythropoietic agents are used.

LENALIDOMIDE-DEXAMETHASONE. Lenalidomide (CC-5013) belongs to a class of thalidomide analogs that are termed *immunomodulatory drugs*. Lenalidomide appears to be safer and more effective than thalidomide in preclinical and clinical studies. Richardson and colleagues reported activity in a multicenter randomized phase II trial that enrolled 102 patients with relapsed or refractory myeloma.[65] The overall response rate with single-agent lenalidomide was 17%. Two large phase III trials have since shown significantly superior TTP with lenalidomide plus dexamethasone (Rev/Dex) compared to placebo plus dexamethasone in relapsed myeloma.[75,76] Rev/Dex is currently approved by the FDA for the treatment of myeloma in patients who have failed one prior therapy.

In newly diagnosed myeloma, a phase II trial conducted at the Mayo Clinic demonstrated remarkably high activity with the Rev/Dex regimen. Thirty-one of 34 patients (91%) achieved an objective response, including 2 (6%) who achieved complete response (CR), and 11 (32%) who met criteria for very good partial response (VGPR).[64] Lacy and colleagues recently updated the results of this study. With longer follow-up, 56% of patients achieved very good partial response or better. In the subset of 21 patients receiving Rev/Dex as primary therapy without ASCT, 67% achieved VGPR or better.[77] Approximately 50% of patients experienced grade III or higher nonhematologic toxicity, similar to rates that are seen with dexamethasone alone.

ECOG recently reported preliminary findings of a randomized trial testing Rev/Dex as administered in the Mayo Phase II trial (and in the regulatory relapsed or refractory myeloma studies) versus Rev/low-dose Dex (40 mg dexamethasone once weekly).[78] Results so far show that toxicity rates are significantly higher with Rev/standard-dose Dex than with Rev/low-dose Dex. Early (first 4 months) mortality rates were low in both arms: 5% and 0.5%, respectively. The early mortality rate in the Rev/low-dose Dex arm is probably the lowest reported in any large phase III trial involving newly diagnosed patients in which enrollment was not restricted by age or eligibility for SCT. DVT rates are also low, making this one of the safest pretransplant induction regimens for myeloma. Moreover, one- and two-year overall survival rates are significantly superior with Rev/low-dose Dex. Consequently, we do not recommend the use of high-dose dexamethasone in the treatment of newly diagnosed myeloma. On the basis of these results, Rev/low-dose Dex is currently the regimen of choice in the Mayo Stratification for Myeloma and Risk-Adapted Therapy (mSMART) protocol for the treatment of standard-risk myeloma in patients who are candidates for ASCT outside the setting of a clinical trial.[66]

The incidence of DVT is low with single-agent lenalidomide or lenalidomide plus low-dose dexamethasone but rises markedly when the agent is combined with high-dose dexamethasone. Recommenda-

tions for thromboprophylaxis are similar to those discussed previously with Thal/Dex. Aspirin alone is probably sufficient for patients receiving lenalidomide plus low-dose dexamethasone.

BORTEZOMIB-BASED REGIMENS. Bortezomib (formerly known as PS-341) is a novel proteasome inhibitor that has been approved for the treatment of patients with relapsed and refractory multiple myeloma. In 202 patients with relapsed or refractory multiple myeloma, approximately one third responded to bortezomib therapy, with an average response duration of 1 year.[62] In a recent randomized trial, progression-free survival (PFS) was superior with bortezomib than with dexamethasone alone in patients with relapsed or refractory multiple myeloma.[63] Bortezomib is currently approved by the FDA for the treatment of myeloma in patients who have failed one prior therapy.

In newly diagnosed myeloma, bortezomib has shown response rates of approximately 40% as a single-agent.[79] Significantly higher response rates (approximately 70% to 90%) have been observed with bortezomib plus dexamethasone (Vel/Dex),[80,81] bortezomib, thalidomide, dexamethasone (VTD), and other bortezomib-based combinations. The CR plus VGPR rate is approximately 25% to 30% with Vel/Dex in one study. No adverse effect on stem cell mobilization was noted. The most common grade II or higher adverse events in one study were sensory neuropathy (31%), constipation (28%), myalgia (28%), and fatigue (25%).[80]

Harousseau and colleagues recently reported preliminary results of a randomized trial comparing VAD and Vel/Dex as pretransplant induction therapy.[82] With over 400 patients enrolled, preliminary results show superior response rates and long-term outcome with Vel/Dex compared to VAD. The DVT risk was low with bortezomib (<5%).

The main drawback of bortezomib-based regimens is the need for intravenous therapy without adequate data that such therapy is significantly superior to orally administered regimens such as Thal/Dex or Rev/Dex. However, bortezomib-based regimens may be of value in patients with renal failure and in patients with high-risk myeloma (see later) and is not associated with high rates of thrombosis.

OTHER INDUCTION REGIMENS. The role of other pretransplant induction regimens, such as those containing doxorubicin or liposomal doxorubicin, need to be weighed in terms of the added side effects that can affect quality of life and should be considered investigational until future studies show that the addition of these agents improves long-term outcome in comparison to the regimens discussed earlier.

Initial Therapy in Standard-Risk Patients Who Are Eligible for Transplantation

Patients who are not transplant candidates are treated with standard alkylating agent therapy. For decades this has meant therapy with MP.[1] Over the years, despite better response rates, no survival benefit has been reported with any of the more aggressive combination chemotherapy regimens compared to MP. Two recent randomized studies show that MPT (melphalan, prednisone, and thalidomide) improves response and event-free survival (EFS) compared to MP;[83,84] an overall survival advantage has been observed in one of the two trials.[84] As a result, MPT has emerged as the current standard of care for patients who are not eligible for ASCT.

MELPHALAN, PREDNISONE, AND THALIDOMIDE. Two randomized trials have compared MP to MPT.[83,84] Palumbo and colleagues randomized patients either to standard-dose MP for 6 months or to MPT for 6 months followed by maintenance thalidomide.[83] Overall response rates were significantly higher with MPT than with MP (76% versus 48%), as was the CR plus near CR rate (28% versus 7%). MPT also resulted in superior 2-year EFS rates (54% versus 27%, $P = 0.0006$) and a trend toward an improved 3-year overall survival (OS).

Facon and colleagues recently reported results of the IFM 99-06 trial, in which 436 patients were randomized to MP versus MPT versus tandem ASCT with reduced dose melphalan (Mel 100 mg/m^2).[84] As in the study by Palumbo and colleagues,[83] significantly higher response and PFS rates were observed with MPT than with either MP or tandem MEL100 groups; the median PFS was 29, 17, and 19 months, respectively. More important, the trial demonstrated a significant survival advantage with MPT; median OS was not reached at 56 months, 30 months, and 39 months, respectively. The early (first 3 months) mortality rate was 8% with MP compared to 3% with MPT.

MPT therapy is associated with greater toxicity than MP. Therefore, not all elderly patients might be able to receive the regimen. Grade III to IV adverse events occur in approximately 50% of patients who were treated with MPT, compared to 25% who were treated with MP.[83] As with Thal/Dex, there is a significant (20%) risk of DVT with MPT in the absence of thromboprophylaxis. However, this rate drops to approximately 3% with the use of thromboprophylaxis (e.g., enoxaparin).[83]

MELPHALAN, PREDNISONE, AND BORTEZOMIB. Mateos and colleagues[85] have reported the first results of the novel combination melphalan, prednisone, and bortezomib (MPV) in newly diagnosed myeloma in patients 65 years or older. Therapy was associated with a response rate of 89%, including a 32% CR rate. Approximately half of the patients with CR also had no residual bone marrow plasma cells by immunophenotypic studies. In addition, MPV appeared to overcome the poor prognosis conferred by deletion 13 and IgH translocations. The EFS and OS rates at 16 months were 83% and 90%, respectively. Most common grade III or higher adverse events were thrombocytopenia (51%), neutropenia (43%), peripheral neuropathy (17%), diarrhea (16%), and infection (16%). Herpes zoster infection occurred without prophylaxis in 13% of patients and was reduced to 7% with prophylactic acyclovir. MPV appears very promising, with high CR rates. A phase III trial comparing MPV to MP has shown survival benefit with MPV. Future studies might need to compare MPV to MPT, given the OS advantage that is seen with the latter regimen compared to MP.

MELPHALAN, PREDNISONE, AND LENALIDOMIDE. Palumbo and colleagues have studied the addition of lenalidomide to MP (MPR) in newly diagnosed patients older than 65 years of age.[86] Fifty-four patients were studied. The overall response rate was 85%, with 42% of patients achieving at least VGPR or better and 17% of patients achieving CR. The PFS rate was 87% at 16 months; and similar to therapy with MPV, therapy with MPR appeared to overcome adverse effect of deletion 13. Major grade III to IV adverse events were neutropenia (66%), thrombocytopenia (34%), anemia (17%), rash (10%), and febrile neutropenia (8%). All patients received prophylactic aspirin; DVT was uncommon, occurring in three patients (6%), including two patients after aspirin discontinuation. On the basis of this trial, MPR appears to be a very effective oral regimen for the treatment of elderly patients with multiple myeloma who are not candidates for ASCT. An ECOG randomized trial is comparing MPR to MPT.

Hematopoietic Stem Cell Transplantation

AUTOLOGOUS STEM CELL TRANSPLANTATION. Although not curative, ASCT improves complete response rates and prolongs median OS in myeloma by approximately 12 months (Table 110-8).[87–89] The mortality rate is 1% to 2%.

Melphalan 200 mg/m^2 is the most widely used preparative (conditioning) regimen for ASCT. It is superior to the older regimen of melphalan 140 mg/m^2 and 8 Gy total body irradiation (TBI).[90] Studies are ongoing to determine whether the conditioning regimen can be improved with the addition of radioactive compounds (holmium (HO^{166} DOTMP) or samarium 153-SM-EDTMP)[91,92] or bortezomib.

Table 110-8 Randomized Trials Comparing Conventional Chemotherapy versus Single Autologous Stem Cell Transplantation

Trial	No. of Patients	CR/VGPR (%)		PFS (MONTHS)		OS (MONTHS)		SCT (%)	
		CCT	ASCT	CCT	ASCT	CCT	ASCT	CCT	ASCT
IFM90[85, 268]	200	13	38*	18	28*	44	57*	9	74
MRC7[86]	401	8	44*	20	32*	42	54*	15	75

S9321[†271]	516	17	15	7 year: 14%	7 year: 17%	7 year: 38%	7 year: 38%	34	82
MMSG[‡,272]	194	6	25*	16	28*	42	58+*	39	92
HOVON-24[§,273]	303	13	28*	23	24*	50	55	—	—

ASCT, autologous stem cell transplant; CCT, conventional chemotherapy; CR/VGPR, complete response or very good partial response; PFS, progression-free survival; ORR, any response greater than or equal to a partial response; OS, overall survival; SCT, percentage of patients known to have received an autologous stem cell transplant.

*Statistically significant difference.

†Trials testing early versus delayed autologous stem cell transplant.

‡Transplant arm is two low-dose (melphalan 100 mg/m^2) autologous stem cell transplants.

§Could be considered "double transplant," since both arms received melphalan 70 mg/m^2 × 2 without stem cell support as induction therapy.

Reproduced with permission from Dispenzieri, A, Rajkumar SV, Gertz MA, et al: Treatment of newly diagnosed multiple myeloma based on Mayo stratification of myeloma and risk-adapted therapy (mSMART): Consenses statement. Mayo Clinic Proc 2007;82:323–341. © Mayo Clinic Proceedings.

Three randomized trials show that survival is similar whether ASCT is done early (immediately following four cycles of induction therapy) or is delayed (at the time of relapse as salvage therapy).[93–95] In a Spanish PETHEMA group randomized trial, patients responding to induction therapy had similar OS and PFS with either ASCT or eight additional courses of chemotherapy,[96] suggesting that the greatest benefit from ASCT might be in patients with disease that is refractory to induction therapy.[97,98]

There is little doubt that ASCT prolongs survival in myeloma, but its timing (early versus delayed) is controversial. Overall, given the inconvenience and side effects of prolonged chemotherapy, insurance, and other issues, we still favor early ASCT, especially for patients who are less than 65 years of age with adequate renal function.[88] However, given effective new agents to treat myeloma, some patients and physicians may choose to delay the procedure. The need for early ASCT is an important question for future clinical trials.

TANDEM TRANSPLANTATION. With tandem (double) ASCT, patients receive a second planned ASCT after recovery from the first procedure.[49,99] The recent IFM 94 randomized trial found significantly better EFS and OS in recipients of double ASCT versus single ASCT (Table 110-9).[100] A similar benefit was demonstrated in a randomized trial conducted in Italy;[101] two other randomized trials have yet to show significant improvement in OS with tandem ASCT, but they have shorter follow-up.[102,103]

In both the French and Italian trials, the benefit of a second ASCT was restricted to patients who failed to achieve a complete response or very good partial response (>90% reduction in M protein level) with the first procedure. On the basis of these results, we now routinely collect enough stem cells for two transplants in all eligible patients. Patients who achieve a complete response or very good partial response with the first transplant are observed or offered clinical trials investigating maintenance therapy, the second ASCT being reserved for relapse.[104] Patients who do not achieve such a response are offered a second ASCT.

ALLOGENEIC TRANSPLANTATION. The advantages of allogeneic transplantation are lack of graft contamination with tumor cells and presence of a graft-versus-myeloma effect.[105,106] However, only 5% to 10% of patients are candidates because of age, availabil-

Table 110-9 Single versus Double Autologous Stem Cell Transplantation in Myeloma

Trial	No. of Patients	Results	Comments
InterGroupe Francophone du Myélome 94[274]	399	Superior event-free and overall survival with double transplantation; 7-year survival rate: 42% with double transplantation versus 21% with single transplantation ($P = 0.01$).	All patients younger than 60 years. Benefit of second transplant restricted to patients who achieved less than a very good partial response with the first
Bologna 96[100]	228	Superior event-free survival with double transplantation. No significant difference in overall survival; median: 60 months with double transplantation versus 56 months with single transplantation; however, compared to single transplant, patients who did not achieve at least a near CR with first transplant had significantly better survival if given second transplant.	Interim analysis of first 228 patients.
Myélome Autogreffe 95[101]	230	No difference in progression-free survival or overall survival between single versus double transplantation.	All patients were younger than 56 years.

ity of a human leukocyte antigen–matched sibling donor, and adequate organ function. Furthermore, the high treatment-related mortality, mainly related to graft-versus-host disease (GVHD), has made conventional allogeneic transplants unacceptable for most patients with myeloma.

Several recent trials have been conducted using nonmyeloablative conditioning regimens (miniallogeneic transplantation).[107] Initial trials evaluating this approach included relapsed or refractory patients, a factor that was thought to account at least in part for the poor outcomes. It also became apparent that this approach was less useful in patients who had significant residual tumor burden at the time of the nonmyeloablative transplant, which led to the concept of a planned autologous SCT followed by a planned reduced-intensity allogeneic SCT a couple of months later.[108] The initial studies had treatment-related mortality rates approaching 25%; 3-year OS and PFS rates were 41% and 21%, respectively. Adverse OS was associated with chemoresistant disease, more than one prior transplantation, and absence of chronic GVHD. In the planned tandem autologous/nonmyeloablative allogeneic SCT approach, outcomes have been better, with treatment-related mortality rates of 15% and 2-year OS rates approaching 75%.[109] However, there is also a high risk of acute and chronic GVHD, and the occurrence of GVHD appears necessary for disease control.

There are published data from only one randomized trial that addresses ASCT in high-risk patients as defined by the presence of deletion 13 by fluorescent in situ hybridization and of β_2-microglobulin greater than 3 mg/L.[110] On the basis of biologic randomization, patients were allocated either to double ASCT or to autologous SCT followed by a reduced-intensity allogeneic SCT. Although patients did better than expected in both arms, with median OS of 41 and 35 months, respectively, there was no significant difference between the two arms with a median follow-up of 24 months. The major criticisms of this study have been that the criteria that were used to select high-risk disease did not select for the highest-risk patients and that the reduced-intensity conditioning that was used might have been too immunosuppressive, thereby abrogating the graft-versus-myeloma effect.

At this time, miniallogeneic transplantation remains investigational. It should be considered only in the context of clinical trials in standard-risk myeloma because current results with the tandem ASCT strategy described earlier yields 7-year survival rates in excess of 40%. In these patients, the treatment-related mortality and GVHD rates with nonmyeloablative allogeneic transplantation are unacceptably high.

Treatment of High-Risk Myeloma

Patients with high-risk myeloma tend to do poorly, with median OS of approximately 2 years even with tandem ASCT. One option for these patients is novel therapeutic strategies.[2,66] For example, bortezomib-containing regimens can be considered early in the disease course as primary therapy, with SCT reserved for relapse. In at least three separate studies, bortezomib appears to overcome the adverse effect of deletion 13.[85,111,112] In elderly patients, MPT remains an option.

Allogeneic approaches might be an option in selected patients, for example, ASCT followed by nonmyeloablative allogeneic transplantation. However, as was mentioned previously, the recent IFM 99 trial in patients with deletion 13 and high β_2-microglobulin levels has not shown significant benefit with this strategy compared to tandem ASCT.[110]

If patients are treated similarly to standard-risk patients, routine maintenance therapy could be considered (e.g., thalidomide plus prednisone), given the high risk of early relapse. Clearly, clinical trials and new agents that are specifically designed for high-risk myeloma are needed.

Maintenance Therapy

Maintenance therapy with interferon-α is of limited value and is seldom used.[113] Recent results from a large intergroup study showed no benefit with interferon as maintenance therapy.[95] A study by Berenson and colleagues suggests that prednisone might be useful for maintenance therapy.[114] PFS (14 months versus 5 months) and OS (37 months versus 26 months) were significantly longer with 50 mg than with 10 mg of prednisone orally every other day. Because this comparison included only patients who responded initially to steroid-based therapy and because patients did not receive ASCT, it is difficult to generalize these results to current practice.

Clinical trials are currently evaluating thalidomide, dendritic cell vaccination, and other novel approaches as maintenance therapy. A recent French trial (IFM 99–02) randomized 597 patients (age < 65 years) following tandem ASCT to no maintenance (arm A), pamidronate (arm B), or pamidronate plus thalidomide (arm C).[115] There was a significant improvement in EFS with maintenance thalidomide plus pamidronate; the 3-year EFS rate from the time of randomization was 36% in arm A, 37% in arm B, and 52% in arm C ($P < 0.009$). The corresponding 4-year OS rates were 77%, 74%, and 87%, respectively ($P < 0.04$; see Table 110-7). Of note, no decrease in the incidence of bone events was noted with pamidronate therapy when arms B and C were compared to arm A in this cohort of patients. Multiple studies addressing the use of immunomodulatory drugs after SCT are ongoing.

Treatment of Relapsed Multiple Myeloma

Almost all patients with myeloma eventually relapse. If relapse occurs more than 6 months after stopping therapy, the initial chemotherapy regimen should be reinstituted. Patients who have cryopreserved stem cells early in the disease course can derive significant benefit from ASCT as salvage therapy.[116]

In general, patients who have indolent relapse can often be treated with single-agents or MP. These patients present with asymptomatic increases in serum and urine M protein levels, progressive anemia, or few small lytic bone lesions. In contrast, patients with more aggressive relapse often require therapy with a combination of active agents. Given the noncurative nature of myeloma, patients with relapsed disease typically continue on one drug or regimen until relapse or toxicity and then try the next option.

GLUCOCORTICOIDS AND ALKYLATING AGENTS. High-dose pulse dexamethasone or intravenous methylprednisolone is a reasonable option, particularly if the patient has had an initial response to steroids and was off high-dose steroids when the relapse occurred.[117,118] Patients who relapse more than 6 to 12 months after an ASCT can respond to MP or MPT, since most patients would not have been exposed to this regimen as induction therapy.

Conventional combination chemotherapy regimens such as VBMCP, VAD, or other alkylator-based regimens can be effective in relapsed and refractory disease. Intravenous melphalan at a dose of 25 mg/m^2 is another active regimen but usually requires transfusion and growth factor support.

THALIDOMIDE AND THALIDOMIDE-BASED REGIMENS. The finding of increased angiogenesis in myeloma and the antiangiogenic properties of thalidomide led to the first clinical trial with the agent at the University of Arkansas. This trial demonstrated a response rate of 25% in heavily pretreated patients with relapsed and refractory disease.[61,119] Since then, several studies have demonstrated that thalidomide produces response rates in about 25% to 35% of patients with relapsed and refractory multiple myeloma.[120–124] The median duration of response is approximately 1 year. Thalidomide is usually given in a dosage of 100 to 200 mg daily. After a response has been achieved, the dosage should be adjusted to the lowest dose that can achieve and maintain a response, in order to minimize long-term toxicity.

Thal/Dex with or without cyclophosphamide has significant activity in the treatment of relapsed multiple myeloma. Studies show that response rates in relapsed disease are about 50% with the combination of thalidomide and steroids[125] and increase to over 65% with an oral three-drug combination of thalidomide, steroids, and cyclophosphamide (CTD).[126–128] Several other combination chemotherapy regimens that contain thalidomide are being studied, including DT-PACE (dexamethasone, thalidomide, cisplatin, Adriamycin, cyclophosphamide, and etoposide), BLT-D (clarithromycin, low-dose thalidomide, and dexamethasone), and MTD (melphalan, thalidomide, and dexamethasone).[129]

The use of thalidomide in pregnancy is absolutely contraindicated, and the System For Thalidomide Education and Prescribing Safety Program must be followed to prevent teratogenicity.[130] The incidence of DVT is only 1% to 3% in patients who receive thalidomide alone but rises to approximately 10% to 15% in patients who receive thalidomide in combination with dexamethasone and to about 25% in patients who receive the agent in combination with other cytotoxic chemotherapeutic agents, particularly doxorubicin.[120,131–134] The management of thalidomide toxicity has been reviewed.[135]

BORTEZOMIB AND BORTEZOMIB-BASED REGIMENS. Bortezomib (formerly known as PS-341) is a novel proteasome inhibitor that has been approved for the treatment of patients with relapsed and refractory multiple myeloma.[136,137] In the first phase II trial, conducted in 202 patients with relapsed or refractory multiple myeloma, approximately one third of patients responded to bortezomib therapy, with an average response duration of 1 year.[62] These results were confirmed in a randomized phase II trial in patients who failed to respond or who relapsed after frontline therapy for myeloma.[138] Although initial trials allowed a maximum of only eight cycles of bortezomib, additional data indicate that it is safe to give at least an additional five or six cycles of therapy without undue toxicity.[138] In a recent randomized trial, PFS was superior with bortezomib compared to dexamethasone alone in patients with relapsed or refractory multiple myeloma (see Table 110-7).[63] The starting dose of bortezomib is 1.3 mg/m^2 given twice weekly on days 1, 4, 8, and 11 every 21 days. The dosage might need to be decreased to 1.0 mg/m^2 or 0.7 mg/m^2 on the basis of toxicity.

Bortezomib with or without dexamethasone is an active regimen for the treatment of aggressive relapse. Bortezomib has also been combined with intravenous liposomal doxorubicin with a high response rate.[139] In a recently presented randomized trial, this combination yielded a superior TTP (9.3 months versus 6.5 months) compared to single-agent bortezomib; however, this promising result has not yet translated into a better OS.[140]

Zangari and colleagues have preliminarily reported their experience with VTD in a phase 1 trial.[141] The overall response rate was 55%; the EFS and OS were 9 and 22 months, respectively. Myelosuppression was the most common grade III to IV toxicity. Peripheral neuropathy worsened above baseline in 5% to 9% of these heavily pretreated patients.

LENALIDOMIDE. Lenalidomide (CC-5013) belongs to a class of thalidomide analogs termed immunomodulatory drugs. It first showed promising activity in multiple myeloma in two phase I trials.[142,143] Richardson and colleagues have reported the preliminary results of a multi-center randomized phase II trial with oral CC-5013 in relapsed/refractory myeloma.[144] Of 83 evaluable patients, 24% responded with at least a 50% or greater reduction in M protein levels.

Two large phase III trials have recently shown significantly superior TTP with lenalidomide plus dexamethasone compared to placebo plus dexamethasone in relapsed myeloma (see Table 110-7).[145] In these trials, grade III to IV neutropenia was more frequently seen with the combination of lenalidomide plus dexamethasone; the frequency of grade III to IV infections were similar in both arms. Typical dosing of lenalidomide for myeloma is 25 to 30 mg per day on days 1 to 21 of a 28-day cycle, with dose adjustments based on toxicity.

OTHERS DRUGS. There is a continued search for other active agents based on advances in myeloma biology.[146] There are preliminary data that suggest modest efficacy with arsenic trioxide,[147] but further confirmation is needed. CC-4047 (pomalidomide, another thalidomide analog) has also shown promising activity.[148]

Complications

Hypercalcemia

Aggressive hydration with isotonic saline and corticosteroids are effective in most cases. A single dose of pamidronate 60 to 90 mg intravenously over 2 to 4 hours[149] or zoledronic acid 4 mg intravenously over 15 minutes[150] will normalize the calcium levels within 24 to 72 hours in most patients

Skeletal Lesions

Surgical fixation of fractures or impending fractures of long bones might be needed. Local radiation should be limited to patients with disabling pain who have a well-defined focal process that has not responded to analgesics and/or chemotherapy. The administration of bisphosphonates significantly reduces the number of skeletal events (pathologic fracture, need for irradiation or surgery on bone and spinal cord compression).[151] In a randomized trial of 392 patients with at least one lytic lesion, skeletal events (pathologic fracture, radiation or surgery to bone, and spinal cord compression) after 9 months of therapy were significantly fewer with pamidronate than with placebo, 24% versus 41%, respectively ($P < 0.001$).[151] More recently, zoledronic acid has been shown to have efficacy comparable to that of pamidronate.[152,153] Either pamidronate (90 mg intravenously over at least 2 hours every 4 weeks) or zoledronic acid (4 mg intravenously over 15 to 30 minutes every 4 weeks) is recommended in patients with multiple myeloma who have one or more lytic lesions on skeletal roentgenograms.[152,154]

The typical recommendation initially was to continue bisphosphonates indefinitely at monthly intervals.[154] However, by 2003, avascular osteonecrosis of the jaw (ONJ) has been described as a new complication associated with their use[155–159] The etiology of ONJ is unclear, but is likely multifactorial in origin. Although most patients who develop ONJ have had recent dental or oral surgical procedures (70%), the remainder develop spontaneous ONJ.[159] Proposed mechanisms include that inhibition of osteoclast activity reduces bone turnover and remodeling and that bisphosphonates prevent release of bone-specific factors that promote bone formation.[160]

The incidence of ONJ ranges from 4.4% to 21% depending on the type and duration of bisphosphonate use.[160,161] Risks increase with duration of therapy and likely with use of zoledronic acid compared to pamidronate or other lower-intensity bisphosphonates. A Mayo Clinic consensus statement recommends pamidronate instead of zoledronic acid as the bisphosphonate of choice for long-term therapy.[160] It also recommends 2 years of monthly bisphosphonate therapy for patients with myelomatous bone disease, followed by cessation of therapy in patient who are off active treatment for their myeloma and continuation of therapy every 3 months for those who are receiving myeloma therapy. These recommendations are bolstered by two recent observations. The first is that the rates of myeloma bone disease in the prebisphosphonate error was highest during the first 2 years after diagnosis.[162] The second supporting data element is the recent finding that pamidronate use after tandem transplant did not provide any significant reduction in skeletal events.[115]

Both vertebroplasty (injection of methylmethacrylate into a collapsed vertebral body) and kyphoplasty (introduction of an inflatable bone tamp into the vertebral body and after inflation the injection of methylmethacrylate into the cavity) have been successfully used to decrease pain and help restore height.[163] Pain relief is generally rapid and can be long-lasting.

Spinal cord compression from an extramedullary plasmacytoma should be suspected in patients with severe back pain, weakness or paresthesias of the lower extremities, bladder or bowel dysfunction, or incontinence. The standard treatment for cord or cauda equina compression are corticosteroids (dexamethasone 10 mg to 40 mg intravenously followed by 4 mg orally or intravenously four times daily) and radiation therapy. On rare occasions, surgical decompression might be necessary.

Renal Insufficiency

Nonsteroidal anti-inflammatory agents can precipitate renal failure and should generally be avoided.[164,165] Dehydration, infection, and radiographic contrast media may also contribute to acute renal failure. Maintenance of a high urinary output (3 L/day) is important in preventing renal failure in patients with high levels of monoclonal light chains in the urine. Patients with acute or subacute renal failure due to light-chain cast nephropathy should be treated with Thal/Dex or dexamethasone to reduce the tumor mass as quickly as possible. A trial of plasmapheresis should be considered in these patients in an attempt to prevent irreversible renal damage.[166]

Anemia

Iron, folate, or B-12 deficiency might be responsible for the anemia as well and, if so, must be recognized and treated. Treatment of the underlying disease and renal failure often leads to improvement in the hemoglobin level. Erythropoietin (40,000 units subcutaneously weekly) or darbepoietin (200 μg subcutaneously every 2 weeks) are useful in patients with persistent symptomatic anemia[167,168] but should be restricted because of a higher risk of DVT when used in combination with thalidomide or lenalidomide. Blood transfusions are indicated for patients with symptomatic anemia who do not obtain benefit from other therapies.

Infections

Patients should receive pneumococcal and influenza vaccinations. Intravenously administered gamma globulin every 3 to 4 weeks is indicated if patients have recurrent serious infections associated with severe hypogammaglobulinemia. The use of prophylactic antibiotics in patients who are receiving chemotherapy for myeloma has not been settled. Prophylaxis against *Pneumocystis carinii* pneumonia should be considered in all patients who are receiving high-dose steroid therapy. A small, randomized, placebo-controlled trial of trimethoprim-sulfamethoxazole in 57 patients with newly diagnosed myeloma demonstrated benefit with routine prophylaxis administered with the first two cycles of chemotherapy.[169] However, owing to the risk of serious skin toxicity, we think that trimethoprim-sulfamethoxazole should be avoided in patients who are receiving Thal/Dex therapy. In patients who are receiving Thal/Dex, prophylaxis with other antibiotics (such as ciprofloxacin, levofloxacin, or cephalosporins) and alternative agents for *P. carinii* pneumonia should be considered. A randomized trial is ongoing in the United States comparing no prophylaxis, trimethoprim-sulfamethoxazole, and ciprofloxacin in patients with newly diagnosed myeloma who are receiving chemotherapy.

Hyperviscosity Syndrome

Infrequently, patients with multiple myeloma develop hyperviscosity syndrome. Plasmapheresis promptly relieves the symptoms and should be done regardless of the viscosity level if the patient has signs or symptoms of hyperviscosity.[170]

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Introduction

MGUS is an asymptomatic, premalignant clonal plasma cell proliferative disorder that is defined by the presence of a serum M protein level lower than 3 g/dL, bone marrow plasma cells less than 10%, plus absence of anemia, hypercalcemia, lytic bone lesions, or renal failure that can be attributed to the plasma cell proliferative disorder.[24,171] It is the most common plasma cell dyscrasia, prevalent in approximately 3% of the general population 50 years of age and older.[172] The prevalence increases with age: 1.7% in those 50 to 59 years of age and over 5% in those over the age of 70. Age-specific incidence is higher in males than in females. MGUS is also twice as common in African Americans as in Caucasians.[173]

MGUS is associated with a lifelong risk of progression to multiple myeloma or a related disorder. The rate of progression of MGUS to multiple myeloma or related malignancy is 1% per year (see Fig. 110-1).[3,174] However, the true lifetime probability of progression is substantially lower when competing causes of death are taken into account: approximately 11% at 25 years (see Fig. 110-1).[175] As was discussed earlier, the risk of progression with MGUS does not diminish with time.[3,176]

Clinical Features and Differential Diagnosis

MGUS is asymptomatic. It is differentiated from multiple myeloma and related disorders on the basis of the presence or absence of end-organ damage that can be attributed to the plasma cell disorder. The differentiation of MGUS from multiple myeloma or other related disorders can be difficult at the time of initial presentation because MGUS is relatively common in the general population over the age of 50 years, and a number of clinical and laboratory abnormalities may be coincidental. The typical laboratory investigations necessary to differentiate MGUS from other related plasma cell disorders are a complete blood count, serum creatinine, serum calcium, and a complete roentgenographic bone survey. If abnormalities are detected on the preceding tests, additional tests to determine the cause of these abnormalities are required; only patients in whom abnormalities are thought to be related to the plasma cell proliferative disorder can be considered to have myeloma or a related malignancy. A bone marrow aspirate and a biopsy are indicated when the M protein is greater than or equal to 1.5 g/dL, in non-IgG MGUS, when serum free light-chain ratio is abnormal (see later), and when abnormalities are noted in the complete blood count, serum creatinine, serum calcium, or radiographic bone survey. A bone marrow aspirate should also be considered in any patient with presumed MGUS in whom there is doubt about the diagnosis.

Prognosis

In a large population-based study of MGUS involving 1384 patients, only the size and type of M protein (IgM and IgA subtypes) were predictive of progression to myeloma or related malignancy.[3] In another study, a bone marrow plasma cell percentage of 6% to 9% carried twice the risk of progression compared to marrow involvement that is 5% or less.[177]

The presence of circulating plasma cells detected by using a sensitive slide-based immunofluorescent assay is also a risk factor for progression.[178] This finding suggests that alterations in expression of adhesion molecules might be involved in the progression of MGUS to myeloma; alternatively, the presence of circulating plasma cells may be a marker of plasma cell proliferative rate. However, the clinical application of this finding is currently limited by the lack of widespread availability of the test in clinical practice.

Table 110-10 Risk Stratification Model to Predict Progression of Monoclonal Gammopathy of Undetermined Significance to Myeloma or Related Disorders

Risk Group	No. of Patients	Relative Risk	Absolute Risk of Progression at 20 Years (%)	Absolute Risk of Progression at 20 Years Accounting for Death as a Competing Risk (%)
Low-risk (serum M protein < 1.5 g/dL, IgG subtype, normal free light chain ratio (0.26–1.65)	449	1	5	2
Low-intermediate-risk (any one factor abnormal)	420	5.4	21	10
High-intermediate-risk (any two factors abnormal)	226	10.1	37	18
High-risk (all three factors abnormal)	53	20.8	58	27

Originally published in Rajkumar SV, Kyle RA, Therneau TM, et al: Serum free light chain ratio is an independent risk factor for progression in monoclonal gammopathy of undetermined significance (MGUS). Blood 2005;106:812–817. © The American Society of Hematology.

An abnormal serum free light-chain ratio using the serum free light-chain assay has been shown to be an important risk factor for progression of MGUS. In a study of 1148 patients, the risk of progression with an abnormal free light-chain ratio at the time of diagnosis of MGUS was significantly higher than a normal ratio (hazard ratio: 3.5, 95% CI: 2.3 to 5.5, $P < 0.001$) and was independent of the size and type of the serum M protein.[175] The risk of progression to myeloma or related malignancy at 10 years was 17% with an abnormal ratio compared to 5% with a normal ratio.

Risk Stratification of Monoclonal Gammopathy of Undetermined Significance

A risk stratification system can be used to predict the risk of progression of MGUS based on three risk factors: the size of the serum M protein, the type of immunoglobulin, and the serum free light-chain ratio (Table 110-10).[175] Patients with three adverse risk factors, namely, an abnormal serum free light-chain ratio, non-IgG MGUS, and a high serum M protein level (≥15 g/L), had a risk of progression at 20 years of 58% (high-risk MGUS) compared to 37% in patients in with any two of these risk factors present (high-intermediate-risk MGUS), 21% with one risk factor present (low-intermediate-risk MGUS), and 5% when none of the risk factors were present (low-risk MGUS). In fact, the low-risk MGUS subset (constituting almost 40% of the cohort) has a lifetime risk of only 2% when competing causes of death are taken into account.

Management

The current standard of care for MGUS is observation alone, without therapy.[1,179] Patients with MGUS might benefit from risk stratification as discussed previously to guide follow-up. Patients with low-risk MGUS can be rechecked in 6 months and then once every 2 years or only at the time of symptoms for evidence of progression.[175] All other subsets of patients need to be rechecked in 6 months and yearly thereafter.

SMOLDERING MULTIPLE MYELOMA

Introduction

Smoldering multiple myeloma is defined by the presence of a serum IgG or IgA M protein level of 3 g/dL or more and/or 10% or more bone marrow plasma cells plus absence of anemia, hypercalcemia, lytic bone lesions, or renal failure that can be attributed to the plasma cell proliferative disorder (see Table 110-1).[180,181] Smoldering multiple myeloma accounts for approximately 15% of all cases with newly diagnosed multiple myeloma.[171,182]

Because the risk of progression to myeloma or related malignancy is much higher in smoldering multiple myeloma than in MGUS, 10% to 20% per year versus 1% per year, respectively, patients with smoldering multiple myeloma and MGUS should be managed differently in terms of frequency of follow-up, development of chemopreventive strategies, and enrollment in clinical trials. Similar to MGUS and active myeloma, almost all patients with smoldering multiple myeloma appear to have evidence of genomic instability manifested as IgH translocations or hyperdiploidy on molecular genetic testing.[183]

Clinical Features and Differential Diagnosis

By definition, smoldering multiple myeloma is asymptomatic. Testing to differentiate smoldering multiple myeloma from active multiple myeloma is the same as the testing that was described for MGUS. Most patients with smoldering multiple myeloma progress eventually to symptomatic disease;[182] however, some patients can remain free of progression for a number of years.[184] The TTP to symptomatic disease is approximately 3 to 4 years but differs greatly depending on the definition that is used for smoldering multiple myeloma.[185] In the subset of smoldering multiple myeloma patients having 10% or more bone marrow plasma cells, the median TTP is approximately 2 to 3 years.[186]

The natural history of smoldering myeloma was recently characterized by a large study from the Mayo Clinic.[187] During 2204 cumulative person-years of follow-up, the overall rate of progression at 10 years was 62%; the median TTP was 5.5 years. Patients were categorized into three groups: group 1 having serum M protein levels of 3 g/dL or more and bone marrow containing 10% or more plasma cells ($N = 113$, 38%), group 2, having bone marrow plasma cells greater than or equal to 10% but serum M protein levels less than 3 g/dL ($N = 158$, 52%), and group 3 having serum M protein levels of 3 g/dL or more but bone marrow plasma cells less than 10% ($N = 30$, 10%). The median TTP was 2.4, 9.2, and 19 years in groups 1, 2, and 3, respectively; correspondingly, at 10 years, progression occurred in 76%, 59%, and 32%, respectively.

Prognosis

Similar to results in MGUS, abnormal peripheral blood monoclonal plasma cell studies, defined as an increase in the number or proliferative rate of circulating plasma cells by slide-based immunofluorescent assays, have been shown to indicate a higher risk of progression

in smoldering multiple myeloma.[186] However, this test is not widely available in clinical practice.

The presence of occult bone lesions on MRI increases the risk of progression in patients who were otherwise defined as having smoldering multiple myeloma.[182] In a recent study, Wang and colleagues estimated risk of progression in 72 patients with smoldering multiple myeloma in whom an MRI of the spine was also performed.[185] The median TTP was significantly shorter with an abnormal MRI than with a normal MRI: 1.5 years versus 5 years, respectively.

Risk Stratification

Weber and colleagues have shown that as in MGUS, the size and type of immunoglobulin are important predictors of progression in smoldering multiple myeloma.[188] Patients with a serum M protein level of 3 g/dL or less and IgG type (about 45% of patients with smoldering multiple myeloma) had a median TTP greater than 4 years. In contrast, patients with a serum M protein level greater than 3 g/dL or of the IgA type (about 45% of patients) had a median TTP of approximately 2 years, while a small subset of patients with less than 3 g/dL IgA smoldering multiple myeloma had a median TTP of 9 months.

Management

The standard of care is observation alone until evidence of progression to myeloma.[1] Patients with smoldering multiple myeloma need more frequent follow-up than do those with MGUS: at least every 3 to 4 months.[24] Two small randomized trials have shown no benefit with early therapy compared to therapy at the time of symptomatic progression.[189,190]

There are preliminary data that thalidomide might delay TTP,[72,191] but data are needed from randomized trials before such therapy can be recommended, particularly given the adverse effects associated with the drug. A randomized phase III trial at Mayo Clinic is currently testing thalidomide plus zoledronic acid versus zoledronic acid in patients with smoldering multiple myeloma; the results of this study will shed light on the utility of thalidomide in this setting. Outside of a clinical trial, therapy with bisphosphonates is not recommended.

With the increasing availability of novel targeted therapies for myeloma,[192–194] clinical trials are ongoing to determine whether the early use of new agents or bisphosphonates can delay progression in smoldering multiple myeloma.

WALDENSTRÖM'S MACROGLOBULINEMIA

Waldenström's macroglobulinemia is a clonal IgM M protein–secreting lymphoid/plasma cell disorder, which currently also includes the entity that was previously referred to as *lymphoplasmacytic lymphoma*. The median age at diagnosis is approximately 65 years, with a slight male predisposition. The typical symptoms at presentation are weakness and fatigue due to anemia. Other clinical manifestations may include constitutional symptoms (fever, night sweats, and weight loss), hepatosplenomegaly, lymphadenopathy, hyperviscosity, cryoglobulinemia, and sensorimotor peripheral neuropathy.[195] Unlike multiple myeloma, primary IgH translocations are not seen in Waldenström's macroglobulinemia.[196]

Diagnosis

The diagnostic criteria for Waldenström's macroglobulinemia are listed in Table 110-1.[197] The diagnostic criteria in Table 110-1 have been updated in an evidence-based manner such that the diagnosis of Waldenström's macroglobulinemia requires 10% or greater lymphoplasmacytic infiltration.[3,198–200] The presence of less than 10% lymphoplasmacytic infiltration in the absence of end-organ damage represents IgM MGUS and not Waldenström's macroglobulinemia; such patients have a risk of progression to symptomatic disease at a rate of only 1.5% per year.[198] In fact, patients with IgM MGUS and smoldering Waldenström's as defined by using the criteria in Table 110-1 have an OS rate similar that of to the general population and are best not considered to have malignant disease.[199]

Patients with a serum IgM M protein level of 3 g/dL or more and/or bone marrow lymphoplasmacytic infiltration of 10% or more and no evidence of end-organ damage such as anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to a plasma cell proliferative disorder are considered to have smoldering Waldenström's macroglobulinemia (also referred to as indolent or asymptomatic Waldenström's macroglobulinemia), an asymptomatic condition that is similar to smoldering multiple myeloma but is associated with a risk of progression to Waldenström's macroglobulinemia.

Historically, patients with an IgM M protein level less than 3 g/dL who meet criteria for Waldenström's macroglobulinemia have been classified as "lymphoplasmacytic lymphoma with an IgM M protein." However, except for hyperviscosity, the clinical picture, therapy, and prognosis in these patients are no different from those of patients who are classified as Waldenström's macroglobulinemia who have an IgM M protein level of 3 g/dL or more.[201] By the current definition, patients are considered to have Waldenström's macroglobulinemia regardless of the size of the serum M protein.

Prognosis

The median survival is approximately 5 years.[195] Adverse prognostic factors include age greater than 70 years, hemoglobin levels less than 9 g/dL, weight loss, and cryoglobulinemia.[202] Morel and colleagues have constructed a risk stratification model based on a set of three adverse prognostic factors: age 65 years or greater, albumin level less than 4.0 g/dL, and cytopenias; cytopenia restricted to one hematopoietic lineage was scored as one risk factor, while two or more cytopenias were scored as two risk factors.[203] Patients with zero or one risk factors (low-risk), two risk factors (intermediate-risk), and three or four risk factors (high-risk) had 5-year survival rates of 87%, 62%, and 25%, respectively.

Treatment

As is the case for smoldering myeloma, patients meeting the diagnostic criteria for Waldenström's macroglobulinemia who are asymptomatic have no need of immediate therapy. The indications for therapy are anemia (hemoglobin < 10 g/dL) or thrombocytopenia (platelet count < 100,000) that is thought to be related to Waldenström's macroglobulinemia; constitutional symptoms such as weakness, fatigue, night sweats, or weight loss; hyperviscosity; symptomatic cryoglobulinemia; and significant hepatosplenomegaly or lymphadenopathy.[195,204,205]

Initial Therapy

There are four options for initial therapy: rituximab, purine nucleoside analogs, alkylators, and combination chemotherapy. Unfortunately, there are no randomized data to determine the best option; therapy is typically decided on the basis of the age of the patient and the aggressiveness of the presentation. Patients should preferably be treated on clinical trials as much as possible.

Single-agent therapy with rituximab, a chimeric anti-CD20 monoclonal antibody, produces a response in approximately 50% of untreated patients.[206,207] Response to rituximab may be affected by polymorphisms in the Fc-gamma RIIIA (CD16) receptor gene.[208] Responses to rituximab can delayed and may occur months after initial therapy. An initial increase in IgM levels (flare) has been reported.[209] The usual dose is 375 mg/m^2 administered intravenously weekly for 4 weeks,[207] with consideration given to further doses or maintenance depending on response.

The purine nucleoside analogs fludarabine or cladribine are also effective as initial therapy.[210–215] Response rates reported vary widely from 40% to 90% and likely reflect patient selection and the stringency and timing of the response assessment. The two agents are likely equally effective; randomized comparisons have not been conducted. We prefer cladribine 5 mg/m^2 intravenously over 2 hours for 5 days, repeated once after 28 days if needed. The need for further cycles is determined by the extent of response to the first two cycles as well as observed toxicity.

Alkylators such as chlorambucil are an option especially for elderly patients as initial therapy. Chlorambucil is administered orally in a dosage of 6 to 8 mg/day with dose adjustments based on blood counts. Patients are treated until the disease has reached a plateau state; the treatment can then be discontinued, and patients are observed closely.

Preliminary results of several combination chemotherapeutic approaches have been reported, with response rates of over 75%.[204] Examples of active combinations include fludarabine plus rituximab, fludarabine plus cyclophosphamide, cladribine plus cyclophosphamide plus rituximab, and R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone).[205,216] Our preferred approach outside a clinical trial setting is to use single-agent therapy in most patients, reserving combination therapy for aggressive disease.

Relapsed Disease and Supportive Care

Options listed for initial therapy discussed previously can be tried at the time of relapse. In fact, the same initial therapy can be tried again at relapse if there was an adequate interval between cessation of therapy and relapse. A response rate of 25% has been reported with single-agent thalidomide.[217] In general, options for relapsed or refractory disease include SCT,[218] interferon-α,[219,220] thalidomide,[221] and bortezomib.[222] Novel agents are also being investigated.[223] A small subset of chemotherapy-resistant patients respond to splenectomy.[205]

Patients with refractory anemia or anemia during chemotherapy will benefit from erythropoietin and/or and red cell transfusions. Plasmapheresis is indicated for the treatment of hyperviscosity syndrome.[205] Plasmapheresis might need to be continued on an intermittent basis until a therapeutic response is achieved with one of the treatment options discussed earlier.

SYSTEMIC IMMUNOGLOBULIN LIGHT-CHAIN AMYLOIDOSIS

Amyloid is a fibrillar proteinaceous material that can be deposited in various tissues and detected with Congo red staining based on a characteristic apple-green birefringence under polarized light.[224] It consists of rigid, linear, nonbranching fibrils, 7.5 to 10 nm in width, aggregated in a β-pleated sheet conformation. There are several distinct types of amyloidosis, which are classified on the basis of the protein composition of the amyloid material (Table 110-11).

Immunoglobulin light-chain (AL) amyloidosis is the type of amyloidosis that is derived from the variable portion of a monoclonal light chain or, in rare instances, intact monoclonal light chain and occurs as a result of a clonal plasma cell proliferative disorder.[225] AL amyloidosis may be localized (a benign disorder) or systemic. Systemic AL amyloidosis has been commonly referred to as *primary systemic amyloidosis* or simply *primary amyloidosis*.

The pathogenesis of AL amyloidosis is not well understood. It involves aberrant de novo synthesis and abnormal proteolytic processing of light chains. The catabolism of amyloid fibrils might also play a role. IgH translocations have been reported in over 70% of patients with systemic AL amyloidosis.[226] There also appears to be a distinct gene expression profile associated with AL amyloidosis compared to myeloma; a set of 12 genes was recently found to discriminate between AL amyloidosis and multiple myeloma with greater than 85% accuracy on gene expression profiling studies.[227]

Table 110-11 Classification of Amyloidosis

Type of Amyloidosis	Major Protein Component
AL amyloidosis* (previously referred to as primary amyloidosis)	κ or λ immunoglobulin light chain
AA amyloidosis (previously referred to as secondary amyloidosis)	Protein A
ATTR amyloidosis	Transthyretin (TTR; prealbumin), mutant form
• Mutant ATTR	
Familial	Transthyretin (TTR; prealbumin), normal, wild-type form
Neurologic	
Cardiopathic	
• Normal ATTR	
Senile amyloidosis	
β_2-Microglobulin amyloidosis (associated with long-term dialysis)	β_2-Microglobulin
Other	
• Familial Mediterranean fever	Protein A
• Fibrinogen α-chain	Fibrinogen α-chain
• Lysozyme	Lysozyme
• Apolipoprotein A-I	Apolipoprotein A-I

*AL amyloidosis is the only form of amyloidosis that is secondary to a clonal plasma cell disorder. AL amyloidosis can be associated with multiple myeloma in approximately 10% of patients.

Reproduced with permission from Rajkumar SV, Dispenzieri A, Kyle RA: Monoclonal gammopathy of undetermined significance, Waldenstrom macroglobulinemia, AL amyloidosis, and related plasma cell disorders: Diagnosis and treatment. Mayo Clinic Proc 2006;81:693–703. © Mayo Clinic Proceedings.

Certain germline immunoglobulin light-chain V genes, 6a(V lambda VI) and 3r (V lambda III), code for the monoclonal light-chain regions that are involved in systemic AL amyloidosis in approximately 40% of patients.[228] Studies show that the nature of organ involvement in AL amyloidosis might be related to which of the various immunoglobulin light-chain germline V genes the plasma cell clone is derived from.[229,230] Patients with clones derived from the 6a (V lambda VI) germline light-chain gene have a greater likelihood of dominant renal amyloidosis. In contrast, patients with clones derived from the 1c, 2a2, and 3r V (lambda) genes are more likely to present with dominant cardiac and multisystem amyloidosis.

Diagnosis

The diagnosis of systemic AL amyloidosis requires documentation of positive amyloid staining on a tissue biopsy as well as supporting evidence that the amyloid is derived from immunoglobulin light chains (see Table 110-1). It should be suspected when patients with the appropriate clinical syndrome, such as nephrotic syndrome, axonal neuropathy, or restrictive cardiomyopathy, display evidence of a plasma cell proliferative disorder such as a serum or urine M protein.

Systemic AL amyloidosis should be differentiated from localized amyloidosis, which can be derived from immunoglobulin light chains in many patients (localized AL amyloidosis).[224] Localized amyloidosis is typically benign and can manifest as isolated carpal tunnel syndrome; isolated lesions in the ureter, urethra, bladder, lung, bronchus, or trachea; or nonpurpuric cutaneous lesions. Localized amyloidosis, regardless of whether the source of the amyloid is immunoglobulin light chain or some other protein, is treated primarily for symptom relief as needed and should not be treated with systemic therapy.

The median age at diagnosis of systemic AL amyloidosis is 65 years. The clinical manifestations vary greatly and depend on the dominant organ that is involved. Nephrotic syndrome, restrictive cardiomyopathy, and peripheral/autonomic neuropathy are common presenting syndromes. Patients may also have associated macroglossia, carpal tunnel syndrome, and purpura involving the neck, face, and eyes. Immunofixation reveals an M protein in the serum or urine in almost 90% of patients at diagnosis. The free light-chain ratio is abnormal in most of the patients with a negative immunofixation.[231] Regardless of the number of bone marrow plasma cells in the bone marrow the syndrome is referred to as AL or primary, as long as the amyloid fibrils are composed of immunoglobulin light chain. Systemic AL amyloidosis and symptomatic multiple myeloma can coexist in a patient, but one of the two disorders usually dominates the clinical picture.

Prognosis

Survival varies greatly depending on the dominant organ that is involved (cardiac amyloid having the worst outcome) and the number of major organs that are affected.[224,232] Patients who are not eligible for SCT have an estimated median survival of 18 months, compared to over 40 months for those who are eligible for transplantation.[232] An elevated level of cardiac troponin T levels carries an adverse prognosis. Median survival for patients with detectable cardiac troponin T (≥0.01 μg/L) is significantly shorter than that for patients with undetectable levels: 6 versus 22 months, respectively.[233] Elevated serum cardiac troponin I and N-terminal pro–brain natriuretic peptide are also valuable prognostic markers.[233,234] A risk stratification model using the cardiac troponin T and N-terminal pro–brain natriuretic peptide levels is given in Table 110-12.[235,236]

Treatment

Response to therapy in AL amyloidosis can be difficult to assess. Specific response criteria to assess hematologic and organ responses in primary amyloidosis have recently been published.[237] Melphalan and prednisone have been the mainstays of treatment for many years, but results have not been satisfactory.[238] Currently, our approach is to stratify patients on the basis of eligibility for SCT. Patients who are not eligible for SCT (poor performance status, major comorbidities, three or more organs involved, and advanced cardiac amyloidosis) are offered therapy on clinical trials or recommended treatment with melphalan plus high-dose dexamethasone.[239] Melphalan is administered in a dose of 0.22 mg/kg/day orally on days 1 through 4 with high-dose dexamethasone 40 mg/day orally on the same 4 days. Cycles are repeated every 28 days for no longer than 9 months. Under this regimen, a hematologic response was noted in 67% of patients in one trial, 33% achieving compete hematologic remission.[240] Improvement in organ function is seen in approximately 50% of responding patients.

Prolonged and impressive organ remissions can be achieved with ASCT in approximately 50% of patients treated with such therapy.[241–244] However, preliminary results of a French randomized trial suggest that OS might not be superior with SCT compared to melphalan plus high-dose dexamethasone.[245] This trial randomized 100 patients; median actuarial survival was 57 months with melphalan plus high-dose dexamethasone and 49 months with transplantation ($P = 0.2$). However, interpretation of this trial is confounded by the relatively short follow-up (29 months) and the very high treatment-related mortality rate that was observed in the transplant arm (24%). In patients who proceed to early transplant, there does not appear to be any need for induction therapy.[246] Excessive fluid accumulation during stem cell mobilization (>2% weight gain) predicts for a higher mortality rate with SCT.[247] The typical conditioning regimen that is used is high-dose intravenous melphalan (100 to 200 mg/m^2) with the exact dose level based on age, presence or absence of cardiac involvement, number of organs involved, and creatinine clearance.[239] Highly selected patients with end-stage amyloid renal disease and end-stage amyloid cardiomyopathy have been considered for sequential kidney stem cell transplantation and sequential cardiac stem cell transplantation, respectively.[248,249]

A recent study found that thalidomide plus dexamethasone could be a second-line treatment option for patients with systemic AL amyloidosis, hematologic responses being seen in 48% of 31 enrolled patients, including complete responses in 19% and organ responses in 26%.[250] However, it must be noted that thalidomide is less well tolerated in amyloidosis than in myeloma,[251] and the regimen is associated with significant side effects. Lenalidomide, an analog of thalidomide with lesser toxicity, has limited activity in AL amyloidosis as single agent but is more potent in combination with dexamethasone.[252,253] A trial of cyclophosphamide, thalidomide, and dexamethasone has reported organ responses in 27% of evaluable patients.[254]

Patients with amyloidosis also require significant supportive care based on the nature of organ involvement, such as treatment of nephrotic syndrome, malabsorption, neuropathy, and heart failure.

Table 110-12 Risk Stratification Model to Predict Progression of Primary Amyloidosis[235,236]

Risk Group	Median Survival in Patients Undergoing Stem Cell Transplantation (months)	Median Survival in Patients Not Undergoing Stem Cell Transplantation (months)
Low-risk (cardiac troponin < 0.035 μg/L and NT-proBNP < 332 ng/L)	Not reached at 40 months	26.4
Intermediate-risk (any one factor abnormal)	Not reached at 40 months	10.5
High-risk (cardiac troponin ≥ 0.035 μg/L and NT-proBNP ≥ 332 ng/L)	8.4	3.5

NT-proBNP, N-terminal pro–brain natriuretic peptide.

Reproduced with permission from Rajkumar SV, Dispenzieri A, Kyle RA: Monoclonal gammopathy of undetermined significance, Waldenstrom macroglobulinemia, AL amyloidosis, and related plasma cell disorders: Diagnosis and treatment. Mayo Clinic Proc 2006;81:693–703. © Mayo Clinic Proceedings.

SOLITARY PLASMACYTOMA

Solitary plasmacytomas may be confined to bone (solitary bone plasmacytoma) or may occur in extramedullary sites (extramedullary plasmacytoma).[255] Extramedullary plasmacytoma is localized to the upper respiratory tract (nasal cavity and sinuses, nasopharynx, and larynx) in over 80% of cases but can also occur in the gastrointestinal tract, central nervous system, urinary bladder, thyroid, breast, testes, parotid gland, or lymph nodes. Patients with solitary plasmacytoma are at risk for progression to multiple myeloma. Increased microvessel density detected in the initial diagnostic tissue specimen has been associated with an increased risk of progression to multiple myeloma, suggesting that the evolution to systemic disease might depend on an angiogenic switch.[32]

Diagnosis and Prognosis

Diagnostic criteria are listed in Table 110-1. An MRI of the spine and pelvis should be performed in addition to a skeletal survey, since approximately one third of patients may have additional occult lesions that will be missed in the absence of an MRI.[256]

Patients with a baseline serum M protein level greater than 1 g/dL have a high risk of persistent M protein following radiation therapy to the involved site.[257] Persistence of M protein 1 year or more after radiation therapy has been associated with an increased probability of progression to multiple myeloma in patients with solitary bone plasmacytoma.[258] The 10-year myeloma-free survival was 29% in patients with persistent serum or urinary M protein compared to 91% in those in whom the M protein was not detectable following radiation therapy.

Treatment

Treatment consists of radiation in the range of 40 to 50 Gy to the involved site.[182] Patients who meet criteria for solitary plasmacytoma except for evidence of clonal involvement of the bone marrow can be also treated with radiation therapy to the involved site and then observed until disease progression similar to that of MGUS (<10% bone marrow plasma cells) or smoldering multiple myeloma (≥10% plasma cells).

Over 50% of patients with a solitary bone plasmacytoma are alive at 10 years,[258] and disease-free survival rates at 10 years range from 25% to 50%.[255] Progression to myeloma, when it occurs, usually appears within 3 years, but patients must be followed indefinitely. Prognosis may be better in patients with solitary extramedullary plasmacytoma, with 10-year disease-free survival rates of approximately 70% to 80%[255]

POEMS SYNDROME

POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, skin changes) syndrome is defined by the criteria listed in Table 110-1.[259] It is a rare, atypical, plasma cell proliferative disorder. POEMS syndrome been variously referred to in the literature as osteosclerotic myeloma, Crow-Fukase syndrome, PEP (plasma cell dyscrasia, endocrinopathy, polyneuropathy) syndrome, and Takatsuki syndrome. In almost all cases, the immunoglobulin light-chain type is lambda.

Diagnosis

The median age at presentation is 51 years. Almost all patients have either osteosclerotic lesions or Castleman's disease. The major clinical features are a predominantly motor chronic inflammatory demyelinating polyneuropathy, sclerotic bone lesions, and a varying number of associated abnormalities such as hepatomegaly, hyperpigmentation, hypertrichosis, gynecomastia, testicular atrophy, clubbing, polycythemia, thrombocytosis, and Castleman's disease. Patients may have respiratory problems ranging from neuromuscular weakness to reduced diffusion capacity of carbon monoxide to pulmonary hypertension. Biopsy of an osteosclerotic lesion might be necessary for the diagnosis.

The pathogenesis of the syndrome is not clear but appears to be at least in part cytokine mediated, and elevated vascular endothelial growth factor levels are commonly found.[260,261]

Treatment

POEMS syndrome may have an indolent or a fulminant course. In one study of 99 patients, median survival was 13.8 years.[262] If the disease is unchecked, the clinical course is characterized by progressive disabling neuropathy, inanition, anasarca, and pulmonary demise. The number of features involved does not predict for survival, but the presence of fingernail clubbing or extravascular volume overload does. When renal failure occurs in POEMS syndrome, it is in the context of extravascular overload, and membranoproliferative features and endothelial injury are seen rather than light-chain deposition.[263,264]

If the lesions are in a limited area, radiation therapy (40 to 50 Gy) produces substantial improvement of clinical symptoms and signs in more than 50% of patients. For patients with widespread osteosclerotic lesions, treatment is similar to that for myeloma and depends on eligibility for SCT. In eligible patients, ASCT has provided significant responses; in one study, all 14 evaluable patients achieved improvement or stabilization of neuropathy.[265] Supportive care, including aggressive physical and occupational therapy, is an important component of care.

HEAVY-CHAIN DISEASES

The heavy-chain diseases (HCDs) are characterized by the presence of an M protein consisting of a portion of the IgH in the serum, urine, or both. These heavy chains are devoid of light chains and represent a lymphoplasma cell proliferative process.

Gamma Heavy-Chain Disease

In gamma heavy-chain disease (γ-hCD), the abnormal protein consists of monoclonal γ chains with significant deletions of amino acids, including the C_{H1} domain of the constant region. The median age of patients is approximately 60 years, although the condition has been noted in individuals younger than age 20 years. Patients with γ-HCD often present with a lymphoma-like illness, but the clinical findings are diverse and range from an aggressive lymphoproliferative process to an asymptomatic state. The electrophoretic pattern often shows a broad-based band that is more suggestive of a polyclonal increase than of an M protein.

Treatment is indicated only for symptomatic patients. Therapy consists of chemotherapy with melphalan plus prednisone or with regimens that are used to treat non-Hodgkin's lymphoma, such as cyclophosphamide, vincristine, and prednisone. The prognosis of γ-HCD is variable and ranges from a rapidly progressive downhill course of a few weeks' duration to the asymptomatic presence of a stable monoclonal heavy chain in the serum or urine.

Alpha Heavy-Chain Disease

Alpha heavy-chain disease (α-HCD) is the most common form of HCD and occurs in patients from the Mediterranean region or Middle East, usually in the second or third decade of life. About 60% are men. Most commonly, the gastrointestinal tract is involved, resulting in severe malabsorption with diarrhea, steatorrhea, and loss of weight. Plasma cell infiltration of the jejunal mucosa is the most frequent pathologic feature. Immunoproliferative small intestinal disease is restricted to patients with small intestinal lesions who have the same pathologic features as those of α-HCD, but these patients do not synthesize α heavy chains.

The serum protein electrophoretic pattern is normal in half the cases; in the remainder, an unimpressive broad band may appear in the α_2 or β regions. The diagnosis depends on the recognition of a monoclonal α heavy chain on immunofixation. The amount of α heavy chain in the urine is small.

In the absence of therapy, α-HCD typically is progressive and fatal. The usual treatment is with antibiotics such as tetracyclines and eradication of any concurrent parasitic infection. Patients who do not respond adequately to antibiotics are treated with chemotherapy similar to that used to treat non-Hodgkin's lymphoma, for example, the CHOP regimen.

Mu Heavy-Chain Disease

Mu heavy-chain disease (μ-HCD) is characterized by the demonstration of a monoclonal μ-chain fragment in the serum. The serum protein electrophoretic pattern is usually normal except for hypogammaglobulinemia. The course of μ-HCD is variable, and survival

ranges from a few months to many years. Treatment is with corticosteroids and alkylating agents.

CRYOGLOBULINEMIA

Cryoglobulins are proteins that precipitate when cooled and dissolve when heated. They are designated as idiopathic or essential when they are not associated with any recognizable disease. Cryoglobulins are classified into three types: type I (monoclonal), type II (mixed monoclonal plus polyclonal), and type III (polyclonal).

Type I Cryoglobulinemia

Type I (monoclonal) cryoglobulinemia is most commonly of the IgM or IgG class, but IgA and Bence Jones cryoglobulins have been reported. Most patients, even with large amounts of type I cryoglobulin, are completely asymptomatic from this source. Others with monoclonal cryoglobulins in the range of 1 to 2 g/dL may have pain, purpura, Raynaud's phenomenon, cyanosis, and even ulceration and sloughing of skin and subcutaneous tissue on exposure to the cold because their cryoglobulins precipitate at relatively high temperatures. Type I cryoglobulins are associated with macroglobulinemia, multiple myeloma, or MGUS. Therapy for patients with type 1 cryoglobulinemia and significant symptoms is similar to that for Waldenström's macroglobulinemia for the IgM type and similar to that for multiple myeloma for the non-IgM type.

Type II Cryoglobulinemia

Type II (mixed) cryoglobulinemia typically consists of an IgM M protein and polyclonal IgG, although monoclonal IgG or monoclonal IgA may also be seen with polyclonal IgM. Serum protein electrophoresis usually shows a normal pattern or a diffuse, polyclonal hypergammaglobulinemic pattern. The quantity of mixed cryoglobulin is usually less than 0.2 g/dL. Hepatic dysfunction and serologic evidence of infection with hepatitis C virus are common, and hepatitis C is thought to be the cause of most cases of type II cryoglobulinemia. Vasculitis, glomerulonephritis, lymphoproliferative disease, and chronic infectious processes have also been associated with the disease.

Most clinical manifestations are related to the development of vasculitis and include purpura, polyarthralgias, and neuropathy. Involvement of the joints is symmetrical, but joint deformities rarely develop. Raynaud's phenomenon, necrosis of the skin, and neurologic involvement may be present. In almost 80% of renal biopsy specimens, glomerular damage can be identified. Nephrotic syndrome may result, but severe renal insufficiency is uncommon.

Early administration of corticosteroids is the most frequent therapy. Therapy should also target underlying hepatitis C infection with interferon-α_2 and ribavarin. Agents such as rituximab, cyclophosphamide, or chlorambucil are used if there is no response. Plasmapheresis is helpful in the acute management of symptoms by removing circulating immune complexes.

Type III Cryoglobulinemia

Type III (polyclonal) cryoglobulinemia does not have a monoclonal component and is not associated with a clonal plasma cell proliferative disorder. Type III cryoglobulins are found in many patients with infections or inflammatory diseases and are usually of no clinical significance unless associated with hepatitis C infection.

111 Hodgkin's Lymphoma

Sandra J. Horning

SUMMARY OF KEY POINTS

Incidence
- 8100 new U.S. cases per year
- Highest incidence in North America and Western Europe
- Lower incidence in black and Asian populations

Etiology and Pathology
- Unknown but aberrant B-cell response to antigen in susceptible individuals suggested
- Relationship to Epstein-Barr virus (EBV) in a subset by unknown mechanism
- Genetic component suggested by increased risk in families

Pathology and Biology
- Classical Hodgkin's lymphoma (HL) diagnosed by $CD15^+$ $CD30^+$ Reed-Sternberg cells within a characteristic inflammatory background
- Nodular lymphocyte predominance HL diagnosed by $CD20^+$ $CD15^-$ $CD30^-$ L&H cells with characteristic architecture and background
- Malignant Hodgkin's Reed-Sternberg cells derive from germinal center and/or postgerminal center B cells that have an interdependent relationship with the surrounding inflammatory cells.

Clinical Presentation
- Lymphadenopathy, particularly supradiaphragmatic
- Chest symptoms related to mediastinal adenopathy
- Constitutional "B" symptoms: night sweats, fevers, weight loss

Staging
- History, physical examination, complete blood count, serum chemistry, ESR
- Radiologic studies: computed tomography of chest, abdomen and pelvis; whole body positron emission tomography
- Bone marrow biopsy for patients with B symptoms and/or advanced disease

Primary Treatment
- Limited stage: brief chemotherapy and involved field radiotherapy; chemotherapy alone an option
- Advanced stage: multiagent chemotherapy for six to eight cycles with ABVD (doxorubicin, bleomycin, vinblastine, doxorubicin) or BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone)

Secondary Treatment
- High dose therapy and autologous stem cell transplantation for advanced stage and extensive symptomatic relapse
- Limited relapse after treatment for early stage disease should be individualized.

Survivorship
- Risks for second solid cancers related to age at treatment, time from treatment, radiation and alkylating agent exposure
- Risks for cardiovascular disease related to chest radiation and anthracycline exposure
- Gonadal toxicity and infertility concerns should be addressed early with treatment selection.
- Long-term survivors require ongoing monitoring, particularly those treated before 1990.

Prognosis
- Favorable, early stage disease cured in greater than 90% of patients
- Advanced disease cured in 60% to 85% of patients, dependent on clinical prognostic score and age
- Relapsed disease cured in approximately 40% to 50% of stem cell transplant recipients
- Early response assessment by FDG-PET appears to be highly predictive.

INTRODUCTION

Definition

Hodgkin's lymphoma is an hematolymphoid neoplasm, primarily of B-cell lineage, with unique molecular, histologic, immunophenotypic, and clinical features. The diagnosis is made by histologic criteria supplemented by immunophenotyping in a representative biopsy of adequate size.

Historical Review

In 1832 English physician Thomas Hodgkin described lymph node and spleen enlargement in a small clinical series "On some morbid appearances of the absorbent glands and spleen."[1] The first microscopic description of the disease that bears his name followed more than 60 years later when German pathologist Carl Sternberg and American pathologist Dorothy Reed independently provided detailed accounts of the giant "Reed-Sternberg" cells so characteristic of Hodgkin's disease.[2,3] Subsequently systems of classification evolved from that of Jackson and Parker to that of Lukes and Butler, which was slightly modified in 1999 by the World Health Organization.[4,5] Current classification is firmly based on microscopic features but also takes advantage of modern immunohistochemical techniques.

Shortly after the description of x-rays, Pusey and Senn applied radiation therapy to treat advanced Hodgkin's disease, noting remarkable regressions.[6,7] However, the first true therapeutic breakthrough with curative treatment came as a result of careful clinical investigations by radiation oncology pioneers, Vera Peterson and Henry Kaplan, the latter of whom introduced the linear accelerator in radiation oncology.[8] The application of extended or wide-field radiation to involved and uninvolved nodal areas revolutionized the field. Key

to this success and future efforts was the concept of the contiguous spread of Hodgkin's disease, documented by careful clinical and radiologic evaluation of disease at diagnosis and at recurrence.[9] Clinical staging and, later, pathologic staging with bone marrow sampling and exploratory laparotomy, were standardized.[10] Steady advances have been made in diagnostic radiology, where computed tomography (CT) and ^{18}F-deoxyglucose–positron emission tomography (FDG-PET) provide accurate assessment of involved areas, and in therapeutic radiation, where technical advances in linear accelerators, dosimetry, computerized simulation, and conformal treatment plans provide more targeted treatment. Appreciation of the late adverse effects of radiation therapy in Hodgkin's survivors and the success of chemotherapy led to current management approaches in which radiation therapy is applied to involved fields and in lower doses in combined-modality approaches.

Although the chemotherapeutic agent nitrogen mustard produced reduction of nodal masses in Hodgkin's disease in 1947, the use of combination chemotherapy, based on the principles of drugs with different cytotoxic mechanisms and nonoverlapping toxicities, at the U.S. National Cancer Institute in 1963 was the breakthrough that changed advanced Hodgkin's disease from a reliably fatal condition to one that could be cured.[11] Dr. Vincent DeVita, Jr., and his team reported an 80% complete remission rate and a nearly 50% cure rate with the MOPP (mustard, vincristine, procarbazine, prednisone) regimen in a seminal publication. Another important milestone was the introduction of the ABVD regimen by Gianni Bonadonna and colleagues in the 1970s (see section on Management).[12] ABVD was successful in treating patients with Hodgkin's disease recurrent after MOPP. Based on this success and a favorable toxicity profile, ABVD advanced to primary treatment, where it is now considered a standard proven to be more effective than MOPP. Additional progress in the field came with the use of high doses of chemotherapy and autologous hematopoietic cell rescue, which is effective as secondary treatment.[13] Building on this experience, newer chemotherapy combinations have been tested in the clinical setting, as discussed in the following sections.

The history of Hodgkin's disease, now Hodgkin's lymphoma, is a success story that in many ways has been transforming in oncology. It brought much needed optimism to the field and served to attract talented young physicians. The therapeutic success in Hodgkin's lymphoma demonstrated the benefits, indeed the necessity, of multidisciplinary expertise and coordination, from pathologic diagnosis to radiologic evaluation to irradiation and medical oncology treatments. Organized prospective investigation of Hodgkin's lymphoma in a series of consecutive, randomized clinical trials, pioneered by Henry Kaplan and Saul Rosenberg at Stanford University, set a standard that evolved into the large, multicenter studies conducted today.[14] Later, as complications of therapy emerged, Hodgkin's lymphoma has instructed the general field of cancer survivorship and served to continue research to document complications and reduce their incidence with refinements in both radiation therapy and chemotherapy.

EPIDEMIOLOGY AND ETIOLOGY

The incidence of Hodgkin's disease is estimated to be 7400 new cases annually in the United States, resulting in an age-adjusted annual rate of 2.7 per 100,000.[15] The bimodal age-incidence curve is a distinguishing epidemiologic feature. There is a peak at age 25, a decline and plateau through middle age, and then an increase with older age. This variation with age has long led to speculation that a biologic agent causes Hodgkin's lymphoma in adolescents and younger adults, whereas the etiology of Hodgkin's lymphoma in older patients may be akin to that of non-Hodgkin's lymphoma. In contrast to the non-Hodgkin's lymphoma, the overall incidence rate of Hodgkin's lymphoma has been relatively stable over the last 3 decades. However, upon closer inspection, the incidence slightly increased for young adults and declined for older adults.

There is a male predominance (1.2:1) in Hodgkin's lymphoma. From 1993 to 2000 the incidence rates were stable among U.S. whites, blacks, and Hispanics, whereas they increased for Asians by 5.2% per year. Table 111-1 demonstrates the age-adjusted annual incidence rates in the U.S. SEER program during that time period, according to gender and race/ethnicity. Incidence of the nodular sclerosis subtype in young adults has been linked to socioeconomic status in several reports. The relationship of incidence to neighborhood socioeconomic status was recently demonstrated for younger but not older adults in California by Clark and colleagues (Fig. 111-1).[16] Speculation and reports about clustering of cases in time and place of diagnosis do not hold up to rigorous statistical methods, and thus, there is no persuasive evidence of disease transmission.

Table 111-1 Age-Adjusted Average Annual Incidence of Hodgkin's Lymphoma 2000–2003*

Group	Males	Females
White (non-Hispanic)	3.5	2.9
Black (non-Hispanic)	2.8	2.1
Hispanic	2.9	1.6
Asian or Pacific Islander (non-Hispanic)	1.4	1.0
American Indian or Alaska Native (non-Hispanic)	1.1	0.7

*Incidence per 100,000 person-years.

Multiple lines of data are consistent with the hypothesis that young adult Hodgkin's lymphoma is associated with late-onset infection of a pathogen. Factors associated with increased risk of Hodgkin's lymphoma in prior reports include high socioeconomic status, high educational level, inverse relationship to sibship size, and early birth order. Of note, studies in the 1990s reported that sibship size and birth order did not associate with Hodgkin's lymphoma risk but, rather, that living in a rented home, sharing a bedroom, and attending day care or nursery school were associated with a reduced risk. These results continue to be consistent with the "hygiene hypothesis"—delayed exposure to an infectious agent. Childhood Hodgkin's lymphoma demonstrates a very different pattern, with a marked male excess (consistent with infectious exposure), a higher incidence in less developed countries, and a relationship to lower socioeconomic status. Among older adults (age ≥55 years) socioeconomic status does not clearly associate with incidence. Taken together,

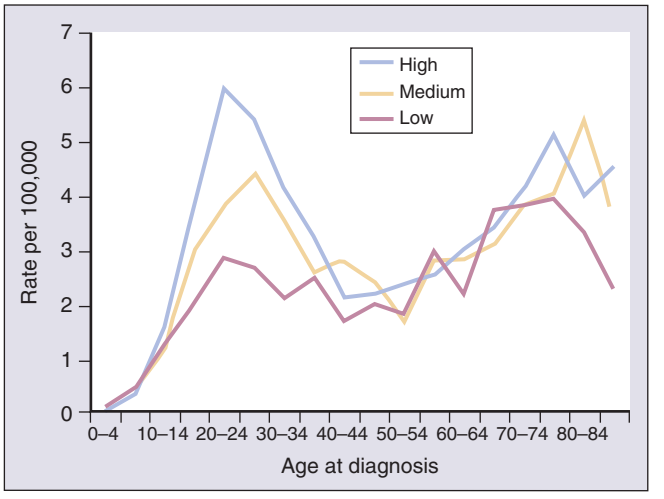

Figure 111-1 • Age-specific incidence of Hodgkin's lymphoma by tertile of neighborhood socioeconomic status, California, 1988–1992. (Reprinted with permission from Clarke C, Glaser S, Keegan T, et al: Neighborhood socioeconomic status and Hodgkin's lymphoma incidence in California. Cancer Epidemiol Biomarkers Prev 2005;14:1441–1447.)

these data suggest three epidemiologic types of Hodgkin's lymphoma that differ related to the maturity of the immune system.

The B-cell tropic Epstein-Barr herpesvirus (EBV) has been implicated in the etiology of Hodgkin's lymphoma. The viral genome can be demonstrated in the Hodgkin/Reed-Sternberg (H-RS) cells of about 40% of Hodgkin's lymphoma cases by in situ hybridization, and the genome is monoclonal.[17] The standard of evidence involves detection of the EBV-encoded RNA (EBER) by in situ hybridization and/or immunohistochemical detection of the latent-membrane protein-1 (LMP-1). A history of infectious mononucleosis increases the risk of Hodgkin's lymphoma threefold, and high levels of the EBV viral capsid antigen and early antigen antedate the diagnosis by several years.[18] Hjalgrim and associates reported that young adults with a history of infectious mononucleosis had an increased risk of EBV^+ Hodgkin's lymphoma but not EBV^- Hodgkin's lymphoma.[19] Although there is discordance among all reported data, Alexander and coworkers confirmed these results suggestive of a causal relationship in EBV^+ young adult Hodgkin's lymphoma.[20] It is important to note, however, that EBV^+ cases are more common among children and older adults and are more likely to have mixed-cellularity histology. Recent epidemiologic data demonstrate an increase in incidence of Hodgkin's lymphoma, which is typically EBV^+, in patients infected with the immunodeficiency virus who have been effectively treated with modern retroviral therapy.[21] These data (as discussed in the following sections) provide further clues to pathogenesis of Hodgkin's lymphoma.

Evidence for a genetic contribution in the etiology of Hodgkin's lymphoma comes from multiple sources. Genetic susceptibility and familial aggregation seem to play an important role in Hodgkin's lymphoma. Siblings have a sevenfold increase in risk, and multiple studies have now confirmed a gender concordance of sibling pairs. Of interest, similar findings have been published for chronic lymphocytic leukemia and for Behçet's disease, multiple sclerosis, and sarcoidosis. These data are compatible with a hypothesis of shared genetic susceptibility and environmental exposure. Alternately, it has been proposed that some of this risk may be related to genes in the pseudoautosomal location of the sex chromosomes. Mack and coworkers published the strongest evidence thus far of genetic susceptibility, observing a 100-fold increased risk in monozygotic twins compared with dizygotic twins.[22] Several groups have described human leukocyte antigen (HLA)–related susceptibility and resistance to Hodgkin's lymphoma, but these data have been relatively weak and sometimes inconsistent. More recent data implicate HLA in EBV-related Hodgkin's lymphoma, where HLA*A-02 was associated with a reduced risk and HLA*-A01 with an increased risk of EBV^+ Hodgkin's lymphoma.[23] These findings strengthen the hypothesis that Hodgkin's lymphoma is related to a genetically related immune response to an environmental pathogen.

PATHOGENESIS

Pathology

The diagnosis of classical Hodgkin's lymphoma requires the recognition of H-RS cells in an appropriate cellular milieu. Because H-RS cells compose a minority, often 1% to 5%, of the total cellular population, an open biopsy is required for unequivocal diagnosis and subtyping. H-RS cells are largeand either multinucleated or with a large polypoid nucleus; each nucleus or lobe contains a prominent eosinophilic nucleolus (Fig. 111-2A). The background cells consist mainly of small lymphocytes together with a smaller number of scattered eosinophils, neutrophils, histiocytes, plasma cells, and fibroblasts (Fig. 111-2B).

There are four morphologic types of classical Hodgkin's lymphoma (Table 111-2). As discussed in the following sections, histologic subtypes correlate with a number of clinical features. Nodular sclerosis is characterized by broad bands of collagen and lacunar cells, which are RS variants seen in formalin-fixed specimens. Nodular sclerosis accounts for about 65% of Hodgkin's lymphoma in the Western world. There have been attempts to further subclassify nodular sclerosis on morphologic criteria, but this has not been widely adopted. Mixed-cellularity subtype is present in about 30% of cases but is more common in developing nations, the elderly, and the immunodeficient. H-RS cells are typically plentiful in mixed-cellularity Hodgkin's lymphoma, whereas fibrosis is absent. Lymphocyte-depleted Hodgkin's lymphoma is exceedingly rare and can present a differential diagnostic dilemma with non-Hodgkin's lymphoma. The relatively newly described lymphocyte-rich subtype may have a nodular or diffuse pattern and can mimic other subtypes as well as nodular lymphocyte predominant (NLPHL).

Immunohistochemical studies are of great usefulness in Hodgkin's lymphoma, and the hallmark of classical Hodgkin's lymphoma is a common immunophenotype (Table 111-3). Classical Hodgkin's lymphoma expresses CD30, a marker of activated B- and T-lymphoid cells, in almost all cases (Fig. 111-2C). About 87% of classical Hodgkin's lymphomas express CD15, the carbohydrate X hapten. CD15 antibodies also stain mature neutrophils, macrophages, and a subset of T cells. CD15 staining is more heterogeneous among H-RS cells compared with CD30. In some analyses absence of CD15 staining has been reported to be an adverse prognostic factor, but this has not been broadly confirmed. $CD15^-$ cases have also been associated with advanced stage, male gender, and older age, each recognized to be a component of the existing clinical prognostic score as detailed later. Classical Hodgkin's lymphoma rarely expresses CD45, also known as common leukocyte antigen, which is expressed by nearly all non-Hodgkin's lymphomas and can serve as a useful marker for differential diagnosis. CD20 staining in classical Hodgkin's lymphoma has been variably reported from 5% to 25% of cases. The pattern of staining is heterogeneous and confined to a subset of H-RS cells, in contrast to uniform and strong staining in non-Hodgkin's lymphoma and NLPHL. Conflicting reports on the prognostic significance of CD20 expression have been reported.

NLPHL is defined on the basis of distinctive morphologic features and surface marker expression. At low power large, tightly packed nodules are typically numerous (Fig. 111-2D). The background includes B-lymphocytes and histiocytes. The neoplastic cells are referred to as L&H (lymphocytic and histiocytic, based on the background) and are notable for a lobulated, "popcorn" appearance. The European Task Force for Lymphoma made a major contribution in establishing the criteria for current diagnosis.[24] Using defined morphologic criteria and immunohistochemistry, 56% of NLPHLs were reclassified as classical Hodgkin's lymphoma or other lymphoid processes. NLPHL has unique clinical features and course as further discussed later.

Derivation of Hodgkin's-Reed-Sternberg and Lymphocytic and Histiocytic Cells

The cell of origin of Hodgkin's lymphoma remained elusive for many years because the characteristic giant multinuclear cells, the H-RS cells, do not resemble any normal hematopoietic cell (Table 111-4). In fact, H-RS cells express markers characteristic of different cell types such as dendritic cells (fascin, TARC), granulocytes and monocytes (CD15), B cells (Pax-5), plasma cells (MUM-1, CD138), and activated lymphocytes (CD30). The ability to microdissect single H-RS cells was a breakthrough that established the B-cell lineage of Hodgkin's lymphoma. Clonal immunoglobulin rearrangements in nearly all cases demonstrated that H-RS cells derive from B cells. Further, the presence of somatic mutations indicates that H-RS cells participated in the germinal center reaction in response to antigen. Notably, H-RS cells lack expression of characteristic B-cell surface markers (CD20, B-cell receptor, etc.), and expression profiling studies have extended this observation in demonstrating the downregulation of B-cell–specific transcription factors (Oct-2, Bob1, Pu.1) and signaling pathways (Syk, Blk), as well as surface markers.

In contrast, CD20 expression implied the B-cell origin of L&H cells, and this was later confirmed by demonstration of immuno-

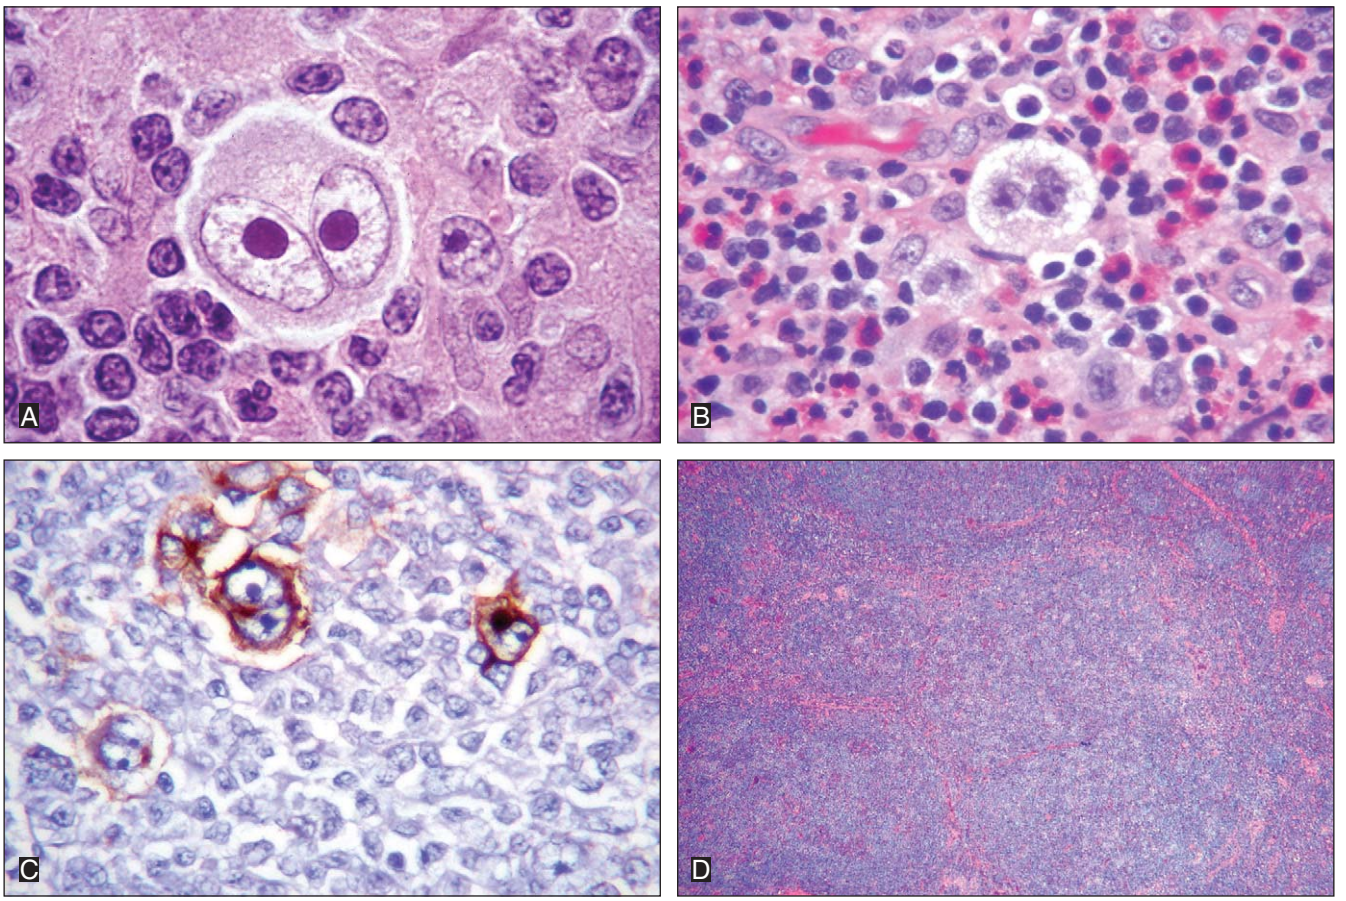

Figure 111-2 • **A,** Classic Reed-Sternberg cell, demonstrating large size, multinucleated nucleus, and prominent eosinophilic nucleolus. **B,** The majority of cells in classical Hodgkin's lymphoma are nonmalignant and consist of a supportive environment that includes lymphocytes, neutrophils, eosinophils, plasma cells, and fibroblasts. **C,** Classical Hodgkin's lymphoma expresses CD30, a marker of activated B- and T-lymphoid cells, in almost all cases. **D,** Nodular lymphocyte–predominant Hodgkin's lymphoma has distinctive surface markers and morphologic features, including numerous, tightly packed nodules at low power.

Table 111-3 Selected Immunophenotypic Markers and Histologic Characteristics of Use in the Differential Diagnosis of Hodgkin's Lymphoma and Other Lymphoid Neoplasms

Maker	Classical HL	Nodular Lymphocyte Predominant HL	TCRBCL	ALCL
CD30	+	–	–	+
CD15	+	–	–	–
CD20	–/+*	+	+	–
CD45	–	+	+	+/–
CD79a	–	+	+	–
ALK	–	–	–	+/–
EMA	–	+	+	+
Nodular growth protein	+/–†	+	–	–

+, >90% of cases positive; +/–, majority of case positive; –/+, minority of cases positive; –, <10% of cases positive; ALCL, anaplastic large cell lymphoma; HL, Hodgkin's lymphoma; TCRBCL, T-cell–rich B-cell lymphoma.

*CD20 positive in classical Hodgkin's lymphoma is quite heterogeneous, with a wide range in brightness of staining.

†In classical Hodgkin's lymphoma, a nodular growth pattern is confined to the nodular sclerosing subtype.

Table 111-4 Genotypic and Phenotypic Features of Hodgkin's-Reed-Sternberg and Lymphocytic and Histiocytic Cells

Feature	H-RS Cells	L&H Cells
Somatically mutated Ig variable genes	Y	Y
Destructive somatic mutations	Y	N
Ongoing somatic mutation	N	Often
Expression of B-cell receptor	N	Y
Expression of B-cell transcription factors	N	Y
Expression of B-cell surface markers	N	Y
Expression of GC markers: Bcl-6, AID	Rare	Y
Plasma cell markers	Often	N
Antigen presentation markers	Y	Y
Expression of non–B-cell markers	Y	N

AID, antigen-induced cytidine deaminase; GC, germinal center; H-RS, Hodgkin's Reed-Sternberg; Ig, immunoglobulin; L&H, lymphocytic and histiocytic.

globulin gene rearrangement (see Table 111-4). In many cases ongoing hypermutation was observed, consistent with a germinal center B-cell derivation. The expression of Bcl-6 and AID (activation-induced cytidine deaminase), a key enzyme for somatic hypermutation and class switching, is consistent with a germinal center origin.

Biology of Malignant Cells and the Microenvironment

The generation and sustenance of H-RS and L&H cells has long been the subject of speculation and interrogation.[25] Typically, antigen-driven B cells migrate and establish germinal centers in secondary lymph nodes where they undergo clonal expansion, acquire affinity-enhancing mutations, and undergo positive selection before exiting the germinal center to become either plasma cells or memory B cells. L&H cells seem to derive from selected, mutating germinal center B cells, whereas H-RS cells have characteristics of preapoptotic germinal center B cells with crippling mutations that should normally lead to cell death. Because classical H-RS cells do not express B-cell surface molecules (including the B-cell receptor), they rely on alternative survival and proliferative pathways activated by transcription factors such as NF-κB, a hallmark of H-RS cells (Fig. 111-3). Constitutive activation of NF-κB is in part due to signaling through members of the tumor necrosis factor receptor family (CD40, CD30) as a result of a complex interplay with surrounding lymphocytes. EBV infection has been directly implicated in transforming "crippled" H-RS cells through activation of NF-κB via LMP-1, sparing them from apoptosis.[26] Additional signaling pathways, including the CD95 pathway, also contribute to apoptosis resistance in H-RS cells as detailed in Figure 111-3.[27]

The brisk inflammatory microenvironment of Hodgkin's lymphoma is the subject of a great deal of current scientific progress and excitement. The large majority of Hodgkin's lymphoma tissues comprises inflammatory cells and stromal elements that are thought to be recruited by cytokines (low-molecular-weight proteins that regulate a variety of biologic processes) and chemokines (cytokines that involve migration of leukocytes) secreted by the H-RS cells. Interleukins (IL-4, IL-6, IL7, IL-9, IL-13, and IL-15) are among the many influential cytokines expressed by H-RS cells.[25,28] The systemic "B" symptoms that occur in about 30% of Hodgkin's lymphoma patients are probably due to these cytokines. Chemokines, such as CCL17 (TARC) in classical Hodgkin's lymphoma, attract specific lymphocyte subsets to the microenvironment and are responsible for the subtypes of Hodgkin's lymphoma.

The inflammatory cells support the H-RS cells, recruit additional cells, and stimulate collagen synthesis by secreting a variety of factors. Hodgkin's lymphoma demonstrates a dysregulated immune response. The reactive T-cell population is predominantly T helper 2 (Th2)-type and $CD4^+CD25$ high $FOXP3^+$ regulatory T cells (Treg) that directly suppress immune responses and protect H-RS cells from immune attack.[29] There is marked under-representation of natural killer (NK), Th1, and cytotoxic T cells. H-RS cells utilize interactions between their tumor necrosis factor family receptors and the natural ligands expressed by these surrounding lymphocytes to support their own growth while causing apoptosis of cytotoxic T and NK cells. Recently the immunoregulatory glycan-binding protein galectin-1, secreted by H-RS cells, has been implicated in the development and maintenance of this skewed environment.[30,31] Manipulation of the microenvironment in Hodgkin's lymphoma provides a potential target for restoring immune surveillance.

CLINICAL FEATURES

Hodgkin's lymphoma typically presents with supradiaphragmatic adenopathy that requires biopsy after the exclusion of benign conditions. The low neck and supraclavicular nodes are particularly common sites. Mediastinal presentations typically occur anterior to the ascending aorta, presenting the differential diagnosis of thymoma, thyroid disease, and tumor. Just 10% of patients have an initial subdiaphragmatic presentation. The abnormal lymph nodes have a characteristic rubbery consistency and are painless. A unique feature of classical Hodgkin's lymphoma is the rapid onset of pain in involved lymph nodes with alcohol consumption. In most cases, peripheral adenopathy brings patients to clinical attention. However, symptoms of chest pressure, cough, or even dyspnea related to large mediastinal masses, 10 cm or greater, are not uncommon.

A subset of about 30% of patients presents with fevers and night sweats without peripheral adenopathy. Historically, Hodgkin's lymphoma was a cause of fever of unknown origin, but modern radiologic techniques typically reveal abnormalities that lead to direct tissue acquisition. The constellation of fevers, night sweats, and unexplained weight loss constitute the classic, "B" symptoms of Hodgkin's lymphoma (Table 111-5) that are hallmarks of the disease for some patients and serve as prognostic factors in limited-stage disease. Another constitutional complaint is unexplained pruritus, which should create suspicion and lead to a complete physical examination and chest radiograph, particularly in young adults.

Presentations of classical Hodgkin's lymphoma correlate with histologic subtype, gender, and age. Nodular sclerosis subtype, the most common subtype in young adults, presents as limited or extensive disease, with involvement of the mediastinum in about 75% of cases.

Table 111-5 Modified Ann Arbor Staging System for Hodgkin's Lymphoma

Stage	Involvement
I	Single lymph node region (I) or one extralymphatic site (I_E).
II	Two or more lymph node regions, same side of the diaphragm (II) or local extralymphatic extension plus one or more lymph node regions or same side of the diaphragm (II_E)
III	Lymph node regions on both sides of the diaphragm (III), which may be accompanied by local extralymphatic extension (III_E).
IV	Diffuse involvement of one or more extralymphatic organs or sites.
A	No B symptoms
B	Presence of at least one of the following symptoms: 1. Unexplained weight loss >10% baseline during 6 months before staging 2. Recurrent unexplained fever >38°C 3. Recurrent night sweats Bulky tumor

Bulky tumor is defined as either a single mass of tumor tissue exceeding 10 cm in largest diameter or a mediastinal mass exceeding one third of the maximum transverse transthoracic diameter measured to the inside of the ribs on a standard posteroanterior chest radiograph.

E lesion: Localized extranodal extension of Hodgkin's lymphoma from a contiguous or nearby nodal site is noted with the designation E, for example, stage II_EA for asymptomatic disease in the mediastinum with contiguous extension into nearby lung.

From Carbone PP, Kaplan HS, Musshoff K, et al: Report of the Committee on Hodgkin's Disease Staging Classification. Cancer Res 1971;31:1860–1861.

Older and immunodeficient patients are more likely to have B symptoms, advanced disease, and mixed-cellularity histology. NLPHL has a marked male predominance and usually occurs in peripheral nodes above or below the diaphragm, sparing the mediastinum. NLPHL patients are nearly always asymptomatic and often have limited disease confined to a single lymph node region.

Bone involvement by classical Hodgkin's lymphoma may cause pain. Bone disease may result from contiguous spread of the disease, such as the sternal involvement from mediastinal adenopathy, or from widespread metastatic disease. Bone marrow involvement rarely results in cytopenias. Hodgkin's lymphoma has been associated with a variety of rare paraneoplastic syndromes that may be presenting features of the disease. These include nephrotic syndrome, neurologic disorders, and jaundice.

INVESTIGATION

Standard Evaluation

After the diagnosis of Hodgkin's lymphoma is made, it is important to establish the extent of disease (Tables 111-5 and 111-6). Notably, Hodgkin's lymphoma typically advances with involvement of contiguous lymph node regions. Knowledge of this informs the interpretation of diagnostic studies and the level of suspicion for disease outside of the lymphoid compartment. This knowledge was gained with diagnostic procedures of the past, including exploratory laparotomy, that were used to stage patients. Splenic disease, for instance, nearly always precedes disease in the lower abdominal lymph nodes or the bone marrow. With rare exceptions, Hodgkin's lymphoma disseminates widely outside of the lymphatic system to only four organs: bone, bone marrow, liver, and lung. As noted previously, selected extranodal extension may occur by contiguous spread, such as to the sternum, chest wall, pleura, pericardium, or single lobe of the lung (see Table 111-5).

The standard evaluation for newly diagnosed Hodgkin's lymphoma is described in Table 111-6. A careful history directed toward constitutional or other disease symptoms and comorbid conditions that might affect the delivery of therapy is essential. The physical examination should include inspection for neck and infraclavicular/

Table 111-6 Diagnostic Evaluation of Hodgkin's Lymphoma

Surgical biopsy
Expert hematopathology review
History directed to systemic symptoms and disseminated disease
Physical examination for lymphadenopathy and organomegaly
Laboratory tests
Complete blood count and differential
Chemistry panel to include albumin, creatinine, liver function tests
Erythrocyte sedimentation rate
HIV test if behavioral risk
Standing posteranterios chest radiograph
CT scan of chest, abdomen, pelvis
PET scan (highly recommended)
Bone marrow biopsy if systemic symptoms, advanced disease, or cytopenia
Bone scan if bone pain and PET scan not available or equivocal

CT, computed tomography; HIV, human immunodeficiency virus; PET, positron emission tomography.

Figure 111-4 • FDG-PET scan in a stage IV patient at diagnosis demonstrating bulky low-neck, mediastinal, and hilar disease with upper abdominal adenopathy, splenic disease, and extensive bone involvement.

chest wall swelling as well as palpation in all nodal areas and abdominal examination for organomegaly. Laboratory tests include a complete blood count with differential, serum chemistry to assess liver and kidney function as well as albumin, and erythrocyte sedimentation rate. Testing for infection with the human immunodeficiency virus (HIV) should be included if the history is suspicious or the presentation unusual.

Great strides have been made in imaging Hodgkin's lymphoma. CT of the neck, chest, abdomen, and pelvis have replaced the exploratory laparotomy and lymphography of the past. FDG-PET, particularly when fused with CT, is an important diagnostic tool in Hodgkin's lymphoma. Multiple studies demonstrated that FDG-PET is both more sensitive and more specific than CT or gallium scanning for Hodgkin's lymphoma at diagnosis and upon restaging to assess treatment response.[32] FDG-PET scans result in a higher stage for a small proportion of patients and a lower stage in very few patients.[33] Rather, PET scans should be viewed as complementary and as establishing a baseline for interpretation upon restaging (Fig. 111-4).

Staging

The Ann Arbor staging system has stood the test of time in Hodgkin's lymphoma (see Table 111-5). Patients are described in four stages, based on the extent of lymph node and disseminated disease:

Stage I—Involvement of a single nodal area
Stage II—Involvement of two or more nodal areas on one side of the diaphragm
Stage III—Involvement of nodal areas on both sides of the diaphragm
Stage IV—Disseminated disease involving one or more extranodal sites

In addition to recording the extent of disease, the staging systemic reflects the absence (A) or presence (B) of systemic symptoms. At the meeting in Ann Arbor, MI, where the staging convention was developed, the conveners designated extranodal (E) lesions, which have led to considerable confusion in staging. The original intent was to identify patients who had disease that could be managed within a single radiation port. With that in mind, E lesions are considerably more easily understood.

In 1989 modifications of the Ann Arbor staging system were recommended at a meeting in the Cotswolds (U.K.). The major proposed alteration was to designate bulky tumors with diameters 10 cm or greater. This was based on the appreciation that large mediastinal disease, then defined as a tumor with a maximum diameter greater than one third of the maximum intrathoracic diameter on standing chest radiograph, conferred a poor prognosis when managed with radiation therapy alone. It has become convention to designate mediastinal disease as bulky (either by the original definition and/or 10 cm or greater disease by CT scan) or not bulky in the Cotswolds modifications.

Risk groupings in early stage Hodgkin's lymphoma, which include mediastinal bulk and other clinical factors, are commonly used in treatment stratification (Table 111-7). These groupings are useful for clinical management, and it is necessary to understand these to interpret the results of recent clinical trials. In North America, patients with bulky or symptomatic stage I and II disease are generally grouped with advanced-stage patients. In contrast, in Europe, patients with stage I and II disease are divided into favorable and unfavorable categories based on risk factors that include the number of nodal sites, erythrocyte sedimentation rate, mediastinal mass size, extranodal disease, and age. With these parameters about 35% of stage I and II patients have favorable disease and 65% have unfavorable disease.

PROGNOSIS

The prognosis for patients with Hodgkin's lymphoma has steadily improved over the past 50 years as a result of advances in diagnosis and therapy. Currently, cure is expected for the great majority of patients irrespective of stage. However, advanced stage and age older than 60 to 65 years continue to pose challenges. Older patients have

Table 111-7 Risk Groups in Early Hodgkin's Lymphoma

North America	EORTC	GHSG
FAVORABLE		
Asymptomatic	Age <50 yr	No extranodal sites
MMR not large	MMR not large	MMR not large
Sites <10 cm	≤3 nodal sites	≤2 nodal sites
	ESR <50 if asymptomatic	ESR <50 if asymptomatic
	<30 if symptomatic	<30 if symptomatic
UNFAVORABLE		
I, IIA bulky	I, II with risk factors	I, II with risk factors
I, IIB

Table 111-8 Adverse Prognostic Factors Identified in the International Prognostic Score

Age ≥45 years
Gender: male
Stage IV
Hemoglobin <10.5 g/dL
White blood cells >15,000/μL
Lymphocytes <600/μL or <8% of total white blood cells
Albumin <4 g/dL

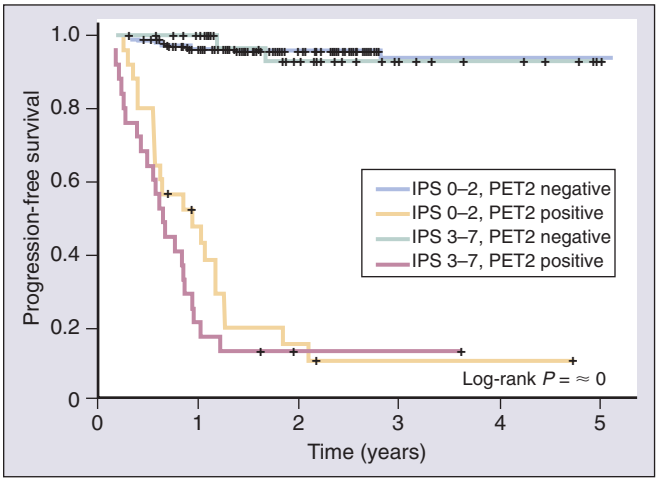

Figure 111-5 • Progression-free survival in bulky and advanced Hodgkin's lymphoma in patients with negative or positive FDG-PET scan results after two cycles of chemotherapy. Data are presented according to IPS score of 0–2 or greater than or equal to 3 (see text). (Reprinted with permission from Gallamini A, Hutchings M, Rigacci L, et al: Early interim 2-[^{18}F]fluoro-2-deoxy-*d*-glucose positron emission tomography is prognostically superior to International Prognostic Score in advanced-stage Hodgkin's lymphoma: a report from a joint Italian-Danish study. J Clin Oncol 2007;25:3746–3752.)

more biologically resistant disease, and their tolerance for very aggressive therapies is limited. Their opportunity for cure is only about half of that for younger patients.[34,35] The other dominant prognostic factor is stage. Patients with favorable, early-stage disease have a cure rate in excess of 90% with modern combined-modality therapy. The risk groupings outlined in Table 111-7, for which therapy has been modified, demonstrate excellent outcomes in unfavorable presentations of limited disease as well. Outcomes for advanced-stage patients are inferior, with cure rates ranging from about 65% to 70% in North American trials to 70% to 85% in European trials. Additional prognostic factors have been identified and widely validated in advanced Hodgkin's lymphoma.

The International Prognostic Score (IPS) is based on seven factors: three clinical (age >45 years, male sex, stage 4) and four laboratory values (albumin <4 g/dL, hemoglobin <10.5 g/dL, white blood count >15 $\times 10^6$ cells/mL, lymphocyte count <8% or <600 cells/mL; Table 111-8).[36] Patients are given a score of from 0 to 7, and disease can be categorized as low (0–1), intermediate (2–3), or high (4–7) risk. As illustrated in Table 111-9, the majority of patients have two or three risk factors. Fewer than 20% have high-risk disease. Five-year freedom from progression (FFP) decreases by about 7% per risk factor. The prognostic score is useful in the interpretation of clinical trials and, with more intensive regimens, improvements in all risk categories have been reported as discussed in the following sections.

Several studies have found that early FDG-PET is superior to the IPS in predicting progression-free survival in advanced Hodgkin's lymphoma.[32] Fig. 111-5 represents data on 260 consecutive cases of advanced Hodgkin's lymphoma combined in centers from Holland and Italy. Of these cases, 65 had an IPS of 3 to 7 and 195 had an IPS of 0 to 2.[37] PET scans were interpreted as negative or positive after just two cycles of ABVD chemotherapy by an expert panel. Negative scans demonstrated no areas of focal FDG uptake above the background level. Among patients with positive scans, 87% had disease progression at 2 years compared with 5% of patients with negative scans. These remarkable outcomes were seen irrespective of IPS (see Fig. 111-5). Based on these data and others, investigators have planned new "response-adapted" clinical trials in which therapy is escalated or de-escalated on the basis of early PET adaptation. This strategy serves to further individualize treatment and balance the risks and benefits of the therapeutic approach.

Table 111-9 International Prognostic Score and Freedom from Progression in Advanced Hodgkin's Lymphoma

N Factors	Frequency (%)	5-Year FFP (%)
0	7	84
1	22	77
2	29	67
3	23	60
4	12	51
5–7	7	42

FFP, freedom from progression.

DIFFERENTIAL DIAGNOSIS

A biopsy with routine use of immunohistochemistry typically leads to an unequivocal diagnosis of Hodgkin's lymphoma (see Table 111-3). There are cases in which the diagnosis can be more challenging, such as instances of an atypical immunophenotype or tissue acquired from extranodal sites. It is always useful to put the pathologic findings into context with the clinical features expected in Hodgkin's lymphoma, namely contiguous spread of disease and a limited number of extranodal sites. Occasional so-called "grey zone" lymphomas provide diagnostic dilemmas when non-Hodgkin's lymphoma is difficult to distinguish from Hodgkin's lymphoma. These diagnostic dilemmas, most common in mediastinal lymph nodes, are usually resolved with additional immunophenotypic and genetic tests. However, as indicated by molecular diagnosis, primary mediastinal large B-cell lymphoma is biologically related to Hodgkin's lymphoma.[38,39] Cases of composite lymphoma, where both Hodgkin's lymphoma and non-Hodgkin's lymphoma occur in the same diagnostic specimen, have been reported. In some carefully studied cases, the non-Hodgkin's lymphoma and Hodgkin's lymphoma shared the same immunoglobulin rearrangement, indicative of a clonal relationship.[40]

Both clinicians and pathologists have more difficulty in the differential diagnosis of NLPHL. NLPHL may be preceded, followed, or concurrent with progressive transformation of germinal centers, a benign condition recognized by morphologic features. Because this condition causes lymphadenopathy indistinguishable from NLPHL, it is essential that patients have an excisional biopsy both at diagnosis and any subsequent recurrence. In addition, NLPHL is associated with the later development of diffuse large B-cell lymphoma and its subtype, T-cell–rich large B-cell lymphoma. Some patterns of NLPHL are very difficult to discriminate from T-cell–rich B-cell lymphoma, requiring expert hematopathology opinion for this rare condition.[41] However, the distinction is quite important as management approaches are dramatically different. Because TCR-BCL frequently involves the bone, bone marrow, liver, spleen, abdominal and mediastinal nodes, clinical features can assist in the differential diagnosis as well.

The current era of FDG-PET scanning presents new differential diagnostic challenges to clinicians. Because FDG is taken up by many tumor types and areas of inflammation and infection, oncologists must be alert to potential "false-positive" signals. This is particularly true in the follow-up setting where the expectation is that a patient is cured of Hodgkin's lymphoma. Scans should be avoided during viral illness, and "positive" areas other than those previously involved with disease should be regarded with suspicion. Biopsy may be the only way to resolve the issue and is recommended before committing patients to additional treatment. Notably, some cases of FDG avidity in the thorax have been ascribed to sarcoidosis rather than recurrent Hodgkin's lymphoma when biopsy was attained.

MANAGEMENT

Primary Therapy of Classical Hodgkin's Lymphoma

After histologic confirmation and complete evaluation, patients are ascribed a stage as in Table 111-5. In addition to stage, patients with limited disease should be further designated according to the risk factors described in Table 111-7, whereas patients with advanced disease should be assigned a prognostic score as in Tables 111-8 and 111-9. This exercise is important to the selection and discussion of appropriate therapy and the expectation of curative outcome and complications of treatment. In addition, full assessment of disease at presentation is essential to the interpretation of the literature that forms the basis of decision analysis.

Early-Stage Disease without Risk Factors

As indicated in Table 111-7, North American stage I and II patients without bulky disease or B symptoms are generally considered in this category. In contrast, the definition of favorable early-stage disease is more restrictive in the two European classification schemes. These differences may become more relevant as therapy for these most favorable patients continues to be reduced in clinical trials. Historically, treatment has evolved from pathologic staging and widespread irradiation to a paradigm of brief chemotherapy followed by involved field radiation therapy at lower dose. The current standard is the result of careful clinical trials that demonstrated three principles: (1) ABVD (Table 111-10) is the preferred chemotherapy based on both efficacy and safety, (2) combined-modality therapy (chemotherapy + radiation therapy) is superior to wide-field radiation therapy alone, and (3) there is no advantage to wide-field radiation therapy over involved-field radiation therapy when given in combination with chemotherapy.

The Milan trial was among the first and most influential in demonstrating the high cure rate of a brief course of ABVD (four cycles) combined with involved-field radiation therapy in limited-stage Hodgkin's lymphoma (Table 111-11).[42] Although patients with large mediastinal masses were included, this study set a high bar with regard to outcomes and also demonstrated the safety of this approach with mature follow-up. Subsequently, multiple trials have explored the questions of how many cycles of ABVD are needed and what radiation dose is needed to maintain these outstanding results (see Table 111-11). Among favorable patients without risk factors, the German Hodgkin's Study Group (GHSG) evaluated two versus four cycles of ABVD and 20 versus 30 Gy involved-field irradiation. The final results of this trial have not been published, but multiple presentations of the data to date have shown FFP rates in excess of 95% for all four treatment arms.[43] Thus, for the approximately 35% of limited-stage patients with very favorable presentations, as few as two cycles of chemotherapy combined with low-dose involved-field irradiation is sufficient for cure. Full trial results are awaited with regard to the question of radiation dose.

Based upon a desire to reduce potential complications of treatment (see later discussion), ongoing clinical trials further address the individual drugs in the ABVD regimen. The GHSG HD13 study evaluated four cycles of ABVD, ABV, AV, and AVD with 30 Gy involved-field radiation therapy. Although the mature results of this trial are awaited, the AV and ABV arms have already closed because of inferiority (unpublished results). This is an important lesson in the requirement to deliver a standard treatment in a highly curable disease outside the context of a clinical investigation. Other studies are asking the question if radiation therapy can be omitted for patients who have a negative early FDG-PET scan. Based on the concerns for late effects from radiation therapy (see later discussion), there is great interest in investigation of this approach.

For patients with unfavorable, limited-stage Hodgkin's lymphoma the subjects of clinical trial inquiry have been chemotherapy combination, number of cycles of chemotherapy, and radiation dose (see Table 111-11). The H9U trial conducted by the EORTC-GELA demonstrated that the less toxic ABVD regimen was as effective as the BEACOPP regimen and that four cycles of treatment were sufficient.[44] Similarly, the GHSG HD11 trial has shown no differences in outcome thus far between ABVD and BEACOPP in limited-stage patients with risk factors.[45] This study also used four cycles of chemotherapy. The dose of radiation therapy is under investigation in this trial and requires longer follow-up. At this time a dose of 30 Gy should be considered standard. One of the challenges in interpretation of the European literature is the lack of separate reporting of outcomes in patients with large mediastinal masses. This distinctive subset may have different requirements to achieve a high rate of cure, particularly with regard to radiation dose.

The success of chemotherapy alone and the late effects of radiation therapy create interest in the use of chemotherapy alone in early-stage Hodgkin's lymphoma (see Table 111-11). Several trials have explored this in a controlled, randomized fashion. The National Cancer Institute of Canada–Eastern Cooperative Oncology Group (NCIC-ECOG) trial compared ABVD for four to six cycles (based upon response) to a strategy including radiation therapy in patients with limited-stage Hodgkin's lymphoma.[46] The trial design was complex, in that very favorable stage I patients and patients with bulky mediastinal disease were first excluded. Eligible patients were then stratified based on clinical features to lesser risk and greater risk. The lesser risk patients received either ABVD alone or the now obsolete, inferior wide-field irradiation (subtotal lymphoid irradiation), whereas the patients at greater risk received either ABVD alone or two cycles of ABVD followed by wide-field irradiation. The data are not sufficiently mature to address the primary study endpoint of survival at 10 years. However, FFP data at 5 years show a significant advantage for combined-modality treatment over ABVD alone. This difference, as expected, is due to the superiority of combined-modality treatment in the greater risk patients. However, there is no difference in overall survival, and much longer follow-up is required for the primary study endpoint. The interpretation of these data has often been based on the biases of the authors. Because of the relatively small absolute differences in FFP, proponents of chemotherapy maintain that the study

Table 111-10 Combination Chemotherapy Regimens for Hodgkin's Lymphoma

demonstrates that chemotherapy alone is the preferred treatment, whereas proponents of radiation therapy point to the superior outcomes achieved with combined-modality treatment.[47,48] Controversies of this type demonstrate the complexity of Hodgkin's lymphoma treatment and the careful balance between cure and complications for individual patients. Hodgkin's lymphoma patients should be carefully counseled by those with sufficient expertise to fully discuss therapeutic recommendations related to the sites and bulk of disease together with the age, gender, and other risk factors for the individual. Meanwhile, guidelines for management of early-stage Hodgkin's lymphoma recommend both combined-modality therapy but allow that chemotherapy alone is an acceptable strategy based on patient characteristics.[49]

Regarding the optimal chemotherapy in early-stage Hodgkin's lymphoma, Table 111-11 details results of the H9F trial from the EORTC using the EBVP (epirubicin, bleomycin, vinblastine, prednisone) regimen. Clearly inferior outcomes were seen with EBVP alone, even among such highly favorable patients.[44] This experience and that described previously in the GHSG HD13 study indicate that it is dangerous to tinker with the standard ABVD regimen, and this should be discouraged in clinical practice.

Advanced-Stage Disease

As noted previously, following the ground-breaking demonstration of cure in advanced Hodgkin's lymphoma with MOPP chemotherapy, a series of clinical trials was set in motion to identify the best chemotherapy regimen in advanced disease and to evaluate the role of radiation therapy in this setting. Based on historical development and the efficacy of ABVD in the relapsed setting, early trials pitted MOPP against ABVD and the alternating MOPP/ABVD regimen. The early CALGB study determined that ABVD-containing combinations were superior.[50,51] A second U.S. Intergroup trial comparing ABVD to the hybrid MOPP/ABV combination developed in Vancouver, concluded that the treatments were similarly efficacious but ABVD was less toxic.[52] On the basis of these trials, ABVD was widely adopted as the standard chemotherapy for advanced Hodgkin's lymphoma with an expected cure rate of about 70%.

Studies of multidrug regimens versus ABVD in the United Kingdom resulted in similar outcome and continued embracement of ABVD as the simpler, less toxic option. Stanford V is a brief, 12-week chemotherapy regimen with minimal alkylating agent and lower cumulative doses of doxorubicin and bleomycin that was

devised to explicitly address late effects of Hodgkin's lymphoma treatment. Radiation therapy is an important aspect of the treatment, delivered at 36 Gy to sites of disease larger than 5 cm or macroscopic splenic disease. Outstanding results were reported in a large phase II experience at Stanford University and within the ECOG.[53,54] The Italian GISL group performed a three-arm comparison of a multidrug regimen, ABVD and the Stanford V regimen.[55] The results in their study were inferior for the Stanford V regimen, possibly as a result of delayed and nonuniform use of radiation therapy as well as uneven determination of early treatment response in the study arms. ECOG has recently completed a phase III comparison of ABVD and Stanford V, the results of which are awaited.

The GHSG developed a novel chemotherapy combination, BEACOPP (Tables 111-10 and 111-12), which combines elements of COPP and ABVD with etoposide. The regimen was designed and tested in standard and escalated forms based on mathematical calculations that a tolerable increase in dose intensity could improve the cure rate by approximately 15%. The HD9 study compared COPP/ABVD with standard and escalated BEACOPP. Published results showed a significantly superior failure-free survival and overall survival for escalated BEACOPP as compared with COPP/ABVD, albeit with the not unanticipated increases in acute toxicity.[56] Radiation therapy was given to two thirds of patients who had initially bulky or residual disease. As discussed in the following sections, a concern with the escalated BEACOPP regimen was a number of secondary leukemias among treated patients. Importantly, only patients younger than 65 years were included in this trial. Older patients were treated on a separate trial. Although the numbers are small, the experience was sufficient to conclude that BEACOPP should not be given to older patients, who had a 21% mortality rate.[34] The HD9 results have been updated at 10 years (see Table 111-12), and they continue to show superiority of the escalated BEACOPP regimen as compared with COPP/ABVD.[44] Notably, superior FFS results are seen in all IPS categories. Overall survival is superior in the largest subgroup of intermediate IPS risk (2 and 3; Table 111-13). A required element of escalated BEACOPP is the use of granulocyte colony-stimulating

factors to maintain dose intensity. In the HD9 study the dose intensity of BEACOPP was excellent compared with an estimated dose intensity of only about 0.67 in the COPP/ABVD patients.

The acute and later toxicities of escalated BEACOPP have led to more cautious adoption than might be expected based on the efficacy data and to alterations by clinical trial groups. The GHSG has tested a schedule of four escalated plus four standard BEACOPP cycles in advanced disease with or without radiation therapy to bulky or residual disease sites. At 4 years, the reported data from this study show no difference among the chemotherapy arms and no difference whether or not radiation therapy was delivered. Further toxicity was less with the four + four regimen. Yet another version of BEACOPP administered at 14-day intervals with growth factors has been developed and studied by the GHSG with encouraging results.[57] Together, these data beg a comparison of BEACOPP with ABVD, and indeed, this is the subject of controlled randomized trials. The EORTC is comparing four standard + four escalated BEACOPP versus ABVD in patients with a high IPS. The GISL study compares ABVD with escalated BEACOPP in all IPS groups.

Together the results of treatment in advanced Hodgkin's lymphoma are highly encouraging but can also be seen as confusing. At face value the cure rates are higher with escalated BEACOPP but at the price of increased toxicity (increased risk of leukemia, sterility, increased acute toxicity) and a survival benefit that is less apparent across IPS risk groups (see Table 111-13). Historically, the dose intensity of delivered ABVD has been variable, but recent data show that full doses can be delivered on time with or without growth factors. As discussed in the following sections, ABVD is not without late effects either. Until results of current trials are mature and fully evaluated, a reasonable strategy is to base treatment recommendations on an analysis of risk for treatment failure and for therapeutic complications for an individual, combined with patient preference. Strong consideration should be given to institutional and cooperative group trials for advanced-disease patients where the incorporation of early FDG-PET results are being used to response-adapt therapy. These strategies hold the promise to limit toxicities to those situations where intensive treatment is required. Further, one should keep in mind that toxicity of treatment, as discussed in the following sections, is an equation that accounts for quantitative as well as qualitative therapeutic differences.

Secondary Therapy of Classical Hodgkin's Lymphoma

Fortunately, many fewer patients with Hodgkin's lymphoma currently progress after primary treatment. Those with advanced disease and a high IPS are at greatest risk. High-dose chemotherapy with either the CBV (cyclophosphamide, carmustine, etoposide) or BEAM (carmustine, etoposide, cytarabine, melphalan) regimen followed by autologous stem cell transplantation has been the most successful approach for patients younger than 60 years based on phase II studies, registry results, and two randomized phase III trials. Of interest, although cure rates are significantly higher with autotransplantation, no survival benefit has emerged to date.[58] With this approach, about half of transplanted patients will be cured of their disease. Prognostic factors for unfavorable outcome with high-dose therapy and autologous transplantation include primary treatment failure, progression within 1 year of primary therapy, extensive disease at relapse, systemic symptoms at relapse, and significant residual disease before transplant.[59] The approach is to treat progressive and relapsing patients with secondary chemotherapy, most commonly the ICE (ifosfamide, cytarabine, etoposide) or DHAP (cisplatin, cytarabine, dexamethasone) regimen, to achieve maximal cytoreduction before transplantation. The achievement of PET-negative disease before transplant is a favorable prognostic factor.[60] Recently a new regimen, IGEV (ifosfamide, gemcitabine, etoposide, vinorelbine), has demonstrated excellent tolerability and efficacy in the second-line setting where the goals of treatment are reduction of Hodgkin's lymphoma, preservation of sufficient hematopoietic cells to support transplantation, and absence of severe toxicity that might interfere with the therapeutic plan.[61] Although prognostic factors are useful, there is an opportunity to eradicate Hodgkin's lymphoma with high-dose chemotherapy and autologous transplant even in poor-risk patients such that treatment should be pursued whenever feasible.

Patients progressing after brief chemotherapy and irradiation or chemotherapy alone may provide an exception to the routine use of intensive therapy, dependent on the disease sites and nature of the relapse. A recent publication evaluating the efficacy of second-line treatment after relapse in the NCIC/ECOG HD6 study demonstrated that patients could be successfully salvaged with a variety of therapeutic approaches.[62]

The circumstances for patients failing both primary treatment and autologous transplantation are grim. Historically, some of these patients had sustained remissions after allogeneic transplantation, but transplant-related mortality was considered to be unacceptable. With the advent of nonmyeloablative and reduced-intensity conditioning allogeneic transplants, there has been a resurgence of interest in this approach. Thus far this remains an investigational procedure. Whereas some data support a graft-versus-Hodgkin's effect, others are more questionable.[63,64] Clearly the transplant-related mortality is less with this approach, but relapse rates are high. The intensity of the conditioning regimen and tumor burden at the time of transplant may be important for the success of this approach. Clearly more clinical investigation is needed to fully assess the potential of this approach.

Therapy of Nodular Lymphocyte–Predominant Hodgkin's Lymphoma

The large majority (~80%) of patients with NLPHL have limited-stage disease at presentation. A pivotal study of the disorder was undertaken by the European Task Force, which found high rates of survival at 10 years but a unique pattern of relapse at 5 or more years after varied treatment.[24] In a recent review, mortality data from several sources indicate that deaths in NLPHL are most likely to be

related to treatment or other causes rather than the underlying disease.[65] Studies from the EORTC and the GHSG have used radiotherapy or combined-modality treatment.[66,67] Of interest, data from the GHSG corroborate the excellent outcomes of NLPHL patients participating in clinical trials and suggest that treatment outcomes may be more durable than reported earlier. Based on the GHSG analysis, treatment for the small number of patients with advanced-stage NLPHL should be systemic therapy as appropriate for classical Hodgkin's lymphoma. However, as noted previously, it is important to distinguish advanced-stage NLPHL from T-cell–rich B-cell lymphoma, a more aggressive disease.

Based on the expression of CD20 in NLPHL and the availability of the anti-CD20 antibody rituximab, the GHSG and the Stanford-Washington University Groups have evaluated this antibody in NLPHL.[68,69] High rates of response were seen in both groups though of variable durability. Use of rituximab in previously treated patients may afford a reprieve from cytotoxic therapy and is certainly deserving of further investigation. However, there are several caveats in the therapy of recurrent NLPHL. First, as noted previously, patients must have biopsies at recurrence because of the occurrence of progressive transformation of germinal centers and reactive hyperplasia, both benign conditions. Also, based on the risk of large B-cell lymphoma, which is often not clearly evident from clinical features, a biopsy is further indicated. NLPHL is an indolent disorder, and some patients with localized disease may be observed without treatment. This approach has been reported for stage I disease in children, where about half of them are free from disease progression at 4 years.[70]

SPECIAL CIRCUMSTANCES

Hodgkin's Lymphoma and Pregnancy

Because of the young age of Hodgkin's lymphoma patients, it is not surprising that the diagnosis is sometimes made during pregnancy. It is usually possible to allow the pregnancy to go to term, but clinical judgment is required in these cases as well as attention to the welfare of the patient and fetus and patient choice. The goal of staging in pregnant patients is to survey for sites of threatening disease that influence the management approach rather than careful, exhaustive cataloging of Hodgkin's lymphoma involvement. A careful history and physical examination, single posteroanterior chest radiograph with shielding, abdominal and pelvic ultrasound, and laboratory evaluation are generally sufficient for staging. Magnetic resonance imaging (MRI) can be considered, but CT should be avoided. Although no large series are available, we and others have anecdotal and published data indicating that an individualized approach is appropriate. For patients with low tumor burden or advanced in pregnancy, many can be observed and carry the pregnancy to term. If patients are very ill or significant disease develops, a limited amount of treatment may achieve desired disease regression until delivery. Single-agent vinblastine, which is neither teratogenic nor carcinogenic, has been effectively used in this setting. Combination chemotherapy has also been safely used in the second and third trimesters, as has radiation therapy with appropriate shielding. Close monitoring and reassessment by an experienced clinician is important for optimal management of the pregnant Hodgkin's lymphoma patient.

Hodgkin's Lymphoma and the Human Immunodeficiency Virus

Hodgkin's lymphoma in patients infected with HIV presents more commonly with symptomatic, advanced-stage, mixed-cellularity histology and EBV^+ disease. The incidence of Hodgkin's lymphoma has actually increased during the era of highly effective anti-retroviral therapy (HAART), whereas the incidence of non-Hodgkin's lymphoma has decreased.[21] The reasons for this are uncertain but lead to further speculation that the role of CD40-CD40L interactions, which would increase with increasing CD4 counts, are integral to the antiapoptotic characteristics of H-RS cells.[71] Treatment has become safer and more effective with the introductive of HAART.[72,73] Xicoy and colleagues reported a 71% event-free survival at 5 years among 62 Spanish Hodgkin's lymphoma patients treated with ABVD and HAART.[74]

Hodgkin's Lymphoma and the Elderly

As noted previously, Hodgkin's lymphoma patients over the age of 60 to 65 years have a relatively poor prognosis.[35] In the GHSG series, FFS was less than 50% for patients treated either with BEACOPP or COPP/ABVD. The reason for the less favorable outcome seems to be a combination of both less tolerance for effective treatment and a biologically less favorable disease.[34] Landgren and colleagues reported that ABVD treatment with a relative dose intensity above 0.65 resulted in superior outcomes.[75] Recently Kolstad and coworkers reported excellent outcomes, 76% progression-free survival at 3 years among 29 patients ages 60 to 91 years with CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) chemotherapy.[76]

COMPLICATIONS

For many years the mainstay of treatment for Hodgkin's lymphoma was radiation therapy, given at doses of 40 Gy or greater to large areas of the body as a single modality. As treatment evolved, chemotherapy was added to irradiation and, in recent years, radiation has been administered in much smaller volumes and in smaller doses or not at all. Part of the evolution of treatment can be attributed to more effective chemotherapy, but the appreciation of late effects of radiation therapy, often with a latency of 10 or more years served as a driving force. In caring for patients treated for Hodgkin's lymphoma, it is important to take into account their risks based upon the era of treatment and, more specifically, on the radiation dose and volume, years elapsed from treatment, age at treatment, and age attained. Table 111-14 outlines the major late complications of Hodgkin's lymphoma treatment together with the offending agents and important modifying factors. Patients with Hodgkin's lymphoma have an increased risk of death that persists for more than 25 years, mainly from cardiovascular disease and second cancers directly linked to radiation therapy exposure.[77] It is important to recognize this ongoing risk for patients treated before about 1990 so that they can be monitored appropriately. Although there is reason for optimism that current treatment with smaller volumes and lesser doses will be associated with a lower risk of these complications, it is too early to fully assess.

Hypothyroidism is a common complication of neck irradiation that occurs in about 50% of patients. Monitoring of thyroid function tests annually and appropriate hormone replacement therapy is indicated. Patients who have been splenectomized or received splenic irradiation should receive pneumococcal vaccination at 5-year intervals and be counseled to seek prompt medical attention for febrile illness. Young patients who wish to retain their fertility must be identified and counseled before the onset of treatment.[78] ABVD does not seem to cause more than temporary cessation of menses in women and temporary oligospermia in men. In contrast, BEACOPP chemotherapy routinely sterilizes males and many young females.[79,80] Semen preservation must take place before chemotherapy. Embryo preservation, which is successful but costly, and/or the use of gonatrophin-stimulating hormone therapy, which has been reported to be effective by some but not others, are options for women at risk (generally over age 25). Preservation of ova remains experimental. Radiation therapy administered before 1975 often led to serious effects on the pericardium, potentially resulting in chronic pericarditis, and myocardial disease. These complications have not been associated with radiation therapy given thereafter, with heart blocks and other technical

Table 111-14 Late Complications of Hodgkin's Lymphoma Therapy

Complication	Therapeutic Risk Factor	Modifying Factor
Hypothyroidism	Neck irradiation	
Sepsis	Splenectomy, splenic irradiation	
Premature menopause	Cumulative-dose alkylating agents	Age at treatment
	Ovarian irradiation	
Female infertility	Cumulative-dose alkylating agents	Age at treatment
	Ovarian irradiation	
Male infertility	Cumulative-dose alkylating agents	
Carotid stenosis	High neck irradiation	RT dose
Coronary artery disease	Chest irradiation	RT dose, field, CAD risk factors
Other heart disease*	Chest irradiation	RT dose, field, technique, anthracycline
Cardiomyopathy	Cumulative-dose anthracycline	Chest irradiation
Secondary leukemia	Cumulative doses of alkylating agents, etoposide	Age, RT
Secondary breast cancer	Axillary, chest irradiation	Age at treatment, hormonal exposure, RT field and dose
Secondary lung cancer	Alkylating agents, chest irradiation	Smoking, age at treatment
Pulmonary toxicity	Cumulative-dose bleomycin	Chest irradiation, ? genetic predisposition
Osteoporosis	Prednisone, alkyating agents	Other risk factors, hormonal milieu
Osteonecrosis	Prednisone, irradiation	RT field

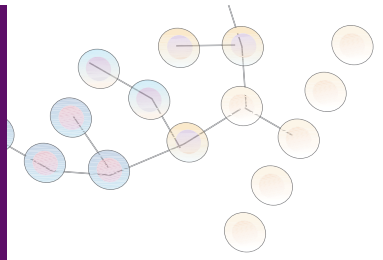
CAD, coronary artery disease; RT, radiation therapy.
*Valvular heart disease, pericardial disease, electrophysiologic disorders.

changes. However, coronary artery disease, valvular disease, and electrophysiologic changes have all been associated with radiation therapy administered at doses of 30 Gy or higher.

In a recent study involving more than 7000 patients followed after Hodgkin's lymphoma treatment, the standard mortality risk for death from myocardial infarction after mediastinal irradiation was 8.9, and the risk remained elevated for more than 25 years.[81] An expert panel concluded that there was insufficient information to recommend screening guidelines for patients exposed to chest irradiation, even though a Stanford study found significant pathology in asymptomatic patients.[82] However, it is prudent to counsel patients about their risks, evaluate and treat other risk factors for cardiovascular disease, and have a low threshold for formal evaluation of cardiac function. Although excess cardiotoxicity has not been described in clinical reports of ABVD, the large United Kingdom study demonstrated a standardized mortality risk of 2.9 for anthracyclines.[81,83] It is known that anthracycline cardiotoxicity can remain silent for long periods of time.[83]

Second cancers are the most feared complication of Hodgkin's lymphoma therapy. Early reports implicated the alkylating agents in MOPP chemotherapy in an increased risk of secondary acute myelocytic leukemia (AML) and myelodysplasia, and this observation served as the basis to recommend radiation therapy only for many years. ABVD chemotherapy does not seem to increase the risk of secondary AML above baseline. The original publication of the HD9 study demonstrating the superiority of BEACOPP chemotherapy was accompanied by an increased risk of secondary AML with this regimen.[56] In this case, etoposide was also implicated. Older patients are at increased risk, which is associated with cumulative exposure. Young women who receive axillary and chest irradiation are at increased risk of secondary breast cancer. Women younger than 30 years at treatment who continue to have menses after treatment are at greatest risk.[84] Studies have suggested that as little as 4 Gy puts individuals at increased risk.[84] The risk of secondary breast cancer has a latency period of 5 to 10 years with risks that persist for at least 25 years. Travis and colleagues have tabulated risks and ascertained that a woman treated at age 25 with 40 Gy chest irradiation has a 29% risk of secondary breast cancer by age 55.[85] This risk projection as stated, however, does not necessarily apply to more recent treatment approaches. Recommendations for mammography have been made for patients at risk for secondary breast cancer, starting 5 to 8 years after the completion of chest irradiation. Recently, MRI has proven to be superior in diagnosing young women at high genetic risk for breast cancer, because premenopausal women have dense breast tissue that reduces the precision of mammography.[86,87] Current recommendations for MRI include women at high risk because of prior chest irradiation.

Lung cancer is emerging as a leading cause of death in Hodgkin's lymphoma patients. Relative risks increase with cumulative dose of alkylating agents and with increasing doses of radiation. The risk after chemotherapy is immediate, whereas there is a latency of about 5 years after radiation therapy. Importantly, the relative risk increases 20-fold with tobacco use, indicating that smoking cessation is absolutely imperative among Hodgkin's lymphoma survivors.[88] The relative risk for secondary lung cancer is greatest among patients treated after age 45, and the absolute excess risk persists for as long as 20 to 25 years.[89] Pulmonary toxicity related to bleomycin has been recognized to be both idiosyncratic and related to cumulative exposure. A recent analysis in 141 patients treated with bleomycin for Hodgkin's lymphoma found an 18% incidence of pulmonary toxicity as defined by the study with an increased incidence in patients on the ABVD regimen, those aged older than 40 years, and those concomitantly receiving growth factors.[90] The authors reported that pulmonary toxicity was associated with inferior survival but also found that bleomycin could be omitted upon signs or symptoms of toxicity without a decrease in remission rate. Bone toxicity in the form of osteoporosis may accompany prednisone use, particularly in the setting of gonadal failure, and bone density should be assessed in individuals at risk. Osteonecrosis is an uncommon complication that occurs in the hips or shoulders in individuals exposed to high cumulative doses of prednisone, particularly with the addition of high-dose radiation therapy.



FUTURE DIRECTIONS

Continued success in the treatment of Hodgkin's lymphoma has been attained through international efforts in controlled clinical trials. Advances in diagnostic radiology with the advent of FDG-PET affords an immediate opportunity to assess this powerful technology as an marker of treatment success and the efficacy of response-adapted strategies that may both improve outcomes and reduce complications. Meanwhile, breakthroughs in understanding the nature of the H-RS cells and the interplay with the microenvironment identify potential new targets for therapeutics. Additional biomarkers from the tumor and the host may allow more appropriate, risk-adapted treatment. Insights into the etiology of Hodgkin's lymphoma and predisposition to late effects are likely to impact future management. In addition to the use of rituximab as a targeted therapy for NLPHL, early leads with immunomodulatory agents, angiogenesis inhibitors, histone deacetylase inhibitors, and other agents are promising in classical Hodgkin's lymphoma therapy. Antiapoptotic agents are coming into clinical use, and inhibitors of NF-κB are on the horizon. These new approaches hold out the promise to maintain and improve the current cure rates with fewer late complications.

SUMMARY OF KEY POINTS

Incidence

- The incidence of non-Hodgkin's lymphoma has steadily increased in the United States since 1976, with 19 per 100,000 people in 2000. Diffuse large B-cell (DLBCL) and follicular lymphoma (FL) are the most common subtypes, each comprising approximately one third of cases in the West.
- Worldwide, there is considerable variability in the incidence of lymphoma subtypes with increased T-cell lymphoma in non-Western countries.

Etiology and Biology

- Etiology of most lymphomas is unknown. Infectious causes are increasingly recognized and include *Helicobacter pylori* in gastric mucosa–associated lymphoid tissue (MALT) lymphoma, Epstein-Barr virus in post-transplant and human immunodeficiency virus in aggressive B-cell and primary central nervous system (CNS) lymphoma, human T-cell leukemia/lymphoma virus-1 in adult T-cell lymphoma/leukemia, hepatitis C in splenic lymphoma, and human herpesvirus 8 in primary effusion lymphoma.
- In the West, some 85% of lymphomas are of B-cell origin, and 15% are of T/NK-cell origin.
- Specific genetic abnormalities associated with lymphomas include translocations of bcl-2 (t(14;18)) in FL and DLBCL; bcl-6 (t(3;16) in DLBCL; bcl-10 (t(11;18) in MALT lymphoma; c-myc (t(8;14), t(2;8), t(8;22)) in Burkitt's lymphoma; bcl-1 (t(11;14)) in mantle cell lymphoma (MCL); and ALK (t(2;5)) in anaplastic large T-cell lymphoma.

Differential Diagnosis

- Lymphoma can manifest as a solid mass and/or leukemia. Leukemic presentations more commonly occur in small lymphocytic, lymphoblastic, Burkitt's, splenic marginal zone, adult T-cell lymphoma/leukemia, and mantle cell lymphomas.
- Lymphomas are usually readily distinguished from other pathology. Benign inflammatory conditions that can be confused with lymphoma include reactive follicular hyperplasia, infectious mononucleosis, and cat scratch disease. Lymphomas that are occasionally confused with solid tumors include anaplastic large cell lymphoma (ALCL) and Hodgkin's lymphoma.
- The World Health Organization Classification of Lymphoid Malignancies should be used for diagnosis. When possible, excisional biopsy should be obtained for initial diagnosis and reviewed by an experienced hematopathologist. Fresh-frozen tissue should be available for further study.

Staging Evaluation

- Standard evaluation includes history and physical examination; complete blood count and chemistry studies including lactate dehydrogenase; computerized tomography of chest, retroperitoneum, and pelvis; and bone marrow biopsy. Positron emission tomography scans are being used with increasing frequency.
- Additional studies may include lumbar puncture in patients who are at risk for CNS involvement.

Primary Therapy

- Treatment is based on multiple factors, including histology, performance status, age, and stage, and is stratified according to clinical risk factors such as the International Prognostic Index.
- Treatment is frequently curative for DLBCL, ALCL, Burkitt's lymphoma, and lymphoblastic lymphoma. Cure is uncommon in most peripheral T-cell lymphomas.
- Follicular lymphoma, marginal zone lymphoma, and small lymphocytic lymphoma can have prolonged survival with intermittent treatment but cure is achieved in a minority of patients.
- MALT lymphomas have an indolent course. In gastric MALT, antibiotic therapy may cure up to 60% of patients.
- MCL varies from indolent to aggressive, and outcome appears to have improved with new treatments but is infrequently cured.

INTRODUCTION

Non-Hodgkin's lymphoma (NHL) includes multiple neoplastic disorders of the lymphoid system with overlapping features. NHL is characterized by a monoclonal expansion of lymphoid cells, excluding those from primitive precursors that give rise to acute lymphoblastic leukemia and plasma cells that give rise to multiple myeloma. The malignant cell for most lymphomas can be traced to a specific stage in lymphoid maturation; lymphomas most commonly derive from mature B cells of germinal center origin. The cell of origin and stage of maturation arrest are important for understanding pathobiology and the identification of potential therapeutic targets.

The clinical presentation is variable and depends on a number of factors, including histology, patient age, and immune status. NHL typically presents with lymphadenopathy that can range from relatively asymptomatic to causing organ compromise such as ureteral obstruction or spinal cord compression. Patients may have constitutional manifestations due to inflammatory molecules and a variety of

other cytokines and chemokines that are produced by the lymphoma cells and/or host tissues. Without effective intervention, death is usually invariable. Current treatments have a powerful effect on the natural history of the disease, resulting in significant prolongation of survival or cure.

EPIDEMIOLOGY AND ETIOLOGY

Incidence

NHLs are the fifth and sixth most common malignancy in men and women, respectively, and are among the most rapidly increasing malignancies.[1] The increase in incidence appears to be worldwide, with incidences ranging from approximately 2 per 100,000 per year in Asia to 19 per 100,000 per year in the United States.[2] Data also suggest that the increase is greatest in the elderly and in diffuse large B-cell lymphoma (DLBCL). According to the Surveillance Epidemiology and End Results data, the incidence has been rising approximately 4% a year and represents a 150% increase between the 1940s and the 1980s. In absolute numbers, this represents approximately 56,000 new cases and 20,000 deaths of NHL in the United States each year (Fig. 112-1). The reasons for the increase in NHL are unclear but are likely due to multiple etiologic factors, including human immunodeficiency virus (HIV) infection.

Etiology

Immune suppression and stimulation are important cofactors for the development of NHL. Both primary and secondary immunodeficiency predispose to an increased incidence of Epstein-Barr virus (EBV) associated NHL (Table 112-1).[3–5] Less well understood but equally important is the role of chronic immune stimulation in diseases such as Sjögren's syndrome and rheumatoid arthritis.[6,7] In these diseases, however, it is difficult to separate the contribution of immune stimulation from secondary immune suppression associated with treatment of the underlying disease.[7] Perhaps less ambiguous is the role of chronic immune stimulation from *Helicobacter pylori* infection in gastric mucosa–associated lymphoid tissue (MALT) lymphoma.[8,9] Additional data also suggest an association between Borrelia infection and cutaneous MALT lymphoma and hepatitis C and splenic lymphoma.[10,11]

Viruses may function as cofactors in lymphomagenesis. They may exert their effect through integration into the genome, leading to alterations in gene expression, and/or may directly affect proliferation. The EBV, human T-cell leukemia/lymphoma virus-1 (HTLV-1), and human herpesvirus 8 (HHV-8) in particular have been implicated.[3,12–14] In the case of EBV, it appears to have a direct role in lymphomas of immunocompromised patients such as HIV and post-transplant lymphoproliferative diseases (PTLD). In contrast, its role in Burkitt's lymphoma (BL) appears indirect and variable, where it occurs in 30% of cases in the West (sporadic) and 95% of cases in Africa (endemic).[15] HTLV-1 appears to have a direct causative role in adult T-cell leukemia/lymphoma, and carriers have a 5% lifetime risk of developing disease. HHV-8, also known as Kaposi's sarcoma herpesvirus, has been associated with primary effusion lymphoma, a rare B-cell lymphoma that occurs primarily in highly immunosuppressed patients with AIDS.[16,17]

Multiple epidemiology studies have examined the role of occupational and environmental factors. Prevalent among these are studies that show a link between agricultural work and lymphoma, which

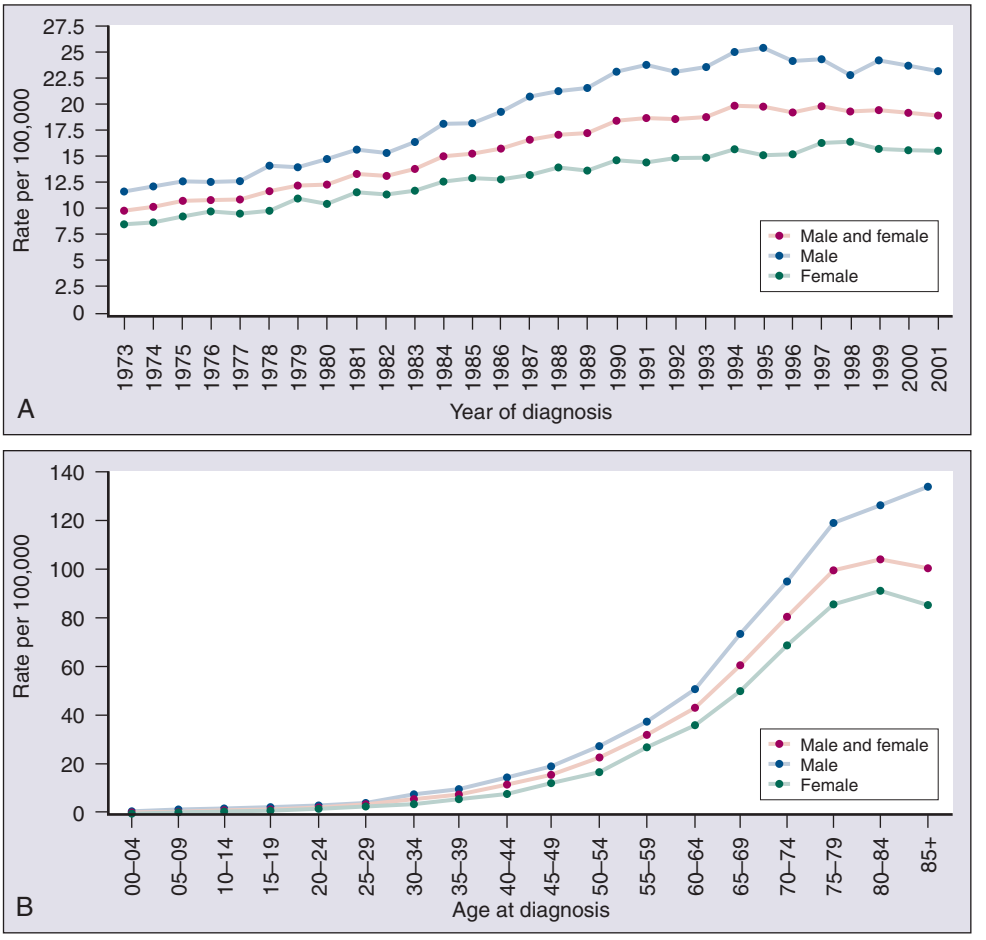

Figure 112-1 • Lymphoma rates from the Surveillance Epidemiology and End Results data from 1973 to 2001. **A,** Age-adjusted rate of non-Hodgkin's lymphoma in males, females, and combined. **B,** Rate of non-Hodgkin's lymphoma in males, females, and combined, according to age. has been attributed to organochlorine-based pesticides.[18] Other studies also suggest that exposure to organic solvents and wood products could increase the risk of lymphoma.[19]

DIAGNOSIS

An adequate biopsy is essential for diagnosis, and when possible, an excisional biopsy should be performed. Attention should be paid to the biopsy site, the largest or most rapidly enlarging node being chosen because it is likely to reveal the most aggressive histology and provide the most tissue. Biopsy of mediastinal or abdominal masses requires appropriate caution. In such cases, a Trucut needle biopsy can be adequate and avoids open surgery. Fine-needle aspiration is rarely if ever adequate for initial diagnosis but may be used to confirm relapse. The storage of fresh-frozen tissue is highly encouraged for future diagnostic tests based on molecular profiling.

CLASSIFICATION

Lymphomas are a heterogeneous group of diseases which clinically vary from indolent to aggressive and from incurable to curable.[20] Histologic classification schemes have been developed to organize lymphomas into groups with shared pathogenesis and clinical behavior with an aim to guide treatment. Over the years, these classifications have evolved from exclusively morphologic classifications to the current ones that incorporate immunophenotype and genetic endpoints, such as the Revised European-American Classification of Lymphoid Neoplasms and the World Health Organization Classification of Neoplastic Diseases of Hematopoietic and Lymphoid Tissues (Table 112-2).[20–22] This evolution is the direct result of insights into the molecular pathogenesis of lymphoma, including the identification of hallmark genetic abnormalities.

The immune phenotype is fundamental for the accurate classification of lymphoma. Early studies showed that most lymphomas are of B-cell origin (Table 112-3).[23] Beginning in the 1970s, classifications first emerged that were based on the putative cell of origin and aggressiveness of malignancy. The Kiel classification, which gained popularity in Europe, incorporated information on the cell of origin, whereas the Working Formulation, which was adopted in North America, provided clinical groupings and pathologic divisions that were largely based on cell size (large versus small), cell shape (round versus not round), and growth pattern (follicular versus diffuse).[24,25]

Advances in molecular biology have further advanced the understanding of lymphomagenesis through identification of relevant genes that are important in cellular proliferation, differentiation, and death. A variety of complementary technologies are now available that can measure the expression of thousands of genes in parallel, termed *molecular profiling*, and can link biology to a genetic expression

Table 112-2 World Health Organization Classification of Lymphomas

B-CELL NEOPLASMS
Precursor B-cell
Precursor B lymphoblastic leukemia/lymphoma
Mature B-cell
Chronic lymphocytic leukemia/small lymphocytic lymphoma

signature. The application of this technology to lymphoma is providing insights into unique molecular signatures of distinct types of B-cell malignancies.[26] It can relate lymphoid neoplasms to normal stages in B-cell development and physiology and has provided a new way to classify lymphomas and to predict clinical outcome.[26,27] Indeed, as the molecular analysis of tumors improves, the classification of human cancers is likely to become more refined and informative.

Molecular Genetics

At a molecular level, the genetic lesions that have been identified in lymphomas include oncogene activation or loss of tumor suppressor genes caused by chromosomal translocation, deletion, or mutation or by introduction of exogenous viral genomes into the human chromosome (Table 112-4). The molecular cloning of genetic loci that are involved in the translocations most frequently associated with lymphomas has led to the identification of a number of proto-oncogenes involved in lymphomagenesis. Distinguishing immunologic and genetic features, presumably reflecting disease biology, have been identified for many lymphoma subtypes and are incorporated into the World Health Organization classification. However, what is absent is an adequate understanding of the ripple effect of these genetic abnormalities on the cellular gene expression.

Owing to the recent development of molecular profiling, the studies have focused primarily on the more common B-cell lymphomas, which are generally categorized as indolent or aggressive. The genetic hallmark of follicular lymphoma (FL), the most common indolent lymphoma subtype, is the t(14;18)(q32;q21) translocation with rearrangement of the *bcl-2* gene, present in 80% to 90% of cases, and overexpression of the *bcl-2* gene product (see Table 112-4).[28,29] Inhibition of apoptosis by *bcl-2*, which occurs in normal germinal center cells, appears to play an important role in lymphomagenesis.[28,30] However, constitutive *bcl-2* expression is not necessarily required for survival, as it may be turned off in FL cells that have undergone aggressive transformation.[31] The role of *p53* mutation/deletion that is observed in some transformed FLs is also uncertain, although loss of *p53* function is associated with decreased apoptosis and clinical drug resistance.[32,33] The functional significance of genetic abnormalities in small lymphocytic lymphoma (SLL)/B-cell chronic lymphocytic leukemia (CLL) is more uncertain, although many of these abnormalities have important clinical effects. Clonal chromosomal abnormalities can be detected in nearly half of these patients, deletions of the long arm of chromosome 13 being the most common.[34] Trisomy 12 anomalies are also frequent, found in 10% to 30% of cases, followed by deletions in the long arm of chromosome 11, termed 11q-, in some 1% to 20% of cases; both anomalies are associated with more aggressive disease compared to patients who harbor the more common del 13q14.[35,36] Abnormalities in the *p53* gene, located on the short arm of chromosome 17, at 17p13, have also been associated with a poor clinical outcome in CLL and are found in half of patients with a Richter's transformation.[37,38] Of developmental and clinical relevance is the mutational status of the immunoglobulin variable heavy (V_H) region in CLL.[39] Normal developmental biology would suggest that CLL cells with or without V_H somatic mutations correspond to antigen-dependent and antigen-independent phases, respectively, and in the former case is associated with longer survival.[39]

Among aggressive lymphomas, DLBCL is the most common type, making up a third of all lymphomas.[40] This histologic category contains multiple disease entities as suggested by its variable clinical presentation, natural history, morphologic variants, and molecular characteristics.[20] The diverse morphologic variants of DLBCL, which include centroblastic, immunoblastic, T-cell/histiocyte-rich, and anaplastic types, have some known molecular correlates but alone cannot reliably be distinguished as distinct diseases.[20] Other DLBCL subtypes such as primary mediastinal B-cell lymphoma (PMBL) and intravascular large B-cell lymphoma have been identified as distinct subtypes of DLBCL on the basis of a combination of clinical, histo-

Table 112-4 Major Molecular Translocations in Non-Hodgkin's Lymphomas

NHL Histologic Type	Translocation	Percentage of Cases Affected	Proto-oncogene Involved	Mechanism of Proto-oncogene Activation	Proto-oncogene Function
Lymphoplasmatic lymphoma	t(9;14)(p13;q32)	50%	*pax-5*	Transcription deregulation	Transcription factor regulating B-cell proliferation and differentiation
Follicular lymphoma	t(14;18)(q32;q21) t(2;18)(p11;q21) t(18;22)(q21;q11)	90%	*bcl-2*	Transcription deregulation	Negative regulator of apoptosis
Mantle cell lymphoma	t(11;14)(q13;q32)	70%	*bcl-1/cyclin D1*	Transcription deregulation	Cell cycle regulator
MALT lymphoma	t(11;18)(q21;q21) t(1;14)(p22;q32)	50%	*api_2/mlt* *bcl-10*	Fusion protein Transcription deregulation	*api_2* has antiapoptotic activity Antiapoptosis (?)
Diffuse large B-cell lymphoma	der(3)(q27)	35%	*bcl-6*	Transcription deregulation	Transcriptional repressor required for GC formation
Burkitt's lymphoma	t(8;14)(q24;q32) t(2;8)(p11;q24) t(8;22)(q24;q11)	80% 15% 5%	*c-myc*	Transcription deregulation	Transcription factor regulating cell proliferation and growth
Anaplastic large T-cell lymphoma	t(2;5)(p23;q35)	60%	*npm/alk*	Fusion protein	*alk* is a tyrosine kinase

logic and molecular findings.[20] It is also important to recognize that large cell "transformation" of an indolent B-cell lymphoma/leukemia, a relatively common occurrence, involves pathways of lymphomagenesis that are distinct from those of de novo DLBCL. However, these entities may share histologic, immunophenotypic, and oncogenetic characteristics.[41]

Within DLBCL, a common molecular abnormality that is seen in over half of cases involves the deregulation of *bcl-6*, either through promoter substitution or by multiple, often biallelic mutation clustering in its 5′noncoding region; up to 35% of cases show abnormalities of the 3q27 region (see Table 112-4).[42] *Bcl-6* protein functions as a transcription factor that binds a specific DNA sequence and represses transcription from linked promoters. It is important in the normal functioning of the germinal center B cells and is required for germinal center cell formation during the antigen-driven immune response.[43] DLBCLs with high expression of *bcl-6* are usually of germinal center B-cell origin, and in part this might help to distinguish them from other DLBCL subtypes.[44] The functional significance of *bcl-6* overexpression and/or deregulation on clinical outcome is uncertain, although some studies have found an improved survival in such patients, possibly related to their association with cells of germinal center origin.[45] Another common, albeit variable, finding is the overexpression of *bcl-2*, which is reported to be present in 24% to 55% of cases from two studies.[46,47] Interestingly, only 14% to 17% of these cases were found to harbor a *bcl-2* gene rearrangement from the t(14;18) translocation, suggesting the presence of variable molecular mechanisms of *bcl-2* overexpression. Paradoxically, overexpression of the bcl-2 protein but not the *bcl-2* gene rearrangement is associated with decreased survival, suggesting that the antiapoptotic effect of the bcl-2 protein is not the important determinant of outcome.[46,47] Microarray profiling studies, however, have shed light on this apparent paradox, as will be discussed later in the chapter. Other variable molecular findings in DLBCL include mutation of the *p53* gene, found in approximately 20% of cases at initial diagnosis; this has also been associated with decreased survival and drug resistance, presumably through its antiapoptotic effects.[32,48] Specific immunophenotypic and genotypic features have also been associated with the PMBL subtype of DLBCL, such as overexpression of the MAL gene, a finding that supports a unique biologic heritage for this disease.[20,49,50]

Burkitt's lymphoma is an uncommon aggressive B-cell lymphoma characterized by a translocation between *c-myc* on chromosome 8 and one of the three immunoglobulin chain loci. These translocations occur with a respective frequency of 80%, 15%, and 5% on chromosomes 14, 22, and 2, respectively, which encode in turn for the immunoglobulin heavy chain and lambda and kappa light chains.[21] As would be expected, the t(8:22) is usually found in lambda-expressing cells, whereas the t(8:2) is found in kappa-expressing cells. Because these translocations bring the *c-myc* oncogene into close approximation with the immunoglobulin gene–inducible promoter, there is abnormal expression of c-myc and overexpression of the functionally intact protein.[15] This finding is consistent with immunohistochemical studies on tumor tissues, which commonly show a quantitative increase in c-myc expression. The quantitative overexpression of c-myc has been shown to result in deregulation of cellular growth and is capable of blocking phenotypic maturation. Hence, c-myc overexpression appears to be central to the pathogenesis of BL, and it is thought that the translocation occurs in pre-B-cell development during the normal rearrangement of the immunoglobulin loci.

Mantle cell lymphoma (MCL) was relatively recently recognized as a distinct B-cell lymphoma.[20] Almost all cases contain the t(11;14)(q13;q32) translocation between the immunoglobulin heavy chain and the *cyclin D1* (PRAD1, *bcl-1*) genes.[51] Deregulation of *bcl-1* leads to overexpression of its gene product cyclin-D1, which promotes progression from G_1 to S of the cell cycle.[52] Unlike DLBCL, most patients are incurable and have a relatively short median survival of 3 to 5 years.[53]

Principles of Evaluation

A thorough history and a physical examination are important for optimal management (Table 112-5). Patients should be questioned

Table 112-5 Evaluation of a New Patient with Non-Hodgkin's Lymphoma

Evaluation	Mandatory	As Indicated
Confirm diagnosis	Adequate biopsy reviewed by experienced hematopathologists	Immunophenotyping
		Cytogenesis
		Molecular studies
General overview	Careful history and physical examination	Blood coagulation studies
	Complete blood count (including platelet count)	Serum and viral protein studies
	Chemistry screen (including liver and renal function studies)	Serum electrolytes, uric acid
	Chest radiograph	
Prognostic categorization	Serum LDH	Erythrocyte sedimentation rate
	Serum albumin	Serum β_2-microglobulin
		Tumor growth fraction
		Microarray analysis
Anatomic disease	Whole-body CT scans	Ultrasonography
		Magnetic resonance imaging
		FDG-PET scans
		Bone scans
Occult sites of involvement	Bone marrow biopsy	Lumbar puncture with flow cytometry
		Biopsy of suspicious sites
		Blood flow cytometry
		Blood and bone marrow PCR

CT, computed tomography; FDG-PET, 18-fluoro-2-deoxyglucose positron emission tomography; PCR, polymerase chain reaction.

about systemic symptoms, and performance status should be assessed. It is useful to query whether there are potential causative factors, such as prior malignancy, chemotherapy, or radiation treatment and/or autoimmune or immunodeficiency disease. A history of infection with or exposure to various pathogens, including HIV, hepatitis C, and HTLV-1, should be excluded. A detailed physical examination should be performed with detailed attention to lymph nodes, liver, and spleen.

Laboratory tests should include a complete blood count and serum chemistry with lactate dehydrogenase (LDH) and HIV and hepatitis serology. Other viral tests, such as testing for HTLV-1, should be included as indicated. EBV viral loads can also be useful in specific lymphomas such as PTLD and nasal NK/T-cell lymphoma.[54,55] Elevated LDH and β_2-microglobulin levels have prognostic implications for certain lymphoma subtypes.

Imaging and Staging

It is important to assess sites of disease involvement and imaging studies should include chest radiography and computed tomography (CT) scanning of the chest, abdomen, and pelvis (see Table 112-5). The need for additional studies, such as magnetic resonance imaging (MRI) and 18-fluoro-2-deoxyglucose (FDG) positron emission tomography (PET) scanning, will depend on the clinical presentation and sites of disease. For example, if there is a risk of central nervous system (CNS) involvement, a head MRI should be performed, and involvement of the bone is best evaluated by MRI and PET scans.

Though PET scanning is now widely used, it does not have an established role in the initial staging of NHL.[56] Nevertheless, PET provides sensitive functional imaging of lymphomas for initial assessment and follow-up. A retrospective evaluation of 172 patients with various histologies of lymphoma found that 98% to 100% of DLBCL, mantle cell, and follicular lymphomas were detectable by FDG-PET.[57] However, detection frequencies were below 70% for patients with marginal zone and peripheral T-cell lymphomas. FDG-PET scans during and/or after therapy have also been shown to have prognostic value. In one study of FDG-PET scans done 1 to 3 months after treatment in 93 patients, 26 were interpreted as positive for residual disease.[58] Whereas all 26 patients relapsed in a median of 73 days, only 11 patients with normal FDG-PET scans relapsed. Early restaging with FDG-PET was of prognostic value in this series.[58] Among 70 patients with aggressive NHL who underwent midtreatment FDG-PET, none of 33 patients with positive FDG-PET achieved durable remissions, whereas 31 of 37 patients with negative FDG-PET remained in complete remission.

Bone marrow involvement often affects management and should be assessed at initial staging. Patients who are at risk of CNS involvement should undergo lumbar puncture with evaluation of the cerebrospinal fluid by cytology and flow cytometry.[59] Specifically, histologic subtypes such as BL and extranodal disease in DLBCL are associated with an increased risk of CNS disease.[60]

The Ann Arbor staging system, which was originally designed for Hodgkin's lymphoma, is the standard for adult lymphomas (Table 112-6). However, because of the heterogeneity and hematogenous pattern of dissemination in NHL, in contrast to contiguous lymph node spread with Hodgkin's lymphoma, the staging system has more limited value. At the same time, important modifications to the Ann Arbor staging system that were made at the Cotswold Conference have made it more applicable to NHL.[61] The Cotswold's modification (see Table 112-6) provides a framework for assigning a clinical stage and incorporates a designation for the presence of "bulk" disease defined as a mass greater than 10 cm or a mediastinal mass greater than one third of the transthoracic width.[61] Extranodal sites are denoted in the anatomic classification by the suffix "E."

Table 112-6 Ann Arbor Staging Classification and the Cotswold Modifications

Stage	Features
I	Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer's ring)
II	Involvement of two or more lymph node regions on the same side of the diaphragm
III	Involvement of lymph regions or structures on both sides of the diaphragm
IV	Involvement of extranodal site(s) beyond that designated E
FOR ALL STAGES	
A	No symptoms
B	Fever (>38°C), drenching sweats, weight loss (10% body weight over 6 months)
FOR STAGES I TO III	
E	Involvement of a single extranodal site contiguous or proximal to known nodal site
COTSWOLD MODIFICATIONS	
(i)	Suffix X to designate bulky disease as more than one third widening of the mediastinum or >10-cm maximum dimension of nodal mass
(ii)	The number of anatomic regions involved should be indicated by a subscript (e.g., II3)
(iii)	Stage III may be subdivided into: III_1, with or without splenic, hilar, celiac, or portal nodes; III_2, with para-aortic, iliac, mesenteric nodes
(iv)	Staging should be identified as clinical stage or pathologic stage
(v)	A new category of response to therapy, unconfirmed/uncertain complete remission should be introduced because of the persistent radiologic abnormalities of uncertain significance

Prognosis

Clinical stage is a powerful and independent predictor of prognosis. To identify prognostic factors in aggressive lymphoma, an international project to correlate clinical variables and outcome in 2031 patients with untreated aggressive lymphoma was undertaken (Table 112-7).[62] The parameters that were independently associated with inferior outcome included age over 60 years, stage III or IV disease, serum LDH above the normal range, Eastern Cooperative Oncology Group performance status of 2 or higher, and involvement of two or more extranodal sites. A clinical prognostic model, termed the International Prognostic Index (IPI), was developed using these five factors (see Table 112-7). In this model, one point was allocated for each feature, and it stratified patients into four groups with 5-year survival rates of 73%, 51%, 43%, and 26% for zero to one, two, three, and four to five risk factors, respectively, with CHOP-based treatment.[62] The IPI has become the standard for assessing clinical prognosis and treatment stratification and for comparison between clinical trials. Although it has yet to be fully revalidated in the rituximab era, a revised prognostic model for R-CHOP, termed R_{evised}-IPI, was recently published based on a limited retrospective series (see Table 112-7).[63] A validated prognostic index based on the IPI was also developed for follicular lymphoma.[64] Age, stage, and serum LDH, in addition to hemoglobin level and number of nodal areas, reliably predicted survival and composed the Follicular Lymphoma International Prognostic Index (see Table 112-7).[64]

Though not yet routinely performed in aggressive NHL, gene expression profiling is emerging as an important prognostic tool.[27,65–67] In DLBCL, for example, morphologically indistinguishable tumors can show marked heterogeneity in gene expression, and

Table 112-7 Clinical Prognostic Indexes

INTERNATIONAL PROGNOSTIC INDEX FOR AGGRESSIVE LYMPHOMAS[62]

Risk Group	IPI Score*	CR Rate (%)	5-Year OS Rate (%)
Low	0, 1	87	73
Low intermediate	2	67	51
High intermediate	3	55	43
High	4, 5	44	26

REVISED INTERNATIONAL PROGNOSTIC INDEX (R-IPI)[63]

Risk Group	IPI Score*	4-Year OS Rate (%)
Very Good	0	94
Good	1–2	79
Poor	3–5	55

FOLLICULAR INTERNATIONAL PROGNOSTIC INDEX (FLIPI)[64]

Risk Group	IPI Score*	Distribution (%)	10-Year Survival Rate (%)
Low	0–1	36	71
Intermediate	2	37	51
Poor	≥3	27	36

CR, complete response; ECOG, Eastern Cooperative Oncology Group; IPI, International Prognostic Index; LDH, lactate dehydrogenase; OS, overall survival.

*One point is given for the presence of each of the following characteristics: age >60 years, elevated serum LDH level, ECOG performance status ≥2, Ann Arbor stage III or IV, and more than two extranodal sites.

these patterns of expression may be classified into signatures that correspond to the cellular origin of the lymphoma according to its stage of differentiation. On the basis of these signatures, DLBCL can be divided into at least three different subtypes: germinal center B-cell (GCB) like, activated B-cell (ABC) like and PMBL. Overall survival (OS) is different in each group and superior in patients with the GCB type compared to the ABC type (Fig. 112-2). Using gene expression profiling, a molecular prognostic model of survival, independent of the IPI, has been also been developed for CHOP-treated DLBCL.[27] However, this model, based on four signatures of germinal center B cells, proliferating cells, reactive stromal and immune cells in the lymph node, and major histocompatibility complex class II cells, has not been applied to rituximab-based treatment. An immunohistochemical model has also been developed to predict GCB and non-GCB subtypes of DLBCL.[68] Although this IHC model requires further validation, its application in two recent studies suggests that the addition of rituximab to chemotherapy ameliorates the adverse outcome of non-GCB DLBCL.[69,70]

Treatment Response and Follow-up

Treatment response should be documented by physical findings, and all abnormal tests should be repeated. Final treatment assessment is usually performed 3 to 6 weeks after completion of therapy unless progression occurs earlier. The frequency and extent of investigations during follow-up depend on the risk of recurrence and the potential for early detection to change further treatment.

A workshop that was held under the auspices of the National Cancer Institute in 1998 standardized response criteria for the first time.[71] By necessity, some standards were arbitrary, such as the definition of normal lymph node size. The spleen was considered to be a nodal site and should be assessed by CT. Focal lesions in the liver were considered measurable. Complete remission required the resolution of symptoms or clinical evidence of lymphoma and no lymph nodes over 1.5 cm on CT scan, and the bone marrow had to be morphologically free of lymphoma. An important contribution was the introduction of a new category termed complete remission (uncertain) which required at least a 75% reduction in tumor masses. A recent update recommended that patients with a complete remission (uncertain) be considered in complete remission if they have a negative FDG-PET scan.[58] Partial remission was defined as at least a 50% reduction in size of tumor masses.

Detection of Minimal Disease

The molecular monitoring of remission can be carried out by using various techniques. The presence of occult lymphoma cells in the blood or bone marrow may have prognostic significance or make a patient a poor candidate for stem cell harvest and autologous transplantation. One sensitive detection method is flow cytometry of the blood or bone marrow for light chain restriction or aberrant phenotype. Another technique involves polymerase chain reaction to detect cells with a specific genetic abnormality or clonal immunoglobulin or T-cell reception rearrangement. A popular test in follicular lymphoma was the detection of cells with *bcl-2* gene rearrangements. In some studies, the presence of t(14;18) in the blood or marrow predicted a poorer treatment outcome.[72,73] Circulating lymphocytes with t(14;18) rearrangements can occasionally be detected in the blood and tonsils of normal individuals.[74] At present, however, detection of minimal residual disease does not have an established clinical role.

PRINCIPLES OF TREATMENT

The fundamental genetic changes that lead to neoplasia involve deregulation of cellular proliferation and death, events that are controlled in large measure by cell cycle checkpoints and by the induction and suppression of apoptosis. Evidence also suggests that abnormalities in these pathways might determine the sensitivity of tumor cells to the cytotoxic effects of irradiation and chemotherapy.[75–77] Clinical strategies that take advantage of the abnormalities that occur in the regulation of the cell cycle and apoptosis are just beginning but have an increasingly important role in the design of therapeutic approaches. The classic principles of chemotherapy, including pharmacology, drug resistance, and tumor cell kinetics, continue to form the foundation of treatment strategies. Understanding these principles provides the basis for good treatment decisions.

Tumor Cell Kinetics

Some 30 years ago, Skipper and associates made several fundamental observations regarding the kinetic features of tumor cell growth and the effect of chemotherapy in an animal model system.[78] From this model, they hypothesized the importance of tumor volume, growth fraction, and the first-order kinetics of chemotherapy cell kill for therapeutic outcome. One of their basic findings was that survival was inversely proportional to the tumor cell inoculum, which follows the known relationship between tumor bulk and outcome in lymphoma. When the outcome of chemotherapy was assessed, the fraction of tumor cells undergoing DNA replication, termed the *growth fraction*, greatly influenced drug sensitivity, a finding that likely reflected the greater sensitivity of tumor cells in the DNA synthetic (S) phase of the cell cycle to many classes of chemotherapeutic agents. As a hypothesis of tumor cell sensitivity, however, the principle of growth fraction was a great oversimplification. Although these concepts have become classic principles of chemotherapy and con-

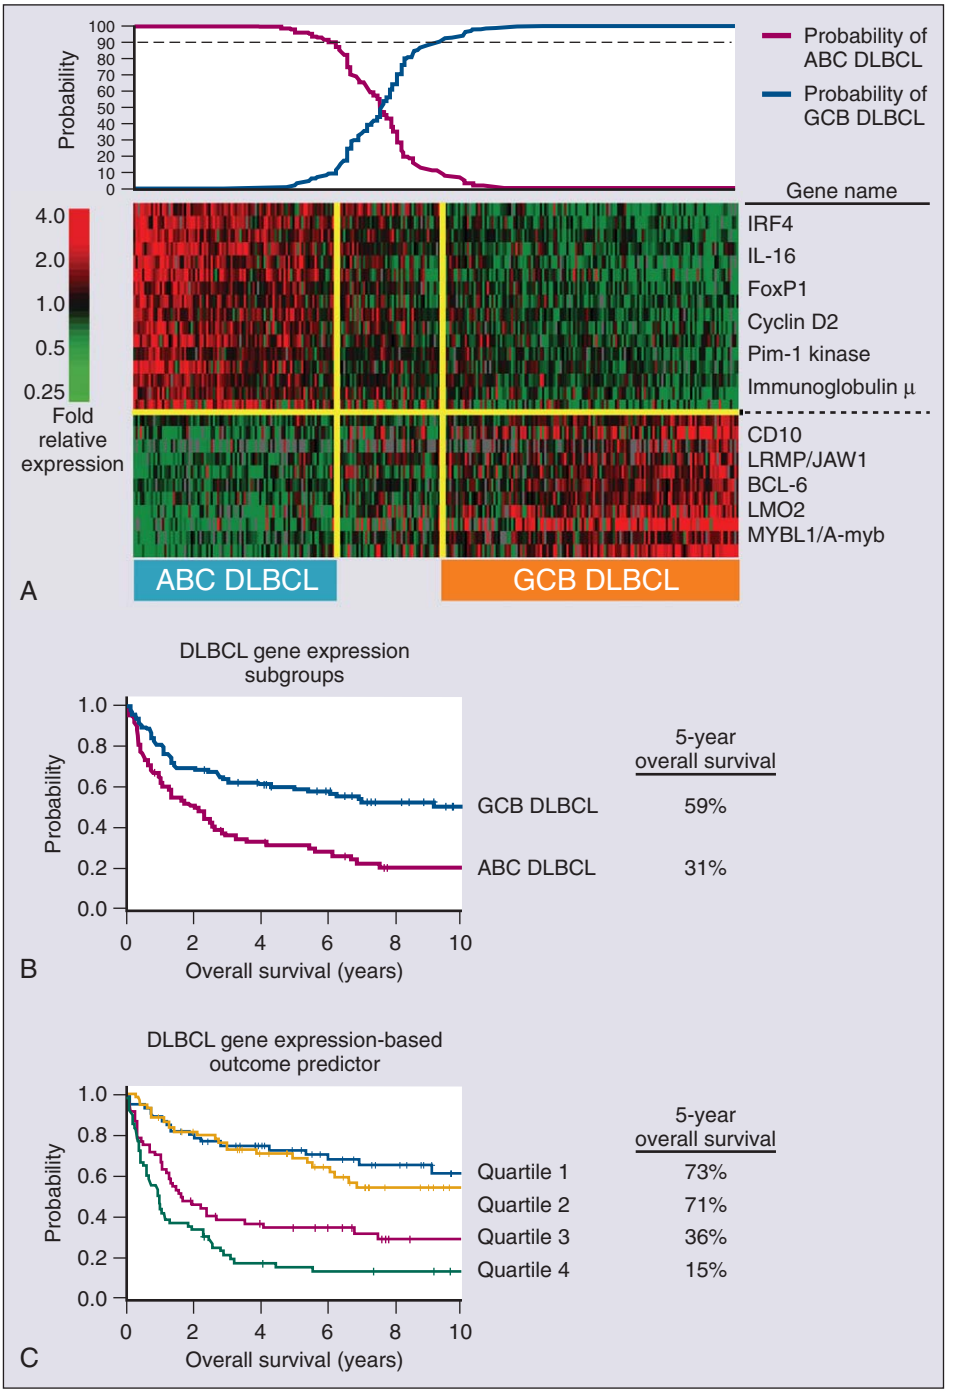

Figure 112-2 • Diagnosis of DLBCL subtypes by gene expression and development of a molecular outcome predictor in previously untreated patients with DLBCL following chemotherapy. **A,** The expression levels of 27 genes from the subgroup predictor in 274 DLBCL samples are shown according to the color scale (*left*). Six named genes that showed increased expression in either the ABC or GCB subgroups are shown at the *right*. The likelihood that a DLBCL sample belongs to the ABC or GCB subgroup is shown on *top*, arranged by probability. **B,** Kaplan-Meier estimates of overall survival according to GCB or ABC DLBCL subtype. **C,** Kaplan-Meier estimates of overall survival according to the molecular outcome predictor for each quartile.

tinue to guide treatment strategies, the clinician should realize that the Skipper model does not capture the heterogeneity of human tumors.

Clinically, tumors are heterogeneous. Tumor masses within the same patient vary, owing to diverse factors such as blood flow, tissue hypoxia, and mutations that determine tumor biology and drug resistance. Moreover, the growth fraction of tumor cells is dynamic, decreasing as tumors grow and increasing as tumor cells are killed by cytoreductive treatment. The growth fraction also does not affect the cytotoxicity of all chemotherapy drugs equally. Although most drugs are more cytotoxic to cells undergoing DNA synthesis, some agents do not show this selectivity. Thus, the growth fraction should be included among the factors that contribute to the sensitivity of tumor cells to therapy but alone is not predictive of a therapeutic response. Low-grade lymphomas are a good example of the limitations of this principle. It has been proposed that the low-growth fraction of indolent lymphomas could explain the incurability of these tumors with chemotherapy. However, most low-grade lymphomas are sensitive to chemotherapy, so tumor growth fraction alone cannot explain the low cure rate.

Skipper and colleagues also observed that the number of tumor cells that are killed by a cycle of chemotherapy depends on first-order kinetics; that is, a given drug dose killed a constant fraction of cells, independent of cell number.[78,79] Of course, the sensitivity of the

tumor to the chemotherapy directly affects the fraction of cells killed, and in practice, this sensitivity changes over multiple courses of chemotherapy. Indeed, the potential of chemotherapy to select resistant cells may lead to decreased fractional cell kill. The fraction of cells that are killed can also be affected by other factors, including tumor perfusion and oxygenation, decreased host resistance to drug side effects, and the proliferation of tumor in sanctuary sites such as the CNS. While the concept of fractional cell kill suggests that surgical resection of tumor, if of sufficient degree, would be beneficial to the therapeutic outcome, it is not clinically useful in most lymphomas.[80]

Another important concept is drug concentration (or dose) and response (or cell kill). For some but not all drugs, a relatively linear relationship exists over a portion of the concentration curve. This applies particularly to alkylating agents. For other drugs (chiefly the antimetabolites) that depend on cell exposure to drug during vulnerable phases of the cell cycle, the duration of exposure might be more important than drug concentration. Clinically, high-dose therapy with stem cell support takes maximal advantage of the drug concentration–response relationship. Alkylating agents and epipodophyllotoxins are the preferred drugs for this approach because of their relatively linear dose response and favorable therapeutic index.[81]

Drug Resistance

Because lymphomas typically present with disseminated disease, chemotherapy is the mainstay of treatment, and drug resistance becomes the primary barrier to cure. In 1979, Goldie and Coldman proposed a drug resistance hypothesis based on the observation that resistance of *Escherichia coli* to infection by bacteriophage occurs through the preferential expansion of bacterial clones that have undergone mutation to a resistant phenotype.[82,83] By extrapolation, Goldie and Coldman predicted that the emergence of drug resistance in human tumors would correlate with the underlying spontaneous mutation rate of specific drug resistance genes. The emergence of resistant cells might be further hastened by the genomic instability associated with tumor cells.[84] Thus, under the selective pressure of chemotherapy, resistant clones would eventually predominate.

The Goldie-Coldman hypothesis provides a rationale for some of the principles that have already been established through empiric observation. In patients with large tumor burdens, there is an increased chance that tumor cells that are resistant to any single cytotoxic drug already exist, providing an explanation for the inverse relationship between tumor cell number and curability and for the greater efficacy of combination chemotherapy compared with single agents. Unfortunately, combination chemotherapy has not been able to overcome resistance in most cases of clinical cancer treatment. It is now clear that the Goldie-Coldman hypothesis is incorrect. Instead, it appears that much of the drug resistance that is observed in vivo is conferred by a high apoptotic threshold, which makes the tumor cells insensitive to multiple agents. In lymphoid malignancies, for example, overexpression of bcl-2, NF κB, and p53, all of which inhibit apoptosis, are associated with drug resistance (see Table 112-4).[47,48,85–88] Evidence also suggests that the cellular apparatus that controls the cell cycle is part of the final common pathways through which cytotoxic agents exert their lethal effects.[76,89,90] If this proves to be correct, deregulation at any number of steps in this pathway could lead to drug resistance. Among the most common oncogene or tumor suppressor gene mutations that are found in lymphoid neoplasms are those that occur in cell cycle control genes, further highlighting the central importance of these pathways.

Apoptosis and Cell Cycle Control

The death of malignant cells may occur by necrosis or by apoptosis.[89] The process of apoptosis can be triggered through multiple pathways, including exposure to cytotoxic agents, the loss of essential growth factors, exposure to negative regulators such as tumor necrosis factor and transforming growth factor-β, and the loss or induction of specific genes such as *c-myc* and *p53*.[89,91,92] Other events suppress apoptosis, such as the addition of growth factors and the induction or suppression of specific genes and viral proteins.[93] Although pathways leading to apoptosis are present in many tumor cells, some of the triggering pathways may be disrupted and absent, and experimental evidence suggests that disruption of these pathways increases the resistance of cancer cells to cytotoxic agents.[94,95]

Apoptosis plays a central role in the normal biology of lymphocytes and in the process of clonal deletion.[96] At least two genes (*bcl-2* and *p53*) that can affect apoptosis have been found to be either abnormal or deregulated in lymphomas.[86,95,97] Translocations of *bcl-2* (t[14;18]) in follicular lymphomas result in elevated levels of the protein product and prolong cell survival by blocking apoptosis.[91,98,99] Although *bcl-2* rearrangements are less frequent in aggressive B-cell lymphomas, they can be increased through amplification or NF-κB.[27,100,101] Viral genes such as EBV LMP-1, which is frequently present in BL, can induce expression of bcl-2 and protect cells from apoptosis. In vitro, cells that express increased bcl-2 are resistant to radiation- and chemotherapy-induced apoptosis. For example, a high level of bcl-2 expression in leukemias correlated with resistance to several apoptosis-inducing cytotoxic agents, including doxorubicin, methotrexate, and cytarabine.[102] At least 20 members of the bcl-2 family have been identified in mammalian species to date and include proteins with antiapoptotic effects such as bcl-2, bcl-X_L, bcl-W, and mcl-1 and others such as Bax, Bad, Bim, Bik, and Noxa, which have proapoptotic properties. The NFκB transcription factor also plays an important role in apoptosis and has been linked to multiple lymphoma types, including DLBCL and SLL.[103,104]

The *p53* tumor suppressor gene plays an important role in apoptosis as well; *p53* controls the cellular responses to DNA damage by arresting cells in G_1 to allow repair of DNA damage; if essential repairs are not possible, p53 may trigger apoptosis.[84] The importance of *p53* mutations in the development of the malignant phenotype is suggested by the presence of *p53* mutations in most types of cancers, including chronic lymphocytic leukemias and lymphomas.[95,105] Mutant *p53* has been detected in tumor biopsy specimens from up to one third of NHLs.[95]

Dose Intensity and Dose Density

Dose intensity, defined as the dose per unit time, has long been considered important for the treatment of lymphomas, although randomized trials comparing dose intensity regimens have had variable results. In one study of 238 patients with untreated aggressive lymphoma who were randomized to receive standard or escalated BACOP (bleomycin, doxorubicin, cyclophosphamide, vincristine, and prednisone) chemotherapy, which had 28% difference in doxorubicin relative dose intensity, there was no difference in outcome.[106] A randomized study of high-dose therapy with autologous stem cell rescue versus CHOP in untreated aggressive lymphoma showed a benefit for the high-dose arm, particularly in high-risk patients.[107] High-dose treatment was also found to be superior in a trial in which patients who were in complete remission with standard therapy were randomized to stop or to receive high-dose consolidation.[108] In contrast, high-dose treatment did not benefit patients with slow responses to CHOP who were randomized to complete CHOP or to undergo high-dose therapy.[109]

In aggressive lymphomas, high tumor proliferation determined by Ki-67 or MIB-1 immunohistochemistry has been shown to be an adverse prognostic finding with CHOP chemotherapy, suggesting that kinetic failure is a problem.[27,110] One strategy to overcome kinetic failure is to increase dose density through frequent chemotherapy administration. This concept was first addressed by MACOP-B, which was administered weekly for 12 weeks. When compared to CHOP in a randomized study, however, MACOP-B had a similar outcome.[111] More recently, the German High Grade Lymphoma Study Group readdressed this concept in a randomized study of

2-weekly versus 3-weekly CHOP with and without etoposide. In this study of 831 patients with aggressive lymphomas older than 60 years, dose dense CHOP-14 was significantly better than CHOP-21, with OS rates of 53.3% and 40.6%, respectively ($P < 0.001$).[112] When the regimens were tested in younger patients, however, dose density was not superior, a finding that lacks an obvious biologic explanation.[113]

Such disparate results appear to challenge the concept of dose intensity, but this conclusion should be interpreted with caution. It is important to recall that dose intensity combines dose rate and dose density, each with a different theoretical benefit. Unfortunately, dose intensity is often misinterpreted as being equivalent to drug exposure. Dose rate, however, is not equivalent to drug exposure because of variable pharmacokinetics, which can result in over tenfold variations in drug area under the curve.[114] Another important variable is dose response, which is dependent on the drug class and the individual tumor cell. Microarray studies in lymphomas clearly illustrate widely variable mechanisms of resistance, which clinically translate into differences in dose response.[85,104] It is not surprising, given these variables and the absence of controls, that studies of dose intensity have been contradictory. Nevertheless, dose-response is an incontrovertible notion that, in the absence of a known optimum dose rate, mandates that a maximum safe dose be administered. Such an approach has been adopted by Wilson and colleagues in the dose-adjusted EPOCH regimen, in which doses are adjusted on the basis of the pharmacodynamics of the administered agents.[114]

CLINICAL MANAGEMENT OF LYMPHOMAS

Optimal care requires an understanding of a patient's unique medical history and physical condition, the patient's disease stage, and, most important, a correct histologic diagnosis. The World Health Organization classification provides a biologic framework for lymphomas, but it is not specifically organized with treatment in mind. Biologically related lymphomas such as those of B-cell origin, however, share features that have treatment implications. Thus, in presenting clinical management, we have organized our discussions around shared biologic and clinical features (Table 112-8); disease types are presented according to mature B-cell origin, precursor B- or T-cell origin, and lymphomas of mature T-cell origin as well as according to clinical aggressiveness and special topics. Two lymphomas of mature T-cell origin—cutaneous T-cell lymphoma/mycosis fungoides and adult T-cell lymphoma/leukemia—will be discussed elsewhere.

Lymphomas of Mature B-Cell Origin

B-cell lymphomas represent approximately 85% to 90% of all non-Hodgkin's lymphomas and can be organized into clinically relevant groups according to their natural history (i.e., indolent versus aggressive). While such clinical groupings provide a framework for management, each case must be considered individually.

Management of Follicular, Small Lymphocytic, and Marginal Zone Lymphoma

Indolent B-cell lymphomas are clinically diverse. Symptomatic patients who do not achieve a durable initial remission will often require intermittent therapy to control clinical signs and symptoms (Table 112-9). There are many effective drug classes that provide disease control, including purine analogs, alkylators, anthracyclines, and rituximab. Furthermore, targeted agents and immunotherapy with idiotype vaccines and allogeneic stem cell transplantation hold promise and are under investigation. Observation is an important option for asymptomatic patients, since early treatment has not been shown to improve survival. Newer approaches, such as early use of monoclonal antibodies and development of patient-specific idiotype vaccines, have changed the natural history of follicular lymphoma, making the decision when to initiate treatment challenging. For the present, treatment of these lymphomas is generally initiated for constitutional symptoms, organ compromise, and/or evidence of rapid tumor growth or bulk during the initial observation period. Symptomatic patients are usually those with bulky disease, diffuse bone marrow infiltration resulting in abnormal blood counts, and threatened organ function.

Follicular Lymphoma

Follicular lymphomas are classified into three grades based on the number of centroblasts per high-power field. Generally, grades 1 and 2 are indolent, whereas grade 3 can be more aggressive. It is now recognized that grade 3 disease is biologically diverse and includes both follicular lymphoma, termed grade 3a, and large B-cell lymphoma, termed grade 3b, which has a follicular growth pattern but is clinically like DLBCL. Unfortunately, the distinction between grades 3a and 3b is difficult.[115] A number of clinical features are associated with outcome of follicular lymphoma (FL). In a study of 4000 patients with FL, age greater than 60 years, Ann Arbor stage III or IV, hemoglobin level less than 12 g/dL, abnormal serum LDH level, and involvement of five or more lymph node areas were adverse prognostic features.[64] Three risk groups were codified into the Follicular Lymphoma International Prognostic Index, which appears to be more discriminating for FL than does the International Prognostic Index that was originally established for aggressive NHL (Fig. 112-3; see Table 112-7).

EARLY-STAGE DISEASE. While most follicular lymphomas present at advanced stage, approximately 15% to 30% are stage I or II. On the basis of older retrospective studies, radiotherapy alone has been the standard of care, with median survival approaching 15 years and up to one third of patients progression free. It is not clear whether these results reflect the benefit of radiotherapy or the indolent natural history of early-stage disease. A relatively recent retrospective analysis of 43 patients with untreated stage I or II FL found that 63% did not require therapy over the median follow-up of 86 months and only 4 patients showed histologic transformation.[116] Furthermore, the 10-year estimated survival rate was 85%. Indeed, an aggressive strategy of combination chemotherapy followed by involved-field radiation therapy in 102 patients with early-stage disease yielded a similar 10-year survival rate of 82%.[117] There were two cases of myelodysplasia and 12 secondary malignancies in this cohort of patients. Although such results raise the question of the benefit from immediate treatment, they were conducted in the pre-rituximab era.[118,119] At present, it is difficult to make firm recommendations regarding treatment. Radiotherapy still remains popular[120] but it can cause significant long-term toxicities depending on the location, field, and dose of radiation. When considering treatment options for early-stage disease, it is important to recognize that there is no clear best option at present and that treatment should be tailored to the individual patient.

ASYMPTOMATIC ADVANCED-STAGE DISEASE. Several randomized trials have compared observation with single-agent or combination chemotherapy in patients with asymptomatic advanced-stage lymphoma. In one randomized study of 104 patients, 44 patients were observed, and 45 received aggressive treatment with ProMace-MOPP chemotherapy and total nodal irradiation; 15 symptomatic patients received immediate treatment.[121] Notably, while complete remission (CR) and disease-free survival were significantly better with immediate treatment, the OS rate was similar at 83% and 84%, respectively, at 4 years median follow-up. Four patients (10%) in the treatment arm developed myelodysplasia. Although the median remission duration exceeded 45 months, which appeared better than that with single-agent alkylators or combination chemotherapy, this study did not prove that early treatment was beneficial. Another randomized study compared observation to oral

chemotherapy in asymptomatic patients with advanced low-grade lymphoma. In this study, 158 patients received chlorambucil 10 mg/day and 151 patients were observed.[122] At a median follow-up of 16 years, the OS was similar at 5.9 and 6.7 years, respectively, and the median cause-specific survival was 9 years in both groups. Approximately 20% of the patients in the observation arm did not require therapy after 10 years follow-up, and 40% of these were at least 70 years old at enrollment. Although these randomized trials support observation, they were performed before the use of rituximab, which has been shown to prolong survival in symptomatic patients.[118] Prospective randomized trials are necessary to readdress the role of observation in the era of rituximab based treatment.

SYMPTOMATIC ADVANCED-STAGE DISEASE. Initial chemotherapy for patients with symptomatic disease should be tailored to the clinical circumstances (see Table 112-9). Patients with high tumor burden and/or threatening symptoms might require more aggressive multiagent regimens, whereas less toxic therapy might be appropriate for patients with slowly progressive disease. Factors such as patient age and condition should be considered as well. Numerous single agents and combination chemotherapy are effective (see Table 112-9). Single-agent chlorambucil or cyclophosphamide with or without prednisone is well tolerated but rarely produces a complete remission. More aggressive regimens produce higher CR rates. In a randomized study of 259 patients with advanced-stage disease, CHOP produced a higher response (60% versus 36%) but similar overall median survival (52 months versus 48 months) compared to oral chlorambucil/prednisone.[123] There is no evidence of a plateau on the survival curve with CHOP treatment in a retrospective review of 415 patients on Southwest Oncology Group trials.[124] In this study, the median survival was 6.9 years.

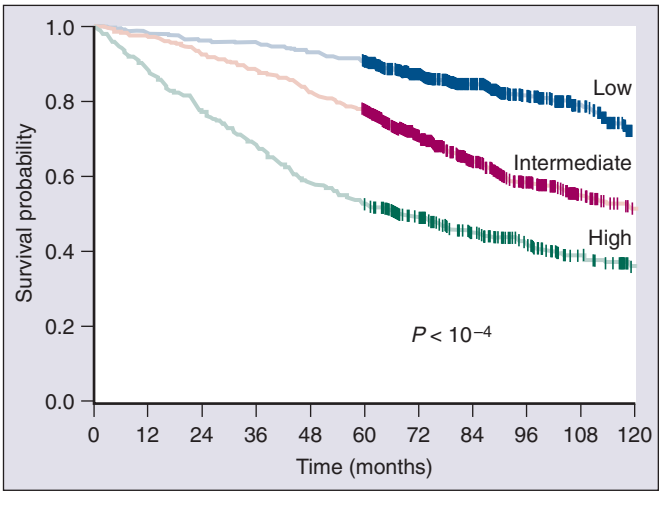

Figure 112-3 • Survival of 1795 patients stratified by Follicular Lymphoma International Prognostic Index. (Data from Solar-Celigny P, Roy P, Colombat P, et al: Follicular Lymphoma International Prognostic Index. Blood 2004;104:1258–1265.)

The most important advance in the treatment of follicular lymphomas over the past 20 years is rituximab. In 41 untreated patients with indolent lymphoma, rituximab yielded an overall response rate of 64%, including a 15% CR rate, and 77% were progression free at 12 months.[125] In another study of untreated patients, molecular remission was associated with particularly durable responses.[126] Rituximab was also tested as a first-line treatment in 62 patients with FL and SLL followed by maintenance therapy every 6 months in patients without progression.[127] Interestingly, the response rate was 47% following induction with an increase to 73% during maintenance, including a 37% CR rate, and the median progression-free survival (PFS) was 34 months. Response rates were similar in follicular lymphoma and SLL. The role of maintenance rituximab was also tested in 202 patients with untreated or relapsed/refractory FL. Treatment involved a 4-week course of rituximab followed by observation or maintenance at 3, 5, 7, and 9 months. The overall response rate was 67% and 46% in untreated and relapsed/refractory patients, respectively, and at the median follow-up of 35 months, the median event-free survival (EFS) was 12 and 23 months for the observation and maintenance groups, respectively.[128] Untreated patients appeared to benefit most from maintenance, the EFS increasing from 19 to 36 months.

The addition of rituximab to chemotherapy has improved response and survival. In the first study of R-CHOP in mostly untreated patients with indolent lymphoma, the overall response rate was 95%, including 55% complete with an 82-month median PFS.[129,130] Hiddemann and colleagues performed a randomized study of CHOP versus R-CHOP in 428 patients with symptomatic advanced-stage FL.[118] Responding patients under 60 years were offered a second randomization following treatment to stem cell transplantation or interferon-α maintenance, whereas older patients received interferon α maintenance. With a median follow-up of 18 months, patients in the R-CHOP arm had a 60% reduction in risk of treatment failure

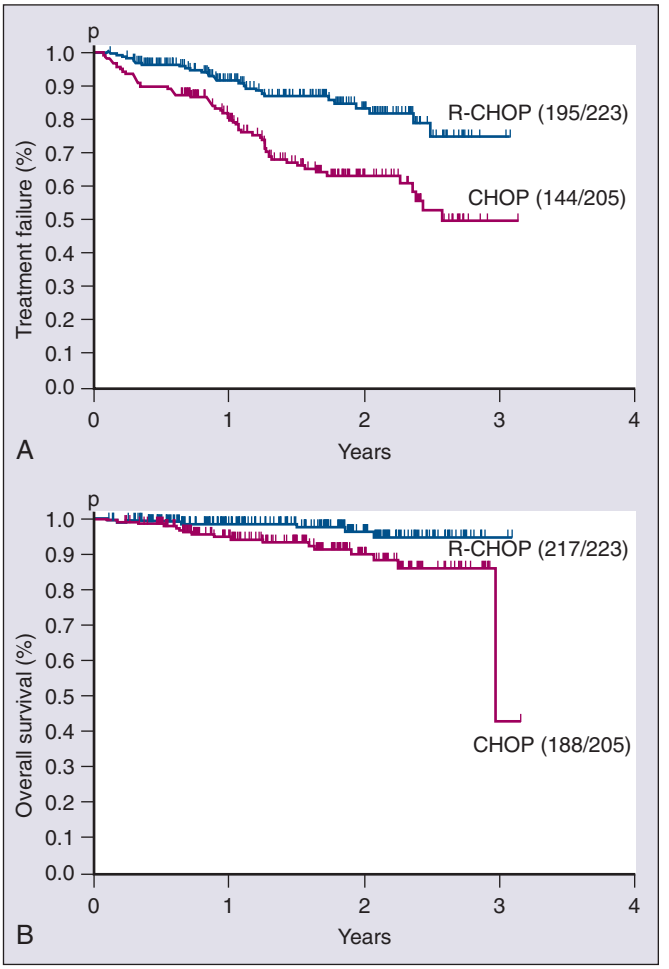

Figure 112-4 • Survival outcomes after CHOP and R-CHOP. **A,** Time to treatment failure after CHOP and R-CHOP ($P < 0.001$). **B,** Overall survival rates after CHOP and R-CHOP ($P = 0.016$). (Data from Hiddemann W, Kneba M, Dreyling M, et al: Frontline therapy with rituximab added to the combination of cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) significantly improves the outcome for patients with advanced-stage follicular lymphoma compared with therapy with CHOP alone: results of prospective randomized study of the German Low-Grade Lymphoma Study Group. Blood 2005;106:3725–3732.)

and a modest albeit significant improvement in OS (Fig. 112-4). It is important to note that the interpretation of this study is confounded by the secondary treatment requirement. In another important randomized study of CVP with or without rituximab, rituximab also significantly improved response, progression, and survival.[131] The role of maintenance was addressed in a randomized study of CVP versus fludarabine/cyclophosphamide (FC) with a second randomization to observation or maintenance rituximab every 6 months for 2 years.[132] Rituximab maintenance was associated with an increase in PFS for 2.5 to 4.5 years. Another randomized study in untreated patients compared fludarabine/mitoxantrone (FM) and CHOP followed by rituximab in patients who did not achieve molecular remission.[133] Although the overall response rate was almost 100% in both arms, the complete responses were greater in patients who received FM (68%) compared to CHOP (42%). Following rituximab treatment, however, the two arms had similar CR rates of 90% and 81%, respectively. Interestingly, the duration of complete remissions following chemotherapy alone or chemotherapy and rituximab were similar, suggesting that rituximab might help to overcome chemotherapy resistance. These trials clearly indicate that rituximab significantly improves the efficacy of chemotherapy and OS.

There is much interest in the mechanism of action and biomarkers of response with rituximab. On the basis of the mechanism of antibody binding, a study investigated and found an association between immunoglobulin-G fragment-C receptor polymorphisms and rituximab response.[134] Polymorphisms structurally affect the affinity of the Fc receptor binding, which is required for antibody-dependent cellular cytotoxicity. Specifically, the valine/valine polymorphism in FCγ receptor 3A (15% of patients) and the histidine/histidine polymorphism in FCγ receptor 2A (25% of patients) were independently associated with response and progression following rituximab.

Other immune strategies that have shown promise include interferon-α and idiotype vaccine. The benefit of interferon-α has been controversial; only some studies show a survival advantage, which is likely due to testing of variable schedules and doses and only modest activity.[135,136] Nevertheless, owing to the efficacy and low toxicity of rituximab, interferon-α is infrequently used in the United States. Idiotype vaccines represent another strategy, much of the initial excitement coming from a small study in which idiotype vaccine induced durable molecular remissions following first clinical remission.[137] Other studies have also shown regression of FL following idiotype vaccines.[138] On the basis of these promising results, two large randomized studies of idiotype vaccine have been conducted, and results should soon be available.

TREATMENT OF RELAPSED DISEASE. Relapsed patients can be successfully retreated with many of the same strategies that were employed for initial treatment. Importantly, patients who show benefit from a prior treatment can be retreated with same agents, although alternative combinations may be selected.[139] There are multiple active regimens for relapsed patients.[140,141] In a phase II trial of 51 patients with relapsed or refractory low-grade lymphoma, the overall and complete response rates were 94% and 47%, respectively, with a 14-month median failure-free survival.[141] Rituximab has been extensively investigated in relapsed indolent lymphoma (see Table 112-9). In a study of 166 patients who were treated with rituximab 375 mg/m^2 weekly for four doses, 48% responded with a 13-month median time to progression.[142] In another study of eight weekly rituximab infusions, 57% responded, and the median time to progression had not been reached at 19.4 months' median follow-up, suggesting more rituximab doses might be more effective.[143] Rituximab has also been studied in retreatment after prior rituximab.[144] While the overall response rate of 40% was similar to that of the first rituximab course, the responders had a longer median time to progression of over 18 months.

Anti-CD20 antibody therapy has also been used for targeted delivery of iodine-131 and yttrium-90 to the tumor. These drugs are now commercially available in the form of iodine-131 tositumomab (Bexxar) and yttrium-90 ibritumomab tiuxetan (Zevalin). Iodine-131 tositumomab was tested in 60 patients with low-grade or transformed B-cell NHL and showed a response rate of 65% and a median response duration of 6.5 months.[145] The 22% of patients who achieved complete remission had a response duration of over 47 months, indicating major treatment benefit. Secondary myelodysplasia is a concern with radiotherapy, particularly in heavily pretreated patients, and was observed in four patients from this study. Other studies have demonstrated equivalent response rates in relapsed and transformed lymphoma.[146] Ibritumomab tiuxetan has been assessed in rituximab failures as defined by no response or progression within 6 months.[147] Among 54 patients with FL, overall and complete responses were observed in 74% and 15% of patients, respectively, and the median PFS was 6.8 months. Ibritumomab tiuxetan was also tested in a randomized controlled trial in patients with relapse or refractory or transformed FL.[147] Compared to rituximab alone, ibritumomab tiuxetan had a higher overall response rate, 80% versus 56%, and a complete response rate of 30% versus 16%, respectively, but a similar response duration and time to progression. The role of radioimmunotherapy is currently

limited to relapsed patients with limited bone marrow involvement but it is under investigation with immunochemotherapy for initial treatment.

High-dose therapy with autologous hematopoietic stem cell support for indolent lymphoma has been tested as consolidation in first response, relapse, and transformation.[148–157] Patients who undergo transplantation early in their disease course have the best outcome. In approximately 250 patients undergoing autotransplantation in first partial response or second complete response at St. Bartholomew's Hospital in London and the University of Nebraska Medical Center, the 10-year PFS rate was approximately 45%. In one study of 92 patients with untreated advanced FL in which 87% underwent high-dose chemotherapy and transplantation, 84% and 67%, respectively, were alive and disease-free at 4 years.[154] The Groupe d'Étude des Lymphomes de l'Adulte (GELA) study group presented preliminary results of chemotherapy followed by interferon compared to chemotherapy followed by high-dose therapy and autologous stem cell transplantation (ASCT) in untreated FL with high tumor burden.[158] With a median follow-up of 56 months, patients who underwent transplant had a statistically higher OS rate of 86% compared to 74% in the interferon arm at 7 years. However, there was no difference in EFS between the two arms.

There have been multiple studies of autologous transplantation in relapsed and transformed indolent lymphomas.[148,156] One large study reported a 42% disease-free rate and a 66% OS rate at 8 years after antibody-purged autologous bone marrow transplantation, the better outcomes being found in patients who were successfully purged.[148] It is important to recognize, however, that successful purging is likely a surrogate marker for lower disease burden and/or sensitive disease and might not be therapeutic.[148] Autologous transplantation is particularly appealing in transformed indolent lymphomas, in which high-dose treatment may be needed to eradicate the transformed clone. Once transformation occurs, prognosis is generally poor, with median survivals of 6 to 18 months; however, not all patients' diseases behave aggressively. Data from European Bone Marrow Transplant Registry in 50 transformed patients revealed a 5-year OS rate of 51% and a PFS rate of and 30%, which were similar to those of a cohort of patients transplanted for indolent or de novo aggressive lymphoma.[156] Overall, these results indicate that autologous transplantation is relatively safe and active in follicular lymphomas.

Several groups have investigated allogeneic transplantation in the hope that graft-versus-lymphoma effect may eradicate residual disease. Results of allogeneic transplant in 10 patients with refractory indolent lymphoma were encouraging, with only one progression after 6 years' median follow-up.[159] Furthermore, a larger series of 113 patients with advanced indolent lymphoma from the International Bone Marrow Transplant Registry reported an overall and disease-free survival rate of 49% at 3 years with only 16% recurrences. These survival curves appeared to plateau, relapses being uncommon after 2 years. However, these promising findings must be considered within the context of the 40% treatment-related mortality.[142] To help ameliorate such toxicity, investigators have turned to reduce intensity stem cell transplants. This approach was tested in 20 patients with indolent and aggressive lymphoma, all of whom had chemotherapy-sensitive or stable disease and had failed prior autologous transplantation.[160] Engraftment was successful in all patients, and with 25 months of median follow-up, the estimated 3-year PFS rate was 95%. Matched unrelated donor bone marrow transplantation has also been explored.[161] Although unrelated donor bone marrow is usually more toxic, the Japanese Marrow Donor Program reported an OS rate of 50% at 3 years with 33% treatment-related mortality in 124 patients. Acute graft-versus-host disease was associated with lower disease progression but more toxicity. While the results of such studies are provocative, larger clinical trials with longer follow-up and randomized study designs are needed to establish the role of allogeneic transplantation in the treatment of indolent lymphomas.

Small Lymphocytic Lymphoma B-Cell Chronic Lymphocytic Leukemia

The same principles of management are applied to these subtypes of lymphoma as to follicular lymphoma, therapy being recommended only if it is clinically indicated. Because the patient population is generally older and more likely to have comorbid problems, there has to date been less enthusiasm for aggressive intervention.[162–166] Unfortunately, this philosophy has been reinforced by the failure of most recent attempts to improve the situation.

As with CLL (see Chapter 108), purine analogs (i.e., fludarabine, cladribine, and pentostatin) alone and in combination have held the greatest promise in terms of new chemotherapy for SLL/B-CLL and the lymphoplasmacytoid lymphomas. The efficacy of fludarabine alone (and cladribine) in previously treated B-CLL inevitably extended interest further, with response rates between 30% and 50%.[167–172]

Several studies investigating combinations of fludarabine with cyclophosphamide[173] or with mitoxantrone and high doses of dexamethasone[174] have been encouraging, although substantial toxicity has been seen. The combination of fludarabine with cyclophosphamide and rituximab has yielded a high proportion of complete remissions, previously a rare outcome in this disease.[175]

The relative seniority of many of the patients as well as the incompleteness of clearance of bone marrow infiltration makes high-dose therapy with hematopoietic stem cell support inappropriate for the majority. Hence, the data about it are sparse and refer to highly selected patients. The declining mortality of the procedure, however, coupled with some encouraging early results certainly warrant further investigation. For younger patients with a human leukocyte antigen–matched sibling, allogeneic transplantation with low-dose conditioning is finding increasing popularity within the research setting.[176–178] It will become clear when larger numbers of patients have been treated how relevant this will be. Monoclonal antibody therapy with rituximab has been evaluated in a single open phase II study in Europe with less impressive results than have been achieved in follicular lymphoma, the response being less than one third in patients with lymphoplasmacytoid lymphoma and less than one fifth in those with SLL (specifically not CLL).[179] Studies that are in progress will elucidate whether the alternative antibody alemtuzumab directed at CD52 is any better.[180,181] Monoclonal antibodies targeted with radionuclide have not really been investigated in this disease because of the large bone marrow involvement.

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphomas are generally treated like other advanced-stage indolent lymphomas. When these lymphomas present with a significant immunoglobulin M paraprotein and bone marrow disease, they are also known as Waldenström's macroglobulinemia and may present with splenomegaly. In Waldenström's macroglobulinemia, the clinical picture may be dominated by symptoms of hyperviscosity (e.g., dizziness, tiredness, and a propensity for bleeding from the mucous membranes) as well as symptoms due to cryoglobulinemia and cold agglutinin anemia.[182] In addition, some patients develop peripheral neuropathy, renal disease, and amyloidosis. Patients with acute symptoms from hyperviscosity might require emergency plasmapheresis. Alkylating agents, purine analogs, and rituximab are quite effective in this disorder.[182]

Extranodal Marginal Zone Lymphoma

While the treatment of most MALT lymphomas is similar to that of other indolent lymphomas, localized gastric MALT lymphoma is unique because of its association with *H. pylori*. In many cases, the MALT clone is indirectly dependent on *H. pylori* and resolves with appropriate antibiotic treatment. Approximately 70% of cases of stage I E-gastric MALT regress following eradication of *H. pylori* with antibiotics.[183] However, the presence of t(11;18) in the tumor cells predicts a poor response to antibiotic therapy.[184] Patients with

localized disease and persistent lymphoma despite antibiotics can be effectively treated with rituximab, chemotherapy, and/or radiotherapy, depending on the clinical circumstances. Durable complete remissions are typical with radiotherapy. Rituximab is active in gastric MALT lymphomas, with overall responses in 64% and complete responses in 29% of patients.[185]

Nodal Marginal Zone B-Cell Lymphoma

This is a rare disease, mainly of older women. Most patients present with lymphadenopathy, often in the neck.[186] Histologically, these tumors are considered to be the lymphomatous counterpart of monocytoid B-cells, but typical monocytoid B-cells might be absent. The latter are reactive cells that are described in association with infections (e.g., toxoplasmosis) and sometimes in the context of other subtypes of NHLs and Hodgkin's disease.

The relationship with MALT lymphomas is complex. As was mentioned previously, they may occur in the context of a MALT lymphoma (e.g., lymph node involvement secondary to a gastric or parotid MALT lymphoma).[187] They may occur in the absence of extranodal disease and are often more aggressive than MALT lymphoma. The immunophenotype is characteristically indistinguishable from that of MALT lymphomas.[188]

There is little consensus about treatment, management being dictated by the site that is involved and the age of the patient. In general, however, the principles of therapy that were described for follicular lymphomas can be applied.

Splenic Marginal Zone Lymphoma

Splenic lymphoma with villous lymphocytes represents another special lymphoma that presents with splenomegaly and B-cells with villous projections in the blood. In these cases, it is hypothesized that the tumor cells originate from the marginal zone of the spleen. In patients with chronic hepatitis C infection, treatment of the hepatitis with interferon-α alone or in combination with the antiviral agent ribavirin was associated with regression of disease in seven of nine patients.[189] Hepatitis C virus–negative patients did not respond to this therapy. Historically, splenectomy was often required to establish the diagnosis, and prolonged responses are often observed, but rituximab is highly effective and should also be considered before splenectomy.[190,191]

Management of Diffuse Large B-cell, Burkitt's, and Mantle Cell Lymphoma

As a group, DLBCL, BL, and MCL. have widely variable natural histories but are usually rapidly progressive and, with the exception of MCL, are quite curable. MCL has a unique natural history that lies between those of indolent and aggressive B-cell lymphomas. It is infrequently curable, and a quarter of cases are low grade, whereas the remaining cases are relatively aggressive.[67] The curative nature of DLBCL and BL set them apart from other lymphomas and requires prompt evaluation and proper therapy. Unlike the more indolent lymphomas, for which treatment strategies are similar, refinements in the management of aggressive lymphomas have led to subtype-specific strategies. As such, the treatment of aggressive B-cell lymphomas is presented for each lymphoma subtype.

Diffuse Large B-Cell Lymphoma

DLBCL is a disease of older adults, with a median presentation in the seventh decade, but it also affects young adults and children.[23] Patients may present with localized or disseminated disease and with nodal or extranodal involvement. Within DLBCL, there are several morphologic variants, including centroblastic, immunoblastic, T-cell rich/histiocyte rich, and anaplastic subtypes, and progress in molecular profiling is further advancing this taxonomy.[20,27] There are also several clinical-pathologic variants of DLBCL. PMBL represents one such variant that more commonly presents in young women and usually remains localized to the mediastinum. It is important to recognize that DLBCL can also arise as a result of histologic transformation from an indolent lymphoma. Though this differentiation might not affect treatment choice initially, it will affect prognosis and natural history and therefore needs to be recognized at diagnosis.

The mainstay of treatment for DLBCL is systemic chemotherapy; radiation treatment alone is inadequate and associated with high recurrence rates.[192] For early-stage disease, whether or not radiation treatment adds benefit to chemotherapy has been controversial. On the basis of a randomized study that showed a survival advantage of limited-course CHOP plus involved field radiation compared to full-course CHOP in early-stage (I/II) aggressive lymphoma, combined-modality therapy became the standard.[193] However, longer patient follow-up showed a convergence of the OS curves due to late systemic relapses in the combined-modality arm, thus reopening the debate on radiation.[120,194] In this regard, a recent prospective GELA study randomized 576 elderly patients with favorable early-stage aggressive lymphoma to receive CHOP alone (four cycles) or CHOP plus radiation and found that combined-modality therapy was not superior to chemotherapy alone.[194] Given these results and the improved outcome of CHOP with rituximab (R-CHOP), the necessity of including radiotherapy in management is not certain.

A possible exception to the omission of radiation, however, is in the treatment of PMBL, depending on the chemotherapy regimen. In a study of 50 untreated patients with PMBL who received MACOP-B followed by radiation, 66% had persistently positive gallium scans after chemotherapy, suggesting active disease. Following consolidation radiotherapy, however, only 19% of patients had a positive gallium scan, and 80% were event free at 39 months' median follow-up.[195] This important study suggested that radiotherapy was necessary following chemotherapy. Furthermore, there is historical evidence that dose-intense regimens such as MACOP-B or VACOP-B are superior to CHOP for PMBL, raising yet another question about the optimal chemotherapy for this disease.[196–198] Recent results with the pharmacodynamically dose-adjusted regimen of doxorubicin, vincristine, and etoposide infused over 96 hours with bolus intravenous cyclophosphamide, rituximab, and oral prednisone (DA-EPOCH-R) may be challenging the need for radiation in PMBL.[199,200] In a phase II study of DA-EPOCH-R in 26 patients with PMBL, 100% and 91% are alive and event free, respectively, at a median 4.2-year follow-up, and only 2 patients required radiation treatment.[201] These results suggest that DA-EPOCH-R obviates the need for radiation in most patients with PMBL, thus eliminating the risk of long-term toxicities such as secondary malignancies and heart disease. This is particularly important given that patients who are afflicted with PMBL are typically young and often women and are at increased risk of breast and other cancers as well as late-term toxicities. Of course, it is possible that patients who receive R-CHOP might not also require radiation therapy, but this question needs to be carefully studied.

Systemic treatment is required for advanced DLBCL (Table 112-10). The CHOP regimen was developed some 30 years ago and was established as the standard by a randomized trial that showed that CHOP was equal in effectiveness to three other common albeit more complex and/or toxic regimens.[111] The fact that only 44% of patients achieved complete remissions with CHOP, however, left significant room for improvement and spawned multiple studies aimed at improving treatment outcome.[111,202] Many of these studies have focused on modifications to the CHOP platform. A GELA study compared doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone (ACVBP) to CHOP in elderly patients with aggressive lymphoma and showed a superior 5-year EFS rate of 39% and an OS rate of 46% compared to 29% and 38%, respectively, for CHOP (Fig. 112-5).[203] Much of the benefit in the ACVBP arm, however, was due to a lower incidence of CNS progression, which could be attributed to the use of CNS prophylaxis with ACVBP. Furthermore, a previous study of ACVBP in low-IPI patients showed

Table 112-10 Treatment Outcome in Untreated Diffuse Large B-cell Lymphoma

Study	Therapy	Patient Group	Event-Free Survival	Overall Survival	Reference
Phase III	R-CHOP	Age ≥60 years	47% at 5 years	58% at 5 years	Coiffier et al;[210] Feugier et al[211]
R-CHOP versus CHOP	GELA	All IPI

CHOP-14, CHOP-21, CHOEP-14, CHOEP-21					
Phase III	CHOP-14	Age 61–75 years	44% at 5 years	53.3% at 5 years	Pfreundschuh et al[205]
Four arms	DSHNHL	All IPI			
CHOP-14, CHOP-21, CHOEP-14, CHOEP-21					
Phase III	R-CHOP-14 (×6)	Age ≥60 years	66% at 3 years	78% at 3 years	Pfreundschuh et al[213]
Four arms	DSHNHL	All IPI			
R-CHOP-14 × 8, R-CHOP-14 × 6, R-CHOP-21 × 8, R-CHOP-21 × 6					

R-CHOP: rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone.
*CHOP-like regimens included CHOP, CHOEP, MACOP-B, and PmitCEBO.

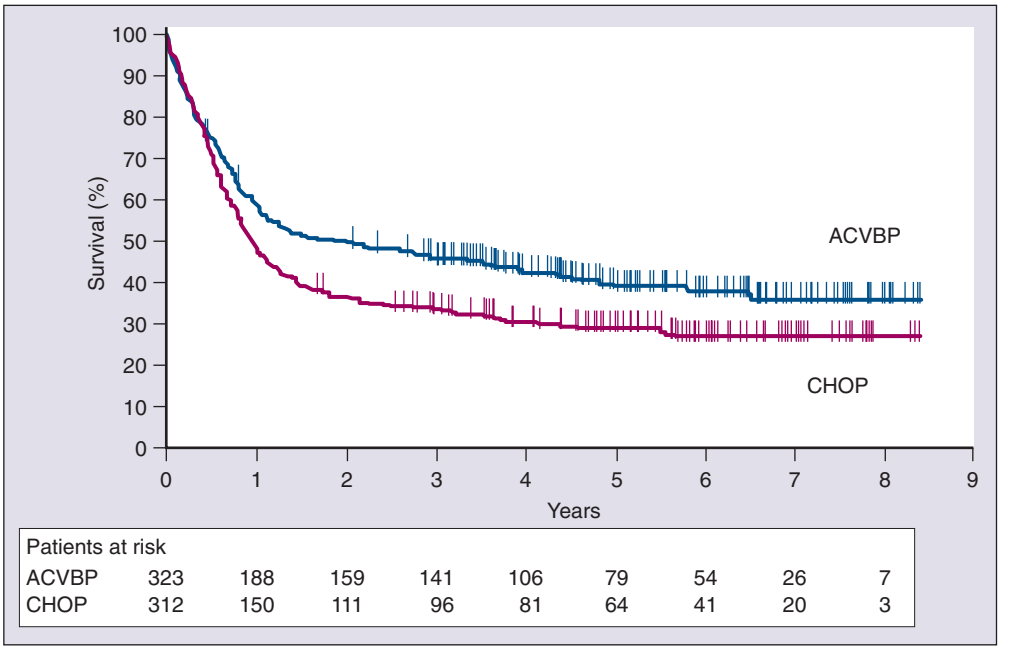

Figure 112-5 • Event-free survival rates of ACVBP versus CHOP in aggressive lymphomas ($P = 0.005$). (Data from Tilly H, Lepage E, Coiffier B, et al: Intensive conventional chemotherapy (ACVBP regimen) compared with standard CHOP for poor-prognosis aggressive non-Hodgkin lymphoma. Blood 2003;102:4284–4289.)

no benefit over m-BACOD, which was shown to be equivalent to CHOP.[204]

In aggressive lymphomas, high tumor proliferation determined by Ki-67 or MIB-1 immunohistochemistry has been shown to be an adverse prognostic finding with CHOP chemotherapy, suggesting that kinetic failure is a problem.[27,110] One strategy to overcome kinetic failure is to increase dose density through frequent chemotherapy administration. The Deutsche Studiengruppe für Hochmaligne Non-Hodgkin Lymphome evaluated the effect of dose density and etoposide in two four-arm studies of CHOP administered every 14 or 21 days, with or without etoposide (CHOEP), in patients older than 60 years and low-risk patients 60 years of age or younger.[205,206] In younger patients, CHOEP-21 showed the best overall results with a CR rate of 88% versus 79% and an EFS rate of 69% versus 58% at 5 years compared to standard CHOP-21, respectively.[206] In older patients, however, dose-dense CHOP-14 showed the best outcome, with a CR rate of 76% versus 60% and an EFS rate of 44% versus 33% at 5 years compared to standard CHOP-21.[205] While these studies provided the best evidence that outcome could be improved through specific changes to the CHOP chemotherapy platform, it remains unclear why the optimal treatment differed in the studies, given the continuum in disease biology across age.[27] The question of whether dose intensity or the addition of etoposide can improve outcome has been and continues to be addressed in various other studies.[207,208]

An alternative strategy to dose density is to increase the fractional cell kill or efficacy of chemotherapy, thereby reducing the number of tumor cells that can survive and proliferate between cycles. Longer drug exposure may take advantage of the increased sensitivity of cycling cells, and in vitro studies have shown that prolonged low-concentration exposure to vincristine and doxorubicin, compared with brief higher-concentration exposure, can increase cytotoxicity by up to 1 log.[209] This approach was translated into the pharmacodynamically dose-adjusted DA-EPOCH regimen, which showed promising PFS and OS rates of 70% and 73%, respectively, at 5 years' median follow-up in newly diagnosed DLBCL.[199] Interestingly, high tumor proliferation was not found to be an adverse biomarker in this study.[199]

It has been the development of rituximab that has made the single greatest impact on the treatment of DLBCL since CHOP was first introduced over 30 years ago. The first study to show the benefit of rituximab was performed by GELA, in which patients over 60 years of age were randomized to receive CHOP or CHOP with rituximab (R-CHOP).[210] In this study, the CR rate (76% versus 63%) and 5-year EFS rate (47% versus 29%) were higher with R-CHOP than with CHOP, respectively, making R-CHOP the de facto standard in DLBCL (Fig. 112-6).[210,211] The benefit of rituximab was later confirmed by the U.S. Intergroup study in a similar patient population.[212]

With the benefit of rituximab established, investigators have gone on to explore its use in a variety of clinical settings and treatment

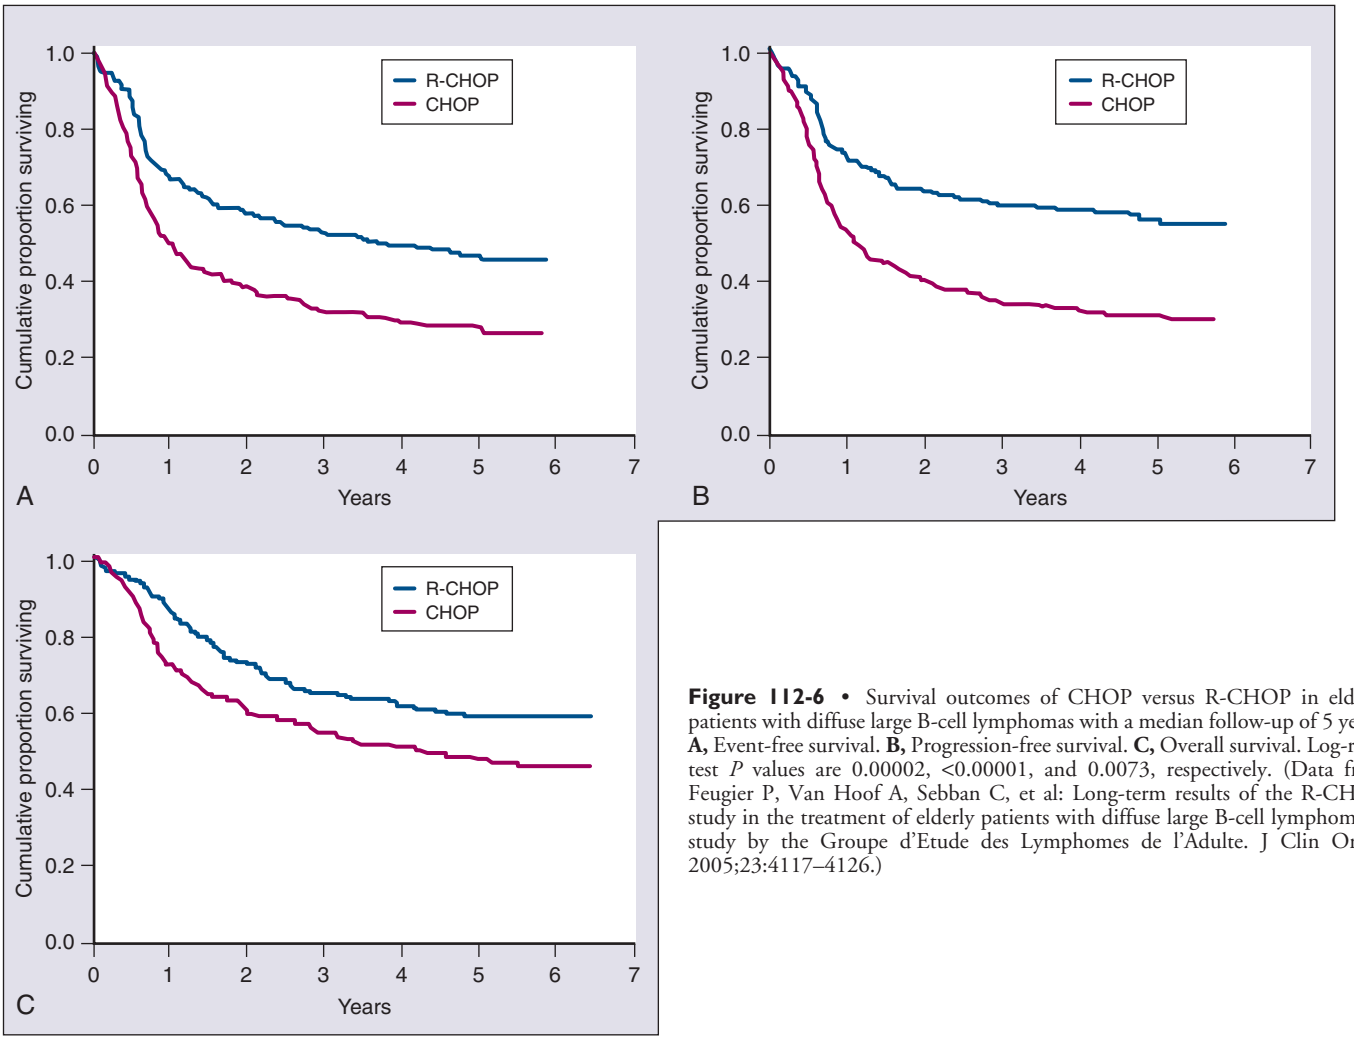

Figure 112-6 • Survival outcomes of CHOP versus R-CHOP in elderly patients with diffuse large B-cell lymphomas with a median follow-up of 5 years. **A,** Event-free survival. **B,** Progression-free survival. **C,** Overall survival. Log-rank test *P* values are 0.00002, <0.00001, and 0.0073, respectively. (Data from Feugier P, Van Hoof A, Sebban C, et al: Long-term results of the R-CHOP study in the treatment of elderly patients with diffuse large B-cell lymphoma: a study by the Groupe d'Etude des Lymphomes de l'Adulte. J Clin Oncol 2005;23:4117–4126.)

strategies. The Deutsche Studiengruppe für Hochmaligne Non-Hodgkin Lymphome explored the question of whether there was a difference in outcome between six and eight cycles of treatment in a randomized study of six versus eight cycles of CHOP-14, with or without rituximab, in elderly patients with DLBCL. In that study, termed the RECOVER-60 trial, they found no difference in outcome with six versus eight cycles of treatment.[213] Although they showed an excellent 3-year EFS rate of 66% with R-CHOP-14 over six cycles, which is somewhat better than the GELA and U.S. Intergroup study results, one cannot conclude that R-CHOP-14 is superior to standard R-CHOP-21, given all the caveats of interstudy comparisons. The MabThera International Trial studied the benefit of rituximab with CHOP-based treatment in younger patients (≤60 years) with favorable characteristics defined as low IPI risk; furthermore, nearly half of patients received involved field radiotherapy.[214] Similarly to the other randomized rituximab studies, patients who received rituximab fared significantly better with a 3-year EFS rate of 79%. As an interesting aside, the MabThera International Trial study also showed that rituximab obviated the benefit of CHOEP in younger patients.[214]

Rituximab has also been tested in combination with the DA-EPOCH regimen.[215] In a recent report of 72 patients, 82% and 79% of patients were progression free and alive, respectively, at the median follow-up of 43 months. Furthermore, 93% and 64% of patients in the low and high IPI risk groups, respectively, had not progressed. While one must be cautious in interpreting preliminary results, it should be noted that these findings are consistent with a recent phase II trial of DA-EPOCH-R in which 91% and 45% of patients with high-intermediate and high IPI, respectively, were event free at 2 years.[216] Evaluation of DA-EPOCH-R versus R-CHOP in untreated DLBCL is currently ongoing in the Cancer and Leukemia Group B Cooperative Group in conjunction with microarray analysis.

While it is clear that rituximab has significantly improved the overall outcome of DLBCL, several studies suggest that its benefit is limited by tumor pathobiology.[217–219] Two studies found that rituximab's benefit was primarily in bcl-2-positive DLBCL, while another study showed that benefit was limited to bcl-6-negative DLBCL (Fig. 112-7).[217–219] These biomarkers likely relate to the new molecular taxonomy of DLBCL defined by gene profiling and suggest that rituximab might primarily benefit tumors that are derived from a postgerminal center B cell.[27,66,220] It appears that patients with both the germinal center B and activated B genetic subtypes benefit from rituximab.[221] At this point, though, it is not possible to accurately identify who will most benefit from rituximab, and further progress is critical to help identify new strategies and molecular targets for patients who do not benefit from rituximab.

The role of high-dose chemotherapy and ASCT in the initial treatment of DLBCL remains controversial.[71,222] Although some studies have suggested benefit, they were performed in the pre-rituximab era.[107] ASCT is also associated with late toxicities,

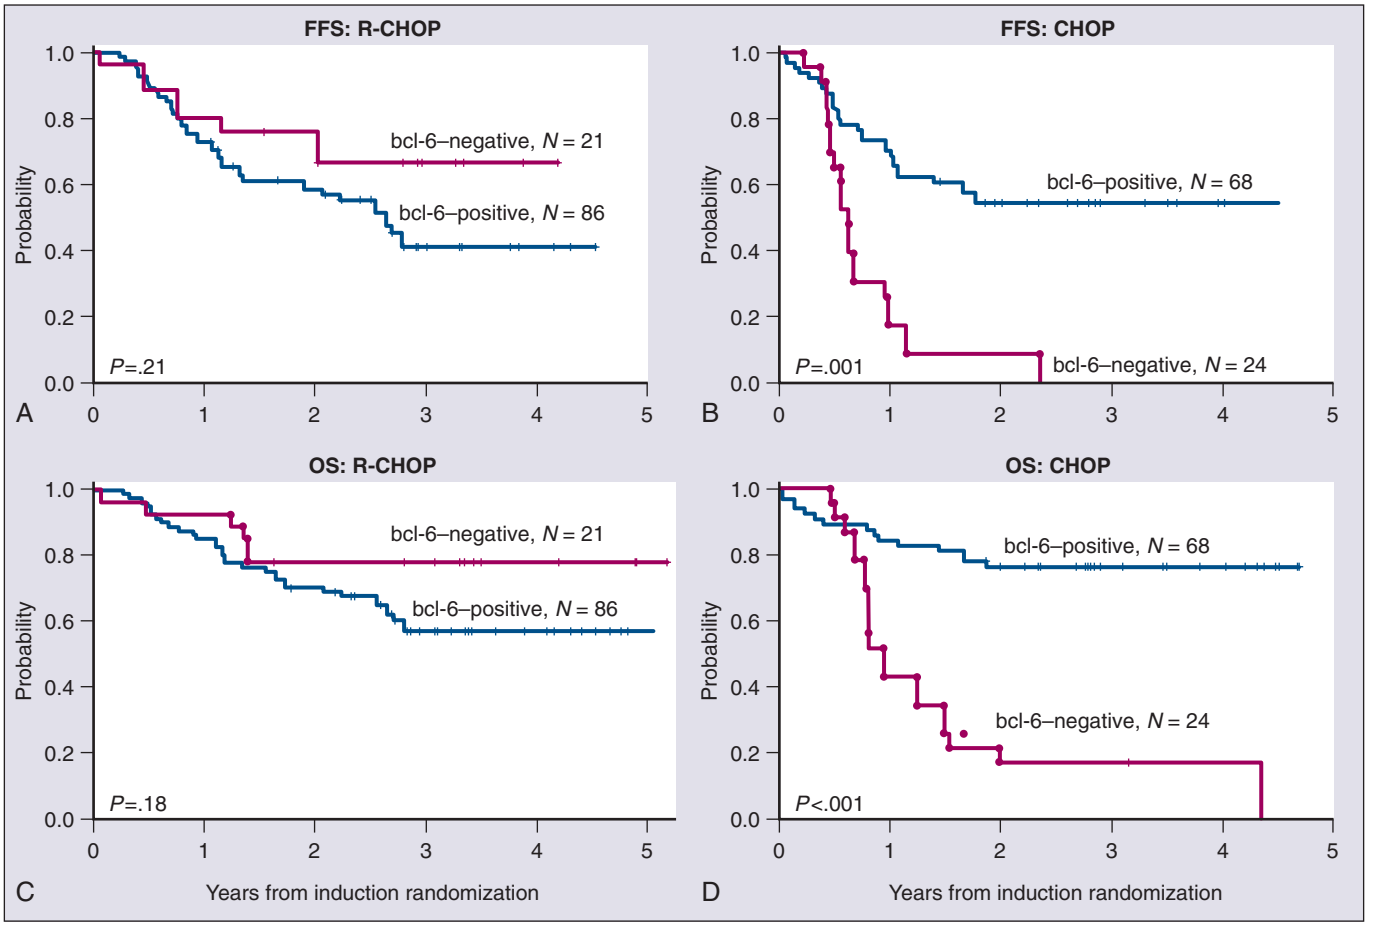

Figure 112-7 • Failure-free survival (FFS) and overall survival (OS) probabilities of R-CHOP versus CHOP according to bcl-6 expression in elderly patients with diffuse large B-cell lymphoma. **A,** FFS of R-CHOP. **B,** FFS of CHOP. **C,** OS of R-CHOP. **D,** OS of CHOP. Significantly longer FFS (54% versus 9%, $P < 0.001$) and OS (77% versus 17%, $P < 0.001$) were observed for bcl-6-positive patients who received CHOP, whereas neither FFS (58% versus 76%, $P = 0.2$) nor OS (71% versus 79%, $P = 0.2$) was influenced by bcl-6 status in patients who received R-CHOP. (Data from Winter JN, Weller EA, Horning SJ, et al: Prognostic significance of Bcl-6 protein expression in DLBCL treated with CHOP or R-CHOP: a prospective correlative study. Blood 2006;107:4207–4213.)

including leukemia and secondary myelodysplasia, which must be considered in the risk benefit of treatment.[223]

Primary Central Nervous System Lymphoma

Primary central nervous system lymphoma (PCNSL) is a rare and highly aggressive lymphoma that is confined to the CNS and is usually of diffuse large B-cell histology. Its unique radiographic findings present challenges in evaluation that have been recently addressed in a report of an international workshop to standardize criteria for baseline evaluation and response.[224] The incidence of PCNSL is particularly high in the setting of HIV infection, in which it often presents with multifocal disease and is virtually always associated with EBV. In contrast, PCNSL in HIV-negative patients often presents with solitary intracranial masses and is rarely associated with EBV.

Treatment of PCNSL differs from that of systemic DLBCL because many chemotherapy agents do not adequately penetrate the blood-brain barrier. Radiotherapy has been a mainstay of treatment because it is effective and sidesteps the limitations of chemotherapy, but responses are usually short-lived, and virtually all patients relapse. High-dose methotrexate on the other hand is a cytotoxic with good CNS penetration, but when used alone, PFS is a relatively short 7 months.[225] A logical step was to combine high-dose methotrexate followed by whole-brain radiotherapy and produced an impressive 82% to 88% CR and median PFS rates of 32 to 40 months.[225–227] Unfortunately, such combined-modality treatment is associated with severe long-term neurotoxicity.[225,228] For this reason, there has been much interest in developing regimens that obviate or defer the need for radiation until relapse. Most promising in this regard are combinations of high-dose methotrexate with systemic agents that cross the blood-brain barrier, such as cytarabine, vincristine, and ifosfamide, particularly in patients under 60 years of age.[228] The Bonn group and others have adopted such an approach and have reported promising results with chemotherapy and deferred radiation in younger patients.[229,230] These results require further validation in trials. Studies are also addressing the role of immunochemotherapy with rituximab and other novel agents that promise to further improve the outcome of PCNSL.[231]

Burkitt's Lymphoma

BL mostly occurs in the first two decades of life and accounts for some 2% of all lymphomas.[23] BL is highly aggressive, as reflected by its 100% tumor proliferation by MIB-1 immunohistochemistry and high spontaneous apoptosis, which accounts for its "starry sky" appearance. Biologically, BL is derived from a germinal center B cell, as indicated by its CD20-positive, CD10-positive, and TdT-negative immunohistochemical profile and gene expression profiling.[232] Three clinical variants are recognized: endemic BL, which is found primarily in equatorial Africa; sporadic BL, which presents worldwide but is the most common type in Western countries; and immunodeficiency-associated BL, which is associated with HIV infection (Table 112-11). There are important clinical differences in these variants. Endemic BL typically presents with jaw and facial bone disease and is virtually always associated with EBV. Sporadic BL usually presents with ileocecal disease and is associated with EBV in 30% to 50% of cases. Immunodeficiency-associated BL usually occurs in HIV-positive populations and is associated with nodal disease and is variably associated with EBV. BL may be associated with CNS involvement, particularly when there is bulky or disseminated disease. Rare cases present as acute leukemia and are included in the French-American-British classification.[23]

BL requires chemotherapy for all disease stages. Several biologic characteristics of BL have helped to guide treatment strategies, including its high proliferative fraction. The high tumor proliferation rate led to the use of dose-intense regimens with a short cycle time to theoretically minimize tumor regrowth between cycles.[233,234] Multiple drugs, typically administered in alternating combinations, are employed, and the high rate of spread to the CNS has led to the standard use of CNS prophylaxis.[15] A variety of dose-intense short-duration regimens have achieved durable complete remissions in 47% to 84% of patients (Table 112-12).[235–238] Included in these are the French LMB and German Berlin-Frankfurt-Munster protocols and the National Cancer Institute CODOX-M/IVAC regimen. These regimens are similar in their drug composition, short cycle length, and CNS prophylaxis. Though most BLs occur in children, Magrath and colleagues demonstrated that adults and children have a similar disease outcome when treated with the same regimen.[233] Toxicity is an important clinical limitation of these regimens in adults, particularly in older patients, in whom severe morbidity and even mortality occur. Therefore, one of the major therapeutic challenges in BL is to develop therapies that are as effective in achieving high cure rates as "standard" regimens but that improve the therapeutic index and reduce toxicity complications. This approach is being investigated in a pilot study of DA-EPOCH-R. On the basis of studies in DLBCL that suggested that DA-EPOCH overcomes the adverse effect of high proliferation, likely owing to its infusional schedule, it appeared to be a good candidate to test in adult BL.[199] Indeed, preliminary results in 17 patients with BL showed EFS and OS rates of 92% and 100%, respectively, at a median follow-up of 28 months, with low toxicity compared to conventional regimens.[199,201]

Table 112-11 Comparison of Endemic, Sporadic, and HIV-Associated Burkitt's Lymphoma

	Endemic	Sporadic	HIV-Associated
Epidemiology	Equatorial Africa and Papua, New Guinea. Geographic association with malaria.	United States and Europe	United States and Europe
Incidence	5–10 cases per 100,000	2–3 cases per million	6 per 1000 AIDS cases
Age and gender	Malignancy of childhood Peak incidence: 4–7 years Male:female ratio:2: 1	Malignancy of childhood and young adults. Median age: 30 years Male : female ratio: 2–3 : 1	Malignancy of adults; associated with higher CD4 counts (>100/mm^3)
Clinical presentation	Jaw and facial bones in ≈50%. Also involves mesentery and gonads. Increased risk of CNS dissemination.	Abdomen most common presentation often involving the ileocecal region. Other extranodal sites include bone marrow, ovaries, kidneys, and breasts. Increased risk of CNS dissemination.	Nodal presentation most common, with occasional bone marrow. Increased risk of CNS dissemination.

CNS, central nervous system.

Table 112-12 Selected Regimens for Burkitt's Lymphoma

Therapy	No. of Patients	Histology (Number)	Median Age in Years (Range)	Stage	EFS Rate	OS Rate
LMB 89	561	Burkitt's and L3 ALL (420)	8 (0.17–18)	III–IV: 79%	92% at 5 years	92% at 5 years
BFM 90	413	Burkitt's and L3 ALL (322)	9 (1.2–17.9)	III–IV: 60%	89% at 6 years	14 deaths
CODOX-M/IVAC	21 children, 20 adult	Burkitt's	12 (3–17) 25 (18–59)	III–IV: 78%	85% (children) and 100% (adults) at 2 years	2 deaths
CODOX-M/IVAC	52	Burkitt's	35 (15–60)	III–IV: 61%	65% at 2 years	73% at 2 years
Hyper-CVAD	26	L3 ALL	58 (17–79)	N/A	61% at 3 years for disease-free survival	49% at 3 years

EFS, event-free survival; OS, overall survival.

Mantle Cell Lymphoma

MCL is a relatively rare B-cell lymphoma that comprises some 3% of all lymphomas and has a median age of 60 years and male predominance.[20] Its pathobiology is characterized by dysregulation of the cell cycle, with almost all cases showing the t(11;14) translocation and overexpression of cyclin D1 (bcl-1). Hence, immunohistochemical detection of cyclin D1 along with CD20 and CD5 is virtually diagnostic of MCL.[23] The biologic importance of cell cycle dysregulation in MCL was elegantly demonstrated by gene expression profiling in which the tumor proliferation signature was the best molecular predictor of survival.[67]

Most patients present with advanced-stage disease and, on the basis of historical series, have a median survival of 3 to 5 years. While OS appears to be improving with the development of more effective therapies, cure remains elusive for most patients.[75] Treatment approaches are constrained by the older median age of patients with MCL, more aggressive regimens often being preferred in younger patients. One of the more promising and aggressive regimens for MCL is fractionated cyclophosphamide administered with doxorubicin, vincristine, and dexamethasone (hyper-CVAD) alternating with high-dose methotrexate and cytarabine.[239] In an initial phase II study of 45 previously treated and untreated patients, 38% achieved CR, with an overall response of 94%; of these patients, 29 went on to receive ASCT consolidation.[239] Among the 25 previously untreated patients, EFS and OS rates at 3 years were 72% and 92%, respectively, which appeared significantly better than historical outcomes with CHOP-based treatment.[240] Recently, a study of hyper-CVAD with rituximab alternating with high-dose methotrexate and cytarabine was reported in untreated MCL.[241] In this study, 87% of patients achieved CR, and at 3 years, 64% were failure free. Though the regimen was effective, the unacceptable toxicity in older patients led the authors to recommend it only in patients under 66 years of age. Other studies have shown that the addition of rituximab to CHOP improves response rates and time to treatment failure but not survival.[242,243] The DA-EPOCH-R regimen has also shown good efficacy in untreated MCL, 93% of patients achieving CR, but as in other studies, most patients ultimately relapse.[244]

There has been much interest in investigating the role of high-dose chemotherapy and ASCT in MCL, and several phase II studies have showed promising results.[245–248] While a number of these studies have shown excellent EFS and OS, patient selection is by necessity biased, and there is no convincing plateau on their Kaplan-Meier curves. Even in the absence of significant cures, it is possible that ASCT might prolong survival, but this can be judged only in the context of a randomized study. Allogeneic stem cell transplantation, frequently of the reduced-intensity variety, has also been investigated in MCL.[249] In one study of 18 patients, 17 achieved CR, and there were only 3 progressions with 26 months' median follow-up.[249] The 3-year EFS rate of 82% suggests that a graft-versus-lymphoma effect plays an important role.

Recently, the proteasome inhibitor bortezomib has shown promising activity in patients with relapsed or refractory MCL. After demonstrating activity in two small phase II studies, a large multicenter study reported a response rate of 33% with 8% CR in relapsed or refractory MCL.[250–252] The mTOR inhibitor temsirolimus has also shown interesting results with a response rate of 38%.[253] A small phase II study also reported a favorable response rate of 90% for the combination of rituximab and thalidomide.[254] Combinations of bortezomib and chemotherapy are being investigated in MCL, and it is likely that in the near future, other novel agents will find their way into clinical trials for untreated patients.

Epstein Barr Virus–Associated Lymphoproliferative Disorders

The loss of adequate EBV immune surveillance underlies the pathobiology of virtually all EBV-associated lymphoproliferative disorders (LPDs).[3] It is useful to consider the origin of the immune suppression as it affects disease biology and treatment. The most commonly recognized diseases are associated with iatrogenic immunosuppression, as exemplified by PTLD and methotrexate-associated LPD.[255,256] Diseases associated with acquired immunosuppression are heterogeneous and include senile EBV-positive B-cell LPD and lymphomatoid granulomatosis.[257–259] Congenital immunodeficiencies make up the last group and include such entities as Wiskott-Aldrich syndrome and X-linked severe combined immunodeficiency, which are associated with EBV-related LPDs.[3]

PTLD encompasses a broad spectrum of diseases that occur in the setting of allogeneic hematologic and solid organ transplantation; as a group, they show considerable heterogeneity.[256,258] PTLD is classically approached by withdrawal of immunosuppression, provided that the possibility of organ rejection is not life threatening, often in conjunction with administration of rituximab. Chemotherapy, however, is frequently required, particularly in patients with monomorphic histology, in which the clone is usually immune independent.[260] EBV-positive LPD arising in the setting of chronic immune suppression with methotrexate can also respond to withdrawal of the offending agent, although most cases require chemotherapy.[255] Senile EBV-positive B-cell LPDs are increasingly being recognized and are postulated to arise in the setting of age-related waning of EBV immune surveillance.[257] In general, they should be approached like other aggressive lymphomas while recognizing that highly localized disease with limited involvement by EBV-positive large B-cells may be self-limited. Lymphomatoid granulomatosis is a rare EBV-

associated LPD that primarily occurs in otherwise healthy patients who, on examination, have evidence of immune deficiency.[258,259] Lymphomatoid granulomatosis virtually always involves extranodal sites and can be treated with interferon or immunochemotherapy, depending on the grade of disease.[258]

AIDS-Related Lymphomas

In the setting of HIV infection, several distinct subtypes of NHL are encountered with varying frequencies. While the overall increased risk of NHL is greater than 100-fold, the incidence of PCNSL is increased 3600-fold and that of BL is increased 1000-fold when compared to HIV-negative populations.[23,261–263] Though they are not AIDS-defining illnesses, the relative risk of other lymphoid neoplasms such as Hodgkin's lymphoma, extranodal marginal zone lymphoma, and certain T-cell lymphomas also appear to be increased in the setting of HIV infection.[264–267] The incidence of various systemic lymphoma subtypes is associated with CD4 cell count. Patients with severe CD4 cell depletion tend to develop the immunoblastic and plasmablastic subtypes, which have a poor prognosis, whereas patients with higher CD4 cell counts tend to develop centroblastic DLBCL and BL.[13,23,268,269] Hence, the decline in patients with low CD4 cell counts in the post–highly active antiretroviral therapy (HAART) era is likely to lead to a shift in histologic subtypes.[13,270–272]

The pathogenesis of AIDS-related lymphomas (ARLs) involves a complex interplay of factors and mechanisms. Among these are CD4-dependent immunodeficiency, chronic antigen stimulation, coinfecting oncogenic viruses such as EBV and HHV8 (also known as Kaposi's sarcoma herpesvirus), cytokine dysregulation, and genetic abnormalities. Most ARLs are of B-cell lineage and, being monoclonal, harbor clonal rearrangement of immunoglobulin genes. Occasional T-cell lymphomas are observed and would have T-cell receptor gene rearrangements.[23,273]

The introduction of HAART in the mid-1990s had a dramatic and positive impact on the outcome of ARL. A comparison of median survival of the pre- and post-HAART eras showed a significant increase from 6.3 months to 21.2 months. Although the reasons for this are multifaceted, they can ultimately be attributed to salutary effects on CD4 cell counts. It was thus clinically predictable that the overall rise in CD4 cell count would improve ARL outcome on the basis of the well-established association between poor outcome and low CD4 cell count.[271,274] Of course, patients with better immune function have a lower risk of infectious complications, thereby enabling chemotherapy administration and reducing infectious deaths. Perhaps most important, however, is the more favorable biology that is associated with lymphomas that occur in patients with higher CD4 cells counts.[13,271]

These findings led to the assumption that HAART during chemotherapy would be beneficial. One of the first trials to investigate the concomitant use of HAART with chemotherapy was performed by the AIDS Malignancy Consortium, in which patients received either modified (m)-dose (50% lower cyclophosphamide and doxorubicin) or standard CHOP chemotherapy.[275] This was not randomized, as the initial 40 patients received modified-dose CHOP and the subsequent 25 patients received CHOP. All patients received a HAART regimen consisting of stavudine, lamivudine, and indinavir. In this study, mCHOP and CHOP had similar toxicity, and both were reasonably well tolerated, providing some assurance for the safety of HAART with CHOP chemotherapy. Perhaps not unexpectedly, patients who received CHOP had a somewhat better outcome than did those who received modified-dose CHOP, but in the absence of a randomized design, the authors could conclude only that the regimens were active and tolerable. A potentially important finding of the study comes from the pharmacokinetic analysis, which showed that cyclophosphamide clearance was reduced 1.5-fold, which will likely result in a reduction of active metabolites and potentially compromise efficacy.[277]

The combination of HAART and infusional CDE (cyclophosphamide, doxorubicin, and etoposide) therapy has also been assessed.[276] Sparano and colleagues evaluated CDE in 43 patients who received concurrent didanosine and 55 patients who received concurrent HAART.[277] Hematologic and nonhematologic toxicity were lower and OS was higher in the CDE-HAART group, providing additional evidence for the safety of HAART and chemotherapy treatment. Of note, in a prior study, Sparano and colleagues had shown that in comparison to CDE alone, the administration of concurrent didanosine resulted in an 11% to 38% reduction in mean steady-state plasma etoposide concentrations and lower hematologic toxicity.[278]

It is prudent to carefully consider the role of concomitant HAART during chemotherapy treatment. While studies show that HAART does not excessively increase the toxicity of chemotherapy, there is no direct evidence that it improves outcome. The argument that control of HIV viral replication by HAART during chemotherapy benefits immune function is sound but should be considered in light of several factors. Perhaps of foremost concern is the potential for adverse pharmacokinetic and pharmacodynamic interactions related to hepatic metabolism and/or the multidrug-resistant pumps.[279] HAART drugs may decrease active cyclophosphamide metabolites and etoposide which could compromise outcome. This is particularly worrisome for infusional-based regimens such as CDE and EPOCH, in which threshold concentrations are of importance.[280] Furthermore, HAART drugs may inhibit multidrug resistance and increase hematologic toxicity and decrease dose-intensity, while conferring no benefit on tumor sensitivity.[281] Of unknown significance are the inhibitory effects of some antiretroviral drugs on lymphoid cell apoptosis, which theoretically could antagonize chemotherapy effects.[282,283] It is also possible that HAART compliance could be compromised by chemotherapy and promote the emergence of HIV viral mutations.

On the basis of such considerations, the National Cancer Institute investigated the effects of suspension of antiretroviral treatment during all courses of DA-EPOCH in 39 patients.[271] Following antiretroviral suspension during DA-EPOCH, the viral loads increased a median of 0.83 $\log_{10}$, and after restarting antiretroviral treatment, the viral loads declined −0.61 $\log_{10}$, below baseline. CD4 cells declined during chemotherapy treatment by a median of 189 cells/μL but recovered to baseline by 6 to 12 months following reinstitution of antiretroviral therapy. New opportunistic infections were only observed in five patients, all following DA-EPOCH completion. The treatment strategy appeared quite effective, with complete remissions in 74% of patients; and at a median follow-up time of 53 months, disease-free and OS rates were 92% and 60%, respectively (Fig. 112-8). Indeed, the salutary effects of HAART on immune function have led to the belief that this benefit exceeds any potential adverse effects on tumor control. Unfortunately, prospective studies have yet to address this potentially important question.

The finding that the addition of rituximab to CHOP chemotherapy significantly improves the survival of HIV-negative patients with DLBCL led to its testing in untreated ARL.[210] Pooled results from three phase II studies of rituximab and CDE in ARL have been recently reported.[284] In this study of 74 patients, 70% achieved complete remission, and at the median follow-up of approximately 2 years, the estimated failure-free and OS rates were 59% and 64%, respectively. New opportunistic infections during or within 3 months of treatment occurred in 14% of patients, and death from infection occurred in 8% of patients. While the good survival outcomes suggest that rituximab conferred a benefit compared to CDE alone, the favorable effects associated with the post-HAART era on survival cannot be discounted.[277]

To help address the role of rituximab, Kaplan and colleagues performed a multicenter randomized phase III trial of CHOP with or without rituximab in untreated ARL patients with concomitant HAART administration.[285] In this trial of 150 patients, disease control was significantly better in patients who received R-CHOP,

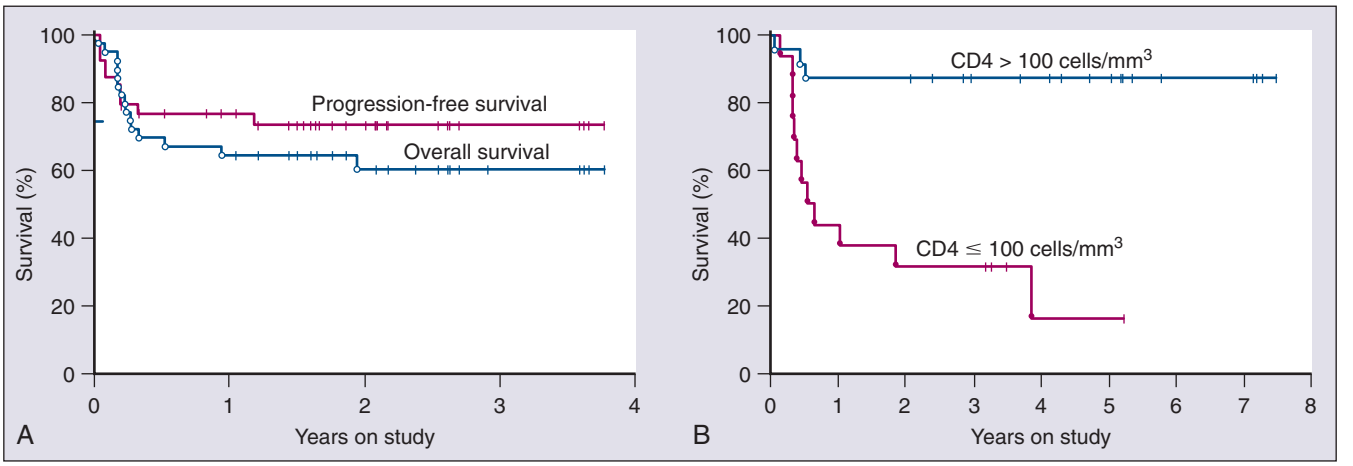

Figure 112-8 • Progression-free and overall survival rates of EPOCH in AIDS-related lymphomas. **A,** Overall and progression-free survival rates of 39 patients with AIDS-related lymphomas. At a median potential follow-up of 53 months, the overall survival probability is 60%, and the progression-free survival probability is 73%. **B,** Overall survival of 16 patients with low CD4-positive cells and 23 patients with high CD4-positive cells (≤100/mm^3 and >100/mm^3, respectively). At 53 months, the overall survival rates are 16% and 87%, respectively. (Data from Little RF, Pittaluga S, Grant N, et al: Highly effective treatment of acquired immunodeficiency syndrome-related lymphoma with dose-adjusted EPOCH: impact of antiretroviral therapy suspension and tumor biology. Blood 2003;101:4653–4659.)

with lower progression on treatment ($P_2 = 0.02$; chi-square test) and death due to lymphoma ($P_2 = 0.02$; chi-squared test).[286] However, because there was no difference in OS or EFS, owing to increased infectious deaths in patients receiving R-CHOP, the authors concluded that rituximab does not improve clinical outcome in ARL. It should not escape attention that most treatment-related infectious deaths occurred in patients with low CD4 cell numbers, a group that was enriched with tumors of ABC type and most likely to benefit from rituximab.[13,69,271] Employing a somewhat different strategy, the National Cancer Institute is investigating the outcome of a short course (SC) of EPOCH with dose-dense rituximab (375 mg/m^2 on days 1 and 5) (SC-EPOCH-R) to reduce treatment-related toxicity. In this study, patients with untreated ARL receive one cycle beyond maximum response, with a minimum of three cycles, compared to six cycles with dose-adjusted (DA) EPOCH alone.[271,287] Preliminary results in 26 patients revealed a PFS rate of 79% and an OS rate of 74% at the 29-month median follow-up. Notably, patients received a median of three treatment cycles, compared to six cycles on the prior DA-EPOCH trial.

While the role of rituximab requires further investigation, these trials suggest that rituximab is of benefit in ARL. To help further define the role of rituximab, the AIDS Malignancy Consortium is currently performing a randomized phase II trial comparing DA-EPOCH-R to DA-EPOCH alone followed by sequential rituximab in responding patients. At the current time, however, we believe it unwise to omit rituximab from the treatment of ARL and hasten to add that while treatment-related infectious deaths can be ameliorated with careful medical attention, disease progression cannot.

Although there has been an improvement in the collective outcome of HIV-associated lymphomas since HAART, a recent study indicates no improvement in the BL subtype.[288–290] These results raise the possibility that the overall improvement in outcome of HIV-associated lymphomas in the HAART era could be primarily attributable to the better outcome of DLBCL, the most common histologic subtype. This does not seem to be the case in BL, which occurs at a high median CD4 cell count and has not shown widely variable pathobiology.[232] The relatively poor outcome of HIV-associated BL might be due to the use of CHOP-based regimens, which are known to have a poor outcome in this disease.[15,232] Dose-intense regimens, such as hyper-CVAD (hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone alternating with high-dose methotrexate and cytarabine) have shown encouraging results in HIV-associated BL, with a CR rate of 92%, but are often quite toxic.[291] Involvement of the CNS by BL may also contribute to reduced survival and highlights the need for CNS prophylaxis.[271]

BL, as an important example, highlights the necessity to balance treatment efficacy and toxicity in patients with HIV infection. Dose-intense Burkitt's lymphoma regimens have been considered too toxic to warrant their general use in HIV positive patients. This has led to the use of CHOP-based treatment with an associated relatively poor outcome. It is worth noting, in this regard, that we are studying the DA-EPOCH-R regimen in BL on the basis of its good activity in highly proliferative DLBCL.[199] Among 11 HIV-negative untreated patients with BL who were treated with DA-EPOCH-R, we have observed a CR rate and OS of 100% at the median follow-up of 31 months (unpublished observations). Such results suggest that DA-EPOCH-R might be an excellent and well-tolerated alternative to dose-intense regimens for BL in HIV-positive patients.

Treatment of Relapsed Aggressive B-Cell Lymphomas

The salvage treatment of relapsed aggressive lymphomas should be approached in an individual manner, as the choice of treatment is influenced by the time to recurrence, prior therapy, medical condition, and the potential for cure. Although most relapsed aggressive lymphomas require combination chemotherapy for adequate disease control, it is important to recognize that patients with local disease can be salvaged with radiation therapy. Examples include primary mediastinal DLBCL, which can remain local even at relapse, and PTLD, which may have an isolated resistant EBV clone following chemotherapy.[292]

There are a variety of active salvage chemotherapy regimens for relapsed or refractory DLBCL (Table 112-13).[293–299] Platinum-containing regimens, such as ESHAP and ICE, are currently among the most widely used types of salvage treatment.[295,297,300] It is a commonly held notion that salvage treatment should include different agents from past treatment to avoid drug resistance. However, recent evidence indicates that sensitivity to apoptosis is a central cause of drug resistance and that drug-specific mechanisms are less important.[27,281] Hence, salvage regimens that were developed around the most active up-front agents should show high activity.[301] This concept was tested with EPOCH chemotherapy in patients who had failed after receiving similar drugs on a bolus schedule.[301] In this study of 67 patients with relapsed or refractory de novo aggressive lymphoma, 70% responded, with a 36% CR rate. The addition of rituximab appears to enhance the activity of salvage regimens as demonstrated by results

Table 112-13 Treatment Outcomes in Relapsed Lymphoma

Therapy	Patient Group	CR Rate	OR Rate	OS Rate	Reference
DHAP	Relapsed or refractory lymphoma	31%	58%	25% at 2 years	Velasquez et al[298]
ESHAP	Relapsed or refractory lymphoma	37%	70%	31% at 3 years	Velasquez et al[299]
EPOCH	Relapsed or refractory DLBCL	36%	70%	30% at 6 years	Guiterrez et al[301]
R-ICE	Relapsed or refractory DLBCL	53%	88%	—	Kewalramani et al[295]

CR, complete response; DHAP: dexamethasone, cytarabine, and cisplatin; ESHAP: etoposide, methyl-prednisone, cytarabine, and cisplatin; EPOCH: etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin; OR, overall response; OS, overall survival; R-ICE: rituximab, ifosfamide, carboplatin, and etoposide.

with R-ICE and ICE, which showed a CR rate of 53% and 27%, respectively.[295,300]

Patients with chemotherapy-sensitive disease have the best outcome with ASCT, and it is recommended at initial relapse; it has yielded OS and EFS rates in the range of 40% to 50% and 30% to 40%, respectively.[295,302] ASCT rarely achieves cure in BL and lymphoblastic lymphoma but is often successful in ALK-positive anaplastic large cell lymphoma (ALCL). Lymphomas that are rarely cured with initial treatment, such as MCL and PTCL, are less likely to benefit from ASCT. It is important to consider, in assessing the outcome of ASCT, that improvements in up-front therapy from rituximab has biased the relapsed population toward greater resistance. The incorporation of rituximab or radioimmunoconjugate into conditioning regimens can also enhance the benefit of ASCT, thus pointing out the importance of controlled ASCT trials in the post-rituximab era.[295,302] Of course, patients with chemotherapy-resistant disease do poorly with ASCT and should be considered for experimental treatments such as allogeneic SCT.

Lymphomas of T/NK Cell Origin

Lymphomas of T/NK cells are relatively uncommon and account for approximately 15% of all NHLs.[23,303] They are distributed over at least 14 different subtypes, all of which are infrequent and not well studied. Tumor types that have an identifiable clinical-pathobiology are classified by name, whereas the other cases are simply described as peripheral T-cell lymphoma unspecified ($PTCL_{us}$), which by design is a heterogeneous group. Generally, T/NK cell lymphomas are clinically aggressive, though some can behave quite indolently, and unlike their aggressive B-cell cousins, most are incurable. Important exceptions to cure include ALCL and early-stage T/NK cell, nasal-type lymphoma.

To help refine the outcome of aggressive T/NK and B-cell lymphomas in the international arena, the Non-Hodgkin's Lymphoma Classification Project examined all newly diagnosed cases of lymphoma over a 2-year period from multiple international centers.[304] A survival analysis predictably demonstrated a poor outcome of $PTCL_{us}$ compared to DLBCL. Similar to DLBCL, the IPI was predictive of outcome in $PTCL_{us}$, and at 5 years, only a little over one quarter of low-IPI patients were alive without disease. This is in contrast to the anaplastic ALCL subtype, in which 80% of patients were alive at 5 years irrespective of the IPI score. Three large series of PTCL patients who were treated with CHOP-based therapy have been reported (Fig. 112-9).[305–307] The overall CR rate varied from 49% to 65%, and in all series, ALCL had a favorable outcome. Like the NHL Classification Project, IPI score predicted outcome with 5-year survival rate of 60% to 80% in low (0 to 1), 20% in intermediate (2 to 3) and 0% in high (4 to 5) IPI patients.[308]

Anaplastic Large Cell Lymphoma

ALCL is a CD30 positive T-cell lymphoma with an excellent prognosis ,and unlike the other PTCLs, it is highly curative. It typically occurs in children and young adults and makes up approximately 3% of all lymphomas in adults. In some 80% of cases, ALCL is associated with the t(2;5)(p23;q35) translocation, resulting in expression of the nucleophosmin anaplastic lymphoma kinase (ALK).[309] While ALK-positive ALCL has a significantly better prognosis than do ALK-negative cases, patients with ALK-negative disease should still be approached with curative intent.[309] In adults, CHOP-based therapy is considered the standard of care and produces durable remissions in approximately 65% of ALK-positive ALCLs and 35% of ALK-negative ALCLs (Fig. 112-10).[310]

Extranodal T/NK-Cell Lymphoma, Nasal Type

This is a rare extranodal lymphoma characterized by a broad morphologic spectrum. It is more prevalent in Asia and Central and South America and is almost always associated with EBV.[20] It has a predilection for the nasal cavity, nasopharynx, palate, skin, gastrointestinal tract, and testis. Hemophagocytic syndrome is a devastating event associated with this tumor type.[311] Disease outside the nasal cavity is usually highly aggressive and associated with a poor prognosis. Because of its rarity and lack of prospective clinical trials, optimal therapy has not been defined. However, disease that is localized to the nasal cavity is quite curative with radiotherapy, though the benefit of chemotherapy in this setting has yet to be defined.[312]

Angioimmunoblastic T-Cell Lymphoma

Angioimmunoblastic T-cell lymphoma is T-cell lymphoma that is characterized by systemic symptoms, skin rash, organomegaly, hypergammaglobulinemia and hemolytic anemia. It most commonly afflicts older patients and frequently presents with peripheral lymphadenopathy, hepatosplenomegaly, skin rash, and constitutional symptoms, which distinguish it from other peripheral T-cell lymphomas.[313] Patients often exhibit some degree of immunodeficiency, polyclonal hypergammaglobulinemia, and other hematologic abnormalities, which are likely related to abnormal immune regulation.[314] The neoplastic T cells appear to be of germinal center origin, known as follicular B helper T cells.[315,316] A prominent histologic feature of acute lymphoblastic leukemia is the near universal presence of EBV-positive B cells within the lesions.[317,318] Optimal therapy has not been defined for acute lymphoblastic leukemia, but anthracycline-based regimens and purine analogs have shown some efficacy.[313,319] Recently, novel approaches, such as the use of cyclosporine and antiangiogenesis therapies such as bevacizumab, have shown activity and warrant further investigation in the future.[320,321] Unfortunately, most patients succumb from infection or disease.

Hepatosplenic T-Cell Lymphoma

This extranodal T-cell lymphoma presents with marked hepatosplenomegaly and bone marrow involvement.[322] Most cases have a γδ T-cell receptor rearrangement that, if present in other PTCLs, portends a particularly poor prognosis.[23,323] The disease not uncommonly afflicts younger males and occurs with increased frequency in the setting of iatrogenic immune suppression.[324] Outcome is extremely poor and is characterized by rapid progression and death, although allogeneic transplantation has been associated with prolonged remission and potential cure.[325]

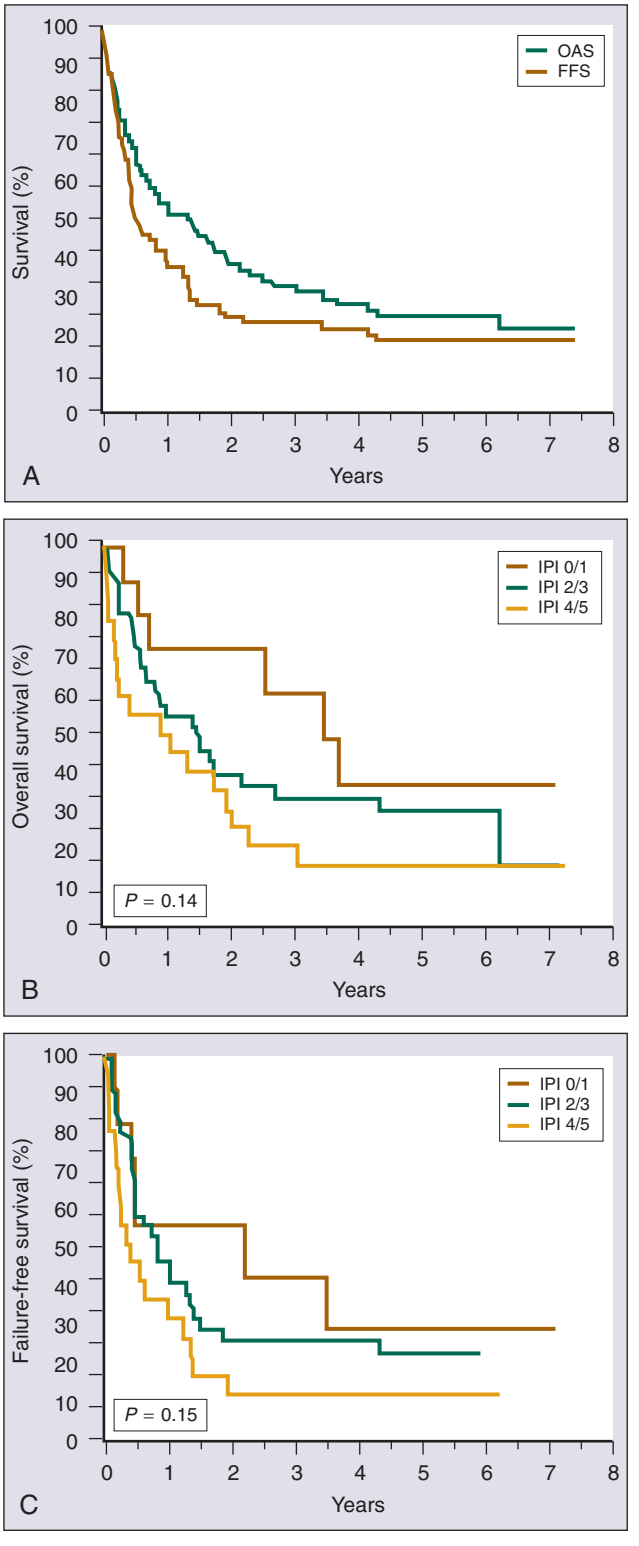

Figure 112-9 • Survival outcomes of peripheral T-cell lymphomas. **A,** Failure-free and overall survival rates. **B,** Overall survival rates by International Prognostic Index score. **C,** Failure-free survival rates by International Prognostic Index score.

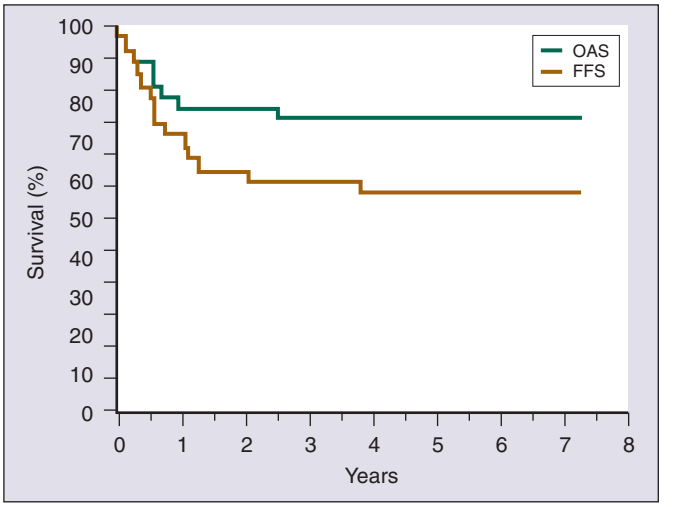

Figure 112-10 • Overall and failure-free survival rates for an unselected group of patients with anaplastic large T/null cell lymphoma.

Subcutaneous Panniculitis-like T-Cell Lymphoma

This rare lymphoma was first described in 1991.[326] Patients present with subcutaneous, sometimes painful, nodules that can ulcerate. Biopsies can be sometimes called atypical panniculitis. The hemophagocytic syndrome can be a fatal complication of this lymphoma. There is no standard treatment. Chemotherapy regimens often cause responses that are usually transient. Involved field radiotherapy is highly effective, but patients often relapse in unirradiated sites.[327,328]

Peripheral T-Cell Lymphoma, Unspecified

The poor outcome of $PTCL_{us}$ has prompted the search for new strategies and targeted agents. Purine analogs are associated with good response rates but are rarely curative.[329] Alemtuzumab, a monoclonal antibody that binds CD52, is expressed on most $PTCL_{us}$ and has shown a 36% response rate in one series of heavily pretreated patients. The success of immunochemotherapy in B-cell lymphomas has led to several ongoing studies of alemtuzumab and chemotherapy.[330] Other novel agents include dinileukin difititox and the histone deacetylase inhibitor depsipeptide.[331,332] While ASCT can provide some benefit, a recent report of a graft-versus-lymphoma effect in PTCL suggests that it might have curative potential.[333,334]

Precursor B-Cell and T-Cell Lymphoma

Precursor B-lymphoblastic and T-lymphoblastic lymphomas are highly aggressive diseases with primarily nodal presentations but are cytologically identical to acute lymphoblastic leukemia (see Chapter 103).[23] Precursor T-lymphoblastic lymphomas make up about 90% of lymphoblastic lymphomas and typically present in young males with a mediastinal mass and occasional involvement of the meningeal space. A variety of chemotherapy regimens have been used, including ACVBP, leukemia-based regimens, and ASCT.[335,336] A recent study published by the British Columbia Transplant Group reported an excellent outcome with induction chemotherapy followed by stem cell transplantation; in this study, 69% of patients were event free at 4 years.[336] An earlier German study evaluated an acute lymphoblastic leukemia–type regimen in 45 adult patients with T-lymphoblastic lymphoma and reported a 62% disease-free survival rate at 7 years.[337] These studies highlight the need for very aggressive therapies in these diseases.

Lymphoma in the Elderly

The incidence of lymphoma increases with advancing age, and the life span is lengthening; at least in the developed world, the

management of older patients with lymphoma is becoming an increasing problem. Regardless of the age cutoff that is used to define *elderly*, the challenge is predominantly that of contending with patients who are at high risk of comorbidity and have social circumstances that might complicate the overall management plan. Clearly, for patients with follicular lymphoma or the other lymphomas that have a relatively long clinical course, an expectant policy or minimal intervention becomes the most appropriate course. Brief treatments such as targeted irradiation are attractive in these circumstances, also for those with large B-cell lymphoma.

For elderly patients with lymphomas for whom prolonged survival is possible only if complete remission is achieved, philosophical as well as pragmatic issues come into play. It is gratifying that rituximab combined with CHOP has proved to be tolerable with a relatively low mortality rate in elderly patients who are being treated with curative intent and that the combination renders a significant proportion of patients disease free for prolonged periods. Data, presented so far only in abstract form, indicate that with the judicious use of growth factors, it is possible to administer CHOP at 14-day intervals instead of 21-day intervals and that this also results in improved outcome in the elderly. It remains to be determined whether the best standard of care at the beginning of twenty-first century will be CHOP-R or CHOP-14-R. Not surprisingly, there is inevitable selection of older patients into clinical trials. A high proportion of cases will, inevitably and appropriately, receive individualized therapy, a multitude of factors beyond the IPI coming into play.

LATE COMPLICATIONS OF TREATMENT

It is important to recognize that successful treatment can be associated with late complications that might not appear for decades. Among the major late-term complications are secondary malignancies, ischemic heart disease, anthracycline-related cardiotoxicity, and radiation- or bleomycin-induced pulmonary toxicity.[338] The risk of developing myelodysplastic disorders and acute myeloid leukemia is related to alkylator and topoisomerase inhibitor use and is enhanced by radiation. Radiation therapy increases the risk of malignancy in the treatment region and, in particular, breast cancer in women and lung cancer in smokers. Indeed, it is imperative to consider late-term toxicity in selecting treatment.

A general guideline for follow-up after initial therapy involves regular visits at decreasing intervals for the first 5 years and annually thereafter. During these visits, examination of the lymph node areas, abdomen, thyroid, and skin is important. It is important to note that CT scans are associated with a relatively high radiation exposure and projected risks and should not be used unnecessarily.[339] PET scans are not recommended for routine follow-up because the high rate of false-positive scans is unlikely to offset the value of early detection. Indeed, the role of PET scans in the overall treatment of lymphomas needs to be prospectively studied.[340] Routine laboratory studies with blood counts, liver function tests, and LDSH should be performed. Patients with disease in the chest can be followed with chest radiographs. The thyroid-stimulating hormone level should be monitored annually in patients who received neck radiotherapy. Mammography for women should begin 10 years from diagnosis of lymphoma or at age 40, whichever comes first. Patients should be immunized against influenza yearly and against *Streptococcus pneumoniae*.

ATYPICAL LYMPHOID PROLIFERATIONS SOMETIMES CONFUSED WITH LYMPHOMA

Not all examples of disordered lymphoid proliferation represent lymphomas. These clinicopathologic entities can present confusing clinical problems, however. These conditions include benign lymphoid proliferations that can be confused with either T- or B-cell lymphomas. To confuse the picture further, these latter entities sometimes evolve into lymphoma.

Of the atypical lymphoid proliferations that can be confused with lymphoma, the most common are processes referred to as reactive or atypical lymphoid hyperplasia. Patients with these disorders present with localized or disseminated lymphadenopathy associated with an underlying condition that might or might not be obvious. The patients sometimes have systemic symptoms, depending on the associated illness. Problems that can underlie this condition include drugs (e.g., dilantin and carbamazepine),[341] autoimmune disorders (e.g., rheumatoid arthritis, systemic lupus erythematosus, and Sjögren's syndrome),[342–345] viral infections (e.g., cytomegalovirus, EBV, and varicella-zoster virus), and bacterial infections (e.g., cat scratch disease). The distinction between these entities and malignant lymphoma is tremendously important. Lymphadenopathy in these patients rarely evolves into malignant lymphoma, and successful treatment of the underlying condition usually resolves the problem. When no explanation can be found for atypical lymphadenopathy, observation of the patient is appropriate. On occasion, subsequent biopsies will demonstrate lymphoma.

An unusual clinical entity that is variously known as Castleman's disease, angiofollicular lymph node hyperplasia, and giant lymph node hyperplasia can be confused with malignant lymphoma. First described in 1956,[346] this entity can present with localized or disseminated lymphadenopathy involving essentially all lymph node–bearing areas.[347] Lymphadenopathy is frequently accompanied by systemic symptoms such as fever, night sweats, or weight loss. The condition is found with increased frequency in patients infected with HIV-1.[348] Castleman's disease can be found in patients with POEMS syndrome.[349] Biopsy of an involved lymph node reveals one of two histologic patterns. The more common pattern involves lymph node effacement by small hyaline, vascular follicles and interfollicular capillary proliferation, while, in a few patients, the histologic pattern is large hyperplastic lymphoid follicles with intervening sheets of plasma cells.[350] The patients often have anemia and polyclonal hypergammaglobulinemia. It is now known that many of the manifestations of this disorder seem to be mediated by excessive production of the cytokine IL-6, and the symptoms of the disease can sometimes be ameliorated by administration of a monoclonal antibody against interleukin-6.[351] Patients with Castleman's disease can die of the disorder or of complications of therapy. Management is further complicated by the fact that some of these patients develop malignant lymphomas on follow-up. The successful management of patients who present with localized involvement can be accomplished with surgery or radiation therapy.[351] Patients with disseminated disease sometimes respond completely to therapy with glucocorticoids.[347] Symptomatic patients who do not respond completely are sometimes treated with chemotherapeutic agents in a manner similar to that used for malignant lymphoma. Successful treatment has been described with interferon,[352] monoclonal anti-IL-6 antibody,[353] rituximab,[354] autologous bone marrow transplantation,[355] and allogeneic bone marrow transplantation.[356] It should be remembered, however, that this disorder sometimes spontaneously remits, and a cause of death has been treatment-related complications.

Among the other unusual disorders that are associated with atypical lymphadenopathy is sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease). First described in 1969,[357] this entity usually presents with bulky lymphadenopathy but can have extranodal sites of involvement.[358] This disorder is most commonly seen in children or young adults. Biopsy reveals lymph nodes with a distorted architecture due to a thickened fibrous capsule, distension of the lymphoid sinuses by histiocytes, and infiltration of the node by plasma cells. The histiocytes in this disorder are morphologically characteristic. The disease is usually nonprogressive and self-limiting. Occasional cases have associated autoimmune hemolytic anemias that can be severe or even fatal but should be treated like other autoim-

mune hemolytic anemias. Surgery or radiation therapy can be utilized to manage symptomatic, bulky disease sites.

Lymphomatoid papulosis represents a clinically benign cutaneous LPD that is often confused with anaplastic large cell lymphoma involving the skin.[359] This is because the cells of lymphomatoid papulosis are atypical and stain for the Ki-1 (CD30) antigen. This is an extremely important distinction that can be effectively made only when the clinician and pathologist communicate.[360] The key to the diagnosis is an accurate history. Patients with lymphomatoid papulosis have waxing and waning skin lesions that usually heal, leaving small scars. Therapy that would be appropriate for malignant lymphoma is contraindicated and dangerous. The clinical picture is complicated by the fact that patients with lymphomatoid papulosis sometimes develop malignant lymphomas.

FUTURE DIRECTIONS

The last several years have witnessed an explosion of insight into the molecular biology of aggressive lymphomas, particularly B-cell diseases. Powerful techniques such as gene expression profiling, array-CGH, and RNAi have paved the way for the identification of new targets and the development of small molecule inhibitors. Indeed, a number of targeted agents have entered clinical trials and are showing promising activity.

113 Cutaneous T-Cell Lymphoma and Cutaneous B-Cell Lymphoma

Thomas M. Habermann and Mark R. Pittelkow

SUMMARY OF KEY POINTS

Incidence

- The estimated annual incidence of cutaneous T-cell lymphoma (CTCL) is 0.4 in 100,000 cases.
- Cutaneous B-cell non-Hodgkin's lymphoma (NHL) represents approximately 10% of all primary cutaneous lymphomas.
- The average age at presentation is 50 to 60 years, but CTCL has been reported in children and adolescents.

Differential Diagnosis CTCL

- The median lag time to diagnosis of CTCL is approximately 6 years.
- Premalignant disorders that may potentially evolve into CTCL include parapsoriasis, lymphomatoid papulosis, pre-Sézary syndrome, atypical dermatitis, and dermal reticulosis.
- Histologic and clinical variants of CTCL constitute 10% of the cases.
- CTCL must be further distinguished from adult T-cell leukemia/lymphoma, Ki-1$^+$ anaplastic large cell lymphoma, peripheral T-cell NHL, cutaneous B-cell lymphomas, T-cell chronic lymphocytic leukemia, leukemia cutis, cutaneous lymphoid hyperplasias, lymphomatoid contact reactions, and insect bites.

Staging Evaluation CTCL

- The initial evaluation of the patient with CTCL should include complete history, physical examination, and complete blood count (CBC) and differential to assess for the presence of disease in peripheral blood; chemistry studies; and chest radiography.
- The physical examination should determine the percentage of body surface area involved.
- Skin biopsy specimens must be obtained for routine histologic studies, immunohistochemistry analysis, and T-cell receptor gene rearrangement or polymerase chain reaction studies at the time of the initial diagnosis.

Natural History CTCL

- CTCL is an extranodal lymphoma, which may be indolent, as in mycosis fungoides, or aggressive, as in Sézary syndrome.
- Localized limited-stage disease is potentially curable. All other presentations are incurable.

Primary Therapy CTCL

- Current initial therapies for CTCL are tailored to extent, burden, and type of disease present and include use of emollients or topical corticosteroids, topical chemotherapy (nitrogen mustard, BCNU, bexarotene), phototherapy, psoralen–ultraviolet A (PUVA) therapy, electron beam irradiation, photon irradiation, extracorporeal photochemotherapy, chemotherapy, peripheral blood stem cell transplantation, and allogeneic transplantation.

Selective Second- and Third-Line Therapies CTCL

- Patients may respond to the same therapeutic modality on more than one occasion.
- Multiple other palliative management options are available as well.

INTRODUCTION

Primary cutaneous lymphomas represent the second most common extranodal site for NHL.[1] CTCL is a heterogeneous group of NHLs that represent about 80% of all primary cutaneous lymphomas. These disorders of malignant lymphocytes have a proclivity for the skin and epidermis. The diagnosis of CTCL is based on clinicopathologic criteria. This class of malignant lymphomas includes mycosis fungoides with variants and Sézary syndrome. In addition to these CTCLs, other malignant lymphoproliferative T-cell diseases that involve the skin include primary cutaneous CD30$^+$ lymphoproliferative disorders, peripheral T-cell lymphoma, adult T-cell leukemia/lymphoma, and others. CTCL forms a group of clinically diverse disorders that include cutaneous B-cell lymphomas (Table 113-1). Cutaneous lymphomas are distinguished on the basis of their clinical, histologic, immunologic, and molecular features. This chapter reviews the clinicopathologic features of and therapy for cutaneous lymphomas including mycosis fungoides, Sézary syndrome, and cutaneous B-cell lymphoma, as well as their variants and related disorders.

EPIDEMIOLOGY

The estimated annual incidence of mycosis fungoides and Sézary syndrome in the SEER (Surveillance, Epidemiology, and End Results) cancer registry was 1 per 100,000 population and in the well-defined population of Rochester, Minnesota, is 0.9 per 100,000 residents.[1,2] Epidemiologic data from the SEER program showed an increase in incidence of CTCL, from 0.2 case per 100,000 in 1973 to 0.4 case per 100,000 in 1984, with no increase from 1983 to 1994.[3,4] The incidence of cutaneous lymphoma increases with age. Most reported cases of CTCL are in adults. The average age at diagnosis is 50 to 60 years,[3] but cases have been reported in children and adolescents.[5] CTCL is more likely to develop in black populations.[3] Mycosis fungoides is the most common CTCL, representing 40% to 82% of new cases.[6]

Although environmental factors have been implicated in the pathogenesis of CTCL, two case-control studies have not supported the concept that industrial or related exposures cause the disease.[7] Furthermore, no significant differences were documented in

cutaneous allergy to plants, metals, and cosmetics or in reactions to medications, foods, or insect bites between cases of mycosis fungoides and controls, indicating that in most cases prolonged exposure to contact allergens is not related to the development of CTCL.[7] In selected cases, however, patients with atopy, contact sensitivity, chronic dermatitis, or immunodeficiency may develop CTCL.[8] The vast majority of patients are human T-cell lymphotrophic virus type 1 (HTLV-1)-negative. CTCL has been documented after B-cell lymphomas, Hodgkin's lymphoma, and renal transplantation.[9–11] CTCL also has been reported in the acquired immunodeficiency syndrome.[12]

CLASSIFICATION

Previous classifications have not adequately characterized the cutaneous lymphomas. The most recent lymphoma classification is the World Health Organization (WHO) classification.[13] The European Organization for Research and Treatment of Cancer (EORTC) proposed a classification that divided patients into those with primary T-cell or B-cell lymphomas.[14] Significant differences, however, exist between the two classification systems. The WHO-EORTC classification for cutaneous lymphomas was the result of consensus meetings (see Table 113-1).[15] The relative frequency and survival data for 1905 patients derived from Dutch and Austrian cutaneous lymphoma registries illustrate the clinical significance of the WHO-EORTC classification (Table 113-2). This classification will lead to a more uniform diagnosis of cutaneous lymphomas and also improves definitions of cutaneous lymphomas other than mycosis fungoides and Sézary syndrome and provides definitions of cutaneous B-cell lymphomas, allowing for a more reliable distinction between aggressive and indolent types of cutaneous B-cell lymphoma.

Of the CTCLs, 50% are mycosis fungoides. The tumor-node-metastasis (TNM) classification system is used in cutaneous lymphoma (Table 113-3). A TNM classification system is used to stage patients with mycosis fungoides and Sézary syndrome but is not appropriate for use with other primary cutaneous lymphomas (Table 113-4). A consensus TNM classification system applicable for all primary cutaneous lymphomas other than mycosis fungoides and Sézary syndrome has been proposed.[16]

GENERAL CLINICAL MANIFESTATIONS OF MYCOSIS FUNGOIDES AND SÉZARY SYNDROME

The cutaneous clinical manifestations of cutaneous lymphoma are diverse, ranging from difficult-to-diagnose to indeterminate dermatitis-like lesions of skin to plaque- or tumor-stage CTCL. The most common cutaneous lymphoma is mycosis fungoides. The second most common cutaneous lymphoma is Sézary syndrome. Sézary syndrome more characteristically arises without a previous history of mycosis fungoides. If mycosis fungoides evolves into Sézary syndrome, then the diagnosis should be erythrodermic mycosis fungoides. Atypical cutaneous lesions eventually are found to represent CTCL. Patients may have a premalignant phase with eczematous or dermatitic skin lesions for several years, or even decades, before the diagnosis is established. The median time from appearance of of the preceding skin eruption to diagnosis is approximately 6 years. Periodic skin examination and repeat skin biopsies as necessary are essential in patients with suspicious cutaneous lesions. The spectrum of premalignant disorders includes various less common but distinctive lymphoid dermatoses, such as large-plaque parapsoriasis, poikiloderma atrophicans vasculare, follicular mucinosis (alopecia mucinosa), pityriasis lichenoides et varioliformis acuta (Mucha-Habermann disease), and other atypical lymphocytic infiltrates of the skin. Generally, no specific clinical or pathologic markers have been identified that clearly delineate those cases that will progress to CTCL.

The classic malignant phases of CTCL are manifested principally in the skin and include patch-stage CTCL, plaque-stage CTCL, tumor-stage CTCL, and erythrodermic CTCL (Fig. 113-1). Extracutaneous involvement, nodal or extranodal, of CTCL develops with disease progression.

The patch stage of mycosis fungoides (see Fig. 113-1A) is characterized by cutaneous erythematous macules and slightly infiltrated patches of variable size, often located over the waist or on the trunk or proximal extremities. Pruritus may or may not be a feature. Individual skin lesions occasionally exhibit superficial scale, whereas induration is minimal or absent. Pigmentation may be altered; depending on the natural degree of pigment, hypopigmentation or hyperpigmentation may be observed. The lesions may be present for months to years before the plaque stage of CTCL develops (see Fig. 113-1B).

Since the initial description of this disease by the French dermatologist Alibert during the early 1800s, the discrete plaque stage and tumor stages of CTCL have been classically defined as mycosis fungoides.[17] The lesions of plaque- and tumor-stage CTCL are sharply demarcated circular plaques that are infiltrated and elevated above the surrounding normal skin on the trunk and extremities. The plaques are erythematous or occasionally violaceous and may exhibit central involution. Individual patches may overlap, producing a geographic appearance. The lesions may be scaly or encrusted, occasionally exhibiting a papular quality (see Fig. 113-1B) They rarely become

vesicular or pustular or exhibit bolus features or a translucent granulomatous appearance. Patches evolve into larger plaques, with oval and well-demarcated lesions with elevated borders. The plaques may affect the face, and the dermal thickening on the face may progress to give the classic leonine facies. Infiltration of the skin of the palms and soles leads to hyperkeratosis and fissuring. More extensive involvement of the scalp and other hair-bearing areas often is accompanied by alopecia (see Fig. 113-1C). Pruritus may be significant and can involve both lesional and nonlesional skin. Rarely, a solitary plaque or nodule of mycosis fungoides has been observed in the complete absence of other skin findings.[18]

Tumor-stage lesions of CTCL have variable growth rates and typically occur at sites of previous plaque-stage involvement. Progression probably reflects local proliferation and evolution of more aggressive clones of malignant cells. Multiple tumor-stage lesions of CTCL arise de novo in the absence of patch-stage or plaque-stage CTCL but, when observed, have been reported as the *d'emblée* form of mycosis fungoides. The tumorous lesions may appear anywhere on the body but have a predilection for the body folds, including groin, antecubital fossa, neck, axilla, and inframammary areas. The nodules and tumors typically are reddish brown or purplish and have a tendency to ulcerate (see Fig. 113-1D). Multiple lobulated and coalescing lesions may develop on the face, resulting in leonine facies (see Fig. 113-1E). Tumor-stage CTCL is more clinically aggressive than patch-stage CTCL, probably owing to the evolution of a later stage of malignancy. Nodular lesions infrequently are pruritic and more often are painful and tender, especially after ulceration has occurred. Ulcerative lesions frequently become colonized with bacteria and purulent. Histologically, the lesions may be similar to those in plaque-stage disease, but they are denser and extend into the deep dermis and subcutaneous fat. Cellular composition may demonstrate lymphoid polymorphism and inflammation, or the lesions may be monomorphous, with almost exclusively less mature malignant T cells and minimal or absent epidermatropism. At presentation, approximately 40% of patients have plaques on less than 10% of the body surface area, 30% have extensive plaques, 15% exhibit a tumor phase, and 10% exhibit an erythroderma phase.

The classic erythrodermic form of CTCL, Sézary syndrome, is a distinctive CTCL entity that derives its name from the descriptive studies and identification of unique blood cells by Sézary and Bouvrain during the 1930s.[19] Although this disease initially was reported in the late 19th century, Sézary and Bouvrain associated the malignant reticulemic (leukemic) erythroderma with circulating hyperchromatic mononuclear cells containing convoluted and/or

Table 113-3 Staging of Cutaneous T-Cell Lymphoma: Tumor-Node-Metastasis Classification

Classification	Description/Definition
T: Skin	
T0	Lesions clinically and/or pathologically suggestive of CTCL
T1	Limited plaques, papules, or eczematous patches covering <10% of skin surface
T2	Generalized plaques, papules, or erythematous patches covering ≥10% of skin surface
T3	Tumors
T4	Generalized erythroderma
N: Lymph nodes	
N0	No palpable adenopathy, lymph node pathology negative for CTCL
N1	Palpable lymphadenopathy; lymph node pathology negative for CTCL
N2	No palpable lymphadenopathy, lymph node pathology positive for CTCL
N3	Palpable adenopathy, lymph node pathology positive for CTCL
B: Peripheral blood	
B0	Atypical circulating cells not present (<5%)
B1	Atypical circulating cells present (>5%)
M: Visceral organs	
M0	No visceral organ involvement
M1	Visceral involvement (must have pathologic confirmation, and organ involved should be specified)

cerebriform nuclei. These same cells infiltrate adenopathic lymph nodes. The cells subsequently were designated *Sézary cells*. The first description in the English literature of Sézary syndrome was by Taswell and Winkelmann in 1961.[20] The clinical presentation of this syndrome includes exfoliative erythroderma, lymphadenopathy, and keratoderma or thickening of the skin of the palms and soles, often with development of cracks and fissures (palmoplantar hyperkeratosis; see Fig. 113-1F and G). Pruritus is a characteristic, often intense symptom leading to excoriations, exudation, and crust formation. Nail dystrophy (onychodystrophy), ectropion (eversion, giving a "pulled-down" appearance) of the lower eyelids, and alopecia frequently are observed.

Table 113-4 Modified Tumor-Node-Metastasis Staging System for Classification of Cutaneous T-Cell Lymphoma

Stage	T	N	M
IA	1	0	0
IB	2	0	0
IIA	1, 2	1	0
IIB	3	0, 1	0
III	4	0, 1	0
IVA	1–4	2, 3	0
IVB	1–4	0–3	1

B, peripheral blood; M, visceral organ; N, lymph node; T, skin.

From Bunn PA Jr, Lamberg SI: Report of the Committee on Staging and Classification of Cutaneous T-Cell Lymphomas. Cancer Treat Rep 1979;63:725–728.

Sézary syndrome is defined by the presence of Sézary cells in the peripheral blood and the characteristic clinical and histologic features of the skin. Although mycosis fungoides may manifest with erythroderma and similar clinical findings, Sézary cells are not detected in the peripheral blood by routine microscopic examination.

Extracutaneous disease involving sites beyond the blood and peripheral lymph nodes occurs in advanced CTCL. The reported frequency of extracutaneous involvement at autopsy ranges from 54% to 100%.[21,22] Loss of epidermotropism may play a role as the disease disseminates.[23] With disease progression, extracutaneous involvement becomes more common.[22] Clinical evidence of extracutaneous involvement of CTCL is classically manifested by peripheral lymhadenopathy.[22] Computed tomography (CT) demonstrates involvement of pelvic, abdominal, and axillary nodes that may not be palpable. Less commonly, thoracic nodal disease is recognized with this imaging technique. CT is not routinely used to stage early CTCL, because the yield is low. Positron emission tomography (PET) may be more sensitive than CT scanning.[24] In a retrospective review of 251 lymph nodes in 200 patients, Vonderheid and colleagues reported lymph node involvement to be associated with a poor prognosis and the survival of patients with small cell type (median survival, 40 months) to be better than that for those with other types (median survival, 20 months).[25] The Dutch Cutaneous Lymphoma Group reported that the presence of extracutaneous disease, the type and extent of cutaneous involvement, the response to initial therapy, and the presence of follicular mucinosis were associated with a higher rate of disease progression and mortality.[26]

Bone marrow involvement may develop during progression of CTCL. At autopsy, the incidence is 27% to 47%.[4,21] At initial staging, 7% to 13% of patients have evidence of marrow involvement.[27] Most patients with bone marrow involvement have concomitant nodal or organ involvement and shortened survival.[28] Liver involvement by CTCL is documented by nodular lymphoid infiltration of the portal tracts on liver biopsy and has been reported in 8% to 16% of patients with CTCL.[29,30] The presence of abnormal cells is not diagnostic of liver involvement.[29] Rarely, involvement of the central nervous system by CTCL has been documented by imaging studies, on tissue biopsy, or at autopsy.

TISSUE DIAGNOSIS

The diagnosis of cutaneous lymphoma is established by tissue biopsy. Punch biopsy of involved skin, to obtain specimens 4 to 6 mm deep, is recommended for evaluation of patch-, plaque-, and tumor-stage lesions. In selected tumor-stage cases, elliptical excision biopsy may be necessary. Several biopsies should be performed because multiple specimens often are required to demonstrate diagnostic findings. Specimens for immunophenotyping and molecular genetic studies should be snap-frozen in liquid nitrogen and stored at −70° C. Cell suspensions for flow cytometry and cytogenetic evaluation may be prepared from tissue.

The classic histologic findings diagnostic of CTCL consist of abnormal lymphocyte morphology, a band-like superficial dermal infiltrate, epidermotropism, and Pautrier's microabscesses (Fig. 113-2). Of note, significant variability exists in the expression of these pathologic characteristics and the degree of individual abnormalities.[31] In addition, significant intraobserver and interobserver variability has been documented. In a study of 73 skin biopsy specimens from patients with mycosis fungoides reviewed on two separate occasions by three expert hematopathologists, an accurate diagnosis was rendered on both readings approximately 50% of the time.[32] No single histopathologic criterion will establish the diagnosis. Lympho-

cytes within the epidermis that are larger than those within the dermis is an important feature of epidermatropism.[33] Pautrier's microabscesses are present in 4% to 37% of cases.[34]

On microscopic examination, the lymphocytes in CTCL (called mycosis cells or Sézary cells) have variable but usually ample cytoplasm. Nucleoli of the neoplastic cells are relatively large and hyperchromatic. Mycosis cells can be isolated from various tissues by touch preparation and microscopic examination. Sézary cells circulate in the blood and can be enriched in vitro by density centrifugation or immunophenotypic characteristics. The prominent characteristics of individual nuclei of Sézary cells are their irregularity, with prominent indentations or convolutions that have a cerebriform appearance[19] (Fig. 113-3). In 1968, Lutzner and Jordan further characterized the serpentine, or cerebriform, nuclei by electron microscopic examination[35] (Fig. 113-4). Reactive lymphoid cells infiltrating the skin in dermatitis, lichen planus, drug eruptions, psoriasis, and other dermatoses may have similar nuclear morphologic features on light microscopy, but further examination reveals a normal nuclear diameter, nuclear-to-cytoplasm ratio, and nuclear contour index in these disorders. A review of 222 biopsy specimens from patients with mycosis fungoides or Sézary syndrome reported that CTCL produces the patterns for diagnosing inflammatory disease, including superficial perivascular invasion and atypical lymphocytes in nearlyt half of the cases.[36] The cells that mimic mycosis cells or Sézary cells represent activated T lymphocytes. Therefore, morphologic examination alone

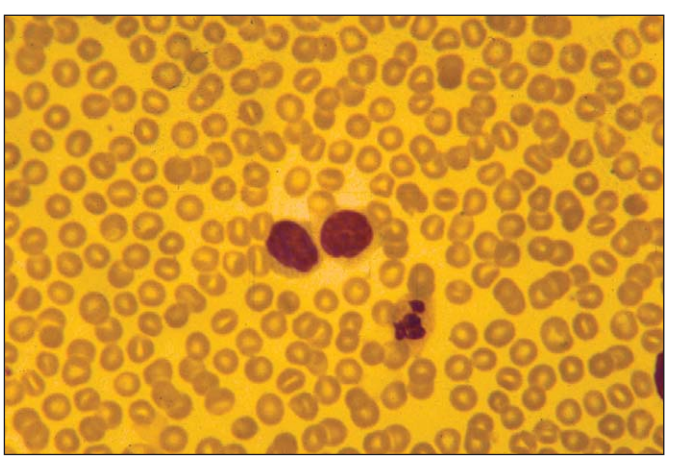

Figure 113-3 • Peripheral blood smear demonstrating irregular Sézary nucleus with cerebriform appearance. (Wright's stain.)

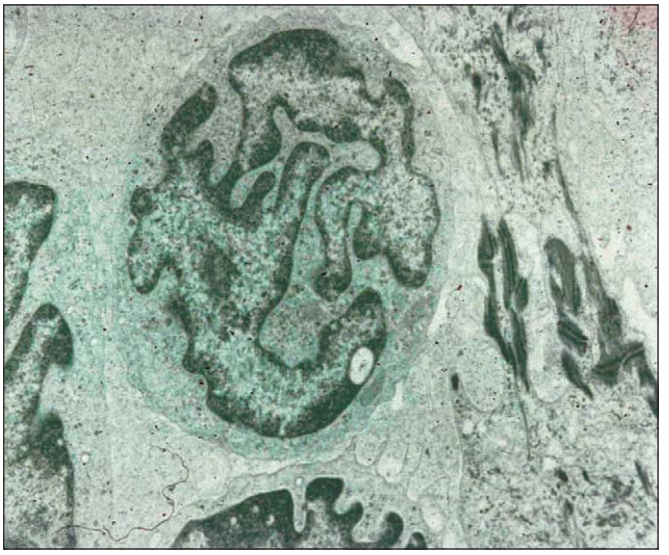

Figure 113-4 • Electron micrograph of "serpentine," or cerebriform, nuclei of Sézary cells from peripheral blood.

can result in misdiagnosis. The limitation of light microscopy has led to the development of more sophisticated approaches to CTCL diagnosis.[15] Of interest, the EORTC reported that identification of epidermal lymphocytes with extremely convoluted nuclei was 100% specific and 92% sensitive in establishing the diagnosis.[32] The tumor stage of CTCL is characterized by a dense dermal infiltrate that often extends into the deep dermis and subcutis and becomes nonepidermotropic or less epidermotropic. The individual malignant cells are pleomorphic large cells with prominent nucleoli. Complete transformation to a large cell variant that resembles diffuse large cell lymphoma or anaplastic large cell lymphoma typically is seen in tumors and occasionally is present in plaques and erythroderma.[37,38] Skin biopsy specimens from patients with Sézary syndrome, in contrast with those from patients with mycosis fungoides, frequently lack prominent epidemotropism. Buechner and Winklemann reported that 17% of skin biopsies from patients with Sézary syndrome were nondiagnostic by light microscopy alone.[39] Patients whose skin biopsy specimen demonstrated only a lichenoid or bandlike infiltrate, without other criteria to establish a diagnosis of mycosis fungoides or Sézary syndrome, have been shown to have CTCL by other diagnostic and laboratory criteria. Nonetheless, the presence of abnormal lymphocytes and characteristic Pautrier's microabscesses is important for the diagnosis of mycosis fungoides and Sézary syndrome. The propensity to develop Pautrier's microabscesses in Sézary syndrome is less prominent, however, which may hinder confirmation of the diagnosis.[40] The cellular composition and morphology of the dermal infiltrate in Sézary syndrome are similar to those in mycosis fungoides. In Sézary syndrome, the abnormal cells characteristically are present and reflect peripheral blood disease, which is a major criterion for establishing the diagnosis.[38,39]

The classic immunophenotype of mycosis fungoides and Sézary syndrome neoplastic cells is $CD3^+$, $CD4^+$, $CD45RO^+$, and $CD8^{-}$[15] (Fig 113-5). Aberrant antigen expression of the malignant T-cell population is observed for mycosis fungoides and Sézary syndrome and is manifested as decreased or absent expression of pan–T-cell antigens (CD2, CD3, CD5), absent expression of subset antigens ($CD4^-$, $CD8^-$), or coexpression of T-cell antigens ($CD4^+$, $CD8^+$).[41] Transformed cells in mycosis fungoides and Sézary syndrome have been shown to acquire CD30 antigens, which may lead to confusion with $CD30^+$ large cell lymphoma or lymphomatoid papulosis.[42] In other cases, neoplastic cells of CTCL may acquire Leu-M1, leading to confusion with Hodgkin's lymphoma.[43] No immunohistochemical techniques clearly demonstrate clonality of T-cell lymphoproliferative disorders. Despite the use of immunohistochemical techniques, a definitive diagnosis may not be possible in the patch stage of mycosis fungoides or in early Sézary syndrome.

Cytogenetic abnormalities have been identified in CTCL. The most common numerical change is loss of the long arm of chromosome 10 (i.e., 10q).[44] Other reported abnormalities from skin, peripheral blood, lymph nodes, and bone marrow include complex translocations or deletions in chromosomes 1, 2, 6, 9, 11, 13, 14, and 17.[44]

Clonal T-cell receptor gene rearrangements are among the most sensitive techniques in CTCL and are detected in most cases. Clonal T-cell antigen receptor (TCR) gene rearrangements are identified as non-germline bands on Southern blot analysis on DNA hybridized to TCR-beta, TCR-gamma, and TCR-delta chain molecular probes[45] (Fig. 113-6). Clonal rearrangements of the TCR-beta gene have been documented in most patients.[46] In early patch-stage mycosis fungoides, the number of infiltrating T cells is minimal, and Southern blot analysis may not detect clonal T-cell populations.[47] Documented

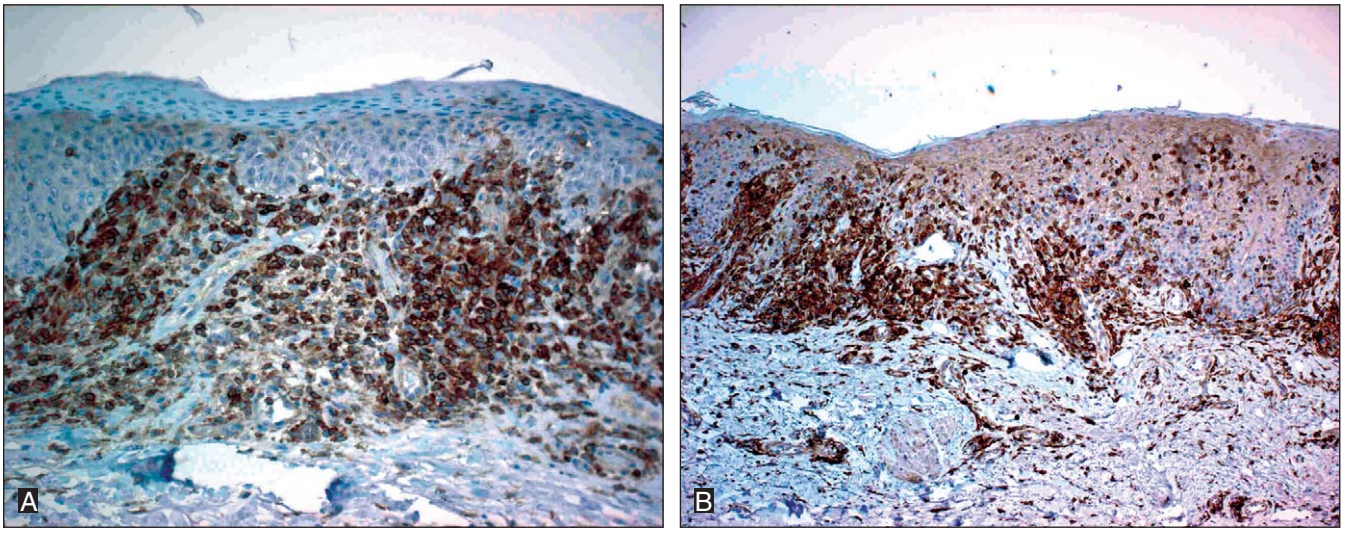

Figure 113-5 • **A,** Uniform $CD4^+$ cellular infiltrate in dense bandlike pattern in papillary dermis of Sézary syndrome. **B,** $CD4^+$ cells forming a dense dermal infiltrate and Pautrier's microabcesses in mycosis fungoides (Hematoxylin-eosin; original magnification, 160×.)

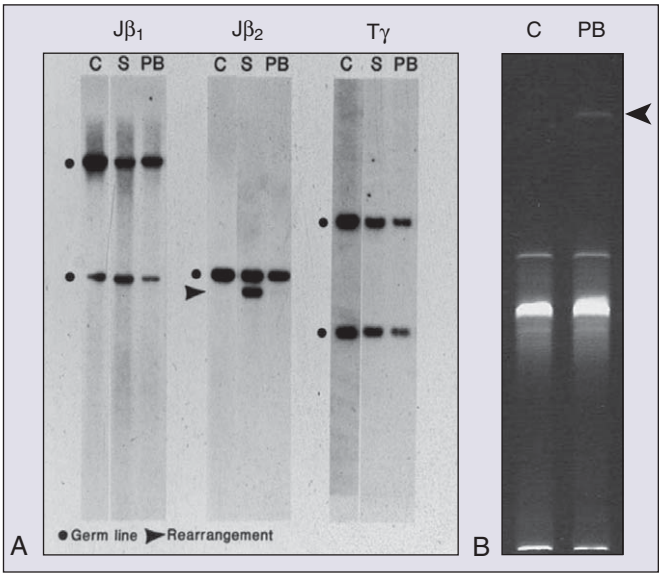

Figure 113-6 • **A,** Immunogenotyping by Southern blot analysis for a patient with Sézary syndrome. Control (C), skin (S), and peripheral blood (PB) specimens. A distinct band of clonal rearrangment is identified *(arrow)* using probes that recognize the T-cell beta chain genes (Jβ2). Only germline bands are identified in the Jβ1 gene. **B,** Polymerase chain reaction (PCR) analysis of PB identified a distinct band of clonal rearrangement *(arrow)*.

lymph node involvement by clonal TCR gene rearrangement has been associated with decreased survival.[48] Clonal TCR gene rearrangements are found in disorders that are not overtly malignant, however, including lymphomatoid papulosis, pityriasis lichenoides, and pagetoid reticulosis. T-cell clonality has been reported in 6% to 24% of benign skin disorders characterized by a lymphoid infiltrate.[49] Polymerase chain reaction (PCR) techniques to amplify specific genetic rearrangements can increase the sensitivity 1000-fold.[50] The detection of circulating clonal cells is not likely to be an indicator of worse prognosis. These technical advances provide the capability to improve monitoring of disease progression and response to treatment and for earlier detection of minimal residual disease, quiescent disease, or relapse.

VARIANTS OF MYCOSIS FUNGOIDES AND SÉZARY SYNDROME AND CUTANEOUS B-CELL LYMPHOMA

A remarkable spectrum of variants of Sézary syndrome and mycosis fungoides and B-cell lymphoma have been recognized. These disorders are characterized by unique immunohistologic features and require disease-specific clinical and therapeutic interventions. The currently recommended therapeutic interventions are summarized in Table 113-3.

Variants and Subtypes of Myosis Fungoides

Folliculotropic mycosis fungoides is a disorder of localized alopecia with mucin deposition in the hair follicle, with variable inflammation, characterized clinically by multiple grouped follicular papules with occasional formation of patches or nodules, with preferential involvement of the head and neck area with severe pruritus[51] (Fig. 113-7). On histopathologic examination, sparing of the epithelium is seen, and most cases demonstrate mucinous degeneration of the follicular epithelium.

Pagetoid reticulosis is characterized by solitary slow-growing plaques (Woringer-Kolopp type) or disseminated patches on the hands or feet that grow slowly and progress to disseminated skin lesions (Ketron-Goodman type).[52] The CD30 antigen often is expressed. The solitary slow-growing lesion has a chronic course of years to decades.

Granulomatous slack skin is a disorder characterized by excessive redundant folds of skin and plaques in the axilla and groin.[53–55] A striking granulomatous reaction and loss of dermal elastic tissue accompany the lymphocytic infiltrate, and the disease may progress to disseminated T-cell lymphoma. Although in most cases the disease has an indolent course, an association with Hodgkin's lymphoma has been reported in one third of affected patients, and an association with mycosis fungoides has been reported.[54]

Variants and Subtypes of Sēzary Syndrome

The variants and subtypes of Sézary syndrome are multiple. They include adult T-cell leukemia/lymphoma; primary cutaneous $CD30^+$ lymphoproliferative disorders (primary cutaneous anaplastic large cell lymphoma, lymphomatoid papulosis, and borderline cases); subcutaneous panniculitis-like T-cell lymphoma; extranodal natural killer (NK)/T-cell lymphoma of nasal type; primary cutaneous peripheral T-cell lymphoma, unspecified; and $CD4^+/CD56^+$ hematodermic neoplasm (blastic NKcell lymphoma).

Adult T-cell leukemia/lymphoma may manifest with skin lesions but few or absent circulating cells and is associated with the human T-cell leukemia virus 1 (HTLV-1) with integrated HTLV-1 genes in all cases.[55] A skin lesion smoldering variant has been reported.[56] Patients may present with papules (22%) or plaques (19%).[57]

Primary cutaneous $CD30^+$ lymphoproliferative disorders, which include primary cutaneous anaplastic large cell lymphoma, lymphomatoid papulosis, and borderline cases, may account for up to 30% of cutaneous lymphomas.[58] Histologic criteria alone do not separate these disorders, and long-term follow-up establishes the diagnosis.[59] Primary cutaneous anaplastic large-cell lymphoma expresses CD30 in more than 75% of cells, and most express the cutaneous lymphocyte antigen (CLA). Patients initially present with localized nodules, tumors, or papules. Up to 20% of patients have multifocal lesions, and 10% have disseminated disease. The survival is greater than 10 years.[59] Lymphomatoid papulosis is defined as a chronic, recurrent, erythematous, and self-healing papulonecrotic or papulonodular skin disease with histologic features suggestive of a ($CD30^+$) malignant lymphoma[60] (Fig. 113-8). The lesions spontaneously resolve in 3 to 12 weeks. The clinical course is unpredictable, with duration of disease activity ranging from a few months to 20 years. Hodgkin's lymphoma, cutaneous anaplastic large cell lymphoma, or mycosis fungoides may precede, be associated with, or follow lymphomatoid papulosis.[59] Morphologic patterns have been classified as types A, B,

Figure 113-7 • Follicular mucinosis manifested as patches of alopecia.

Figure 113-8 • Lymphomatoid papulosis: Characteristic erythematous papulonodules with crust and ulceration.

and C.[60] Type A lesions resemble those of CD30$^+$ anaplastic large cell lymphoma or Hodgkin's lymphoma, and type B lesions are composed of small lymphoid cells. In one series of 118 patients with lymphomatoid papulosis, progressive disease developed in only 4%; 2% died of systemic disease.[59]

Subcutaneous panniculitis-like T-cell lymphoma characteristically involves the legs, with infiltrates of γ/β$^+$, CD3$^+$, CD8$^+$, and CD4$^-$ cytotoxic protein–expressing lymphocytes that may rim fat cells accompanied by many macrophages; the epidermis and dermis remain uninvolved.[15] Fevers, fatigue, weight loss, and the hemophagocytic syndrome may be clinical manifestations and are associated with a rapid and progressive course.[61] The nodules or plaques may be solitary or multiple (Fig. 113-9).

Other disorders to be considered in the differential diagnosis include extranodal NK/T-cell lymphoma, nasal type; primary cutaneous peripheral T-cell lymphoma, unspecified; primary cutaneous aggressive epidermotropic CD8$^+$ cytotoxic T-cell lymphoma (provisional entity); cutaneous gamma/delta T-cell lymphoma (provisional entity); primary cutaneous CD4$^+$ small or medium-sized pleomorphic T-cell lymphoma (provisional entity); primary cutaneous peripheral T-cell lymphoma, unspecified; and CD4$^+$/CD56$^+$ hematodermic neoplasm (blastic NK-cell lymphoma).[15] The management of disorders other than mycosis fungoides and Sézary syndrome as recommended by the WHO-EORTC is outlined in Table 113-5.

Figure 113-9 • Subcutaneous T-cell lymphoma.

Cutaneous B-Cell Lymphomas

Primary cutaneous B-cell lymphoma may account for to 20% of cutaneous lymphomas[62] (Fig. 113-10). This group of disorders must be distinguished from pseudolymphoma.[63] The WHO-EORTC classification recognizes primary cutaneous marginal zone B-cell lymphoma (PCMZL); primary cutaneous follicle center lymphoma (PCFCL); primary cutaneous large B-cell lymphoma, leg type (PCLBCL-LT); and primary cutaneous large B-cell lymphoma, other (PCLBL–other). The reclassification resulted in reassignment to other categories for 5.3% of the EORTC scheme cases and 36.3% of the WHO scheme cases.[64] The 5-year disease specific survival rates are 98% in PCMZL, 95% in PCFCL, and 50% in PCLBCL-LT.[64] In this classification, PCFCL is defined as a tumor of follicle center cells,composed predominantly of large cleaved cells that do not express Bcl-2 and MUM-1, in contradistinction to PCLBCL-LT cells, which express Bcl-2 and MUM-1.[65] PCFCL-LT has been associated with a poor prognosis. The reported disease-specific 5-year survival rate was 50%, and the overall survival (OS) rate was 37%.[64]

PCMZL is an indolent lymphoma composed of small B cells and is considered to be part of the spectrum of extranodal marginal zone B-cell lymphomas, which commonly involve mucosal sites, called mucosa-associated lymphoid tissue (MALT) lymphomas. This group includes cases previously designated as primary cutaneous immunocytoma and includes primary cutaneous myeloma (extramedullary plasmacytoma of skin).[66,67] These lesions occur most commonly in females and most commonly develop on sun-exposed areas of the skin, especially on the arms. The lesions are violaceous papules, plaques, or nodules. Dissemination is rare.[67] These lymphomas are nodular or diffuse, with sparing of the epidermis, and rarely transform into diffuse large B-cell lymphoma. The lesions are CD20$^+$, CD79a$^+$, Bcl-2$^+$, CD5$^-$, CD10$^-$, and Bcl-6$^-$, with clonally rearranged immunoglobulin heavy chain (IgH) genes. Localized lesions can be treated with radiation therapy or surgical resection. Multifocal lesions can be treated with oral chlorambucil, interferon-α (intralesional or subcutaneous), or rituximab.[68]

PCFCLs are follicular, follicular and diffuse, or diffuse, with sparing of the epidermis; lesions typically appear on the head and torso. Patients present with solitary or grouped plaques and tumors. In a minority of cases, the initial presentation is with multifocal disease, which has an unfavorable prognosis.[69] The cells are CD20$^+$, CD79a$^+$, CD10$^+$ in follicular cases, CD5$^-$, and Bcl-2$^-$, and genes are clonally rearranged with no consistent cytogenetic abnormalities.[15] In contrast with systemic follicular lymphoma, these lesions do not demonstrate the t(14;18) translocation.[70] The therapy of choice in patients with localized disease is radiation therapy, even in cases with a predominance of large "cleaved" cells.[71] Cutaneous relapses may be treated with radiation therapy. Anthracycline-based chemotherapy is recommended in patients with extensive cutaneous disease and extracutaneous disease.[72] Systemic and intralesional rituximab is active in this disease.[73] Recent studies report t(14;18) and Bcl-2 expression; expression of Bcl-2 by more than 50% of neoplastic cells in patients with a diffuse pattern is associated with an unfavorable prognosis.[74,75]

PCLBCL-LT is PCLBCL characteristically manifesting with red or bluish-red skin lesions on the lower extremities, and uncommonly seen in other sites, that often disseminate to extracutaneous sites and occurs predominantly in females.[64] The cells are CD20$^+$, CD79a$^+$, and Bcl-2$^+$. Patients with a single lesion on one leg had a 5-year disease-free survival rate of 100%, versus 45% for patients with multiple skin lesions on one leg and 36% for those with lesions on

Table 113-5 Management of Disorders Other Than Mycosis Fungoides and Sézary Syndrome as Recommended by the WHO-EORTC

Disease Type	Management Strategies
Folliculotropic mycosis fungoides	Total body electron beam irradiation
	PUVA combined with retinoids or interferon-α
	Local radiation therapy
Pagetoid reticulosis	Radiation therapy or surgical excision
	Topical steroids or topical nitrogen mustard
Granulomatous slack skin	Radiation therapy
	Surgical excision
Adult T-cell leukemia/lymphoma	In chronic and smoldering cases affecting skin only, skin-targeted therapies
Primary cutaneous anaplastic large-cell lymphoma	Solitary or localized: Radiation therapy or surgical excision
Extracutaneous or progressive disease	Anthracycline-based chemotherapy
Lymphomatoid papulosis	Observation
	Methotrexate 5–20 mg/week
	PUVA
	Topical chemotherapy
Subcutaneous panniculitis-like T-cell lymphoma	Systemic corticosteroids
	Anthracyline chemotherapy and radiation therapy
Extranodal NK/T-cell lymphoma, nasal type	Radiation therapy ± chemotherapy (stage I/II disease)
	Chemotherapy for advanced disease
Primary cutaneous aggressive epidermotropic $CD8^+$ cytotoxic T-cell lymphoma	Anthracycline chemotherapy
Cutaneous gamma/delta T-cell lymphoma	Systemic chemotherapy
Primary cutaneous $CD4^+$ small or medium-sized pleomorphic T-cell lymphoma	Radiation therapy or surgical excision
	Cyclophosphamide
	Interferon-α
Primary cutaneous peripheral T-cell lymphoma, unspecified	Anthracycline chemotherapy
$CD4^+/CD56^+$ hematodermic neoplasm (blastic NK-cell lymphoma)	Acute leukemia systemic therapy regimens

NK, natural killer; WHO-EORTC, World Health Organization–European Organization for Research and Treatment of Cancer.
Data from Willemze R, Jaffe ES, Burg G, et al: WHO-EORTC classification for cutaneous lymphomas. Blood 2005;105:3768–3785.

both legs.[76] Systemic anthracycline-based chemotherapy is recommended.[76] Rituximab is active in this disease in combination with systemic chemotherapy.[73]

Primary cutaneous diffuse large B-cell lymphoma–other includes morphologic variants of lymphoma, plasmablastic lymphomas, primary cutaneous T-cell or histiocyte-rich B-cell lymphomas, and intravascular large B-cell lymphoma. Intravascular large B-cell lymphoma is characterized by an accumulation of malignant large B cells within the blood vessels that affects the central nervous system, lungs, and skin.[77] Patients characteristically present with disseminated disease but initially may exhibit only skin involvement, with violaceous patches or plaques or telangiectasias of the legs or torso.[78] Patients presenting with only cutaneous disease enjoy better survival, with a 3-year OS rate of 56%, versus 22% for the disseminated form.[78] Anthracycline-based chemotherapy is associated with a 60% response rate and a 3-year OS rate greater than 30%.[77] The R-CHOP regimen (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone) should be considered as an initial treatment approach.[77]

STAGING AND PROGNOSIS OF MYCOSIS FUNGOIDES AND SÉZARY SYNDROME

As with Hodgkin's disease and NHL, the prognosis for CTCL and its variants is related to the stage of the disease. The significant prognostic factors in CTCL are the extent and type of skin involvement. The Mycosis Fungoides Cooperative Group adopted a modified TNM classification in 1975, which was further modified by the Staging Committee at the International Workshop on Mycosis Fungoides (see Tables 113-3 and 113-4).[79] A modified TNM classification for primary cutaneous lymphomas other than mycosis fungoides and Sézary syndrome has been proposed.[80] The TNM classification system is not routinely used in clinical practice.

The greater the percentage of involvement of skin surface area by CTCL, the worse the prognosis. Involvement of less than 10% of the body surface area by CTCL—stage IA—portends a better prognosis than that associated with stage IB, defined as greater than 10% skin involvement. Patients with plaque-stage disease have a more favorable prognosis than that for patients with tumor-stage disease. In mycosis fungoides, 90% of patients with patch- or plaque-stage disease with less than 10% skin involvement survived 15 years or longer.[81] Among 309 patients with mycosis fungoides, the 5-year disease-free survival rate was 100% for those with limited cutaneous disease, 80% for those with tumor-phase disease, and 40% for those with lymph node–phase disease.[82] Survival of patients with tumor-stage disease is reported to be better than that of patients with stage III or erythrodermic disease.[83] For patients with limited patch- or plaque-stage mycosis fungoides, life expectancy is similar to that for an age-, sex-, and race-matched control population. Unequivocal histologic involvement in the lymph nodes is predictive of survival, with a median survival actuarial survival of 53 months with such involvement and 137 months without.[84] The prognosis in Sézary syndrome is poor, with a median survival time of 2 to 4 years.[85]

The recommended approach to clinical evaluation for staging is outlined in Box 113-1 and can serve as a general guide for clinical trials.[79] Liver biopsies are not indicated in routine staging for patients with CTCL. The role of CT scans is controversial. Routine CT scanning does not improve detection of advanced disease but may be clinically useful in early plaque-stage disease.[86] CT provides only anatomic information. Lymphadenopathy in CTCL may be related to underlying disease but also to dermatopathic lymphadenopathy.[87] In a study at Stanford University, only 5 patients had enlarged lymph nodes on CT, whereas integrated PET and CT (PET/CT) revealed metabolic activity in all 13 patients.[88] The intensity of PET activity correlated with the histologic lymph node grade.

On initial diagnosis, approximately 42% of patients have plaques covering less than 10% of the body surface (T1), 30% are characterized by T2, 16% have tumors (T3), and 12% have erythroderma (T4).[79,83]

Box 113-1. APPROACH TO CLINICAL EVALUATION FOR STAGING OF CUTANEOUS T-CELL LYMPHOMA

- Complete history and physical examination
- Whole-body mapping of skin lesions with or without photography
- Complete blood count, differential count, and platelet count; Sézary cell count
- Serum chemistries (liver and renal function tests; determination of serum levels of calcium, phosphorus, creatinine, and uric acid)
- Chest radiography
- Skin biopsy for routine histology and possible immunophenotyping/T-cell receptor gene rearrangement analysis
- Lymph node biopsy (palpable node from draining area; cervical before axillary before inguinal)
- Evaluation of other organs if foregoing tests suggest involvement; computed tomographic scan, liver biopsy, and bone marrow biopsy only for patients with stage II, III, and IV disease

Bone marrow involvement is determined by the method of assessment. On morphologic analysis, Salhany and colleagues demonstrated aggregates of lymphocytes and cerebriform nuclei in 21.7% of cases and abnormal lymphoid aggregates in 31.6%.[89] Infiltrative disease was associated with peripheral blood involvement. The frequency of clonal T-cell involvement in the bone marrow has been reported to be 75% and does not alter prognosis.[90]

Other prognostic factors have been reported. The absence or presence of greater than 5% of Sézary cells in total lymphocyte count and a $CD4^+/CD7^-$ phenotype double the risk of death.[91] Additional prognostic factors include age of 60 years or older, elevated lactate dehydrogenase (LDH) level, and a low percentage of $CD8^+$ cells in the lymph node.[92,93]

HISTOLOGIC TRANSFORMATION

Transformation is defined as the presence of greater than 25% large cells and represents an evolution of the original clone. The risk of transformation has been reported to be 12% to 23%, with the reported median times from diagnosis to transformation of 12 months to 6.5 years and a median survival time of 19 to 22 months.[94,95] Age and extracutaneous involvement were associated with worse prognosis.[95]

SECOND CANCERS

The Finnish Cancer Registry and others have reported an increased overall risk of lung cancer, small cell lung cancer, Hodgkin's lymphoma, and NHL.[96,97]

CAUSE OF DEATH

The most common cause of death in CTCL is infection, the most common organisms of which are *Staphylococcus aureus*, members of the family Enterobacteriaceae, and *Pseudomonas aeruginosa*.[98, 99] Disseminated herpes and fungal infections may occur in patients with advanced disease. Up to 47% of deaths are caused by cardiopulmonary disease and secondary malignancy.[99, 100] Patients with cutaneous tumors and erythroderma characteristically die of complications of progressive disease.

THERAPY

Overview

Therapeutically, CTCL is similar to low-grade NHL in that only limited stage disease is potentially curable, and both of these diseases are remarkably responsive to many different therapeutic modalities despite eventual relapse. Patients with either type of lymphoma may respond to the same therapeutic modality on more than one occasion, and they typically survive for years after the initial diagnosis. Advanced

disease is rarely curable, and both CTCL and indolent NHL may transform into higher-grade lymphoproliferative disorders. In the absence of a therapeutic approach that leads to long-term disease-free survival and cure, current therapies are tailored to the extent, burden, and type of disease present. The primary goals of treatment are to control the cutaneous disease, to obtain symptomatic relief, and to achieve complete clinical remission.

Therapies available for the treatment of CTCL are wide ranging and illustrate the distinctive presentation and disease course of this type of lymphoproliferative disorder, as well as reflecting unique challenges that face clinicians and therapists in treatment of CTCL and in clinical management of the patient. Therapies broadly include skin-directed biologic response modifiers, monoclonal antibodies, and cytotoxic therapy. Therapeutic options include topical treatments with corticosteroids, chemotherapy with nitrogen mustard or carmustine (BCNU), ultraviolet B (UVB) phototherapy, photochemotherapy with psoralen plus ultraviolet A (PUVA), irradiation with electron beam or photon therapy, systemic chemotherapy with either single or multiple agents, combined-modality therapy (chemotherapy, electron beam radiation therapy, and other combinations), extracorporeal photochemotherapy, interferons, monoclonal antibody therapy, retinoids, purine analogs, cyclosporine, acyclovir, autologous peripheral blood stem cell transplantation, allogeneic bone marrow transplantation, dentileukin difitox, and alemtuzumab (Table 113-6).

Factors other than disease stage that require consideration in the management of patients with CTCL include the general health and age of the patient, availability of various therapeutic options, and the extent and aggressiveness of the disease (see Table 113-6). In the context of therapeutic results and toxicities, it must be recognized that many of the published studies of CTCL are not prospective randomized trials with control groups. Because CTCL is an uncommon disease, multicenter cooperative clinical trials have been limited, and consensus is not well defined at this time. Table 113-7 details specific treatment options for different stages of mycosis fungoides and Sézary syndrome.

Table 113-6 Therapeutic Options for Cutaneous T-Cell Lymphoma

Topical medications
Corticosteroid
Mechlorethamine (nitrogen mustard)
Carmustine (BCNU)
Bexarotene gel
Imiquimod
UVB phototherapy
PUVA photochemotherapy
High-intensity UVAI phototherapy
Photodynamic therapy (PDT)-5-ALA
Radiotherapy with electron beam
Photon irradiation
Single-agent chemotherapy
Methotrexate
Pegylated liposomal doxorubicin
Temozolomide
Combination chemotherapy
CHOP
Combined-modality therapy
Extracorporeal phototherapy (ECP)
Cytokines
Interferons
Interleukin-2
Thymopetin
Monoclonal antibody therapy
Alemtuzumab (anti-CD52)
Anti-CD4
Retinoids
Isotretinoin
Acitretin
Bexarotene
Purine nucleoside analogs
2′-Deoxycoformycin (pentostatin)
Fludarabine
2-Chlorodeoxyadenosine (cladribine)
Gemcitabine
Immunotoxins
IL-2 fusion toxin (denileukin diftitox)
Pseudomonas immunotoxin anti-Tac(Fv)-PE38 (LMB-2)
Histone deacetylase inhibitors
Vorinostat
Depsipeptide
Vaccination-immunotherapy
Bone marrow transplantation
Autologous
Allogeneic
Nonmyeloablative allogeneic

CHOP, cyclophosphamide, doxorubicin, vincristine, prednisone; IL-2, interleukin-2; PUVA, psoralen plus ultraviolet light A; UVB, ultraviolet (light) B.

General Skin Care Measures

Nonspecific topical treatment of mycosis fungoides and Sézary syndrome includes supportive therapies that miminize skin irritation, provide lubrication and adequate hydration, and ameliorate inflammatory reactions of the skin that accompany CTCL. After the diagnosis of CTCL has been established with skin biopsy, low-potency and mid-potency topical corticosteroid creams or ointments may be used to control the symptoms of pruritus and dermatitis.[101] Topical corticosteroids should be avoided or discontinued for several weeks before skin biopsy because these agents suppress cutaneous inflammatory responses and can potentially mask the histopathologic features of CTCL. Regular soaking baths and application of lubricating cream to maintain skin hydration also are beneficial. Prompt treatment of infected areas of the skin and colonized or purulent ulcers minimizes the potential for more serious infections.[99]

Topical Therapies

Topical Chemotherapy

Topical corticosteroids are the mainstay of treatment for CTCL. Twice-daily application of topical class I steroids for 2 to 3 months is effective in mycosis fungoides plaque- and patch-stage disease, probably by inducing apoptosis. Skin atrophy and adrenal suppression are potential complications. In a series of 79 patients, 63% achieved a complete remission and 31% a partial remission on follow-up evaluation at a median of 9 months.[102]

Mechlorethamine (nitrogen mustard), available as mechlorethamine hydrochloride, was the first topical agent with demonstrated efficacy in CTCL.[103] Since its initial clinical use during the late 1940s at the Mayo Clinic, this alkylating drug has proved effective

Table 113-7 Stage-Specific Options for Management of Cutaneous T-Cell Lymphoma

PATCH, LIMITED AND GENERALIZED PLAQUE

CHOP, cyclophosphamide, doxorubicin, vincristine, prednisone; PUVA, psoralen plus ultraviolet light A; UVAI, ultraviolet light A; UVB, ultraviolet light B.

in limiting the progression of disease and controlling symptoms of cutaneous lesions in patients with CTCL. The agent undergoes rapid degradation to an active ethylenimonium ion, which has high antimitotic activity and a half-life of less than 10 minutes. Mechlorethamine may be prepared and applied in any of several different ways. It is soluble in water and typically is formulated at a concentration of 10 to 20 mg/dL. Alternatively, an alcoholic extract of mechlorethamine can be suspended in an oil-water base such as Aquaphor, which remains stable for longer than a month. Mechlorethamine is routinely applied to the entire skin surface, except the eyelids, genitalia, rectum, and intertriginous areas, where the potential for significant irritation limits its use. Application of the solution is performed daily and increased to twice a day, or the concentration can be doubled. The initial treatment program lasts 6 to 12 months, and maintenance therapy 3 times per week is continued for 1 to 2 years or longer. The agent does not cause cytopenias or secondary leukemias because it is not absorbed systemically. Its use as described is an efficient and conservative outpatient program in patients without large tumors or systemic involvement.

Mechlorethamine had been evaluated in clinical trials. Vonderheid and colleagues reported on 324 patients with CTCL, with complete remission rates of 80% in stage IA disease, 68% in stage IB, 61% in stage IIA, 49% in stage IIB, and 60% in stage III.[104] Twenty percent of patients had a complete remission of 4 years or more, and 11% had continuous complete remission. Other therapies have been used in numerous patients, including local irradiation, electron beam radiation therapy, PUVA therapy, UVB phototherapy, and chemotherapy. None of the 34 patients who were in long-term complete response (CR) received electron beam radiation therapy or phototherapy, but 9 patients received chemotherapy, including intravenous methotrexate and mechlorethamine. Therapy was discontinued within 6 months of attainment of CR in 10 of 34 patients, who did not experience a relapse after 8 years. The probability of achieving a CR at 2 years was 75.8% for stage I, 44.6% for stage II, and 48.6% for stage III in 117 patients for whom the only other treatment was radiation therapy, and the median time to CR was 11 months.[105] In 123 patients who received only ointment-based mechlorethamine in Aquaphor or polyethylene gel, the CR rate was 51% in T1 disease; 26% in T2 disease; zero in T3; and 22% in T4.[106,107] Of the patients who relapsed, 54% achieved a second CR.[107] The treatment durations were variable, with Hoppe and associates recommending treatment for 1 to 2 years after achieving a response,[106] Ramsay and coworkers, treatment for 6 months after clearing and a taper of 1.5 years,[105] and Vonderheid and colleagues, only 6 months of therapy.[104] The major toxic effect of mechlorethamine is allergic toxic contact dermatitis, which occurs in 35% to 65% of patients.[104–107] The incidence can be decreased to less than 10% with use of mechlorethamine dissolved in ointment. Avoidance of skin exposure to sunlight is recommended. Other toxicities include dry skin, irritant dermatitis, hyperpigmentation, bullous reactions, urticaria, Stevens-Johnson syndrome, and telangiectasias.[106] An increased risk of second malignancies of squamous cell carcinoma and basal cell carcinoma with use of this agent has been recognized,[104,106] although most patients received multiple other therapies. In the series reported by Hoppe and associates,[106] secondary cutaneous malignancies developed in only 1 of 14 patients who received mechlorethamine alone. No randomized trials with adequate patient numbers have compared topical therapy with other therapeutic modalities.

Carmustine applied at daily doses of 10 to 20 mg per day for 4 to 8 weeks produced responses similar to those observed with mechlorethamine.[108] In contrast with the absence of such effects with mechlorethamine, bone marrow suppression occurred in 7.4% of patients. Chronic skin telangiectasias also may develop with use of carmustine.

Topical bexarotene 1%, applied twice daily, is the first synthetic retinoid approved by the U.S. Food and Drug Administration (FDA). The complete remission rates ranges from 21% to 23%, and the mean overall response (OR) rate is 63%, with a median time to progression of 149 days (range, 52 to 342 days).[109,110] The response rate in a series of 94 patients was reported to be 45% with a dose schedule of 300 mg/m^2 per day.[110] Rash was reported in 56% of the patients and pruritus in 18%. The most frequent side effects are hypertriglyceridemia, pancreatitis, hypercholesterolemia, hypothyroidism, and headaches. Bexarotene induces apoptosis in CTCL.[111]

Other topical agents that have been evaluated include cytarabine, dianhydrogalactitol, dacarbazine, guanazole, teniposide, hydroxyurea, thiotepa, and methotrexate.[112]

Ultraviolet B Phototherapy and Ultraviolet A Photochemotherapy

UVB phototherapy has been used for years in the treatment of early patch-stage CTCL and the premalignant dermatosis, large-plaque parapsoriasis. The treatment is administered three times per week. A retrospective study has supported the clinical observations that UVB phototherapy provides favorable responses including clinical remission and lasting improvement in early patch-stage CTCL.[113] UVB penetrates only the epidermis and the superficial dermis, however, and has no effect on more indurated plaque-stage or extensive forms of CTCL. UVB phototherapy in patients with darkly pigmented skin is less effective because melanin absorbs the ultraviolet radiation.[114] UVB phototherapy has a tendency to aggravate the erythroderma and pruritus of Sézary syndrome and should be avoided for this disorder.

Treatment of CTCL with PUVA with 8-methoxypsoralen preparations administered orally has been shown to be effective in the control of early disease. 8-Methoxypsoralen is a member of a family of photoactivated compounds that inhibit DNA synthesis through formation of monofunctional or bifunctional adducts and crosslinks of nucleic acids, resulting in apoptotic cell death. PUVA has other biologic effects that may contribute to the responses in CTCL, including direct cytotoxic, anti-inflammatory, and immunomodulatory reactions. A dose of 0.6 mg/kg of 8-methoxypsoralen is given 2 hours before UVA treatment, or an encapsulated form (Oxsoralen Ultra or Uvadex) is ingested 1 hour before treatment. The main toxicity is nausea and vomiting, which may be avoided by using 5-methoxypsoralen.[115] This drug is contraindicated in liver disease.

The patient is exposed to UVA lamps, which emit long UV (A-band) radiation in the wavelength range of 320 to 400 nm. UV-protective eyeglasses are worn for 24 hours after treatment. This therapy usually is given three times per week for 3 to 6 months, followed by tapering. After an initial report by Gilchrest and colleagues, multiple trials of efficacy of PUVA in early-stage disease have been reported.[116,117] Roenigk and colleagues reported that at a mean follow-up of 45 months, 82% of patients had complete clearing of plaque disease, with 88% remaining in complete remission for a median duration of 13 months.[118] Clearing of lesions was observed in 51.9% of the patients with extensive plaque disease, with a mean duration of 11 months; no clearing occurred in patients with tumor-stage or nodal-stage disease. In erythrodermic CTCL, 46% of the patients demonstrated clearing of the disease, but 75% relapsed. In patients followed for a mean of 44 months, no recurrences were noted in 55.6% of patients with stage 1A disease and in 38.5% of patients with stage IIB disease.[119]

PUVA has been combined with topical nitrogen mustard, retinoids, aerosolized granulocytemacrophage colony stimulating factor (GM-CSF), and interferon alfa-2a.[120–124] Retinoids have been reported to decrease the number of PUVA treatments and the total UVA dose.[123] The OR rate in 39 patients with mycosis fungoides was 90% (62% CR and 28% partial response [PR]), with a median response duration of 28 months. Retrospective evaluation of data for 30 patients who received low-dose interferon alfa-2a showed a CR in 83% (25 of 30) after a median of 5 months of treatment, with a median remission duration of 22 months.[125]

Contraindications to UV radiation therapy include systemic lupus erythematosus, skin cancer, porphyria, and genetic syndromes secondary to DNA repair defects.[115] Toxic reactions from PUVA therapy include nausea, vomiting, pruritus, erythema, xerosis, dry skin, blistering, and burns. Other, less common or potential side effects include development of pigmented melanocytic macules of the skin, nail pigmentation, and cataract formation.[125] Amyloid deposition has been reported.[126] UV light–blocking eyeglasses should be worn for 24 hours after psoralen is administered. Long-term toxic reactions of greater concern include squamous cell carcinoma of the skin or genitalia, photoaging, and amyloid deposition in the skin.[127]

Electron Beam Radiation Therapy

Electron beam radiation therapy was first used for malignant cutaneous lesions lesions in 1953 and has been advocated for treatment of CTCL with both limited and extensive cutaneous involvement.[128,129] Electrons are delivered to a depth of several millimeters to 1 cm. In a series of 192 patients with CTCL treated at Stanford University between 1966 and 1987 to a total dose of more than 2000 cGy, the complete remission rate in limited plaque disease (T1) was 98%, with a freedom-from-relapse rate of 50%; in generalized plaque disease (T2), 71%, with a freedom-from-relapse rate of 20%; in tumor-stage disease, 36%; and, in erythroderma, 64%.[130] Most relapses occur within 5 years. The 10-year survivor rate was 46%. Other studies have reported an OS rate of 70%.[131] The usual total dose is 3000 to 3600 cGy delivered over 8 to 10 weeks of treatment. The toxic reactions include desquamative skin reactions on the feet and toes, erythema, blister formation, exfoliation, dryness, extensive alopecia with eventual recovery of hair growth, temporary nail loss, inability to sweat because of loss of sweat glands, hyperpigmentation, and telangiectasias.[128–130] The increased risk of squamous and basal cell carcinomas is perhaps greatest in those patients who have received multiple therapies including irradiation, topical nitrogen mustard, and PUVA.[132] Most patients are given only a single course of treatment. One study evaluating retreatment for CTCL, however, reported 6 CRs and 8 PRs in 15 patients.[133] Adjuvant therapy with nitrogen mustard, PUVA, or extracorporeal photochemotherapy may be used to decrease the risk of relapse.[134]

Systemic Therapies

Extracorporeal Photochemotherapy

Extracorporeal photochemotherapy (ECP), or photopheresis, is a systemic form of PUVA therapy that combines leukapheresis with photochemotherapy and is efficacious in Sézary syndrome and erythrodermic mycosis fungoides. The biologic mechanisms of action that mediate clinical responses to ECP in CTCL are not clearly defined. Direct effects on DNA synthesis and membrane alterations induced by psoralens and UVA may cause cytotoxicity with release of tumor antigens, resulting in a systemic antitumor response, but the immunomodulatory effects and possible induction of immune responses to the malignant lymphoid cell population also may explain the clinical responses observed.[135] The ECP process induces an anti-idiotypic cytotoxic T-cell response against circulating CTCL cells, which subsequently undergo apoptosis. Patients ingest 8-methoxypsoralen and then undergo leukapheresis and cell separation. Cells of the mononuclear fraction are exposed to ultraviolet (UVA) radiation from lamps housed ex vivo in the apheresis device followed by reinfusion of the treated cells. This results in DNA crosslinking, apoptosis, and cell death. The process usually is performed on two consecutive days every 4 weeks.

The initial experience by Edelson and colleagues reported that 27 of 37 patients with therapy-resistant or -refractory CTCL exhibited greater than 25% skin improvement.[136] Long-term follow-up evaluation of patients with erythroderma revealed a median survival time of 60.3 months and a median survival time from onset of treatment of 47.9 months, with a CR rate of 21%.[137] Clinical indications for favorable ECP results include Sézary syndrome, widespread disease of less than 2 years' duration, and CTCL cases in which the patient's $CD8^+$ count is near normal.[135] Significant beneficial responses have not been demonstrated in patients with patch- or plaque-stage or tumor-stage mycosis fungoides or with advanced CTCL, but this treatment may prolong remission in patients who had previously received radiation therapy.[138] After a minimum of six cycles of ECP, photopheresis is continued through clearing and for approximately 6

additional months of treatment.[136,138] A higher baseline lymphocyte count and higher absolute Sézary cell count were associated with a decrease in skin score and response after 6 months.[139] Toxicities include nausea, fever, occasional erythematous flares after reinfusion, and hypotension during apheresis. Septicemia has occurred and probably is related to the immunocompromised state associated with CTCL. OR rates range from 54% to 75%, and 15% to 25% of patients achieve a CR.[140] Other agents have been added to photopheresis, including methotrexate, interferon, and immunomodulatory therapy.[141] ECP is not active in limited-stage mycosis fungoides.

Interferons

Interferon is the therapeutic agent of choice in advanced stages of mycosis fungoides and Sézary syndrome and is the most effective agent in the treatment of advanced SS/mycosis fungoides alone or in combination with interferon alfa-2a (Roferon-A, Hoffman-LaRoche, Inc., Nutley, NJ) and interferon alfa-2b (Intron-A, Shering-Plough Corp., Kenilworth, NJ), which differ by only one amino acid, have significant activity in mycosis fungoides and Sézary syndrome. Initially, high doses of drug were used.[142] The OR rates up to 60% have been reported.[143] In a randomized trial of intralesional interferon alfa-2b at a dose of 1×10^6 IU three times daily for 4 weeks resulted in CR in 10 of 12 patients who received the drug, compared with 1 of 12 patients whose lesions were treated with placebo.[144] The suggested systemic dose of interferon is 1 to 3×10^6 IU administered three times weekly, increased to 9 to 12×10^6 IU daily or as tolerated, because no dose-response data have been published.[145] A tachyphylaxis develops subsequent to the initial fevers and chills. Leukopenia occurs in the first 3 months of therapy but usually is of no clinical significance. Patients may experience chronic fatigue while receiving recombinant interferon.

Systemic Chemotherapy

Chemotherapy, administered orally or parenterally in either a single-agent or a combination regimen, is used in patients with CTCL, in patients with relapsed or refractory disease, and in patients whose tumor cells have undergone histologic transformation. Patients with extracutaneous or extranodal disease are candidates for systemic chemotherapy. Initial results of chemotherapy have been reviewed.[146] The duration of response to single-agent therapy ranged from 3 to 22 months. In a total of 331 patients with CTCL treated with combination chemotherapy, the OR rate was 81%, but the median duration of response was less than 1 year.

Moderate doses of methotrexate (60 to 240 mg/m^2) accompanied by oral leucovorin calcium followed by maintenance oral methotrexate for 6 to 30 months resulted in a CR in 7 of 11 patients and a PR in 2 of 9 patients.[147] A common intravenous regimen is the combination of cyclophosphamide, vincristine, prednisone (CVP); doxorubicin (Adriamycin) may be added to CVP (CHOP), as well as methotrexate and other agents.[148] Seven of 10 patients receiving bleomycin, doxorubicin, methotrexate, and topical nitrogen mustard exhibited a CR, with a median duration of response of 19 months.[149] Pegylated liposomal doxorubicin (Doxil) at a dose of 20 to 40 mg/m^2 every 4 weeks resulted in a CR in 6 and a PR in 2 of 10 patients, with a response duration of 15 months.[150] A retrospective multicenter study in 34 patients reported an 88% OR rate.[151]

Valid interpretation of the efficacy of chemotherapy in CTCL is complex. The current role of chemotherapy in the management of CTCL compared with other therapies is difficult to determine. In published studies, patients have received multiple and variable previous treatments; the series have reported small numbers of patients; stage of disease was not reported; various stages of CTCL were included; pathologic documentation of extra cutaneous disease often was lacking; and studies often combined patients with Sézary syndrome and those with mycosis fungoides. No clinical trial has demonstrated a survival benefit in patients receiving aggressive treatment. Therefore, more aggressive chemotherapy should be reserved for clinical studies or should be used after topical regimens have failed or other therapies no longer provide benefit. This therapy is palliative.

Purine Nucleoside Analogs

The purine nucleoside analogs in CTCL have been evaluated in several clinical trials. The class of drugs includes 2′-deoxycoformycin, fludarabine, cladribine, and gemcitabine. Of 34 patients with CTCL treated with single-agent pentostatin in five phase II studies, the CR rate was 7%, with an OR rate of 40% and a median time to progression of 1.3 to 8.3 months.[152] The OR rate with fludarabine was 19% in 33 patients in a Southwestern Oncology Group trial.[153] Fludarabine followed by ECP produced an overall response rate of 63.2% versus 29.5% in patients treated with fludarabine monotherapy.[154] Aproximately one third of patients respond to cladribine.[155] These agents have been combined with other therapeutic approaches such as interferon therapy. Neutropenia and thrombocytopenia are adverse effects associated with use of these agents. In a recent study, gemcitabine at a dose of 1200 mg/m^2 intravenously was given on days 1, 8, and 15 of a 28-day schedule for a total of three courses in 30 patients with mycosis fungoides; a CR rate of 10% and a PR rate of 60% were reported, with a median duration of 15 months.[156]

Vitamin A Analogs

Retinoids are derivatives of vitamin A that have been reported to be effective in CTCL. Isotretinoin (Accutane) and acitretin (Soriatane) have moderate activity. Of 25 patients with disease staged as T2 or higher, 11 (44%) had a response to isotretinoin (13-*cis*-retinoic acid), with a median duration of 8 months.[157] As single agents, retinoids have limited clinical use. Toxic effects include dry mucous membranes, skin fragility, arthralgias, myalgias, headache, fatigue, and increased triglyceride levels. The results of multiple studies suggest a CR rate of 19% and an OR rate of 58%.

Bexarotene at a dose of 300 mg/m^2 is a retinoid approved by the FDA for the treatment of refractory or relapsed CTCL that selectively activates retinoid X receptors.[158,159] In 94 patients, the OR rate was 49%, with a CR rate of 4% and a median duration of response of 10 months.[158] Toxic effects include hyperlipidemia, hypothyroidism, and cytopenias. In patients with disease staged as IB or higher, oral bexarotene may be considered a first-line treatment alone or in combination with PUVA. Combining PUVA and bexarotene allows for a decreased dose of both but does not increase the response rates.

Other Oral Chemotherapy Agent Approaches

Chlorambucil in a dose of 0.1 to 0.2 mg/kg daily for 2 to 4 weeks for 6 to 8 cycles results in a reported OR rate of 25% to 30%, with a median duration of response of 3 to 22 months.[146]

Etoposide in a dose of 50 mg/m^2 daily for 21 days every 28 to 35 days is active in chemotherapy-refractory disease.[160] Temozolomide, an oral alkylating agent, in a dose of 150 to 200 mg/m^2 for 5 days every 28 days also is active.

Monoclonal Antibodies

Murine monoclonal antibodies have been used as unaltered immunoglobulin, conjugated to toxins, conjugated to radioisotopes, or modified as chimeric antibodies. Initial trials included ^{90}Y-T101, ^{90}Y–anti-CD25, and anti-Tac *Pseudomonas* exotoxin. Anti-CD52 monoclonal antibody, alemtuzumab (Campath-1H), produced a CR rate of 23% and an OR rate of 59% in patients with erythroderma and 40% in those with plaque and skin tumors, with a median time to treatment failure of 12 months.[161] Alefecept (Aminvive, Biogen Idec) is a fully humanized recombinant protein that has been designed to modulate immune responses through interaction with the CD2 receptor on T lymphocytes inhibiting LFA-3/CD2 interaction that is FDA approved for psoriasis and is now in phase I trials for CTCL. The reduction in CD2$^+$ cells results in a reduction in CD4$^+$ and CD8$^+$ T-lymphocyte counts. Toxic effects include urticaria, infections, angioedema, and injection site reactions. Alemtuzumab is associated with significant myelosuppression, with associated viral, fungal,

and bacterial infections, including reactivation of cytomegalovirus infection, herpes zoster, and herpes simplex. Prophylactic antibiotics and antiviral and antifungal agents are required.

Interleukins and Recombinant Fusion Proteins

Bioactive recombinant interleukins and other cytokines have favorable prospects in the treatment of CTCL. Recombinant interleukin-2 (IL-2) was administered in four patients, and all had a response, with two CRs.[162] Approximately half of the patients with mycosis fungoides or Sézary syndrome have IL-2 receptors (IL-2R alpha chain, CD25). Denileukin diftitox (Ontak) is a genetically engineered fusion protein containing the portion of IL-2 that interacts with IL-2 and a synthetic protein identical to diphtheria toxin. The IL-2 portion of this drug binds with IL-2R on the mycosis fungoides/SS cells, the toxin is internalized, and apoptosis is induced. Denileukin diftitox administered at a dose of 9 or 18 μg daily for 5 days every 21 days is FDA approved. A randomized double-blind study of 71 patients with CD25 expression in 20% of lymphocytes or greater reported an OR rate of 30% (10% CR and 20% PR), with a median duration of response of 6.9 months (range, 2.7 to 46.1 months).[163] Toxic effects include flu-like symptoms, acute infusion-related events (episodes of hypotension, chest pain, and back pain), vascular leak syndrome, elevated liver function tests (61%), and hypoalbuminemia (79%). Bexarotene upregulates the expression of the high-affinity IL-2R. The OR rate with denileukin diftitox with escalating doses of bexarotene was 57%.[164]

Histone Deacetylase Inhibitor

Vorinostat (Zolinza) is a histone deacetylase inhibitor that results in histone acetylation and activation of gene expression and is FDA approved. The recommended dose is 400 mg per day orally, with treatment continuing until disease progression. In a phase II trial in 33 patients who previously had received a median of five prior therapies, 8 patients achieved a PR, 7 of whom had Sézary syndrome.[165] The median time to response was 11.9 weeks. Fourteen of 31 evaluable patients experienced relief of pruritus. Of 74 patients enrolled in a phase IIB trial,[166] the OR rate was 29.7% in all patients and similar in those with disease staged as IIB or higher. The median time to progression was 4.9 months in all patients and up to 9.8 months in responders with stage IIB or higher disease.

Common toxic effects include diarrhea, fatigue, nausea, dysgeusia, and anorexia. Less common toxicities include severe thrombocytopenia, pulmonary embolism, and elevations in creatinine level. Prolongation of the prothrombin time in patients receiving concomitant coumarin derivative anticoagulants may occur.

Other Therapies

Antithymocyte globulin, cyclosporine, and acyclovir have been reported to induce transient responses.[167–169]

Stem Cell Transplantation

Studies of autologous peripheral blood stem cell transplantation and allogeneic transplantation strategies are ongoing. Five of six patients who underwent autologous bone marrow transplantation responded, but three of these patients relapsed in less than 100 days.[170] With use of a T cell–depleted peripheral transplant strategy, seven of nine patients relapsed at a median of 7 months (range 2 to 14 months), engraftment did not occur in one patient, and another patient died of sepsis.[171] In studies of allogeneic bone marrow transplantation, 3 patients were alive and disease-free 15 months to 4 years.[172,173] Allogeneic transplantation produces more durable complete remissions, an outcome attributed to an immune-mediated graft-versus-lymphoma effect.[174] Mortality is significant with this approach, however, and other associated toxicities including graft-versus-host disease create much higher risks for morbidity and early death. Nonmyeloablative ("mini") allogeneic transplantation creates a graft-versus-lymphoma effect, with less conditioning regimen–related toxicity. Engraftment occurred in 10 of 11 patients, and after a median follow-up period of 2.9 years (range, 3 months to 4.4 years), 7 of the patients were in remission and 4 had chronic graft-versus-host disease necessitating treatment.[175]

Combined-Modality Therapy

In one study, results with the combination of electron beam radiation therapy and local radiation therapy followed by combination chemotherapy suggested that survival and remission duration may be improved.[176] The median disease-free survival period was 12 months, and all patients with plaque-stage disease relapsed within 25 months.[177] Fifty nonrandomized patients received total-skin electron beam radiation therapy followed by combination chemotherapy with doxorubicin and cyclophosphamide.[178] The CR rate was 88%, with a significant increase in the duration of response in early-stage CTCL but not in advanced disease.

The first randomized clinical trial compared conservative sequential topical therapy with total electron beam radiation therapy in 103 patients.[179] Patients with disease of all stages were eligible, and no restrictions were assigned on the basis of performance status. The sequential topical regimen was initiated with topical nitrogen mustard and was changed to PUVA if progression of CTCL occurred or toxicity developed from the topical nitrogen mustard. For continued disease progression, the patient received total-skin electron beam radiation therapy, followed by methotrexate administered orally. If extracutaneous disease developed, systemic chemotherapy was administered. The combination regimen consisted of 3000 cGy total-skin electron beam radiation therapy followed by cyclophosphamide, doxorubicin, etoposide, and vincristine administered intravenously. After a median follow-up period of 75 months, the only significant difference was in the CR rates for the two treatment groups: 38% in the combined-modality group and 10% in the topical group. No statistical difference was observed in the disease-free survival rate or OS rate as a group or by stage for the two treatment groups. Toxicity was greater in the combined-modality group and included myelosuppression, radiodermatitis, neuropathy, and congestive heart failure. Less than 10% of patients in both groups remained disease free. Other regimens and approaches have been published.[180,181]

In another study, 124 patients with early stage I and II mycosis fungoides disease were randomized to receive PUVA or PUVA plus interferon alfa-2a (Roferon-A) at a dose of 9×10^6 U three times per week.[182] Fifty patients in the PUVA treatment group and 43 patients in the interferon-PUVA treatment group were evaluable. On follow-up evaluation at a median of 101 weeks, median progression-free survival times were 53 weeks with PUVA and 113 weeks with interferon-PUVA ($P = 0.0398$). This combination therapy is the initial treatment of choice for limited-stage disease.

CONCLUSIONS

Most cases, of CTCL cannot be cured. Early-stage (i.e., IA to IIA) mycosis fungoides should be treated with skin-targeted therapeutic interventions to achieve a complete remission. Disease recurrence is frequent, but long-term survival is not influenced by relapse status. Progress has been made in defining and classifying the cutaneous lymphomas, and in characterizing the relationship of mycosis fungoides and Sézary syndrome and other premalignant conditions with CTCL and B-cell lymphomas. Recent advances in immunobiology, cell biology, and molecular biology have further identified and defined the malignant lymphoid population involved in CTCL and the mechanisms by which these cells may interact with skin and manifest the clinical features of CTCL.[183] Treatment approaches are institution dependent, although consensus guidelines are published for this complex group of diseases.[184] Continued advances in the understanding of the pathobiology of CTCL and the uncovering of potential targets will provide new therapeutic interventions that will improve the outcomes with cutaneous T-cell and B-cell lymphomas.

114 Adult T-Cell Leukemia-Lymphoma

Kensei Tobinai and Toshiki Watanabe

SUMMARY OF KEY POINTS

Background
- Adult T-cell leukemia-lymphoma (ATLL) is a distinct peripheral T-cell malignancy that is associated with human T-cell leukemia virus type I (HTLV-I).

Virology
- HTLV-I is reverse-transcribed into DNA and integrated into the host cell.
- The HTLV-I genome encodes two unique regulatory proteins—Tax and Rex—that are responsible for viral expression and cellular transformation. Tax *trans*-activates viral and cellular genes that could be involved in the pathogenesis of ATLL.

Epidemiology
- The major cluster of HTLV-I-infected individuals and patients with ATLL exists in Japan, where approximately 1.2 million people are infected with the virus.
- Other clusters have been noted in the Caribbean islands (African), tropical Africa (African), South America (Mongoloid), and northern Oceania (Melanesian).
- HTLV-I is transmitted by mother to child through breast-feeding, by sexual contact, and by blood-borne transmission.
- The estimated cumulative risk of the development of ATLL in HTLV-I-positive individuals is 2.5%.

Clinical Manifestations
- Patients with ATLL show diverse clinical features, and four clinical subtypes have been recognized: acute, lymphoma, chronic, and smoldering types.
- The typical manifestations of acute-type ATLL include circulating neoplastic cells in the peripheral blood, generalized lymph node swelling, hepatosplenomegaly, skin involvement, and hypercalcemia.

Histopathology
- Leukemic cells in the peripheral blood characteristically show markedly polylobated nuclei, the so-called flower cells. Their immunophenotypes are CD4-positive and CD8-negative T-cell in most cases.
- All histopathologic specimens show the findings of peripheral T-cell lymphoma of various subtypes.

Diagnosis
- ATLL is suspected when the aforementioned characteristic clinical manifestations and/or the cytologic findings of leukemic cells in the peripheral blood are recognized.
- An immunophenotypic analysis of neoplastic cells and a serologic assay against HTLV-I are required for the clinical diagnosis of ATLL.
- The demonstration of the monoclonal integration of HTLV-I proviral DNA in the tumor cells can lead to a definite diagnosis of ATLL.

Treatment
- An accurate diagnosis of the clinical subtype is vital for appropriate decisions regarding treatment.
- Combination chemotherapies used in the treatment of non-Hodgkin's lymphoma are usually given to patients with the acute or lymphoma subtype of ATLL; however, most patients with ATLL are not curable with current chemotherapy regimens.
- Further efforts to incorporate new, innovative treatment modalities, such as new anticancer agents, monoclonal antibody therapy, molecular-targeting therapy, and allogeneic hematopoietic stem cell transplantation, are needed.

INTRODUCTION

Adult T-cell leukemia-lymphoma (ATLL) was first recognized in Japan in 1977s.[1] The disease was characterized as leukemia of peripheral T cells, generalized lymphadenopathy, hepatosplenomegaly, and skin involvement. Owing to its unusual geographic clustering in southwestern Japan, it was postulated that some infectious agent(s) had causative roles. Human T-lymphotropic virus (HTLV) was first isolated by Poiesz and associates[2] in the United States from cultured cells from one patient with an aggressive variant of mycosis fungoides and from one with Sézary syndrome. Although both patients were diagnosed clinically as having cutaneous T-cell lymphoma (CTCL) at the time of reporting, their clinical features were later found to closely resemble those of Japanese patients with ATLL.

In 1980, Miyoshi and coworkers[3] established the first cell line (MT-1) derived from neoplastic cells in an ATLL patient. They cocultured neoplastic cells from an ATLL patient with normal human cord blood lymphocytes and established the cell line MT-2 (derived from cord blood lymphocytes), which produced high amounts of type C retrovirus.[4] Using the MT-1 cell line, Hinuma and colleagues[5] found that patients with ATLL had antibodies against the virus-associated antigen in their sera. The "ATLL virus" was then isolated and characterized as an RNA retrovirus.[6] As HTLV and ATLL virus were found to be identical by a DNA sequence analysis, this virus was designated human T-cell leukemia virus type I or human T-lymphotropic virus type I (HTLV-I).[7]

The etiologic association of HTLV-I and ATLL is based on the findings that follow.

- The areas of high incidence of patients with ATLL closely correspond with those of high prevalence of HTLV-I carriers.[8]
- HTLV-I immortalizes T cells in vitro.[9]
- HTLV-I proviral DNA is detected in the neoplastic cells of ATLL.[10]
- Almost all patients with ATLL have antibodies against HTLV-I in their sera.

HTLV-I is the first retrovirus that was found to be associated with a malignant neoplasm in humans.

VIROLOGY AND PATHOGENESIS

HTLV-I is reverse-transcribed into DNA and integrated as a proviral DNA in the host cell. The HTLV-I provirus is 9.0 kilobases long and has structural genes in the order 5′-gag-pol-env-3′. Both ends of the HTLV-I proviral DNA contain repeats called long terminal repeats (LTRs). No specific integration sites of the HTLV-I provirus in the host cellular chromosomes have been identified.[11] A unique feature of the viral structure of HTLV-I provirus is the presence of a long sequence between *env* and 3′ LTR. One product of this *pX* gene, p40*tax*, acts on the LTRs for the *trans*-activation of the viral gene.[12]

The HTLV-I gene encodes three structural proteins: group antigen (*gag*), reverse transcriptase (*pol*), and envelope (*env*) proteins. The full-length mRNA is used for synthesis of *gag* and *pol* gene products. The gag protein is synthesized as a precursor polypeptide of 55 kilodaltons that is proteolytically cleaved into the individual gag proteins p19, p24, and p15. The protease is encoded in a different reading frame that spans the 3′ part of the *gag* region and the 5′ part of the *pol* region. The *pol* region encodes the reverse transcriptase, integrase, and RNase H. The *env* gene encodes two proteins made from a singly spliced mRNA. It is then cleaved intracellularly into an extracellular glycosylated protein (gp46) and a transmembrane (gp21). The *pX* region at the 3′ end of the genome has the potential to encode essential regulatory proteins (Tax and Rex) and three accessory proteins—p12, p13, and p30—that are important for viral infectivity and replication by influencing cellular signaling and gene expression.[13,14]

The life cycle of a retrovirus begins with the binding of the virus to specific receptors on the cell surface via viral envelope proteins. HTLV-1 is transmitted through a viral synapse and enters target cells via interaction with the glucose transporter GLUT1.[15] However, other molecules have also been reported to be involved in virus entry, for example, HSC70,[16] heparan sulfate proteoglycans,[17] and neurophilin-1.[18]

Role of Tax

The onset of ATLL is preceded by a long period of clinical latency, frequently lasting more than four decades. In addition, fewer than 5% of all infected individuals with HTLV-I develop ATLL. The promoter insertion model was rejected as the leukemogenic mechanism because integration sites of the provirus were random depending on the patient.[11] Consequently, a *trans*-acting viral factor, Tax, has been shown to be oncogenic, since it transforms and immortalizes rodent fibroblasts and T lymphocytes as well as human T lymphocytes. Tax *trans*-activates viral transcription through interaction with the cellular basic domain/leucine zipper transcription factors CREB and ATF-1. Tax interacts with numerous cellular proteins to reprogram cellular processes, including, but not limited to, transcription, cell cycle regulation, DNA repair, and apoptosis. Tax transcriptionally regulates cellular genes by interaction with enhancer-binding proteins such as CREB, NF-κB, and serum response factor and by tethering coactivators to the DNA-bound transcription factors. Tax also stimulates cell growth by direct binding to cyclin-dependent kinase holoenzymes and/or inactivating tumor suppressors such as p53 and DLG. Furthermore, Tax silences cellular checkpoints, which guard against DNA structural damage and chromosomal missegregation, thereby favoring the manifestation of a mutator phenotype in cells.[13,19]

Tax interacts and activates specific components of growth factor signal transduction pathways, such as IKK-IκB-NF-κB, RAS/mitogen-activated protein kinase, protein kinase A, and protein kinase C.[20,21] Interaction with IKKγ, a component of IKK complex, results in constitutive activation of this kinase complex.[22] Constitutive activation of the JAK-STAT pathway in HTLV-I-transformed cells has also been reported, although the mechanisms are not well understood.[23] Thus, HTLV-I infection results in aberrant activation of growth-promoting signaling pathways.

The oncogenic capacity of Tax has been reported in various systems; however, cellular transformation by HTLV-I in vivo is a multistage process, and viral gene expression is absent in ATLL cells in vivo.[24,25] Moreover, proviruses integrated in ATLL cells are frequently defective, have mutations in the coding region of Tax, and/or are methylated in the 5′ and 5′ LTR regions.[26–28] Thus, in addition to promoting growth directly, Tax should endow the infected T cells with capacities that aid the progression to transformed phenotypes in the absence of Tax. In this context, induction of a mutator phenotype by Tax in the infected cells appears to play an important role.[29] The roles of HTLV-I Tax in the multistep leukemogenesis of ATLL are illustrated in Figure 114-1.

Expression of antisense strand RNA with capacity encoding a zinc finger protein (HTLV-I basic leucine zipper factor) has opened a new research field. HTLV-I basic leucine zipper factor inhibits Tax-dependent viral transcription[30] and might be involved in growth of ATLL cells.[31]

Role of Chromosomal Abnormalities

Various karyotypic abnormalities have been reported in neoplastic cells of ATLL; however, no specific karyotypic abnormality has been

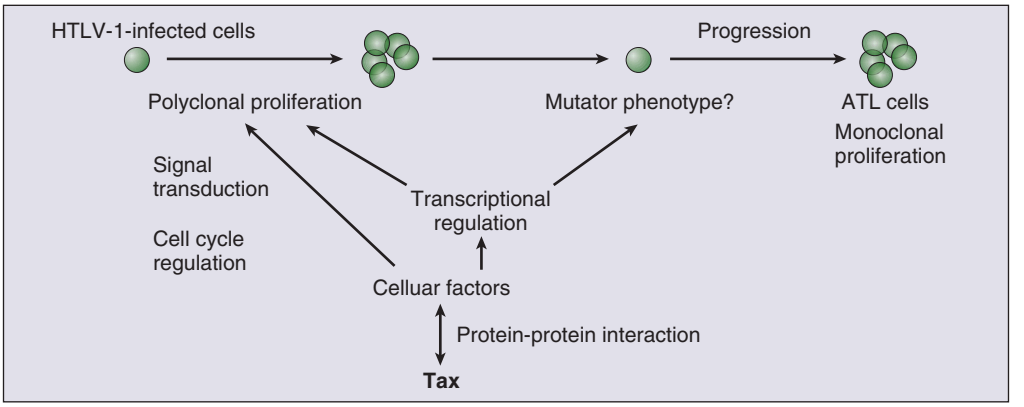

Figure 114-1 • Roles of HTLV-I Tax in the multistep leukemogenesis of ATLL. Tax exerts its biologic effects mainly through protein-protein interaction, resulting in deregulation of transcription, cell cycle control, and signal transduction. It also impairs the cell's ability to repair DNA damage, which can lead to the mutator phenotype of the infected cells.

found. In general, the chromosomal abnormalities are more complex in the acute type compared with those in the chronic type. Itoyama and colleagues[32] reported the results of cytogenetic analysis of 50 cases of ATLL and found aneuploidy and multiple breaks more frequently in acute and lymphoma types. Multiple breaks and partial loss of chromosomes correlated with shorter survival. The authors claim that one model of an oncogenic mechanism—activation of a proto-oncogene by translocation of a T-cell receptor (TCR) gene—might not be applicable to the main pathway of development of ATLL and that a multistep process of leukemogenesis is required.

In a study by Tsukasaki and associates,[33] 64 patients with ATLL were analyzed by using comparative genomic hybridization (CGH). The most frequent observations were gains at chromosomes 14q, 7q, and 3p and losses at chromosomes 6q and 13q. Chromosome imbalances, losses, and gains were observed more frequently in acute or lymphoma types. An increased number of chromosomal imbalances were associated with a shorter survival. Paired samples (i.e., samples obtained at different sites from four patients) and sequential samples from 13 patients (from six during both chronic phase and acute crisis and from seven during both acute onset and relapse) were examined by CGH and Southern blotting for HTLV-I. All but two paired samples showed differences on CGH assessment. Two chronic/crisis samples showed distinct results regarding both CGH and HTLV-I integration sites, suggesting clonal changes in ATLL at crisis. In 11 patients, the finding of identical HTLV-I sites and clonally related CGH results suggested a common origin of sequential samples. In contrast to chronic/crisis samples, CGH results with all acute/relapse sample pairs showed the presence of clonally related but not evolutional subclones at relapse. It was concluded that clonal diversity is common during progression of ATLL and that CGH alterations are associated with clinical course.

Role of *p53* and Other Tumor Suppressor Genes

p53 is a nuclear phosphoprotein that functions as a tumor suppressor gene. A loss of normally functioning *p53* through mutation or allelic loss has been found in several kinds of malignant neoplasms. Mutations of the *p53* gene have also been found in some patients with ATLL.[34,35] According to the study by Cesarman and coworkers,[35] no p53 mutations were detected in samples from 11 patients with the chronic type of ATLL, whereas 9 (28%) of 28 samples from patients with the acute type of ATLL exhibited p53 mutations. In one patient, a tumor sample obtained during the chronic phase did not have a mutation of the p53 gene, but the mutation was subsequently detected in a sample that was obtained at crisis. These results suggest that alterations of the p53 gene might contribute to disease progression in a fraction of patients with ATLL.

Other putative tumor suppressor genes, $p15^{INK4B}$ and $p16^{INK4A}$, were reported to be associated with ATLL.[36–38] Yamada and associates[37] reported that 28 (25%) of 114 patients with ATLL showed homozygous deletions of the *p15* and/or *p16* genes. These results correlated well with the clinical subtypes of ATLL. In addition, the patients with deleted *p15* and/or *p16* genes showed significantly shorter survival than did patients in whom both genes were preserved ($P < 0.0001$). Moreover, three of the five chronic-type patients who progressed to acute-type ATLL lost the *p16* gene alone or both genes at their exacerbation phase. These results suggest that the deletions of *p15* and/or *p16* genes play a key role in the disease progression of some patients with ATLL. Uchida and colleagues[38] found the point mutation of the *p16* gene in 3 (7%) of 44 patients with ATLL. It is suggested that the *p16* gene is inactivated not only by homozygous deletion, but also by point mutation.

Role of HTLV-I Provirus

Several investigators have analyzed the implications of the integration pattern of HTLV-I provirus in the disease progression of ATLL.[39,40] It is known that the neoplastic cells of ATLL have one copy of complete HTLV-I provirus per cell in some patients (complete-type), while others have multiple complete copies of the virus per cell (multiple-type). The HTLV-I proviruses in the remaining patients do not have the complete genome but rather have a defective genome (defective-type). Tsukasaki and associates[40] found that the median survival times (MST) for patients were 7 months, 24 months, and 33 months for defective-type, complete-type, and multiple-type ATLL, respectively ($P = 0.006$). Among 52 sequentially examined patients, the HTLV-I integration patterns changed in four patients (8%). In three of these four, the rearrangements of the TCR-β gene changed concomitantly, suggesting the appearance of a new ATLL clone. The researchers concluded that the frequent clonal change of ATLL at crisis reflects the emergence of multiple premalignant clones in viral leukemogenesis.

Tamiya and coworkers[39] reported the presence of two types of defective virus. Among them, type 2 defective virus with the deletion that includes 5′ LTR was found more frequently in the acute and lymphoma types (39%, 21 of 54) than in the chronic type (6%, 1 of 18). It is postulated that the high frequency of the type 2 defective viruses is caused by the genetic instability of HTLV-I provirus and that this defective virus is selected because it escapes from the immune surveillance system in the host.

HTLV-I is an etiologic agent not only in ATLL, but also in the neurologic disorder known as tropical spastic paraparesis (TSP) or as HTLV-I-associated myelopathy (HAM).[41,42] In TSP/HAM, the HTLV-I provirus remains randomly integrated, whereas in ATLL, the provirus is monoclonally integrated.

EPIDEMIOLOGY OF HTLV-I AND ADULT T-CELL LEUKEMIA-LYMPHOMA

Southwestern Japan has the highest recorded prevalence of HTLV-I infection and the highest incidence of patients with ATLL in the world.[8,42–44] A high prevalence of HTLV-I is also found in the Caribbean islands (African), tropical Africa (African), South America (Mongoloid), and northern Oceania (Melanesian).[43–46] Many patients who have been diagnosed as having ATLL in Western countries are immigrants from the West Indies and tropical Africa. The world map of the distribution of HTLV-I and HTLV-II and the presumed routes of spread are shown in Figure 114-2.[44] The geographic clustering of HTLV-I carriers is suggested to be strongly associated with a high frequency of mother-to-child transmission of the virus under closed conditions in particular groups.[47]

It has been estimated that approximately 1.2 million HTLV-I-infected individuals reside in Japan, and the annual incidence of ATLL has been estimated to be approximately 700 in Japan.[8] The annual rate of ATLL development among HTLV-I carriers older than 40 years is estimated at 1.5 per 1000 in males and 0.5 per 1000 in females, and the cumulative risk of ATLL development among the HTLV-I carriers is estimated to be 2.5% to 5% over the course of a 70-year life span.[48]

In a national survey in Japan, the mean age of patients with ATLL has been estimated at 57.6 years, and this age appears to have increased over time.[8] It has been reported that the age of patients with ATLL in areas outside Japan is somewhat lower, with an overall mean age in the mid-forties.[49] In endemic areas, there is a marked increase in HTLV-I prevalence with age until age 70 years and an increased prevalence among females compared with males. Transmission occurs via sexual and blood-borne routes. A major reason for the increase in seroprevalence with age appears to be the decreasing prevalence of HTLV-I in the population over time, at least in Japan, where it has been most extensively studied. Yamaguchi and coworkers[50] reported that the HTLV-I carrier rates among blood donors in Japan had fallen since 1986 in all age groups under 50 years and in both genders. This decrease in HTLV-I carriers among younger blood donors might be explained by improvements in sanitation and general lifestyle changes in recent years. A shorter duration of breast-feeding,

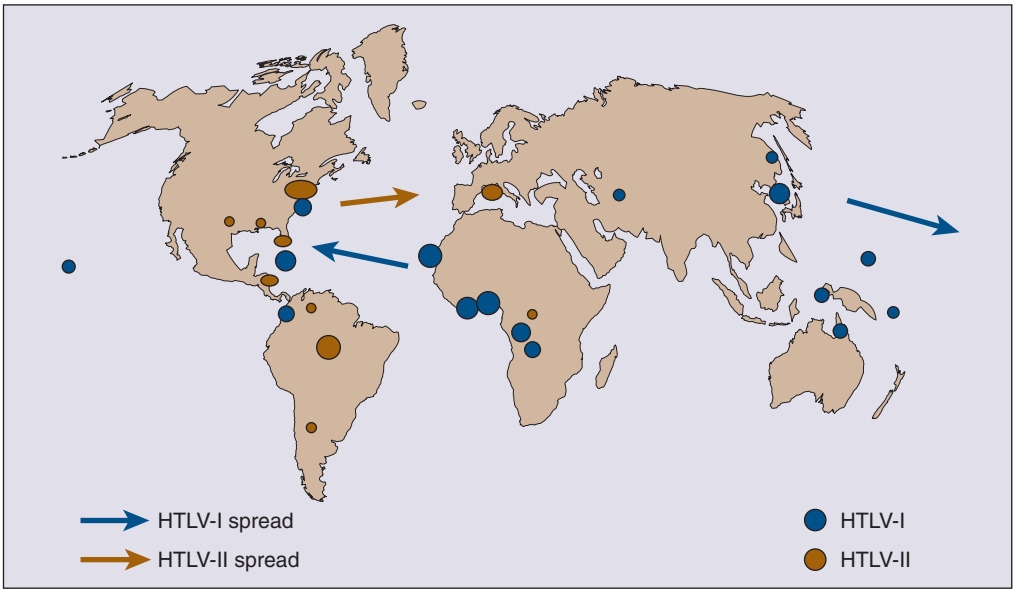

Figure 114-2 • World map of HTLV distribution and its presumed routes of spread. (From Blattner WA, Gallo RC: Epidemiology of HTLV-I and HTLV-II infection. In Takatsuki K [ed]: Adult T-cell Leukaemia. Oxford, UK, Oxford University Press, 1994, p 45. Prepared by Dr. Robert J Biggar, National Cancer Institute, USA.)

the increasing use of artificial feeding for babies, and decreasing family size are also likely to be factors for the recent decline in the vertical transmission rates of HTLV-I.[50] Overall, there is a slight male predominance of ATLL patients, the male-to-female ratio ranging from 1.1 to 1.5. This is in contrast to TSP and HAM, which affect females more frequently than males.

It has been shown that HTLV-I is transmitted by at least three routes:

1. Mother-to child-transmission, mainly by HTLV-I-positive lymphocytes in breast milk.[51]
2. Sexual transmission, more commonly from males to females.
3. Blood-borne transmission, including blood transfusions and sharing of needles by intravenous drug abusers.[52,53]

The first route is vertical transmission from mother to child via HTLV-I-positive lymphocytes in breast milk. The overall infection rate of HTLV-I in children by seropositive mothers has been estimated to be 10% to 30%. HTLV-I infection has also been reported in children who had not been breast-fed, however, which suggests the possibility of intrauterine or transvaginal infection. Several kinds of intervention trials are being conducted in HTLV-I-endemic areas in Japan, where seropositive pregnant women are advised not to breast-feed.[47]

The second route is transmission through sexual contact. Transmission of HTLV-I frequently occurs from male to female but rarely from female to male. HTLV-I has been isolated in semen. It appears likely that the risk of development of ATLL after HTLV-I infection by this route of transmission is not high.

To prevent HTLV-I transmission through blood transfusions, serologic screening of all blood donors for HTLV-I has been conducted in Japan since November 1986. Inaba and coworkers[54] reviewed the effectiveness of the donor screening in preventing transmission of HTLV-I through blood transfusion in Japan. Seroconversion was found in only 1 of 4672 transfused patients, but the donor was confirmed to be negative for anti-HTLV-I antibody and virus genome by nested polymerase chain reaction (PCR). A total of 23,323 red cell concentrates and 17,237 platelet concentrates were transfused to these 4672 patients. Therefore, the anti-HTLV-I prevalence in blood for transfusion after screening was estimated at 1 in 45,560 (0.0022%; the upper 95% confidence interval (CI) was 0.0080%). This study confirmed that the present donor screening program for HTLV-I can almost completely prevent virus transmission by transfusion in Japan. In contrast to red cell and platelet concentrates, fresh-frozen plasma and plasma fractions have never been shown to transmit HTLV-I.

From the viewpoint of the epidemiologic aspects of HTLV-I and ATLL, several points can be made in ATLL leukemogenesis:

- Viral infection alone is not adequate for the expression of the malignant phenotype.
- The timing and/or length of viral exposure is critical.
- The long latency period suggests that the disease progression is a multistep process. This is in contrast to TSP/HAM, which can occur with a shorter latency period, especially among recipients of blood transfusions.

CLINICAL MANIFESTATIONS

After HTLV-I was revealed to be associated with ATLL, it was found that ATLL shows a marked diversity in its clinical manifestations. ATLL cases have been subdivided into four distinct clinicopathologic entities: acute, lymphoma, chronic, and smoldering types. The recognition of the four clinical subtypes is important in understanding the natural history, clinical features, treatment strategy, and leukemogenesis of ATLL. On the basis of the nationwide survey of 854 patients with ATLL who were diagnosed between 1983 and 1987 in Japan, the Lymphoma Study Group proposed the diagnostic criteria of the four clinical subtypes (Table 114-1):[55]

1. The acute type shows a rapidly progressive clinical course and most of the characteristic features of ATLL: generalized lymphadenopathy, hepatomegaly, splenomegaly, skin involvement, hypercalcemia, and organ infiltration (lung, gastrointestinal tract, etc.). The symptoms and signs include abdominal pain, diarrhea, ascites, pleural effusion, cough, sputum, and chest x-ray abnormalities.
2. The smoldering type shows an indolent clinical course and only a small percentage of leukemic cells, but it also can include skin involvement.
3. The chronic type, with a high percentage of leukemic cells, is occasionally associated with skin involvement, lymphadenopathy, and hepatosplenomegaly and also shows an indolent clinical course.
4. The lymphoma type includes patients who present with the manifestations of non-Hodgkin's lymphoma (NHL) without circulat-

ing malignant cells in the peripheral blood. When patients with ATLL are staged according to the Ann Arbor classification, most patients are categorized as stage IV, because leukemic cells are recognized even in clinically indolent forms such as the smoldering type and chronic type. Therefore, in ATLL, the clinical subtype is more important than the Ann Arbor stage for predicting prognosis and determining appropriate treatment strategies for individual patients.

ATLL, particularly the aggressive forms (acute and lymphoma types), has been found to infiltrate the stomach and the intestines in 29% and 25% of patients, respectively, at autopsy.[56] The involvement may be focal as an isolated gastric lesion or so diffuse as to involve the entire gastrointestinal tract. Extensive infiltration of the intestines can lead to moderate to severe diarrhea and malabsorption. Patients with ATLL suffer from a variety of abdominal symptoms (e.g., nausea, vomiting, abdominal fullness, and diarrhea), which might be attributable to infiltration by neoplastic cells, but because of the associated immunodeficiency, various opportunistic infections such as Strongyloidiasis can complicate cases.

Hepatic involvement of ATLL cells can be found in up to one fourth of patients with acute and lymphoma subtypes and not infrequently manifests with jaundice and hepatic transaminase elevations. Yamada and coworkers[57] examined 111 patients with acute-type or lymphoma-type ATLL and compared them with 106 patients with NHL other than ATLL. Among patients with ATLL, there were more frequent palpable hepatomegaly, higher total bilirubin, hepatic transaminase, LDH, and alkaline phosphatase values than among other NHL patients. Autopsy liver samples disclosed that the portal area was most frequently infiltrated with ATLL cells.

Pulmonary complications, which are common in ATLL, are due to leukemic infiltration in one half of patients and to infections with a variety of bacterial and opportunistic organisms in the other half.[58] Of 854 Japanese patients with ATLL, 26% had active infections at the time of diagnosis.[55] The incidence was highest among patients with the chronic and smoldering types (36%) and lower for patients with the acute (27%) and lymphoma (11%) subtypes. The infections that were encountered were bacterial (pneumonias, sepsis, and tuberculosis) in 43%, fungal in 31%, protozoal in 18%, and viral in 8% of patients with ATLL (Table 114-2). The immunodeficiency at presentation in ATLL can be exacerbated by the neutropenia that is produced by cytotoxic chemotherapy, leading to an extremely high risk of infection throughout the course of therapy. Infections are responsible for the patient's death in about half of the cases.

Central nervous system involvement occurs in approximately 10% of patients with ATLL. Teshima and associates[59] identified 15 instances of central nervous system involvement in 10 of 99 patients with ATLL. Leptomeningeal involvement was present in 9 of 10 patients, intracerebral infiltration was noted in 3, and the spinal cord was involved in 2. The initial symptoms included muscle weakness (47%), altered mental status (47%), paresthesias (40%), headache (33%), and urinary incontinence (27%). Signs included nuchal rigidity (33%) and cranial nerve palsies (13%). Hyponatremia secondary to the syndrome of inappropriate secretion of antidiuretic hormone was observed in four patients.

LABORATORY FINDINGS

Laboratory findings also depend on the clinical subtype of ATLL (see Table 114-1).[55] Leukocytosis is found among patients with the acute or chronic subtype at presentation, exhibiting characteristic atypical lymphoid cells with markedly lobated nuclei, termed *flower cells*. Although not all patients present with a leukemic feature, peripheral blood involvement develops in most patients at some time during the course of their disease. Most patients with the acute or lymphoma subtype of ATLL have elevated serum LDH levels.

The most striking laboratory finding in patients with ATLL is hypercalcemia, which was evident in 32% of Japanese patients with ATLL.[55] Multiple factors have been suggested to contribute to the development of hypercalcemia. Lytic bone lesions have been described in some patients; however, examinations of bone obtained at autopsy or from bone marrow biopsies usually reveal activated osteoclasts with increased bone resorption; infiltrating neoplastic T cells are rarely found. Patients with ATLL have low phosphate levels, hypercalciuria, high levels of nephrogenous cyclic adenosine monophosphate, and low levels of 1,25-dihydroxyvitamin D. This pattern suggests the presence of humoral hypercalcemia of malignancy, which was found to be secondary to the production of a parathyroid hormone (PTH)-like molecule by malignant cells. HTLV-I-infected cells were found to produce a protein with PTH-like activity, such as PTH-related peptide.[60–62] Another suggested contributor to hypercalcemia in patients with ATLL is cytokine production by the tumor cells. HTLV-I-infected cell lines and fresh ATLL cells from hypercalcemic patients produce TNF-α, TNF-β, IL-1α, and IL-1β. Each of these cytokines can enhance osteoclast activity and bone-resorbing activity in animal models. Ishibashi and colleagues[63] demonstrated elevated serum levels of TNF-β in seven of eight patients with ATLL who had complications of hypercalcemia and in none of 28 patients with ATLL who had normal serum calcium levels.

Nosaka and coworkers[64] analyzed the expression of various genes that were suggested to regulate serum calcium levels in ATLL and reported that the overexpression of the receptor activator of NF-κB (RANK) ligand gene correlated with hypercalcemia. ATLL cells from patients with hypercalcemia, which highly expressed the transcripts of the RANK ligand (RANKL) gene, induced the differentiation of human hematopoietic precursor cells (HPCs) into osteoclasts in vitro in the presence of macrophage colony-stimulating factor. In contrast, ATLL cells from patients without hypercalcemia did not induce such

differentiation, suggesting that the induction of the differentiation correlated with the expression of the RANKL gene in ATLL cells. Cell differentiation was suppressed by osteoprotegerin/Fc, an inhibitor of RANKL, suggesting that such differentiation occurred through the RANK-RANKL pathway. In addition, direct contact between ATLL cells and hematopoietic precursor cells was essential for the differentiation, suggesting that membrane-bound RANKL rather than the soluble form plays a role in this process. The authors claimed that ATLL cells induce the differentiation of hematopoietic precursor cells to osteoclasts through RANKL expressed on their surface, in cooperation with macrophage colony-stimulating factor, and that they ultimately cause hypercalcemia. The etiology of hypercalcemia in ATLL is likely to be multifactorial and in individual patients is probably due to some combination of the factors just described.

Elevated serum levels of soluble interleukin-2 receptor in patients with ATLL, especially in those with the acute or lymphoma subtype, have been noted in several studies.[65] The serum level of soluble interleukin-2 receptor is suggested to be one of the useful markers for evaluating the clinical aggressiveness of the disease and for monitoring the response to therapy in patients with ATLL.

Histopathology

The circulating cells in the peripheral blood have markedly polylobated nuclei with homogeneous and condensed chromatin, small or absent nucleoli, and agranular and basophilic cytoplasm—the so-called flower cells that are characteristic of ATLL (Fig. 114-3).[55] A considerable diversity of morphology among ATLL cells has been recognized, however. Tsukasaki and associates[66] investigated the morphology of ATLL cells in 36 acute cases and 14 chronic cases. Chronic lymphocytic leukemia–like morphology with round nuclei was more frequent in the chronic type than in the acute type. In contrast, unusual morphology (lymphoblastic, vacuolated, granular pleomorphic, or large cells) was more frequent in the acute type than in the chronic type.

The swollen lymph nodes in patients with ATLL show diffuse NHL of various histologic subtypes, including pleomorphic, large cell, mixed cell, or medium-sized cell types.[67,68] Figure 114-4 shows the histology of a biopsied swollen lymph node from a patient with lymphoma-type ATLL. The pleomorphic pattern (i.e., a mixture of various-sized lymphoma cells from small cells to giant cells) and nuclear polymorphism are recognized. Lymph nodes from some patients in the incipient or early neoplastic phase of ATLL histologically resemble those that are found in Hodgkin's lymphoma.[69–71]

ATLL cells frequently involve the skin. Generalized nodular or papulonodular eruptions, as shown in Figure 114-5A, are common; however, tumorous lesions are also recognized in some patients. Erythematous plaque formation and sometimes nodular tumors are other cutaneous manifestations.[71,72] Histologically, diffuse or patchy infiltration of atypical lymphoid cells—usually small or medium in size with polymorphic nuclear contours in the upper dermis, sometimes with an intraepidermal infiltration—is noted (Fig. 114-5B). Large nuclear cells with highly irregular or cerebriform features are intermingled in some cases.

One of the difficult issues in the diagnosis of ATLL is its relationship with other peripheral T-cell malignancies that are not associated with HTLV-I. The clinical diagnosis of ATLL is suspected by the unique combination of its clinical and pathologic features. One of the T-cell malignancies that is likely to be confused with ATLL is mycosis fungoides/Sézary syndrome (MF/SS). Because cutaneous involvement is frequent in ATLL, the differentiation of smoldering-type ATLL from MF/SS is often difficult on the basis of the clinical manifestations alone. In the differential diagnosis of ATLL and other peripheral T-cell malignancies, HTLV-I serology and the molecular detection of the monoclonal integration of HTLV-I proviral DNA are important. Various kinds of serologic assays have been used, including the immunofluorescence assay, the particle agglutination assay, the enzyme-linked immunosorbent assay (ELISA), and the Western blot assay. In general, a particle agglutination assay or ELISA is useful as a screening test, and Western blotting is used for the confirmation of the presence of serum antibody to HTLV-I. As shown in Figure 114-6, the demonstration of the monoclonal integration of HTLV-I proviral DNA by Southern blot analysis can lead to a definite diagnosis of ATLL.

Several studies have reported the presence of seronegative HTLV-I carriers, and some HTLV-I carriers have been reported to be negative for serum anti-HTLV-I antibodies against viral structural proteins on screening examinations.[73] Kinoshita and associates[74] examined peripheral blood mononuclear cells from 209 healthy subjects living in an HTLV-I-endemic district in Japan for HTLV-I provirus, using PCR. A total of 76 subjects were positive for the provirus and 133 were negative, showing a close correlation with the results of the previously mentioned assays for anti-HTLV-I serum antibodies. None of the seronegative subjects reacted positively in PCR analysis. Infrequent HTLV-I infection among seronegative subjects in Japan was also suggested by the finding that the screening of blood donors for serum HTLV-I antibodies by the PA assay has reduced markedly the risk of HTLV-I transmission by blood transfusions.[75] Furthermore, by using PCR analysis, the absence of seronegative HTLV-I carriers among blood donors and healthy junior high school students in Japan was confirmed.[76] These observations suggest that seronegative HTLV-I carriers are extremely rare, although the possibility of their existence remains.

In Western countries, it has been reported that the HTLV-I viral genome was detected in the genomic DNA from patients with MF/SS, and a causal relation between HTLV-I and MF/SS was proposed.[77,78] An opposite conclusion was reached in a Japanese study; using PCR with four sets of primers (including *gag*, *pol*, *env*, and *pX* regions of HTLV-I), Kikuchi and colleagues[79] investigated both fresh and cultured T cells (128 specimens) derived from 50 Japanese patients with CTCL. In their study, none of the 128 DNA samples revealed positive results for HTLV-I. They concluded that CTCL, which does not include HTLV-I, is present in Japan. The absence of a correlation between HTLV-I and CTCL was confirmed by an international cooperative study reported by Bazarbachi and coworkers.[80] These researchers analyzed 128 patients (85 with MF, 28 with SS, 5 with Sézary cell leukemia, 4 with lymphomatoid papulosis, and 5 with unspecified CTCL) originating from Europe (France, Spain, United Kingdom, or Portugal) or from the United States (California) for the presence of HTLV-I infection markers, using a serologic analysis for antibody to HTLV-I, a reverse transcriptase assay, and a molecular analysis with PCR-amplified specimens. The results of this international study suggest that MF and SS are not associated with HTLV-I infection.

HTLV-I can infect lymphoid cells of different cell lineages in vitro, but the neoplastic cells in the great majority of ATLL cases exhibit the phenotype of mature CD4-positive T cells.[81] Malignant cells from the peripheral blood or from involved lymph nodes express CD2, CD3, CD4, CD5, the αβ-chains of the TCR, CD25 (IL-2Rα), CD45, CD29, and HLA-DR.[82,83] It is known that the expression of the CD3/TCR complex is decreased in ATLL cells.[84] Most ATLL cells lack CD7. Considerable phenotypic heterogeneity has been found in the neoplastic cells of ATLL. Although the most common phenotype is CD4-positive/CD8-negative, some patients with ATL exhibit a CD4-positive/CD8-positive, CD4-negative/CD8-positive, or CD4-negative/CD8-negative phenotype. In addition, some patients with ATLL show phenotypic changes throughout the course of their disease. As regulatory T cells (Treg cells) express CD4-positive and CD25-positive molecules and possess potent immune response suppressive activity, several investigators analyzed a possible link between ATLL cells and Treg cells and found that forkhead/winged helix transcription factor (FoxP3), a

Lymphoma cells of various sizes—small cells, medium-size cells, large cells, and giant cells—are present. Nuclear polymorphism is present in most lymphoma cells.

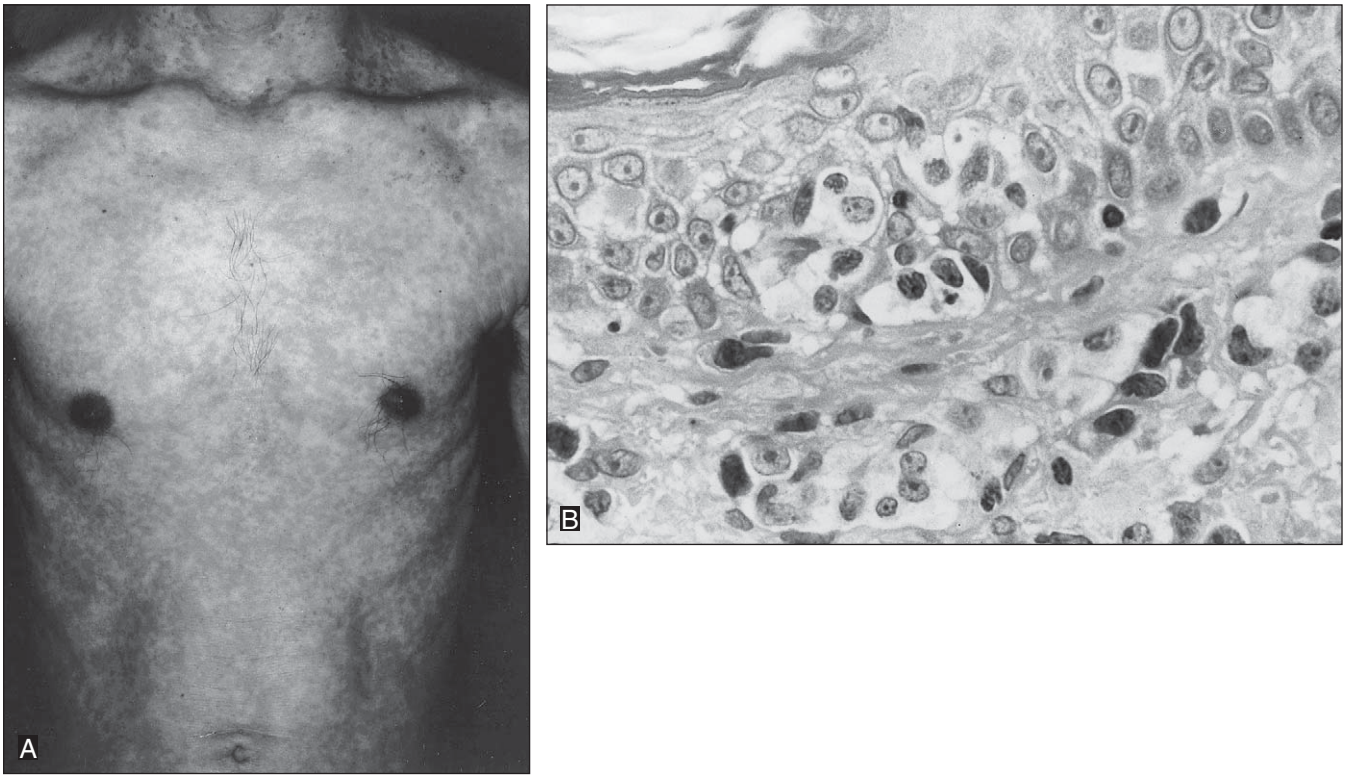

Figure 114-5 • Skin involvement of ATLL. **A,** Photograph of skin lesions in a patient with acute-type ATLL. **B,** Histology of skin infiltration of ATLL cells in the same patient; infiltrating leukemic cells are present in the epidermis.

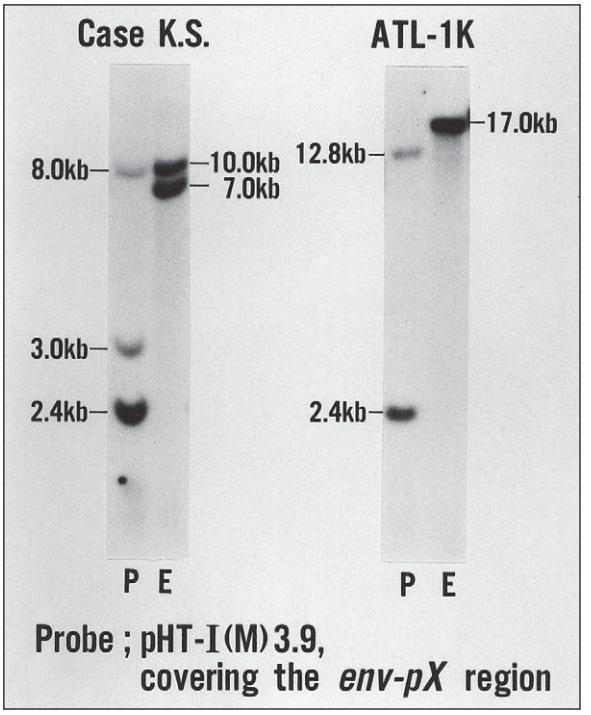

Figure 114-6 • Southern blot analysis of HTLV-I proviral DNA in peripheral blood mononuclear cells from an ATLL patient. The genomic probe, pHT-I (M) 3.9, covering the env-pX region, was used. ATL-1K, a cultured cell line from ATLL, was used as a positive control. The restriction enzymes Pst I (P) and EcoRI (E) were used. In the cellular DNA from this patient, two bands are present in the EcoRI digest, indicating the monoclonal integration of HTLV-I proviral DNA.

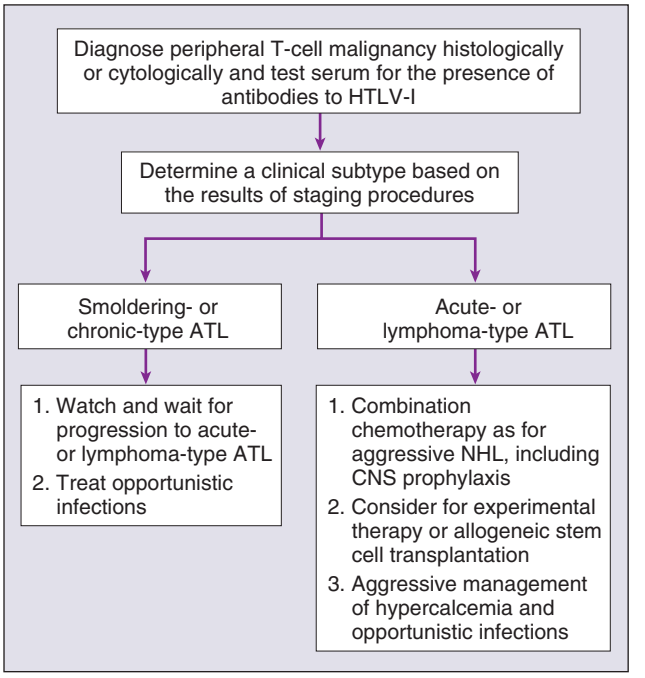

Figure 114-7 • Approach to the patient with adult T-cell leukemia-lymphoma.

specific marker that is important for the function of Treg, on most ATLL cells. These results suggest the origin of ATLL cells to be derived from Treg.[85–87]

One of the remarkable features of ATLL cells (and of most HTLV-I-infected cells) is the expression of IL-2R. Both the α- and β-chains of IL-2R are expressed on the surface of ATLL cells. It is postulated that IL-2 and IL-2R are implicated in the pathogenesis of ATLL. IL-2R is expected to be an excellent target for monoclonal antibody therapy.[88]

CLINICAL COURSE AND TREATMENT

ATLL most often pursues the prototypic acute course; however, approximately one fourth of patients show a more indolent course (chronic and smoldering types), with disease limited predominantly to the peripheral blood and/or skin. These patients might experience multiple infections but can remain free of disease progression for many years.[55] These indolent diseases frequently progress to full-blown acute or lymphomatous ATLL, an event that is sometimes called the crisis. Some studies have reported that various kinds of infectious episodes might predispose to the transformation from an indolent to an aggressive disease course. At present, however, it is impossible to identify patients at the highest risk of transformation (Fig. 114-7).

Most patients with ATLL are not curable with current treatment modalities, even at the early stage of disease. In addition, no treatment has been shown to prevent progression to a more aggressive disease. Patients with chronic- or smoldering-type ATLL should be watched carefully for the development of infectious complications and for signs of progression to acute or lymphomatous ATLL.

Without treatment, most previously untreated patients with aggressive forms (acute or lymphoma type) of ATLL die within weeks or months of diagnosis. The treatment of patients with acute or lymphomatous ATLL has not been very successful. Figure 114-8 shows the overall survival (OS) of 818 patients with ATLL regardless of disease subtype, and Figure 114-9 presents their survival curves according to the four clinical subtypes.[55] Some 85% of the patients received chemotherapy with one of a variety of different regimens. Most of the patients with smoldering-type ATLL lived well without chemotherapy for a long period. Approximately two thirds of the chronic-type patients died within about 2.5 years of diagnosis. Patients with lymphoma-type ATLL had poor prognoses, with an MST of 10.2 months. The most aggressive type of ATLL was the

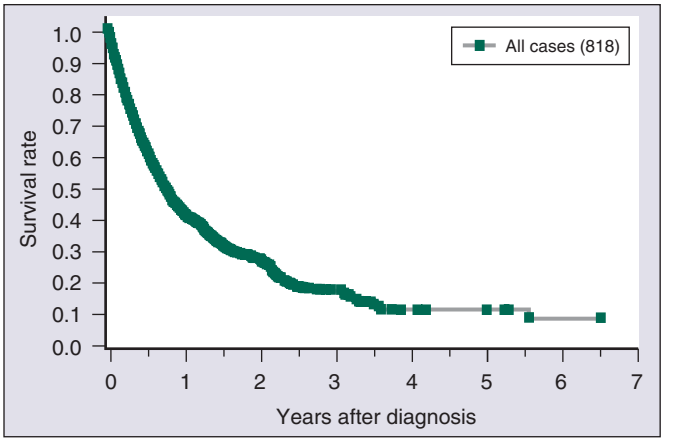

Figure 114-8 • Survival curves of 818 patients with ATLL. Number in parentheses indicates number of patients. (From Shimoyama M, and members of the Lymphoma Study Group, 1984–1987: Diagnostic criteria and classification of clinical subtypes of adult T-cell leukemia-lymphoma. Br J Haematol 1991;79:428.)

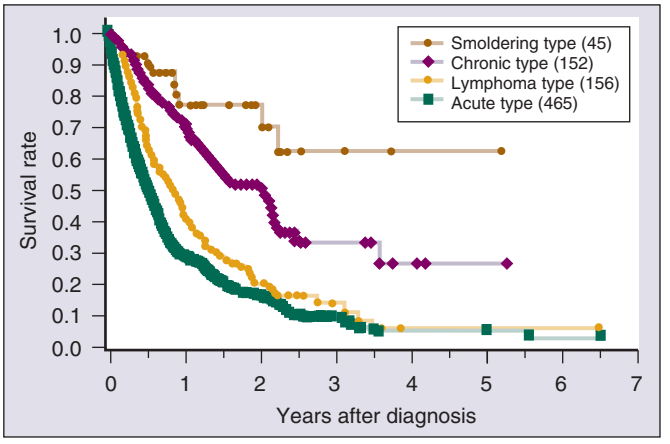

Figure 114-9 • Survival curves of 818 patients with ATLL according to four clinical subtypes defined by the diagnostic criteria. Numbers in parentheses indicate number of patients. (From Shimoyama M and members of the Lymphoma Study Group, 1984–1987: Diagnostic criteria and classification of clinical subtypes of adult T-cell leukemia-lymphoma. Br J Haematol 1991;79:428.)

acute type, with an MST of 6.2 months. The projected 4-year survival rates of patients with the lymphoma and acute types were only 5%. The clinical subtype clearly determines the prognosis of each patient, suggesting that it can be used as a prognostic indicator for patients with ATLL.[55]

The Lymphoma Study Group (LSG) in Japan has analyzed prognostic factors for each subtype of ATLL.[89–91] In all patients with ATLL, advanced age (40 years or greater), poor performance status, high serum LDH, hypercalcemia, and four or more involved lesions were unfavorable factors. For patients with chronic-type ATLL, the major prognostic factors were the serum LDH, albumin, and blood urea nitrogen. Patients with chronic-type ATLL and normal values for the three factors (30% of patients with chronic type disease) showed a prognosis as good as that of patients with smoldering-type ATLL. Thus, patients with the favorable chronic type with normal LDH, albumin, and blood urea nitrogen values need not be treated immediately and can be placed on follow-up without treatment, whereas patients with the unfavorable chronic type who have an abnormal value in at least one of the three factors are candidates for cytotoxic chemotherapy[91] (Box 114-1).

Clinical Trials by the Japan Clinical Oncology Group

Six consecutive chemotherapy trials focusing on ATLL have been conducted by the Lymphoma Study Group (LSG) of the Japan Clinical Oncology Group (JCOG) since 1978.[92–99] The first trial, called LSG1 protocol (1978 to 1980), utilized VEPA therapy, which consisted of vincristine (VCR), cyclophosphamide (CPA), prednisolone (PSL), and doxorubicin (DOX). In this study, patients with NHL (including ATLL) at an advanced stage were enrolled. The complete remission (CR) rate was lowest (18%) for ATLL, intermediate (36%) for peripheral non-ATLL T-lymphoma (PNTL), and highest (64%) for B-cell lymphoma.[92,93] Between 1981 and 1983, the JCOG-LSG conducted a phase III trial using LSG1-VEPA versus LSG2-VEPA-M (VEPA + methotrexate) against advanced NHL, including ATLL.[94,95] Patients' sera were examined for anti-HTLV-I antibody to distinguish ATLL from PNTL.[100] The CR rate for patients who were given LSG2-VEPA-M for ATLL (37%) was higher than that for patients who were given LSG1-VEPA (17%; $P = 0.09$). In the LSG1/LSG2 trial, however, the CR rate was significantly lower for ATLL than for B-cell lymphoma and PNTL ($P < 0.001$). The MST of the 54 patients with ATLL treated with LSG1/LSG2 was 6 months, and the estimated 4-year survival rate was only 8%.[94,95] These results suggest that CHOP-like chemotherapy of the first generation was not very effective against ATLL.

Between 1987 and 1991, the JCOG-LSG conducted a combination phase II study (JCOG8701) of a second-generation combination chemotherapy against advanced aggressive NHL (including ATLL). This combination chemotherapy, called LSG4, consisted of three different regimens:

1. VEPA-B-VCR, CPA, PSL, DOX, and bleomycin (BLM)
2. M-FEPA-methotrexate (MTX), vindesine (VDS), CPA, PSL, and DOX
3. VEPP-B-VCR, etoposide (ETP), procarbazine (PCZ), PSL, and BLM[96]

The CR rate (72%) for the LSG4 protocol among patients with aggressive NHL was significantly higher than that for the LSG1/LSG2 trial (57%; $P < 0.05$). The CR rate for ATLL was improved from 28% (LSG1/LSG2) to 43% (LSG4). On the other hand, the CR rate for LSG4 was significantly lower for ATLL than for B lymphoma and PNTL ($P < 0.01$). The patients with ATLL still showed a poor prognosis, with an MST of 8 months and a 4-year survival rate of 12%; however, the continued CR rate was increased to 12% (5 of 43) compared with 4% (2 of 54) in the LSG1/LSG2 trial. A multivariate analysis of the 267 patients with advanced aggressive NHL who were treated with the LSG4 demonstrated that the clinical diagnosis of ATLL was the most significant unfavorable prognostic factor (relative risk: 3.185; $P = 0.0001$) for aggressive NHL patients in Japan.[96]

The disappointing results with conventional chemotherapies have led to the search for new active agents. 2′-Deoxycoformycin (DCF;

Box 114-1. MANAGEMENT STRATEGY FOR PATIENTS WITH ADULT T-CELL LEUKEMIA-LYMPHOMA

When oncologists diagnose patients who are suspected of lymphoid malignancy, it is important to consider the possibility of ATLL. A routine check for serum HTLV-I antibody is recommended at initial diagnosis. The following three points are essential for the diagnosis of ATLL:

1. Cytologically or histologically proven lymphoid malignancy
2. Mature T-cell phenotype, mostly CD4-positive, determined by flow cytometry or immunohistochemistry
3. Positive for anti-HTLV-I antibody

When a patient is diagnosed with ATLL, it is important to determine the clinical subtype for the sake of optimizing treatment strategy. For patients with smoldering- or chronic-type ATLL, close observation is recommended. Careful monitoring for opportunistic infections—including bacterial, fungal, or *Pneumocystis carinii* infection—is also needed. For patients with acute- or lymphoma-type ATLL, the serum calcium level should be checked immediately. For those with complications of hypercalcemia, prompt management includes fluid therapy, bisphosphonate, and chemotherapy. Patients with acute- or lymphoma-type ATLL that requires therapy should be enrolled in clinical trials if these are available. When there is no active clinical trial or if a patient is ineligible for the trial, chemotherapy for aggressive NHL should be considered. For such patients, we usually give the LSG15 regimen, a multiagent dose-intensified regimen,[98] or CHOP therapy with prophylactic intrathecal administration of MTX. Because most patients with ATLL are not curable with current chemotherapy regimens, it is reasonable to consider the applicability of allogeneic stem cell transplantation for patients who have responded to chemotherapy. For relapsed or refractory patients, consider allogeneic stem cell transplantation or enrollment in a clinical trial of a new chemotherapeutic agent.

pentostatin), an irreversible inhibitor of adenosine deaminase, has been shown to be effective in a number of lymphoid malignancies. On the basis of the promising results of some single-institute studies of DCF, multicenter phase I and phase II studies of DCF were conducted against ATLL in Japan.[91,101] The phase II study of DCF revealed a response rate of 32% (10 of 31) in relapsed or refractory ATLL, using the weekly intravenous administration of 5 mg/m^2. Two patients achieved CR, and eight patients achieved partial response (PR).[91] These encouraging results prompted the Japanese investigators to conduct a DCF-containing combination phase II trial (JCOG9109; LSG11) as initial chemotherapy for ATLL.[97] Sixty-two previously untreated patients with ATLL (34 patients with acute, 21 with lymphoma, and 7 with chronic subtypes) were enrolled. VCR (1 mg/m^2 intravenously on days 1 and 8), DOX (40 mg/m^2 intravenously on day 1), ETP (100 mg/m^2 intravenously on days 1 through 3), PSL (40 mg/m^2 orally on days 1 and 2), and DCF (5 mg/m^2 intravenously on days 8, 15, and 22) were administered every 28 days for 10 cycles unless disease progression or toxic complications occurred. Among the 61 patients who were evaluable for toxicity, 4 patients (7%) died of fatal infections (2 of sepsis and 2 of cytomegalovirus pneumonia). No other fatal nonhematologic toxicities occurred. In the 60 eligible patients, 17 (28%; 95% CI: 19% to 41%) achieved CR, while 14 achieved PR (response rate: 52%; 95% CI: 39% to 64%). After a median observation time of 27 months, the MST was 7.4 months, and the estimated 2-year survival rate was 17%, findings that were identical to those for the 43 patients with ATL who were treated with the previous LSG4 (JCOG8701).[96,97] Two conclusions were reached on the basis of the JCOG9109 study. First, patients with ATLL who were treated with a DCF-containing five-drug regimen (the LSG11) showed survival comparable with that of patients who were treated with a nine-drug regimen (the LSG4). Second, the prognosis of the patients with ATLL remained poor even though they were treated with a DCF-containing combination chemotherapy.

In 1994, JCOG-LSG initiated a new multiagent combination phase II study (JCOG9303; LSG15): a nine-drug regimen consisting of VCR, CPA, DOX, PSL, nimustine (MCNU), VDS, ETP, and carboplatin (CBDCA) with the intrathecal administration of MTX and PSL, for untreated patients with ATLL.[98] In this study, the elevation of relative dose intensity was attempted with the prophylactic use of granulocyte colony-stimulating factor. In addition, non-cross-resistant agents such as MCNU and CBDCA were incorporated into the regimens. Ninety-six previously untreated patients with aggressive ATLL were enrolled: 58 with acute type, 28 with lymphoma type, and 10 with unfavorable chronic type. Of the 93 eligible patients, 81% responded (75 of 93), 33 patients (35%) achieving CR and 42 (45%) achieving PR. Patients with lymphoma-type ATLL showed a better CR rate (67%, 18 of 27) than patients with acute-type ATLL (20%, 11 of 56) and patients with unfavorable chronic-type ATLL (40%, 4 of 10). The OS rate of 93 eligible patients at 2 years was 31% (Fig. 114-10). The MST was 13 months, and the median follow-up duration of the 20 surviving patients was 4.2 years. A trend toward better survival for patients with lymphoma-type ATLL (MST, 20 months) compared with patients with acute-type ATLL (MST: 11 months) was recognized (hazard ratio: 1.65). Grade 4 hematologic toxicities of neutropenia and thrombocytopenia were observed in 65% and 53% of the patients, respectively, but grade 4 nonhematologic toxicity was observed in only one patient. It was concluded that the LSG15 was feasible with mild nonhematologic toxicity and that it improved the clinical outcome of patients with ATLL.

To confirm whether the LSG15 is a new standard for the treatment of aggressive ATLL, JCOG-LSG conducted a phase III study comparing the LSG15 and biweekly CHOP (CPA, DOX, VCR, and PSL). Previously untreated patients with aggressive ATLL were randomized to receive either six courses of the LSG15 every 4 weeks or eight courses of biweekly CHOP. Both regimens were supported with granulocyte colony-stimulating factor and intrathecal prophylaxis. One hundred and eighteen patients were randomized. Seventy-two percent of the patients responded, with 23 patients achieving CR (40%) and 18 achieving PR (32%) in the LSG15. The ORR was 66%, with 15 patients achieving CR (25%) and 25 achieving PR (41%) in biweekly CHOP. The median progression-free survival (PFS) time and PFS at 1-year in the former were 7.0 months and 28%, respectively, whereas 5.4 months and 16% in the latter (P = 0.10). The MST and OS at 3 years in the former were 12.7 months and 24%, respectively, whereas 10.9 months and 13% in the latter (P = 0.085). After adjustment of patients' characteristics by Cox regression, the P value for OS became 0.029 because of unbalanced prognostic factors such as bulky lesion. In the LSG15 versus biweekly CHOP, percentage of grade 4 neutropenia, percentage of grade 4 thrombocytopenia, and percentage of grade 3 to 4 infection were 98% versus 83%, 74% versus 17%, and 32% versus 15%, respectively. Three toxic deaths were reported in the former. These results demonstrate that the LSG15 yields longer OS time than biweekly CHOP but with higher toxicity profiles that are acceptable and suggest that the LSG15 should be the new standard therapy for aggressive ATLL.[99]

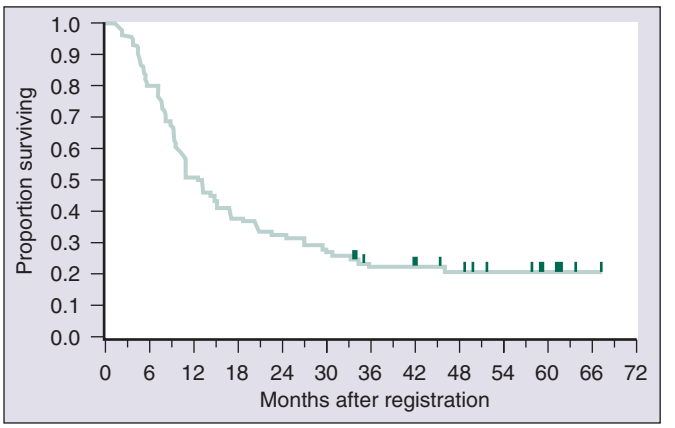

Figure 114-10 • Kaplan-Meier estimate of the overall survival (OS) for the 93 eligible patients with aggressive ATLL. OS was defined as the time from registration until death from any cause or until the last follow-up evaluation for patients who were still alive (20 patients). (From Yamada Y, Tomonaga M, Fukuda H, et al: A new G-CSF-supported combination chemotherapy, LSG15, for adult T-cell leukemia-lymphoma [ATL]: Japan Clinical Oncology Group (JCOG) Study 9303. Br J Haematol 2001; 113:375.)

Development of New Agents for Therapy of Adult T-Cell Leukemia-Lymphoma

In addition to DCF, several types of new agents against ATLL have been investigated.

Irinotecan Hydrochloride

Irinotecan hydrochloride (CPT-11) is a semisynthetic camptothecin with inhibitory activity against topoisomerase I. Preclinical studies of CPT-11 have suggested a lack of cross-resistance between topoisomerase I inhibitors and other anticancer agents. Multicenter phase II studies of CPT-11 have been conducted against relapsed or refractory NHL in Japan.[102,103] In this study, 9 patients achieved CR, and 17 patients achieved PR (response rate 38%: 26 of 69), using a weekly intravenous administration of 40 mg/m^2/day for 3 consecutive days. Within this group, 5 of 13 patients with ATLL (38%) responded to CPT-11 (1 patient achieving CR and 4 achieving PR).[103,104] The major toxicities of CPT-11 were leukopenia, diarrhea, and nausea and/or vomiting. Subsequently, to develop a new effective chemo-

therapy regimen against NHL and ATLL, two kinds of phase I/II studies of CPT-11 in combination with CBDCA or ETP were conducted for relapsed or refractory NHL.[105,106] In both studies, however, dose escalation was halted because of hematologic toxicity (in combination with CBDCA) and hepatotoxicity (in combination with ETP).

Interferon-α

On the basis of preliminary documentation of the efficacy of interferon-α against ATLL, two kinds of phase II trials of high-dose interferon-α have been conducted; however, the results have not been impressive. In 1995, Gill and associates[107] reported that 11 of 19 patients with acute- or lymphoma-type ATLL achieved major responses (5 CR and 6 PR) by the combination therapy of interferon-α and zidovudine. The efficacy of this combination was also observed in a French study; major objective responses were obtained in all five patients with ATLL (four with acute type and one with smoldering type).[108] Although the results of this combination are encouraging, the OS of previously untreated patients with ATLL was relatively short (4.8 months) compared with the survival of those in the chemotherapy trials conducted by the JCOG-LSG (7 to 8 months). Furthermore, the CR rate that was associated with the use of interferon-α and zidovudine among previously untreated patients (25%: 3 of 12) was not superior to the CR rates among those who were treated with the JCOG-LSG chemotherapy protocols (28% to 42%).[109] In 2001, White and colleagues[110] reported the results of this combination used for 18 patients with ATLL; only three patients (17%) showed objective responses (one CR and two PRs). Seventeen patients died with an MST after initiation of therapy of 6 months. To evaluate the role of this combination in ATLL, further studies are needed.

Cladribine

Cladribine (2-chlorodeoxyadenosine) is a chlorinated purine analog that resists degradation by adenosine deaminase. Cladribine has been found to be effective against various B-cell malignancies such as hairy cell leukemia, B-cell chronic lymphoid leukemia, and indolent B-cell NHL. It is known that deoxycytidine kinase is rich in T cells, and an in vitro study showed the sensitivity of T-lymphoblastoid cell lines to cladribine. In addition, cladribine was reported to be effective against CTCL. With the aim of establishing an effective treatment against ATLL, clinical trials of cladribine were conducted in Japan. In the Japanese phase I study of cladribine, one relapsed patient with ATLL achieved PR.[111] On the basis of this encouraging result, a multicenter phase II study of cladribine against ATLL was conducted in Japan.[112] Cladribine was administered as 0.09 mg/kg/day by 7-day continuous intravenous infusion every 28 days up to six courses. When the planned interim analysis revealed that only 1 of the 15 eligible patients showed PR (response rate: 7%; 90% CI: 0% to 28%), however, patient entry into the phase II study was terminated.

Monoclonal Antibodies

Because most ATLL cells express the α-chain of IL-2R (CD25), Waldmann and colleagues have treated patients with ATLL with monoclonal antibodies to CD25.[88] Anti-Tac (anti-CD25) is a murine monoclonal IgG2a antibody that does not fix human complement, nor does it mediate antibody-dependent cell-mediated cytotoxicity. Anti-Tac has been shown to prevent the growth of certain cell lines in vitro, however, even in the absence of complement, by blocking IL-2 from gaining access to its receptor. Six of 19 patients (32%) who were treated with anti-Tac showed PR (4 patients) or CR (2 patients) lasting from 9 weeks to more than 3 years.[113] One of the significant impediments to this approach is that a quantity of soluble IL-2R is shed by the tumor cells into the circulation. The soluble IL-2R can bind to anti-Tac and inhibit binding to the tumor cell.

Other strategies using IL-2R as a target for the treatment of ATLL are conjugation with an immunotoxin (Pseudomonas exotoxin) or radioisotope (yttrium-90).[114,115] Anti-Tac coupled with Pseudomonas exotoxin, which inhibits protein synthesis, has been administered to patients with ATLL.[114] The action of immunotoxins depends on the expression of the target antigen on all malignant cells and on the cell's ability to internalize the antigen-antibody-complex that contains the toxin. To circumvent findings that not all malignant cells express the target antigen and that not all cells internalize bound substances, radiolabeled monoclonal antibodies (radioimmunoconjugates) were developed. Radioimmunoconjugates have the advantage of killing adjacent antigen-negative neoplastic cells or cells that fail to internalize the antigen-antibody complex. Waldmann and associates[115] have developed a stable conjugate of anti-Tac with yttrium-90. They have treated 18 patients with ATLL using this radioimmunoconjugate. Among the 16 patients who received 5- to 15-mCi doses, 9 (56%) showed objective responses (2 CR and 7 PR). The duration of response was longer than the previous results with unconjugated anti-Tac. Grade 3 or greater toxicities were limited largely to hematologic toxicities. The researchers claim that yttrium-90-labeled anti-Tac might provide a useful approach for the treatment of ATLL.

Prolonged circulation of radioimmunoconjugate irradiates normal tissues and radiosensitive bone marrow, producing DLTs (including myelosuppression), which limit the radiation dose that can be administered safely. In addition, the large size of the antibodies yields only slow access to tumor cells in bulky masses, precluding the use of short-lived radionuclides. In the pretargeting system, antibody and radionuclides are administered separately, and radioactivity rapidly and selectively accumulates in tumors, with a parallel reduction of radioactivity in normal tissues. Several molecular pairs with a high binding affinity, such as avidin and biotin, can be utilized for this purpose. Pretargeting is a novel technique in radioimmunotherapy that might offer means to deliver higher doses of radioimmunoconjugates in a way that significantly reduces exposure to normal tissues.[116]

Ishida and coworkers conducted immunostaining analysis for anti-CC chemokine receptor 4 (CCR4) expression in ATLL cells obtained from 103 patients with ATLL, and the clinical parameters and OS of the CCR4-positive and CCR4-negative patients were compared. Ninety-one (88%) of the 103 cases were positive for CCR4 staining. Multivariate analysis revealed that CCR4 expression was an independent prognostic factor ($P < 0.05$).[117] A novel humanized CCR4 monoclonal antibody has been developed, the Fc region of which is defucosylated to enhance antibody-dependent cellular cytotoxicity by increasing its binding affinity to Fc receptor on effector cells. A phase I study of this anti-CCR4 mAb in patients with CCR4-positive T-cell malignancy including ATLL has been initiated in Japan.[118]

One of the potentially promising strategies for developing a new treatment against ATLL is to overcome drug resistance.[119,120] Kuwazuru and colleagues[119] analyzed the expression of p-glycoprotein (P-gp) in samples from 25 patients with ATLL by immunoblotting with a monoclonal antibody against P-gp. All six patients at relapsed were P-gp positive. More important, neoplastic cells from 8 of 20 patients with ATLL expressed P-gp at initial presentation. These results suggest that the expression of multidrug-resistant (mdr1) P-gp might correlate with the refractory nature of ATLL cells to cytotoxic chemotherapy. Subsequently, Lau and coworkers[120] reported the results of their investigation of the presence of an active multidrug-resistance phenotype in freshly isolated peripheral blood mononuclear cells from asymptomatic HTLV-I carriers, patients with TSP/HAM, and patients with ATLL. Significant P-gp-mediated efflux activity and enhanced mdr1 mRNA expression were observed in CD3-positive T-cell populations from 9 of 10 subjects. Furthermore, it was found that mdr1 gene promoter is transcriptionally activated by the HTLV-I Tax protein. These observations suggest the possibility of new

chemotherapeutic strategies against ATLL through the use of P-gp inhibitors.

Arsenic Trioxide

Arsenic trioxide (As_2O_3) is an effective agent for acute promyelocytic leukemia. Ishitsuka and associates[121] examined the suppressing effect of As_2O_3 on in vitro growth of HTLV-I-infected T-cell lines and fresh ATLL cells. Proliferation of four HTLV-I-infected T-cell lines was reduced significantly by As_2O_3. The authors claimed that As_2O_3 has therapeutic potential for the treatment of ATLL. Bazarbachi and colleagues[122] tested the effects of the combination of As_2O_3 and interferon-α on cell proliferation, cell cycle phase distribution, and apoptosis in ATLL-derived T-cell lines; they found a synergistic effect between both.

Allogeneic Hematopoietic Stem Cell Transplantation

The results of allogeneic hematopoietic stem cell transplantation (allo-HSCT) for ATLL were reported by Japanese investigators.[123,124] In the report by Utsunomiya and associates,[123] 10 patients tolerated well the conditioning regimens, including total body irradiation. The median disease-free survival (DFS) after allo-HSCT was more than 17.5 months. Four patients died during the study period from acute graft-versus-host disease (grade IV), pneumonitis, gastrointestinal bleeding, or renal insufficiency. Two of 10 patients with no symptoms of graft-versus-host disease relapsed. In the more recent report by Fukushima and associates,[124] the authors analyzed 40 patients with acute and lymphoma types of ATLL who were treated with allo-HSCT in Japan between 1997 and 2002. All evaluable patients achieved CR after allo-HSCT, and the median survival time was 9.6 months. The estimated 3-year OS, DFS, and disease relapse rates were 45%, 34%, and 39%, respectively. Among 10 patients with relapsed ATLL after allo-HSCT, 5 patients achieved CR again: 3 by the reduction or cessation of immunosuppressive agents, which suggested a graft-versus-ATLL effect. These results suggested that allo-HSCT was effective for some patients with aggressive ATLL. In addition to the conventional allo-HSCT, Okamura and associates reported the results of a multicenter feasibility study of reduced-intensity allo-HSCT against ATLL.[125] Sixteen patients, all over 50 years of age, underwent allo-HSCT from human leukocyte antigen–matched sibling donors after a reduced-intensity allo-HSCT consisting of fludarabine (180 mg/m^2), busulfan (8 mg/kg), and rabbit antithymocyte globulin (5 mg/kg). The observed regimen-related toxicities and nonhematologic toxicities were acceptable. Disease relapse was the main cause of treatment failure. Three patients who had a relapse subsequently responded to a rapid discontinuation of the immunosuppressive agent and thereafter achieved another remission. After reduced-intensity allo-HSCT, the HTLV-1 proviral load became undetectable in eight patients. Reduced-intensity allo-HSCT is thus considered to be a feasible treatment for ATLL, warranting further investigations.

Treatment of Complications

Hypercalcemia, which eventually occurs in most patients with ATLL, usually can be controlled with antitumor therapy and the appropriate use of other calcium-lowering agents.

Another major obstacle for the successful treatment of ATLL is T-cell immunodeficiency. Patients with ATLL often have infectious complications at diagnosis. As is shown in Table 114-2, 26% had infections at initial presentation, more than half of which were fungal, protozoal, and viral infections.[55] This finding could be due to a profound T-cell immunodeficiency. Other frequently encountered opportunistic infections include *Pneumocystis jirovecci* infection, tuberculosis, cytomegalovirus infection, and adenovirus infection.

Subclinical immunodeficiency was also evident among healthy carriers of HTLV-I. Strongyloidiasis is frequently associated with smoldering-type ATLL and an intermediate state between the healthy carrier state and smoldering-type ATLL. HTLV-I is known to induce the suppression or alteration of T-cell function. Yasunaga and coworkers,[126] in a study of peripheral blood mononuclear cells from HTLV-I-infected individuals, found a decrease in naive T cells and decreased levels of TCR gene rearrangement excision circles (generated by DNA recombination during early T lymphopoiesis) and an increase in Epstein-Barr virus DNA. It was suggested that the low number of naive T cells was due to suppressed production of T cells in the thymus, which might account for immunodeficiency in HTLV-I-infected individuals. Patients with ATLL require some supportive or preventive therapies for fungal, protozoal, and viral infections. A low dose of cotrimexazole and an oral antifungal agent are recommended for use, together with cytotoxic chemotherapy.

There are case reports of B-cell NHL associated with Epstein-Barr virus and of Kaposi's sarcoma in patients with ATLL.[127,128] The profound immunodeficient state in patients with ATLL might allow the emergence of such opportunistic tumors.

  chromosomal abnormalities in, 2217–2219, 2218f, 2219f
  classification of, 2215
    FAB system for, 2219–2221, 2220f, 2223t
    WHO system for, 2133–2135, 2134t, 2215, 2221, 2223t
  clinical manifestations of, 2222–2223, 2223f, 2224f
Acute myeloid (myelogenous, myelocytic, myeloblastic, nonlymphoblastic) leukemia (AML) (*cont.*)
  cytogenetics of, 253t, 2220–2221, 2221t, 2222f, 2222t
  cytopenias in, 684
  diagnosis of, 2215
  differential diagnosis of, 2224
  with differentiation, 2220
  epidemiology of, 2215, 2216f
  erythroid, 2220, 2220f
  etiology of, 2215–2217
  familial clustering of, 2216
  flow cytometry of, 243
  genetic syndromes associated with, 2216–2217
  immunophenotypes of, 2220
  laboratory manifestations of, 2223–2224
  with maturation, 2220, 2220f
  megakaryoblastic, 2220, 2220f
  with minimal or no maturation, 2220, 2220f
  minimally differentiated, 2220
  monoblastic, 2220f
  monocytic, 2220, 2220f
  morphology of, 2219–2220, 2220f
  with multilineage dysplasia, 2223t
  myelomonocytic, 2220, 2220f
  ocular involvement in, 1149f
  pathology of, 2219–2221, 2220f, 2221t, 2222f, 2222t
    molecular, 2217–2219, 2218f, 2219f
  pathophysiology of, 2217
  during pregnancy, 1057
  prognosis for, age-related changes in, 1042t
  promyelocytic (*See* Acute promyelocytic leukemia [APL])
  recurrent, 2227–2228, 2227b
  with recurrent genetic abnormalities, 2223t
  as second malignant neoplasm
    in adults, 1029, 1031–1033
    in children, 1026–1027, 1027f
    with Hodgkin's lymphoma, 2367
  treatment of, 2215, 2224–2230
    emergency, 2224
    future directions in, 2230
    hematopoietic stem cell transplantation for, 505, 2226–2228
    lintuzumab for, 534
    monitoring response to, 2229–2230
    in older patients, 2225–2226
    postremission, 2226, 2227
    primary, 2224–2227
    for recurrent disease, 2227–2228, 2227b
    reinduction chemotherapy for, 2227–2228, 2227b
    remission induction in, 2224–2226
  treatment-related, 2216, 2223t
  tumor biology of, 2215, 2217–2219, 2218f, 2219f
Acute myelomonocytic leukemia, 2220, 2220f
  in children, 2145, 2145t
Acute necrotizing myopathy, paraneoplastic, 775
Acute promyelocytic leukemia (APL)
  in children, 2145, 2145t, 2148–2149
  flow cytometry of, 243
  morphology of, 2220f
  during pregnancy, 1057
  treatment of, 2228–2229, 2228b
Acute respiratory distress syndrome, grading of, 972t
ACVBP regimen, for diffuse large B-cell lymphoma, 2386–2388, 2387f, 2387t
Acyclovir, for herpes simplex virus infections, 727–728
ADA (adenosine deaminase), in hairy cell leukemia, 2312
ADA (adenosine deaminase) deficiency, gene therapy for, 524–525, 525f
Adamantinoma, of bone, 1994, 1996f
Adaptive immune response, in carcinogenesis, 88
Adaptor proteins, in intracellular signaling, 22, 25
ADCC (antibody-dependent cell-mediated cytotoxicity), 532f, 533, 538
Addiction, 571t
Addison's disease, hyperpigmentation due to, 632
Adenoacanthoma, of endometrium, 1797
Adeno-associated viral (AAV) vectors, 516
Adenocarcinoma(s)
  cervical, 1748, 1750f, 1757–1758
  endometrioid
    ciliated cell, 1797
    grading of, 1797
    molecular pathology and biology of, 1799–1800
    pathogenesis of, 1795–1796
    pathology of, 1796–1797, 1796f
    risk factors for, 1794–1795, 1794t
    secretory, 1797
    with squamous differentiation, 1797
    villoglandular, 1797
  esophageal (*See also* Esophageal cancer)
    classification of, 1400, 1400t
    clinical risk factors for, 1401
    pathogenesis of, 1401–1402
    prognosis for, 1409
  immunodeficiency and, 225t
  of lung, 1313–1316, 1315f, 1319t
  pancreatic, 1596–1597
  of salivary gland, 1181–1182
  of small bowel, 1467, 1467f
  of unknown primary (*See* Carcinoma of unknown primary [CUP])
  of vagina, 1779, 1782–1783
Adenoid cystic carcinoma
  of lacrimal gland, 1163–1164, 1163f
  of salivary gland, 1182, 1183f
Adenoma(s)
  adrenocortical, 1283–1286, 1284f–1285f
    imaging of, 294
  of colon, 363f, 369
    and colorectal cancer, 1481, 1483
    familial (*See* Familial adenomatous polyposis [FAP])
    surgical management of, 1505, 1506f

Adenoma(s) (*cont.*)
pituitary, 1111–1114
classification of, 1111–1112, 1112t
clinical and pathologic considerations for, 1111–1112, 1112t
genetics of, 1111
macro-, 1111
micro-, 1111
reproductive effects of, 1000
therapy for
medical, 1112–1113
radiation, 1113–1114
recommended approach for, 1114, 1114b
surgical, 1112
salivary gland, cytogenetic aberrations in, 258t
of small bowel, 1466
Adenoma malignum, of cervix, 1748, 1750f
Adenomatous hyperplasia, atypical, of lung, 1313, 1313f, 1319t
Adenomatous polyps, of colon, 363f, 369
and colorectal cancer, 1481, 1483
familial (*See* Familial adenomatous polyposis [FAP])
surgical management of, 1505, 1506f
Adenosine deaminase (ADA), in hairy cell leukemia, 2312
Adenosine deaminase (ADA) deficiency, gene therapy for, 524–525, 525f
Adenosquamous carcinoma
of cervix, 1749–1750
of endometrium, 1797
pancreatic, 1596
of vulva, 1776
Adenoviral (Adv) vectors, 515–516, 515f, 516b, 523–526
Adenovirus(es), 728
conditionally replicative, for gene therapy, 522–523, 522t
Adenovirus replication, transcriptional regulation of, 522, 522t
ADEPT (antibody-directed enzyme prodrug therapy), 532f, 537
ADH. *See* Antidiuretic hormone (ADH).
Adipocyte sarcomas, 2015t
Adipose tissue, in cachexia, 592–593, 593f
Adjustment, 353
Adjuvant biochemotherapy, for melanoma, 1242
Adjuvant chemoradiation therapy
for esophageal cancer, 1403, 1404t, 1414
for gastric cancer, 1444–1445, 1444t, 1445t
Adjuvant chemotherapy, 449b, 455, 455b, 459
for bladder cancer, 1646–1647, 1647t
for breast cancer, 1919–1920, 1921t
for cholangiocarcinoma, 1589–1590
for colorectal cancer, 1512–1516, 1515t, 1517t
for gallbladder cancer, 1584
for gastric cancer, 1440–1442, 1441t
for head and neck cancer, 1205–1206
for hepatocellular carcinoma, 898
for liver metastases, 896–898, 896f, 897t
for melanoma, 1241–1242
Adjuvant chemotherapy (*cont.*)
for non–small cell lung cancer, 1334–1335, 1334t, 1335f
for osteosarcoma, 1953–1955, 2081–2082
for ovarian cancer, 1843–1845, 1843t–1845t
for penile cancer, 1708–1709
for rectal cancer, 1548–1549
for soft-tissue sarcoma, 2028–2029, 2028t, 2029t
for Wilms' tumor, 2098–2100, 2099t
Adjuvant radiation therapy, 438
for breast cancer, 1916, 1916b, 1917f
for colorectal cancer, 1517–1518
for endometrial cancer, 1803b, 1804t, 1806–1808, 1808t
for gastric cancer, 1442, 1443t
for head and neck cancer, 1189, 1199–1201, 1200f, 1201f
for head and neck sarcomas, 2042
for non–small cell lung cancer, 1335
for retroperitoneal sarcomas, 2039
for soft-tissue sarcoma, 2025–2027, 2025t, 2026f
for vulvar cancer, 1772
Adjuvant therapy
for pancreatic cancer, 1606–1607
for primitive neuroectodermal tumors, 1120
for rectal cancer
advantages and disadvantages of, 1540–1541, 1540t
chemotherapy for, 1548–1549
after local excision, 1549–1550, 1549t
randomized trials of, 1543–1544, 1544t
timing after surgery of, 1541
toxicity of, 1542–1543
ADL (activities of daily living), 1043
rehabilitation for, 586
Administrative censoring, 350
Adnexal involvement, endometrial cancer with, 1802, 1813
Adnexal metastases, of gestational trophoblastic disease, 1869
Adolescents
acute lymphocytic leukemia in, 2205
second malignant neoplasms in, 1023–1028
with chemotherapy, 1026–1028, 1027f
epidemiology of, 1023
genetic predisposition to, 1023–1024, 1024f
with hormone therapy, 1025–1026
with immunosuppression, 1028
with radiation therapy, 1024–1025, 1025f, 1026f
recommendations on, 1023, 1028
with surgery, 1024
Adoptive immunotherapy, for melanoma, 1245
ADR-529 (dexrazoxane), 466
for cardioprotection, 989, 989f, 992b
Adrenal adenomas, 1283–1286, 1284f–1285f
imaging of, 294
Adrenal cancer, 1271, 1281–1286
clinical features of, 1271, 1281–1282, 1281t
diagnosis of, 1271, 1282, 1282f
incidence of, 1271, 1281
pathology of, 1282
Adrenal cancer (*cont.*)
prognosis for, 1282–1283
treatment of, 1271, 1282–1286
antihormonal therapy for, 1283
antineoplastic therapy for, 1283
for metastatic disease, 1283
for primary tumor, 1282–1283
surgical, 1283–1286, 1284f–1285f
Adrenal crisis, acute, 1019, 1019b
Adrenal disorders
chemotherapy-related, 1016
evaluation of, 1013, 1017t
treatment of, 1013, 1019, 1019b
Adrenal insufficiency
chemotherapy-related, 1016
evaluation of, 1013, 1017t, 1019
hyponatremia due to, 754
treatment of, 1013, 1019, 1019b
Adrenal masses, imaging of, 294, 294f, 302
Adrenal metastases, imaging of, 294, 294f
Adrenalectomy, 1283–1286, 1284f–1285f
Adrenocortical adenomas, 1283–1286, 1284f–1285f
imaging of, 294
Adrenocortical carcinoma (ACC), 1271, 1281–1286
in children, 2078, 2116–2117
clinical features of, 1271, 1281–1282, 1281t
diagnosis of, 1271, 1282, 1282f
incidence of, 1271, 1281
pathology of, 1282
prognosis for, 1282–1283
treatment of, 1271, 1282–1286
antihormonal therapy for, 1283
antineoplastic therapy for, 1283
for metastatic disease, 1283
for primary tumor, 1282–1283
surgical, 1283–1286, 1284f–1285f
Adrenocorticotropic hormone (ACTH)
ectopic production of, due to lung cancer, 1323–1324
in hyperpigmentation, 631
Adrenocorticotropic hormone (ACTH)-secreting adenomas, 1111–1112, 1112t
Adriamycin (Adria). *See* Doxorubicin (Adriamycin, Rubex, Adria, hydroxydaunorubicin).
Adrucil. *See* 5-Fluorouracil (Adrucil, Efudex, 5-FU).
ADT. *See* Androgen deprivation therapy (ADT).
Adult T-cell leukemia-lymphoma (ATLL), 2425–2438
background of, 2425
clinical course of, 2434–2435, 2434f, 2435f
clinical manifestations of, 2425, 2428–2429, 2429t, 2430t
complications of, 2429, 2430t
treatment of, 2438
diagnosis of, 2425, 2430–2434
differential diagnosis of, 2431
epidemiology of, 2425, 2427–2428, 2428f
histopathology of, 2425, 2431–2434, 2432f–2434f

Adult T-cell leukemia-lymphoma (ATLL) (*cont.*)
HTLV-I and, 159–160, 2372, 2425–2427, 2426f
laboratory findings in, 2430–2434
pathogenesis of, 2426–2427, 2426f
prognosis for, 2434–2435, 2434f, 2435f
skin lesions in, 2412, 2414t
subtypes of, 2428–2429, 2429t, 2435b
treatment of, 2425, 2434–2438
allogeneic hematopoietic stem cell transplantation for, 2438
approach to, 2434f, 2435b
for complications, 2438
JCOG clinical trials of chemotherapy for, 2435–2436, 2436f
new agents for, 2436–2438
Adv (adenoviral) vectors, 515–516, 515f, 516b, 523–526
Advanced disease, chemotherapy for, 456, 456b
Adynamic ileus, 795
AEDs (antiepileptic drugs)
for brain metastases, 830
for pain management, 570, 573t, 575
for seizures due to brain tumors, 1083, 1083t
Aerodigestive malignancies
chemoprevention of, 368
risk reduction for, 367
screening for and early detection of, 363f, 367–368
AF9 gene, in childhood leukemia, 2149
AFIP (Armed Forces Institute of Pathology), 234
Aflatoxins, as carcinogens, 128–129
AFP. *See* α-fetoprotein (AFP).
AG13637 (axitinib), for renal cell carcinoma, 1627–1628
Agammaglobulinemia, X-linked, 225t
Age
and chemotherapy, 457
as confounder, 201
Age at onset, in linkage analysis, 194, 199, 200
Aggressive fibromatoses, 2044, 2044t
Aging. *See also* Elderly.
biology of, 1040–1041
and carcinogenesis, 1039, 1041
and colorectal cancer, 1478–1479, 1508, 1516–1517
laboratory markers of, 1044
physiology of, 1041
and tumor growth, 1041, 1041f, 1042t
Agitation, in dying patient, 667t, 669–672, 669f, 670b, 671b
Agnogenic myeloid metaplasia. *See* Primary myelofibrosis (PMF).
Agrylin (anagrelide), 459–460
for polycythemia vera, 2266t
AGUS (atypical glandular cells of undetermined significance), 1752
AIDS (acquired immunodeficiency syndrome). *See* Human immunodeficiency virus (HIV).
AIDS-related lymphoma (ARL), 228, 1065–1069
Burkitt's, 1066, 2390, 2390t
clinical aspects of, 1066–1067, 1067f
epidemiology of, 1061, 1065, 2392
AIDS-related lymphoma (ARL) (*cont.*)
etiology and pathogenesis of, 1061, 1065–1066, 1066f, 2392
evaluation of, 1061
Hodgkin's, 1065–1069, 2366
primary CNS, 1105
treatment of, 1061, 1067–1068, 1067b–1069b, 2392–2393, 2393f
AIF (apoptosis-inducing factor), 68
AJCC (American Joint Committee on Cancer) staging system
for melanoma, 1235, 1235t, 1236f, 1236t
for soft-tissue sarcoma, 2018–2019, 2019f, 2019t
Akt, in apoptosis, 72, 72f, 73b
Akt kinase, as molecular target, 487t
AKT2 gene, 211t
AL amyloidosis, 2324, 2343–2344
classification of, 2343, 2343t
diagnosis of, 2325t, 2343–2344
prognosis for, 2344, 2344t
treatment of, 2344
ALCL. *See* Anaplastic large cell lymphoma (ALCL).
Alcohol blocks, 573–574, 574t
Alcohol use
and breast cancer, 375, 1877
and chemotherapy-induced nausea and vomiting, 601
and colorectal cancer, 370, 1482
and esophageal cancer, 1400–1401
and head and neck squamous cell carcinoma, 1179
and smoking cessation among cancer patients, 400
Aldara (imiquimod), cutaneous reactions to, 637
Aldehydes, in tobacco smoke, 129t
Aldesleukin. *See* Interleukin-2 (Proleukin, aldesleukin, IL-2, T-cell growth factor).
Alefacept (Amevive), for cutaneous T-cell lymphoma, 2419
Alemtuzumab (Campath), 453, 459
for chronic lymphoid leukemia, 534, 2303
for cutaneous T-cell lymphoma, 2419–2420
and infection, 729t, 732
Alimta (pemetrexed), 477
for non-small cell lung cancer, 1342–1343, 1343t
Alitretinoin (9-*cis*-retinoic acid), for Kaposi's sarcoma, 1065
ALK (anaplastic lymphoma kinase), in anaplastic large cell lymphoma, 2176, 2177
ALK (anaplastic lymphoma kinase) lymphoma (ALKoma), 2176
Alkalosis, hypokalemic, due to adrenocortical cancer, 1282
Alkeran. *See* Melphalan (Alkeran, L-PAM, L-phenylalanine mustard, L-sarcolysin).
Alkylating agents
cutaneous side effects of, 627t
hyperpigmentation due to, 631
for multiple myeloma, 2338
during pregnancy, 1005–1006, 1051–1052, 1052t
Alkylating agents (*cont.*)
pulmonary toxicity of, 977–978
reproductive complications of, 999, 1003–1004
second malignant neoplasms due to, 1026, 1032
O^6-Alkylguanine DNA alkyltransferase, as molecular target, 486t
ALL. *See* Acute lymphocytic (lymphoblastic, lymphoid) leukemia (ALL).
Allele imbalance, 271
Allogeneic hematopoietic stem cell transplantation (alloHSCT), 501–504, 502t
for adult T-cell leukemia-lymphoma, 2438
for follicular lymphoma, 2385
infection prevention with, 729t, 730, 730t, 731f
for leukemia
acute lymphocytic, 2200–2202, 2201t
acute myeloid, 2226–2228
chronic lymphoid, 2304, 2304t
chronic myeloid, 2285–2286, 2286f
for multiple myeloma, 2337–2338
for myelodysplastic syndrome, 2242, 2247–2250, 2247t, 2249t
during pregnancy, 1056
Allografts
carcinomas after, 228–229, 228b
for osteosarcoma, 1965–1973, 1967f–1969f
Allophycocyanin, in flow cytometry, 242
Allopurinol
for acute lymphocytic leukemia, 2196
for tumor lysis syndrome, 761f, 762, 763, 763f
with childhood lymphoma, 2181
All-*trans*-retinoic acid (ATRA), 453, 480
for acute promyelocytic leukemia, 2228–2229, 2228b
fluid retention due to, 993
during pregnancy, 1057
ALM (acral lentiginous melanoma), 1231, 1232
ALND. *See* Axillary lymph node dissection (ALND).
Alopecia, chemotherapy-induced, 626–627
Alpha heavy-chain disease (α-HCD), 2345
α particles, in radioimmunotherapy, 535, 535t
α-fetoprotein (AFP), as tumor marker, 277–279
for carcinoma of unknown primary, 2064, 2070
for hepatoblastoma, 2113, 2114
for hepatocellular carcinoma, 1570
for intracranial germ cell tumors, 1126, 1126t
for testicular cancer, 1720–1721, 1720t
α-interferon. *See* Interferon-α (Intron A, Roferon, α-interferon, IFN-α).
α-methyl-CoA racemase (AMACR), in prostate cancer, 1660, 1665
Alpha-tocopherol
for cancer prevention, 547
of head and neck cancer, 1207
for cancer treatment, 554
Alphavirus vectors, 517

ALPS (autoimmune lymphoproliferative syndrome), 226t, 227
Alternating non–cross-resistant chemotherapy, 451
Alternative medicine. *See* Complementary and alternative medicine (CAM).
Alternative systems of medical practice, 546b
Altretamine (Hexalen, hexamethylmelamine, HMM), 459
Aluminum hydroxide, for tumor lysis syndrome, 763
Alvac-CEA, 517
Alveolar rhabdomyosarcoma
  in children, 2101
  cytogenetic aberrations in, 259t
Alveolar soft part sarcoma (ASPS), 2012t
  cytogenetic aberrations in, 260t
AMACR (α-methyl-CoA racemase), in prostate cancer, 1660, 1665
Amenorrhea
  due to bone marrow transplantation, 1004–1005
  due to chemotherapy, 1003–1004
American Cancer Society, cervical cancer screening guidelines of, 1746, 1746t
American College of Surgeons Oncology Group (ACOSOG), 408
American Joint Committee on Cancer (AJCC) staging system
  for melanoma, 1235, 1235t, 1236f, 1236t
  for soft-tissue sarcoma, 2018–2019, 2019f, 2019t
American Society for Colposcopy and Cervical Pathology (ASCCP), 1752
American Society of Anesthesiologists Physical Status Classification, 413, 413t
Amethopterin. *See* Methotrexate (Mexate, Folex, MTX, amethopterin).
Amevive (alefacept), for cutaneous T-cell lymphoma, 2419
AMG531, 683
  for myelodysplastic syndrome, 2243, 2244t
Amifostine (Ethyol, WR-2721, ethiofos), 459
  for neuroprotection, 962
  for radiation pulmonary fibrosis, 975–976, 976t
  for radiation-induced mucositis, 616
  for radiation-induced xerostomia, 618
  as radioprotector, 432
    for head and neck cancer, 1199
Amine precursor uptake and decarboxylase (APUD) tumors (APUDomas), 1295
Amino acids, for prevention of oral complications, 613
Aminoglutethimide (Cytadren)
  adrenal effects of, 1016
  for adrenocortical cancer, 1283
  thyroid disorders due to, 1016
Aminohydroxypropylidene. *See* Pamidronate (Aredia, APD, aminohydroxypropylidene diphosphonate).
Aminohydroxypropylidene diphosphonate. *See* Pamidronate (Aredia, APD, aminohydroxypropylidene diphosphonate).
Aminopurine-6-thiol hemihydrate (thioguanine), 479
Amitriptyline, for pain management, 575
AML. *See* Acute myeloid (myelogenous, myelocytic, myeloblastic, nonlymphoblastic) leukemia (AML).
AML1, in childhood leukemia, 2149
AMN107 (nilotinib), for chronic myeloid leukemia, 2287, 2288t
Amplicons, in polymerase chain reaction, 5–6, 6f
Amputation
  for Ewing's sarcoma, 1992
  for osteosarcoma, 1962–1965, 1973, 2081
    in children, 2081
  rehabilitation after, 583–584
  for soft-tissue sarcomas, 2022, 2023f
Amygdalin, adverse effects of, 554t, 555
Amyloidosis
  classification of, 2343, 2343t
  systemic immunoglobulin light-chain (AL, primary), 2324, 2343–2344
    diagnosis of, 2325t, 2343–2344
    prognosis for, 2344, 2344t
    treatment of, 2344
Anagen effluvium, 626
Anagrelide (Agrylin), 459–460
  for polycythemia vera, 2266t
Anal canal, anatomy of, 1557, 1558f
Anal cancer, 1557–1567
  classification of, 1560, 1560b
  clinical presentation and diagnosis of, 1559, 1559f, 1560b
  epidemiology of, 1557
  etiology and risk factors for, 1557–1558
  histopathology of, 1559–1560
  with HIV, 1069, 1557–1558
  metastatic, 1559, 1566
  natural history of, 1558–1559
  recurrence of, 1561
  screening, early detection, and prevention of, 1558
  staging of, 1559, 1561t
  treatment of, 1560–1567
    algorithm for, 1560t
    chemotherapy for, 1561b, 1564, 1564t
    combined-modality, 1561b, 1562–1564, 1563t, 1564t, 1566
    for metastatic disease, 1566
    radiotherapy for, 1561–1562, 1562t, 1564–1566, 1565f
    recommendations on, 1566–1567
    surgical, 1560–1561, 1561t, 1566
Anal margin, 1557, 1558f
Anal margin tumors, 1557, 1559, 1566–1567
Anal sphincter function, radiation effect on, 1543
Anal squamous intraepithelial lesions (ASILs), 1558
Anal verge, 1557, 1558f
Analgesia
  for oral complications
    chemotherapy-induced, 614
    radiation-induced, 615
  for spinal metastases, 819
Anaphase, 55, 56f
Anaphase-promoting complex (APC), 51f, 52
Anaphase-promoting complex (APC) gene. *See* *APC* gene.
Anaphase-promoting complex (APC) inactivation, and cancer phenotype, 215–216, 217f
Anaplastic astrocytoma (AA)
  chemotherapy for, 1100–1103, 1103t
  histologic appearance of, 1092–1093, 1092f
  imaging of, 1094, 1094f
  management of, 1097b
  pathology of, 1092–1093, 1092f, 1093f
  radiation therapy for, 1098–1100, 1099t
Anaplastic large cell lymphoma (ALCL)
  molecular genetics of, 2375t
  pathology and tumor biology of, 2174f, 2176–2177
  primary cutaneous, 2412, 2414t
  treatment of, 2183–2184, 2183t, 2394, 2395f
Anaplastic lymphoma kinase (ALK), in anaplastic large cell lymphoma, 2176, 2177
Anaplastic lymphoma kinase (ALK) lymphoma (ALKoma), 2176
Anaplastic oligoastrocytoma (AOA), chemotherapy for, 1103, 1103t
Anaplastic oligodendroglioma (AO)
  chemotherapy for, 1102–1103, 1103t
  pathology of, 1093, 1093f
Anaplastic Wilms' tumor, 2097, 2097f, 2099–2100
Anastomosis, in colon surgery, 1503–1504
Anastomotic leaks, after colon cancer surgery, 1508
Anastrozole (Arimidex), 460
  for prevention of breast cancer, 376
  reproductive effects of, 1003
Anatomolecular imaging, 283
ANC (absolute neutrophil count), 720
  and infections, 718, 718f
Androgen blockade, "complete," for prostate cancer, 1683–1685, 1684f, 1685f
Androgen deprivation therapy (ADT)
  bone loss due to, 865–866
  for prostate cancer
    anti-androgens and 5α-reductase inhibitors in, 1683
    with brachytherapy, 1675
    "complete" androgen blockade in, 1683–1685, 1684f, 1685f
    intermittent, 1686
    for localized disease, 1667–1680, 1677f
    for metastatic disease, 1681–1686, 1682f, 1684f, 1685f
    optimal timing of, 1685–1686
    with radiation therapy, 1676–1679, 1677f
    "second line," 1686
    strategies of, 1681–1682, 1681b
Anemia, 677–681
  aplastic, cytogenetic aberrations in, 253t
  in cervical cancer, 1756–1757
  in elderly, 1043, 1046
  erythropoiesis-stimulating proteins for, 678–681
    problem of iron with, 678–680, 679t, 680f
    safety of, 680–681

Anemia (*cont.*)
Fanconi, 135
as cancer predisposition syndrome, 175t
DNA damage in, 141t, 149
fatigue due to, 660
in multiple myeloma, 2340
pathophysiology of, 677, 678f
refractory, 2239t, 2240t, 2241
Anesthesia, for surgical interventions, 407–408
Aneuploid tumors, 246
Aneuploidy, in carcinoma of unknown primary, 2061–2062
Ang II (angiotensin II), in cachexia, 594
Angioblasts, in vascularization, 106
Angiofollicular lymph node hyperplasia, 2396
Angiogenesis, 105–108
activators and inhibitors of, 107–108, 107t, 108f
in brain tumors, 1079
cellular mechanisms of, 106–107, 106f
in metastasis, 34f, 39
molecular mechanisms of, 107–108, 107t, 108f
as molecular target, 486t, 487t, 488
"sprouting," 106, 106f
Angiogenesis inhibitor(s), 453
for breast cancer, 1932
for gliomas, 1104
for renal cell carcinoma, 1624–1629
axitinib as, 1627–1628
bevacizumab as, 1627
everolimus as, 1628
future directions for, 1628–1629, 1628f, 1629f
guidelines for, 1626f
mechanism of action of, 1624, 1625f
pazopanib as, 1628
sorafenib as, 1624–1625, 1630
sunitinib as, 1625, 1630
temsirolimus as, 1625–1627
voloxicimab as, 1627
Angiogenic activity, as signature trait of cancer cells, 215, 216f
Angiography, 288–289, 291t
CT, 288, 289
helical (spiral), of pulmonary embolism, 706
of liver metastases, 886, 1492, 1493f
of hepatocellular carcinoma, 1571
magnetic resonance
of brain tumors, 1085
of pulmonary embolism, 706
of small bowel tumors, 1470
of spinal metastases, 818
Angioimmunoblastic T-cell lymphoma, 2394
Angiopoietins, in lymphangiogenesis, 112
Angiosarcoma(s), 2045, 2046f
of breast, 1934
cutaneous, 1265–1266, 1265f, 2045
of head and neck, 1184–1185
surgery-related, 1029
Angiotensin II (Ang II), in cachexia, 594
Angiotensin-converting enzyme inhibitors, for radiation pulmonary fibrosis, 976
Animal bioassays, for carcinogenicity, 135
Animal models
of cancer, 15–17, 16f, 17f
of chronic myeloid leukemia, 2281
Ann Arbor Staging System, for lymphoma, 1161, 1162t
Hodgkin's, 2358t, 2359
non-Hodgkin's, 2376–2377, 2378t
Anoikis resistance, in metastasis, 38
Anorexia, and cachexia, 591–592
Anterior mediastinal tumor(s), 1380t, 1381–1387
biopsy of, 1381, 1381t
germ cell, 1368, 1384–1386, 1385f
lymphoma as, 1368, 1386–1387, 1387f
thymic carcinoid as, 1384, 1384f
thymic carcinoma as, 1384
thymoma as, 1367–1368, 1381–1384
classification of, 1381–1382
clinical manifestations of, 1382–1383, 1383f
differential diagnosis of, 1368
epidemiology of, 1367–1368, 1382
pathogenesis of, 1381
pathology of, 1382, 1382f
staging and evaluation of, 1368, 1382, 1382t
treatment of, 1368, 1383–1384
Anterior mediastinum, 1380
Anterior pituitary dysfunction, radiation-induced, 1014
Anthracyclines
for breast cancer, 1919–1920, 1920t
cardiac effects of, 984t, 985–989, 985t, 1925
in children, 989
diagnosis of, 987–988, 987t
etiology of, 985–986
incidence of, 983, 985, 986f
natural history of, 986
pathophysiology of, 986–987, 986f
risk factors for, 986
treatment of, 983, 988–989, 989f, 991, 992b
for leukemia
acute lymphocytic, 2197
acute myeloid, 2224, 2225
liposomal
for Kaposi's sarcoma, 1064b, 1065
for soft-tissue sarcoma, 2034
during pregnancy, 1006, 1052t, 1053
pulmonary toxicity of, 978
second malignant neoplasms due to, 1027–1028
Antiandrogenic agents
for prostate cancer, 1682f, 1683–1685, 1685f
reproductive complications of, 999, 1003
Antiangiogenic agents, 106, 118–120, 118f–119f
for colorectal cancer, 1524
for gliomas, 1104
for hepatocellular carcinoma, 1577–1578
for melanoma, 1245
pulmonary toxicity of, 979
Antiangiogenic molecules, 107–108, 107t, 108f
Antibiotic therapy
empirical, 720–723
duration of, 723
general principles for, 720–721
subsequent modifications of, 722–723
for unstable patients, 722
vancomycin or other gram-positive agents for, 721–722, 722t
for neutropenia, 681
during pregnancy, 1006
Antibiotic-associated diarrhea, 1502
Antibiotics, antitumor
cutaneous side effects of, 627t
hyperpigmentation due to, 631, 631f
Antibody probes, for molecularly targeted therapy, 494t
Antibody-dependent cell-mediated cytotoxicity (ADCC), 532f, 533, 538
Antibody-directed enzyme prodrug therapy (ADEPT), 532f, 537
Anticarcinogenic roles, of immune response, 87–88, 88f
Anticarcinogens, in diet, 133–134
Anti-CC chemokine receptor 4 (anti-CCR4), for adult T-cell leukemia-lymphoma, 2437
Anti-CD20 (tositumomab). *See* Tositumomab (Bexxar, anti-CD20).
Anti-CD25 antibodies, for adult T-cell leukemia-lymphoma, 2437
Anti-CD52 antibodies, for acute lymphocytic leukemia, 2207
Anticholinergics, for prevention of oral complications, 612
Anticipation, in chronic lymphoid leukemia, 2294
Anticipatory nausea and vomiting, 601, 605
Anticoagulant therapy
challenges of, 697–698
for deep venous thrombosis
chronic, 703
inferior vena cava and intra-abdominal, 707–708
initial, 703
long-term, 703–704
lower-extremity, 702–704, 702b, 704t
upper-extremity, 705
patient response to, 699
for pulmonary embolism, 707
Anticoagulation-related hemorrhage, 698
Anticonvulsants
for brain metastases, 830
for pain management, 570, 573t, 575
for seizures due to brain tumors, 1083, 1083t
Antidepressants, for pain management, 570, 573t, 574–575
Antidiuretic hormone (ADH)
in osmolar homeostasis, 750
syndrome of inappropriate secretion of
causes of, 754
chemotherapy-induced, 1013, 1015
hyponatremia due to, 752f, 753–757
due to lung cancer, 1323
management of, 754–756, 1018
Anti-EGFR. *See* Cetuximab (Erbitux, chIgG1, anti-EGFR).

Antiemetic(s)
benzodiazepines as, 603t, 605
butyrophenones as, 605
cannabinoids as, 603t, 605
clinical trials of, 602–603
combination therapy with, 605
corticosteroids as, 603t, 604
dopamine antagonists/substituted benzamides as, 603t, 604
dosing of, 603t
future directions for, 606
5-HT3 receptor antagonists as, 603–604, 603t
for nausea and vomiting
acute, 603–605, 603t, 604b
anticipatory, 605
delayed, 603t, 605–606
radiation-induced, 606
neurokinin-1 receptor antagonists as, 603t, 604
phenothiazines as, 605
recommendations for, 606
Antiepileptic drugs (AEDs)
for brain metastases, 830
for pain management, 570, 573t, 575
for seizures due to brain tumors, 1083, 1083t
Antiestrogens, for breast cancer, 1931
Antifungal therapy, empirical, 723
Anti-GD2, for neuroblastoma, 534, 536
Anti-GD3, for melanoma, 534
Antigens
tumor-selective, 78
tumor-specific, 77–78
Anti-HER2 therapy, for breast cancer, 1921, 1922t, 1923t, 1932
Antihormonal therapy
for adrenocortical cancer, 1283
for carcinoid tumor, 1293
Anti-idiotype antibodies, in colorectal cancer, 1525
Anti-inflammatory agents, for oral complications, 612, 614
Antimetabolites
cutaneous side effects of, 627t
hyperpigmentation due to, 632
during pregnancy, 1005–1006, 1051
pulmonary toxicity of, 977
Antimetastatic therapy, 42–43, 44f
Antimicrobial agents, for prevention of oral complications, 612
Antineoplastic therapy. *See* Chemotherapy.
Antineoplastins, 554t, 558t
Antineuronal antibodies, in paraneoplastic neurologic syndromes, 768, 768t
Antioncogene, 208
Antioxidants
for cancer prevention, 135, 146b, 546–547
colorectal, 1486–1489
for cancer treatment, 553–554
for prevention of oral complications, 612
Antiresorptive therapy, for hypercalcemia of malignancy, 744–745, 745f
Antiretroviral therapy, for HIV, 1062, 1064, 1068, 1069
Antisense oligonucleotides, inhibition of survival factors by, 74
Antisense therapy, 453, 519
Antisepsis, for surgical interventions, 408
Antispasmodics, for pain management, 570, 573t
Anti-Tac, for adult T-cell leukemia-lymphoma, 2437
Antithrombotic therapy
challenges of, 697–698
for deep venous thrombosis
inferior vena cava and intra-abdominal, 707–708
lower-extremity, 702–704, 702b, 704t
upper-extremity, 705
patient response to, 699
for pulmonary embolism, 707
for thromboprophylaxis, 708–711
Antithymocyte globulin (ATG)
for myelodysplastic syndrome, 2243, 2244t
second malignant neoplasms due to, 1028
Antitumor antibiotics
cutaneous side effects of, 627t
hyperpigmentation due to, 631, 631f
Anti-VEGF. *See* Bevacizumab (Avastin, anti-VEGF).
Anti-VEGF therapy, 118, 118f–119f
for hepatocellular carcinoma, 1577
for renal cell carcinoma, 1624–1629, 1625f, 1628f
Anxiety
in dying patient, 667t, 668
rehabilitation for, 581
AO (anaplastic oligodendroglioma)
chemotherapy for, 1102–1103, 1103t
pathology of, 1093, 1093f
AOA (anaplastic oligoastrocytoma), chemotherapy for, 1103, 1103t
AP23573, for soft-tissue sarcoma, 2037
Apaf-1, in apoptosis, 73, 73f
APC (anaphase-promoting complex), 51f, 52
APC gene
in colorectal cancer, 1479, 1480f
in esophageal cancer, 1403
in familial adenomatous polyposis, 180
in familial infiltrative fibromatosis, 2011
in hepatoblastoma, 2113
mutations in, 212t, 214–215, 214f
APC (anaphase-promoting complex)
inactivation, and cancer phenotype, 215–216, 217f
APD. *See* Pamidronate (Aredia, APD, aminohydroxypropylidene diphosphonate).
APL. *See* Acute promyelocytic leukemia (APL).
Aplastic anemia, cytogenetic aberrations in, 253t
Apnea, grading of, 958t
APO regimen, for large cell lymphoma in children, 2183–2184
Apoptosis, 67–75
in cancer, 70–73
epigenetic gene silencing and, 73, 73f
metabolic deregulation and, 73b
oncogenes as triggers of, 70
survival factors preventing, 71–72, 72f, 73b
tumor suppressor genes as promoters of, 70–71
Apoptosis (*cont.*)
in cancer treatment, 73–75
due to DNA damage, 140
instructional, 28
in lymphoma, 2380
mechanism of, 68–69, 68f, 69f
mitochondria in, 68, 69f
as molecular target, 487t
by murder, 68, 68f
due to radiation, 424–425
by suicide, 68, 69f
Apoptosis-inducing cues, resistance to, as signature trait of cancer cells, 215, 216f
Apoptosis-inducing factor (AIF), 68
Apoptosome, 68
Apoptotic capability, restoration of, 74
Apoptotic pathways
and melanoma, 1233–1234
as molecular target, 487t
Apoptotic resistance, in metastasis, 38
Appendices epiploicae, 1499
Appendicitis, 794–795
Appendix, tumors of
carcinoid, 1290
surgical management of, 1509
APR (abdominoperineal resection), for anal cancer, 1560–1561, 1561t, 1566
Aprepitant
as antiemetic, 603t, 604–606
during pregnancy, 1053
APUD (amine precursor uptake and decarboxylase) tumors (APUDomas), 1295
AR gene, in prostate cancer, 1660
AraC. *See* Cytarabine (Cytosar-U, AraC, cytosine arabinoside).
Arachnoiditis, grading of, 958t
Aranesp (darbopoetin alfa), 464–465
for anemia, 678
Aredia. *See* Pamidronate (Aredia, APD, aminohydroxypropylidene diphosphonate).
Arginine stimulation test, 1017
Arginine vasopressin (AVP). *See* Antidiuretic hormone (ADH).
Arginine vasopressin (AVP) receptor antagonists, hyponatremia due to, 756
Arimidex (anastrozole), 460
for prevention of breast cancer, 376
reproductive effects of, 1003
Aristolochia fangchi, adverse effects of, 555
ARL. *See* AIDS-related lymphoma (ARL).
Armed Forces Institute of Pathology (AFIP), 234
Aromasin (exemestane), 467–468
Aromatase inhibitors
for breast cancer, 1918, 1924, 1931
reproductive effects of, 1003
Aromatic amines, as carcinogens, 127–128, 129t, 133b
Arranon (nelarabine), 475
Arrhythmias
due to cancer therapy, 983, 992
due to vascular access device, 787
Arsenic, as carcinogen, 132

Arsenic trioxide (Trisenox, As_2O_3), 460
  for acute promyelocytic leukemia, 2229
  for adult T-cell leukemia-lymphoma, 2438
  dysrhythmias due to, 992
  for myelodysplastic syndrome, 2244t, 2245
Arterial blood gas analysis, in presurgical evaluation for lung cancer, 1328
Arterioenterocutaneous fistula, 800f
Arthrodesis, for osteosarcoma, 1973–1974
Arthroplasty, for osteosarcoma, 1974
Arylamine *N*-acetyltransferase, hepatic, and susceptibility, 134
As_2O_3. *See* Arsenic trioxide (Trisenox, As_2O_3).

    of breast mass, 1892–1893, 1892f
    and flow cytometry, 245
    of thyroid nodule, 1275–1276
  and flow cytometry, 245
Aspirin
  for colorectal cancer prevention, 1487t, 1488t, 1489
  for essential thrombocythemia, 2269–2270, 2269t
  for pain management, 569
  for polycythemia vera, 2265–2266, 2267, 2267t
ASPS (alveolar soft part sarcoma), 2012t
  cytogenetic aberrations in, 260t
Assisted reproductive technologies, 1008
Association
  aspects of, 359
  measures of, 352–353
  strength of, 352
Association studies, 200–202
  for assessment of candidate genes, 200–201
  confounders and sources of bias in, 201–202
  design of, 201
  genome-wide, 201–202
  relative risks in, 202
  SNP genotyping and, 202
Astrocytomas
  cerebellar, 1123
  classification of, 1091–1093, 1092f, 1093f
  cytogenetic aberrations in, 258t
  genetic changes in, 1094
  grade IV (*See* Glioblastoma[s])
  high-grade (anaplastic, grade III)
    chemotherapy for, 1100–1103, 1103t
    histologic appearance of, 1092–1093, 1092f
    imaging of, 1094, 1094f
    management of, 1097b
    pathology of, 1092–1093, 1092f, 1093f
    radiation therapy for, 1098–1100, 1099t
  low-grade (diffuse, grade II)
    chemotherapy for, 1102, 1102f
    of childhood, 1122–1123
    clinical presentation of, 1091
    histologic appearance of, 1092, 1092f
    imaging of, 1094, 1094f
    management of, 1097b
    radiation therapy for, 1097–1098, 1097t
  pathology of, 1091–1093, 1092f, 1093f
  pilocytic (grade I), 1091, 1094, 1097b
    cerebellar, 1120f
  prognosis for, 1094, 1097–1098
  spinal, 1117–1119, 1117t
ASUS (atypical squamous cells of undetermined significance), 1752
Ataxia, grading of, 958t
Ataxia telangiectasia (AT), 135, 230
  and acute myelogenous leukemia, 2217
  brain tumors in, 1078t
  as cancer predisposition syndrome, 173t
  DNA damage in, 141t, 147–148
  immunodeficiency and cancer in, 229t, 230
  and lymphoma, 225t
  tumor distribution with, 225t
Ataxia telangiectasia and Rad3-related (ATR) protein, 57, 57f, 59
Ataxia telangiectasia (AT)-like disorder, DNA damage in, 141t, 148
Ataxia telangiectasia mutated *(ATM)* gene
  and ataxia telangiectasia, 230
  and breast cancer predisposition, 172, 178t
  and second malignant neoplasms, 1029
Ataxia telangiectasia mutated (ATM) protein
  in DNA damage response, 57, 57f, 58, 147–148
  in human cancers, 59, 61
Atelectasis, grading of, 972t
ATG (antithymocyte globulin)
  for myelodysplastic syndrome, 2243, 2244t
  second malignant neoplasms due to, 1028
Atlas of Tumor Pathology, 234
ATLL. *See* Adult T-cell leukemia-lymphoma (ATLL).
ATM (ataxia telangiectasia mutated) gene
  and ataxia telangiectasia, 230
  and breast cancer predisposition, 172, 178t
  and second malignant neoplasms, 1029
ATM (ataxia telangiectasia mutated) protein
  in DNA damage response, 57, 57f, 58, 147–148
  in human cancers, 59, 61
ATR (ataxia telangiectasia and Rad3-related) protein, 57, 57f, 59
ATRA. *See* All-*trans*-retinoic acid (ATRA).
Attenuation, 420, 421, 421f
Attributable risk, 352–353
A-type cyclins, 52
Atypical adenomatous hyperplasia (AAH), of lung, 1313, 1313f, 1319t
Atypical glandular cells of undetermined significance (AGUS), 1752
Atypical lymphoid proliferations, *vs.* lymphomas, 2396–2397
Atypical squamous cells (ASCs), 1752
Atypical squamous cells of undetermined significance (ASUS), 1752
Auditing, of clinical trials, 329, 333–334
Autoimmune complications, of chronic lymphoid leukemia, 2299, 2301b, 2302
Autoimmune lymphoproliferative syndrome (ALPS), 226t, 227
Autologous hematopoietic stem cell transplantation (ASCT), 501, 502t, 504

adjuvant, 1646–1647, 1647t
for metastatic disease, 1648–1649
neoadjuvant, 1646–1648
cystectomy for
partial, 1642
total, 1642–1643
urinary diversion after, 1643, 1644f
intravesical therapy for, 1640–1641
with invasive disease, 1641–1643
radiation therapy for, 1644–1646
transurethral resection as, 1637, 1640, 1640f, 1642
Bladder hyperreflexia, 585, 586t
Bladder management program, 585, 586t
Bladder preservation, with bladder cancer, 1645–1646
Blastic natural killer cell lymphoma, 2135
Bleeding
anticoagulation-related, 698
gastrointestinal, 791–793, 793f
due to cytotoxic agents, 793–794
intra-abdominal, 793, 793f
due to vascular access device, 786–787
Bleomycin (Blenoxane), 462
for gestational trophoblastic neoplasia, 1868
hyperpigmentation due to, 631, 631f
for intrapleural therapy, 932
for penile cancer, 1708, 1708t
for pleurodesis, 931–932
during pregnancy, 1052t
pulmonary toxicity of, 976–977
for testicular cancer, 1738
for vulvar cancer, 1776t
Blinding, in clinical trials, 314
Blindness, cortical, due to cisplatin, 948
BLM gene, 230
BLM helicase, 148
Blood cell production
disorders of, 677–684
cellular treatment of, 684
marrow failure states as, 683
platelet, 682–683, 683f
red cell, 677–681, 678f, 679t, 680f
white cell, 681–682
normal, 677
regulation of, 677
Blood cultures, for infection, 720
Blood flow, 108–109, 109f, 110f
Blood specimen, for cytogenetic analysis, 250
Blood transfusions
for cytopenia, 684
risks of, 684
Blood urea nitrogen, in tumor lysis syndrome, 761–762
Blood velocity, 109, 110f
Blood-brain barrier
and brain metastases, 41
and chemotherapy, 1090–1091
Bloom syndrome
and acute myelogenous leukemia, 2216–2217
as cancer predisposition syndrome, 175t
DNA damage in, 135, 141t, 148
helicase gene defects in, 1254
immunodeficiency and cancer in, 229t, 230
BMD (bone mineral density), cancer treatment and, 865
bmi-1, in regulation of self-renewal, 96–97
BMPR1A gene, 212t
BMS354825. *See* Dasatinib (Sprycel, BMS354825).
BMT. *See* Bone marrow transplantation (BMT).
Body mass index (BMI)
and breast cancer, 1877
and endometrial cancer, 1795
Body-cavity–based lymphomas, 162
BOLD regimen, for melanoma, 1243
Bonadonna, Gianni, 2354
Bone alkaline phosphatase (BALP), as bone formation marker, 852–853
Bone allografts, for osteosarcoma, 1965–1973, 1967f–1969f
Bone cancer, predisposition syndromes for, 177t
Bone formation markers, 852–853, 856, 856t
Bone lesions, in multiple myeloma, 2327, 2327f, 2328f, 2329, 2329f, 2339–2340
Bone loss
in breast cancer, 865
in prostate cancer, 865–866
Bone marrow, hematopoietic stem cells from, 504
Bone marrow aspiration, 250
for leukemia
acute lymphocytic, 2195
chronic lymphoid, 2299, 2302
for multiple myeloma, 2329–2330
Bone marrow biopsy
for leukemia
acute lymphocytic, 2195
chronic lymphoid, 2299, 2302
hairy cell, 2310–2311, 2311f
for multiple myeloma, 2329–2330
Bone marrow niche, in metastasis, 39, 40f
Bone marrow transplantation (BMT). *See also* Hematopoietic stem cell transplantation (HSCT).
carcinomas after, 228
gastrointestinal problems after, 797–798, 798f
molecular diagnostics for, 269–270
reproductive complications of, 999, 1004–1005
second malignant neoplasms after, 1028
thyroid disorders after, 1015–1016
Bone metabolism, biochemical markers of, 846, 852–856, 856t
Bone metastasis(es), 845–868
biochemical markers of, 846, 852–856, 856t
causes of, 845–849, 847f, 848f
complications of, 845, 866–868
diagnosis of, 845, 849–854
biochemical markers in, 852–854
computed tomography in, 851, 852f
differential, 849, 849t
MRI in, 851, 852f
PET in, 293–294, 851–852
radionuclide bone scan in, 850–851, 850f–852f
skeletal radiography in, 849–850, 850f
evaluation of patient with, 845, 854
gene expression profiling and, 846
incidence of, 845–846, 846t
lytic, 847–848, 850, 850f
osteoblastic and osteolytic, 40–41, 41f
prevention of, 864–865
rehabilitation for, 583–584
sclerotic, 848–849, 850, 850f
treatment of, 845, 856–866
algorithm for, 856, 857f
assessment of response to, 845, 854–856, 855f, 856t
bisphosphonates for, 859–864, 860f, 861t, 862f
external beam radiation therapy for, 856–858
new targeted therapies for, 864
systemic therapy for, 858–859
targeted radioisotope therapy for, 858
Bone mineral density (BMD), cancer treatment and, 865
Bone necrosis, radiation-induced, 619
Bone pain, 866
bisphosphonates for, 860
radiation therapy for, 857
Bone remodeling, and bone metastases, 846–847, 847f
Bone resorption, and bone metastasis, 846–848, 847f, 848f
Bone resorption markers, 853–854, 856, 856t
Bone sarcoma(s), 1945–2001
chondrosarcoma as, 1980–1982, 1982f, 1983f
of spine, 1998, 1998f–1999f
chordoma as, 1998–2001, 2000f
diagnosis of, 1945
Ewing's sarcoma as (*See* Ewing's sarcoma [EWS])
extracompartmental, 1946, 1946t
extraskeletal, 2015t
histopathologic grading of, 1945–1947, 1947t
incidence and epidemiology of, 1945
intracompartmental, 1946, 1946t
malignant fibrous histiocytoma as, 1994, 1995f, 1996f
osteosarcoma as (*See* Osteosarcoma)
as second malignant neoplasms, 1025, 1026f
of spine, 1994–1998, 1997f, 1997t

Bone sarcoma(s) (*cont.*)
staging of, 1945
biopsy for, 1947
radiographic, 1945, 1947, 1947t
surgical, 1945–1947, 1946t, 1947t
surgical margins for, 1946
therapy for, 1945
Bone scan(s), 283
of bone metastases, 850–851, 851f, 852f, 855
in prostate cancer, 296
for carcinoma of unknown primary, 2065
of osteosarcoma, 1951, 1952f
of spinal metastases, 817–818
Bone sialoprotein (BSP), as bone resorption marker, 846, 854
Bone tumor(s)
adamantinoma as, 1994, 1996f
cytogenetic aberrations in, 260t
rehabilitation for, 583–584
Bone-targeted radionuclides, for prostate cancer, 1687
BOP-CISCA-POMB-ACE regimen, for testicular cancer, 1733
BOP-VIP regimen, for testicular cancer, 1732–1733
Bortezomib (PS-341), 453
cutaneous reactions to, 636–637
inhibition of survival factors by, 74
for mantle cell lymphoma, 2391
for multiple myeloma
newly diagnosed, 2332t
in patients not eligible for transplantation, 2336
relapsed, 2339
results of, 2334t, 2335t
neurotoxicity of, 952
Bosutinib (SKI606), for chronic myeloid leukemia, 2288
Boveri, Theodor, 249
Bovine papillomavirus (BPV), 158
Bowel function, radiation effects on, 434t, 1543
Bowel management program, 585
Bowel obstruction, 791, 795–797, 796f
Bowel perforation, 791, 792
due to cytotoxic agents, 793–794
Bowel preparation, for colon surgery, 1502, 1502b
Bowenoid dysplasia. *See* Vulvar intraepithelial neoplasia (VIN).
Bowenoid papulosis (BP), 1702, 1702b. *See also* Vulvar intraepithelial neoplasia (VIN).
Bowen's disease (BD), 1257–1260, 1702. *See also* Vulvar intraepithelial neoplasia (VIN).
Bowman-Birk trypsin inhibitor (BBI), for cancer prevention, 548
2,3-BPG (2,3-bisphosphoglycerate) deficiency, in polycythemia vera, 2264
BPV (bovine papillomavirus), 158
Brachial plexopathy
grading of, 958t
radiation-induced, 953
Brachial plexus blocks, 574
Brachytherapy, 419, 439
for brain metastases, 836–837, 837t
for breast cancer, 1911f
for cervical cancer, 1759–1762, 1760f–1762f
for endometrial cancer
early-stage, 1808–1810, 1809t, 1810t
medically inoperable, 1811
recurrent, 1819
for esophageal cancer, 1417, 1419–1420
for gliomas, 1098
for head and neck cancer, 1201–1202
high-dose-rate, 439
for endometrial cancer, 1809–1810, 1810t, 1819
interstitial, 439
for endometrial cancer, 1819
intracavitary, 439
intravascular, 439
for liver metastases, 915–916
low-dose-rate, 439
for endometrial cancer, 1808–1809, 1809t, 1819
for prostate cancer, 1673–1676, 1674f, 1675t
pulmonary complications of, 976
remote afterloading, 439
for retroperitoneal sarcomas, 2039–2040
for soft-tissue sarcoma, 2025, 2025t, 2027
for squamous cell carcinoma, of eyelid, 1159
for tongue cancer, 1213
for uveal melanoma, 1146, 1146b, 1146t, 1147f
for vaginal cancer, 1781, 1782
BRAF mutations
in melanoma, 1232–1233, 1246
as molecular target, 486t
BRAF pathway, in active mediation of tumor–immune system interactions, 85
Bragg peak, 443, 443f
Brain
radiation necrosis of, 1086f
radiation tolerance dose of, 435t
Brain herniation, due to brain tumor, 1080, 1080f, 1081t
Brain lymphoma, with HIV, 1066–1068, 1066f, 1069b
Brain metastasis(es), 41, 827–839
clinical presentation of, 828
diagnosis of, 827–829, 829f
epidemiology of, 827–828
of gestational trophoblastic disease, 1863, 1870
multiple, 828, 833
of non-small cell lung cancer, 1333
pathophysiology of, 828
prognosis with, 827, 829, 830t
single, 828
solitary, 828
of testicular cancer, 1734
treatment of, 827, 829–839
anticonvulsants for, 830
brachytherapy for, 836–837, 837t
chemotherapy for, 827, 837–839
corticosteroids for, 829–830
external beam radiation therapy for, 827, 830–833, 830f, 831t, 833t
Brain metastasis(es) (*cont.*)
treatment of (*cont.*)
follow-up and salvage therapy for, 839
radiosurgery for, 834–836, 834f, 834t, 835t, 837t
surgical, 832–834, 832f, 833t, 836, 837t
Brain necrosis, due to cranial irradiation, 1088
Brain tumor(s), 1075–1127
acoustic neuroma as, 1114–1115
cerebellar hemangioblastomas as, 1115
childhood, 1119–1127
brainstem glioma as, 1123–1125, 1124f, 1125f
craniopharyngioma as, 1126–1127, 1126f
ependymoma as, 1123
epidemiology of, 1076, 1076f, 1077t
in infants, 1127
intracranial germ cell tumors as, 1125–1126, 1126t
low-grade astrocytomas as, 1122–1123
primitive neuroectodermal, 1119–1122, 1120f, 1121f, 1122b
chordomas and chondrosarcomas involving base of skull as, 1115–1116
classification of, 1075, 1076, 1076f, 1077t
clinical presentation of, 1075, 1079–1083
diagnosis of, 304, 304f, 1075, 1083–1085
computed tomography for, 1084
intraoperative ultrasound for, 1085
lumbar puncture for, 1083–1084
MRI for, 1084–1085, 1085f
PET for, 1085, 1086f
skull x-ray studies for, 1084
epidemiology of, 1075–1078, 1076f, 1077t
glomus tumors of base of skull as, 1116–1117
hemiplegia due to, 581–582
hereditary syndromes associated with, 1078, 1078t
histologic types of, 1075, 1076, 1076f, 1077t
lymphoma as, 1105–1109
clinical diagnosis and staging of, 1105–1106, 1106f
pathology of, 1105
treatment for, 1106–1109, 1107f, 1108b, 1108f
tumor biology of, 1105, 1105f
meningioma as, 1109–1111
clinical and pathologic considerations for, 1109–1110, 1109t, 1110f
therapy for
medical, 1111, 1111b
stereotactic radiation, 1110–1111
surgical and conventional radiation, 1110
pathology of, 1075, 1076, 1076f, 1077t
of pineal region, 1117
pituitary adenoma as, 1111–1114
clinical and pathologic considerations for, 1111–1112, 1112t
therapy for
medical, 1112–1113
radiation, 1113–1114
recommended approach for, 1114, 1114b
surgical, 1112

Brain tumor(s) (*cont.*)
predisposition syndromes for, 177t
radiation-induced, 1031, 1076–1077
risk factors for, 1031, 1076–1078
signs and symptoms of, 1075, 1079–1083
general, 1075, 1080–1082
localizing, 1075, 1082
pathophysiology of, 1079–1080, 1080f, 1081t
treatment of, 1082–1083, 1083t
supratentorial gliomas as, 1091–1105
clinical considerations with, 1091
genetics of, 1094–1095, 1095f
imaging of, 1094, 1094f
pathology of, 1091–1094, 1092f, 1093f
prognosis for, 1094, 1097–1098
therapy for
approach to, 1097, 1097b
chemo-, 1100–1103, 1100t, 1101f, 1102f, 1103t
in elderly patients, 1103–1104
new approaches to, 1104–1105
quality of life after, 1104
radiation, 1097–1100, 1097t, 1099t
surgical, 1095–1097, 1097b
therapy for, 1075
chemo-, 1090–1091
radiation, 1087–1090, 1090f
surgical, 1085–1087
tumor biology of, 1078–1079
and venous thromboembolic disease, 698
Brain Tumor Study Group (BTSG), 1098, 1099t
Brainstem gliomas, 1123–1125, 1124f, 1125f
Brainstem tumors, signs of, 1082
BRCA1 gene
functions of, 1879
mutations in, 212t
and breast cancer risk, 178t, 374, 1875, 1879
and breast cancer treatment, 1879
and breast-ovarian cancer susceptibility, 148–149, 149b, 172, 179
clinical management of, 179, 1879
epidemiology of, 179
founder, 179
genetic counseling on, 203
genetic testing for, 410
linkage analysis of, 196
and ovarian cancer, 383, 384, 1830

papillary, 1899, 1900f
pathologic factors for, 1898–1900, 1899f–1901f, 1899t
predictive and prognostic factors for, 1916–1918, 1916t
risk of, 1916–1918, 1916t
lobular carcinoma in situ and, 1901
sentinel lymph node biopsy for, 1909–1910, 1910t
tubular, 1899, 1901f

Breast cancer (*cont.*)
linkage analysis of, 195, 196
lobular
in situ, 1875, 1900–1902
anatomy and pathology of, 1900, 1901f
bilaterality of, 1901
classic, 1900
core biopsy of, 1893
incidence of, 1900–1901, 1901f, 1902f
multicentricity of, 1901
and risk of invasive cancer, 1901
treatment of, 1902
invasive, 1899f
local osteolytic hypercalcemia in, 741–742
locally advanced, 1876, 1927–1928, 1928t, 1929t
long-term follow-up for, 1926–1927
lymphedema in, 585, 642
male, 1906, 1933
medullary, 1899, 1901f
metastatic
to axilla, with occult primary, 1933–1934
to bone
bisphosphonates for, 860–863, 862f, 864–865
endocrine therapy for, 858–859
epidemiology of, 845
tumor markers for, 855
to brain, 828, 839
to choroid, 1148f
epidemiology of, 1930
evaluation of, 1930
imaging of, 295, 1930
immunohistochemistry of, 236f
to liver, 890–891, 898
to lungs, 880–881
management of, 1876, 1929–1933, 1930t, 1931t
microcalcifications in, 1875
molecular profiling in, 1880–1882, 1881f, 1882f
mucinous, 1899, 1900f
noninvasive (in situ)
ductal, 1875–1876, 1902–1907
anatomic histology of, 1902–1904, 1903f–1905f
biology of, 1905–1906, 1905t
calcifications in, 1890f, 1906
clinical diagnosis of, 1905
comedo, 1903, 1904f
core biopsy of, 1893
cribriform, 1903, 1903f
defined, 1902
evaluation of, 1902–1904, 1902t
grading of, 1903–1904
incidence of, 1900, 1901f, 1902f, 1905
and invasive disease, 1905–1906, 1905t
in males, 1906
micropapillary, 1903, 1904f
multicentricity of, 1905
papillary, 1903, 1905f
pathologic classification of, 1903, 1903f–1905f
treatment of, 1902t, 1906–1907, 1907t

Breast cancer (*cont.*)
noninvasive (in situ) (*cont.*)
lobular, 1875, 1900–1902
anatomy and pathology of, 1900, 1901f
bilaterality of, 1901
classic, 1900
core biopsy of, 1893
incidence of, 1900–1901, 1901f, 1902f
multicentricity of, 1901
and risk of invasive cancer, 1901
treatment of, 1902
management of, 1875–1876, 1900–1907
and risk of developing invasive disease, 1893, 1901, 1902
occult, 1933–1934
ovarian cancer and, 1030
Paget's disease as, 1905, 1934
papillary, 1899, 1900f
during pregnancy, 1054, 1055f, 1933
pregnancy after, 1933
prevention of, 373–376
chemo-, 366t, 376, 1879, 1883–1884
in high-risk individuals, 1883–1884
phytoestrogens for, 1877
prophylactic mastectomy or oophorectomy for, 376, 410–411, 1879, 1884
prognosis for
age-related changes in, 1042t
pathologic factors in, 1898–1900, 1899f–1901f, 1899t
staging and, 1895–1898, 1896t–1898t
radiation-induced, 1025, 1031, 1031t, 1877
recurrence of
age and, 1913, 1914t
in axillary lymph nodes, 1911
after breast-conservation therapy, 1928–1929
factors affecting, 1913–1914, 1914t
histology and, 1914
locoregional, 1911, 1913, 1913f, 1914f
radiation therapy and, 1911, 1912f
treatment of, 1876
tumor size and, 1913–1914
risk factor(s) for, 374–375, 1877
alcohol use as, 375, 1877
diet as, 375, 1877
genetic, 1877, 1879–1880
hormone replacement therapy as, 374–375, 1877, 1878f
ionizing radiation as, 1025, 1031, 1031t, 1877
obesity as, 375, 1877
oral contraceptives as, 375, 1877
reproductive, 1877
risk of
estimation of, 1875, 1877, 1877t
high, 1883–1884, 1888
sarcomas as, 1934, 2044–2045
screening for and early detection of, 375–376, 1875, 1884–1888
alternative methods of, 1888
ductal lavage in, 1888

Breast cancer (*cont.*)
screening for and early detection of (*cont.*)
efficacy of, 365t, 1884–1886, 1885t–1887t
in elderly, 1045, 1888
guidelines for, 364, 1886, 1888t
in high-risk individuals, 1883, 1888
mammography in, 376, 1884–1888
efficacy of, 1884–1886, 1885t–1886t
in elderly, 1888
guidelines for, 1883, 1884, 1888t
for high-risk individuals, 1883, 1888
patient compliance with, 1886
sensitivity of, 1886–1888
MRI in, 1888
patient compliance with, 1886
sensitivity of, 1886–1888
surgical oncologist's role in, 410–411
as second malignant neoplasm with Hodgkin's lymphoma, 2367
second malignant neoplasms with, 1031, 1031t, 1033
sentinel lymph node biopsy in
for ductal carcinoma in situ, 1906–1907
for invasive disease, 1909–1910, 1910t
for staging, 1895, 1909–1910, 1910t
staging of, 1895–1900, 1896t–1898t
axillary, 1908–1909, 1909f, 1910, 1910t
sentinel lymph node biopsy for, 1895, 1909–1910, 1910t
and survival, 1884, 1885t, 1886t
stem cells of, 1882, 1883f
treatment of, 1875–1876, 1883–1934
aromatase inhibitors in, 1918, 1924, 1931
axillary staging in, 1908–1909, 1909f
bisphosphonates in, 1932
chemotherapy in
adjuvant, 1918–1920, 1921t
for early stage disease, 1918–1920, 1920t, 1921t, 1925–1926
for locally advanced disease, 1927
for metastatic disease, 1931–1932, 1931t
neoadjuvant, 1907, 1925
secondary effects of, 1925–1926
combined chemoendocrine therapy in, 1920t, 1924–1925
conditionally replicative adenoviruses in, 522–523
for early stage disease, 1876, 1907–1927
axillary staging in, 1908–1909, 1909f
breast-conservation therapy in, 1907–1908, 1913
in elderly patients, 1911
factors affecting outcome of, 1913–1914, 1914t
and local recurrences, 1913, 1913f, 1914f
mastectomy for, 1914–1916
new strategies for, 1927
predictive and prognostic factors for, 1916–1918, 1916t
radiation therapy in, 1910–1913, 1911f–1913f, 1916, 1916b, 1917f
resection of primary lesion in, 1908

Breast cancer (*cont.*)
treatment of (*cont.*)
sentinel lymph node biopsy in, 1909–1910, 1910t
systemic therapy in, 1918–1927, 1919t–1923t
endocrine therapy in
for early stage disease, 1920t, 1921–1924
for metastatic disease, 1930–1931, 1930t, 1931t
secondary effects of, 1926
hematopoietic stem cell transplantation in, 507
hepatic artery infusion in, 906t
for inflammatory disease, 1928, 1929t
for invasive disease, sentinel lymph node biopsy in, 1909–1910, 1910t
for locally advanced disease, 1876, 1927–1929, 1928t, 1929t
for locally recurrent disease, 1876
for metastatic disease, 1876, 1929–1933, 1930t, 1931t
molecularly targeted therapy in, 494
new strategies for, 1927, 1932–1933
for noninvasive disease
ductal, 1902t, 1906–1907, 1907t
lobular, 1875, 1902
ovarian function suppression in, 1918, 1922–1924, 1931
radiation therapy in
adjuvant, 1916, 1916b, 1917f
boost doses of, 1911
complications of, 1913
for ductal carcinoma in situ, 1906
for early stage disease, 1910–1913, 1911f–1913f, 1916, 1916b, 1917f
for locally advanced disease, 1927
partial breast, 1911–1912, 1913f
and recurrence, 1911, 1912f
whole breast, 1910–1911, 1911f, 1912f
surgical
breast conservation (lumpectomy) as, 1906–1908, 1907t, 1927–1929
for ductal carcinoma in situ, 1906
mastectomy as, 1914–1916
reproductive effects of, 1001
tamoxifen in
chemotherapy with, 1924–1925
for ductal carcinoma in situ, 1906
for early stage disease, 1918, 1920t, 1921–1922
for metastatic disease, 1930–1931
secondary effects of, 1926
trastuzumab in, 534
for early stage disease, 1920–1921, 1922t, 1923t
with *HER2* mutation, 1880
for metastatic disease, 1932
triple-negative, 1879, 1918
tubular, 1899, 1901f
tumor markers for, 1916–1918, 1916t
Breast Cancer Profiling (BCP) assay, 1918
Breast conservation therapy
complications of, 1913
for ductal carcinoma in situ, 1906, 1907t
Breast conservation therapy (*cont.*)
for early-stage disease, 1907–1908
for locally advanced disease, 1927–1929, 1928t
recurrence after, 1928–1929
Breast masses, 1889, 1889f, 1890f
management of, 1890–1893, 1892f, 1893t
Breast reconstruction, 1914–1916
Breast sarcomas, 1934, 2044–2045
Breast self-examination, 376
Breast-ovarian cancer predisposition syndromes, 172–179, 173t
and breast cancer risk, 179
clinical features of, 172–179
clinical management of, 179
DNA damage in, 141t, 148–149
epidemiology of, 172, 179
founder mutations in, 179
genes associated with, 172–179, 173t, 178t
genetics of, 179
Bremsstrahlung x-rays, 420
Brennan, Murray, 408
Breslow thickness, 1231, 1234, 1236, 1238
BRIP1 mutations, and breast cancer predisposition, 178t, 179
BRMs. *See* Biologic response modifiers (BRMs).
Broder classification, for penile carcinoma, 1704f, 1704t, 2004
Bromocriptine
for hyperprolactinemia, 1018
for prolactinomas, 1112–1113
Bronchioloalveolar carcinoma (BAC), 1313–1316, 1314f, 1319t
Bronchopleural fistula, radiation-induced, 976
Bronchoscopic specimens, 1312
BSF. *See* Busulfan (Myleran, BSF).
BSP (bone sialoprotein), as bone resorption marker, 846, 854
BTA test, for bladder cancer, 1637
BTSG (Brain Tumor Study Group), 1098, 1099t
B-type cyclins, 52
Buccal mucosa, cancer of, 1212–1213
Budding uninhibited by benzimidazole 1 (BUB1), 59, 60f, 61
Budding uninhibited by benzimidazole–related kinase 1 (BUBR1), 59, 60f
Build-up region, 421
Bupropion SR (Zyban), for smoking cessation, 399–400, 399t
Burkitt, Dennis, 153
Burkitt's lymphoma (BL)
in children
clinical presentation of, 2179
epidemiology of, 2173
Epstein-Barr virus and, 153–156, 1066
genetics of, 2173
with HIV, 1066
pathology and tumor biology of, 2173–2175, 2174f
treatment of, 2181–2182, 2182t
clinical characteristics of, 2382t
endemic, 2390, 2390t
genetic basis for, 2174–2175
HIV-associated, 1066, 2390, 2390t, 2393
immunophenotypic and genetic abnormalities in, 256t, 2374t
Burkitt's lymphoma (BL) (*cont.*)
molecular genetics of, 2375t, 2376
sporadic, 2390, 2390t
treatment of, 2390, 2391t
Burzynski Clinic, 558t
Buserelin (Suprefact, HOE 766), 462
Bushke-Lowenstein tumor, 1702–1703
Busulfan (Myleran, BSF), 462
for chronic myeloid leukemia, 2288
hyperpigmentation due to, 631
neurotoxicity of, 947
Butyrophenones, as antiemetics, 605

C

C225, for head and neck cancer, 1207–1208
CA 15-3, in breast cancer, 855
CA 19-9, as tumor marker, 280
for pancreatic cancer, 1601
CA27.29, as tumor marker, 280
CA-125
in ascitic fluid, 938
and ovarian cancer, 384, 1830, 1840–1841, 1847
as tumor marker, 279, 280, 281
for carcinoma of unknown primary, 2064
Cabergoline, for hyperprolactinemia, 1018
caBIG (cancer bioinformatics grid), 329
Cachexia, 591–596
adipose tissue in, 592–593, 593f
anorexia and, 591–592
hydrazine sulfate for, 552
incidence of, 591
pharmacologic treatment of, 595–596
skeletal muscle in, 593–595, 594f
Cachexia-anorexia syndrome, 591–592
Cadmium, as carcinogen, 132
Caisse, Renee, 553
CAIX (carbonic anhydrase IX), in renal cell carcinoma, 1623
CAK (CDK-activating kinase), 50–51
Calcifications, in breast, 1889, 1889f, 1890f, 1891t, 1906
Calcimimetics, for hypercalcemia of malignancy, 745–746
Calcitonin
in calcium homeostasis, 740
for hypercalcemia of malignancy, 744, 746
in medullary thyroid carcinoma, 1280
Calcitriol, for cancer prevention, 547
Calcium
as bone resorption marker, 853, 856
for cancer prevention, 547
plasma, 740, 740f
Calcium gluconate, for tumor lysis syndrome, 763
Calcium homeostasis, 739–740, 740f
Calcium intake, and colorectal cancer, 1482, 1486, 1487t, 1488t
Calcium reabsorption, 740
Calcium supplementation, for colorectal cancer prevention, 1486, 1487t, 1488t
Calcium-sensing receptor (CaSR), 740, 745
Calciuretic therapy, for hypercalcemia of malignancy, 744
Calicheamicin, 537

  prostate, 323, 1668–1669
  for renal cell carcinoma, 1629–1630
Cancer-associated antigens. *See* Tumor marker(s).
Cancer-related fatigue (CRF), 657–662
  acupuncture for, 549
  clinical interventions for, 659f, 660–662b
  etiology of, 658
  evaluation of, 658–659, 659f
  factors contributing to, 658–659
  future research on, 661, 662b
  incidence of, 657–658
  intensity of, 658
  patterns of, 658
  rehabilitation for, 581
Cancer-testis antigens, 78
Candidate genes, 3, 200–201
Candidemia, 725
Candidiasis, 725
  hepatosplenic, 726
  oral, due to corticosteroid therapy, 1081
Cannabinoids, as antiemetics, 603t, 605
Capecitabine (Xeloda), 462
  for colorectal cancer, 1516, 1517t, 1520–1521, 1522t, 1548
  for gastric cancer, 1457
  myocardial ischemia due to, 993
  during pregnancy, 1053
Capsaicin, for pain management, 575
Captopril, for radiation pulmonary fibrosis, 976
Carbolic acid, for antisepsis, 408

Carbon monoxide diffusion capacity (DLCO)
  grading of, 972t
  in presurgical evaluation for lung cancer, 1328
  with radiation pneumonitis, 974
Carbonic anhydrase IX (CAIX), in renal cell carcinoma, 1623
Carboplatin (Paraplatin, Carbo, CBDCA), 462
  for gastric cancer, 1457
  for lung cancer
    non-small cell, 1340t, 1341
    small cell, 1350
  for ovarian cancer
    advanced, 1832–1834, 1834t, 1835t, 1836–1840, 1837t, 1840t
    limited, 1844–1845, 1845t
    recurrent, 1846
  for soft-tissue sarcoma, 2036
  for testicular cancer, 1723–1724, 1732, 1736
Carcinoembryonic antigen (CEA)
  in ascitic fluid, 938
  with carcinoma of unknown primary, 2064
  in colorectal cancer, 1509–1511, 1519, 1537
  with liver metastases, 888, 892, 900, 900f
  with pulmonary metastases, 878
  as tumor marker, 277, 280
  in vaccinia viral vectors, 517
Carcinoembryonic antigen (CEA) vaccine, 517
Carcinogen(s), 125–137, 126t, 365
  chemical, 127–130, 364
    aflatoxins as, 128–129
    aromatic amines as, 127–128
    benzene as, 128
    polycyclic aromatic hydrocarbons as, 127, 128f
    in tobacco, 129–130, 129t
  chemotherapeutic, 130
  dietary, 133–134, 133b
  exposure biomarkers and susceptibility factors for, 134–135
  fibers and dusts as, 132–133
  identification of
    in cancer prevention, 135, 137b
    history of, 125–127
  metal(s) as, 132
  natural, 133
  public health approach to, 135–136, 136f, 137b
  radiation as, 130–131, 435–436
    ionizing, 130–131, 131t
    of oral cavity, 620
    principles of, 435–436, 435f
    due to radon, 131
    ultraviolet, 130
Carcinogen metabolites, 134
Carcinogen-DNA adducts, 134
Carcinogenesis
  aging and, 1039, 1041
  and chemoprevention, 365–367, 366t
  markers of, 365
  model of, 365
  prevention of, 361, 362f
  radiation-induced, 435–436, 435f
Carcinogen-protein adducts, 134
Carcinoid syndrome, 1290–1291
Carcinoid tumor(s), 1271, 1290–1294
  of appendix, 1290
  carcinoid syndrome due to, 1290–1291
  clinical pathology of, 1290
  of colon, 1509
  diagnosis of, 1271, 1291, 1292f, 1293f
  epidemiology of, 1271, 1290
  hepatic metastases of, 1291, 1294
  of lungs, 1317, 1318f, 1319t
  pathogenesis of, 1290
  prognosis for, 1290
  of rectum, 1290, 1537
  of small bowel
    clinical presentation of, 1469
    pathology of, 1467, 1467f
    prognosis for, 1471
    treatment of, 1472
  of small intestine, 1290
  thymic, 1384, 1384f
  treatment of, 1271, 1291–1294, 1294t
Carcinoid tumorlet, of lungs, 1317
Carcinoma(s)
  after allografting, 228–229, 228b
  immunodeficiency and, 225t, 228–230, 228b, 229t
  in organ transplant recipients, 228–229, 228b, 229t
Carcinoma ex pleomorphic adenoma, of salivary gland, 1183f–1184f, 1184
Carcinoma in situ (CIS)
  of bladder, 1638
  of breast
    ductal, 1875–1876, 1902–1907
      anatomic histology of, 1902–1904, 1903f–1905f
      biology of, 1905–1906, 1905t
      calcifications in, 1890f, 1906
      clinical diagnosis of, 1905
      comedo, 1903, 1904f
      core biopsy of, 1893
      cribriform, 1903, 1903f
      evaluation of, 1902–1904, 1902t
      grading of, 1903–1904
      incidence of, 1900, 1901f, 1902f, 1905
      and invasive disease, 1905–1906, 1905t
      in males, 1906
      micropapillary, 1903, 1904f
      multicentricity of, 1905
      papillary, 1903, 1905f
      pathologic classification of, 1903, 1903f–1905f
      treatment of, 1902t, 1906–1907, 1907t
    lobular, 1875, 1900–1902
      anatomy and pathology of, 1900, 1901f
      bilaterality of, 1901
      classic, 1900
      core biopsy of, 1893
      incidence of, 1900–1901, 1901f, 1902f
      multicentricity of, 1901
      and risk of invasive cancer, 1901
      treatment of, 1902
  of penis, 1702
Carcinoma of unknown primary (CUP), 2057–2072
  aneuploidy in, 2061–2062
  axillary adenopathy due to, 2068–2069, 2069f
  cervical lymphadenopathy due to, 2067, 2067t, 2068
  chromosomal abnormalities in, 2062
  clinical manifestations of, 2068, 2069t
  differential diagnosis of, 2057
  epidemiology of, 2057, 2058, 2058t
  etiology of, 2058, 2058t
  evaluation of, 2057–2058, 2063–2068
    gene expression analysis in, 2067–2068
    history and physical examination in, 2063
    laboratory studies in, 2063–2064
    pathologic, 2064–2065, 2065t, 2066f
    radiographic studies in, 2065–2067, 2067t
    tumor markers in, 2063–2065, 2065t, 2066f
  favorable clinical subsets of, 2068–2070, 2068t, 2069f, 2069t
  histologic subtypes of, 2058, 2059f, 2059t
  microvessel density in, 2063
  oncogenes in, 2062–2063
  peritoneal carcinomatosis due to, 2069
  poorly differentiated and undifferentiated, 2070
    neuroendocrine, 2070
  prognostic factors for, 2058–2060, 2059f, 2060f
  therapy for, 2068–2072, 2068b
    chemotherapy in, 2070–2072, 2071t
    primary, 2057
    salvage, 2057
  tumor markers for, 2063–2065, 2065t, 2066f
  tumor suppressor genes in, 2063
  unique biology of, 2060–2062, 2062t
  in unselected patients, 2070–2072, 2071t
Carcinoma simplex, vulvar. *See* Vulvar intraepithelial neoplasia (VIN).
Carcinosarcoma
  of breast, 1934
  uterine, 1798, 1798f
Cardiac arrhythmias
  due to cancer therapy, 983, 992
  due to vascular access device, 787
Cardiac disease, in carcinoid syndrome, 1291
Cardiac effect(s), of cancer therapy, 983–995
  with anthracyclines, 984t, 985–989, 985t, 1925
    in children, 989
    diagnosis of, 987–988, 987t
    etiology of, 985–986
    incidence of, 983, 985, 986f
    natural history of, 986
    pathophysiology of, 986–987, 986f
    risk factors for, 986
    treatment of, 983, 988–989, 989f, 991, 992b
  arrhythmias/dysrhythmias as, 983, 992
  with biologic response modifiers, 984t, 994

Cardiac effect(s), of cancer therapy (*cont.*)
cardiomyopathy/congestive heart failure as, 983, 985–991
in children, 989
diagnosis of, 987–988, 987t
etiology of, 985–986, 989–991
incidence of, 985, 986f
natural history of, 986
pathophysiology of, 986–987, 986f
risk factors for, 986
treatment of, 983, 988–989, 989f, 991, 992b
with chemotherapy drugs, 984t
long-term, 994–995
diagnosis of, 983
endocardial fibrosis as, 983
etiology of, 983–985, 985f
fluid retention as, 983, 993
with hematopoietic stem cell transplantation, 507
hypertension as, 983
hypotension as, 983
incidence of, 983
myocardial ischemia as, 983, 992–993
pericardial disease as, 983, 993
radiation-induced, 983, 994
peripheral vascular disease as, 993
with radiation, 983, 991, 993, 994
treatment of, 983
Cardiac failure, congestive. *See* Congestive heart failure (CHF).
Cardiac myxomas, 1387, 1388f
Cardiac toxicity. *See* Cardiac effect(s).
Cardiac troponins, in anthracycline-induced cardiomyopathy, 987
Cardiac tumors, 1387–1388, 1388f
Cardiomyopathy, due to cancer therapy, 983, 985–991
in children, 989
diagnosis of, 987–988, 987t
etiology of, 985–986, 989–991
incidence of, 985, 986f
natural history of, 986
pathophysiology of, 986–987, 986f
risk factors for, 986
treatment of, 983, 988–989, 989f, 991, 992b
Cardioprotection, dexrazoxane for, 989, 989f, 992b
Cardiopulmonary exercise testing (CPET), in presurgical evaluation for lung cancer, 1328
Cardiotoxicity. *See* Cardiac effect(s).
Cardiovascular status, in presurgical evaluation for lung cancer, 1329
Caregiver, of dying patient, 670–671, 670b, 671b
Caretaker genes
and cancer phenotype, 219
cancer predisposition syndromes due to, 171
in nonmelanoma skin cancer, 1254–1255
Caries, radiation-induced, 618–619
Carinal resection, 1332–1333
Carmustine (BiCNU, BCNU, bis-chloronitrosourea), 462–463
hyperpigmentation due to, 631
neurotoxicity of, 950
pulmonary toxicity of, 978
Carmustine impregnated wafer (Gliadel, polifeprosan 20 with carmustine implant), 463
for gliomas, 1101–1102
Carney complex (CNC), 174t, 177t, 183–184
β-Carotene
for cancer prevention, 547
colorectal, 1487t
for cancer treatment, 554
and lung cancer, 368
Carotid baroceptors, 750
CAS (cutaneous angiosarcoma), 1265–1266, 1265f, 2045
Case(s), 353
Case definition, 345–346
Case mix, heterogeneous, 345–346
Case report, 310
Case series, 310
Case-cohort study, 354, 354f
Case-control study(ies), 201, 354–358
comparability in, 355–357, 356f
design of, 354–357, 355f, 356f
hospital (clinic)-based, 201, 354
nested, 353–354, 353f
population-based, 201, 354–355
schematic of, 355f
statistical analysis of, 357–358, 358f
temporality in, 355
Casodex (bicalutamide), 461
for prostate cancer, 1683
reproductive effects of, 1003
Caspases, in apoptosis, 67–68, 68f
CaSR (calcium-sensing receptor), 740, 745
Castleman's disease, 773
vs. lymphoma, 2396
multicentric, 162
β-CAT gene, 211t
Cataracts, radiation-induced, 1139–1140, 1140f, 1141f
Catecholamines, with pheochromocytoma, 1286
Categorical outcomes, of clinical trials, 314
β-Catenin, 214–215, 214f
in colorectal cancer, 1479–1481, 1480f
in intracellular signaling, 28, 29f
in regulation of self-renewal, 97
β-Catenin deregulation, and cancer phenotype, 215–216, 217f
Catheter(s), heparin flushing of, 710
Catheter colonization, 787
Catheter thrombus, 787–788, 788t, 789b
Catheter-associated bacteremia, 787
Catheter-related candidemia, 725
Catheter-related infections, 727, 787
Cat's eye reflex, in retinoblastoma, 1150, 1151f
Cauda equina compression, due to bone metastases, 868
Causal inference(s)
case-cohort studies of, 354, 354f
case-control studies of, 354–358, 355f
comparability in, 355–357, 356f
design of, 354–357, 355f, 356f
nested, 353–354, 353f
statistical analysis of, 357–358, 358f
temporality in, 355
Causal inference(s) (*cont.*)
cohort studies of, 346–353
comparability in, 348–350
design of, 346–350, 347f, 348f
measures of association in, 352–353
measures of occurrence of endpoint in, 350–352, 351f, 352f
statistical analysis of, 350–353
temporality in, 346–348, 347f, 348f
epidemiologic methods of drawing, 358–359
Cavitron ultrasonic aspirator, for hepatic resection, 889
CBDCA. *See* Carboplatin (Paraplatin, Carbo, CBDCA).
CBE (clinical breast examination), 376
in elderly, 1045
CBF (core binding factor), in acute myelogenous leukemia, 2218, 2218f
CBF (core binding factor) complex, in childhood leukemia, 2141, 2149
C-BOP/PEB regimen, for testicular cancer, 1733
CBT (cognitive-behavioral therapy), for smoking cessation, 398, 401, 402t
CBV regimen, for Hodgkin's lymphoma, 2365
CC-5013. *See* Lenalidomide (CC-5013, Revlimid).
CCA. *See* Choriocarcinoma (CCA).

Celomic epithelial carcinoma (*cont.*)
treatment of (*cont.*)
platinum-based, 1832–1834, 1833t, 1834t, 1838
salvage, 1833t, 1845–1847, 1846t
single-agent, 1832, 1832t, 1833t
stem cell–supported high-dose, 1840
cytoreductive surgery for, 1831–1832, 1831t, 1847
decisions on, 1841b
initial, 1827, 1831–1832, 1831t
for limited disease, 1827, 1841–1845, 1842t–1845t
radiation therapy for, 1842, 1843
radioactive isotopes for, 1842–1844, 1843t, 1844t
for recurrent, persistent, or progressive disease, 1827, 1845–1848, 1845b, 1846t
second-look laparotomy for, 1841
Center for Cell Specific Therapy, 558t
Centimorgans (cM), 196
Central herniation syndrome, due to brain tumor, 1080, 1081t
Central institutional review board (CIRB), 329–330
Central lines
guidelines for, 782t
percutaneous, 779–780
surgically tunneled, 780, 780f
Central nervous system (CNS), paraneoplastic syndromes of, 768–772, 770f, 771f
Central nervous system (CNS) cancer, 1075–1127
acoustic neuroma as, 1114–1115
cerebellar hemangioblastomas as, 1115
childhood brain tumors as, 1119–1127
brainstem glioma as, 1123–1125, 1124f, 1125f
craniopharyngioma as, 1126–1127, 1126f
ependymoma as, 1123
epidemiology of, 1076, 1076f, 1077t
in infants, 1127
intracranial germ cell tumors as, 1125–1126, 1126t
low-grade astrocytomas as, 1122–1123
primitive neuroectodermal, 1119–1122, 1120f, 1121f, 1122b
chordomas and chondrosarcomas involving base of skull as, 1115–1116
classification of, 1075, 1076, 1076f, 1077t
clinical presentation of, 1075, 1079–1083
diagnosis of, 304, 1075, 1083–1085
computed tomography for, 1084
intraoperative ultrasound for, 1085
lumbar puncture for, 1083–1084
MRI for, 304, 304f, 1084–1085, 1085f
PET for, 304, 1085, 1086f
skull x-ray studies for, 1084
epidemiology of, 1075–1078, 1076f, 1077t
glomus tumors of base of skull as, 1116–1117
hemiplegia due to, 581–582
hereditary syndromes associated with, 1078, 1078t

Central nervous system (CNS) cancer (*cont.*)
histologic types of, 1075, 1076, 1076f, 1077t
lymphoma as, 1105–1109
clinical diagnosis and staging of, 1105–1106, 1106f
pathology of, 1105
treatment for, 1106–1109, 1107f, 1108b, 1108f
tumor biology of, 1105, 1105f
meningioma as, 1109–1111
clinical and pathologic considerations for, 1109–1110, 1109t, 1110f
therapy for
medical, 1111, 1111b
stereotactic radiation, 1110–1111
surgical and conventional radiation, 1110
pathology of, 1075, 1076, 1076f, 1077t
of pineal region, 1082, 1117
pituitary adenoma as, 1111–1114
clinical and pathologic considerations for, 1111–1112, 1112t
therapy for
medical, 1112–1113
radiation, 1113–1114
recommended approach for, 1114, 1114b
surgical, 1112
predisposition syndromes for, 177t
radiation-induced, 1031, 1076–1077
risk factors for, 1031, 1076–1078
signs and symptoms of, 1075, 1079–1083
general, 1075, 1080–1082
localizing, 1075, 1082
pathophysiology of, 1079–1080, 1080f, 1081t
treatment of, 1082–1083, 1083t
of spinal axis, 1117–1119, 1117t
supratentorial gliomas as, 1091–1105
clinical considerations with, 1091
genetics of, 1094–1095, 1095f
imaging of, 1094, 1094f
pathology of, 1091–1094, 1092f, 1093f
treatment of
approach to, 1097, 1097b
chemotherapy for, 1100–1103, 1100t, 1101f, 1102f, 1103t
in elderly patients, 1103–1104
new approaches to, 1104–1105
quality of life after, 1104
radiation therapy for, 1097–1100, 1097t, 1099t
surgical, 1095–1097, 1097b
treatment of, 1075
chemotherapy for, 1090–1091
radiation therapy for, 1087–1090, 1090f
surgical, 1085–1087
tumor biology of, 1078–1079
and venous thromboembolic disease, 698
Central nervous system (CNS) infections, 727
Central nervous system (CNS) involvement, in adult T-cell leukemia-lymphoma, 2429
Central nervous system (CNS) ischemia, grading of, 958t
Central nervous system (CNS) leukemia(s)
acute lymphocytic, 2199–2200
of childhood, 2142, 2154–2158, 2156t–2157t
Central nervous system (CNS) lymphoma, 1105–1109
clinical diagnosis and staging of, 1105–1106, 1106f
with HIV, 1066–1068, 1066f, 1069b
pathology of, 1105
treatment of, 2390
tumor biology of, 1105, 1105f
Central nervous system (CNS) metastases, and venous thromboembolic disease, 698
Central nervous system (CNS) necrosis, grading of, 958t
Central nervous system (CNS) prophylaxis and treatment, for lymphoma in children, 2184
Central nervous system (CNS) toxicity. *See* Neurotoxicity.
Central nervous system (CNS) tumors, cytogenetic aberrations in, 258t–259t
Central venous access device(s), 779–789
central lines as
guidelines for, 782t
percutaneous, 779–780
surgically tunneled, 780, 780f
choice of, 779–781, 780f–782f, 782t
complications of, 786–788
dressings for, 782t
flushing of, 782t
Groshong catheter as, 782t
Hickman catheter as, 780, 780f
guidelines for, 782t
insertion of, 784, 785f
insertion of, 781–784
complications of, 784
introducer kit for, 784, 786f
location for, 781–782
for permanent Silastic catheter, 784, 785f
preparation for, 782–783
Seldinger technique for, 783, 783f
technique for, 783–784, 783f–786f
using veins in neck for, 783–784, 784f
long-line central access (peripherally inserted central catheter lines) as, 780–781
guidelines for, 782t
maintenance of, 782t, 789, 789b
nonfunctioning, 788–789, 788t, 789b
surgically implanted infusion/injection ports as, 780, 781f, 782f
guidelines for, 782t
placement of, 784, 786f
venous thromboembolic disease with, 695, 705, 709–710
Centrosome separation, 52
Cerebellar astrocytomas, 1123
Cerebellar degeneration, paraneoplastic, 770–771, 771f, 1324
Cerebellar dysfunction
due to cytosine arabinoside, 946
differential diagnosis of, 955–956
due to 5-fluorouracil, 949
Cerebellar hemangioblastomas, 1115
Cerebellar mutism, 1120
Cerebellar pilocytic astrocytoma, 1120f
Cerebellopontine angle tumors, 1082
Cerebral metastases. *See* Brain metastasis(es).
Cerebral salt wasting (CSW), hyponatremia due to, 754
Cerebrospinal fluid (CSF) evaluation, for leptomeningeal dissemination, 840
Cerebrospinal fluid (CSF) leak, grading of, 959t
Cerebrospinal fluid (CSF) spread, metastasis via, 816
Cerebrovascular events, due to L-asparaginase, 946
Cervical adenocarcinoma, 1748, 1750f, 1757–1758
Cervical adenosquamous carcinoma, 1749–1750
Cervical cancer, 1745–1765
adenocarcinoma as, 1748, 1750f, 1757–1758
adenosquamous carcinoma as, 1749–1750
anemia in, 1756–1757
cervical intraepithelial neoplasia and, 1746, 1746t, 1748, 1749f–1750f
clinical presentation of, 1750–1751
diagnosis of, 1745, 1752–1757
colposcopy in, 1752, 1753f
endocervical curettage or endocervical brush in, 1752
excision biopsy in, 1752
excisional conization (cone biopsy) in, 1752–1753
history and physical examination in, 1753–1754
imaging in, 298, 1754–1756, 1754f, 1756f, 1757f
with invasive disease, 1753–1754
laboratory evaluation in, 1756–1757
loop electrodiathermy excision procedure in, 1752, 1753f
epidemiology of, 1745, 1746
etiology of, 1745
with HIV, 1069
human papillomavirus and, 157–159, 385–387, 1746–1748, 1747f, 1752
infectious etiology of, 363t
lymphovascular space invasion by, 1757, 1764
metastatic
imaging of, 1754, 1754f
treatment of, 1765
neuroendocrine tumors as, 1750
Pap smear for, 163
pathology of, 1748–1750, 1748f–1750f
post-transplant, 229
during pregnancy, 1054–1055
prevention of
chemo-, 366t, 387
primary, 385–387, 385t
prognostic factors for, 1757–1758
recurrence of, 1745
risk factors for, 385–386, 385t, 1745, 1746
risk reduction for, 385–387, 385t

Cervical cancer (*cont.*)
screening for and early detection of, 365t, 386–387, 386f, 1751–1752, 1751f
American Cancer Society guidelines for, 1746, 1746t
Bethesda system for, 1751–1752, 1751t
second malignant neoplasms with, 1030
sexual activity and, 1746
squamous cell carcinoma as, 1748, 1748f, 1750f
staging of, 1745, 1754, 1755t–1756t
and treatment, 1758, 1763–1765
treatment of, 1745, 1758–1765
chemoradiation for, 1762–1765
hysterectomy for, 1758–1759, 1759f
surgical alternatives to, 1759
for locoregional disease, 1763–1765
with metastases, 1765
overview of, 1758
partial exenteration for, 1759
primary, 1745
radiation therapy for, 1759–1765, 1760f–1762f
radical cervicectomy for, 1759
for recurrent disease, 1745
salvage chemotherapy for, 1765
by stage, 1758, 1763–1765
superficial ablative therapy for, 1758
vulvar cancer and, 1766
Cervical chordoma, 1998–1999
Cervical esophageal cancer, 1417
Cervical intraepithelial neoplasia (CIN), 1746, 1746t, 1748, 1749f–1750f
Cervical lymphadenectomy, for melanoma, 1240
Cervical lymphadenopathy, due to carcinoma of unknown primary, 2067, 2067t, 2068
Cervical squamous cell carcinoma, 1748, 1748f, 1750f
Cervicectomy, radical, 1759
Cervicomedullary tumors, 1125
Cervix, anatomy of, 1748, 1748f
Cesium 137, 419
CESS (Cooperative Ewing's Sarcoma Study), 2089t
Cetuximab (Erbitux, chIgG1, anti-EGFR), 453, 463
for colorectal cancer, 534, 1524–1525
for hepatocellular carcinoma, 1577
for non–small cell lung cancer, 1339–1340, 1343
CFS (congenital fibrosarcoma), cytogenetic aberrations in, 260t
CFTβ, in childhood leukemia, 2149
CGA (comprehensive geriatric assessment), 1039, 1041–1044, 1042t
CGH (comparative genome hybridization), 200, 252
in adult T-cell leukemia-lymphoma, 2427
microarray, 252
Chance variability, 358–359
Chantix (varenicline), for smoking cessation, 399t, 400
Characteristic x-ray, 420
Charles procedure, 650
CHD1 gene, and gastric cancer predisposition, 185
Chédiak-Higashi syndrome (CHS), 226t, 227
CHEK2 mutations, and breast cancer predisposition, 172, 178t
Chemical carcinogen(s), 127–130, 364
aflatoxins as, 128–129
aromatic amines as, 127–128
benzene as, 128
polycyclic aromatic hydrocarbons as, 127, 128f
in tobacco, 129–130, 129t
Chemical cellulitis, 627–629
Chemical exposure, and soft-tissue sarcoma, 2010, 2010t
Chemical pleurodesis, for pleural effusion, 930–932
Chemical-induced brain tumors, 1077–1078
Chemodectomas, 186, 1116–1117
Chemoembolization, for liver metastases, 909–910
Chemoendocrine therapy, for breast cancer, 1920t, 1924–1925
Chemohormonal therapy, 458
Chemoimmunotherapy, for chronic lymphoid leukemia, 2302–2304, 2303f
Chemokines, in cancer immunology, 78
Chemoprevention, 135–136
of aerodigestive malignancies, 368
of breast cancer, 366t, 376, 1879, 1883–1884
carcinogenesis and, 365–367, 366t
of cervical cancer, 366t, 387
of colorectal cancer, 366t, 372–373, 373f
development of agents for, 366–367
in elderly, 1044
of head and neck cancer, 366t, 1206–1207
of hepatocellular carcinoma, 387
of leukoplakia, 366t
of lung cancer, 366t
of ovarian cancer, 384
of prostate cancer, 366t, 378–379
of skin cancer, 366t, 382
Chemoradiation therapy (CRT), 438
adjuvant
for esophageal cancer, 1403, 1404t, 1414
for gastric cancer, 1444–1445, 1444t, 1445t
for rectal cancer, 1540–1541, 1540t, 1546
for anal cancer, 1561b, 1562–1564, 1563t, 1564t, 1566
for bladder cancer, 1645–1646
for cervical cancer, 1762–1765
for cholangiocarcinoma, 1590
for colorectal cancer, 1517–1518
for esophageal cancer
definitive, 1404t, 1405, 1414–1415, 1416t
postoperative, 1403, 1404t, 1414
preoperative, 1403–1405, 1404t, 1410–1414, 1411t, 1413t
salvage therapy after, 1415
for gastric cancer
adjuvant, 1444–1445, 1444t, 1445t
for locally advanced disease, 1451–1452, 1452t, 1454
Chemoradiation therapy (CRT) (*cont.*)
for gastric cancer (*cont.*)
neoadjuvant, 1445, 1454
nutritional support during, 1459
palliative, 1455
for head and neck cancer, 1191, 1204–1205, 1204f, 1205f, 1206t
for lung cancer
non-small cell, 1332
concurrent, 1337–1339, 1338t
with consolidation or induction chemotherapy, 1338–1339, 1338t
induction, 1332
neoadjuvant, 1336
sequential, 1337–1339, 1337t, 1338t
small cell, 1351–1353
for nasopharyngeal cancer, 1209
neoadjuvant
for esophageal cancer, 1403–1405, 1404t, 1410–1414, 1411t, 1413t
for gastric cancer, 1445, 1454
non-small cell lung cancer, 1336
for rectal cancer, 1540–1541, 1540t, 1546
for vulvar cancer, 1772–1773, 1773f, 1774t, 1775t
for pancreatic cancer, 1606–1607
for penile cancer, 1709
for rectal cancer
locally advanced, 1550–1551
in medically inoperable patients, 1550
novel agents in, 1546–1548, 1547t
planning of, 1541–1542, 1542f
preoperative vs. postoperative, 1540–1541, 1540t, 1546
randomized trials of, 1543–1546, 1544t–1546t, 1545f, 1546f
toxicity of, 1542–1543
for soft-tissue sarcoma, 2030–2031, 2031f
for vaginal cancer, 1781
for vulvar cancer, 1772–1773, 1773f, 1774t, 1775t
Chemoreceptor trigger zone (CTZ), in vomiting reflex, 599, 600f
Chemoreduction, for retinoblastoma, 1153–1154, 1153f
Chemotherapeutic agent(s), 459–481
alemtuzumab as, 459
altretamine as, 459
amifostine as, 459
anagrelide as, 459–460
anastrozole as, 460
arsenic trioxide as, 460
L-asparaginase as, 460
azacytidine as, 460–461
azathioprine as, 461
bacillus Calmette-Guérin as, 461
bevacizumab as, 461
bexarotene as, 461
bicalutamide as, 462
bleomycin as, 462
buserelin as, 462
busulfan as, 462
capecitabine as, 462
carboplatin as, 462
as carcinogens, 130
carmustine as, 462–463

Chemotherapeutic agent(s) (*cont.*)
carmustine impregnated wafer as, 463
cetuximab as, 463
chlorambucil as, 463
cisplatin as, 463
cladribine as, 463
clofarabine as, 463–464
cyclophosphamide as, 464
cytarabine as, 464
liposomal, 464
dacarbazine as, 464
dactinomycin as, 464
darbopoetin alfa as, 464–465
dasatinib as, 465
daunorubicin as, 465
decitabine as, 465
denileukin diftitox as, 465
dexamethasone as, 465–466
dexrazoxane as, 466
docetaxel as, 466
doxorubicin as, 466
liposomal, 466
epirubicin as, 466–467
erlotinib as, 467
erythropoietin as, 467
estramustine as, 467
etoposide as, 467
exemestane as, 467–468
filgrastim as, 468
floxuridine as, 468
fludarabine as, 468
5-fluorouracil as, 468
fluoxymesterone as, 468–469
flutamide as, 469
fulvestrant as, 469
gallium nitrate as, 469
gemcitabine as, 469
gemtuzumab ozogamicin as, 469
goserelin acetate as, 469–470
hydroxyurea as, 470
ibritumomab tiuxetan as, 470
idarubicin as, 470
ifosfamide as, 470
imatinib mesylate as, 470–471
interferon-α as, 471
interleukin-2 as, 471
irinotecan as, 471
isotretinoin as, 471–472
ketoconazole as, 472
lenalidomide as, 472
letrozole as, 472
leucovorin calcium as, 472
leuprolide acetate as, 472–473
lomustine as, 473
mechlorethamine as, 473
medroxyprogesterone acetate as, 473
megestrol acetate as, 473
melphalan as, 473–474
mercaptopurine as, 474
mesna as, 474
methotrexate as, 474
mitomycin C as, 474
mitotane as, 474–475
mitoxantrone as, 475
nelarabine as, 475
nilutamide as, 475
octreotide as, 475
oprelevkin as, 475
oxaliplatin as, 475–476
paclitaxel as, 476
protein bound, 476
pamidronate as, 476
panitumumab as, 476
PEG-asparaginase as, 460
pegfilgastrim as, 476–477
pemetrexed as, 477
pentostatin as, 477
plicamycin as, 477
prednisone as, 477
procarbazine as, 477–478
rituximab as, 478
sargramostim as, 478
sorafenib as, 478
streptozocin as, 478
sunitinib maleate as, 478
tamoxifen as, 478
temozolomide as, 479
teniposide as, 479
thalidomide as, 479
thioguanine as, 479
thiotepa as, 479
topotecan as, 479–480
toremifene as, 480
trastuzumab as, 480
tretinoin as, 480
vinblastine as, 480
vincristine as, 480–481
vinorelbine as, 481
zoledronic acid as, 481
Chemotherapy, 449–481
adjuvant, 449b, 455, 455b, 459
for bladder cancer, 1646–1647, 1647t
for breast cancer, 1919–1920, 1921t
for cholangiocarcinoma, 1589–1590
for colorectal cancer, 1512–1516, 1515t, 1517t
for gallbladder cancer, 1584
for gastric cancer, 1440–1442, 1441t
for head and neck cancer, 1205–1206
for hepatocellular carcinoma, 898, 1578
for liver metastases, 896–898, 896f, 897t
for melanoma, 1241–1242
for non–small cell lung cancer, 1334–1335, 1334t, 1335f
for osteosarcoma, 1953–1955, 2081–2082
for ovarian cancer, 1843–1845, 1843t–1845t
for penile cancer, 1708–1709
for rectal cancer, 1548–1549
for soft-tissue sarcoma, 2028–2029, 2028t, 2029t
for Wilms' tumor, 2098–2100, 2099t
for adrenocortical cancer, 1283
for advanced and metastatic disease, 456, 456b
age and, 457
alternating non–cross-resistant, 451
for anal cancer, 1561b, 1564, 1564t
for ascites, 940–941
for bladder cancer, 1646–1649
adjuvant, 1646–1647, 1647t
metastatic, 1648–1649
neoadjuvant, 1646–1648
for bone metastases, 858–859
for brain metastases, 827, 837–839
for brain tumors, 1090–1091
for breast cancer
adjuvant, 1918–1920, 1921t
early stage, 1918–1920, 1920t, 1921t, 1925–1926
locally advanced, 1927
metastatic, 1931–1932, 1931t
neoadjuvant, 1907, 1925
secondary effects of, 1925–1926
for carcinoid tumor, 1293–1294, 1294t
for carcinoma of unknown primary, 2070–2072, 2071t
for cholangiocarcinoma, 1589–1590
clinical uses of, 455–456
coexisting illnesses and, 457
for colorectal cancer
adjuvant, 1512–1516, 1515t, 1517t
capecitabine in, 1516, 1520–1521
early trials of, 1512, 1513t
evaluation of, 1518–1519
fluoropyrimidines in, 1512, 1513t, 1514–1516, 1515t, 1519–1524, 1520t, 1522t
indications for, 1511–1512
irinotecan in, 1516, 1523–1524
leucovorin with, 1514, 1515t, 1516, 1520, 1520t, 1522t
for metastatic disease, 1478, 1518–1525
oxaliplatin in, 1516, 1521–1523, 1522t
combination, 450–452, 451b, 458
for ovarian cancer, 1832–1838, 1833t–1835t, 1837t
for penile cancer, 1708
for soft-tissue sarcoma, 2035–2036
computer modeling and combinatorial chemistry for, 454
for conjunctival squamous cell carcinoma, 1154–1155
consolidation
for acute lymphocytic leukemia, 2197–2199
for acute myeloid leukemia, 2226, 2227b
in children, 2153, 2155
for acute promyelocytic leukemia, 2228, 2228b
for non–small cell lung cancer, 1338–1339, 1338t
for ovarian cancer, 1838–1839, 1838t
for desmoid tumors, 2044
dose modification for, 458t, 459
dose-dense, 451, 452
dose-intense, 451, 452
drug development for, 450, 453–454
drug selection for, 458–459, 458t
in elderly, 1039, 1045–1046, 1046f
for endometrial cancer, 1815, 1816
for esophageal cancer
advanced, 1421–1423, 1422t
preoperative, 1404t, 1405, 1409–1410
for Ewing's sarcoma, 1985, 1986, 2088–2091, 2089t
histopathologic response to, 1992
follow-up of, 459
for gallbladder cancer, 1584

Chemotherapy (*cont.*)
for gastric cancer
adjuvant, 1440–1442, 1441t
intraperitoneal, 1442, 1453–1454
for locally advanced disease, 1453–1454, 1454t
neoadjuvant, 1453–1454, 1453t
palliative, 1455–1457, 1456t
perioperative, 1454
for gestational trophoblastic disease, 1865–1868, 1867t, 1868t, 1871
for gestational trophoblastic neoplasia, 1866–1868, 1867t, 1868t
for GISTs, 2041
for gliomas, 1100–1103, 1100t, 1101f, 1102f, 1103t
with HAART, 1069
for hairy cell leukemia, 2312
for head and neck cancer, 1202–1207
complications of, 1177
neoadjuvant and induction, 1190, 1202–1204, 1203f
postoperative and adjuvant, 1205–1206
prognostic factors for, 1202
with radiation therapy, 1191, 1204–1205, 1204f, 1205f, 1206t
for hepatoblastoma, 2114–2115
for hepatocellular carcinoma, 898, 1576–1577
adjuvant, 898, 1578
intra-arterial, 907t, 1578
high-dose
for ovarian cancer, 1840
for primitive neuroectodermal tumors, 1121–1122
for testicular cancer, 1733, 1734f, 1736, 1737
history of, 450
hybrid, 451–452
induction
for acute lymphoblastic leukemia, in children, 2152–2153
for acute lymphocytic leukemia, 2197
for acute myeloid leukemia, 2224–2226, 2227b
in children, 2155
for acute promyelocytic leukemia, 2228, 2228b
for head and neck cancer, 1202–1204, 1203f
for myelodysplastic syndrome, 2246–2247, 2248–2249
for non-small cell lung cancer, 1329, 1335–1336
with radiation therapy, 1338–1339, 1338t
and infection, 717–733
adjunctive therapies for, 723–724
approach to, 719, 719t
bacteremia as, 724
catheter-related, 787
central nervous system, 727
empirical antibiotic therapy for, 720–723
duration of, 723
general principles for, 720–721
subsequent modifications of, 722–723
for unstable patients, 722
Chemotherapy (*cont.*)
and infection (*cont.*)
vancomycin or other gram-positive agents for, 721–722, 722t
empirical antifungal therapy for, 723
fungal, 723, 725–726
gastrointestinal, 726–727
granulocyte transfusions for, 724
hematopoietic growth factors for, 723–724
initial evaluation of, 720
prevention of, 728–733
with acute leukemia, 728–730, 729t
with alemtuzumab, 729t, 732
general guidelines for, 729t
with graft-*versus*-host disease, 729t, 730–732
with hematopoietic stem cell transplantation, 729t, 730, 730t, 731f
in low-risk patients, 728
pretransplantation measures for, 732–733
with purine analogs, 729t, 732
pulmonary, 724–725, 725t
risk assessment for, 720, 721t
risk factors for, 717–718, 718f
sources of, 718
due to vascular access devices, 727
viral, 727–728
intra-arterial
for cholangiocarcinoma, 1590
for hepatocellular carcinoma, 907t, 1578
for soft-tissue sarcoma, 2029–2030
intraperitoneal
for gastric cancer, 1442, 1453–1454
for ovarian cancer, 1839–1840
intrathecal
for acute lymphocytic leukemia, 2199
for neoplastic meningitis, 840–841
late intensification (*See* Chemotherapy, consolidation)
for leukemia
acute lymphocytic, 2196–2199, 2198t
in children, 2152–2154, 2152t
acute myeloid
in children, 2154–2158, 2156t–2157t
induction, 2224–2226
postremission, 2226, 2227
reinduction, 2227–2228
acute promyelocytic, 2228–2229, 2228b
chronic lymphoid, 2302–2303
B-cell, 2385
for liver metastases, 885, 898
adjuvant, 896–898, 896f, 897t
hepatic artery infusion of, 885, 898–905
neoadjuvant, 894, 905–908, 907t
with whole-liver irradiation, 912, 913t
for lung cancer
non-small cell, 1340–1343, 1340t, 1343t
adjuvant, 1334–1335, 1334t, 1335f
consolidation, 1338–1339, 1338t
EGFR inhibitor with, 1344–1345, 1345t
in elderly patients, 1342
induction, 1329, 1338–1339, 1338t
with locally advanced disease, 1339
Chemotherapy (*cont.*)
for lung cancer (*cont.*)
with metastatic disease, 1340–1343, 1340t, 1343t
neoadjuvant, 1335–1336
in patients with poor performance status, 1342
second-line, 1342–1343, 1343t
for symptom palliation, 1342
small cell
for extensive-stage disease, 1348–1350, 1349t
for limited-stage disease, 1351, 1352
maintenance, 1350
overview of, 1348, 1348t
second-line, 1354
for lymphoma
Burkitt's, 2390, 2391t
in children, 2180–2185
cutaneous T-cell, 2419
diffuse large B-cell, 2386–2390, 2387f–2389f, 2387t
follicular, 2381–2383
Hodgkin's, 2353, 2361–2365
advanced-stage, 2363–2365, 2364t, 2365t
early-stage, 2361–2363, 2362t, 2363t
orbital, 1162–1163
primary CNS, 1106–1108, 1108b, 1108f
small lymphocytic, 2385
maintenance
for celomic epithelial carcinoma, 1838–1839, 1838t
for leukemia
acute lymphocytic, 2199
acute promyelocytic, 2228–2229, 2228b
for ovarian cancer, 1838–1839, 1838t
for small cell lung cancer, 1350
manipulation of cell death in, 73–75
for melanoma, 1229, 1241–1242, 1243
for mesothelioma, 1367, 1375–1377, 1376t, 1377t, 1378
molecularly targeted therapy with, 495
myeloablative, 503–504
for myelodysplastic syndrome, 2246–2247, 2248–2250, 2249t
neoadjuvant, 455–456, 455b
for bladder cancer, 1646–1648
for breast cancer, 1907, 1925
for esophageal cancer, 1404t, 1405, 1409–1410
for gastric cancer, 1453–1454, 1453t
for head and neck cancer, 1190, 1202–1204, 1203f
for liver metastases, 894, 905–908, 907t
for non–small cell lung cancer, 1335–1336
for osteosarcoma, 1954–1955, 1957–1958, 2082
for penile cancer, 1708
for soft-tissue sarcoma, 2029–2030
for neoplastic meningitis, 840–841
for neuroblastoma, 2095–2096
neuroprotection during, 961–962
nutrition and, 457
obesity and, 457
organ function and, 457

Chemotherapy (*cont.*)
for osteosarcoma
adjuvant, 1953–1955, 2081–2082
in children, 2081–2084
cisplatin in, 1954, 2084
ifosfamide in, 1954, 1955, 2082–2084
late effects of, 1975
neoadjuvant, 1954–1955, 1957–1958, 2082
protocols for, 2081–2084, 2083t
for ovarian cancer, 1832–1840
adjuvant, 1843–1845, 1843t–1845t
combination, 1832–1838, 1833t–1835t, 1837t
consolidation or maintenance, 1838–1839, 1838t
controversies and issues on, 1839
current standard of care for, 1839
dose intensity of, 1834–1836, 1835t
germ cell, 1848, 1849t
intraperitoneal, 1839–1840
paclitaxel in, 1832, 1833t, 1836–1838, 1837t
for paclitaxel/platinum-resistant disease, 1840, 1840t, 1846t, 1847
platinum-based, 1832, 1833–1834, 1833t, 1834t, 1838
salvage, 1833t, 1845–1847, 1846t
single-agent, 1832, 1832t, 1833t
stem cell–supported high-dose, 1840
pain due to, 565
for pain management, 572
palliative
for gastric cancer, 1455–1457, 1456t
for non–small cell lung cancer, 1342
for pancreatic cancer, 1607–1608
for pancreatic islet cell tumors, 1298–1299
patient selection for, 457, 457t
for penile cancer, 1707–1709, 1708t
for pericardial effusion, 935, 936–937
perioperative, for gastric cancer, 1454
pharmacogenetics of, 454, 457
pharmacokinetics/pharmacodynamics of, 454–455
for pleural effusions, 930
postremission, for acute myeloid leukemia, 2226, 2227, 2227b
during pregnancy, 1005–1006, 1051–1054
dosing of, 1054
experience with specific drugs for, 1051–1053, 1052t
in first trimester, 1053–1054
maternal physiology and, 1049–1050, 1050b
risk categories for, 1051, 1051t
in second and third trimesters, 1054
teratogenicity of, 999, 1005–1006, 1005b, 1051, 1051t
for primitive neuroectodermal tumors, 1121–1122
principles of, 451–452, 451b
prior, 457
prophylactic, for molar pregnancy, 1865–1866
for prostate cancer, 1687–1688, 1688b, 1688f
with radiation therapy (*See* Chemoradiation therapy (CRT))

Chemotherapy (*cont.*)
for rectal cancer, 1548–1549
reinduction
for acute lymphocytic leukemia, 2197, 2199
for acute myeloid leukemia, 2227–2228
for renal cell carcinoma, 1630
reproductive complications of, 999, 1003–1005
requirements for, 457, 457b
resistance to, 451
response criteria for, 459
for retinoblastoma, 2112
for retroperitoneal sarcomas, 2040
for rhabdomyosarcoma, 2103–2105
route of administration of, 458
salvage
for cervical cancer, 1765
for gestational trophoblastic disease, 1871
for lymphoma
aggressive B-cell, 2393–2394, 2394t
in children, 2184–2185
for ovarian cancer, 1833t, 1845–1847, 1846t
and second malignant neoplasms
in adults, 1032–1033
in children and adolescents, 1026–1028, 1027f
second-line
for lung cancer
non-small cell, 1342–1343, 1343t
small cell, 1354
for soft-tissue sarcoma, 2036–2037
for seminoma, 1723–1724
single-agent, 458
for small lymphocytic lymphoma/B-cell chronic lymphocytic leukemia, 2385
and soft-tissue sarcoma, 2010, 2010t
for soft-tissue sarcoma, 2034–2036
adjuvant, 2028–2029, 2028t, 2029t
combination, 2035–2036
first-line, 2034–2036
neoadjuvant, 2029–2030
second-line, 2036–2037
for spinal metastases, 818
for superior vena cava obstruction, 809
targeted agents and new directions in, 452–453
teratogenicity of, 999, 1005–1006, 1005b, 1051, 1051t
for testicular cancer
advanced, 1729–1733, 1730t
residual masses after, 1734–1736
salvage, 1736
stage I, 1723–1724, 1725–1726
stage II, 1727, 1728–1729
toxicity of, 1738, 1739
thromboprophylaxis during, 710
for thymoma, 1383–1384
for thyroid cancer, 1280
tumor cell growth kinetics in, 450–451
for uterine sarcomas, 2043–2044
for vaginal cancer, 1783
and venous thromboembolic disease, 710
for vulvar cancer, 1774–1776, 1776t
for Wilms' tumor, 2098–2100, 2099t

Chemotherapy-induced cardiac effects, 983–995
of anthracyclines, 984t, 985–989, 985t
in children, 989
diagnosis of, 987–988, 987t
etiology of, 985–986
incidence of, 983, 985, 986f
natural history of, 986
pathophysiology of, 986–987, 986f
risk factors for, 986
treatment of, 983, 988–989, 989f, 991, 992b
arrhythmias/dysrhythmias as, 983, 992
cardiomyopathy/congestive heart failure as, 983, 985–991
in children, 989
diagnosis of, 987–988, 987t
etiology of, 985–986, 989–991
incidence of, 985, 986f
natural history of, 986
pathophysiology of, 986–987, 986f
risk factors for, 986
treatment of, 983, 988–989, 989f, 991, 992b
diagnosis of, 983
endocardial fibrosis as, 983
etiology of, 983, 984–985, 984t, 985f
fluid retention as, 983, 993
hypertension as, 983
hypotension as, 983
incidence of, 983
long-term, 994–995
myocardial ischemia as, 983, 992–993
pericardial disease as, 983, 993
peripheral vascular disease as, 993
treatment of, 983
Chemotherapy-induced endocrine dysfunction, 1015–1016
Chemotherapy-induced hypothalamic-pituitary axis disorders, 1015
Chemotherapy-induced lung injury, 969, 976–979, 977t
due to alkylators and nitrosoureas, 977–978
due to anthracyclines, 978
due to antimetabolites, 977
due to biologic agents, 978–979, 978f
due to bleomycin, 976–977
diagnosis of, 969
risk factors for, 969
due to taxanes, 978
treatment for, 969
Chemotherapy-induced mucositis, 610–614
in elderly, 1046
incidence of and risk factors for, 610–611, 610f, 611f
prevention of, 611–613, 611b
treatment of, 613–614, 614b
Chemotherapy-induced myelodysplastic syndrome, 2236
Chemotherapy-induced nausea and vomiting, 599–606
acute, 600, 603–605
anticipatory, 601, 605
clinical features of, 600–603
clinical syndromes of, 600–601
delayed, 601, 603t, 605–606

Chemotherapy-induced nausea and vomiting (*cont.*)
future directions for, 606
prognostic factors for, 601–603, 601t–603t
treatment of, 603–606, 603t, 604b
Chemotherapy-induced neurotoxicity, 945–963
differential diagnosis of, 953–957, 954f, 955t, 957t
etiology of, 945
evaluation of, 945
factors contributing to increase in, 945–946
grading of, 945, 957, 958t–961t
incidence of, 945
prevention of, 957–963
risk factors for, 962–963, 962f, 963f
with specific agents, 946–951, 947f, 950f
treatment for, 945, 957–963, 962f, 963f
Chest radiograph(s)
for carcinoma of unknown primary, 2065
of lung cancer, 1324, 1325f
of pleural effusion, 927–928
Chest wall, Ewing's sarcoma of, 1987
Chest wall invasion, by non-small cell lung cancer, 1331
CHF. *See* Congestive heart failure (CHF).

of melanoma, 299–300
metastatic, 1234
of osteosarcoma, 2079
of pancreatic cancer, 300, 302f, 1599, 1600f
of pleural effusion, 928
of prostate cancer, 296, 296f
of pulmonary metastases, 874–875, 875f, 876f, 876t
of radiation pneumonitis, 970f, 974
of renal cell carcinoma, 301–302, 303f
single-photon emission, 283, 290–291, 291t
of small bowel tumors, 1470
of soft-tissue sarcoma, 2017, 2019f
of spinal metastases, 818
of testicular cancer, 1721
Computed tomography (CT) angiography, 288, 289
helical (spiral), of pulmonary embolism, 706
of liver metastases, 886, 1492, 1493f
Computed tomography colonography (CTC), 297
Computer modeling, in chemotherapy drug development, 454
COMS (Collaborative Ocular Melanoma Study) trial, 1146–1147
Concomitant boost, 430t, 431
Conditional expression systems, 15–17, 17f
Conditional gene targeting, 519–523, 521t, 522t
Conditional mutagenesis, 15–17, 17f
Conditional probability, 350
Conditional replication, and inducible promoters, for gene therapy, 520–523, 521t, 522t
Conditionally replicative adenoviruses (CRAds), for gene therapy, 522–523, 522t
Conditionally replicative viruses, for gene therapy, 522–523, 522t
Condyloma acuminatum, giant, of penis, 1702–1703
Condylomatous dysplasia, vulvar. *See* Vulvar intraepithelial neoplasia (VIN).
Cone biopsy, for cervical cancer, 1752–1753
Confidence intervals, for clinical trials, 315, 318–320, 319t, 320t
Conflict of interest, in study sponsorship, 339, 340
Conformal radiation therapy (CRT), 440
for liver metastases, 912–914, 913f, 914f, 914t
for prostate cancer, 1672, 1672f, 1673f
for soft-tissue sarcoma, 2027
three-dimensional, 440, 441f
for prostate cancer, 1672–1673, 1672f, 1673f
Confounders, 201–202, 349, 357
Confounding by indication, 349
Confusion, grading of, 958t
Congenital fibrosarcoma (CFS), cytogenetic aberrations in, 260t
Congenital mesoblastic nephroma (CMN), cytogenetic aberrations in, 258t, 260t
Congestive heart failure (CHF), due to cancer therapy, 983, 985–991
in children, 989
diagnosis of, 987–988, 987t
etiology of, 985–986, 989–991
incidence of, 985, 986f
natural history of, 986
pathophysiology of, 986–987, 986f
risk factors for, 986
treatment of, 983, 988–989, 989f, 991, 992b
Conjunctival tumor(s), 1137, 1154–1157
classification of, 1138t
Kaposi's sarcoma as, 1156–1157, 1157f
melanoma as, 1155–1156, 1156f
squamous cell carcinoma as, 1154–1155, 1155f
Consent, informed, for genetic testing, 171, 172b
Conservative management, of prostate cancer, 1668, 1670f
Consolidation chemotherapy
for leukemia
acute lymphocytic, 2197–2199
acute myeloid, 2226, 2227b
in children, 2153, 2155
acute promyelocytic, 2228, 2228b
for non-small cell lung cancer, 1338–1339, 1338t
for ovarian cancer, 1838–1839, 1838t
Constipation, due to opioids, 571t
Continuously varying measurements, as endpoints of clinical trials, 314
Contraception, and cervical cancer, 386
Contractile ring, 57
Contralateral testicular cancer (CLTC), 1737–1738
Contrast radiographic studies, for carcinoma of unknown primary, 2065
Contrast venacavograms, of superior vena cava syndrome, 806
Contrast venography, of deep venous thrombosis
inferior vena cava and intra-abdominal, 707
lower-extremity, 699–700
upper-extremity, 704
Contrast-enhanced computed tomography
of deep venous thrombosis
inferior vena cava and intra-abdominal, 707
lower-extremity, 701
of superior vena cava syndrome, 805–806, 806f
Control(s), 353, 354
Control group, 201
Convection-enhanced delivery, for supratentorial gliomas, 1096–1097
Convenience samples, 344
Cooperative Ewing's Sarcoma Study (CESS), 2089t
Cooperative Group trials, 327–328, 328b, 330–331
Co-option, in tumor vascularization, 106, 106f
COPP regimen, for Hodgkin's lymphoma, 2364, 2364t, 2365t
Cord blood, hematopoietic stem cells from, 503, 504
for acute lymphocytic leukemia, 2202
for myelodysplastic syndrome, 2250
Cordotomy, for pain management, 574
Core binding factor (CBF), in acute myelogenous leukemia, 2218, 2218f
Core binding factor (CBF) complex, in childhood leukemia, 2141, 2149
Core biopsy, 411
of breast, 1892–1893, 1892f
Cornea, radiation toxicity in, 1139
Coronary artery disease, radiation-induced, 992–993
Cortical blindness, due to cisplatin, 948
Corticosteroids
for acute lymphocytic leukemia, 2197
as antiemetics, 603t, 604, 605
for brain metastases, 829–830
for brain tumors, 1081–1083
for cachexia, 595
for hypercalcemia of malignancy, 746, 746t
and infections, 718
for lymphoma
cutaneous T-cell, 2416
primary CNS, 1108–1109
for pain management, 570, 573t
during pregnancy, 1052t
for radiation pneumonitis, 974
for spinal metastases, 818–819
Corticotropin fragments, for neuroprotection, 962
Cosmegen. *See* Dactinomycin (Cosmegen, actinomycin D, ACT-D).
Cost(s)
of cancer treatment, 337–339
categories of, 337–339
estimation from Medicare populations of, 339–341, 340t
factors contributing to, 337
surrogate measures for, 341
of clinical trials, 337–338

Cost identification, 339
Cost-benefit analysis, 338
Cost-effectiveness analysis, 338–339
Cost-utility analysis, 339
Cough, grading of, 972t
Couinaud's hepatic segments, 889, 890f
Coumarin, for lymphedema, 645
Council on Chiropractic Education (CCE), 551
Counts, as endpoints of clinical trials, 314
Coutard, Henri, 418
Cowden syndrome (CS), 184
  brain tumors in, 1078t
  and breast cancer predisposition, 172, 173t
  clinical features of, 184
  and genitourinary tumors, 184
  risk management for, 184
  and skin cancer, 174t
COX. *See* Cyclooxygenase (COX).
CP-31398, to restore apoptotic capability, 74
CPET (cardiopulmonary exercise testing), in presurgical evaluation for lung cancer, 1328
CpG island(s), 213, 272
CpG island methylator phenotype (CIMP)
  in colorectal cancer, 1512
  in prostate cancer, 1659–1660
CPM. *See* Cyclophosphamide (Cytoxan, Neosar, CTX, CPM, Cy).
CPT 11. *See* Irinotecan hydrochloride (Camptosar, camptothecin-11, CPT-11).

Desmoid fibromatosis, genetic predisposition to, 2011t
Desmoid tumors, 2044, 2044t
Desmoplastic melanoma (DM), 1231, 1232
Desmoplastic small round cell tumor (DSRCT), 2012t
cytogenetic aberrations in, 260t
Detection bias, 350, 356
Detrusor hypo- or areflexia, 585, 586t
Devil's claw, interactions with, 555t
DeVita, Vincent, Jr., 2354
Dexamethasone (Decadron, Dex, DXM), 465–466
for acute lymphoblastic leukemia in children, 2153, 2154
as antiemetic, 603t, 604–606
for brain metastases, 830
for increased intracranial pressure, 1082
for liver metastases, 896, 897, 902
for multiple myeloma, 2333–2335
newly diagnosed, 2332t, 2333–2335
relapsed, 2338
results of, 2333–2335, 2334t, 2335t
for spinal metastases, 819
as target for gene therapy, 521
Dexrazoxane (Zinecard, ADR-529, ICRF-187), 466
for cardioprotection, 989, 989f, 992b
DFMO (difluoromethylornithine), for prevention of colorectal cancer, 373
DFSP (dermatofibrosarcoma protuberans), 1263–1265, 1264f
cytogenetic aberrations in, 260t, 2012t, 2013
DHAD (dihydroxyanthracenedione), 475
congestive heart failure due to, 990
DHAP regimen
for Hodgkin's lymphoma, 2365
for relapsed aggressive B-cell lymphoma, 2394t
Diabetes mellitus
chemotherapy-related, 1016
and endometrial cancer, 1795
and pancreatic cancer, 1596
Diagnosis
surgeon's role in, 411
tumor markers in, 279–280
Diagnostic radiology, during pregnancy, 1050–1051, 1050t
Diarrhea, 726
antibiotic-associated, 1502
in carcinoid syndrome, 1290–1291
Diazoxide, for insulinomas, 1296
DIC. *See* Dacarbazine (DTIC-Dome, DTIC, DIC, imidazole carboxamide).
Dichotomous measures, as endpoints of clinical trials, 314
Dickkopf 1 (DKK1), in multiple myeloma, 2327
Diet
for ascites, 939
and breast cancer, 375, 1877
in cancer prevention, 135, 546–547, 546b, 553–554
in cancer therapy, 548, 552–553, 552b
carcinogens and anticarcinogens in, 133–134, 133b
and colorectal cancer
in prevention, 372–373, 1486, 1487t
as risk factor, 133b, 370, 371f, 1481–1482
and esophageal cancer, 1401
and gastric cancer, 1432
and lung cancer, 1309–1310
macrobiotic, 553, 558t
and pancreatic cancer, 1596

and prostate cancer, 1657
and small bowel tumors, 1466
Dietary Supplement and Health Education Act (DSHEA), 548
Diethylenetriamine pentaacetic acid (DTPA), with monoclonal antibodies, 537
Diethylstilbestrol (DES)
and cervical cancer, 1748
and endometrial cancer, 1797–1798
for prostate cancer, 1682
and vaginal cancer, 1779
Differential time to positivity, 727
Differentiating agents, 453, 458
Diffuse histiocytic lymphoma. *See* Primary CNS lymphoma (PCNSL).

Diffuse large B-cell lymphoma (DLBCL)
AIDS-related, 2393
in children, 2177–2178, 2183
classification of, 2133
clinical characteristics of, 2382t
gene expression profiling for, 2377, 2379f
immunophenotypic and genetic abnormalities in, 2374t
mediastinal, 1386
in children, 2178, 2179
clinical characteristics of, 2382t
immunophenotypic and genetic abnormalities in, 2374t
treatment of, 2386
molecular genetics of, 2375–2376, 2375t
primary cutaneous, 2413f, 2414–2415
treatment of, 2386–2390, 2387f–2389f, 2387t
for relapsed or refractory disease, 2393–2394, 2394t
Diffuse optical imaging, 364
Diffusion-limited hypoxia, 116
radiation effect of, 431–432, 432f
Difluoromethylornithine (DFMO), for prevention of colorectal cancer, 373
Digital clubbing, due to lung cancer, 1323
Digital Mammographic Imaging Screening Trial (DMIST), 288, 295
Digital rectal examination (DRE)
for colorectal cancer, 370–371
for prostate cancer, 377, 1662, 1663t
Digitally reconstructed radiographs (DRRs), 436, 437f
Dignity Psychotherapy Question Protocol, 666t
Dihydropyrimidine dehydrogenase deficiency, 5-fluorouracil with, 457
Dihydroxyanthracenedione (DHAD), 475
congestive heart failure due to, 990
1,25-Dihydroxyvitamin D, for cancer prevention, 547
Dimerization partner (DP), 53
17-(dimethylaminoethylamino)-17-demethoxygeldanamycin (17-DMAG), in molecularly targeted therapy, 496
Direct costs, 337
Direct extension, metastasis via, 816
Disability, epidemiology of, 579
Disease progression, 459
Disregulated proteins, as molecular targets, 486t, 487t
Disseminated tumor cells (DTCs), in breast cancer, 1882
Distal femur, osteosarcoma of, 1950f, 1971
Distal pancreatectomy, 1606
Distraction osteogenesis, for osteosarcoma, 1959, 1962f–1963f
Distress, in dying patients, 666–669, 667t
Diuretics
for ascites, 939
hyponatremia due to, 751–752, 756
Dizziness, grading of, 958t
DKK1 (Dickkopf 1), in multiple myeloma, 2327
DLBCL. *See* Diffuse large B-cell lymphoma (DLBCL).
DLCO (carbon monoxide diffusion capacity)
grading of, 972t
in presurgical evaluation for lung cancer, 1328
with radiation pneumonitis, 974
DM (desmoplastic melanoma), 1231, 1232
17-DMAG [17-(dimethylaminoethylamino)-17-demethoxygeldanamycin], in molecularly targeted therapy, 496
DMIST (Digital Mammographic Imaging Screening Trial), 288, 295
DNA
chromatin compression of, 9, 11f
complementary, 7
structure of, 3, 4f
DNA amplification, in breast cancer, 1881
DNA content, nomenclature for, 250t
DNA content analysis, of solid tumors, 246
DNA damage, 139–150
cellular responses to, 139–140, 142f
consequences of, 140, 142f
endogenous, 142f
environmental, 142f
in pathogenesis of cancer, 139
due to radiation, 423–425, 424f, 425f
types of, 140, 142f
DNA damage checkpoints, 140
DNA damage response (DDR), 57–59, 57f, 58f
therapeutic manipulation of, 62
DNA damage response (DDR) genes, 139
DNA damage response (DDR) pathways, 140–142
genetic diseases involving defect in, 141t
and genetic stability, 139
DNA hypomethylating agents, 453
DNA injection, 518
DNA lesions, 140, 142f
DNA library, 7
DNA methyltransferase, as molecular target, 486t
DNA microarray(s), 9, 12, 12f, 200
in breast cancer, 1875
DNA polymerases, in DNA repair, 143–144
DNA probe, 7
DNA regulatory sequences, 7–9, 10f
DNA repair
and cancer treatment, 149b
DNA damage response pathways in, 140–142
and genetic stability, 139
interstrand cross-link, 149
and susceptibility, 135
type(s) of, 142–148
base excision, 144–145, 144f, 145f
double-strand break, 147, 147f
and cancer, 147–148
mismatch, 145, 145f
and cancer, 145–146
nucleotide excision, 142–144, 143f, 145f
and cancer, 144
DNA repair disorders, immunodeficiency and cancer in, 229–230, 230t
DNA repair genes, 139
and cancer risk, 146b
mutations in, 208
DNA repair machinery, as molecular target, 486t
DNA repair pathways, 140, 140t, 142f
DNA replication
in cell cycle, 54, 55f
lesions that interfere with, 140
DNA samples, for molecular diagnostics, 265–266, 266t
DNA sequencing, 266, 267f
DNA transcription, lesions that interfere with, 140
DNA transduction, 518–519
Docetaxel (Taxotere, RP-56976), 466
for carcinoma of unknown primary, 2070
cardiotoxicity of, 991, 993
for esophageal cancer, 1421, 1422
fluid retention due to, 993
for gastric cancer, 1455–1456
neurotoxicity of, 951
for non-small cell lung cancer, 1340t, 1342–1343, 1343t
for ovarian cancer, 1832
for prostate cancer, 1687–1688, 1688b, 1688f
pulmonary toxicity of, 978
Dolasetron, as antiemetic, 603–604, 603t
Dong quai, interactions with, 555t
Dopamine agonists, for hyperprolactinemia, 1018
Dopamine antagonists, as antiemetics, 603t, 604
Dormant cells, 42
Dorsal root ganglionitis, 957
Dorsally exophytic brainstem gliomas, 1124–1125, 1125f
Dose density, for lymphoma, 2380–2381
Dose finding, clinical trials for, 311–312
Dose intensity, for lymphoma, 2380–2381
Dose rate effects, of radiation, 428
Dose-dense chemotherapy, 451, 452
Dose-intense chemotherapy, 451, 452
Dose-volume histogram (DVH), 437, 438f
for radiation pneumonitis, 973–974, 974f
DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid), with monoclonal antibodies, 537
"Double duct" sign, 1599
Double-contrast barium enema, for colorectal cancer, 1484, 1490–1491, 1491f
Double-strand break(s) (DSBs)
and ATM/ATR signaling, 57, 57f
and G_1/S checkpoint, 58
and intra-S phase checkpoint, 59
due to radiation, 424, 424f
Double-strand break (DSB) repair, 147, 147f
and cancer, 147–148, 229
Down syndrome, and childhood leukemia, 2140, 2143t, 2150
Doxil. *See* Pegylated liposomal doxorubicin, (Doxil, PLD).
Doxorubicin, pegylated liposomal (Doxil, PLD), 466–467
decreased cardiotoxicity of, 988–989
for Kaposi's sarcoma, 1064b, 1065
for ovarian cancer, 1840, 1840t

Doxorubicin (Adriamycin, Rubex, Adria, hydroxydaunorubicin), 466
for carcinoid tumors, 1293–1294
for carcinoma of unknown primary, 2070
cardiomyopathy due to
in combination chemotherapy, 991
diagnosis of, 987–988, 987t
pathophysiology of, 986–987, 986f
treatment of, 988–989, 989f
for Ewing's sarcoma, 1985
for hepatoblastoma, 2114–2115
hyperpigmentation due to, 631
for osteosarcoma, 1954
for ovarian cancer, 1833, 1833t, 1834, 1834t, 1840, 1840t
pulmonary toxicity of, 978
reproductive effects of, 1004
second malignant neoplasms due to, 1027–1028
for soft-tissue sarcoma, 2028t, 2029–2031, 2029t, 2034–2036
venous flare reaction due to, 628, 628f
for Wilms' tumor, 2098
Doxycycline
for intrapleural therapy, 932
for pleurodesis, 931
DP (dimerization partner), 53
DPD (deoxypyridinoline), as bone resorption marker, 853, 856
Drainage catheter, for pleural effusion, 932–933
Drainage catheters, for ascites, 940
DRE (digital rectal examination)
for colorectal cancer, 370–371
for prostate cancer, 377, 1662, 1663t
Drivers, 210
Dronabinol, as antiemetic, 603t, 605
Droperidol, as antiemetic, 605
DRRs (digitally reconstructed radiographs), 436, 437f
Drug abuse, pain management with history of, 575–576
Drug activity, clinical trials for, 312
Drug companies, clinical trials sponsored by, 331–333
Drug resistance, 451, 2380
Drug safety, clinical trials for, 312
Drug-induced lung injury, 969, 976–979, 977t
due to alkylators and nitrosoureas, 977–978
due to anthracyclines, 978
due to antimetabolites, 977
due to biologic agents, 978–979, 978f
due to bleomycin, 976–977
diagnosis of, 969
risk factors for, 969
due to taxanes, 978
treatment for, 969
Drug-induced pneumonopathy. *See* Drug-induced lung injury.
Dry eye syndrome, due to radiation toxicity, 1138–1139
DSBs. *See* Double-strand break(s) (DSBs).
DSHEA (Dietary Supplement and Health Education Act), 548
DSRCT (desmoplastic small round cell tumor), 2012t
cytogenetic aberrations in, 260t
DTCs (disseminated tumor cells), in breast cancer, 1882
DTIC. *See* Dacarbazine (DTIC-Dome, DTIC, DIC, imidazole carboxamide).
DTIC-Dome. *See* Dacarbazine (DTIC-Dome, DTIC, DIC, imidazole carboxamide).

    pathogenesis of, 1039, 1041
    prevention of, 1039, 1044–1045
    treatment of, 1039, 1045–1046, 1046f
  leukemia in
    acute lymphocytic, 2203–2205, 2205t
    acute myeloid, 2225–2226
  lymphoma in
    Hodgkin's, 2366
    non-Hodgkin's, 2395–2396
  malignant gliomas in, 1103–1104
Electrical alternans, 934
Electrofulguration, for esophageal cancer, 1420
Electromagnetic radiation, 418
Electromagnetic spectrum, 418–419
Electron beam, 420
Electron beam radiation therapy, for cutaneous T-cell lymphoma, 2418
Electron microscopy, for carcinoma of unknown primary, 2065
Electrotrichogenesis, for alopecia, 627
Elephantiasis, 641–642
Eligibility check, for clinical trial, 315
Eligibility criteria, for clinical trials, 310, 313, 317, 320, 322
Eligibility failures, in clinical trials, 321
ELISA (enzyme-linked immunosorbent assays), for D-dimer, 702
Ellence. *See* Epirubicin (Ellence, epidoxorubicin).
Eloxatin. *See* Oxaliplatin (Eloxatin, Oxali).
Elspar. *See* L-Asparaginase (Elspar, colaspase).
Eltrombopag, 683
EMACE regimen, for gestational trophoblastic neoplasia, 1868, 1868t
EMACO regimen, for gestational trophoblastic neoplasia, 1867–1868, 1868t
Embryonal carcinoma
  histology of, 1716f–1717f, 1717
  risk assessment for, 1724, 1724f
Embryonal rhabdomyosarcoma, 2101–2102
Embryonic stem (ES) cells, 17, 18f
EMC (extraskeletal myxoid chondrosarcoma), 2012t
  cytogenetic aberrations in, 260t
Emcyt (estramustine), 467
Emergency surgery, 414
Emergency treatment
  for acute myeloid leukemia, 2224
  for lymphoma in children, 2184
Emesis. *See* Nausea and vomiting.
Emetogenic potential
  formula for estimation of, 601, 603t
  in management approach, 604b
Empirical antibiotic therapy, 720–723
  duration of, 723
  general principles for, 720–721
  subsequent modifications of, 722–723
  for unstable patients, 722
  vancomycin or other gram-positive agents for, 721–722, 722t
Empirical antifungal therapy, 723
EMT (epithelial to mesenchymal transition), in metastasis, 36, 36f, 37f
Encephalitis, paraneoplastic limbic, 768–770, 770f, 953
Encephalomyelitis, paraneoplastic, 768, 1324
  progressive, with rigidity, 772
Encephalopathy
  chemotherapy-induced
    due to cisplatin, 948–949
    due to cyclophosphamide, 949
    due to cytosine arabinoside, 946
    differential diagnosis of, 953–954, 954f
    due to ifosfamide, 949
    due to methotrexate, 947
    due to paclitaxel and docetaxel, 951
    due to vinca alkaloids, 948
  grading of, 959t
Endobronchial brachytherapy, pulmonary complications of, 976
Endocardial fibrosis, due to cancer therapy, 983
Endocervical brush, for cervical cancer, 1752
Endocervical curettage (ECC), for cervical cancer, 1752
Endocrine cancer, 1271–1299
  adrenocortical, 1271, 1281–1286
    clinical features of, 1271, 1281–1282, 1281t
    diagnosis of, 1271, 1282, 1282f
    incidence of, 1271, 1281
    pathology of, 1282
    treatment of, 1271, 1282–1286
      antihormonal therapy for, 1283
      antineoplastic therapy for, 1283
      for metastatic disease, 1283
      for primary tumor, 1282–1283
      surgical, 1283–1286, 1284f–1285f
  carcinoid tumors as, 1271, 1290–1294
    carcinoid syndrome due to, 1290–1291
    clinical pathology of, 1290
    diagnosis of, 1271, 1291, 1292f, 1293f
    incidence of, 1271
    treatment of, 1271, 1291–1294, 1294t
  imaging of, 302–304, 303f
  malignant pheochromocytoma as, 1271, 1286–1288, 1287f
  multiple endocrine neoplasia as, 1288–1289, 1288t
  pancreatic islet cell tumor(s) as, 1271–1272, 1294–1299
    diagnosis of, 1271–1272, 1295–1296, 1295f
    gastrinoma as, 1295f, 1297, 1298
    ghrelinoma as, 1298
    glucagonoma as, 1295f, 1296
    incidence of, 1271

Endocrine cancer (*cont.*)
pancreatic islet cell tumor(s) as (*cont.*)
insulinoma as, 1295f, 1296, 1298
with MEN-1, 1289
pathology of, 1294–1295
somatostatinoma as, 1295f, 1296–1297
treatment of, 1272, 1298–1299
VIPoma as, 1295f, 1297
parathyroid carcinoma as, 1271, 1288
predisposition syndromes for, 177t, 182
of thyroid, 1271–1281
classification of, 1271–1274, 1273f, 1273t
clinical presentation of, 1271
diagnosis of, 1271, 1274–1276, 1275t
etiology of, 1272
incidence of, 1271, 1272
medullary carcinoma as, 1280–1281, 1280f
postradiation, 1280
prognosis for, 1272–1274
staging of, 1274t, 1275t
treatment of, 1271, 1276–1281
chemotherapy for, 1280
radiation therapy for, 1276–1279, 1277f–1279f
surgical, 1276, 1277f
thyroid preparation for suppression of TSH in, 1279–1280
Endocrine complication(s), 1013–1019
adrenal dysfunction as, 1013, 1016, 1017t, 1019, 1019b
of biologic agents, 1016–1017
causes of, 1013, 1014t
evaluation and treatment of, 1013, 1017–1019, 1017t, 1019b
gonadal dysfunction as, 1013
hypothalamic-pituitary axis disorders as, 1013–1015, 1017–1019, 1017t
pancreatic dysfunction as, 1013, 1016
of radiation therapy, 1014–1015, 1014t
of surgical therapy, 1014
surveillance of childhood cancer survivors for, 1019, 1019b
of systemic therapy, 1015–1016
thyroid dysfunction as, 1013, 1015–1017, 1017t
Endocrine deficits, after cranial or spinal irradiation, 1089
Endocrine therapy
for bone metastases, 858–859
for breast cancer
early stage, 1920t, 1921–1924
metastatic, 1930–1931, 1930t, 1931t
secondary effects of, 1926
Endocrinologic effects, of cranial radiation therapy, 952–953
Endocurietherapy, 439
Endodermal sinus tumors, of vagina, 1783
End-of-life care, 665–675
for agitation, 669–672, 669f, 670b, 671b
communication needs of patients and families in, 666, 666t
cultural considerations in, 670–671, 671b
for distress, 666–669, 667t
for family and caregiver, 670–671, 670b, 671b
End-of-life care (*cont.*)
for grief and bereavement, 673–675, 674b
hospice in, 672–673, 672t
palliative sedation in, 671–672
spiritual/existential concerns in, 671
Endogenous erythroid colony growth, in polycythemia vera, 2262
Endometrial cancer, 1793–1819
with adnexal involvement, 1802, 1813
biology of, 1793, 1799–1800
classification of, 1795, 1796t
clear cell carcinoma as
molecular pathology and biology of, 1800
pathology of, 1797–1798, 1798f
clinical presentation of, 1793, 1801
depth of invasion of, 1802
differential diagnosis of, 1793, 1800
endometrial intraepithelial carcinoma as, 1797, 1797f
endometrioid adenocarcinoma as
ciliated cell, 1797
grading of, 1797
molecular pathology and biology of, 1799–1800
pathogenesis of, 1795–1796
pathology of, 1796–1797, 1796f
risk factors for, 1794–1795, 1794t
secretory, 1797
with squamous differentiation, 1797
villoglandular, 1797
epidemiology of, 1793, 1794, 1794t
future issues for, 1819
grading of, 1797
and prognosis, 1802
histologic subtypes of, 1795–1800, 1796f–1799f, 1796t
and prognosis, 1802
hyperplasia and, 1796, 1796t
laboratory and imaging studies of, 1801
with lymphovascular invasion, 1802, 1805, 1813–1814, 1814t
metastatic
imaging of, 1801
to lymph nodes, 1805, 1813–1814, 1814t
mixed cell, 1798
mucinous, 1798
pathogenesis of, 1794–1800
pathology of, 1793, 1795–1800, 1796f–1799f, 1796t
patient evaluation for, 1800–1801
with positive peritoneal washings, 1802, 1812–1813, 1812t
prognosis for, 1793, 1802–1803
protective factors for, 1795
recurrent, 1803b, 1805–1806, 1817–1819, 1818t
risk factors for, 1794–1795, 1794t
sarcoma as
carcino- (mixed malignant müllerian tumor) as, 1798, 1798f
classification of, 1796t
epidemiology of, 1795
leiomyo-, 1798–1799, 2012t, 2016, 2043–2044
pathology of, 1798–1799, 1799f
systemic treatment of, 1816
Endometrial cancer (*cont.*)
sarcoma as (*cont.*)
molecular pathology and biology of, 1800
pathology of, 1798–1799, 1799f
stromal, 1799, 1799f, 1816
systemic therapy for, 1816
undifferentiated, 1799
screening for, 1801
squamous cell, 1798
staging of, 1793, 1801–1802
and prognosis, 1802
surgical, 1801–1802, 1802t, 1805
treatment of, 1793, 1803–1819
for advanced disease, 1811–1815, 1812t, 1814t
brachytherapy for
with early-stage disease, 1808–1810, 1809t, 1810t
with medically inoperable disease, 1811
with recurrent disease, 1819
chemotherapy for, 1815, 1816
complications of, 1793, 1803b, 1816
debulking in, 1814–1815
for early-stage disease, 1803–1811
hormonal therapy for, 1815–1816
medically inoperable, 1810–1811, 1811t, 1814–1815
primary, 1793
radiation therapy for
adjuvant, 1803b, 1804t, 1806–1808, 1808t
for advanced disease, 1811–1814
complications of, 1816
for early-stage disease, 1803b, 1804t, 1806–1808
in medically inoperable disease, 1810–1811, 1811t
neoadjuvant, 1807–1808, 1808t
palliative, 1815
for recurrent disease, 1817, 1818
as sole modality, 1810–1811, 1811t
for recurrent disease, 1817–1819, 1818t
salvage, 1793
surgical, 1804–1806, 1805b, 1806t
systemic, 1815–1816
undifferentiated, 1798
uterine serous carcinoma as
molecular pathology and biology of, 1800
pathology of, 1797, 1797f
Endometrial clear cell carcinoma
molecular pathology and biology of, 1800
pathology of, 1797–1798, 1798f
Endometrial hyperplasia, 1796, 1796t
Endometrial intraepithelial carcinoma, 1797, 1797f
Endometrial stromal sarcoma, 1799, 1799f, 1816
Endometrioid adenocarcinoma
ciliated cell, 1797
grading of, 1797
molecular pathology and biology of, 1799–1800
pathogenesis of, 1795–1796
pathology of, 1796–1797, 1796f

Endometrioid adenocarcinoma (*cont.*)
risk factors for, 1794–1795, 1794t
secretory, 1797
with squamous differentiation, 1797
villoglandular, 1797
Endometrium, metastasis to, 1798
Endomyocardial biopsy, for anthracycline-induced cardiomyopathy, 988
Endoprostheses, for osteosarcoma, 1965, 1966f
Endorectal ultrasound, of rectal cancer, 1536, 1536f
Endoscopic laser surgery, for gastric cancer, 1439
Endoscopic laser therapy, for esophageal cancer, 1420
Endoscopic palliation, for esophageal cancer, 1403, 1420–1421
Endoscopic retrograde cholangiopancreatography (ERCP)
of cholangiocarcinoma, 1586f, 1588
of pancreatic cancer, 1599, 1601f
Endoscopic ultrasonography (EUS), of pancreatic cancer, 1599–1601
Endothelial cells (ECs), in angiogenesis, 106, 107
Endothelial precursor cells (EPCs), in vascularization, 106
Endothelin-1 (ET-1), in bone metastases, 848
Endovascular stents, for superior vena cava syndrome, 810–812, 810f, 810t
Endpoint(s), of clinical trials, 314
clinical, 322–323
intermediate, 314
surrogate, 312, 323
Endpoint odds ratio, 358
Endpoint of interest, 345–346
measures of occurrence of, 350–352, 351f, 352f
Energy balance, and colorectal cancer, 1482
Energy conservation, for fatigue, 661
Engraftment syndrome, after hematopoietic stem cell transplantation, 507
Enhancer of zeste homolog 2 (EZH2), in prostate cancer, 1660
Enhancer sequences, 7, 10f
ENL gene, in childhood leukemia, 2149
Enoxaparin
for thromboprophylaxis, 709
for venous thromboembolic disease, 703
Enteritis, 726
Enteroclysis, for small bowel tumors, 1469–1470
Enterocolitis, neutropenic (necrotizing), 726–727, 791, 794, 794b
Enterocutaneous fistulae, 798, 800f
Enteromesenteric bridge procedure, for lymphedema, 646
Enteroscopy, for small bowel tumors, 1470
Entry-site infections, 727
Enucleation
for retinoblastoma, 1154, 2110
for uveal melanoma, 1146, 1146b
Environmental factor(s), 125–137, 126t
chemical, 127–130
aflatoxins as, 128–129
aromatic amines as, 127–128
benzene as, 128
polycyclic aromatic hydrocarbons as, 127, 128f
in tobacco, 129–130, 129t
chemotherapeutic, 130
dietary, 133–134, 133b
exposure biomarkers and susceptibility factors for, 134–135
fibers and dusts as, 132–133
history of identification of, 125–127
metal(s) as, 132
public health approach to, 135–136, 136f, 137b
radiation as, 130–131
ionizing, 130–131, 131t
due to radon, 131
ultraviolet, 130
Environmental tobacco smoke (ETS), and lung cancer, 1309
Enzyme-linked immunosorbent assays (ELISA), for D-dimer, 702
EORTC. *See* European Organization for Research and Treatment of Cancer (EORTC).
EP regimen, for testicular cancer, 1732, 1738
EPA (eicosapentaenoic acid), for cachexia, 595
EPC (external pneumatic compression) boots, 709
EPCs (endothelial precursor cells), in vascularization, 106
Ependomyoblastoma, 1123
Ependymomas
of childhood, 1123
cytogenetic aberrations in, 259t
of posterior fossa, 1120f
spinal, 1117–1118, 1117t
EPHB2, and prostate cancer, 181
Ephedra, adverse effects of, 554t
Epidemiologic study(ies), 343–360
case-cohort, 354, 354f
case-control, 354–358, 355f
comparability in, 355–357, 356f
design of, 354–357, 355f, 356f
nested, 353–354, 353f
statistical analysis of, 357–358, 358f
temporality in, 355
cohort, 346–353
comparability in, 348–350
design of, 346–350, 347f, 348f
measures of association in, 352–353
measures of occurrence of endpoint in, 350–352, 351f, 352f
statistical analysis of, 350–353
temporality in, 346–348, 347f, 348f
drawing inferences from, 358–359
endpoint of interest in
defining, 345–346
measures of occurrence of, 350–352, 351f, 352f
factor of interest in, 346
restating research questions as hypotheses, 344
target, source, and study populations of, 344–345, 344f
Epidermal growth factor receptor (EGFR)
in carcinoma of unknown primary, 2062
as molecular target, 486t
Epidermal growth factor receptor *(EGFR)* gene, 211t, 271
in glioblastomas, 1095
in lung cancer, 1310, 1317, 1343–1344, 1344f, 1354
non-small cell, 494–495
Epidermal growth factor receptor (EGFR) inhibitors
for cholangiocarcinoma, 1590
for colorectal cancer, 1524–1525
cutaneous reactions to, 637–638, 638f
for gliomas, 1104
for head and neck cancer, 1207–1208
for hepatocellular carcinoma, 1577–1578
for lung cancer
non-small cell, 1339–1340, 1343–1345, 1343t–1345t, 1344f, 1345f
small cell, 1354
Epidoxorubicin. *See* Epirubicin (Ellence, epidoxorubicin).
Epigenetic gene silencing
in apoptosis, 73, 73f
as molecular target, 486t
Epigenetic markers, 272
Epigenetic mechanisms
in esophageal cancer, 1402, 1403
of proto-oncogene activation and tumor suppressor inactivation, 208, 211–214, 213f
Epigenetically altered gene, tumor-selective expression of, 78
Epigenetics, 9, 11f
Epipodophyllotoxin(s). *See also* Etoposide (Vepesid, VP-16).
second malignant neoplasms due to, 1026
Epiregulin, in metastasis, 43
Epirubicin (Ellence, epidoxorubicin), 466–467
decreased cardiotoxicity of, 988–989
for ovarian cancer, 1835
for small cell lung cancer, 1349, 1349t
for soft-tissue sarcoma, 2029t, 2034, 2036
Episodic pain, 575
Epithelial immunity, and tumor immune surveillance, 80–81, 81f
Epithelial to mesenchymal transition (EMT), in metastasis, 36, 36f, 37f
EPO. *See* Erythropoietin (EPO).
EPOCH regimen
for AIDS-related lymphoma, 2392, 2393, 2393f
for relapsed aggressive B-cell lymphoma, 2394t
Epoetin alfa (erythropoietin alfa), 467
for anemia, 678
for fatigue, 660
Epogen (erythropoietin alfa), 467
for anemia, 678
for fatigue, 660
EPP (extrapleural pneumonectomy), for mesothelioma, 1374–1375, 1375t, 1378
Epratuzumab (LL2, humanized anti-CD22), for lymphoma, 536, 536t
Epstein, Tony, 153

Epstein-Barr virus (EBV)
genome of, 154, 155f
"latent" phase of, 154
life cycle of, 154
and lymphoma, 224, 225, 227, 228, 2372
Burkitt's, 153–156, 2173
with HIV, 1066, 1066f
Hodgkin's, 2355
"lytic" phase of, 154
molecular diagnostics for, 270
and nasopharyngeal carcinoma, 154, 387, 1179, 2117
and thymic carcinoma, 1384
Epstein-Barr virus (EBV)-associated lymphoproliferative disorders, 2391–2392
post-transplant, 154
EQ (erythroplasia of Queyrat), 1702. *See also* Vulvar intraepithelial neoplasia (VIN).
ER. *See* Estrogen receptors (ER).
ERBB gene, 211t
erbB-2
as molecular target, 486t
in osteosarcoma, 2084
ERBB2 gene, 211t
in breast cancer, 1875, 1880, 1917
Erbitux. *See* Cetuximab (Erbitux, chIgG1, anti-EGFR).
ERCP (endoscopic retrograde cholangiopancreatography)
of cholangiocarcinoma, 1586f, 1588
of pancreatic cancer, 1599, 1601f
ERE (estrogen responsive elements), 1878
Erectile dysfunction
management of, 1008
prostate cancer and
after brachytherapy, 1676
radiation-related, 1671–1672
after radical prostatectomy, 1669
radiation-related, 999, 1002
with prostate cancer, 1671–1672
surgery-related, 999, 1001
after radical prostatectomy, 1669
Erlotinib (Tarceva), 452, 467
for carcinoma of unknown primary, 2071–2072
for hepatocellular carcinoma, 1577–1578
for lung cancer
non-small cell, 1343, 1343t, 1344, 1344f, 1345f, 1345t
small cell, 1354
during pregnancy, 1053
pulmonary toxicity of, 978, 978f
Erythema, acral, 629–630, 630f
Erythroblastic leukemia, acute. *See* Erythroleukemia.
Erythrodysesthesia, palmar-plantar, 629–630, 630f
Erythroid cells, in polycythemia vera, 2262–2263
Erythroid leukemia, acute. *See* Erythroleukemia.
Erythroleukemia, acute, 2220, 2220f
in children, 2145, 2145t
Erythroplakia, 363f
Erythroplasia of Queyrat (EQ), 1702. *See also* Vulvar intraepithelial neoplasia (VIN).
Erythropoiesis-stimulating proteins (ESPs), 678–681
problem of iron with, 678–680, 679t, 680f
safety of, 680–681
Erythropoietin (EPO)
in anemia, 677, 678, 678f, 680
autoantibodies to, 680
for myelodysplastic syndrome, 2242, 2243, 2244t
in polycythemia vera, 2262–2264
Erythropoietin alfa (Epogen, Procrit, epoetin alfa), 467
for anemia, 678
for fatigue, 660
Erythropoietin receptor (EPO-R), 681
ES (embryonic stem) cells, 17, 18f
ESFTs. *See* Ewing's sarcoma family tumors (ESFTs).
ESHAP regimen, for relapsed aggressive B-cell lymphoma, 2393, 2394t
Esophageal cancer, 1399–1423
adenocarcinoma as
classification of, 1400, 1400t
clinical risk factors for, 1401
pathogenesis of, 1401–1402
prognosis for, 1409
Barrett's esophagus and, 1401–1402, 1423
cervical, 1417
chemoprevention of, 368
classification of, 1399, 1400, 1400t
clinical risk factors for, 1399–1401
diagnosis of, 1399, 1405–1406
dysphagia due to, 1419–1421
GERD and, 1401–1402
imaging of, 304
incidence of, 1399, 1400
location of, 1400
metastatic
chemotherapy for, 1421–1423, 1422t
diagnosis and evaluation of, 1406
molecular progression to, 1402–1403
pathogenesis of, 1399–1403
prognosis for, 1408–1409, 1412–1414
recurrent, 1421–1423, 1422t
screening for and early detection of, 367
squamous cell
classification of, 1400, 1400t
clinical risk factors for, 1400–1401
epidemiology of, 1400
pathogenesis of, 1400–1401, 1403
prognosis for, 1409
staging of, 1399, 1403, 1405t, 1409
treatment of, 1399, 1403–1423
brachytherapy for, 1417, 1419–1420
chemoradiation for
definitive, 1404t, 1405, 1414–1415, 1416t
followed by surgery, 1403–1405, 1404t, 1410–1414, 1411t, 1413t
postoperative, 1403, 1404t, 1414
salvage therapy after, 1415
chemotherapy for
in advanced disease, 1421–1423, 1422t
followed by surgery, 1404t, 1405, 1409–1410
Esophageal cancer (*cont.*)
treatment of (*cont.*)
choice of, 1403–1405, 1404t
endoscopic palliation in, 1403, 1420–1421
photodynamic therapy for, 1405, 1417, 1420–1421
radiation therapy for
dose selection and outcomes of, 1417–1418
palliative, 1419–1420
as sole modality, 1403, 1404t, 1417–1420
techniques of, 1418–1419
toxicities of, 1419
with tracheoesophageal fistula, 1415–1417
salvage therapy after local failure for, 1415
surgery for
chemoradiation followed by, 1403–1405, 1404t, 1410–1414, 1411t, 1413t
chemotherapy followed by, 1404t, 1405, 1409–1410
as sole modality, 1403, 1404t, 1406–1409, 1406f, 1407f
Esophageal ultrasound (EUS), of esophageal cancer, 1406
Esophagectomy
after chemoradiation, 1412
for esophageal cancer, 1406–1409, 1406f
minimally invasive, 1408
palliative, 1406
partial, 1406–1407, 1406f, 1408
radical, 1408
transhiatal, 1407
Esophagitis, 726
Esophagogastrectomy, partial, for esophageal cancer, 1406–1408, 1407f
Esophagus
Barrett's, 363f
and esophageal adenocarcinoma, 1401–1402, 1423
radiation effects on, 434t
radiation tolerance dose of, 435t
Esorubicin, decreased cardiotoxicity of, 988–989
ESPs (erythropoiesis-stimulating proteins), 678–681
problem of iron with, 678–680, 679t, 680f
safety of, 680–681
Essential thrombocythemia (ET), 2267–2270
diagnosis of, 2268–2269, 2268b, 2268t, 2269f
diagnostic criteria for, 2269t
incidence of, 2267

  fluorochromes and fluorescence in, 241–242
  forward scatter and side scatter in, 241, 242f
  future of, 246
  gating in, 241, 242f
  of leukemia
    acute, 242–243, 242b, 242f, 243f
    chronic, 245
  of lymphoma and lymphoproliferative disorders, 242b, 243–246, 245f
  methods of, 241–242
  multiparameter, 241
  of myelodysplasia and chronic myeloproliferative disorders, 243
Flower cells, in adult T-cell leukemia-lymphoma, 2430, 2431, 2432f
Floxed gene, 17f
Floxuridine (FUDR, FdUR, fluorodeoxyuridine), 468
  for gestational trophoblastic neoplasia, 1868
  for liver metastases
    adjuvant, 896–897, 896f
    intrahepatic, 899–902, 901f
      increasing response rate of, 902–903
      toxicity of, 902–904, 903t, 904b
FLT3 (FMS-like tyrosine kinase 3)
  in acute myelogenous leukemia, 2219, 2221
  in childhood leukemia, 2141, 2149, 2152
  as molecular target, 486t
Fluconazole, prophylactic, with hematopoietic stem cell transplantation, 730
Fludarabine (Fludara, FAMP), 468
  for chronic lymphoid leukemia, 2301b, 2302–2303
  neurotoxicity of, 950
  pulmonary toxicity of, 977
  for Waldenström's macroglobulinemia, 2343
Fluid balance management, for ascites, 939
Fluid replacement, for hypercalcemia of malignancy, 744
Fluid retention, due to cancer therapy, 983, 993
Fluorescein isothiocyanate (FITC), in flow cytometry, 242
Fluorescence, in flow cytometry, 241–242
Fluorescence endoscopy, of lung cancer, 1322
Fluorescence in situ hybridization (FISH) analysis, 6, 6f, 249–251, 251t
  for acute myeloid leukemia, 2221
  multiplex, 252
Fluoride, for radiation-induced dental caries, 618
Fluorochromes, in flow cytometry, 241–242
[^{18}F]Fluorodeoxyglucose positron emission tomography (FDG-PET)
  of bladder cancer, 300
  of brain tumors, 1085, 1086f
  for carcinoma of unknown primary, 2067
  of cervical cancer, 1756
  of colorectal cancer, 297–298, 297f
    metastatic, 1494, 1494f
    recurrent, 1511
  of gestational trophoblastic disease, 1864
  of head and neck cancer, 300, 301f
  of hepatocellular carcinoma, 1571–1572
  of liver metastases, 887–888, 1494, 1494f
  of lung cancer, 292, 293f, 1321, 1324, 1326f, 1347
    metastatic, 293–294
  of lymphoma, 297–298, 297f, 2376
    Hodgkin's, 2359–2361, 2359f, 2360f
  of melanoma, 299–300
    metastatic, 1234
  for molecularly targeted therapy, 493
  of multiple myeloma, 2329, 2329f
  of osteosarcoma, 1951
  of pancreatic cancer, 1599
  of pulmonary metastases, 875–876
  of small bowel tumors, 1470
  of soft-tissue sarcoma, 2017–2018
  of testicular cancer, 1721
Fluorodeoxyuridine. *See* Floxuridine (FUDR, FdUR, fluorodeoxyuridine).
Fluoropyrimidines
  for colorectal cancer, 1512–1524, 1513t, 1515t, 1517t, 1520t, 1522t
  for gastric cancer, 1455, 1456t, 1457
  myocardial ischemia due to, 993
5-Fluorouracil (Adrucil, Efudex, 5-FU), 468
  for anal cancer, 1561b, 1562–1564, 1563t, 1566
  for carcinoid tumors, 1293–1294
  for cervical cancer, 1762, 1763
  for colorectal cancer
    clinical trials of, 1512, 1513t, 1520
    commonly used regimens of, 1520, 1520t, 1522t
    evaluation of, 1519
    with irinotecan, 1522t, 1523–1524
    with lymph node involvement, 1514–1516, 1515t
    metastatic, 1519–1524, 1520t, 1522t
    with negative lymph nodes, 1514–1516
    oral preparations of, 1520–1521
    with oxaliplatin, 1516, 1521–1523, 1522t
    with radiation therapy, 1517–1518
  with dihydropyrimidine dehydrogenase deficiency, 457
  for esophageal cancer, 1409–1411, 1411t, 1413t, 1421, 1422
  for gastric cancer, 1455, 1456t
  for gestational trophoblastic neoplasia, 1867, 1868
  for hepatoblastoma, 2115
  hyperpigmentation due to, 632
  for intrapleural therapy, 932

5-Fluorouracil (Adrucil, Efudex, 5-FU) (*cont.*)
for liver metastases
adjuvant, 896–898, 896f
intrahepatic, 899, 901, 902, 903t
neoadjuvant, 905, 907t
myocardial ischemia due to, 993
neurotoxicity of, 949–950, 950f
oral mucositis due to, 610, 611f, 612
palmar-plantar dysesthesia and erythrodysesthesia syndrome due to, 629
for pancreatic cancer, 1607
for pancreatic islet cell tumors, 1298–1299
during pregnancy, 1051, 1056
as radiosensitizer, 433t
for rectal cancer, 1544, 1546–1547, 1550, 1551
thyroid disorders due to, 1016
Fluoxymesterone (Halotestin, Ora-Testryl), 468–469
for primary myelofibrosis, 2273
Flushing, in carcinoid syndrome, 1290
Flutamide (Eulexin), 469
for prostate cancer, 1683–1684, 1684f, 1686
FMCT (familial medullary carcinoma of the thyroid), 182
FMS gene, in acute myelogenous leukemia, 2219
FMS-like tyrosine kinase 3 *(FLT3)*
in acute myelogenous leukemia, 2219, 2221
in childhood leukemia, 2141, 2149, 2152
as molecular target, 486t
FNA. *See* Fine-needle aspiration (FNA).
FNCLCC (Federation Nationale des Centres de Lutte Contre le Cancer), soft-tissue sarcoma grading system of, 2016
FNMTC (familial nonmedullary thyroid cancer), 1272
FOBT (fecal occult blood testing), 370–371
for colorectal cancer screening, 1484
Focal adhesion kinase (FAK), in metastasis, 36, 37f
Folate, and colorectal cancer, 1482, 1486
Folex. *See* Methotrexate (Mexate, Folex, MTX, amethopterin).
FOLFOX regimen, for colorectal cancer, 1517t, 1521–1523, 1522t
FOLFOX4 regimen, for rectal cancer, 1548
Folic acid, and colorectal cancer, 1482, 1486
Folinic acid (FA). *See* Leucovorin calcium (Wellcovorin, citrovorum factor, folinic acid, FA, LV).
Follicle-stimulating hormone (FSH), 1000
Follicular lymphoma (FL), 2178
classification of, 2381
clinical characteristics of, 2381, 2382t
immunophenotypic and genetic abnormalities in, 2295t, 2374t
molecular genetics of, 2375, 2375t
primary cutaneous, 2413, 2414
prognosis for, 2381, 2383f
treatment of, 2381–2385, 2384f
for advanced-stage disease
asymptomatic, 2381–2383
symptomatic, 2383–2384, 2384f
for early-stage disease, 2381
for relapsed disease, 2384–2385
Follicular mucinosis, 2412, 2412f, 2414t
Follistatin, 1000
Fondaparinux, for venous thromboembolic disease, 694, 703
Food and Drug Administration (FDA), tumor markers approved by, 277–278, 278t
Food-borne infections, 718, 733
Forced expiratory volume in one second (FEV1)
grading of, 972t
in presurgical evaluation for lung cancer, 1328
Forward scatter, in flow cytometry, 241
Foscarnet, for Kaposi's sarcoma, 1065
Four-dimensional radiation therapy, 440
FPF (false-positive fraction), 285–286, 285f
FPSA ("free" prostate-specific antigen), 1664, 1664t
Fractionated stereotactic radiotherapy (FSRT)
for acoustic neuromas, 1115
for meningiomas, 1111
Fractionation, of radiation therapy, 428–429
altered schemes of, 429–431, 430f, 430t
for head and neck cancer, 1189–1191, 1193–1199, 1195f, 1196f, 1196t–1198t
Fracture(s)
pathologic
due to bone metastases, 866–867
heparin-induced, 698
due to osteosarcoma, 1959, 1960f, 1974–1975
traumatic, bone metastases vs., 849t
Frailty, 1043
Frameshift mutation, 267f
Free jejunal interposition, for esophageal cancer, 1408
Free light-chain assay, for multiple myeloma, 2329
"Free" prostate-specific antigen (FPSA), 1664, 1664t
French-American-British (FAB) classification
of childhood leukemia, 2142–2143, 2143t
of hematologic malignancies by, 2132, 2133
of myelodysplastic syndrome, 2239, 2239t
Frequency matching, 357
Frizzled receptors, in intracellular signaling, 24
Frontal lobe tumors, signs of, 1082
Frozen sections, in surgical pathology, 235, 235b
FSH (follicle-stimulating hormone), 1000
FSRT (fractionated stereotactic radiotherapy)
for acoustic neuromas, 1115
for meningiomas, 1111
FTIs (farnesyl transferase inhibitors), for head and neck cancer, 1208
5-FU. *See* 5-Fluorouracil (Adrucil, Efudex, 5-FU).
FUDR. *See* Floxuridine (FUDR, FdUR, fluorodeoxyuridine).
Fulvestrant (Faslodex), 469
for breast cancer, 1931
Fumarate hydratase *(FH)* gene, in renal cell carcinoma, 1616
Function, assessment of, 1043
Functional imaging, for molecularly targeted therapy, 493–494, 494t
Functional subunits, 433–434
Fungal infections, 723, 725–726
FUO (fever of undetermined origin), 718
Furosemide
for hypercalcemia of malignancy, 744
for hyponatremia, 755, 756
Fusarium infections, 726
Fusion protein, 16–17
Futile energy cycles, in cachexia, 593, 593f
FWT1, in Wilms' tumor, 2097
FWT2, in Wilms' tumor, 2097

G

G protein–coupled receptors (GPCRs)
in intracellular signaling, 22
viral, KSHV and, 163
G_0 state, 49, 50, 50f
G_1 (first gap) phase, 50, 50f
G_1/S checkpoint, 58–59, 58f
G_2 checkpoint, 58f, 59
G_2 (second gap) phase, 50, 50f
Gabapentin, for pain management, 575
Gadolinium (Gd)-containing contrast agents, 289, 289b
Gait disorders, due to brain tumors, 1082
Gallbladder, porcelain, 1580–1581, 1580f
Gallbladder cancer, 1580–1585
clinical presentation and evaluation of, 1581
epidemiology of, 1580
etiology and pathogenesis of, 1580–1581, 1580f
future issues with, 1584
incidentally and laparoscopically discovered, 1584
laboratory and imaging studies of, 1581, 1581f
metastatic, 1584
pathology of, 1581
prevention of, 1580
prognosis for, 1582
recurrence of, 1585
risk factors for, 1580
staging of, 1581–1582, 1582t, 1583f
treatment of, 1582–1585
adjuvant therapy in, 1584
cholecystectomy for, 1582–1584, 1583t
follow-up after, 1585
complications of, 1585
for metastatic disease, 1584
novel therapies in, 1584–1585
primary, 1582–1584
staging laparoscopy in, 1582, 1583f
tumor biology of, 1581
Gallium nitrate (Ganite), 469
for hypercalcemia of malignancy, 745
Gallstones, and gallbladder cancer, 1580
Gamma interferon, for ovarian cancer, 1840
Gamma Knife radiosurgery
for acoustic neuromas, 1114–1115
for brain tumors, 1087
Gamma rays, 419
γ particles, in radioimmunotherapy, 535, 535t
Ganciclovir
for cytomegalovirus, 728
for Kaposi's sarcoma, 1065

Gangliogliomas, spinal, 1119
Ganglion impar blocks, 574
Ganglioneuroblastoma, 2092, 2092f
  of posterior mediastinum, 1389
Ganglioneuroma, 2092, 2092f
  of posterior mediastinum, 1389
Ganite (gallium nitrate), 469
  for hypercalcemia of malignancy, 745
Gardner's syndrome, 2011
Garlic, interactions with, 555t
Gasserian ganglion neurolysis, 574
Gastrectomy, for gastric cancer, 1437, 1438f
Gastric cancer, 1431–1459
  biologic characteristics of, 1431, 1434, 1436t
  clinical manifestations of, 1434–1437
  diagnostic evaluation of, 1436–1437
  epidemiology of, 1431, 1432, 1432f, 1433f
  etiology of, 1432
    infectious, 363t
  Helicobacter pylori and, 223, 228, 387, 1432
  hereditary/familial, 173t, 185, 1433
  imaging of, 304
  immunodeficiency and, 227
  pathology of, 1431, 1433–1434, 1435f, 1436f
  prevention and early detection of, 387, 1432–1433
  prognostic factors for, 1434, 1436t
  spread of, 1434, 1436f
  staging of, 1431, 1437, 1437t
    and treatment, 1458–1459, 1458t, 1459f
  therapy for, 1431, 1437–1459
    adjuvant, 1431, 1440–1450
      chemoradiation as, 1444–1445, 1444t, 1445t
      intraperitoneal chemotherapy as, 1442, 1453–1454
      radiation therapy as, 1442, 1443t
      systemic chemotherapy as, 1440–1442, 1441t
    chemoradiation as
      adjuvant, 1444–1445, 1444t, 1445t
      for locally advanced disease, 1451–1452, 1452t, 1454
      neoadjuvant, 1445, 1454
      nutritional support during, 1459
      palliative, 1455
    chemotherapy as
      adjuvant, 1440–1442, 1441t
      intraperitoneal, 1442, 1453–1454
      for locally advanced disease, 1453–1454, 1454t
      neoadjuvant, 1453–1454, 1453t
      palliative, 1455–1457, 1456t
      perioperative, 1454
    future of, 1457–1459, 1458t, 1459f
    for locally advanced disease, 1431, 1450–1454
      chemoradiation as, 1451–1452, 1452t
      chemotherapy as, 1453–1454, 1454t
      future of, 1458
      radiation therapy as, 1451
      surgical, 1450–1451
    lymphadenectomy as, 1437–1439, 1445, 1445t, 1457
Gastric cancer (*cont.*)
  therapy for (*cont.*)
    neoadjuvant
      chemoradiation as, 1445, 1454
      chemotherapy as, 1453–1454, 1453t
      radiation therapy as, 1442–1444
    palliative, 1431, 1454–1457, 1456t
    primary, 1431, 1437–1440
    radiation
      adjuvant, 1442, 1443t
      for locally advanced disease, 1451
      neoadjuvant, 1442–1444
      palliative, 1455
      techniques of, 1445–1450, 1446f–1449f, 1450t, 1451t
    staging and, 1458–1459, 1458t, 1459f
    surgical, 1437–1440, 1438f
      for locally advanced disease, 1450–1451
      palliative, 1455
      relapse patterns after, 1439–1440, 1440t
      survival after, 1439, 1439t
Gastric emptying, delayed, after pancreaticoduodenectomy, 1602–1604
Gastric outlet obstruction, 796
  due to pancreatic cancer, 1608
Gastrin, 1297
Gastrinoma, 1295f, 1297, 1298
Gastroesophageal reflux disease (GERD), and esophageal adenocarcinoma, 1401–1402
Gastrointestinal (GI) bleeding, 791–793, 793f
  due to cytotoxic agents, 793–794
Gastrointestinal (GI) cancer
  predisposition syndromes for, 173t–174t, 179–181t
  during pregnancy, 1056
Gastrointestinal (GI) disorder(s), 791–800
  acute abdomen as, 791–792, 792b
  appendicitis as, 794–795
  bleeding as, 791–793, 793f
    due to cytotoxic agents, 793–794
  after bone marrow transplantation, 797–798, 798f
  fistulae as, 791, 798–799, 800f
  inflammatory, 794–795, 794b
  neutropenic (necrotizing) enterocolitis as, 791, 794, 794b
  obstructive, 791, 795–797, 796f
  pancreatitis as, 795
  perforation as, 791, 792
    due to cytotoxic agents, 793–794
  perianal and perirectal infections as, 795
Gastrointestinal (GI) fistulae, 798–799, 800f
Gastrointestinal (GI) infections, 726–727
Gastrointestinal (GI) involvement, in adult T-cell leukemia-lymphoma, 2429
Gastrointestinal (GI) lymphoma, perforation of, 792
Gastrointestinal (GI) neuroendocrine tumors, liver metastases of, 891
Gastrointestinal (GI) obstruction, 791, 795–797, 796f
Gastrointestinal (GI) perforation, 791, 792
  due to cytotoxic agents, 793–794
Gastrointestinal stromal tumors (GISTs)
  biology of, 1468
  clinical presentation of, 1469
  of colon, 1508–1509
  cytogenetic aberrations in, 258t, 1468, 2012t
  defined, 1468
  familial, 174t, 2011–2013, 2011t
  follow-up for, 1473
  imaging of, 304, 1470
  incidence of, 1465
  KIT in, 1468, 1471–1472, 2021, 2041
  metastatic, 1473, 2041
    to liver, 891
  pathology of, 1468, 1468f
  prognosis for, 1471–1472
  of rectum, 1537, 1537f
  recurrent, 1473
  treatment for, 1472–1473, 2040–2041
Gastrointestinal Tumor Study Group (GITSG) trial, 1543–1544, 1544t
"Gatekeeper" genes
  and cancer phenotype, 219
  cancer predisposition syndromes due to, 171
Gating, in flow cytometry, 241, 242f
GCBs (germinal center B cells), 2133
GCF (giant cell fibroblastoma), cytogenetic aberrations in, 260t
G-CSF. *See* Granulocyte colony-stimulating factor (G-CSF).
GCTs. *See* Germ cell tumor(s) (GCTs).
Gd (gadolinium)-containing contrast agents, 289, 289b
Gefitinib
  for lung cancer
    non-small cell, 494–495, 1339, 1343, 1343t, 1344, 1344f, 1345f
    small cell, 1354
  pulmonary toxicity of, 978
Gel electrophoresis, 7, 8f–9f
Gelatinase, in metastasis, 38
Gemcitabine (Gemzar), 469
  for bladder cancer, 1646, 1648, 1649
  for carcinoma of unknown primary, 2070–2071
  for esophageal cancer, 1422
  for non-small cell lung cancer, 1340t, 1342
  for ovarian cancer, 1840, 1840t
  for pancreatic cancer, 1607
  pulmonary toxicity of, 977
  as radiosensitizer, 433t
  for soft-tissue sarcoma, 2036
Geminin, 54, 55f
Gemtuzumab ozogamicin (Mylotarg), 453, 469
  for acute myeloid leukemia, 2228
  with calicheamicin, 537
Gemzar. *See* Gemcitabine (Gemzar).
Genasense (oblimersen), 453
  inhibition of survival factors by, 74
Gendicine, 526
Gene(s), 3, 10f
  candidate, 3
Gene analysis, 7
Gene clustering, in breast cancer, 1880, 1881f

Gene defects, cancers arising from accumulation of multiple, 208–209
Gene expression, 3, 10f
  changes in levels and/or patterns of, 213
    in prostate cancer, 1660
  serial analysis of, 9–10
  targeted (*See* Targeted gene expression)
Gene expression profiling, 9, 12f
  and bone metastases, 846

  for carcinoma of unknown primary, 2067–2068
  in childhood leukemia, 2150
Gene gun, 518
Gene knockout strategies, 17–19, 18f
Gene mutations
  in hematolymphoid neoplasms, 270
  progression to cancer from, 207–221
  in solid tumors, 271–272, 271f, 272f
Gene rearrangement assays, for hematolymphoid neoplasms, 267–268, 268f, 268t
Gene targeting, 519–524, 521t, 522t
  conditional, 519–523, 521t, 522t
  conditional replication and inducible promoters in, 520–522
  conditionally replicative viruses in, 522–523, 522t
  tissue-specific promoters in, 520, 521t
  tumor-associated promoters in, 520
  tumor-specific promoters in, 520
Gene therapy, 453, 513–526
  clinical trial strategies for, 524–526, 525f
  current concerns regarding, 513
  future directions of, 513
  for gliomas, 1104
  history of, 513
  for liver metastases, 912
  for mesothelioma, 1378
  for radiation pulmonary fibrosis, 976
  recent improvements in, 513
  to restore apoptotic capability, 74
  for severe combined immune deficiency X1, 524–525, 525f
  for small cell lung cancer, 525
  suicide, 518
  target(s) for, 519–524, 521t, 522t
    conditionally replicative viruses as, 522–523, 522t
    inducible, 520–522, 521t
    tissue-specific, 520, 521t
    tumor-associated, 520
    tumor-specific, 520
    vectors as, 523–524
  transcriptional control of, 520, 521t
  transgenes in, 513, 514, 518
  vectors for, 513–518
    ideal attributes of, 513
    nonviral, 517–518, 524
      antisense, 519
      via ballistic delivery (gene gun), 518
      via DNA transduction, 518–519
      via hydrodynamic gene delivery, 518
      via liposomes and virosomes, 518, 524
      nanoparticles as, 518
      via nucleic acid–based therapeutics, 518–519
Gene therapy (*cont.*)
  vectors for (*cont.*)
      oligonucleotides as, 519
      plasmids as, 518–519, 518b
      ribozymes as, 519
      via RNA transduction, 518–519
      small interfering RNA as, 519
    retroviral, 514–515, 515f, 518b, 524
    viral, 513–517
      recombinant adeno-associated virus as, 516
      recombinant adenoviral, 515–516, 515f, 516b, 523–524, 525–526
      recombinant alphavirus (Sindbis), 517
      recombinant herpes simplex virus as, 516
      recombinant lentivirus as, 514–515
      recombinant Moloney murine leukemia virus as, 514, 514f
      recombinant pox (vaccinia virus), 516–517, 517b
Gene transfer, targeted in vivo, 523
Gene vector(s), 513–518
  ideal attributes of, 513
  nonviral, 517–518, 524
    antisense, 519
    via ballistic delivery (gene gun), 518
    via direct DNA injection/transduction, 518
    via DNA transduction, 518–519
    via hydrodynamic gene delivery, 518
    via liposomes and virosomes, 518, 524
    nanoparticles as, 518
    via nucleic acid–based therapeutics, 518–519
    oligonucleotides as, 519
    plasmids as, 518–519, 518b
    ribozymes as, 519
    via RNA transduction, 518–519
    small interfering RNA as, 519
  retroviral, 514–515, 515f, 518b, 524
  viral, 513–517
    recombinant adeno-associated virus as, 516
    recombinant adenoviral, 515–516, 515f, 516b, 523–524, 525–526
    recombinant alphavirus (Sindbis), 517
    recombinant herpes simplex virus as, 516
    recombinant lentivirus as, 514–515
    recombinant Moloney murine leukemia virus as, 514, 514f
    recombinant pox (vaccinia virus), 516–517, 517b
GeneChip, 198f, 201
General health education (GHE), for smoking cessation, 401, 402t
Genetic counseling, 202–203
  on retinoblastoma, 2109
Genetic linkage analysis. *See* Linkage analysis.
Genetic markers, for genetic linkage mapping, 196–198, 197f–199f
Genetic recombination, and linkage analysis, 196, 196f, 197f
Genetic stability, DNA damage response pathways and, 139
Genetic testing, 202–203
  for breast cancer, 374, 374b
  criteria for, 411t
  informed consent for, 171, 172b
  for ovarian cancer, 1830, 1830t
  surgeon's role in, 411
Genitourinary (GU) cancer
  cytogenetic aberrations in, 257–258

radiation therapy for, 1097–1100, 1097t, 1099t
surgical, 1095–1097, 1097b
Glioma Outcome Project, 1096
Global genomic repair (GGR), 143
Globe, tumors of. *See* Intraocular tumor(s).
Glomerular filtration rate (GFR), in elderly, 1045
Glomus jugulare tumors, 1116
Glomus tumors, of base of skull, 1116–1117
Glottis, cancer of, 1216–1217, 1216t
Glucagonoma, 1295f, 1296
Glucocorticoid(s)
for hypercalcemia of malignancy, 746, 746t
for multiple myeloma, 2338
Glucocorticoid deficiency, hyponatremia due to, 754
Glucose uptake, in cancer, 73b
Glutamine
for neuroprotection, 962
for prevention of oral complications, 613
L-Glutamine (Saforis), for prevention of oral complications, 613
Glutathione *S*-transferase pi 1 (GSTP1), in prostate cancer, 1659–1660
Glycolysis, in cancer, 73b
Glycopyrrolate, for death rattle, 667t, 668
GM-CSF. *See* Granulocyte-macrophage colony-stimulating factor (G-CSF).
GnRH. *See* Gonadotropin-releasing hormone (GnRH).
Goldenseal, adverse effects of, 554t
Goldie-Coldman model, 451, 452, 2380
Gompertzian model, of tumor growth, 450
Gonad(s), form and function of, 1000
Gonadal shielding, 1008
Gonadal toxicity, prevention of, 1007–1008, 1007b
Gonadal tumors, reproductive effects of, 1000
Gonadotropin(s), 1000
human chorionic (*See* Human chorionic gonadotropin [hCG])
Gonadotropin secretion, radiation effect on, 1014–1015
Gonadotropin-releasing hormone (GnRH), 1000
radiation effect on, 1014–1015
Gonadotropin-releasing hormone (GnRH) agonists and antagonists, reproductive complications of, 999, 1002–1003, 1007
Gonadotropin-secreting adenomas, 1111, 1112t
Gorlin syndrome, 182–183
Goserelin acetate (Zoladex), 469–470
for prostate cancer, 1683–1684
reproductive effects of, 1002
GPCRs (G protein–coupled receptors)
in intracellular signaling, 22
viral, KSHV and, 163
Grading, of tumors, 234–235
Graft rejection, after hematopoietic stem cell transplantation, 507
Graft-versus-host disease (GVHD)
acral erythema with, 629
gastrointestinal problems due to, 797
after hematopoietic stem cell transplantation, 502, 503, 508, 508t
for chronic myeloid leukemia, 2285, 2286
for myelodysplastic syndrome, 2248
for renal cell carcinoma, 1629
infection with, 729t, 730–732
Graft-versus-leukemia effect, 503
Graft-versus-tumor effect, 503
Gram-positive agents, for febrile neutropenic patient, 721–722, 722t
Granisetron, as antiemetic, 603–604, 603t

Granulocyte colony-stimulating factor (G-CSF)
for acute lymphocytic leukemia, 2196
for endometrial cancer, 1815
for Ewing's sarcoma, 2088
for Kaposi's sarcoma, 1064b
for myelodysplastic syndrome, 2242, 2243, 2244t
for neutropenia, 681–682
congenital and cyclic, 684
for osteosarcoma, 1955
during pregnancy, 1053
for soft-tissue sarcoma, 2029t, 2035
Granulocyte transfusions, 684
for infection, 724
Granulocyte-macrophage colony-stimulating factor (GM-CSF), 478
for acute lymphocytic leukemia, 2196
for melanoma, 1242
for myelodysplastic syndrome, 2243, 2244t
in neutropenia, 681–682
for oral complications
chemotherapy-induced, 613, 614
radiation-induced, 616
for soft-tissue sarcoma, 2035
in tumor microenvironment, 86
Granulocytic sarcomas, in childhood leukemia, 2142
Granulomatosis, lymphoid, 2391–2392
Granulomatous slack skin, 2412, 2414t
Granulosa cells, 1000
Graves disease
evaluation of, 1018
radiation-induced, 1015
Gray (Gy), 418
Green tea, adverse effects of, 554t
Grief, 673–675, 674b
Groin lymph node dissection, for vulvar cancer, 1770–1772, 1771t, 1772f
Groin radiation, for vulvar cancer, 1773–1774, 1774t
Grolin's syndrome, brain tumors in, 1078t
Groshong catheter, 782t
Gross tumor volume (GTV), 436, 1087
Growth factor(s)
as molecular targets, 486t–487t
for myelodysplastic syndrome, 2242, 2243, 2244t
for oral complications, 613, 614
Growth factor receptors, as molecular targets, 486t–487t
Growth fraction, 2378–2379
Growth hormone deficiency (GHD)
chemotherapy-induced, 1015
after cranial or spinal irradiation, 1089
evaluation and treatment of, 1017–1018, 1017t
radiation-induced, 1014
Growth hormone (GH)-secreting adenomas, 1111–1113, 1112t
Growth hormone (GH) therapy, 1018
second malignant neoplasms due to, 1025–1026
Growth-inhibitory cues, resistance to, as signature trait of cancer cells, 215, 216f
Growth-promoting signals, enhanced response to, as signature trait of cancer cells, 215, 216f
GSK-3β, in colorectal cancer, 1479–1481, 1480f
gsp gene, in pituitary adenoma, 1111
GSTP1 (glutathione *S*-transferase pi 1), in prostate cancer, 1659–1660
GTD. *See* Gestational trophoblastic disease (GTD).
GTN. *See* Gestational trophoblastic neoplasia (GTN).
GTV (gross tumor volume), 436, 1087
GU. *See* Genitourinary (GU).
Guided imagery, 551–552
GVHD. *See* Graft-versus-host disease (GVHD).
Gy (gray), 418
Gynecologic cancer
imaging of, 298, 298f
second malignant neoplasms with, 1030
Gynecologic surgery, reproductive complications of, 999, 1001

H

H101, 522
HA22, for hairy cell leukemia, 2317
HAART (highly active antiretroviral therapy), 1064, 1068, 1069
and Hodgkin's lymphoma, 2366
and non-Hodgkin's lymphoma, 2392–2393
HAE. *See* Hepatic artery embolization (HAE).
Hair loss, 626–627
due to cranial irradiation, 1088
Hairy cell leukemia (HCL), 2309–2318
clinical presentation of, 2310
differential diagnosis of, 2295t, 2311–2312, 2312t
epidemiology of, 2309
etiology and pathogenesis of, 2309–2310
flow cytometry of, 245, 245f, 2311
immunophenotype of, 2295t, 2311
laboratory evaluation of, 2310–2311, 2310f, 2311f
minimal residual disease in, 2316, 2316f
prognosis for, 2315–2316
relapse of, 2316
second malignancies with, 2316
treatment of, 2312–2315

sarcomas as, 1184–1185
screening for and early detection of, 367–368
second malignant neoplasms with, 1030
speech and swallowing disorders due to, 583
squamous cell carcinoma as (*See* Head and neck squamous cell carcinoma [HNSCC])
staging of, 1177, 1186, 1186t
treatment for, 1177, 1188–1219
chemotherapy in, 1202–1207
complications of, 1177
with concurrent and concomitant radiation therapy, 1191, 1204–1205, 1204f, 1205f, 1206t
neoadjuvant and induction, 1190, 1202–1204, 1203f
postoperative and adjuvant, 1205–1206
prognostic factors for, 1202
future directions in, 1177, 1219
general principles of, 1188–1191
and organ preservation, 1190–1191
palliative, 1188
prognosis and, 1188–1192
radiation therapy in, 1177, 1193–1202
brachytherapy as, 1201–1202
complications of, 1177
Head and neck cancer (*cont.*)
treatment for (*cont.*)
with concurrent and concomitant chemotherapy, 1191, 1204–1205, 1204f, 1205f, 1206t
fractionation of, 1189–1191, 1193–1199, 1195f, 1196f, 1196t–1198t
intensity-modulated, 1193, 1199
with nodal metastases, 1193, 1194t, 1195t
patient setup for, 1193, 1193f
postoperative, 1189, 1199–1201, 1200f, 1201f
toxicities of, 1188–1189, 1199
salvage, 1177
site-specific considerations for, 1208–1219
surgical, 1177, 1192–1193, 1192f
targeted therapy and novel approaches to, 1207–1208
tumor biology of, 1177, 1185–1186
Head and neck sarcomas, 1184–1185, 2041–2042
Head and neck squamous cell carcinoma (HNSCC)
epidemiology of, 1178
etiology and pathogenesis of, 1178–1179
gene therapy for, 526
nodal metastases of, 1178
pathology of, 1180–1181, 1180f–1182f
prognosis for, 1187
recurrent and second primary, 1218–1219
risk reduction for, 367
treatment for, 1177, 1188–1219
chemotherapy in, 1202–1207
complications of, 1177
neoadjuvant and induction, 1190, 1202–1204, 1203f
postoperative and adjuvant, 1205–1206
prognostic factors for, 1202
with radiation therapy, 1191, 1204–1205, 1204f, 1205f, 1206t
future directions in, 1177, 1219
general principles of, 1188–1191
and organ preservation, 1190–1191
palliative, 1188
prognosis and, 1188–1192
radiation therapy in, 1177, 1193–1202
brachytherapy as, 1201–1202
with chemotherapy, 1191, 1204–1205, 1204f, 1205f, 1206t
complications of, 1177
fractionation of, 1189–1191, 1193–1199, 1195f, 1196f, 1196t–1198t
intensity-modulated, 1193, 1199
with nodal metastases, 1193, 1194t, 1195t
patient setup for, 1193, 1193f
postoperative, 1189, 1199–1201, 1200f, 1201f
toxicities of, 1188–1189, 1199
salvage, 1177
site-specific considerations for, 1208–1219
surgical, 1192–1193, 1192f
complications of, 1177
Head and neck squamous cell carcinoma (HNSCC) (*cont.*)
treatment for (*cont.*)
targeted therapy and novel approaches to, 1207–1208
tumor biology of, 1185–1186
Headache, due to brain tumor, 1080–1081
Health Insurance Plan (HIP) of Greater New York study, of breast cancer screening, 1884–1886, 1887t
Health insurance reimbursement, for clinical trials, 338
Healthy worker effect, 350
Hearing loss, due to cisplatin, 949
Heart, radiation tolerance dose of, 435t
Heart disease, in carcinoid syndrome, 1291
Heart failure, congestive. *See* Congestive heart failure (CHF).
Heat shock protein 70 (Hsp70), in gene therapy, 520
Heat shock protein 90 (Hsp90)
as molecular target, 487t
in molecularly targeted therapy, 496
Heat treatment, for lymphedema, 652
Heavy-chain disease(s) (HCDs), 2345–2346
α-Heavy-chain disease (α-HCD), 2345
γ-Heavy-chain disease (γ-HCD), 2345
μ-Heavy-chain disease (μ-HCD), 2345–2346
Helical CT, of hepatic metastases, 1493f
Helical CT angiography, of pulmonary embolism, 706
Helical CT venography, of lower-extremity deep venous thrombosis, 701
Helicases, 148
Helicobacter pylori
and gastric cancers, 223, 228, 387, 1432
and MALT lymphomas, 223, 228, 2372, 2385
Hemangioblastomas
cerebellar, 1115
spinal, 1118, 1119
Hemangiomas, hepatic, *vs.* liver metastases, 888, 889f
Hemangiopericytoma, 2045
Hemangiosarcoma, 2045
Hematogenous metastases, of non-small cell lung cancer, 1333
Hematogenous spread, metastasis via, 816
Hematologic malignancies
during pregnancy, 1056–1058
WHO classification of, 2131–2136, 2133t, 2134b–2135b
Hematologic tumors, specimen for cytogenetic analysis of, 250
Hematolymphoid neoplasms
Ewing's sarcoma vs., 2086t
molecular diagnostics for, 267–270
with bone marrow transplantation, 269–270
chromosomal translocations in, 268–269, 268t
gene mutations in, 270
gene rearrangement assays in, 267–268, 268f, 268t
polymerase chain reaction in, 270

Hematopoiesis
extramedullary, due to primary myelofibrosis, 2274
radiation effects on, 434t
Hematopoietic cell transplantation (HCT). *See* Hematopoietic stem cell transplantation (HSCT).
Hematopoietic growth factors
for acute lymphocytic leukemia, 2196
for infection, 723–724
Hematopoietic stem cell(s) (HSCs), 95
acquisition and processing of, 504
long-term, 95–96, 96f
multipotent, 95–96, 96f
properties of, 95–96, 96f
self-renewal in, 95–96
genetic regulation of, 96–97
short-term, 95–96, 96f
as targets for malignant transformation, 97–99, 98f
Hematopoietic stem cell transplantation (HSCT), 501–509
for adult T-cell leukemia-lymphoma, 2438
allogeneic, 501–504, 502t
for adult T-cell leukemia-lymphoma, 2438
for follicular lymphoma, 2385
infection prevention with, 729t, 730, 730t, 731f
for leukemia
acute lymphocytic, 2200–2202, 2201t
acute myeloid, 2226–2228
chronic lymphoid, 2304, 2304t
chronic myeloid, 2285–2286, 2286f
for multiple myeloma, 2337–2338
for myelodysplastic syndrome, 2242, 2247–2250, 2247t, 2249t
autologous, 501, 502t, 504
for Ewing's sarcoma, 2091
infection prevention with, 729t
for leukemia
acute lymphocytic, 2201, 2202
acute myeloid, 2226, 2228
chronic lymphoid, 2304
for lymphoma
diffuse large B-cell, 2389–2390
follicular, 2385
mantle cell, 2391
relapsed aggressive B-cell, 2394
for multiple myeloma, 2323, 2336–2338, 2337t
for myelodysplastic syndrome, 2250
for primary amyloidosis, 2344
for breast cancer, 507
complications after, 507–509, 508t
defined, 501
for Ewing's sarcoma, 2091
for germ cell tumors, 507
graft rejection after, 507
graft-versus-host disease after, 502, 503, 508, 508t
haploidentical, 503
for acute lymphocytic leukemia, 2202
for myelodysplastic syndrome, 2251
history of, 501–502, 502f
indications for, 504–507, 505f
Hematopoietic stem cell transplantation (HSCT) (*cont.*)
for leukemia
acute lymphocytic, 505–506, 2200–2203, 2201t, 2203t
acute myeloid, 505, 2226, 2228
in children, 2158
chronic lymphoid, 506, 2304, 2304t
chronic myeloid, 506, 2285–2286, 2286f
for lymphoma
in children, 2185
cutaneous T-cell, 2420
diffuse large B-cell, 2389–2390
follicular, 2385
Hodgkin's, 506
mantle cell, 2391
non-Hodgkin's, 506
relapsed aggressive B-cell, 2394
lymphoma after, 227
matched unrelated donor, for acute lymphocytic leukemia, 2201, 2202
for multiple myeloma, 506, 2323, 2336–2338, 2337t
for myelodysplastic syndrome, 505, 2242, 2247–2251, 2247t, 2249t
for myeloproliferative disorders, 506
for neuroblastoma, 507
nonmyeloablative, for acute lymphocytic leukemia, 2201–2202
during pregnancy, 1056
for primary amyloidosis, 2344
for primary myelofibrosis, 2273
for renal cell carcinoma, 507, 1629
second malignancies after, 509
for soft tissue sarcomas, 507
syngeneic, 501, 504
tandem, for multiple myeloma, 2337, 2337t
for testicular cancer, 1733, 1734f, 1736
types of, 502–504
vaccines after, 730, 730t
Hemicolectomy, 1502–1503, 1502f, 1503f
Hemiplegia, rehabilitation for, 581–582
Hemochromatosis, hyperpigmentation due to, 632
Hemodialysis
for hypercalcemia of malignancy, 746
for tumor lysis syndrome, 763
Hemoglobin (Hb)
in acute lymphocytic leukemia, 2195t
optimal level of, 680
Hemorrhage
anticoagulation-related, 698
gastrointestinal, 791–793, 793f
due to cytotoxic agents, 793–794
intra-abdominal, 793, 793f
due to vascular access device, 786–787
HEPA (high-efficiency particulate air) filtration, 733
Heparin(s)
low-molecular-weight
cancer patient response to, 699
long-term therapy with, 703–704, 704t
for thromboprophylaxis, 711
for venous thromboembolic disease, 694, 703–704
Heparin(s) (*cont.*)
unfractionated
cancer patient response to, 699
for deep venous thrombosis, 703
for pulmonary embolism, 707
for thromboprophylaxis, 709
Heparin flushing, of catheters, 710
Heparin resistance, 697
Heparin-induced thrombocytopenia (HIT), 697
Hepatectomy
for gallbladder cancer, 1583–1584
for hepatocellular carcinoma, 1573t, 1574, 1574t
Hepatic arterial radioisotopes, for liver metastases, 915
Hepatic artery embolization (HAE), 885, 908–909, 908f
chemo-, 909–910
complications of, 909, 909t
for hepatocellular carcinoma, 1576
Hepatic artery infusion (HAI)
for hepatocellular carcinoma, 907t, 1578
for liver metastases, 885, 898–905
adjuvant, 896–898, 896f, 897t
drugs for, 899, 899t
efficacy of, 904–905, 905t
with external pump, 899, 899t
increased response rate and decreased extrahepatic disease with, 902–903
with internal pump, 899, 900t
complications of, 904, 904b
randomized studies of, 899–902, 900f, 901f, 901t
rationale for, 898–899, 899t
as second-line therapy, 904, 905f, 906t
toxicity of, 902–904, 903t, 904b
for other tumor types, 905, 906t, 907t
Hepatic artery ligation (HAL), 908, 909t
Hepatic artery occlusion (HAO), for carcinoid tumors, 1294
Hepatic arylamine *N*-acetyltransferase, and susceptibility, 134
Hepatic flexure, 1499
Hepatic hemangiomas, vs. liver metastases, 888, 889f
Hepatic involvement, in adult T-cell leukemia-lymphoma, 2429
Hepatic mesenchymal hamartoma (HMH), cytogenetic aberrations in, 258t
Hepatic metastases. *See* Liver metastasis(es).
Hepatic resection, for metastatic disease, 885, 888–898
adjuvant therapy after, 896–898, 896f, 897t
from breast cancer, 890–891
chemotherapy downstaging prior to, 894, 905–908, 907t
from colorectal cancer, 892, 892t–894t, 896
Couinaud's hepatic anatomic segments in, 889, 890f
drainage after, 890
with extrahepatic metastases, 894–895
from GI neuroendocrine tumors, 891
guidelines for, 891b
historical background of, 888–889
indications for, 890

Hepatic resection, for metastatic disease (*cont.*)
margin of, 893, 894t
from melanoma, 891–892
new devices and techniques in, 889
prognostic variables for, 892, 893, 893t
relapse rates after, 895, 895t
repeat, 895, 895t
from sarcomas, 891
for synchronous metastases, 896
Hepatic segments, 889, 890f
Hepatic transplantation
for cholangiocarcinoma, 1589
for hepatocellular carcinoma, 1573t, 1574–1575
Hepatitis, radiation, 915
Hepatitis B virus (HBV), 156–157
and aflatoxins, 129
genome of, 156–157, 157f
and hepatocellular carcinoma, 156–157, 387, 1570
life cycle of, 157
and transplantation, 732
vaccine for, 164
Hepatitis C virus (HCV), 160–161
genome of, 161, 161f
and hepatocellular carcinoma, 87, 160–161, 387
and transplantation, 732
treatment of, 161
Hepatoblastoma, 2077–2078, 2113–2116
clinical manifestations and pattern of spread of, 2077, 2114
cytogenetic aberrations in, 258t
differential diagnosis of, 2077
epidemiology of, 2077, 2113
etiology of, 2077
laboratory and radiologic evaluation of, 2114
pathology of, 2077, 2113
recurrence of, 2116
staging of, 2077–2078, 2114, 2114t, 2115f
treatment of, 2078, 2114–2116, 2115b
tumor biology of, 2077, 2113
Hepatocellular carcinoma (HCC), 1569–1579
clinical presentation and evaluation for, 1569, 1570
diagnostic studies for, 1571–1572, 1571f, 1571t, 1572f
differential diagnosis of, 1569
epidemiology of, 1569–1570
etiology and pathogenesis of, 1569, 1570
follow-up program for, 1579
future issues with, 1579
hepatitis B virus and, 156–157, 387, 1570
hepatitis C virus and, 87, 160–161, 387
imaging of, 301, 303f, 1571–1572, 1571f, 1572f
incidence of, 1569–1570
infectious etiology of, 363t
metastatic, 1570
pathology of, 1569, 1570
prevention of, 387
prognosis for, 1569, 1572–1574, 1573t, 1574t
recurrence of, 1570, 1574, 1578
risk factors for, 387
screening tests for, 1570–1571
Hepatocellular carcinoma (HCC) (*cont.*)
staging classification for, 1572, 1572t
treatment of, 1569, 1574–1579, 1578b
adjuvant, 1578
chemotherapy for, 898, 1576–1577
adjuvant, 898, 1578
intra-arterial, 907t, 1578
complications of, 1578
cryosurgery for, 1575, 1576f
ethanol injection for, 1575, 1577f
hepatic artery embolization for, 1576
microwave ablation for, 1575
novel therapies for, 1577–1578
partial hepatectomy for, 1573t, 1574, 1574t
primary, 1569, 1574–1578
radiofrequency ablation for, 1575, 1576f
for recurrence, 1578
salvage, 1569
total hepatectomy and transplantation for, 1573t, 1574–1575
tumor biology of, 1569, 1570
tumor marker for, 278–279
vascular invasion by, 1571, 1572f
Hepatocyte growth factor (HGF), in metastasis, 36
Hepatosplenic candidiasis, 726
Hepatosplenic T-cell lymphoma, 2394
Hepcidin, in anemia, 677, 678f
HER2
in breast cancer, 1875, 1880, 1881
and adjuvant systemic therapy, 1918, 1920–1921, 1922t, 1923t
metastatic, 1932
as prognostic factor, 1916–1917
in carcinoma of unknown primary, 2062
and monoclonal antibodies, 539
mutations in, 211t
in osteosarcoma, 2084
Herbal medicine, 546b, 548, 552–553, 552b
regulation of, 548
usage of, 548
Herceptin. *See* Trastuzumab (Herceptin).
Hereditary cancer, 194
Hereditary cancer predisposition syndromes. *See* Cancer predisposition syndromes.

of breast cancer, 860, 861t, 862–863
of multiple myeloma, 863
for hypercalcemia of malignancy, 744, 745
IBD (inflammatory bowel disease), and colorectal cancer, 1483
Ibritumomab tiuxetan (Zevalin), 453, 470
for follicular lymphoma, 2384
for lymphoma, 535–536, 536t
ICE regimen
for Hodgkin's lymphoma, 2365
for relapsed aggressive B-cell lymphoma, 2394
ICF (intracellular fluid), tonicity of, 750
ICF (intracellular fluid) compartment, in hyponatremic states, 752f
ICP (intracranial pressure), increased, due to brain tumor, 1080, 1080f, 1082–1083
ICR (Immunodeficiency Cancer Registry), 224–225, 225t
ICRF-187 (dexrazoxane), 466
for cardioprotection, 989, 989f, 992b
ICSI (intracytoplasmic sperm injection), 1008
ICTP (pyridinoline cross-linked C-terminal telopeptide of type I collagen), as bone resorption marker, 853
Id genes, in melanoma, 1233
Idarubicin (Idamycin, 4-demethoxydaunorubicin), 470
for acute myeloid leukemia, 2225, 2227b
in children, 2155
IDO (indolamine-2,3 dioxygenase), in tumor microenvironment, 86
IELs (intraepithelial lymphocytes), in tumor immune surveillance, 80–81, 81f
IESS (Intergroup Ewing Sarcoma Study), 2088, 2089t
IFE (immunofixation), for multiple myeloma, 2328–2329, 2328f
IFN(s). *See* Interferon(s) (IFNs).
IFN-α. *See* Interferon-α (Intron A, Roferon, α-interferon, IFN-α).
Ifosfamide (Ifex), 470
congestive heart failure due to, 990
for Ewing's sarcoma, 1985, 2088
for head and neck cancer prevention, 1206–1207
hyperpigmentation due to, 632
neurotoxicity of, 949
for osteosarcoma, 1954, 1955, 2082–2084
for small cell lung cancer, 1348, 1349t
for soft-tissue sarcoma, 2029, 2029t, 2030, 2034–2036
for synovial sarcomas, 2045–2046
for testicular cancer, 1736
IFP (interstitial fluid pressure), 113–115, 114f–115f, 115t, 116f
IFRT (involved-field radiation therapy), for Hodgkin's lymphoma, 2363t, 2364t
Ig. *See* Immunoglobulin (Ig).
IGCCCG (International Germ Cell Cancer Collaborative Group), 1730–1731, 1731t
IGF-1 (insulin-like growth factor 1), in osteosarcoma, 2079
IGF-1R, as molecular target, 486t
IGF2 gene, and hepatoblastoma, 2113
IGFBP3, as molecular target, 487t
IGH gene(s), in childhood leukemia, 2159
IGH gene breakpoints, in Burkitt's lymphoma, 2174
IGS (invasiveness gene signature), 101
IHC (immunohistochemistry), 235–237, 236f
for carcinoma of unknown primary, 2064–2065, 2065t, 2066f
IHT (insulin-induced hypoglycemia therapy), 557, 1017
IκB kinase (IKK)
in active mediation of tumor–immune system interactions, 84, 87
in apoptosis, 68f, 71, 72f
IL(s). *See* Interleukin(s) (ILs).
Ileal colic reservoir, for bladder cancer, 1642
Ileocecal valve, 1499
Ileus
adynamic, 795
after colon cancer surgery, 1508
Iliac lymph node dissection, for melanoma, 1240
ILND (inguinal lymph node dissection)
for melanoma, 1240
for penile cancer, 1706–1707
ILP (isolated lung perfusion), for pulmonary metastases, 882
ILSG (International Lymphoma Study Group), 2132–2133
Imagery, guided, 551–552
Imaging, 283–306
accuracy of, 285–286, 285f
anatomic, 291
anatomolecular, 283
to assess suitability for aggressive therapy, 304
disease-specific recommendations on, 283, 291–304
for adrenal masses, 294, 294f, 302
for bladder carcinoma, 300
for brain tumors, 304, 304f
for breast cancer, 294–295, 295f
for colon cancer, 297–298, 297f
for endocrine tumors, 302–304, 303f
for esophageal and gastric cancer, 304
for gastrointestinal stromal tumors, 304
for gynecologic neoplasms, 298, 298f
for head and neck cancer, 300, 301f
for kidney cancer, 301–302, 303f
for liver cancer, 301, 303f
for lung cancer, 283, 292–294, 293f, 294f
for lymphoma, 298–299, 299f
for melanoma, 299–300
for pancreatic carcinoma, 300–301, 302f
for pediatric tumors, 304
for prostate cancer, 283, 295–297, 296f
for sarcomas, 304
emerging opportunities in, 283–284, 305, 305t
functional, 291, 305
general considerations for, 284–288, 285f
for guidance of radiation therapy, 304–305
for interventional procedures, 305
metrics for, 284–286, 285f
modality(ies) of, 283, 288–291, 291t
angiography as, 288–289, 291t
computed tomography as, 283, 288, 291t
magnetic resonance imaging as, 283, 289–290, 289b, 290f, 291t
magnetic resonance spectroscopy as, 289
mammography as, 283, 288, 291t
nuclear medicine as, 283, 290–291, 291t
optical, 291
plain film x-rays as, 283, 288, 291t
positron emission tomography as, 283, 290–291, 291t
SPECT as, 283, 290–291, 291t
ultrasound as, 289, 291t
positive and negative predictive values of, 284t, 285
during pregnancy, 1050–1051, 1050t
receiver operator characteristic curves for, 285–286, 285f
robustness of, 285–286
for screening, 286–287

Imaging (*cont.*)
sensitivity of, 284–286, 284t, 285f
size of lesions detectable by, 287–288
specificity of, 284t, 285–286, 285f
in staging, 288
uses for, 283, 284, 284t
Imaging probes, for molecularly targeted therapy, 493–494, 494t
Imatinib mesylate (Gleevec), 452, 470–471, 485–487
for acute lymphocytic leukemia, 2207–2208
bowel perforation and hemorrhage due to, 793–794
for chronic myeloid leukemia, 324, 2284–2285
mechanism of action of, 2284, 2284f
monitoring of, 2283, 2285
prognosis with, 2283, 2284f
resistance to, 2286–2288, 2287f, 2289
results of, 2284–2285, 2285t, 2288
side effects of, 2285
congestive heart failure due to, 990–991
for GISTs, 1473, 2041
for melanoma, 1246
during pregnancy, 1006, 1052t, 1058
thyroid dysfunction due to, 1017
IMC-C225, for head and neck cancer, 1207–1208
Imidazole carboxamide. *See* Dacarbazine (DTIC-Dome, DTIC, DIC, imidazole carboxamide).
Imidazoquinolines, cutaneous reactions to, 637
Imiquimod (Aldara), cutaneous reactions to, 637
Immature myeloid cells (iMCs), in tumor microenvironment, 85–86
Immune associations, in paraneoplastic neurologic syndromes, 767–768, 768t
Immune deficiency. *See* Immunodeficiency.
Immune evasion, 81–83, 83f
as signature trait of cancer cells, 215, 216f
Immune resistance, 79f
as signature trait of cancer cells, 215, 216f
Immune response
procarcinogenic *vs.* anticarcinogenic roles of, 87–88, 88f
to tumor cells, manipulation of, 88–89, 89b
Immune surveillance
evidence pro and con for, 78–80, 79f
importance of, 79b
innate immunity, epithelial immunity, and, 80–81, 81f
Immune system–tumor interactions, active mediation by oncogenic pathways of, 84–85
Immune thrombocytopenic purpura, 683
Immune tolerance, 78, 79f, 81–83, 83f, 86–87
Immunity, and tumor immune surveillance
epithelial, 80–81, 81f
innate, 80–81, 81f
Immunoaugmentative therapy (IAT), 555, 558t
Immuno-Augmentive Centre, 558t
Immunocompromised hosts, nonmelanoma skin cancer in, 1260–1261
Immunoconjugates, 453, 534–538
with bispecific antibodies, 538
immunocytokines as, 537
immunoenzymes as, 537
immunoliposomes as, 537–538
immunotoxins as, 537
radio-, 535–537, 535t, 536t
Immunocytokines, with monoclonal antibodies, 537
Immunodeficiency
and cancer, 223–230
in genetic disorders of DNA repair, 229–230, 229t
historical background of, 223–224
incidence of, 79–80
infection with, 224
and carcinomas, 225t, 228–230, 228b, 229t
common variable
as cancer predisposition syndrome, 175t
lymphoma with, 225t, 226t
tumor distribution with, 225t
and lymphomas, 224–228, 225t, 226t
childhood, 2172–2173
clinical characteristics of, 224–226, 225t
contributors to increased risk of, 224
with Epstein-Barr virus, 224, 225, 227, 228
after hematopoietic stem cell transplantation, 227
with HIV infection, 228
primary, 226–227, 226t
after solid-organ grafting, 227–228
treatment of, 226
and second malignant neoplasms, 1028–1029
severe combined (*See* Severe combined immunodeficiency [SCID])
Immunodeficiency Cancer Registry (ICR), 224–225, 225t
Immunodeficiency syndrome(s)
acquired (*See* Human immunodeficiency virus [HIV])
as cancer predisposition syndromes, 175t–176t
Immunoenzymes, with monoclonal antibodies, 537
Immunofixation (IFE), for multiple myeloma, 2328–2329, 2328f
Immunoglobulin A (IgA) deficiency, 225t, 226t
Immunoglobulin G (IgG), Fc receptors of, 531–533, 532t, 538
Immunoglobulin light-chain (AL) amyloidosis, 2324, 2343–2344
classification of, 2343, 2343t
diagnosis of, 2325t, 2343–2344
prognosis for, 2344, 2344t
treatment of, 2344
Immunoglobulin variable gene region (IgV), in chronic lymphoid leukemia, 2294, 2297, 2298
Immunohistochemistry (IHC), 235–237, 236f
for carcinoma of unknown primary, 2064–2065, 2065t, 2066f
Immunoliposomes, with monoclonal antibodies, 537–538
Immunologic characteristics, of tumor microenvironment, 78, 85–87, 85f
Immunology, 77–89
clinical implications for manipulation of immune response to tumor cells in, 88–89, 89b
immune surveillance in
evidence pro and con for, 78–80, 79f
importance of, 79b
innate immunity, epithelial immunity, and, 80–81, 81f
immune tolerance and immune evasion in, 81–83, 83f
immunologic characteristics of tumor microenvironment in, 78, 85–87, 85f
oncogenic pathways mediating tumor–immune system interactions in, 84–85
overview of, 77
procarcinogenic vs. anticarcinogenic roles of immune response in, 87–88, 88f, 89f
regulatory T cells in, 83–84
tumors vs. self tissues in, 77–78
Immunomodulators
for myelodysplastic syndrome, 2243–2245, 2244t
during pregnancy, 1006
pulmonary toxicity of, 978
Immunophenotyping, 241–246
of acute leukemia, 242–243, 242b, 242f, 243f
future of, 246
of lymphoma and lymphoproliferative disorders, 242b, 243–246, 245f
methods of, 241–242
of myelodysplasia and chronic myeloproliferative disorders, 243
Immunoreceptor tyrosine kinase–based inhibitory motif (ITIM), in tumor immune surveillance, 80
Immunosuppression
and cervical cancer, 386
and second malignant neoplasms
in adults, 1033
in children and adolescents, 1028
and tumor incidence, 79
Immunotherapy, 88–89, 89b
adoptive, 1245
for chronic lymphoid leukemia, 2303
for colorectal cancer, 1525
endocrine effects of, 1016–1017
for liver metastases, 912
for melanoma, 1241–1245
for prostate cancer, 1688–1689
Immunotoxins, with monoclonal antibodies, 537
Impairments, 580b
rehabilitation for, 580–586
Implantable infusion/injection ports, 780, 781f, 782f
guidelines for, 782t
placement of, 784, 786f
Implantation, 1049
IMRT. *See* Intensity-modulated radiation therapy (IMRT).
Imuran (azathioprine), 461

In vivo modeling, of cancer, 15–17, 16f, 17f
Inactivating mutations, 208, 210
Inbred populations, linkage analysis of, 196
^{111}In-capromab pendetide immunoscintigraphy, of prostate cancer, 1666
Incidence, cumulative, 350–352, 351f
Incidence density sampling, 353
Incidence rate, 351–352, 352f
Incidental pain, 575
Incisional biopsy, 411
  of osteosarcoma, 1948b
Incontinence
  due to brain tumor, 1081
  after radical prostatectomy, 1669
  rehabilitation for, 585, 586t
Incremental cost-effectiveness ratio, 338–339
IND (Investigational New Drug) studies, of molecularly targeted therapy, 492
Independent assortment, and linkage analysis, 196
Indiana pouch, for bladder cancer, 1642
Indiana regimen, for testicular cancer, 1731
Indirect costs, 337
Individual matching, 357
Indolamine-2,3 dioxygenase (IDO), in tumor microenvironment, 86
Indomethacin, for hypercalcemia of malignancy, 746
Inducible promoters, for gene therapy, 520–522, 521t
Induction chemoradiation therapy, for non–small cell lung cancer, 1332
Induction chemotherapy
  for acute lymphocytic leukemia, 2197
    in children, 2152–2153
  for acute myeloid leukemia, 2224–2226, 2227b
    in children, 2155
  for acute promyelocytic leukemia, 2228, 2228b
  for head and neck cancer, 1202–1204, 1203f
  for myelodysplastic syndrome, 2246–2247
  for non-small cell lung cancer, 1329, 1332, 1335–1336
    concurrent chemoradiation therapy with, 1338–1339, 1338t
Industry-sponsored clinical trials, 331–333
Infant(s)
  acute lymphoblastic leukemia in, 2154
  brain tumors in, 1127
Infantile monosomy 7 syndrome, 2140, 2150
Infection(s), 717–733
  adjunctive therapies for, 723–724
  in adult T-cell leukemia-lymphoma, 2429, 2430t, 2438
  bacteremia as, 724
  catheter-related, 727, 787
  central nervous system, 727
  empirical antibiotic therapy for, 720–723
    duration of, 723
    general principles for, 720–721
    subsequent modifications of, 722–723
    for unstable patients, 722
    vancomycin or other gram-positive agents for, 721–722, 722t
Infection(s) (*cont.*)
  empirical antifungal therapy for, 723
  entry-site, 727
  food-borne, 718, 733
  fungal, 723, 725–726
  gastrointestinal, 726–727
  granulocyte transfusions for, 724
  hematopoietic growth factors for, 723–724
  with immunodeficiency and cancer, 224
  initial evaluation of, 680
  in leukemia
    acute lymphocytic, 2196
    chronic lymphoid, 2298–2299, 2302
    hairy cell, 2310
  in multiple myeloma, 2340
  neutropenia and, 719–720, 681–682
    approach to, 719, 719t
    in elderly, 1046
    relationship between, 717–718, 718f

International Lymphoma Study Group (ILSG), 2132–2133
International Neuroblastoma Staging System (NSS), 2094
International Prognostic Score (IPS), for Hodgkin's lymphoma, 2360, 2360t
International Prognostic Scoring System (IPSS), for myelodysplastic syndrome, 2240–2242, 2241t
International Prostate Symptom Score (I-PSS), 1675
International Staging System (ISS), for multiple myeloma, 2330
International Union Against Cancer (UICC) staging system, for soft-tissue sarcoma, 2018–2019, 2019t
Internationally important cancers, 387
Internet, and complementary and alternative medicine, 556, 557b, 557t
Interphase, 56f
Interstitial brachytherapy, 439
for endometrial cancer, 1819
Interstitial fluid, 111, 112
Interstitial fluid pressure (IFP), 113–115, 114f–115f, 115t, 116f
Interstitial hypertension, 113–115, 115t, 116f
Interstitial matrix, 111
Interstitial space, 112
Interstitial transport, 112, 113f
Interstrand cross-link repair, 149
Interviewer bias, 357
Intestinal obstruction, 791, 795–797, 796f
due to ovarian cancer, 1848
Intra-abdominal deep vein thrombosis, 707
Intra-abdominal hemorrhage, 793, 793f
Intra-arterial (IA) chemotherapy
for cholangiocarcinoma, 1590
for hepatocellular carcinoma, 907t, 1578
for soft-tissue sarcoma, 2029–2030
Intracavitary brachytherapy, 439
Intracellular fluid (ICF), tonicity of, 750
Intracellular fluid (ICF) compartment, in hyponatremic states, 752f
Intracellular signaling, 21–29
adaptor or scaffolding proteins in, 22, 25
applications of, 28
clinical relevance of, 21–22, 28
cross-talk in, 22
cytokine receptors in, 24
cytoplasmic serine/threonine kinases in, 25–26, 25f, 26f
cytoplasmic tyrosine kinases in, 25
Frizzled receptors in, 24
G protein–coupled receptors in, 22
general principles of, 22, 23f
inside-out, 23–24
integrin receptors in, 23–24
lipid signaling in, 26–27, 26f
negative regulators of, 27
Notch receptors in, 24
nuclear hormone receptors in, 24
platelet-derived growth factor receptor in, 27–28, 27f
receptor activation by ligand in, 22–24
Intracellular signaling (*cont.*)
receptor tyrosine kinases in, 22–23, 27–28, 27f
serine/threonine kinase receptors in, 23
transforming growth factor β receptor in, 23, 28
tumor necrosis factor receptor in, 24, 28
Wnt signaling in, 28, 29f
Intracellular signaling pathways
components of, 25–27, 25f, 26f
examples of, 27–28, 27f, 29f
Intracranial germ cell tumors, 1125–1126, 1126t
Intracranial herniation, due to brain tumor, 1080, 1080f, 1081t
Intracranial pressure (ICP), increased, due to brain tumor, 1080, 1080f, 1082–1083
Intracytoplasmic sperm injection (ICSI), 1008
Intraductal papillary mucinous neoplasms (IPMN), 1598
Intraepithelial carcinoma, endometrial, 1797, 1797f
Intraepithelial lymphocytes (IELs), in tumor immune surveillance, 80–81, 81f
Intraepithelial neoplasia, 362, 362t, 363f
Intramedulary osteosarcoma, low-grade, 2080
Intraocular components, radiation toxicity in
anterior, 1139–1141, 1140f, 1141f
posterior, 1141, 1142f
Intraocular lymphoma, 1148–1150, 1149f
Intraocular tumor(s), 1137, 1143–1154
classification of, 1138t
leukemia as, 1147–1148, 1149f
lymphoma as, 1148–1150, 1149f
metastatic, 1147, 1148b, 1148f
retinoblastoma as, 1150–1154
classification of, 1152, 1153t
clinical features of, 1150–1152, 1151f, 1322f
differential diagnosis of, 1153
management of, 1153–1154, 1153f
pathogenesis of, 1150
uveal melanoma as, 1143–1147
classification of, 1143t
clinical features of, 1143–1145, 1143f–1145f
differential diagnosis of, 1145
management of, 1145–1147, 1146b, 1146t, 1147f
pathogenesis of, 1143
Intraoperative consultation, pathology in, 235, 235b
Intraoperative radiation therapy (IORT)
for rectal cancer, 1550, 1551, 1551t
for retroperitoneal sarcomas, 2040
Intraoperative ultrasound
of brain tumors, 1085
of hepatic metastases, 1491, 1492f
Intrapericardial sclerosing agents, for pericardial effusion, 936–937
Intraperitoneal chemotherapy
for gastric cancer, 1442, 1453–1454
for ovarian cancer, 1839–1840
Intraperitoneal therapy, for ascites, 940–941

Intrapleural therapy
for mesothelioma, 1376–1377
for pleural effusion, 932
Intra-S phase checkpoint, 58f, 59
Intraspinal opioids, 572
Intrathecal chemotherapy
for acute lymphocytic leukemia, 2199
for neoplastic meningitis, 840–841
Intrauterine insemination, 1008
Intravasation, 110
in metastasis, 34f, 38
Intravascular brachytherapy, 439
Intravascular stents, for superior vena cava syndrome, 810–812, 810f, 810t
Intravenous immune globulin (IVIG), for cytomegalovirus, 728
Intravenous (IV) solutions, sodium content of, 755b
Intravesical treatments, for bladder cancer, 1640–1641
Intrinsic gene set, for breast cancer, 1880, 1881, 1881f
Introducer kit, for insertion of vascular access device, 784, 786f
Intron(s), 10f
Intron A. *See* Interferon-α (Intron A, Roferon, α-interferon, IFN-α).
Intubation, prolonged, grading of, 972t
Intussusception, 106, 106f
Inv(16), in acute myelogenous leukemia, 2218
Invasion, in metastasis, 34f, 35–38
Invasive capacity, as signature trait of cancer cells, 215, 216f
Invasive migration, in metastasis, 36–38, 37f, 37t
Invasive mole
epidemiology of, 1859
pathology of, 1860, 1860f
Invasive therapy, for pain management, 572–573
Invasiveness gene signature (IGS), 101
Inverse planning, 440–441
Investigational New Drug (IND) studies, of molecularly targeted therapy, 492
Involuntary movement, grading of, 959t
Involved-field radiation therapy (IFRT), for Hodgkin's lymphoma, 2363t, 2364t
Iodine 125, 419
Iodine uptake, in thyroid cancer, 1275
Iodine-131 tositumomab. *See* Tositumomab (Bexxar, anti-CD20).
Ionizing radiation. *See also* Radiation.
brain tumors due to, 1031, 1076–1077
and breast cancer, 1025, 1031, 1031t, 1877
as carcinogen, 130–131, 131t
fetal exposure to, 1050
IORT (intraoperative radiation therapy)
for rectal cancer, 1550, 1551, 1551t
for retroperitoneal sarcomas, 2040
Ipilimumab, 539
IPMN (intraductal papillary mucinous neoplasms), 1598
Iproplatin, for ovarian cancer, 1846
IPS (International Prognostic Score), for Hodgkin's lymphoma, 2360, 2360t
IPSS (International Prognostic Scoring System), for myelodysplastic syndrome, 2240–2242, 2241t
I-PSS (International Prostate Symptom Score), 1675
IRBs (institutional review boards), 329–330
Iridium 192, 419
Irinotecan hydrochloride (Camptosar, camptothecin-11, CPT-11), 471
for adult T-cell leukemia-lymphoma, 2436–2437
for astrocytoma, 1102
for carcinoma of unknown primary, 2071
for colorectal cancer, 1516, 1523–1524
for esophageal cancer, 1421, 1422
for gastric cancer, 1457
for liver metastases
adjuvant, 897, 898
intrahepatic, 899
neoadjuvant, 906, 907t, 908
during pregnancy, 1053
for rectal cancer, 1547–1548
for small cell lung cancer, 1349–1350, 1349t
Iris, radiation toxicity in, 1139
Iron deficiency, due to erythropoiesis-stimulating proteins, 678–680, 679t, 680f
Iron preparations, parenteral, 679, 679t
Irritability, grading of, 959t
IRSG (Intergroup Rhabdomyosarcoma Study Group), 2105
Islet cell tumor(s), 1271–1272, 1294–1299
diagnosis of, 1271–1272, 1295–1296, 1295f
gastrinoma as, 1295f, 1297, 1298
ghrelinoma as, 1298
glucagonoma as, 1295f, 1296
incidence of, 1271
insulinoma as, 1295f, 1296, 1298
with MEN-1, 1289
pathology of, 1294–1295
somatostatinoma as, 1295f, 1296–1297
treatment of, 1272, 1298–1299
VIPoma as, 1295f, 1297
Isocentric radiation treatments, 437–438
Isolated limb perfusion/infusion, for melanoma, 1241
Isolated lung perfusion (ILP), for pulmonary metastases, 882
Isolated populations, linkage analysis of, 196
Isolated tumor cells (ITCs), in colorectal cancer, 1497
Isolation perfusion, for liver metastases, 911
Isolation procedures, 733
Isotretinoin (Accutane, 13-cis-retinoic acid, 13-CRA), 471–472
for chemoprevention of oral cancer, 368
for prevention of skin cancer, 382
Isovolemia, hyponatremia with, 753–755, 753t, 757
ISS (International Staging System), for multiple myeloma, 2330
ITCs (isolated tumor cells), in colorectal cancer, 1497
ITDs (internal tandem duplications), in childhood leukemia, 2149, 2152
ITIM (immunoreceptor tyrosine kinase–based inhibitory motif), in tumor immune surveillance, 80
IUCC (International Union Against Cancer) staging system, for soft-tissue sarcoma, 2018–2019, 2019t
IV (intravenous) solutions, sodium content of, 755b
IVC (inferior vena cava) filters, 698, 708
IVC (inferior vena cava) thrombosis, 707
IVIG (intravenous immune globulin), for cytomegalovirus, 728
Ivor-Lewis approach, for esophagogastrectomy, 1407

      with aberrant lymphoid or myeloid antigen expression, 2146
      erythroblastic, 2145, 2145t
      lymphoblastic (*See* Acute lymphocytic (lymphoblastic, lymphoid) leukemia (ALL), in children)
      megakaryoblastic, 2145, 2145t
      monocytic, 2145, 2145t
      myeloid (*See* Acute myeloid (myelogenous, myelocytic, myeloblastic, nonlymphoblastic) leukemia (AML), in children)
      myelomonocytic, 2145, 2145t
      rare, 2146
    of central nervous system, 2142, 2154–2158, 2156t–2157t
    classification of
      cytogenetic and molecular, 2146–2150, 2146f, 2148f
      immunologic, 2144–2146, 2144t, 2145t
      morphologic and cytochemical, 2142–2143, 2143f, 2143t
    clinical and laboratory features of, 2139, 2142
    differential diagnosis of, 2139, 2142
    epidemiology of, 2139, 2140, 2140t
    etiology of, 2139–2141
    future issues for, 2160
    juvenile myelomonocytic, 2140, 2142, 2150
    minimal residual disease in, 2158–2160, 2158t, 2159f
    morphologic and cytochemical analysis for, 2142–2143, 2143f, 2143t
    pathogenesis of, 2141–2142
    prognosis for, 2139, 2150–2152, 2151f
    relapse of, 2150
    risk factors for, 2140–2141, 2140t
    treatment of, 2139, 2152–2158, 2152t, 2156t–2157t
  chronic
    flow cytometry of, 245
    lymphocytic (*See* Chronic lymphocytic leukemia [CLL])
    myeloid (*See* Chronic myeloid (myelogenous, myelocytic) leukemia [CML])
    during pregnancy, 1057–1058
  hairy cell (*See* Hairy cell leukemia [HCL])
  immunodeficiency and, 225t
  monoclonal antibodies for, 533t, 534, 536
  ocular, 1147–1148, 1149f
  plasma cell
    cytogenetic aberrations in, 256t
    with HIV, 1067f
  predisposition syndromes for, 175t–176t
Leukemia(s) (*cont.*)
  prolymphocytic, 2296f, 2304–2305
  as second malignant neoplasm
    in adults, 1031–1033
    in children, 1026–1028, 1027f
  WHO classification of, 2131–2136, 2133t, 2134b–2135b
Leukemia cutis, in acute myeloid leukemia, 2223, 2224f
Leukeran. *See* Chlorambucil (Leukeran).
Leukine (sargramostim), 478. *See also* Granulocyte-macrophage colony-stimulating factor (GM-CSF).
  for neutropenia, 681–682
Leukocoria, in retinoblastoma, 1150, 1151f, 2110, 2110f
Leukocyte count, in acute lymphocytic leukemia, 2195, 2195t
Leukocytosis, 682
Leukoencephalopathy
  due to BCNU, 950
  due to cranial irradiation, 1088
  due to cytosine arabinoside, 946
  due to 5-fluorouracil, 949–950, 950f
  grading of, 959t
  due to methotrexate, 947, 947f
  radiation-induced necrotizing, 952
Leukomax (sargramostim), 478. *See also* Granulocyte-macrophage colony-stimulating factor (GM-CSF).
  for neutropenia, 681–682
Leukoplakia
  oral, 363f
    chemoprevention of, 366t, 368
  and penile carcinoma, 1702
  and skin cancer, 380
Leuprolide acetate (Lupron, leuprorelin acetate), 472–473
  for prostate cancer, 1683
  reproductive effects of, 1002
Leurocristine. *See* Vincristine (Oncovin, Vincasar, leurocristine, VCR).
Leustatin. *See* Cladribine (Leustatin, 2-chlorodeoxyadenosine, 2-CdA).
Levamisole
  leukoencephalopathy due to, 949–950, 950f
  for rectal cancer, 1544
Levorphanol, 570t
Leydig cell(s), 1000
Leydig cell dysfunction, due to radiation therapy, 999
LFS. *See* Li-Fraumeni syndrome (LFS).
LH (luteinizing hormone), 1000
L&H (lymphocytic and histiocytic) cells, in Hodgkin's lymphoma, 2356–2357, 2357t
Lhermitte's sign
  due to cisplatin, 948
  due to oxaliplatin, 949
  due to radiation therapy, 953
LHRH (luteinizing hormone–releasing hormone) agonists, for breast cancer, 1924, 1931
LHRH (luteinizing hormone–releasing hormone) analogs, for prostate cancer, 1681–1683, 1682f

LHRH (luteinizing hormone–releasing hormone) antagonists, for prostate cancer, 1682, 1682f
Lichen sclerosis, and penile carcinoma, 1702
Licorice, interactions with, 555t
Lidocaine, for pain management, 575
Lifestyle modification, for breast cancer prevention, 1883
Li-Fraumeni syndrome (LFS)
  and acute myelogenous leukemia, 2217
  brain tumors in, 1078t
  breast cancer in, 1879
  as cancer predisposition syndrome, 172, 173t, 177t
    for soft-tissue sarcoma, 2011, 2011t
  DNA damage in, 141t, 148
  and nonrhabdomyosarcoma soft-tissue sarcoma, 2105
  p53 gene and, 148
  and rhabdomyosarcoma, 2102
  second malignant neoplasms in, 1024, 1029
Li-Fraumeni–like syndrome, DNA damage in, 141t
Ligand, receptor activation by, in intracellular signaling, 22–24
Ligand binder, for monoclonal antibodies, 537
Ligand-directed liposomes, in gene therapy, 524
Ligand-directed targeting, of gene vectors, 523
Light microscopy, for carcinoma of unknown primary, 2064
Light, Richard, 928
Limb girth, measurement of, 644, 644b, 644f
Limb salvage reconstruction, for osteosarcoma, 1965–1973
  bone allografts in, 1965–1973, 1967f–1969f
  choice of, 1959
  of distal femur, 1971
  endoprostheses in, 1965, 1966f
  historical review of, 1948
  of pelvis, 1970–1971
  of proximal femur, 1971, 1972f
  of proximal humerus, 1970, 1970f
  of proximal tibia, 1971–1973
Limbic encephalitis, paraneoplastic, 768–770, 770f, 953
Limb-sparing procedures
  for osteosarcoma, 1948, 1958–1959, 2081
  rehabilitation after, 583–584
  for soft-tissue sarcomas, 2022, 2023f
Linear accelerators, radiation production from, 420, 420f–422f
Linear energy transfer (LET), low vs. high, 419, 419f
Linear quadratic model, 426, 426f, 426t
Linkage analysis, 194
  age at onset in, 194, 199, 200
  comparative genome hybridization for, 200
  expression arrays for, 200
  family collection for, 194–195, 195f
  genome-wide scans for, 196–202
  limitations and sources of error in, 198–199
  locus heterogeneity and, 195–196
  marker informativeness in, 196–198, 197f–199f
  measures of linkage for, 198–200, 198b
Linkage analysis (*cont.*)
  missing data in, 199
  nonparametric, 199–200
  positional cloning resources for, 200
  principles of, 196, 196f, 197f
  requirements for, 194
  suggestive, significant, and highly significant linkage in, 198
  tissue banks for, 200
Lintuzumab, for myeloid leukemia, 534
Lip cancer
  etiology and pathogenesis of, 1179
  treatment of, 1211–1212
Lipectomy, suction-assisted, for lymphedema, 652
Lipedema, 643
Lipid signaling, 26–27, 26f
Lipoma, cytogenetic aberrations in, 260t
Lipoprotein lipase (LPL), in cachexia, 592
Liposarcoma(s), 2012t, 2046
  cytogenetic aberrations in, 260t
Liposomes, in gene therapy, 518, 524
Liposuction, for lymphedema, 652
LIRB (local institutional review board), 329
Lister, Joseph, 408
Liver
  radiation effects on, 434t
  radiation tolerance dose of, 435t
  segments of, 889, 890f
Liver biopsy, ultrasound-guided, 1491, 1492f
Liver cancer, 1569–1579
  aflatoxins and, 128–129
  clinical presentation and evaluation for, 1569, 1570
  cytogenetic aberrations in, 258t
  diagnostic studies for, 1571–1572, 1571f, 1571t, 1572f
  differential diagnosis of, 1569
  epidemiology of, 1569–1570
  etiology and pathogenesis of, 1569, 1570
  follow-up program for, 1579
  future issues with, 1579
  hepatitis B virus and, 156–157, 387, 1570
  imaging of, 301, 303f, 1571–1572, 1571f, 1572f
  incidence of, 1569–1570
  metastatic, 1570
  pathology of, 1569, 1570
  prognosis for, 1569, 1572–1574, 1573t, 1574t
  recurrence of, 1570, 1574, 1578
  screening tests for, 1570–1571
  staging classification for, 1572, 1572t
  treatment of, 1569, 1574–1579, 1578b
    adjuvant, 1578
    chemotherapy for, 898, 1576–1577
      adjuvant, 898, 1578
      intra-arterial, 907t, 1578
    complications of, 1578
    cryosurgery for, 1575, 1576f
    ethanol injection for, 1575, 1577f
    hepatic artery embolization for, 1576
    microwave ablation for, 1575
    novel therapies for, 1577–1578
    partial hepatectomy for, 1573t, 1574, 1574t
    primary, 1569, 1574–1578
Liver cancer (*cont.*)
  treatment of (*cont.*)
    radiofrequency ablation for, 1575, 1576f
    for recurrence, 1578
    salvage, 1569
    total hepatectomy and transplantation for, 1573t, 1574–1575
  tumor biology of, 1569, 1570
  vascular invasion by, 1571, 1572f
Liver disease
  acral erythema with, 629
  fatty
    and hepatocellular carcinoma, 1570
    vs. liver metastases, 890f
  radiation-induced, 915
Liver function tests, for liver metastases, 888
Liver impairment, Child-Pugh score for, 1571, 1571t, 1573, 1578b
Liver metastasis(es), 41–42, 885–916
  of carcinoid tumor, 1291, 1294
  of colorectal cancer, 892, 892t–895t, 896, 898, 1518
    imaging of, 1491–1494, 1492f–1494f, 1494t
    radiation therapy for, 1518
    synchronous, 1507
  diagnosis of, 885–888
    biochemical laboratory tests in, 888
    computed tomography in, 301, 886, 888
    differential, 888, 889f, 889t, 890f
    MRI in, 301, 303f, 886–888, 887f
    PET in, 301, 887–888
    ultrasonography in, 298, 887, 888
  etiology of, 885
  of gestational trophoblastic disease, 1862–1863, 1870
  incidence of, 885
  intraoperative ultrasound of, 1491, 1492f
  of pancreatic islet cell tumors, 1299
  and survival, 900, 900f
  treatment of, 885
    chemotherapy for, 885, 898
      adjuvant, 896–898, 896f, 897t
      hepatic artery infusion of, 885, 898–905
      neoadjuvant, 894, 905–908, 907t
      with whole-liver irradiation, 912, 913t
    cryosurgery for, 885, 895, 910
    future directions in, 915–916
    gene therapy for, 912
    hepatic artery embolization for, 885, 908–909, 908f
      chemo-, 909–910
      complications of, 909, 909t
    hepatic resection for, 885, 888–898
      adjuvant therapy after, 896–898, 896f, 897t
      from breast cancer, 890–891, 898
      chemotherapy downstaging prior to, 894, 905–908, 907t
      from colorectal cancer, 892, 892t–895t, 896, 898
      Couinaud's hepatic anatomic segments in, 889, 890f
      drainage after, 890
      with extrahepatic metastases, 894–895
      from GI neuroendocrine tumors, 891

incidence of, 873
investigational approaches to, 882
nonsurgical approaches to, 881–882, 881t
of osteosarcoma, 876f, 878–879, 879t, 1975, 2084
of soft-tissue sarcoma, 878–879, 879t, 2032–2034, 2033t, 2034f
surgical treatment of, 873, 876–881 (*See also* Pulmonary metastectomy)
approaches for, 876–877, 876t, 877f
for bone and soft-tissue sarcoma, 878–879, 879t
for breast cancer, 880–881
for colorectal cancer, 877–878, 878t
criteria for, 873–874
for germ cell tumors, 880, 880t
for head and neck cancer, 880, 880t
history of, 873
for melanoma, 879, 879t
prognostic factors with, 873, 874, 874f, 874t
for renal cell carcinoma, 879–880, 880t
for soft-tissue sarcoma, 2033–2034, 2033t, 2034f
tissue and cytologic diagnosis of, 1311–1312
tumor biology of, 1310–1311
uranium and, 131
Lupron (leuprolide acetate), 472–473
for prostate cancer, 1683
reproductive effects of, 1002
Lust, Benedict, 550
Luteinizing hormone (LH), 1000
Luteinizing hormone–releasing hormone (LHRH) agonists, for breast cancer, 1924, 1931
Luteinizing hormone–releasing hormone (LHRH) analogs, for prostate cancer, 1681–1683, 1682f
Luteinizing hormone–releasing hormone (LHRH) antagonists, for prostate cancer, 1682, 1682f
LV. *See* Leucovorin calcium (Wellcovorin, citrovorum factor, folinic acid, FA, LV).
LVA (lymphaticovenous anastomoses), for lymphedema, 646–649, 647b, 647t, 648f, 652, 653f
LVEF (left ventricular ejection fraction), in anthracycline-induced cardiomyopathy, 987
LVSI (lymphovascular space invasion)
by cervical cancer, 1757, 1764
by endometrial cancer, 1802, 1805, 1813–1814, 1814t
LYL1 gene, in childhood leukemia, 2148
Lymph nodal–venous shunts, for lymphedema, 646
Lymph node, sentinel, 1909
Lymph node dissection
axillary (*See* Axillary lymph node dissection [ALND])
for melanoma, 1238–1240
for penile cancer, 1706–1707
sentinel (*See* Sentinel lymph node biopsy [SLNB])
for soft-tissue sarcoma, 2024
for vulvar cancer, 1770–1772, 1771t, 1772f
Lymphadenectomy
for bladder cancer, 1642–1643
for colorectal cancer, 1504
for gastric cancer, 1437–1439, 1445, 1445t, 1457
for melanoma, 1238–1240, 1239f, 1247
for pancreatic cancer, 1605
for renal cell carcinoma, 1623
Lymphangiogenesis, 112–113, 114f–115f
Lymphangioplasty, for lymphedema, 645
Lymphangiosarcoma, 643–644, 2045
Lymphatic bridging, for lymphedema, 645–646, 646f, 647f
Lymphatic filariasis, 641–642
Lymphatic mapping
for colorectal cancer, 1504
for melanoma, 1238–1239
Lymphatic metastasis, 39
of bladder cancer, 1642–1643
of colorectal cancer, 1504
of head and neck cancer, 1178
of non-small cell lung cancer, 1331–1332
of squamous cell carcinoma, 1258, 1260
of vulvar cancer, 1769, 1769f, 1769t
management of, 1773–1774, 1774t, 1775t
Lymphatic transport, 112–113, 114f–115f
Lymphaticolymphatic anastomosis, for lymphedema, 649f, 650
Lymphaticovenous anastomoses (LVA), for lymphedema, 646–649, 647b, 647t, 648f, 652, 653f
Lymphedema, 641–653
congenital, 641
diagnosis of, 642–644, 643f, 643t
etiology and classification of, 641–642
genetic, 642
heat treatment for, 652
incidence of, 641
measurement of, 644, 644b, 644f
medical management of, 644–645, 645b
pathophysiology of, 642, 642b
praecox, 641, 651f
primary, 641, 651f
rehabilitation for, 585
secondary, 641–642
and soft-tissue sarcoma, 2010, 2010t
surgical management of, 645–652
drainage into deep lymphatics for, 646
excisional, 645b, 650–652, 650f, 651f
indications for, 645, 645b
lymph nodal–venous shunts for, 646
lymphatic bridging for, 645–646, 646f, 647f
lymphaticolymphatic anastomosis for, 649f, 650
lymphaticovenous anastomoses for, 646–649, 647b, 647t, 648f, 652, 653f
micro-, 646–650, 647b, 647t, 648f, 649f
physiologic, 645–646, 645b, 646f, 647f, 653f
suction-assisted lipectomy for, 652
syndromic, 642
tarda, 641, 650f
Lymphoblastic leukemia, acute. *See* Acute lymphocytic (lymphoblastic, lymphoid) leukemia (ALL), in children.
Lymphoblastic lymphoma
clinical presentation of, 2179, 2382t
immunophenotypic and genetic abnormalities in, 2176, 2374t
mediastinal, 1386–1387
pathology and tumor biology of, 2174f, 2175–2176, 2175t
treatment of, 2182–2183, 2182t
Lymphocytic and histiocytic (L&H) cells, in Hodgkin's lymphoma, 2356–2357, 2357t
Lymphocytic leukemia, chronic. *See* Chronic lymphoid (lymphocytic) leukemia (CLL).
Lymphocytic lymphoma, small. *See* Small lymphocytic lymphoma (SLL).
Lymphoid granulomatosis, 2391–2392
Lymphoid hyperplasia, reactive or atypical, 2396
Lymphoid leukemia
acute (*See* Acute lymphocytic (lymphoblastic, lymphoid) leukemia [ALL])
chronic (*See* Chronic lymphoid (lymphocytic) leukemia [CLL])

Lymphoid proliferations, atypical, vs. lymphomas, 2396–2397
Lymphoid tumors, of head and neck, 1184
Lymphoma(s). *See also* Non-Hodgkin's lymphoma (NHL).
  anaplastic lymphoma kinase (ALK), 2176
  angiocentric, of head and neck, 1184
  of anterior mediastinum, 1368, 1386–1387, 1387f
  vs. atypical lymphoid proliferations, 2396–2397
  B-cell (*See* B-cell lymphoma[s])
  biology of, 2371
  body-cavity–based (primary effusion), 162
  Burkitt's (*See* Burkitt's lymphoma [BL])
  central nervous system (*See* Central nervous system [CNS] lymphoma)
  childhood, 2171–2185
    anaplastic large cell
      pathology and tumor biology of, 2174f, 2176–2177
      treatment of, 2183–2184, 2183t
    Burkitt's
      clinical presentation of, 2179
      pathology and tumor biology of, 2173–2175, 2174f
      treatment of, 2181–2182, 2182t
    classification of, 2173, 2173t
    clinical presentation of, 2171, 2178–2179
    common, 2173–2178, 2173t
    diagnosis and differential diagnosis of, 2171, 2179
    epidemiology of, 2171–2173
    etiology and pathogenesis of, 2171–2173
    follicular, 2178
    immunophenotypic features of, 2175t
    initial workup and staging of, 2171, 2179, 2180f, 2181t
    large B-cell, 2183t
      diffuse, 2177–2178, 2183
      mediastinal (thymic), 2178, 2179
    lymphoblastic
      clinical presentation of, 2179
      pathology and tumor biology of, 2174f, 2175–2176, 2175t
      treatment of, 2182–2183, 2182t
    pathology and tumor biology of, 2171, 2173–2178, 2173t
    prognostic factors for, 2172, 2179–2180
    risk factors for, 2171–2173
    treatment of, 2171–2172, 2180–2185
      for advanced-stage disease, 2181–2184, 2182t, 2183t
      CNS prophylaxis in, 2184
      complications of, 2172, 2184
      emergency, 2184
      future directions for, 2185
      initial management in, 2181
      for limited-stage disease, 2181
      primary, 2171–2172
      salvage, 2172, 2184–2185
    uncommon, 2173t, 2178
  classification of, 2373–2376, 2373t–2375t, 2382t
  clinical characteristics of, 2382t
  of colon, 1509
  cytogenetic aberrations in, 256t, 260t
Lymphoma(s) (*cont.*)
  diagnostic evaluation of, 2373, 2376, 2377t
  differential diagnosis of, 2371
  diffuse histiocytic (*See* Primary central nervous system lymphoma [PCNSL])
  in elderly, 2395–2396
  Epstein-Barr–associated, 224, 225, 227, 228, 2372
    with HIV, 1066, 1066f
  etiology of, 2371–2373, 2373t
  extranodal, of head and neck, 1184
  flow cytometry of, 242b, 243–246, 245f
  follicular (*See* Follicular lymphoma [FL])
  gastrointestinal, perforation of, 792
  HIV-associated, 228, 1065–1069
    clinical aspects of, 1066–1067, 1067f
    epidemiology of, 1061, 1065, 2392
    etiology and pathogenesis of, 1061, 1065–1066, 1066f, 2392
    evaluation of, 1061
    treatment of, 1061, 1067–1068, 1067b–1069b, 2392–2393, 2393f
  Hodgkin's (*See* Hodgkin's lymphoma)
  imaging of, 298–299, 299f, 2376
  immunodeficiency and, 224–228, 225t, 226t
    clinical characteristics of, 224–226, 225t
    contributors to increased risk of, 224
    with Epstein-Barr virus, 224, 225, 227, 228
    after hematopoietic stem cell transplantation, 227
    with HIV infection, 228
    primary, 226–227, 226t
    after solid-organ grafting, 227–228
    treatment of, 226
  immunophenotypes of, 2373, 2374t
  incidence of, 2371, 2372, 2372f
  indolent, 2381–2386, 2383t
  intraocular, 1148–1150, 1149f
  lacrimal gland, 1161, 1163
  lymphoblastic (*See* Lymphoblastic lymphoma)
  lymphoplasmacytic, 2305, 2342
    immunophenotype of, 2295t
    molecular genetics of, 2375t
    treatment of, 2385
  mantle cell (*See* Mantle cell lymphoma [MCL])
  marginal zone (*See* Marginal zone lymphoma [MZL])
  minimal disease with, 2378
  molecular genetics of, 2375–2376, 2375t
  monoclonal antibodies for, 533–534, 533t, 535–536, 536t
  mucosa-associated lymphoid tissue (MALT) (*See* Mucosa-associated lymphoid tissue [MALT] lymphoma)
  natural killer cell, 2394
    blastic, 2135
  null cell, clinical characteristics of, 2382t
  orbital, 1160–1163

  of bone sarcomas, 1947
  of brain metastases, 828, 829f
  of brain tumors, 304, 304f, 1084–1085, 1085f
  of breast cancer, 295, 1888, 1893–1895, 1905, 1934
  for carcinoma of unknown primary, 2066
  of cervical cancer, 1754–1756, 1756f, 1757f
  contrast agents for, 289, 289b
  diffusion, 289
  of Ewing's sarcoma, 2087, 2088f
  fetal exposure to, 1050–1051
  of gestational trophoblastic disease, 1864
  of head and neck cancer, 300
  of hepatocellular carcinoma, 1571
  of liver metastases, 301, 303f, 886–887, 887f
    of colorectal cancer, 1493, 1494f
Magnetic resonance imaging (MRI) (*cont.*)
  of metastatic lung cancer, 293–294
  of osteosarcoma, 1951, 1953f, 2079–2080, 2080f
  of prostate cancer, 296
  of pulmonary metastases, 875
  of soft-tissue sarcoma, 2017, 2017f, 2018f
  of spinal metastases, 817, 818
  whole-body, 290, 290f, 291t
Magnetic resonance spectroscopy (MRS), 289
  of brain tumors, 1084–1085, 1085f
Magnetic resonance venography (MRV)
  of brain tumors, 1085
  of deep venous thrombosis
    inferior vena cava and intra-abdominal, 707
    lower-extremity, 701
    upper-extremity, 704–705
Maintenance chemotherapy
  for celomic epithelial carcinoma, 1838–1839, 1838t
  for leukemia
    acute lymphocytic, 2199
    acute promyelocytic, 2228–2229, 2228b
  for ovarian cancer, 1838–1839, 1838t
  for small cell lung cancer, 1350
Male sex cord tumors, reproductive effects of, 1000
Malignant effusions, due to ovarian cancer, 938, 1848
Malignant fibrous histiocytoma (MFH), 2012t, 2017f, 2018f
  of bone, 1994, 1995f
  myxoid, 2012t
Malignant melanoma. *See* Melanoma.
Malignant peripheral nerve sheath tumor (MPNST), 1390
  genetic predisposition to, 2011, 2011t, 2012t
  neurofibromatosis type 1 and, 2105
Malignant tumors, defined, 33
Malnutrition, anticoagulation therapy with, 697
MALT lymphoma. *See* Mucosa-associated lymphoid tissue (MALT) lymphoma.
Mammalian target of rapamycin (mTOR)
  in apoptosis, 72
  in intracellular signaling, 26, 26f
  as molecular target, 486t, 488
Mammalian target of rapamycin (mTOR) inhibitors
  for renal cell carcinoma, 1625–1628
  for soft-tissue sarcoma, 2037
MammaPrint assay, 1918
Mammography, 283, 288, 291t, 294–295, 295f
  abnormalities on, 1888–1890, 1893
    biopsy for, 1893, 1894f, 1895f
    calcifications as, 1889, 1889f, 1890f, 1891t
    masses as, 1889, 1889f, 1890f
    ultrasonography of, 1889–1890, 1890f, 1891f
  for carcinoma of unknown primary, 2066
  diagnostic, 1891, 1893
  digital, 1884
Mammography (*cont.*)
  of nonpalpable breast mass, 1893
  of palpable breast mass, 1891
  during pregnancy, 1056
  screening, 376, 1884–1888
    efficacy of, 1884–1886, 1885t–1886t
    in elderly, 1888
    guidelines for, 1883, 1884, 1888t
    for high-risk individuals, 1883, 1888
    patient compliance with, 1886
    sensitivity of, 1886–1888
Mannitol, for increased intracranial pressure, 1082
Mantle cell lymphoma (MCL)
  clinical characteristics of, 2382t
  differential diagnosis of, 2295t, 2296, 2296f, 2305
  immunophenotypic and genetic abnormalities in, 256t, 2374t
  molecular genetics of, 2375t, 2376
  treatment of, 2391
Manual healing methods, 546b
MAP (*MYH*-associated polyposis), 145, 180
MAPK. *See* Mitogen-activated protein kinase (MAPK).
MAR (melanoma-associated retinopathy), 772
Margin(s)
  for colorectal cancer, 1497–1498
  for melanoma, 1238
Marginal zone lymphoma (MZL), 2305
  clinical characteristics of, 2382t
  extranodal, 2385–2386
  immunophenotypic and genetic abnormalities in, 2295t, 2374t
  nodal, 2374t, 2382t, 2386
  primary cutaneous, 2413, 2414
  splenic, 2386
  treatment of, 2308, 2385–2386
Margin(s) of resection, adequate, 413, 414t
Marijuana, as antiemetic, 605
Marimastat, for small cell lung cancer, 1350
Markers
  for genetic linkage mapping, 196–198, 197f–199f
  tumor (*See* Tumor marker[s])
Marrow failure states, 683
Masking, in clinical trials, 314
Mass spectrometry, 14
Mass spectroscopy, 14
Massage, 550
Mastectomy
  for breast cancer, 1914–1916
  breast reconstruction after, 1914–1916
  modified radical, 1914
  nipple-sparing, 1915
  procedure for, 1915–1916
  prophylactic, 376, 410–411, 1879, 1884
  radiation therapy after, 1916, 1916b, 1917f
  radical, 1914
  skin-sparing, 1914–1915
  Stewart-Treves syndrome after, 1265
  total or simple, 1914
Mastocytosis, systemic, cytogenetic aberrations in, 253t
Matched odds ratio, 357, 358f

Matched unrelated donor stem cell transplantation (MUD SCT), for acute lymphocytic leukemia, 2201, 2202
Matching, in study design, 353–354, 357

organ specificity in, 40–42, 41f
premetastatic niche in, 39–40, 40f
tumor microenvironment acting as selection pressure for, 33–35, 34f, 35t
Methadone, 570t
Methicillin-resistant *Staphylococcus aureus* (MRSA), 724
Methionine, and colorectal cancer, 1482
Methotrexate (Mexate, Folex, MTX, amethopterin), 474
for gestational trophoblastic neoplasia, 1866–1868, 1867t, 1868t
hyperpigmentation due to, 632
for leukemia, acute lymphocytic, 2199, 2200
in children, 2153, 2154
for lymphoma
in children, 2182, 2183
cutaneous T-cell, 2419
primary CNS, 1106–1108, 1108b, 1108f
for neoplastic meningitis, 841
neurotoxicity of, 947–948, 947f
for osteosarcoma, 1954, 1955
for penile cancer, 1708, 1708t

Methotrexate (Mexate, Folex, MTX, amethopterin) (*cont.*)
for pleural effusions, 930
during pregnancy, 1005, 1006, 1051, 1052t
pulmonary toxicity of, 977
for vulvar cancer, 1776t
Methylation, in apoptosis, 73, 73f
Methylation markers, 272
Methylene blue, for neuroprotection, 962
O^6-Methylguanine DNA-methyltransferase (MGMT)
and chemotherapy for gliomas, 1100, 1100t
and resistance to chemotherapy, 1091
N-Methylhydrazine (procarbazine), 477–478
neurotoxicity of, 950–951
second malignant neoplasms due to, 1026
Methylphenidate
for depression in dying patient, 667t, 668
for fatigue, 660
Methylprednisolone, for multiple myeloma, 2338
Metoclopramide
as antiemetic, 603t, 604, 605
for bowel preparation, 1502b
for nausea in dying patient, 667t
Metyrapone, for adrenocortical cancer, 1283
Mexate. *See* Methotrexate (Mexate, Folex, MTX, amethopterin).
MFH (malignant fibrous histiocytoma), 2012t, 2017f, 2018f
of bone, 1994, 1995f
myxoid, 2012t
M-FISH (multiplex fluorescence in situ hybridization) analysis, 252
MG (myasthenia gravis)
paraneoplastic, 774
and thymoma, 1382–1383
MGDF (megakaryocyte growth and differentiation factor), 683
MGMT (O^6-methylguanine DNA-methyltransferase)
and chemotherapy for gliomas, 1100, 1100t
and resistance to chemotherapy, 1091
MGUS. *See* Monoclonal gammopathy of undetermined significance (MGUS).
MHL1 gene, 212t
MIBG (metaiodobenzylguanidine) scan, of pheochromocytoma, 1286, 1287f
MICA/B, in tumor immune surveillance, 80–81, 81f
Microadenomas, pituitary, 1111
Microarray(s), 9, 12, 12f, 200, 272
Microarray "chips," 266–267
Microarray comparative genome hybridization (microarray CGH), 252
Microarray expression profiling, 272
Microarray studies, in breast cancer, 1875, 1881–1882, 1882f
Microcalcifications
in breast, 1889, 1889f, 1890f, 1891t
in breast cancer, 1875
Microcirculation, 109, 110f
Microenvironment
immunologic characteristics of, 78, 85–87, 85f
as selection pressure for metastatic tumor cells, 33–35, 34f, 35t
Microglioma. *See* Primary CNS lymphoma (PCNSL).
Micrometastases, 42
of colorectal cancer, 1497, 1512
MicroRNAs (miRNAs), 10–12, 13f
in molecular diagnostics, 273
as post-transcriptional regulators of gene function, 217–219, 219t
Microsatellite(s), 266
Microsatellite instability (MSI), 145, 146, 149b, 271, 272f
Microsatellite markers, 197, 197f
Microvascular pressure (MVP), and interstitial fluid pressure, 115
Microvasculitis, paraneoplastic, 773
Microvessel density (MVD), in carcinoma of unknown primary, 2063
Microwave coagulation (MC)
for hepatocellular carcinoma, 1575
for liver metastases, 910–911
Midazolam, for agitated delirium in dying patient, 667t
Middle mediastinum, 1380
tumors of, 1380t, 1387–1388, 1388f
Migratory thrombophlebitis, 708
Milroy disease, 641
Milstein, Caesar, 532b
Mind-body techniques, 546b, 551–552
Mineralizing angiopathy, radiation-induced, 952
Mineralocorticoid deficiency, hyponatremia due to, 754
Mini Nutritional Assessment (MNA), 1043
Minimal deviation adenocarcinoma, of cervix, 1748, 1750f
Minimal residual disease (MRD)
assessment of, 268–269, 268t
in cancer vaccine trials, 323
in chronic lymphoproliferative disorders, 246
FISH analysis for, 251
in leukemia
acute, 243, 244f
in children, 2158–2160, 2158t, 2159f
lymphocytic, 2193–2194, 2206–2207, 2206t
chronic lymphoid, 2303
hairy cell, 2316, 2316f
in non-Hodgkin's lymphoma, 2378
Minimally invasive esophagectomy, for esophageal cancer, 1408
Minimally invasive laparoscopic colorectal surgery, 1507–1508
Minimally invasive techniques
for primary cancer surgery, 413–414
for staging, 411
miRNAs (microRNAs), 10–12, 13f
in molecular diagnostics, 273
as post-transcriptional regulators of gene function, 217–219, 219t
Mismatch repair (MMR), 145, 145f
and cancer, 145–146
colorectal, 1481
Missense mutation, 267f
Mistletoe, 553, 554t
Mithramycin (Mithracin, plicamycin), 477
for hypercalcemia of malignancy, 746
hyperpigmentation due to, 632
Mitochondria, in apoptosis, 68, 69f
Mitogen-activated protein kinase (MAPK), in intracellular signaling, 25–26, 25f
Mitogen-activated protein kinase kinase(s) (MKKs), in intracellular signaling, 25–26, 25f
Mitogen-activated protein kinase kinase kinases (MKKKs), in intracellular signaling, 25
Mitogen-activated protein kinase (MAPK) pathway, in melanoma, 1233
Mitogen-activated protein kinase phosphatases (MKPs), in intracellular signaling, 27
Mitogenic growth factors, 50
Mitomycin C (MMC, Mutamycin), 474
for anal cancer, 1561b, 1562–1564, 1563t, 1566
pulmonary toxicity of, 978
as radiosensitizer, 433t
for vulvar cancer, 1776t
Mitosis, 54–57, 56f
Mitosis (M) phase, 50, 50f
Mitotane (Lysodren, o,p'-DDD), 474–475
adrenal effects of, 1016
for adrenocortical carcinoma, 1283, 2116–2117
Mitotic arrest deficient 1 (MAD1), 59, 60f
Mitotic arrest deficient 2 (MAD2), 59, 60f
Mitotic inhibitors, hyperpigmentation due to, 632
Mitotic spindle, 54–55
Mitotic spindle checkpoint, 55
Mitoxantrone (Novantrone, DHAD, dihydroxyanthracenedione), 475
congestive heart failure due to, 990
Mixed germ cell tumor, 1716f–1717f
Mixed gliomas, 1093–1094
Mixed malignant müllerian tumor, of uterus, 1798, 1798f
Mixed müllerian sarcomas (MMS), 2043
Mixed-lineage leukemia *(MLL)* gene
in acute myelogenous leukemia, 2219
in childhood leukemia, 2141, 2147, 2149, 2151
MK0457, for chronic myeloid leukemia, 2288
MKK(s) (mitogen-activated protein kinase kinases), in intracellular signaling, 25–26, 25f
MKKKs (mitogen-activated protein kinase kinase kinases), in intracellular signaling, 25
MKPs (mitogen-activated protein kinase phosphatases), in intracellular signaling, 27
MLC (multilead collimator), 437, 438f
MLH1 gene, 1255
and breast cancer, 172
and colon cancer, 180–181
MLL (mixed-lineage leukemia) gene
in acute myelogenous leukemia, 2219
in childhood leukemia, 2141, 2147, 2149, 2151
MLL-AF4 fusion gene, in childhood leukemia, 2141
MM. *See* Multiple myeloma (MM).

MM (myeloid metaplasia)
agnogenic (*See* Primary myelofibrosis [PMF])
cytogenetic aberrations in, 254t
myelofibrosis with, 2271b
MMAC1 gene, 212t
MMC. *See* Mitomycin C (MMC, Mutamycin).
MMLV (Moloney murine leukemia virus) vectors, 514
MMPs. *See* Matrix metalloproteinase(s) (MMPs).
MMR (mismatch repair), 145, 145f
and cancer, 145–146
colorectal, 1481
MMS (mixed müllerian sarcomas), 2043
MNA (Mini Nutritional Assessment), 1043
Modafinil, for fatigue, 660
Modeling, in cancer
in vivo, 15–17, 16f, 17f
of recessive gene mutations, 17–19, 18f
Modified vaccinia Ankara (MVA), 516
Mohs' micrographic surgery
for basal cell carcinoma, 1257
for dermatofibrosarcoma protuberans, 1264
for ocular sebaceous carcinoma, 1262
for penile cancer, 1706
for squamous cell carcinoma, 1259
for Stewart-Treves syndrome, 1266
Molar pregnancy
complete
clinical presentation of, 1861, 1861t
epidemiology of, 1858
etiology and pathogenesis of, 1859, 1859f
immunobiology of, 1861
laboratory and imaging studies for, 1863–1864, 1864f
pathology of, 1859–1860, 1860t
pregnancy after, 1871, 1871t
follow-up for, 1871
invasive
epidemiology of, 1859
pathology of, 1860, 1860f
partial
clinical presentation of, 1861–1862, 1861t
epidemiology of, 1859
etiology and pathogenesis of, 1859
laboratory and imaging studies for, 1863–1864
pathology of, 1860, 1860f, 1860t
pregnancy after, 1871–1872, 1872t
treatment for, 1865–1866, 1866t
Mole(s), and melanoma, 380, 381
Molecular cytogenetic analysis, 249–251, 251t
Molecular diagnostics, 265–273
business, regulatory, and ethical issues in, 273
DNA sequencing in, 266, 267f
epigenetic markers in, 272
for hematolymphoid neoplasms, 267–270
with bone marrow transplantation, 269–270
chromosomal translocations in, 268–269, 268t
gene mutations in, 270
gene rearrangement assays in, 267–268, 268f, 268t
polymerase chain reaction in, 270
Molecular diagnostics (*cont.*)
methods in, 265–267
microarray "chips" in, 266–267, 272
microRNAs in, 273
newer techniques in, 272–273
pharmacogenetic assays in, 272
polymerase chain reaction in, 266
for solid tumors, 270–272
allele imbalance and/or copy number variation in, 271
gene mutations in, 271–272, 271f, 272f
due to hereditary cancer syndromes, 270–271
Southern blotting in, 266, 268f
specimens for, 265–266, 266t
tumor-specific markers at low levels in, 272–273
Molecular imaging, for molecularly targeted therapy, 493–494, 494t
Molecular profiling
in breast cancer, 1880–1882, 1881f, 1882f
in lymphoma, 2373–2375
Molecular research tool(s), 3–19
advances in, 3
for analyzing genes, 7
candidate genes as, 3
chromatin immunoprecipitation with microarray (ChIP-on-chip) as, 14, 15f
chromatin in, 9, 11f
conditional mutagenesis as, 15–17, 16f, 17f
DNA in, 3, 4f
DNA library as, 7
DNA probe as, 7
epigenetics as, 9, 11f
fluorescent in situ hybridization as, 6, 6f
gel electrophoresis as, 7, 8f–9f
in vivo modeling as, 15–17, 16f, 17f
mass spectrometry as, 14
microarray analysis as, 9, 12f
microRNAs as, 10–12, 13f
models of recessive gene mutations as, 17–19, 18f
monoclonal antibodies as, 14
Northern blot analysis as, 9f, 12
polymerase chain reaction as, 5–6, 6f, 8f–9f
for profiling tumors, 9–12, 12f, 13f
proteomics as, 12–15, 14f, 15f
regulatory DNA sequences as, 7–9, 10f
restriction enzymes as, 7, 8f–9f
restriction-fragment-length polymorphisms as, 7, 8f–9f
RNA splicing as, 3–4, 5f
serial analysis of gene expression as, 9–10
single-nucleotide polymorphisms as, 4–7, 5f
Southern blotting as, 8f–9f
yeast two-hybrid system as, 13–14, 14f
Molecularly targeted anticancer agents (MTAs), 452–453, 485–497
for bone metastases, 864
bowel perforation and hemorrhage due to, 793–794
for carcinoma of unknown primary, 2071–2072
clinical development of, 490–493, 490t
for colorectal cancer, 1524–1525
Molecularly targeted anticancer agents (MTAs) (*cont.*)
combination therapy with, 495–497, 495t, 496f
cytostatic vs. cytotoxic, 492, 493
dose determination for, 490–492, 490f, 491t
efficacy evaluation of, 492
functional and molecular imaging with, 493–494, 494t
future directions of, 497
for lung cancer
non-small cell, 1339–1340, 1343–1345, 1343t–1345t, 1344f, 1345f
small cell, 1354
for melanoma, 1245–1246
patient selection for, 494–495, 495t
pharmacodynamic markers for, 492–493, 493t
preclinical development of, 488–490, 489f, 489t
for renal cell carcinoma, 1628–1629
for soft-tissue sarcomas, 2021
targets of, 485–488, 486t–487t, 488f
high-throughput screening of, 489, 489f
validation and prioritization of, 488, 489t
Moloney murine leukemia virus (MMLV) vectors, 514
Monitoring
of clinical trials, 316, 323–324
tumor markers for, 280
Monoblastic leukemia, acute, 2220f
Monoclonal antibodies (MAbs), 453, 531–539
for adult T-cell leukemia-lymphoma, 2437–2438
alternative targets for, 539, 539b
chimeric, 538, 538f
clinical application of naked, 533–534, 533t
complications and contraindications of, 534
cytophilic, 531–533, 532t
effector mechanisms of, 531–533, 532f, 532t
historical perspective on, 531, 532b
humanized, 14, 538, 538f
immunoconjugates with, 534–538
with bispecific antibodies, 538
immunocytokines as, 537
immunoenzymes as, 537
immunoliposomes as, 537–538
immunotoxins as, 537
radio-, 535–537, 535t, 536t
immunogenicity of, 538, 538f
improving efficacy of, 538, 538f
for leukemia, 533–534, 533t, 535–536
acute lymphocytic, 2207–2208, 2207t
chronic lymphoid, 2303
hairy cell, 2316–2317, 2317t
licensed by FDA for specific cancers, 531
for lymphoma, 533–536, 533t
cutaneous T-cell, 2419–2420
multistep targeting or pretargeting for, 537
receptor blockade by, 531
as research tool, 14
for solid tumors, 533t, 534, 536–537

Monoclonal gammopathy of undetermined significance (MGUS), 2323, 2340–2341
clinical features and differential diagnosis of, 2340
cytogenetic classification of, 2326, 2326t
definition and diagnostic criteria for, 2324, 2325t, 2340
epidemiology of, 2324, 2340
management of, 2341
and multiple myeloma, 2324–2327, 2326f, 2340, 2341t
pathogenesis of, 2324–2327, 2326f
prognosis for, 2340–2341
risk stratification of, 2341, 2341t
Monoclonal (M) proteins, in multiple myeloma, 2328–2329, 2328f
Monocytic leukemia, acute, 2220, 2220f
in children, 2145, 2145t
Mononucleosis, infectious, Epstein-Barr virus and, 154
Monosomy 7 syndrome, infantile, 2140, 2150
Mood alteration, grading of, 959t
Mood disorders, rehabilitation for, 581
MOPP regimen, 451
for Hodgkin's lymphoma, 2354, 2362t, 2363, 2364t
reproductive effects of, 1003, 1004
Morcellation, of renal cell carcinoma, 1619–1620
Morgan, Thomas Hunt, 196
Morphine, 570t
in dying patient
for dyspnea, 667t
for pain, 667, 667t
Mortality rate, 351
Morton, William T., 408
MOSAIC trial, 1548
Motor dysfunction, due to spinal metastasis, 817
Motor neuron syndromes, paraneoplastic, 771
Motor neuropathy, grading of, 960t
Mouse models, of cancer, 15–17, 16f, 17f
Mouth cancer. *See* Oral cancer.
Mouthwashes, for oral complications, 613, 614
6-MP (6-mercaptopurine), 474
for acute lymphoblastic leukemia in children, 2153–2154
MPA (medroxyprogesterone acetate), 473
for cachexia, 595
for colorectal cancer prevention, 1487t, 1489
for endometrial cancer, 1816
MPDs. *See* Myeloproliferative disorder(s) (MPDs).
MPNST (malignant peripheral nerve sheath tumor), 1390
genetic predisposition to, 2011, 2011t, 2012t
neurofibromatosis type 1 and, 2105
MRA (magnetic resonance angiography)
of brain tumors, 1085
of pulmonary embolism, 706
MRC (Medical Research Council)
on acute myeloid leukemia in children, 2155
on Ewing's sarcoma, 2089t
MRCP (magnetic resonance cholangiopancreatography), 1581
MRD. *See* Minimal residual disease (MRD).
MRE11 mutation, 61
Mre11-Rad50-Nbs1 (MRN) complex, 58
MRI. *See* Magnetic resonance imaging (MRI).
mRNA (messenger RNA), 3
MRS (magnetic resonance spectroscopy), 289
of brain tumors, 1084–1085, 1085f
MRSA (methicillin-resistant *Staphylococcus aureus*), 724
MRV. *See* Magnetic resonance venography (MRV).
MS 275, cutaneous reactions to, 637
MSCs (myeloid suppressor cells), in tumor microenvironment, 85–86
MSH (melanocyte-stimulating hormone), in hyperpigmentation, 631
MSH2 gene, 212t, 1255
and breast cancer, 172
and colon cancer, 180–181
MSH6 gene, 212t
and colon cancer, 180–181
MSI (microsatellite instability), 145, 146, 149b, 271, 272f
MSR1 gene, in prostate cancer, 1656
MSTS (Musculoskeletal Tumor Society), functional evaluation system of, 1973–1974
MTAs. *See* Molecularly targeted anticancer agents (MTAs).
MTC (medullary thyroid carcinoma), 1273f, 1280–1281, 1280f
familial, 182
in MEN-2, 1289
MTD (maximum tolerated dose), of molecularly targeted therapy, 490, 490f
MTG8 gene, in childhood leukemia, 2149
mTOR. *See* Mammalian target of rapamycin (mTOR).
MTS (Muir-Torre syndrome), 172, 175t
nonmelanoma skin cancer in, 1254–1255
ocular sebaceous carcinoma in, 1261
MTX. *See* Methotrexate (Mexate, Folex, MTX, amethopterin).
Mucinosis, follicular, 2412, 2412f, 2414t
Mucinous cancers, of endometrium, 1798
Mucinous cystic neoplasms, of pancreas, 1597
Mucoepidermoid carcinoma
cytogenetic aberrations in, 258t
of salivary gland, 1181, 1183f
Mucor infection, 726
Mucosa-associated lymphoid tissue (MALT) lymphoma
clinical characteristics of, 2382t
Helicobacter pylori and, 223, 228, 2372, 2385
immunophenotypic and genetic abnormalities in, 256t, 2374t
molecular genetics of, 2375t
primary cutaneous, 2414
treatment of, 2385–2386
Mucosal melanoma, 1184, 1185f, 1247
Mucositis, 726
assessment of, 610
chemotherapy-induced, 610–614
in elderly, 1046
incidence of and risk factors for, 610–611, 610f, 611f
prevention of, 611–613, 611b
treatment of, 613–614, 614b
pathophysiology of, 609–610, 610f
radiation-induced, 614–616
Mucous membranes, radiation effects on, 434t
MUD SCT (matched unrelated donor stem cell transplantation), for acute lymphocytic leukemia, 2201, 2202
MUGA (multiple gated acquisition) scans, of anthracycline-induced cardiomyopathy, 987
Muir-Torre syndrome (MTS), 172, 175t
nonmelanoma skin cancer in, 1254–1255
ocular sebaceous carcinoma in, 1261
Müllerian tumor, mixed malignant, of uterus, 1798, 1798f
Multidisciplinary management, surgeon's role in, 412
Multidrug resistance gene 1 *(MDR-1)*
in acute lymphocytic leukemia, 2207
in myelodysplastic syndrome, 2246–2247
and resistance to chemotherapy, 1091
as target for gene therapy, 520–521
Multifocal extraovarian serous carcinoma, 2069
Multikinase inhibitors, 452
Multilead collimator (MLC), 437, 438f
Multiparameter flow cytometry, 241
Multiple endocrine neoplasia (MEN), 1288–1289, 1288t
hypercalcemia in, 742
Multiple endocrine neoplasia type 1 (MEN-1), 177t, 1288t, 1289
brain tumors in, 1078t
clinical features of, 1289
pituitary adenoma in, 1111
surgery for, 1289
Multiple endocrine neoplasia type 1 (MEN-1) gene, 212t
Multiple endocrine neoplasia type 2 (MEN-2), 177t, 182, 1288t, 1289
clinical features of, 182, 1289
clinical management of, 182
genetics of, 182
surgery for, 1289
and thyroid cancer, 1272, 1280, 1281
Multiple endocrine neoplasia type 2a (MEN2a), 182
Multiple endocrine neoplasia type 2b (MEN2b), 182, 1288t, 1289
Multiple gated acquisition (MUGA) scans, of anthracycline-induced cardiomyopathy, 987
Multiple myeloma (MM), 2323–2340
bone metastases in, 848–849, 863, 864
clinical features of, 2327, 2327f, 2328f
complications of, 2339–2340
cytogenetic aberrations in, 256t, 2326, 2326t
definition and diagnostic criteria for, 2324, 2325t

Multiple myeloma (MM) (*cont.*)
diagnosis of, 2323, 2328–2330, 2328f, 2329f
differential diagnosis of, 2330
epidemiology of, 2323, 2324
high-risk, 2330, 2331t, 2338
local osteolytic hypercalcemia in, 741
paraneoplastic sensorimotor neuropathy in, 773
pathogenesis of, 2324–2327, 2326f, 2326t
prognosis for, 2323, 2330, 2330t, 2331t
progression of MGUS to, 2324–2327, 2326f, 2340, 2341t
pseudohyponatremia in, 751
relapse of, 2338–2339
risk stratification for, 2330, 2331t
smoldering, 2323–2324, 2325t, 2341–2342
staging of, 2330
treatment of, 2323, 2331–2340
for complications, 2339–2340
hematopoietic stem cell transplantation for, 506, 2323, 2336–2338, 2337t
for high-risk disease, 2338
maintenance therapy in, 2338
for newly diagnosed disease, 2331–2336, 2331f, 2332t–2335t
for patients eligible for transplantation, 2331–2336, 2331f, 2332t–2335t
for patients not eligible for transplantation, 2331f, 2336
for relapse, 2338–2339
response to, 2333t
Multiple regression analyses, 321
Multiplex fluorescence in situ hybridization (M-FISH) analysis, 252
Multipotent cells, 95–96
Multiprobe bipolar radiofrequency device, for hepatic resection, 889
Muscle atrophy, in cachexia, 593–595, 594f
Muscle injury, from radiation treatment, 953
Muscle relaxants, for pain management, 570, 573t
Muscle vasculitis, paraneoplastic, 773
Musculoskeletal Tumor Society (MSTS), functional evaluation system of, 1973–1974
Mustargen (mechlorethamine), 473
for cutaneous T-cell lymphoma, 2416–2417
hyperpigmentation due to, 631
Mutagenesis, conditional, 15–17, 17f
Mutamycin. *See* Mitomycin C (MMC, Mutamycin).
Mutation(s)
activating, 208, 210
in cancer immunology, 77–78
defined, 435
detection of, 3–6, 4f–6f, 8f, 9f
in DNA repair genes, 208
frameshift, 267f
germline, 208
and cancer phenotype, 219–220, 220f
inactivating, 208, 210
loss-of-function, 208, 210
missense, 267f
in oncogenes, 208
progression to cancer from, 207–221
radiation-induced, 435–436, 435f
Mutation(s) (*cont.*)
recessive gene, 17–19, 18f
modeling of, 17–19, 18f
somatic, 208
clonal, 210
in tumor suppressor genes, 208
Mutation rate, increased, as signature trait of cancer cells, 215, 216f
"Mutator phenotype," 146b, 208
Mutism, cerebellar, 1120
MVA (modified vaccinia Ankara), 516
MVAC regimen, for bladder cancer, 1647, 1647t, 1648
MVD (microvessel density), in carcinoma of unknown primary, 2063
MVP (microvascular pressure), and interstitial fluid pressure, 115
Myasthenia gravis (MG)
paraneoplastic, 774
and thymoma, 1382–1383
MYC oncogene, in Burkitt's lymphoma, 2175
MYCN oncogene, in neuroblastoma, 2091, 2094, 2094t
Mycobacterium smegmatis, and penile carcinoma, 1701
Mycosis cells, 2410
Mycosis fungoides
clinical manifestations of, 2406–2407, 2409f
d'emblée form of, 2407
folliculotropic, 2412, 2412f, 2414t
staging of, 2415, 2415b
therapy for, 2405, 2415–2420
tissue diagnosis of, 2408–2412, 2410f, 2411f
variants and subtypes of, 2412, 2412f, 2414t
Myelitis, grading of, 960t
Myeloablative chemotherapy, 503–504
Myeloablative conditioning, in older patients, 2248
Myeloblastic leukemia, acute. *See* Acute myeloid (myelogenous, myelocytic, myeloblastic, nonlymphoblastic) leukemia (AML).
Myeloblastomas, in childhood leukemia, 2142
Myelocytic leukemia
acute (*See* Acute myeloid (myelogenous, myelocytic, myeloblastic, nonlymphoblastic) leukemia [AML])
chronic (*See* Chronic myeloid (myelogenous, myelocytic) leukemia [CML])
Myelodysplasia
flow cytometry of, 243
in WHO classification, 2135
Myelodysplastic neoplasms, classification of, 2134t
Myelodysplastic syndrome(s) (MDS), 2235–2251
and acute myeloid leukemia, 2133–2135
in children, 2140, 2251
classification of, 2143, 2143t
differential diagnosis of, 2142
genetic abnormalities in, 2150
prognosis for, 2152
Myelodysplastic syndrome(s) (MDS) (*cont.*)
classification of, 2134t, 2135, 2235, 2239
in children, 2143, 2143t
French-American-British, 2239, 2239t
World Health Organization, 2239, 2240t
clinical presentation of, 2237
cytogenetic aberrations in, 253t, 2239–2240
cytopenias in, 684
differential diagnosis of, 2235
epidemiology of, 2235, 2236
etiology of, 2235, 2236
flow cytometry of, 243
genetic alterations in, 2150
historical background of, 2236
in HIV/AIDS, 2251
laboratory evaluation of, 2237–2239, 2238f
pathogenesis of, 2236–2237
pathology of, 2235, 2239
prevention of, 2251
prognosis for, 2235, 2240–2243, 2241t
risk factors for, 2236
secondary, 2236
treatment of, 2235, 2243–2251
for advanced disease, 2245–2251
arsenic trioxide for, 2244t, 2245
decision tree for, 2242–2243, 2242f
experimental, 2251
growth factors for, 2242, 2243, 2244t
hypomethylating agents for, 2244t, 2245–2246
immunomodulatory agents for, 2243–2245, 2244t
induction chemotherapy for, 2246–2249
for low-risk disease, 2243–2245
stem cell transplantation for, 505, 2242, 2247–2251, 2247t, 2249t
treatment-related, 2236, 2248
Myelofibrosis
cytogenetic aberrations in, 254t
with myeloid metaplasia, 2271b
primary (chronic idiopathic), 2270–2274
clinical course of, 2270
diagnosis of, 2271–2272, 2271b, 2272f, 2272t
diagnostic criteria for, 2270, 2270t
incidence of, 2270
pathogenesis of, 2270–2271, 2271f
prognostic factors for, 2272–2273, 2273t
treatment of, 2271b, 2273–2274, 2273t
Myelogenous leukemia
acute (*See* Acute myeloid [myelogenous, myelocytic, myeloblastic, nonlymphoblastic] leukemia [AML])
chronic (*See* Chronic myeloid [myelogenous, myelocytic] leukemia [CML])
Myeloid antigens, 243
Myeloid disorders, cytogenetic aberrations in, 252f, 253t–254t
Myeloid growth factors, for neutropenia, 681–682
Myeloid leukemia
acute (*See* Acute myeloid [myelogenous, myelocytic, myeloblastic, nonlymphoblastic] leukemia [AML])
chronic (*See* Chronic myeloid [myelogenous, myelocytic] leukemia [CML])

Myeloid metaplasia (MM)
agnogenic (*See* Primary myelofibrosis [PMF])
cytogenetic aberrations in, 254t
myelofibrosis with, 2271b
Myeloid suppressor cells (MSCs), in tumor microenvironment, 85–86
Myeloma
flow cytometry of, 245–246
multiple (*See* Multiple myeloma [MM])
osteosclerotic, paraneoplastic sensorimotor neuropathy in, 773
Myelomonocytic leukemia
acute, 2220, 2220f
in children, 2145, 2145t, 2150
chronic, 2239t, 2241
juvenile, 2140
clinical features of, 2142
differential diagnosis of, 2142
genetic alterations in, 2150
prognosis for, 2152
Myelopathy
due to cytosine arabinoside, 946
due to methotrexate, 947–948
radiation, 953
after spinal irradiation, 1089–1090
Myelophthisis, 2271, 2272f
Myelopoiesis, transient abnormal, 2140
Myeloproliferative disorder(s) (MPDs), 2261–2274
in children, 2140, 2143, 2143t
chronic
cytogenetic aberrations in, 254t
flow cytometry of, 243
classic, 2261–2262, 2262t
classification of, 2261–2262, 2262t
cytogenetic aberrations in, 253t–254t
diagnostic evaluation of, 2261
differential diagnosis of, 2261
essential thrombocythemia as, 2267–2270
diagnosis of, 2268–2269, 2268b, 2268t, 2269f
diagnostic criteria for, 2269t
incidence of, 2267
pathogenesis of, 2267–2268
pregnancy with, 2270
risk stratification for, 2267t
treatment of, 2268t, 2269–2270, 2269t
incidence of, 2261
JAK2 in, 2135
nonclassic, 2262, 2262t
polycythemia vera as, 2262–2267
diagnosis of, 2263–2265, 2263f, 2264f
diagnostic criteria for, 2263, 2265t
incidence of, 2262
pathogenesis of, 2262–2263
risk stratification for, 2267t
treatment of, 2265–2267, 2265b, 2266t
primary myelofibrosis as, 2270–2274
clinical course of, 2270
diagnosis of, 2271–2272, 2271b, 2272f, 2272t
diagnostic criteria for, 2270, 2270t
incidence of, 2270
pathogenesis of, 2270–2271, 2271f
prognostic factors for, 2272–2273, 2273t
treatment of, 2271b, 2273–2274, 2273t
Myeloproliferative disorder(s) (MPDs) (*cont.*)
risk stratification for, 2261
treatment of, 2261
hematopoietic stem cell transplantation for, 506
Myeloproliferative neoplasms, classification of, 2134t
Myeloradiculopathy, due to cytosine arabinoside, 946
Myelosuppression, due to cytotoxic chemotherapy, in elderly, 1046
MYH11 gene, in childhood leukemia, 2149
MYH-associated polyposis (MAP), 145, 180
Myleran. *See* Busulfan (Myleran, BSF).
Mylotarg (gemtuzumab ozogamicin), 453, 469
for acute myeloid leukemia, 2228
with calicheamicin, 537
Myocardial fibrosis, radiation-induced, 991
Myocardial ischemia, due to cancer therapy, 983, 992–993
Myoclonus
due to opioids, 571t
paraneoplastic, 772

drug resistance and, 2380
hematopoietic stem cell transplantation for, 506
late complications of, 2396
monoclonal antibodies for, 533–536, 536t
principles of, 2378–2381
response to, 2377–2378
tumor cell kinetics and, 2378–2380
Nonhomologous end joining (NHEJ), 147f, 424
Non-Langerhans cells (nLCs), 1166
Nonlymphoblastic leukemia, acute. *See* Acute myeloid [myelogenous, myelocytic, myeloblastic, nonlymphoblastic] leukemia [AML].
Nonmelanoma skin cancer (NMSC), 1253–1266
basal cell carcinoma as, 1255–1257, 1255f–1257f
biopsy for, 1266
clinical findings with, 1253
complications of, 1253
cutaneous angiosarcoma as, 1265–1266, 1265f
dermatofibrosarcoma protuberans as, 1263–1265, 1264f
differential diagnosis and staging of, 1253
etiology/epidemiology of, 1253
genetics of, 1253–1255
in immunocompromised hosts, 1260–1261
incidence of, 1253
keratoacanthoma as, 1260
Merkel cell carcinoma as, 1262–1263, 1262f
pathology and tumor biology of, 1253
primary and salvage therapy for, 1253
prognosis for, 1253
screening for and prevention of, 1266
sebaceous carcinoma as, 1261–1262, 1261f
squamous cell carcinoma and Bowen's disease as, 1257–1260, 1258f, 1259f
Nonmyeloablative stem cell transplantation (NMSCT), for acute lymphocytic leukemia, 2201–2202
Non-nucleoside reverse transcriptase inhibitors, for HIV, 1062
Nonparametric linkage (NPL), 199–200
Nonrhabdomyosarcoma soft-tissue sarcoma (NRSTS), 2077, 2105–2108
clinical manifestations of, 2106
diagnostic evaluation of, 2106–2107
differential diagnosis of, 2077
Nonrhabdomyosarcoma soft-tissue sarcoma (NRSTS) (*cont.*)
epidemiology of, 2077, 2105
grading system for, 2106
metastatic, 2107
pathology of, 2106, 2106t
prognostic factors for, 2107
risk categories for, 2107
staging of, 2077
treatment for, 2077, 2107, 2108b, 2108f
tumor biology of, 2105
Nonseminoma germ cell tumors (NSGCTs)
cytogenetic aberrations in, 260t
epidemiology of, 1714
extragonadal, 1733
histology of, 1716f–1717f, 1717–1718
mediastinal, 1386
residual masses in, 1734–1735
risk assessment of
for stage I disease, 1724–1725, 1724f, 1724t
for stage II disease, 1728
treatment of, 1713
for advanced disease, 1729–1734
for stage I disease, 1725–1727, 1727f
adjuvant chemotherapy in, 1725–1726
adjuvant radiation therapy in, 1725
retroperitoneal lymph node dissection in, 1725, 1726f
surveillance in, 1726–1727
for stage II disease, 1728–1729, 1728f
Non-small cell lung cancer (NSCLC), 1327–1346
cytogenetic aberrations in, 260t
EGFR gene mutations, 494–495
incidence and epidemiology of, 1307, 1327
metastatic, 1340–1346
to brain, 838
chemotherapy for, 1340–1343, 1340t, 1343t
EGFR inhibitors for, 1343–1345, 1343t–1345t, 1344f, 1345f
to lymph nodes, 1331–1333
surgical resection for, 1331–1334
vaccines for, 1345–1346
VEGF inhibitors for, 1345
prognosis for, age-related changes in, 1042t
screening for, 1307
staging evaluation of, 1307, 1324–1327, 1325f, 1325t
superior vena cava syndrome due to, 809
treatment of, 1307
chemoradiation for, 1332
concurrent, 1337–1339, 1338t
with consolidation or induction chemotherapy, 1338–1339, 1338t
induction, 1332
neoadjuvant, 1336
sequential, 1337–1339, 1337t, 1338t
chemotherapy for
adjuvant, 1334–1335, 1334t, 1335f
consolidation, 1338–1339, 1338t
with EGFR inhibitors, 1344–1345, 1345t
for elderly patients, 1342
induction, 1329, 1335–1336, 1338–1339, 1338t
Non-small cell lung cancer (NSCLC) (*cont.*)
treatment of (*cont.*)
for locally advanced disease, 1339
for metastatic disease, 1340–1343, 1340t, 1343t
neoadjuvant, 1335–1336
for patients with poor performance status, 1342
second-line, 1342–1343, 1343t
for symptom palliation, 1342
with chest wall invasion, 1331
epidermal growth factor receptor inhibitors for, 1339–1340, 1343–1345, 1343t–1345t, 1344f, 1345f
for locally advanced disease, 1331–1332
unresectable, 1332, 1336–1340, 1337t, 1338t
with malignant pleural effusions, 1333
with mediastinal involvement, 1331, 1333
for metastatic disease, 1331–1334, 1340–1346
molecular-targeted therapy for, 1339–1340, 1343–1345, 1343t–1345t, 1344f, 1345f
for occult disease, 1330
radiation therapy for, 1332, 1337, 1337t
adjuvant, 1335
neoadjuvant, 1336
with satellite nodules, 1333
with second primary tumors or metastasis, 1333–1334
for stage I disease, 1330
for stage II disease, 1330–1331
for stage III disease, 1331–1333
for stage IV disease, 1333
for superior sulcus tumors, 1331
surgical, 1329–1334
presurgical evaluation for, 1327–1329
smoking cessation prior to, 1327–1328
vaccines for, 1345–1346
vascular endothelial growth factor inhibitors for, 1345
Nonsteroidal anti-inflammatory drugs (NSAIDs)
for cancer prevention

for ovarian cancer, 383–384, 1830
Open cordotomy, for pain management, 574
OPG (osteoprotegerin)
for hypercalcemia of malignancy, 746
in multiple myeloma, 741
as osteoclastogenesis marker, 854
Ophthalmic tumor(s), 1137–1170
classification of, 1137, 1138t, 1139t
conjunctival, 1137, 1154–1157
classification of, 1138t
Kaposi's sarcoma as, 1156–1157, 1157f
melanoma as, 1155–1156, 1156f
squamous cell carcinoma as, 1154–1155, 1155f
of eyelid, 1137, 1157–1160
basal cell carcinoma as, 1157–1158, 1158f
classification of, 1138t
sebaceous gland carcinoma as, 1159–1160, 1160f
squamous cell carcinoma as, 1158–1159, 1159f
intraocular, 1137, 1143–1153
classification of, 1138t
leukemia as, 1147–1148, 1149f
lymphoma as, 1148–1150, 1149f
metastatic, 1147, 1148b, 1148f
retinoblastoma as, 1150–1154
classification of, 1152, 1153t
clinical features of, 1150–1152, 1151f, 1152f
differential diagnosis of, 1153
management of, 1153–1154, 1153f
pathogenesis of, 1150
uveal melanoma as, 1143–1147
classification of, 1143t
clinical features of, 1143–1145, 1143f–1145f
differential diagnosis of, 1145
management of, 1145–1147, 1146b, 1146t, 1147f
pathogenesis of, 1143
orbital, 1137, 1160–1170
classification of, 1139t
glioma as, 1168–1169, 1169f
histiocytosis as, 1165–1166, 1166f
of lacrimal gland, 1163–1164, 1163f
lymphoma as, 1160–1163
classification of, 1161, 1162t
clinical features of, 1160–1161, 1161f
differential diagnosis of, 1161
management of, 26f, 1161–1163
pathogenesis of, 1160
staging of, 1161, 1162t
meningioma as, 1167–1168, 1167f
metastatic and secondary, 1169–1170, 1169f
rhabdomyosarcoma as, 1164–1165, 1164f, 1165f
radiation therapy for, 1137
toxicity of, 1138–1143, 1140f–1143f
Opioids, 569–572
classification of, 570
dependence on, tolerance to, and addiction to, 569, 571t
in end-of-life care, 667
for mild to moderate pain, 569, 569t
for moderate to severe pain, 569, 570t
routes of administration of, 570–572
side effects of, 569–570, 571t
tenets of prescribing, 570, 572b
withdrawal from, 571t
Opportunistic infections, with HIV, 1062, 1062t
Oprelvekin (Neumega), 475
dysrhythmias due to, 992
for thrombocytopenia, 683
Opsoclonus-myoclonus, paraneoplastic, 772
Optic nerve gliomas, 1168–1169, 1169f
anterior to chiasm, 1122
Optic nerve sheath meningiomas (ONMs), 1167–1168
Optic neuritis, paraneoplastic, 772
Optic neuropathy
due to cisplatin, 948
differential diagnosis of, 956
radiation-induced, 1089, 1141
Optic pathway gliomas, 1122–1123
Optical imaging methods, 291
Optimal biologic dose (OBD), of molecularly targeted therapy, 490, 490f
Optimization, in intensity-modulated radiation therapy, 441
OR. *See* Odds ratio (OR).
Oral cancer
etiology and pathogenesis of, 1179
pathology of, 1180, 1180f
risk reduction for, 367
staging of, 1211, 1212t
treatment of, 1211–1214
Oral candidiasis, due to corticosteroid therapy, 1081
Oral cavity, anatomy of, 1211, 1212f
Oral complication(s), 609–620
assessment of, 610
chemotherapy-induced, 610–614
incidence of and risk factors for, 610–611, 610f, 611f
prevention of, 611–613, 611b
treatment of, 613–614, 614b
pathophysiology of, 609–610, 610f
radiation-induced, 614–620
dental caries as, 618–619
malignancy as, 620
mucositis as, 614–616
prevention and treatment of, 620
soft-tissue and bone necrosis as, 619
taste alterations as, 619
trismus as, 619–620
xerostomia as, 616–618, 617b
Oral contraceptives
and breast cancer, 375, 1877
and ovarian cancer, 1830
Oral hygiene, for prevention of oral complications, 611–612
Oral mucous membranes, radiation effects on, 434t
Oral submucous fibrosis, 1179
Oral transmucosal fentanyl citrate (OTFC), 572
Ora-Testryl (fluoxymesterone), 468–469
for primary myelofibrosis, 2273
Orbital glioma, 1168–1169, 1169f
Orbital histiocytosis, 1165–1166, 1166f
Orbital lymphoma, 1160–1163
classification of, 1161, 1162t
clinical features of, 1160–1161, 1161f
differential diagnosis of, 1161
management of, 26f, 1161–1163
pathogenesis of, 1160
staging of, 1161, 1162t
Orbital meningioma, 1167–1168, 1167f
Orbital metastases, 1169–1170, 1169f
Orbital rhabdomyosarcoma, 1164–1165, 1164f, 1165f
Orbital tissues, radiation toxicity in, 1142, 1143f
Orbital tumor(s), 1137, 1160–1170
classification of, 1139t
glioma as, 1168–1169, 1169f
histiocytosis as, 1165–1166, 1166f
of lacrimal gland, 1163–1164, 1163f
lymphoma as, 1160–1163
classification of, 1161, 1162t
clinical features of, 1160–1161, 1161f
differential diagnosis of, 1161
management of, 26f, 1161–1163
pathogenesis of, 1160
staging of, 1161, 1162t
meningioma as, 1167–1168, 1167f
metastatic and secondary, 1169–1170, 1169f
rhabdomyosarcoma as, 1164–1165, 1164f, 1165f
xanthogranuloma as, 1166, 1166f
ORC (origin recognition complex), 54, 55f
Orchiectomy
for prostate cancer, 1681, 1683–1684, 1684f
for testicular cancer, 1719
Ordered categories, as endpoints of clinical trials, 314
ORG 2766, for neuroprotection, 961–962
"Organ preserving" radiation therapy, 438, 439
"Organ sparing" radiation therapy, 438, 439
Organ specificity, of metastasis, 40–42, 41f
Organ transplant recipients (OTRs), nonmelanoma skin cancer in, 1260–1261
Organ transplantation
carcinoma after, 228–229, 228b, 229t
liver
for cholangiocarcinoma, 1589
for hepatocellular carcinoma, 1573t, 1574–1575
lymphoma after, 227–228
Organic brain syndrome, due to 5-fluorouracil, 949
Organogenesis, 1005, 1049
Origin licensing, 54, 55f
Origin recognition complex (ORC), 54, 55f
Oropharyngeal cancer
risk reduction for, 367
screening for and early detection of, 363f, 367
treatment of, 1214–1215

Oropharynx, anatomy of, 1212f
OSC (ocular sebaceous carcinoma), 1261–1262, 1261f
OSI-774, for head and neck cancer, 1208
Osler, William, 408
Osmolality, 749–750
  plasma
    calculation of, 752b

Pain (*cont.*)
  due to spinal metastases, 819
  surgery-induced, 565
  sympathetically maintained, 569t
  undertreatment of, 566–567, 567f, 580
  visceral, 569t, 580
Pain management, 569–576
  acupuncture for, 549
  adjuvant analgesics for, 570, 573t
  antineoplastic therapy for, 572
  aspirin and NSAIDs for, 569
  barriers to adequate, 566–567, 567f
  in children, 567
  current status of, 566
  in end-of-life care, 667, 667t
  for episodic or incidental pain, 575
  with history of substance abuse, 575–576
  with impaired cognitive or communicative function, 575
  invasive therapy for, 572–573
  neuroablative procedures for, 574
  for neuropathic pain, 574–575
  nonpharmacologic therapy for, 572
  opioids for, 569–572
    classification of, 570
    dependence on, tolerance to, and addiction to, 569, 571t
    for mild to moderate pain, 569, 569t
    for moderate to severe pain, 569, 570t
    routes of administration of, 570–572
    side effects of, 569–570, 571t
    tenets of prescribing, 570, 572b
  with pancreatic cancer, 1608
  regional analgesia for, 573–574, 574t
Pair production, 421, 422f
PALB2 mutations, and breast cancer predisposition, 178t, 179
Palifermin, for prevention of oral complications, 613
Palladium 103, 419
Palliative chemotherapy
  for gastric cancer, 1455–1457, 1456t
  for non-small cell lung cancer, 1342
Palliative esophagectomy, 1406
Palliative radiation therapy
  for bladder cancer, 1644–1645
  for endometrial cancer, 1815
  for gastric cancer, 1455
Palliative sedation, of dying patient, 671–672
Palliative surgery, 414
Palliative therapy
  for cholangiocarcinoma, 1589
  for esophageal cancer, 1405, 1415–1417, 1419–1423
  for gastric cancer, 1431, 1454–1457, 1456t
  for head and neck cancer, 1188
  for pancreatic cancer, 1595, 1608
Palmar-plantar dysesthesia and erythrodysesthesia syndrome, 629–630, 630f
Palmaz stent, for superior vena cava syndrome, 810
Palmer, Daniel David, 550
Palonosetron, as antiemetic, 603t, 604, 606
L-PAM. *See* Melphalan (Alkeran, L-PAM, L-phenylalanine mustard, L-sarcolysin).

PAM (primary acquired melanosis), conjunctival melanoma due to, 1155–1156, 1156f
Pamidronate (Aredia, APD, aminohydroxypropylidene diphosphonate), 476
  for bone metastases
    of breast cancer, 861t, 862, 862f
    of prostate cancer, 863
  for hypercalcemia of malignancy, 744–745, 746t
  for multiple myeloma, 2334t, 2339
PAMPs (pathogen-associated molecular patterns), in immune tolerance, 83f
Panax ginseng, 553
Pancoast syndrome, 1331
Pancreas, cystic neoplasms of, 1597–1598
Pancreatectomy
  distal, 1606
  regional, 1604
  total, 1604
Pancreatic adenocarcinoma, 1596–1597
Pancreatic adenosquamous carcinoma, 1596
Pancreatic cancer, 1595–1608
  clinical presentation of, 1595, 1598–1599, 1599t
  cystic, 1597–1598
  diagnosis of, 1595, 1598–1602, 1599f, 1601f
    imaging in, 300–301, 302f
  familial, 1598
  histologic classification of, 1596–1597, 1597t
  incidence and epidemiology of, 1595, 1596
  molecular genetics of, 1598
  pathology and tumor biology of, 1595–1598, 1596f
  predisposition syndromes for, 174t
  radiologic evaluation of, 1599–1601, 1600f, 1601f
  risk factors for, 1596, 1596t
  staging of, 1595, 1597, 1597t, 1601–1602
  therapy for, 1595, 1602–1608
    adjuvant and neoadjuvant, 1606–1607
    with locally advanced or metastatic disease, 1607–1608
    palliative, 1595, 1608
    surgical, 1602–1606, 1603f
    survival after, 1595, 1604
  tumor markers for, 1601
Pancreatic disorders, cancer- or treatment-related, 1013, 1016
Pancreatic fistula, 1602, 1605–1606
Pancreatic insufficiency, chemotherapy-related, 1016
Pancreatic intraepithelial neoplasms (PanINs), 1598
Pancreatic islet cell tumor(s), 1271–1272, 1294–1299
  diagnosis of, 1271–1272, 1295–1296, 1295f
  gastrinoma as, 1295f, 1297, 1298
  ghrelinoma as, 1298
  glucagonoma as, 1295f, 1296
  hepatic metastases of, 1299
  incidence of, 1271
  insulinoma as, 1295f, 1296, 1298
Pancreatic islet cell tumor(s) (*cont.*)
  with MEN-1, 1289
  pathology of, 1294–1295
  somatostatinoma as, 1295f, 1296–1297
  treatment of, 1272, 1298–1299
  VIPoma as, 1295f, 1297
Pancreatic tumors
  cystic, 1597–1598
  histologic classification of, 1596–1597, 1597t
Pancreaticoduodenectomy
  for pancreatic cancer, 1602–1604, 1603f
  pancreatic fistula after, 1602, 1605–1606
  pylorus-preserving, 1605
  for small bowel tumors, 1472
Pancreaticoenteric anastomosis, 1602, 1605–1606
Pancreatitis, 795
  chemotherapy-related, 841
  hereditary, 174t
PanINs (pancreatic intraepithelial neoplasms), 1598
Panitumumab (Vectibix), 453, 476
  for colorectal cancer, 1525
Panniculitis-like T-cell lymphoma, subcutaneous, 2395, 2413, 2413f, 2414t
PAP (prostatic acid phosphatase), 1667
Pap smear
  accuracy of, 386
  for cervical cancer, 163, 386–387, 386f
Papanicolaou, George, 237
Papillary renal cancer syndrome, 176t
Papillary serous carcinoma, of peritoneum, 938, 1829
Papillary urothelial carcinoma, 1638
Papilledema, due to brain tumor, 1081–1082
Papulosis, lymphomatoid, 2397, 2412–2413, 2413f, 2414t
Para-aortic lymph node involvement, in endometrial cancer, 1805, 1813–1814, 1814t
Paracentesis, for ascites, 939
Paragangliomas
  hereditary, 177t, 186
  nonchromaffin, 1116–1117
Paranasal sinus tumors
  pathology of, 1181
  proton radiation therapy for, 443
  treatment of, 1210–1211, 1211f
Paraneoplastic cerebellar degeneration (PCD), 770–771, 771f, 1324
Paraneoplastic encephalomyelitis (PEM), 768, 1324
Paraneoplastic neurologic syndrome(s), 767–775
  acute necrotizing myopathy as, 775
  autonomic neuropathy as, 774
  of central nervous system, 768–772, 770f, 771f
  cerebellar degeneration as, 770–771, 770f, 1324
  diagnosis of, 768, 769b, 769f
  encephalomyelitis as, 768, 1324
  immune associations in, 767–768, 768t
  Lambert-Eaton myasthenic syndrome as, 767, 774, 774f, 1324
Paraneoplastic neurologic syndrome(s) (*cont.*)
  limbic encephalitis as, 768–770, 770f, 953
  due to lung cancer, 1324
  motor neuron syndrome as, 771
  myasthenia gravis as, 767, 774
  myopathic, 774–775
  of neuromuscular junction, 774, 774f
  opsoclonus-myoclonus as, 772
  peripheral nerve hyperexcitability as, 771
  of peripheral nervous system, 772–774, 773f
  polymyositis-dermatomyositis as, 774–775
  progressive encephalomyelitis with rigidity as, 772
  sensorimotor neuropathies as, 773
  sensory neuropathy as, 768, 772–773, 773f
  stiff-man syndrome as, 772
  treatment and prognosis for, 775, 775t
  vasculitis neuropathy as, 773
  of visual system, 772
Paraneoplastic opsoclonus-myoclonus, 772
Paraneoplastic sensory neuropathy (PSN), 768, 772–773, 773f, 1324
Paraneoplastic syndromes
  due to lung cancer, 1323–1324
  reproductive effects of, 1000
Paraplatin. *See* Carboplatin (Paraplatin, Carbo, CBDCA).
Paraplegia, rehabilitation for, 582–583
Parathyroid carcinoma, 1271, 1288
Parathyroid disorders, radiation-induced, 1015
Parathyroid hormone (PTH), in calcium homeostasis, 740
Parathyroid hormone–related protein (PTHrP)
  and bone metastases, 40–41, 41f, 846, 848
  humanized antibodies to, 746
  in hypercalcemia of malignancy, 741, 741f, 745
Parathyroid hyperplasia, in MEN-1, 1289
Parietal lobe tumors, signs of, 1082
Parinaud's syndrome, 1082
Parkinsonism, due to cytosine arabinoside, 946
Parotid gland tumors, 1183f–1184f, 1217–1218
PARP, as molecular target, 486t
PARP [poly-(ADP-ribose) polymerase], in necrosis, 70
PARP [poly-(ADP-ribose) polymerase] inhibitors, for breast cancer, 1879
PARP-1 [poly-(ADP-ribose) polymerase 1], in DNA repair, 149b
Partial brain radiotherapy, 831
Partial breast irradiation (PBI), 1911–1912, 1913f
Partial exenteration, for cervical cancer, 1759
Partial hydatidiform mole (PHM)
  clinical presentation of, 1861–1862, 1861t
  epidemiology of, 1859
  etiology and pathogenesis of, 1859
  laboratory and imaging studies for, 1863–1864
  pathology of, 1860, 1860f, 1860t
  pregnancy after, 1871–1872, 1872t
Partial responses, 456, 459
Partial thromboplastin time, in acute lymphocytic leukemia, 2195t

Participation restrictions, 580b
rehabilitation for, 587
Particle radiation therapy, 442–445, 442f–444f, 445b
Passengers, 210
Patched 1 (Ptch1), in basal cell carcinoma, 1254
Pathogen-associated molecular patterns (PAMPs), in immune tolerance, 83f
Pathologic fractures
due to bone metastases, 866–867
heparin-induced, 698
due to osteosarcoma, 1959, 1960f, 1974–1975
Pathologic staging (pTNM), 234
Pathology, 233–238
fine-needle aspiration in, 237
future directions for, 237–238
historical background of, 234
immunohistochemistry in, 235–237, 236f
intraoperative consultation in, 235, 235b
staging in, 234
tumor classification in, 234
tumor grading in, 234–235
Pathology report, 234–235
Patient exclusions, from clinical trials, 310, 313, 322
Patient treatment volume (PTV), 1087
Pauling, Linus, 553–554
Pautrier's microabscess, 2408, 2410f, 2411, 2411f
PAX5 gene, in childhood leukemia, 2141
Pazopanib, for renal cell carcinoma, 1628
PBI (partial breast irradiation), 1911–1912, 1913f
PBMCs (peripheral blood mononuclear cells), in clinical trials of molecularly targeted therapy, 491
PBSCs (peripheral blood stem cells), for myelodysplastic syndrome, 2250
PBX1 gene, in childhood leukemia, 2140, 2141, 2147
PCD (paraneoplastic cerebellar degeneration), 770–771, 771f, 1324
PCI (prophylactic cranial irradiation), for small cell lung cancer, 1353–1354
PCL (plasma cell leukemia)
cytogenetic aberrations in, 256t
with HIV, 1067f
PCNSL. *See* Primary CNS lymphoma (PCNSL).
PCPT (Prostate Cancer Prevention Trial), 1661
PCR. *See* Polymerase chain reaction (PCR).
PC-SPES, for prostate cancer, 552, 552b, 1686
PCV regimen, for gliomas, 1100, 1102–1103
PD (pharmacodynamic) markers, for molecularly targeted therapy, 492–493, 493t
PD1 (programmed death 1), in tumor microenvironment, 87
PDGFR. *See* Platelet-derived growth factor receptor (PDGFR).
PDQ (Physician Data Query), 334
PDT (photodynamic therapy)
for Barrett's esophagus, 1423
for esophageal cancer, 1405, 1417, 1420–1421
for mesothelioma, 1378
PE. *See* Pulmonary embolism (PE).
PE (phycoerythrin), in flow cytometry, 242
PE regimen, for testicular cancer, 1730t, 1732
Pearl, Raymond, 1307
PEB regimen, for testicular cancer, 1726, 1729, 1730t, 1731–1733, 1738
Pediatric Oncology Group (POG)
on acute myeloid leukemia, 2155
economic analysis by, 340t, 341
Pediatric Oncology Group–Children's Cancer Group (POG-CCG) trial, for Ewing's sarcoma, 2089t, 2090
Pediatric tumors. *See* Children.
Pedicle flap procedures, for lymphedema, 645–646
PEG (polyethylene glycol) shielding, in gene therapy, 524
PEG-Asparaginase (Oncaspar, pegaspargase), 460
Pegfilgrastim (Neulasta), 476–477
for neutropenia, 681–682
Pegylated liposomal doxorubicin (Doxil, PLD), 466–467
decreased cardiotoxicity of, 988–989
for Kaposi's sarcoma, 1064b, 1065
for ovarian cancer, 1840, 1840t
PEIT (percutaneous ethanol injection therapy), for liver metastases, 911
PEL (primary effusion lymphoma), 162, 929
Pelvic examination, for cervical cancer, 1753–1754
Pelvic exenteration, for rectal cancer, 1552
Pelvic lymph node involvement
endometrial cancer with, 1805, 1813–1814, 1814t
prostate cancer with, 1679
Pelvic lymphadenectomy, for penile cancer, 1707
Pelvic radiation, reproductive effects of, 1002
Pelvic recurrence, of endometrial cancer, 1817–1818
Pelvis
Ewing's sarcoma of, 1987, 1991–1992, 1991f
osteosarcoma of, 1970–1971
PEM (paraneoplastic encephalomyelitis), 768, 1324
Pemetrexed (Alimta), 477
for non-small cell lung cancer, 1342–1343, 1343t
Pemoline, for fatigue, 660
Pemtumomab, 536t
Penectomy, for penile cancer, 1706
Penetrance, of cancer susceptibility genes, 193, 202
Penile cancer, 1701–1709
basal cell, 1703
classification of, 1702–1704, 1704t
clinical manifestations of, 1704–1705, 1705f
diagnosis of, 1704–1706, 1704f, 1705f
epidemiology of, 1701
Penile cancer (*cont.*)
etiology of, 1701–1702
grading of, 1703–1704, 1704f, 1704t
inguinal lymphadenopathy with, 1705–1707
in situ, 1702
invasive squamous cell, 1703–1706
melanoma as, 1703
natural history of, 1704, 1704f
nonsquamous cell, 1703
Paget's disease as, 1703
pathology of, 1702–1704, 1702b, 1704f
reproductive effects of, 1000
staging and prognosis for, 1705–1706, 1705t
treatment of, 1706–1709
chemotherapy for, 1707–1709, 1708t
radiation for, 1709
stage-based guidelines for, 1709, 1709t
surgical, 1706–1707, 1707b, 1709
verrucous, 1702–1703
Penis, metastatic tumors of, 1703
Pentobarbital, for agitated delirium in dying patient, 667t
Pentostatin (2'-deoxycoformycin, 2'-DCF, Nipent), 477
for adult T-cell leukemia-lymphoma, 2435–2436
for chronic lymphoid leukemia, 2303
for hairy cell leukemia, 2313, 2313f, 2313t, 2315–2316
PEP (protein electrophoresis), for multiple myeloma, 2328–2329, 2328f
Peptide probes, for molecularly targeted therapy, 494t
Peptide receptor radiation therapy, 440
Percutaneous balloon pericardiotomy, for pericardial effusion, 936
Percutaneous celiac plexus neurolysis, 574
Percutaneous central lines, 779–780
Percutaneous cordotomy, for pain management, 574
Percutaneous ethanol injection therapy (PEIT), for liver metastases, 911
Percutaneous spine biopsy, for spinal metastases, 818
Percutaneous tube pericardiostomy, for pericardial effusion, 935–936
Percutaneous vertebroplasty and kyphoplasty, for spinal metastases, 823, 824f, 867
Performance status (PS), 1043
Perfusion-limited hypoxia, 116
Perianal infections, 795
Pericardial disease
due to cancer therapy, 983, 993
radiation-induced, 983, 994
Pericardial effusions, 925, 933–937, 1387, 1388f
approach to, 933, 933f
background of, 925
clinical presentation of, 934
diagnosis and evaluation of, 925, 934–935, 934t
etiology and pathogenesis of, 933
incidence of, 925
treatment and management of, 925, 935–937

Pericardial fluid, 933
evaluation of, 934–935
Pericardial space, 933
Pericardial tamponade, 934
Pericardial tumors, 1387–1388, 1388f
Pericardiocentesis, 934
Pericardioscopy, 935
Pericardiostomy
percutaneous tube, 935–936
subxiphoid, 936
Pericardiotomy, percutaneous balloon, 936
Pericardium, malignant mesothelioma of, 1388
Perineal dermatitis, due to radiation therapy, 1542
Peripheral blood counts, in acute lymphocytic leukemia, 2195, 2195t
Peripheral blood mononuclear cells (PBMCs), in clinical trials of molecularly targeted therapy, 491
Peripheral blood progenitor cells, 684
Peripheral blood stem cells (PBSCs), for myelodysplastic syndrome, 2250
Peripheral nerve hyperexcitability (PNH), paraneoplastic, 771
Peripheral nerve sheath tumor, malignant, 1390
genetic predisposition to, 2011, 2011t, 2012t
neurofibromatosis type 1 and, 2105
Peripheral nervous system, paraneoplastic syndromes of, 772–774, 773f
Peripheral neuroepithelioma
differential diagnosis of, 2085, 2086t
of thorax, 1389
Peripheral neuropathy
due to bortezomib, 952
due to cisplatin, 948
due to cytosine arabinoside, 946
differential diagnosis of, 956–957, 957t
due to interferons, 951
due to paclitaxel and docetaxel, 951
due to procarbazine, 950–951
radiation-induced, 953
due to vinca alkaloids, 948
Peripheral T-cell lymphoma (PTCL)
clinical characteristics of, 2382t
treatment of, 2395
Peripheral vascular disease, due to cancer therapy, 993
Peripherally inserted central catheter (PICC), 780–781, 782t
Perirectal infections, 727, 795
Peritoneal carcinomatosis, due to carcinoma of unknown primary, 2069
Peritoneal papillary serous carcinoma, 2069
Peritoneal washings, positive, endometrial cancer with, 1802, 1812–1813, 1812t
Peritonectomy, for ascites, 940
Peritoneovenous shunting, for ascites, 939–940
Peritoneum, papillary serous carcinoma of, 938, 1829
Peritonitis, 792
spontaneous bacterial, 938
“Perivascular” cuffs, 106
Permanent Silastic catheter, 780, 780f
guidelines for, 782t
insertion of, 784, 785f
Personality changes, grading of, 960t
PET. *See* Positron emission tomography (PET).
Petrosphenoidal syndrome, 1208
Peutz-Jeghers syndrome, 172, 174t
small bowel tumors in, 1466, 1466f
pH
of pleural effusions, 928–929
of tumor environment, 116, 117f
Ph (Philadelphia) chromosome
in acute lymphocytic leukemia, 2193, 2207–2208
in chronic myeloid leukemia, 2280, 2280f, 2282
Pharmaceutical industry, clinical trials sponsored by, 331–333
Pharmacodynamic (PD) markers, for molecularly targeted therapy, 492–493, 493t
Pharmacodynamics, 454–455
Pharmacoeconomics research, conflict of interest in, 339, 340
Pharmacogenetic assays, 272
Pharmacogenetics, 454, 457
Pharmacogenomics, 454
Pharmacokinetics, 454
Pharmacoproteomics, 454
Pharyngolaryngodysesthesia, due to oxaliplatin, 949
Phenix device, for osteosarcoma in children, 2081, 2082f
Phenol blocks, 573–574, 574t
Phenothiazines, as antiemetics, 605
L-Phenylalanine mustard. *See* Melphalan (Alkeran, L-PAM, L-phenylalanine mustard, L-sarcolysin).
Pheochromocytoma, 1286
imaging of, 302
malignant, 1271, 1286–1288
course and treatment of, 1271, 1286–1288
diagnosis of, 1271, 1286, 1287f
disorders associated with, 1286
mediastinal, 1389–1390
in MEN-2, 1289
Philadelphia (Ph) chromosome
in acute lymphocytic leukemia, 2193, 2207–2208
in chronic myeloid leukemia, 2280, 2280f, 2282
Phimosis, and penile carcinoma, 1701
PhIP, as carcinogen, 133b
Phlebitis, chemotherapy-induced, 627–629
Phlebotomy, for polycythemia vera, 2265, 2267, 2267t
PHM. *See* Partial hydatidiform mole (PHM).
Phosphatase and tensin homolog *(PTEN)* gene, 212t
and breast cancer predisposition, 172, 178t, 1880
in Cowden syndrome, 184
in glioblastomas, 1095
in intracellular signaling, 27
promotion of apoptosis by, 71
in prostate cancer, 1660
Phosphatase and tensin homolog (PTEN) pathway, in active mediation of tumor–immune system interactions, 85
Phosphate, for hypercalcemia of malignancy, 746t
Phosphatidylinositol 3,4,5-triphosphate (PIP_3) kinase(s) (PI3Ks)
in apoptosis, 72, 72f
in breast cancer, 1880
in intracellular signaling, 26, 26f
Phosphoramide mustards, congestive heart failure due to, 990
Phosphorus, radioactive, for polycythemia vera, 2265, 2266t, 2267
Photochemotherapy, for cutaneous T-cell lymphoma, 2418–2419
Photocoagulation, for retinoblastoma, 2110
Photodisintegration, 421
Photodynamic therapy (PDT)
for Barrett’s esophagus, 1423
for esophageal cancer, 1405, 1417, 1420–1421
for mesothelioma, 1378
Photoelectric effect, 421, 422f
Photomultiplier tubes (PMTs), in flow cytometry, 241
Photon, 418
Phototherapy, for cutaneous T-cell lymphoma, 2418
Phrenic nerve dysfunction, grading of, 960t
Phycoerythrin (PE), in flow cytometry, 242
Physical activity
and colorectal cancer, 370, 1482
for fatigue, 660–661, 660b
in rehabilitation, 586–587
Physical dependence, 571t
Physical modalities, in rehabilitation, 587
Physician Data Query (PDQ), 334
Phytoestrogens
and breast cancer, 1877
for cancer prevention, 547
PI3Ks (phosphatidylinositol 3,4,5-triphosphate kinases)
in apoptosis, 72, 72f
in breast cancer, 1880
in intracellular signaling, 26, 26f
PIA (proliferative inflammatory atrophy), and prostate cancer, 1657–1658, 1657f, 1658b, 1666
PIC (polymorphism information content), 196–197
PICC (peripherally inserted central catheter), 780–781, 782t
PICP (C-terminal propeptide of procollagen type 1), as bone formation marker, 853
PIF (proteolysis-inducing factor), in cachexia, 594
PIK3CA gene, 211t
Pilocarpine, for xerostomia, 617–618
PIN (prostatic intraepithelial neoplasia), 379, 1654, 1666
Pineal parenchyma tumors (PPTs), 1117
Pineal region tumors, 1082, 1117
Pineoblastomas, 1117
Pineocytomas, 1117

PINP (N-terminal propeptide of procollagen type 1), as bone formation marker, 853
PIOL (primary intraocular lymphoma), 1148–1150, 1149f
PIOPED (Prospective Investigation of PE Diagnosis) Study, 696, 705
PIP_3 (phosphatidylinositol 3,4,5-triphosphate) kinase(s) (PI3Ks)
in apoptosis, 72, 72f
in breast cancer, 1880
in intracellular signaling, 26, 26f
Pipe smoking, and head and neck cancer, 1179
Pipobroman, for polycythemia vera, 2265, 2266, 2266t
Pituitary, radiation tolerance dose of, 435t
Pituitary adenoma(s), 1111–1114
classification of, 1111–1112, 1112t
clinical and pathologic considerations for, 1111–1112, 1112t
genetics of, 1111
macro-, 1111
micro-, 1111
reproductive effects of, 1000
therapy for
medical, 1112–1113
radiation, 1113–1114
recommended approach for, 1114, 1114b
surgical, 1112
Pituitary apoplexy, due to brain tumor, 1081t
Pituitary dysfunction, cancer- or treatment-related, 1013–1015, 1017–1019, 1017t, 1143
Pituitary irradiation, late effects of, 1113
Pituitary tumors
second malignant neoplasms with, 1031
signs of, 1082
PKB (protein kinase B), in apoptosis, 72, 72f
Placenta, 1049
Placental alkaline phosphatase (PLAP), as tumor marker for intracranial germ cell tumors, 1126
Placental site trophoblastic tumor (PSTT)
clinical presentation of, 1863
pathology of, 1861, 1861f
treatment for, 1868–1869
Plain films, 283, 288, 291t
of bone metastases, 849–850, 850f, 855
of brain tumors, 1084
for carcinoma of unknown primary, 2065
of Ewing's sarcoma, 2087, 2088f
of osteosarcoma, 1951, 1952f, 2079, 2079f
of pulmonary metastases, 874, 875f
of spinal metastases, 817
Planning target volume (PTV), 436
Plant alkaloids, cutaneous side effects of, 627t
PLAP (placental alkaline phosphatase), as tumor marker for intracranial germ cell tumors, 1126
Plaque radiotherapy, for retinoblastoma, 1154
Plasma cell leukemia (PCL)
cytogenetic aberrations in, 256t
with HIV, 1067f
Plasma osmolality
calculation of, 752b
and hyponatremia, 750, 751f
Plasmacytoma(s)
of head and neck, 1184
solitary, 2324, 2325t, 2344–2345
multiple, 2329
Plasmid vectors, 518–519, 518b
Platelet(s), in metastasis, 38
Platelet count, 682
in acute lymphocytic leukemia, 2195t
in cervical cancer, 1757
Platelet disorders, 682–683, 683f
Platelet transfusions, 683
Platelet-derived growth factor receptor (PDGFR)
in astrocytomas, 1094
in intracellular signaling, 27–28, 27f
Platelet-derived growth factor receptor α (PDGFR-α), as molecular target, 486t
Platelet-derived growth factor receptor β (PDGFR-β), as molecular target, 486t
Platinol. *See* Cisplatin (Platinol, cDDP, DDP, cisplatinum, *cis*-diamminedichloroplatinum).
Platinum agents
for gastric cancer, 1456–1457
for non–small cell lung cancer, 1340–1342, 1340t
for ovarian cancer, 1832–1834, 1833t, 1834t, 1838
during pregnancy, 1006, 1053
as radiosensitizers, 433t
Platinum-resistant ovarian cancer, 1840, 1840t, 1846t, 1847
PLCO (Prostate, Lung, Colorectal and Ovarian) Cancer Screening Trial, 368, 378
PLD. *See* Pegylated liposomal doxorubicin, (Doxil, PLD).
Pleomorphic adenoma, salivary gland, 258t
Pleural biopsy, closed, 929
Pleural effusions, 925–933, 1379–1380
approach to, 926, 926f
background of, 925
diagnosis and evaluation of, 925–929
cell count and cytology in, 929
closed pleural biopsy in, 929
history and physical examination in, 927
pH in, 928–929
radiologic evaluation in, 927–928
thoracentesis in, 928
thoracoscopy in, 929
transudates vs. exudates in, 928
visual examination in, 928
etiology and pathogenesis of, 926, 927t, 929
grading of, 972t
incidence of, 925, 926
loculated, 928
non-small cell lung cancer with, 1333
due to ovarian cancer, 1848
transudative vs. exudative, 928
Pleural effusions (*cont.*)
treatment of, 925, 929–933
chemical pleurodesis for, 930–932
chemotherapy for, 930
intrapleural therapy for, 932
long-term drainage catheters for, 932–933
radiation therapy for, 930
shunts for, 932
surgical, 932
thoracentesis for, 930
Pleural fluid, 926
Pleural fluid cytology, 929
Pleural mesothelioma, 1317
benign, 1369
malignant, 1367, 1369–1378
clinical presentation of, 1370–1371, 1370f–1372f
diagnosis of, 1370–1371, 1370f–1372f
differential diagnosis of, 1367
epidemiology of, 1367, 1369–1370
epithelial, 1371, 1372t, 1375
imaging of, 1371, 1372f
mixed, 1371, 1375
natural history of, 1370–1371, 1370f
pathology of, 1370f, 1371, 1371f, 1372t
prognosis for, 1375
sarcomatous, 1371, 1375
staging of, 1367, 1371, 1373t
therapy for, 1367, 1373–1378, 1374f
biologic and targeted, 1377–1378, 1377t
chemo-, 1367, 1375–1377, 1376t, 1377t

pathology of, 1370f, 1371, 1371f, 1372t
prognosis for, 1375
sarcomatous, 1371, 1375
staging of, 1367, 1371, 1373t
therapy for, 1367, 1373–1378, 1374f
biologic and targeted, 1377–1378, 1377t
chemo-, 1367, 1375–1377, 1376t, 1377t
combined-modality, 1378
gene, 1378
intrapleural instillation as, 1376–1377
radiation, 1367, 1375
surgical, 1367, 1373–1375, 1374t, 1375t

Pleural tumor(s) (*cont.*)
metastatic, 1367, 1378–1380
primary, 1368–1378
Pleurectomy, for mesothelioma, 1373–1374, 1374t, 1378
Pleurodesis, 1379–1380
for mesothelioma, 1373
for pleural effusion, 930–932
Pleuroperitoneal shunt, 932
PLGA (polymorphous low-grade adenocarcinoma), of salivary gland, 1184
Plicamycin (Mithracin, mithramycin), 477
for hypercalcemia of malignancy, 746
hyperpigmentation due to, 632
"Ploidy," nomenclature for, 250t
PMBL (primary mediastinal B-cell lymphoma), 2386
PMF. *See* Primary myelofibrosis (PMF).
PML (promyelocytic leukemia), acute. *See* Acute promyelocytic leukemia (APL).
PML gene, in childhood leukemia, 2148–2149
PML (promyelocytic leukemia) gene, in acute myelogenous leukemia, 2218, 2219f
PML-RAR, as molecular target, 486t
PML-RARA fusion gene, in childhood leukemia, 2148–2149
PML-RARα gene, 211t
PMS1 gene, 212t
PMS2 gene, 212t
PMTs (photomultiplier tubes), in flow cytometry, 241
PNETs. *See* Primitive neuroectodermal tumors (PNETs).
Pneumocystis pneumonia
with HIV, 1062
Kaposi's sarcoma vs., 1064
Pneumonectomy, extrapleural, for mesothelioma, 1374–1375, 1375t, 1378
Pneumonia, 724–725, 725t
Pneumonitis
grading of, 972t
radiation, 969–976
diagnosis of, 969, 970f, 974, 975t
incidence of, 971–974, 971t–973t
pathophysiology of, 971
risk factors for, 969, 971, 973–974, 973f
scoring systems for, 971–973, 971t, 972t
treatment for, 969, 974–976, 976t
Pneumonopathy, 969–979
drug-induced, 969, 976–979, 977t
due to alkylators and nitrosoureas, 977–978
due to anthracyclines, 978
due to antimetabolites, 977
due to biologic agents, 978–979, 978f
due to bleomycin, 976–977
diagnosis of, 969
risk factors for, 969
due to taxanes, 978
treatment for, 969
Pneumonopathy (*cont.*)
radiation-induced, 969–976
diagnosis of, 969, 970f, 974, 975t
incidence of, 971–974, 971t–973t
pathophysiology of, 971
risk factors for, 969, 971, 973–974, 973f
scoring systems for, 971–973, 971t, 972t
treatment for, 969, 974–976, 976t
Pneumothorax
grading of, 972t
due to vascular access device, 786
PNH (peripheral nerve hyperexcitability), paraneoplastic, 771
PNP (purine nucleoside phosphorylase) deficiency, 226, 226t
Pocket proteins, 53, 54f
Podoplanin, in lymphangiogenesis, 112
POEMS syndrome, 2325t, 2345
in myeloma, 773
POG (Pediatric Oncology Group)
on acute myeloid leukemia, 2155
economic analysis by, 340t, 341
POG-CCG (Pediatric Oncology Group–Children's Cancer Group) trial, for Ewing's sarcoma, 2089t, 2090
Polifeprosan 20 with carmustine implant, 463
for gliomas, 1101–1102
Polonium, 419
PolyA tail, 10f
Poly-(ADP-ribose) polymerase (PARP), in necrosis, 70
Poly-(ADP-ribose) polymerase 1 (PARP-1), in DNA repair, 149b
Poly-(ADP-ribose) polymerase (PARP) inhibitors, for breast cancer, 1879
Polycyclic aromatic hydrocarbons (PAH), as carcinogens, 127, 128f, 129t, 133b
biomarkers of, 134
Polycythemia, 681
Polycythemia vera (PV), 2262–2267
complications of, 2267
diagnosis of, 2263–2265, 2263f, 2264f
diagnostic criteria for, 2263, 2265t
incidence of, 2262
pathogenesis of, 2262–2263
risk stratification for, 2266, 2267t
treatment of, 2265–2267, 2265b, 2266t
Polyethylene glycol (PEG) shielding, in gene therapy, 524
Polymerase chain reaction (PCR), 5–6, 6f, 8f–9f, 266
in hematolymphoid neoplasms
for chromosomal translocations, 268–269, 268t
for gene rearrangement assays, 267–268, 268t, 269f
"long distance," 266
nested, 266, 268
reverse transcriptase, 266, 268, 269f
Polymorphism information content (PIC), 196–197
Polymorphous low-grade adenocarcinoma (PLGA), of salivary gland, 1184
Polymyositis
differential diagnosis of, 957
paraneoplastic, 774–775
Polyp(s), of colon
adenomatous, 363f, 369
and colorectal cancer, 1481, 1483
familial (*See* Polyposis, familial adenomatous)
surgical management of, 1505, 1506f
malignant, 1505, 1506f
Polypharmacy, by elderly, 1043
Polyposis
familial adenomatous, 173t, 179–180, 369, 1482–1483
clinical features of, 179–180, 369, 1483f
clinical management of, 180
and colorectal cancer, 1482–1483
genetics of, 180, 369
and hepatoblastoma, 2113
screening for, 372
juvenile, 173t
MYH-associated, 145, 180
Pomalidomide, for primary myelofibrosis, 2274
POMB-ACE regimen, for testicular cancer, 1733
Pontomedullary brainstem gliomas, 1124, 1124f
Poorly differentiated carcinoma, of unknown primary, 2070
Poorly differentiated tumors, 234
Population(s), target, source, and study, 344–345, 344f
Population attributable risk percent, 353
Population stratification, 357
Population-based case-control studies, 201, 354–355
Porcelain gallbladder, 1580–1581, 1580f
PORT (postoperative radiotherapy). *See* Adjuvant radiation therapy.
Portal vein invasion, by cholangiocarcinoma, 1587, 1587f
Portal vein resection, for pancreatic cancer, 1604–1605
PORTEC (Post-Operative Radiation Therapy in Endometrial Cancer) Study Group, 1803b, 1806, 1817
Positional cloning resources, 200
Positive predictive value, of imaging, 284t, 285
Positive selection, in hematopoietic stem cell transplantation, 504
Positron emission tomography (PET), 73b, 283, 290–291, 291t
of bladder cancer, 300
of bone metastases, 293–294, 851–852, 855
of bone sarcomas, 1947
of brain tumors, 1085, 1086f
for carcinoma of unknown primary, 2067, 2067t
of cervical cancer, 1756
of colorectal cancer, 297–298, 297f
metastatic, 1494, 1494f
recurrent, 1511
of esophageal cancer, 1406
fetal exposure to, 1051
of gestational trophoblastic disease, 1864
of head and neck cancer, 300, 301f
of hepatocellular carcinoma, 1571–1572

Positron emission tomography (PET) (*cont.*)
of liver metastases, 887–888, 1494, 1494f
of lung cancer, 292–293, 293f, 294f, 1321–1322, 1324, 1326f, 1347
metastatic, 293–294, 294f
of lymphoma, 298–299, 299f, 2376
Hodgkin's, 2359–2341, 2359f, 2360f
of melanoma, 299–300
metastatic, 1234
for molecularly targeted therapy, 493
of multiple myeloma, 2329, 2329f
of osteosarcoma, 1951
of pancreatic cancer, 1599
of pulmonary metastases, 875–876
of soft-tissue sarcoma, 2017–2018
of testicular cancer, 1721
Posterior fossa tumors, 1120, 1120f
Posterior mediastinum, 1380
tumors of, 1380t, 1388–1390, 1388f
Posterior reversible encephalopathy syndrome (PRES), differential diagnosis of, 954, 954f
Postmastectomy syndrome, 565
"Postnatal" vasculogenesis, 106
Post-Operative Radiation Therapy in Endometrial Cancer (PORTEC) Study Group, 1803b, 1806, 1817
Postoperative radiotherapy (PORT). *See* Adjuvant radiation therapy.
Postremission chemotherapy, for acute myeloid leukemia, 2226, 2227, 2227b
Post-thoracotomy syndrome, 565
Post-transcriptional processing, 10f
Post-transplant lymphoproliferative disorder (PTLD), 154, 227–228, 2391
Post-traumatic stress disorder, rehabilitation for, 581
Potentially lethal damage repair, 427–428
Pott, Percival, 127
Power, of clinical trial, 310–311, 315
Power analysis, 195
Pox vectors, 516–517, 517b
PPTs (pineal parenchyma tumors), 1117
PR (progesterone receptors)
in breast cancer, 1878–1879, 1918
in endometrioid adenocarcinoma, 1799
pRb. *See* Retinoblastoma protein (pRb).

biopsy of, 1663, 1664–1665
bone loss in, 865–866
cadmium and, 132
cytogenetic aberrations in, 258t, 1658–1659
diagnosis of, 1653, 1662–1665
clinical evaluation in, 1662, 1663t
digital rectal examination of, 1662, 1663t
prostate-specific antigen in, 1662–1664, 1663t, 1664f, 1664t
transrectal ultrasound-guided biopsy in, 1664–1665
Prostate cancer (*cont.*)
epidemiology of, 376, 1653–1654, 1656–1657
etiology of, 376–377, 1656–1658, 1657f, 1658b
evaluation of extent of, 1666
hereditary predisposition to, 176t, 181–182, 181t, 1656
histopathology of, 1665–1666, 1665t
imaging of, 295–297, 296f, 1666
incidence of, 1653
linkage analysis of, 195, 196
metastatic
to bone, 846
bisphosphonates for, 863, 864, 1687
bone-targeted radionuclides for, 1687
imaging of, 296
sclerotic, 848
systemic therapy for, 859
tumor markers for, 855–856
clinical evaluation of, 1662
natural history of, 872–873, 1681t
treatment of, 1680–1689, 1681b
androgen deprivation therapy for, 1681–1686, 1682f, 1684f, 1685f
for androgen-independent disease, 1686–1689, 1688b, 1688f
bisphosphonates for, 863, 864, 1687
bone-targeted radionuclides for, 1687
docetaxel for, 1687–1688, 1688b, 1688f
immunotherapy for, 1688–1689
molecular pathogenesis of, 1653, 1658–1661, 1658f, 1659f
natural history of, 1668, 1680–1681, 1681t
PC-SPES for, 552, 552b
with pelvic lymph node involvement, 1679
prevention of, 366t, 378–379, 1653, 1661
prostate inflammation and, 1657–1658, 1657f, 1658b
screening for and early detection of, 365t, 377–378, 377f, 1653, 1665, 1665b
in elderly, 1045
second malignant neoplasms with, 1030–1031
staging of, 1662t, 1666–1667
treatment of, 1667–1689
androgen deprivation therapy for
anti-androgens and 5α-reductase inhibitors in, 1683
with brachytherapy, 1675
"complete" androgen blockade in, 1683–1685, 1684f, 1685f
intermittent, 1686
for localized disease, 1667–1680, 1677f
for metastatic disease, 1681–1686, 1682f, 1684f, 1685f
optimal timing of, 1685–1686
with radiation therapy, 1676–1679, 1677f
"second line," 1686
strategies of, 1681–1682, 1681b
for androgen-independent (hormone-refractory) disease, 1681, 1686–1689, 1688b, 1688f
bisphosphonates for, 863, 864, 1687

Prostate cancer (*cont.*)
treatment of (*cont.*)
bone-targeted radionuclides for, 1687
brachytherapy for, 1673–1676, 1674f, 1675t
docetaxel for, 1687–1688, 1688b, 1688f
for high-risk disease, 1677
immunotherapy for, 1688–1689
for intermediate-risk disease, 1677
for localized disease, 1667–1680, 1667b, 1667t
for locally advanced disease, 1677–1679
for low-risk disease, 1676, 1677f
for metastatic disease, 1653, 1680–1689
androgen deprivation therapy for, 1681–1686, 1682f, 1684f, 1685f
for androgen-independent disease, 1686–1689, 1688b, 1688f
bisphosphonates for, 863, 864, 1687
bone-targeted radionuclides for, 1687
docetaxel for, 1687–1688, 1688b, 1688f
immunotherapy for, 1688–1689
radiation therapy for, 1669–1680
adjuvant endocrine therapy and, 1676–1679, 1677f
conventional, 1671–1672
external beam, 1671–1672, 1671t
history of, 1669–1671
intensity-modulated, 1672f, 1673
pelvic lymph node involvement and, 1679
postprostatectomy, 1679–1680
proton beam, 444–445, 1676
reproductive effects of, 999, 1002
salvage, 1680
three-dimensional conformal, 1672–1673, 1672f, 1673f
toxicity of, 1671–1672, 1671t
radical prostatectomy for, 1668–1669, 1670f
radiation therapy after, 1679–1680
selection of approach for, 1667–1668, 1667b, 1667t
watchful waiting for, 1668, 1670f
tumor marker for, 279
Prostate Cancer Prevention Trial (PCPT), 1661
Prostate inflammation, and prostate cancer, 1657–1658, 1657f, 1658b
Prostate, Lung, Colorectal and Ovarian (PLCO) Cancer Screening Trial, 368, 378
Prostatectomy
radical, 1668–1669, 1670f
erectile function after, 1669
radiation therapy after, 1679–1680
urinary continence after, 1669
reproductive complications of, 999, 1001
Prostate-specific antigen (PSA), 1662–1664
with brachytherapy, 1675
for diagnosis, 1662–1663
and extent of prostate cancer, 1666
"free," 1664, 1664t
molecular forms of, 1664, 1664t
in molecular staging, 1667
and prostate biopsy, 1663
Prostate-specific antigen (PSA) (*cont.*)
and prostatic intraepithelial neoplasia, 1666
screening for, 182, 377–378, 1665, 1665b
as target for gene therapy, 520
as tumor marker, 279–281, 855–856
for carcinoma of unknown primary, 2064
and watchful waiting, 1668
Prostate-specific antigen (PSA) "density," 1663, 1664t, 1668
Prostate-specific antigen (PSA) spike, with brachytherapy, 1675
Prostate-specific antigen "velocity" (PSAV), 1663–1664, 1664f
Prostatic acid phosphatase (PAP), 1667
Prostatic hyperplasia, benign, 1654, 1655f
Prostatic intraepithelial neoplasia (PIN), 379, 1654, 1666
Prostheses, for osteosarcoma
endo-, 1965, 1966f
expandable, 1959–1962, 1964f–1965f, 2081, 2082f
Protease inhibitors, for HIV, 1062
Proteasome inhibitors, cutaneous reactions to, 636–637
Protein electrophoresis (PEP), for multiple myeloma, 2328–2329, 2328f
Protein kinase B (PKB), in apoptosis, 72, 72f
Protein-protein interactions, 13–14, 14f
Proteolysis-inducing factor (PIF), in cachexia, 594
Proteome, defined, 12–13
Proteomics, 12–15, 14f, 15f
Proteosome, as molecular target, 486t
Proteosome inhibitors, 453
Prothrombin time, in acute lymphocytic leukemia, 2195t
Proton beam radiation therapy, 443–445, 443f, 444f
for chordomas and chondrosarcomas, 445b, 1116
for pancreatic cancer, 1607
for prostate cancer, 444–445, 1676
for uveal melanoma, 1146
Proto-oncogene(s), 208
mutations in, 210, 211t
Proto-oncogene activation, epigenetic mechanisms of, 208, 211–214, 213f
Provera (medroxyprogesterone acetate), 473
for cachexia, 595
for colorectal cancer prevention, 1487t, 1489
for endometrial cancer, 1816
Proximal femur
Ewing's sarcoma of, 1987
osteosarcoma of, 1971, 1972f
Proximal humerus
Ewing's sarcoma of, 1987–1991, 1990f
osteosarcoma of, 1970, 1970f
Proximal tibia, osteosarcoma of, 1952f, 1971–1973
Pruritus
due to opioids, 571t
in polycythemia vera, 2267
PS (performance status), 1043
PS-341. *See* Bortezomib (PS-341).
PSA. *See* Prostate-specific antigen (PSA).
Pseudohypercalcemia, 742
Pseudohyponatremia, 750–751, 752b
Pseudomonas exotoxin, for adult T-cell leukemia-lymphoma, 2437
Pseudopalisading, in glioblastoma, 1092, 1092f
Pseudo–Pelger-Huet anomaly, in myelodysplastic syndrome, 2238f
Pseudotyping, of retroviral vectors, 524
PSN (paraneoplastic sensory neuropathy), 768, 772–773, 773f, 1324
Psoralens with ultraviolet A (PUVA), for cutaneous T-cell lymphoma, 2418
PSTT (placental site trophoblastic tumor)
clinical presentation of, 1863
pathology of, 1861, 1861f
treatment for, 1868–1869
Psychological dependence, 571t
Psychosis, grading of, 960t
Psychosocial consequences, of gestational trophoblastic neoplasia, 1872
Psychosocial interventions, for fatigue, 661
Psychostimulants
for fatigue, 660
for pain management, 570, 573t
PTCH gene, 212t
in nevoid basal cell carcinoma syndrome, 183
Ptch1 (patched 1), in basal cell carcinoma, 1254
PTCL (peripheral T-cell lymphoma)
clinical characteristics of, 2382t
treatment of, 2395
PTEN. *See* Phosphatase and tensin homolog (PTEN).
PTG (teniposide), 479
for brain metastases, 838–839
PTH (parathyroid hormone), in calcium homeostasis, 740
PTHrP (parathyroid hormone–related protein)
and bone metastases, 40–41, 41f, 846, 848
humanized antibodies to, 746
in hypercalcemia of malignancy, 741, 741f, 745
PTLD (post-transplant lymphoproliferative disorder), 154, 227–228, 2391
pTNM (pathologic staging), 234
PTV (patient treatment volume), 1087
PTV (planning target volume), 436
Puberty, precocious
due to adrenocortical cancer, 1282
after cranial or spinal irradiation, 1089
Public health approaches, to cancer prevention, 135–136, 136f, 137b
Pulmonary angiography, of pulmonary embolism, 705
Pulmonary complication(s), of anticancer treatment, 969–979
drug-induced, 969, 976–979, 977t
due to alkylators and nitrosoureas, 977–978
due to anthracyclines, 978
due to antimetabolites, 977
due to biologic agents, 978–979, 978f
due to bleomycin, 976–977
diagnosis of, 969
risk factors for, 969

Pulmonary complication(s), of anticancer treatment (*cont.*)
drug-induced (*cont.*)
due to taxanes, 978
treatment for, 969
radiation-induced, 969–976
diagnosis of, 969, 970f, 974, 975t
incidence of, 971–974, 971t–973t
pathophysiology of, 971
risk factors for, 969, 971, 973–974, 973f
scoring systems for, 971–973, 971t, 972t
treatment for, 969, 974–976, 976t
Pulmonary embolism (PE), 705–707
central venous access device–associated, 705, 709–710
diagnosis of, 696, 705–706, 705t
treatment of, 707
Pulmonary fibrosis
grading of, 972t
radiation, 975–976, 976t
Pulmonary function testing, for radiation pneumonitis, 974
Pulmonary infections, 724–725, 725t
Pulmonary infiltrates, 724–725, 725t
grading of, 972t
Pulmonary involvement, in adult T-cell leukemia-lymphoma, 2429
Pulmonary metastasis(es). *See* Lung metastasis(es).
Pulmonary metastectomy, 873, 876–881
approaches for, 876–877, 876t, 877f
for bone and soft-tissue sarcoma, 878–879, 879t
for breast cancer, 880–881
for colorectal cancer, 877–878, 878t
criteria for, 873–874
for germ cell tumors, 880, 880t
for head and neck cancer, 880, 880t
history of, 873
for melanoma, 879, 879t
prognostic factors after, 873, 874, 874f, 874t
for renal cell carcinoma, 879–880, 880t
for soft-tissue sarcoma, 2033–2034, 2033t, 2034f
Pulmonary nodule, solitary, 1326–1327, 1327f
imaging of, 292, 293f
Pulmonary perfusion imaging, 304
Pulmonary resection
for non-small cell lung cancer, 1329–1334
presurgical evaluation for, 1327–1329
smoking cessation prior to, 1327–1328
for small cell lung cancer, 1353
Pulmonary toxicity
of chemotherapy (*See* Pneumonopathy, drug-induced)
after hematopoietic stem cell transplantation, 507
of radiation therapy (*See* Pneumonopathy, radiation-induced)
Pulse oximetry, for radiation pneumonitis, 974
Pulsus paradoxus, 934
Purging, in hematopoietic stem cell transplantation, 504
Purine analog(s)
for cutaneous T-cell lymphoma, 2419
for hairy cell leukemia, 2312–2315
cladribine as, 2313–2316, 2314t, 2315f
immunosuppression with, 2315
minimal residual disease with, 2316, 2316f
pentostatin as, 2313, 2313f, 2313t, 2315–2316
prognosis with, 2315–2316
and infection, 729t, 732
Purine nucleoside phosphorylase (PNP) deficiency, 226, 226t
Purinethol (mercaptopurine), 474
for acute lymphoblastic leukemia in children, 2153–2154
PUVA (psoralens with ultraviolet A), for cutaneous T-cell lymphoma, 2418
PV. *See* Polycythemia vera (PV).
PVB regimen, for testicular cancer, 1728, 1729, 1731, 1732, 1738
pX, in hepatitis B virus, 157
Pylorus preservation, with pancreaticoduodenectomy, 1605
Pyramidal tract dysfunction, grading of, 960t
Pyridinoline (PYD), as bone resorption marker, 853, 856
Pyridinoline cross-linked C-terminal telopeptide of type I collagen (ICTP), as bone resorption marker, 853
Pyriform sinuses, tumors of, 1217
Pyrimidines, as radiosensitizers, 432
Pyrosequencing, 266

Q

5q$^-$ syndrome, in myelodysplastic syndrome, 2238, 2238f, 2240, 2240t
QALYs (quality-adjusted life-years), screening costs as, 287
QOL (quality of life), with osteosarcoma, 1973–1974
Quadrantectomy, for breast cancer, 1908
Quadriplegia, due to vinca alkaloids, 948
Quality assessment, of economic analyses, 339, 340
Quality control, for clinical trials, 315, 333–334
Quality of life (QOL), with osteosarcoma, 1973–1974
Quality-adjusted life-years (QALYs), screening costs as, 287
Quantitative perfusion study, in presurgical evaluation for lung cancer, 1328

R

RA (refractory anemia), 2239t, 2240t, 2241
Rad, 418
RAD001 (everolimus), for renal cell carcinoma, 1628
Radial growth phase, of melanoma, 1231
Radiation
biologic effect(s) of, 423–433
apoptosis as, 424–425
on cell cycle, 428, 429f
and cell survival curves, 425–426, 425f, 426f, 426t
Radiation (*cont.*)
biologic effect(s) of (*cont.*)
and cellular repair, 427–428, 427f
clinical applications of, 433–436
direct and indirect, 423–424, 423f
DNA damage as, 423–425, 423f, 424f
dose rate effects as, 428
and fractionation, 428–429
altered schemes of, 429–431, 430f, 430t
on normal tissue, 434–436
acute, 434, 434t
carcinogenesis as, 435–436, 435f
late, 434–435, 435t
oxygen effect as, 431–432, 431f, 432f
as carcinogen, 130–131, 435–436
ionizing, 130–131, 131t
of oral cavity, 620
principles of, 435–436, 435f
due to radon, 131
ultraviolet, 130
conformal, 440
ionizing
brain tumors due to, 1031, 1076–1077
and breast cancer, 1025, 1031, 1031t, 1877
as carcinogen, 130–131, 131t
fetal exposure to, 1050
physics of, 418–423
production of, 419–420, 420t
from linear accelerators, 420, 420f–422f
shielding of normal tissue from, 437
types of, 418–419, 419f
Radiation enhancement, 633–634
Radiation fields, designing of, 436–437, 438f
Radiation hepatitis, 915
Radiation myelopathy, 953
Radiation necrosis
of brain, 1086f
of spinal cord, 1090f
Radiation plexopathy, 953
Radiation pneumonitis, 969–976
diagnosis of, 969, 970f, 974, 975t
incidence of, 971–974, 971t–973t
pathophysiology of, 971
risk factors for, 969, 971, 973–974, 973f
scoring systems for, 971–973, 971t, 972t
treatment for, 969, 974–976, 976t
Radiation pneumonopathy. *See* Radiation pneumonitis.
Radiation pulmonary fibrosis, 975–976, 976t
Radiation recall, 633, 633f
Radiation therapy (RT), 417–445
for acoustic neuromas, 1114–1115
adjuvant, 438
for breast cancer, 1916, 1916b, 1917f
for colorectal cancer, 1517–1518
for endometrial cancer, 1803b, 1804t, 1806–1808, 1808t
for gastric cancer, 1442, 1443t
for head and neck cancer, 1189, 1199–1201, 1200f, 1201f
for head and neck sarcomas, 2042
for non–small cell lung cancer, 1335
for retroperitoneal sarcomas, 2039
for soft-tissue sarcoma, 2025–2027, 2025t, 2026f
for vulvar cancer, 1772

Radiation therapy (RT) (*cont.*)
for anal cancer, 1561–1562, 1562t, 1564–1566, 1565f
for bladder cancer, 1644–1646
for bone metastases, 856–858
for brain metastases, 830–833
partial brain, 831
whole-brain, 830–833
with chemotherapy, 838
portal image of, 830f
with radiosurgery, 834t, 835–836, 835t
randomized trials of, 830–831, 831t
response and local control with, 831
with surgery, 832–833, 833t
toxicity of, 831–832
for brain tumors, 1087–1090
adverse effects of, 1088–1090, 1090f
for breast cancer
adjuvant, 1916, 1916b, 1917f
boost doses of, 1911
complications of, 1913
ductal carcinoma in situ, 1906
early stage, 1910–1913, 1911f–1913f, 1916, 1916b, 1917f
locally advanced, 1927
partial breast, 1911–1912, 1913f
and recurrence, 1911, 1912f
whole breast, 1910–1911, 1911f, 1912f
for carcinoid tumor, 1291–1293
for cerebellar hemangioblastomas, 1115
for cervical cancer, 1759–1762, 1760f–1762f, 1763, 1764, 1765
with chemotherapy (*See* Chemoradiation therapy [CRT])
for cholangiocarcinoma, 1590
for chordomas and chondrosarcomas, 1116
clinical use of, 438, 439t
for colorectal cancer, 1517–1518
conformal, 440
for liver metastases, 912–914, 913f, 914f, 914t
for prostate cancer, 1672, 1672f, 1673f
for soft-tissue sarcoma, 2027
cranial
for acute myeloid leukemia in children, 2154–2158
adverse effects of, 1088–1089
brain tumors due to, 1031, 1076–1077
for CNS leukemia in children, 2154
reproductive effects of, 1001–1002
for small cell lung cancer prophylaxis, 1353–1354
definitive, 438
concomitant chemotherapy with, 438
for vulvar cancer, 1773
deposition of dose in, 421–423, 422f, 423f
for desmoid tumors, 2044
in elderly, 1039, 1045
electron beam, for cutaneous T-cell lymphoma, 2418
for endometrial cancer
adjuvant, 1803b, 1804t, 1806–1808, 1808t
for advanced disease, 1811–1814
complications of, 1816
early-stage, 1803b, 1804t, 1806–1808

Radiation therapy (RT) (*cont.*)
for endometrial cancer (*cont.*)
medically inoperable, 1810–1811, 1811t
neoadjuvant, 1807–1808, 1808t
palliative, 1815
recurrent, 1817, 1818
as sole modality, 1810–1811, 1811t
for esophageal cancer
dose selection and outcomes for, 1417–1418
palliative, 1419–1420
as sole modality, 1403, 1404t, 1417–1420
techniques for, 1418–1419
toxicities of, 1419
with tracheoesophageal fistula, 1415–1417
for Ewing's sarcoma, 1986–1987
late effects of, 1992–1993
four-dimensional, 440
fractionation of, 428–429
altered schemes of, 429–431, 430f, 430t
for head and neck cancer, 1189–1191, 1193–1199, 1195f, 1196f, 1196t–1198t
hyper-, for gliomas, 1098
Gamma Knife
for acoustic neuromas, 1114–1115
for brain tumors, 1087
for gastric cancer
adjuvant, 1442, 1443t
locally advanced, 1451
neoadjuvant, 1442–1444
palliative, 1455
techniques of, 1445–1450, 1446f–1449f, 1450t, 1451t
for glomus tumors, 1116–1117
guidance of, 304–305
for head and neck cancer, 1177, 1193–1202
brachytherapy as, 1201–1202
complications of, 1177
with concurrent and concomitant chemotherapy, 1191, 1204–1205, 1204f, 1205f, 1206t
fractionation of, 1189–1191, 1193–1199, 1195f, 1196f, 1196t–1198t
intensity-modulated, 1193, 1199
with nodal metastases, 1193, 1194t, 1195t
patient setup for, 1193, 1193f
postoperative, 1189, 1199–1201, 1200f, 1201f
toxicities of, 1188–1189, 1199
for head and neck sarcomas, 2042
for hepatoblastoma, 2116
historical perspective on, 417–418, 418f
intensity-modulated, 440–442, 441f
for brain tumors, 1087–1088
for head and neck cancer, 1193, 1199
for prostate cancer, 1672f, 1673
and second malignant neoplasms, 1032
for soft-tissue sarcoma, 2027
for vaginal cancer, 1782
interaction of x-rays with matter in, 420–421, 422f
intraoperative
for rectal cancer, 1550, 1551, 1551t
for retroperitoneal sarcomas, 2040

Radiation therapy (RT) (*cont.*)
involved-field, for Hodgkin's lymphoma, 2363t, 2364t
isocentric, 437–438
for Kaposi's sarcoma, 1065
for leukemia, in children
acute myeloid, 2154–2158
CNS, 2154
for liver metastases, 885, 912–915
brachytherapy as, 915–916
conformal, 912–914, 913f, 914f, 914t
hepatic arterial radioisotopes in, 915
liver tolerance to, 915
stereotactic body, 913, 914t
whole-liver, 912, 912t, 913t
for lung cancer
non-small cell, 1332, 1337, 1337t
adjuvant, 1335
neoadjuvant, 1336
small cell, 1351–1353, 1351f, 1352t
for lymphoma
in children, 2184
cutaneous T-cell, 2418
follicular, 2381
Hodgkin's, 2353–2354, 2363t, 2364t
complications of, 2353, 2366–2367, 2367t
orbital, 1162
primary CNS, 1106, 2390
primary mediastinal B-cell, 2386
for melanoma, 1240
uveal, 1146, 1146b, 1146t, 1147f
for meningiomas, 1110
for Merkel cell carcinoma, 1263
for mesothelioma, 1367, 1375, 1378
molecularly targeted therapy with, 495
neoadjuvant, 438
for bladder cancer, 1644
for endometrial cancer, 1807–1808, 1808t
for gastric cancer, 1442–1444
for head and neck sarcomas, 2042
for non-small cell lung cancer, 1336
for retroperitoneal sarcomas, 2039–2040
for soft-tissue sarcoma, 2025–2027, 2025t, 2026f
for neoplastic meningitis, 840
for neuroblastoma, 2095
neutron, 442–443, 442f
for soft-tissue sarcoma, 2028
new modality(ies) in, 439–445
brachytherapy as, 419, 439
intensity-modulated, 440–442, 441f
particle, 442–445, 442f–444f, 445b
systemic targeted radionuclide therapy as, 439–440
for ophthalmic tumors, 1137
toxicity of, 1138–1143, 1140f–1143f
"organ sparing" or "organ preserving," 438, 439
for ovarian cancer, 1842, 1843
pain due to, 565–566
for pain management, 572
palliative
for bladder cancer, 1644–1645
for endometrial cancer, 1815
for gastric cancer, 1455

Radiation therapy (RT) (*cont.*)
for pancreatic cancer, 1607
particle, 442–445, 442f–444f, 445b
for penile cancer, 1709
peptide receptor, 440
for pituitary adenomas, 1113–1114
for pleural effusion, 930
positioning for, 437–438
during pregnancy, 999, 1005b, 1007, 1058
for primary myelofibrosis, 2274
for primitive neuroectodermal tumors, 1121
for prostate cancer, 1669–1680
adjuvant endocrine therapy and, 1676–1679, 1677f
conventional (external beam), 1671–1672, 1671t
history of, 1669–1671
intensity-modulated, 1672f, 1673
pelvic lymph node involvement and, 1679
postprostatectomy, 1679–1680
proton beam, 444–445, 1676
reproductive effects of, 999, 1002
salvage, 1680
three-dimensional conformal, 1672–1673, 1672f, 1673f
toxicity of, 1671–1672, 1671t
proton beam, 443–445, 443f, 444f, 445b
for chordomas and chondrosarcomas, 1116
for pancreatic cancer, 1607
for prostate cancer, 444–445, 1676
for uveal melanoma, 1146
radioprotectors with, 432–433, 433f
radiosensitizers with, 432–433, 433t
for rectal cancer
intraoperative, 1550, 1551, 1551t
in medically inoperable patients, 1550
planning of, 1541–1542, 1542f
preoperative vs. postoperative, 1540–1541, 1540t, 1546
randomized trials of, 1543–1546, 1544t–1546t, 1545f, 1546f
toxicity of, 1542–1543
reproductive complications of, 999, 1001–1002
for retinoblastoma, 1154, 2111–2112
for retroperitoneal sarcomas, 2039–2040
for rhabdomyosarcoma, 2105
salvage, after radical prostatectomy, 1680
sealed source, 439
and second malignant neoplasms
in adults, 1028–1032, 1031t
in children and adolescents, 1024–1025, 1025f, 1026f
for seminoma, 1723
and soft-tissue sarcoma, 2010, 2010t
for soft-tissue sarcoma
complications and function after, 2027
conformal and intensity-modulated, 2027
for locally recurrent disease, 2032
neutron, 2028
preoperative or postoperative, 2025–2027, 2025t, 2026f
without surgery, 2027–2028
for spinal metastases, 819–822, 822t
Radiation therapy (RT) (*cont.*)
for squamous cell carcinoma, 1259–1260
of eyelid, 1159
stereotactic, 420
for acoustic neuromas, 1115
for brain tumors, 1087
for gliomas, 1099
for meningiomas, 1110–1111
for pituitary adenomas, 1113–1114
stereotactic body
for liver metastases, 913, 914t, 915
for pulmonary metastases, 881–882, 881t
for superior vena cava obstruction, 808–809, 809t
for supratentorial gliomas, 1097–1100, 1097t, 1099t
systemic therapies and, 432–433
for testicular cancer
stage I, 1723, 1725
stage II, 1727–1728
toxicity of, 1739
thoracic
fractionation of, 1352, 1352t
for non–small cell lung cancer, 1332, 1337, 1337t
adjuvant, 1335
neoadjuvant, 1336
pulmonary toxicity of (*See* Radiation pneumonitis)
for small cell lung cancer, 1351–1353, 1351f, 1352t
three-dimensional, 440, 441f
for prostate cancer, 1672–1673, 1672f, 1673f
for thyroid cancer, 1276–1279, 1277f–1279f
treatment planning for, 436–438, 437f, 438f
for vaginal cancer, 1781, 1782–1783
for vulvar cancer, 1772–1774, 1773t–1775t, 1774f
whole-brain, 830–833
with chemotherapy, 838
for gliomas, 1098
portal image of, 830f
with radiosurgery, 834t, 835–836, 835t
randomized trials of, 830–831, 831t
response and local control with, 831
with surgery, 832–833, 833t
toxicity of, 831–832
Radiation Therapy Oncology Group (RTOG)
economic analysis by, 340t, 341
scoring system for radiation lung injury based on, 971–973, 971t, 972t
Radiation Therapy Oncology Group (RTOG) trials
for rectal cancer, 1547t, 1548
for soft-tissue sarcoma, 2031
Radiation thryoiditis, acute, 1015
Radiation toxicity, in eye, 1138–1142, 1140f–1143f
Radiation-associated cutaneous reactions, 633–635, 633f, 634f
Radiation-induced acute lymphocytic leukemia, 2194
Radiation-induced brain tumors, 1031, 1076–1077
Radiation-induced breast cancer, 1025, 1031, 1031t, 1877
Radiation-induced carcinogenesis, 130–131, 131t, 435–436, 435f
Radiation-induced cardiotoxicity, 983, 991, 993, 994
Radiation-induced dysrhythmias, 992
Radiation-induced endocrine dysfunction, 1014–1015, 1014t
Radiation-induced endometrial cancer, 1795
Radiation-induced hypothalamic-pituitary axis disorders, 1014–1015, 1143
Radiation-induced liver disease (RILD), 915
Radiation-induced meningioma, 1024–1025, 1109
Radiation-induced myocardial fibrosis, 991
Radiation-induced nausea and vomiting, 606
Radiation-induced neurotoxicity, 945–963
clinical manifestations of, 952–953
differential diagnosis of, 953–957, 954f, 955t, 957t
etiology of, 945
evaluation of, 945
grading of, 945, 957, 958t–961t
incidence of, 945
treatment for, 945, 957–963, 962f, 963f
Radiation-induced oral complications, 614–620
dental caries as, 618–619
implementation of prevention and treatment of, 620
malignancy as, 620
mucositis as, 614–616
soft-tissue and bone necrosis as, 619
taste alterations as, 619
trismus as, 619–620
xerostomia as, 616–618, 617b
Radiation-induced osteosarcoma, 620, 1978
Radiation-induced pericardial disease, 983, 994
Radiation-induced thyroid cancer, 1024, 1272
Radical cervicectomy, 1759
Radical prostatectomy, 1668–1669, 1670f
erectile function after, 1669
radiation therapy after, 1679–1680
urinary continence after, 1669
Radical vulvectomy, 1770, 1771f
Radicular pain, due to spinal metastasis, 817
Radioactive decay, radiation production by, 419–420, 420t
Radioactive implants, for gliomas, 1098
Radioactive isotopes, for ovarian cancer, 1842–1844, 1843t, 1844t
Radioactive phosphorus (^{32}P), for polycythemia vera, 2265, 2266t, 2267
Radioactive plaque technique, for retinoblastoma, 2111–2112
Radioactive species, 419
Radioactivity, discovery of, 418
Radioembolization, for liver metastases, 910
Radiofrequency ablation (RFA)
for debulking, 414
for hepatocellular carcinoma, 1575, 1576f
of liver metastases, 885, 891, 895–896, 910–911
for pulmonary metastases, 882

Radioimmunoconjugates, 535–537, 535t, 536t
for adult T-cell leukemia-lymphoma, 2437
Radioimmunotherapy (RIT), 440
for follicular lymphoma, 2384–2385
monoclonal antibodies in, 535–537, 535t, 536t
Radioiodine therapy, 439
for thyroid cancer, 1276–1279, 1277f–1279f, 1281
Radioisotope(s), 419–420, 420t
for radioimmunoconjugates, 535, 535t
in systemic targeted radionuclide therapy, 439–440
Radioisotope therapy, targeted, for bone metastases, 858
Radiolabeled monoclonal antibodies
for leukemia, 536
for lymphoma, 535–536, 536t
Radiologic examination, during pregnancy, 1050–1051, 1050t
Radionuclide bone scan
of bone metastases, 850–851, 851f, 852f, 855
of spinal metastases, 817–818
Radionuclide imaging, 283, 290–291, 291t
for carcinoma of unknown primary, 2065
Radionuclide therapy
and second malignant neoplasms, 1032
targeted
for bone metastases, 858
systemic, 439–440
Radioprotectors, 432, 433f
with non-small cell lung cancer, 1339
Radioresistance, 425
Radiosensitivity, 425
hypoxia and, 116
Radiosensitizers, 432–433, 433t
radiation enhancement due to, 633–634
Radiosurgery, 420
of brain metastases, 834–836
dose-response relationships for, 834–835
results of, 834, 834f, 834t
surgery vs., 836, 837t
toxicity of, 836
whole-brain radiotherapy with, 835–836, 835t
for cerebellar hemangioblastomas, 1115
Gamma Knife, for brain tumors, 1087
stereotactic
for acoustic neuromas, 1115
for brain tumors, 1087
for pituitary adenomas, 1113
Radiotherapy. *See* Radiation therapy (RT).
Radium, 419
Radon
as carcinogen, 131
in radiation production, 419
RAEB (refractory anemia with excess blasts), 2239t, 2240t, 2241, 2248
RAEB-T (refractory anemia with excess blasts in transformation), 2239t, 2241
RAF, as molecular target, 487t
RafB mutations, in melanoma, 381
Raloxifene
and ovarian cancer, 1831
for prevention of breast cancer, 376, 1883
Random errors, in clinical trials, 310–311, 310t
Randomization, in clinical trials, 314
Randomized design, 348–349
Randomized discontinuation design, for molecularly targeted therapy, 492
RANK (receptor activator of nuclear factor-κβ)
in adult T-cell leukemia-lymphoma, 2430–2431
as osteoclastogenesis marker, 854
RANKL (receptor activator of nuclear factor-κβ ligand)
in adult T-cell leukemia-lymphoma, 2430–2431
in bone metastasis, 41, 41f
in multiple myeloma, 741
as osteoclastogenesis marker, 854
Rappaport classification, of hematologic malignancies, 2132
RAR-α (retinoic acid receptor-α)
in acute myelogenous leukemia, 2218, 2219f
in childhood leukemia, 2148–2149
RARS (refractory anemia with ringed sideroblasts), 2239t, 2240t, 2241
Ras inhibitors, for head and neck cancer, 1208
Ras oncogene
in acute myelogenous leukemia, 2219
in brain tumors, 1079
and cancer phenotype, 217, 218f
in melanoma, 1232–1233
as molecular target, 487t
in nonmelanoma skin cancer, 1255
Ras signaling pathway defects, and cancer phenotype, 217, 218f
Rasburicase, for tumor lysis syndrome, 761f, 762, 763, 763f
with childhood lymphoma, 2181
Ras-MAPK, in metastasis, 36, 36f
Rate difference, 352
Rate ratio, 352
Raynaud phenomenon, chemotherapy-induced, 993
RB gene
in nonrhabdomyosarcoma soft-tissue sarcoma, 2105
in osteosarcoma, 1950–1951
Rb pathway, in astrocytomas, 1094
RB1 gene, 212t, 214
and cancer phenotype, 220, 220f
and cell cycle deregulation, 59
in osteosarcoma, 2078–2079
in retinoblastoma, 1150, 2108–2109
RCC. *See* Renal cell carcinoma (RCC).
R-CHOP regimen
for AIDS-related lymphoma, 2392–2393
for diffuse large B-cell lymphoma, 2387t, 2388, 2388f, 2389, 2389f
RCM (red cell mass), in polycythemia vera, 2263
RCMD (refractory cytopenia with multilineage dysplasia), 2240t, 2241
RCMD-RS (refractory cytopenia with multilineage dysplasia and ringed sideroblasts), 2240t, 2241
Reactivation dermatitis, radiation-associated, 634, 634f
Reactive nitrogen species, in tumor microenvironment, 86
Reactive oxygen species (ROS), in tumor microenvironment, 86
REAL classification (Revised European-American Classification of Lymphoid Neoplasms), 1161, 1162t, 2132–2133
Recall bias, 202, 356
Receiver operator characteristic (ROC) curves, for imaging, 285–286, 285f
Receptor activation, by ligand, in intracellular signaling, 22–24
Receptor activator of nuclear factor-κβ (RANK)
in adult T-cell leukemia-lymphoma, 2430–2431
as osteoclastogenesis marker, 854
Receptor activator of nuclear factor-κβ ligand (RANKL)
in adult T-cell leukemia-lymphoma, 2430–2431
in bone metastasis, 41, 41f
in multiple myeloma, 741
as osteoclastogenesis marker, 854
Receptor tyrosine kinases (RTKs)
for gliomas, 1104
in intracellular signaling, 22–23, 27–28, 27f
Receptor-interacting protein (RIP), in apoptosis, 68, 68f
Recessive gene mutations, models of, 17–19, 18f
Recombinant adeno-associated viral vectors, 516
Recombinant adenoviral vectors, 515–516, 515f, 516b, 523–526
Recombinant alphavirus vectors, 517
Recombinant haplotypes, 196, 197f
Recombinant herpes simplex virus vectors, 516
Recombinant human thyroid-stimulating hormone (rhTSH), for thyroid cancer, 1279
Recombinant lentivirus vectors, 514–515
Recombinant Moloney murine leukemia virus vectors, 514
Recombinant pox vectors, 516–517, 517b
Recombination, and linkage analysis, 196, 196f, 197f
Recombination fractions, 196
Recombination frequency, 196
Reconstructive surgery, 414
recQ gene, diseases involving homologs of, 148
Recreation, rehabilitation for, 587
Rectal bleeding, evaluation of, 1536
Rectal cancer, 1535–1553. *See also* Colorectal cancer (CRC).
clinical presentation of, 1535, 1536
differential diagnosis of, 1535, 1537, 1537f
epidemiology of, 1535, 1536
metastasis of, 1537
staging and assessment of, 1535–1537, 1536f

Rectal cancer (*cont.*)
treatment of, 1535, 1537–1553
adjuvant
advantages and disadvantages of, 1540–1541, 1540t
chemotherapy for, 1548–1549
after local excision, 1549–1550, 1549t
randomized trials of, 1543–1544, 1544t
timing after surgery of, 1541
toxicity of, 1542–1543
chemoradiation for
with locally advanced disease, 1550–1551
in medically inoperable patients, 1550
novel agents in, 1546–1548, 1547t
planning of, 1541–1542, 1542f
preoperative vs. postoperative, 1540–1541, 1540t, 1546
randomized trials of, 1543–1546, 1544t–1546t, 1545f, 1546f
toxicity of, 1542–1543
future issues in, 1552
for isolated local/pelvic failure, 1551–1552
for locally advanced disease, 1550–1551, 1551t
for medically inoperable patients, 1550
neoadjuvant
advantages and disadvantages of, 1540–1541, 1540t
novel agents in, 1546–1548, 1547t
randomized trials of, 1544–1546, 1544t–1546t, 1545f, 1546f
timing of surgery after, 1541
toxicity of, 1542–1543
salvage therapy in, 1552
surgical, 1537–1540
laparoscopic, 1539–1540
local, 1537–1538, 1538t
margins for, 1498
patterns of failure with, 1540, 1540t
radical, 1538–1539, 1539f
Rectal carcinoids, 1537
Rectal examination, digital
for colorectal cancer, 370–371
for prostate cancer, 377, 1662, 1663t
Rectal surgery, reproductive effects of, 1001
Rectum
carcinoid tumors of, 1290
obstruction of, 797
radiation effects on, 434t
radiation tolerance dose of, 435t
Red cell aplasia
due to erythropoiesis-stimulating proteins, 680
with thymoma, 1383
Red cell disorders, 677–681, 678f, 679t, 680f
Red cell mass (RCM), in polycythemia vera, 2263
Reduced-intensity conditioning (RIC), for myelodysplastic syndrome, 2249–2250, 2249t
5α-Reductase inhibitors, for prostate cancer, 1682f, 1683
prevention of, 1661
Reed, Dorothy, 2353
Reed-Sternberg (RS) cells
biology of, 2357, 2357f
derivation of, 2356–2357, 2357t
discovery of, 2353
Epstein-Barr virus in, 2355
pathology of, 2355, 2356f
"Reference" cell population, 200
Refractory anemia (RA), 2239t, 2240t, 2241
Refractory anemia with excess blasts (RAEB), 2239t, 2240t, 2241, 2248
Refractory anemia with excess blasts in transformation (RAEB-T), 2239t, 2241
Refractory anemia with ringed sideroblasts (RARS), 2239t, 2240t, 2241
Refractory cytopenia with multilineage dysplasia (RCMD), 2240t, 2241
Refractory cytopenia with multilineage dysplasia and ringed sideroblasts (RCMD-RS), 2240t, 2241
Regaud, Claude, 418
Regional analgesia, 573–574, 574t
Regional hyperthermia (RHT), for soft-tissue sarcoma, 2031–2032
Regional lymph nodes (RLNs), in metastasis, 39
Regional pancreatectomy, 1604
Regresser tumors, 79
Regression methods, in clinical trials, 319–321, 320t
Regression techniques, 353
Regulatory DNA sequences, 7–9, 10f
Regulatory issues, in molecular diagnostics, 273
Regulatory T cells, and cancer, 83–84
Rehabilitation, 579–587
active participation of patient in, 579
for activity limitations, 586–587
for bladder and bowel management, 584, 585t
for bone tumors, amputation, and bony metastases, 583–584
components of, 579
for delirium and cognitive dysfunction, 581
epidemiology of cancer disability and, 579
for fatigue, 581
goal-oriented, 579
for hemiplegia, 581–582
for impairments, 580–586
interdisciplinary team approach to, 579
for mood disorders, 581
for neurologic impairments, 581
outcome measures for, 580
for pain, 580
for paraplegia/tetraplegia, 582–583
for participation restrictions, 587
patient-centered, 579
phases of, 580, 580t
for sexual function, 584–585
for soft-tissue impairments, 584
for speech, swallowing, and nutrition, 583
vocational, 587
Rehabilitative surgery, 414
Rehn, Ludwig, 127
Reimbursement
for clinical trials, 329, 337–338
for molecular testing, 273
Reinduction chemotherapy
for acute lymphocytic leukemia, 2197, 2199
for acute myeloid leukemia, 2227–2228
Relapse, 459
Relative risk (RR), 194, 201, 202, 352
Remission induction, for acute myeloid leukemia, 2224–2226
Remote afterloading brachytherapy, 439
Renal cell carcinoma (RCC), 1613–1631
advanced
angiogenesis inhibitor(s) for, 1624–1629
chemotherapy for, 1630
cytokine therapies for, 1623–1624
lymphadenectomy for, 1623
in children, 2076, 2100–2101, 2101t
chromophobe, 1614, 1614t
clear cell, 1614, 1614t
familial, 1616
collecting duct, 1614t, 1630
diagnosis of, 1616
familial, 1614t, 1615–1616, 1621
genetics of, 257t–258t, 1614–1616, 1615f
histologic classification of, 1614, 1614t
imaging of, 301–302, 303f
incidence and risk factors for, 1613–1614
leiomyomatosis and, 177t, 185–186, 1614t, 1616
medullary, 1614t
metastatic
to brain, 828, 1623
cytoreductive nephrectomy for, 510
to lungs, 879–880, 880t
resection of, 1622–1623
mucinous tubular and spindle cell, 1614t
multilocular cystic, 1614t
neuroblastoma-associated, 1614t
papillary, 1614, 1614t
hereditary, 1614t, 1616
pathology of, 1614, 1614t
predisposition syndromes for, 176t, 177t, 185–186, 1614t, 1615–1616
prognostic factors for, 1618–1619
recurrence of, 1618–1622
sarcomatous differentiation in, 1630
staging of, 1616–1618, 1617t, 1621
treatment of, 1619–1631
adjuvant therapy for, 509–510
angiogenesis inhibitor(s) for, 1624–1629
axitinib as, 1627–1628
bevacizumab as, 1627
everolimus as, 1628
future directions for, 1628–1629, 1628f, 1629f
guidelines for, 1626f
mechanism of action of, 1624, 1625f
pazopanib as, 1628
sorafenib as, 1624–1625, 1630
sunitinib as, 1625, 1630
temsirolimus as, 1625–1627
voloxicimab as, 1627
chemotherapy for, 518
cryosurgery for, 508
cytokine therapies for, 1623–1624
hematopoietic stem cell transplantation for, 507, 1629
interferon alfa-2b for, 1621–1622

Renal cell carcinoma (RCC) (*cont.*)
treatment of (*cont.*)
lymphadenectomy for, 1623
NCCN guidelines for, 1626f
nephrectomy for, 507–509
cytoreductive, 510
laparoscopic, 507–508
and morcellation, 507–508
nephron-sparing, 508
open, 507
surveillance after, 508–509
resection of metastases for, 1622–1623
vaccine for, 1629–1630
Renal failure, hyponatremia due to, 753
Renal insufficiency, in multiple myeloma, 2340
Renal toxicity, after hematopoietic stem cell transplantation, 508
Reoxygenation, with radiation, 432
Repiphysis device, for osteosarcoma, in children, 2081, 2082f
Replicative stress, 58f, 59
Repopulation, 428
Reporter genes, 7
Reproducibility, 493t
Reproductive complication(s), 999–1008
of bone marrow transplantation, 999, 1004–1005
cancer-related, 999–1001
chemotherapy-related, 999, 1003–1005
of hormonal therapy, 999, 1002–1003
pregnancy-related, 999, 1005–1007, 1005b
prevention of, 999, 1007–1008, 1007b
radiation-related, 999, 1001–1002
surgery-related, 999, 1001
treatment of, 999, 1007b, 1008
Reproductive physiology, 1000
Research questions, as testable hypotheses, 344
Research studies, conflict of interest in sponsorship of, 339, 340
Resolution, 55
Respiratory complications. *See* Pulmonary complication(s).
Respiratory infections, 724–725, 725t
Respiratory syncytial virus (RSV), 728
Rest, for fatigue, 661
Restlessness, in dying patient, 667t, 669–672, 669f, 670b, 671b
Restriction enzymes, 7, 8f–9f, 266, 268f
Restriction point, 50, 50f, 54, 54f
Restriction-fragment-length polymorphisms, 7, 8f–9f
RET gene, 211t
in MEN-2, 182, 1289
as molecular target, 487t
in thyroid cancer, 1272
Reticulosis, pagetoid, 2412, 2414t
Reticulum cell sarcoma. *See* Primary CNS lymphoma (PCNSL).
Retina, radiation toxicity in, 1141, 1142f
Retinal toxicity, of nitrosoureas, 950
Retinoblastoma, 1150–1154
bilateral or multifocal, 2108, 2112, 2112b
in children, 2077, 2108–2113
classification of, 1152, 1153t
clinical features of, 1150–1152, 1151f, 1152f, 2077, 2109–2110, 2110f
Retinoblastoma (*cont.*)
clinical forms of, 2077, 2108
cytogenetic aberrations in, 260t
diagnosis of, 1150–1152, 1151f
differential diagnosis of, 1153, 2077
epidemiology of, 2077, 2108
evaluation of, 2110, 2110f
genetic counseling on, 2109
hereditary, 1150
brain tumors in, 1078t
and osteosarcoma, 2078–2079
management of, 1153–1154, 1153f, 2077, 2110–2113, 2112b
metastatic, 1152, 2110
natural history of, 1152, 1152f
and osteosarcoma, 1950–1951
pathogenesis of, 1150
pathology of, 2109
predisposition syndrome for, 177t
second malignant neoplasms with, 1023–1025, 1024f, 1026f, 1150, 2113
and soft-tissue sarcoma, 2011, 2011t
staging of, 2077, 2110, 2111t
trilateral, 2110
tumor biology of, 2108–2109
two-hit hypothesis for, 1150, 2108–2109
unilateral or unifocal, 2108, 2112, 2112b
Retinoblastoma pathway, in melanoma, 1233
Retinoblastoma protein (pRb), 52–54, 54f
and cancer phenotype, 219–220, 220f
in cancer target conserved signaling network, 214, 214f, 215
and prognosis for soft-tissue sarcomas, 2020
in retinoblastoma, 1150, 2108–2109
Retinocytoma, 2109
cis-Retinoic acid, for chemoprevention of head and neck cancer, 1206–1207
9-*cis*-Retinoic acid (aliretinoin), for Kaposi's sarcoma, 1065
Retinoic acid receptor-α (RARα)
in acute myelogenous leukemia, 2218, 2219f
in childhood leukemia, 2148–2149
Retinoic acid syndrome, 2229
Retinoids, 453
for cancer prevention
in elderly, 1044
of head and neck cancer, 1206–1207
for cutaneous T-cell lymphoma, 2419
Retinol, for prevention of skin cancer, 382
Retinoma, 2109
Retinopathy(ies)
melanoma-associated, 772
paraneoplastic, 772
radiation, 1141, 1142f
Retroparotidian syndrome, 1208
Retroperitoneal lymph node dissection (RPLND)
reproductive effects of, 1001
for testicular cancer, 1725, 1726f, 1728–1729
alternatives to, 1725–1727

Serous carcinoma
papillary, of peritoneum, 938, 1829
uterine, pathology and biology of, 1797, 1797f
molecular, 1800
Serous cystadenoma, of pancreas, 1597
Serrated adenoma, and colorectal cancer, 1481
Sertoli cells, 1000
Serum free light-chain assay, for multiple myeloma, 2329
Serum protein electrophoresis (SPEP), for multiple myeloma, 2328–2329, 2328f
Severe combined immunodeficiency (SCID)
as cancer predisposition syndrome, 176t
and lymphoma, 225t, 226t
tumor distribution with, 225t
X-linked, 226, 226t
gene therapy for, 524–525, 525f
Severe combined immunodeficiency X1 (SCID-X1), gene therapy for, 524–525, 525f
Sexual activity, and cervical cancer, 1746
Sexual complications. *See* Reproductive complication(s).
Sexual dysfunction, rehabilitation for, 585–586
Sézary cells, 2408, 2410, 2410f, 2411f
Sézary syndrome
clinical manifestations of, 2406–2408, 2409f
staging of, 2415, 2415b
therapy for, 2405, 2415–2420
tissue diagnosis of, 2408–2412, 2410f–2412f
variants and subtypes of, 2412–2413, 2413f, 2414t
SFKs (Src family of tyrosine kinases), in intracellular signaling, 27
SFV (Semliki Forest virus) vectors, 517
SH2 domain, in intracellular signaling, 27, 27f
Shark cartilage, 552–553, 554t
Shh (sonic hedgehog), in regulation of self-renewal, 96
Shh (sonic hedgehog) pathway, in basal cell carcinoma, 1254
Short tandem repeat (STR) markers, 270
Short-term hematopoietic stem cells (ST-HSCs), 95–96, 96f
Shwachman syndrome, and acute myelogenous leukemia, 2217
Shwachman-Diamond syndrome, 175t
SIADH. *See* Syndrome of inappropriate secretion of antidiuretic hormone (SIADH).
Side scatter, in flow cytometry, 241, 242f
Sigmoiditis, due to cervical irradiation, 1762
Sigmoidoscopy, screening, 371
Signal transduction, 21–29
aberrant, as molecular target, 487t
adaptor or scaffolding proteins in, 22, 25
applications of, 28
clinical relevance of, 21–22, 28
cross-talk in, 22
cytokine receptors in, 24
cytoplasmic serine/threonine kinases in, 25–26, 25f, 26f
cytoplasmic tyrosine kinases in, 25
Frizzled receptors in, 24
G protein–coupled receptors in, 22
general principles of, 22, 23f
inside-out, 23–24
integrin receptors in, 23–24
lipid signaling in, 26–27, 26f

Signal transduction (*cont.*)
negative regulators of, 27
Notch receptors in, 24
nuclear hormone receptors in, 24
platelet-derived growth factor receptor in, 27–28, 27f
receptor activation by ligand in, 22–24
receptor tyrosine kinases in, 22–23, 27–28, 27f
serine/threonine kinase receptors in, 23
transforming growth factor β receptor in, 23, 28
tumor necrosis factor receptor in, 24, 28
Wnt signaling in, 28, 29f
Signal transduction pathways
components of, 25–27, 25f, 26f
examples of, 27–28, 27f, 29f
Signature traits, of cancer cells, 215, 216f
contribution of gene defects to, 215–221
for APC inactivation and β-catenin deregulation, 215–216, 217f
clinical implications of, 221
microRNAs in, 217–219, 219t
for RAS-signaling pathway defects, 217, 218f
role of tissue and context differences in, 219–221, 220f
Significant linkage, 198
SIL(s) (squamous intraepithelial lesions), 1751–1752
Silastic catheter, permanent, 780, 780f
guidelines for, 782t
insertion of, 784, 785f
Sildenafil citrate (Viagra), 1008
Silica, as carcinogen, 132
Simple tandem repeats (STRs), 266
Simpson-Golabi-Behmel syndrome, 176t
Simulation, of radiation field, 436–437, 438f
Sindbis virus vectors, 517
Single-nucleotide polymorphisms (SNPs), 4–7, 5f, 197
in association studies, 201, 202
in DNA repair genes, 146b
in linkage analysis, 197–198, 198f, 199f
microarray chips for, 266–267
Single-photon emission computed tomography (SPECT), 283, 290–291, 291t
Sinus cancer
pathology of, 1181
proton radiation therapy for, 443
treatment of, 1210–1211, 1211f
Sinus histiocytosis, with massive lymphadenopathy, 2396–2397
SIOPEL studies, of hepatoblastoma, 2115
siRNA (small interfering RNA), in gene therapy, 519
Sister chromatids, 55, 56
Skeletal health, effects of cancer treatments on, 865–866
Skeletal lesions, in multiple myeloma, 2327, 2327f, 2328f, 2329, 2329f, 2339–2340
Skeletal metastases. *See* Bone metastasis(es).
Skeletal muscle, in cachexia, 593–595, 594f
Skeletal muscle sarcomas, 2015t
Skeletal radiography, of bone metastases, 849–850, 850f, 855
SKI606 (bosutinib), for chronic myeloid leukemia, 2288
Skin
radiation effects on, 434t
radiation tolerance dose of, 435t
Skin cancer
arsenic and, 132
chemoprevention of, 366t, 382
epidemiology of, 379
etiology and primary prevention of, 379–381, 380t, 381f
melanoma as (*See* Melanoma)
nonmelanoma, 1253–1266
basal cell carcinoma as, 1255–1257, 1255f–1257f
biopsy for, 1266
clinical findings with, 1253
complications of, 1253

Stress reduction, for fatigue, 661
Stress-associated genes, as targets for gene therapy, 520–521
Stromal cell tumors, histology of, 1718
Stromal sarcoma, endometrial, 1799, 1799f
Stromal tumors
  gastrointestinal (*See* Gastrointestinal stromal tumors [GISTs])
  ovarian sex cord–, reproductive effects of, 1000
Strongyloidiasis, in adult T-cell leukemia-lymphoma, 2438
STRs (simple tandem repeats), 266
STS. *See* Soft-tissue sarcoma (STS).
STSC (Soft Tissue Sarcoma Committee), 2105
Study population, 344–345, 344f
  of clinical trial
    description of, 317, 321
    eligibility and exclusion criteria for, 310, 313, 317, 322
Study sponsorship, conflict of interest in, 339, 340
SU22348. *See* Sunitinib maleate (Sutent, SU22348).
Subclavian vein, insertion of vascular access device in, 781–782, 783, 783f
Subcohort, 354, 354f
Subcutaneous opioid injections, 572
Subcutaneous panniculitis-like T-cell lymphoma, 2395, 2413, 2413f, 2414t
Subependymomas, spinal, 1119
Suberoylanilide hydroxamic acid (SAHA)
  cutaneous reactions to, 637
  for renal cell carcinoma, 1628–1629
  to restore apoptotic capability, 74
Subglottis, cancer of, 1216t, 1217
Sublethal damage repair, 427–428, 427f
Submandibular gland tumors, 1218
Substance abuse, pain management with history of, 575–576
Substernal thyroid, 1380–1381
Substituted benzamides, as antiemetics, 604
Subtotal lymphoid irradiation (STLI), for Hodgkin's lymphoma, 2363t
Subxiphoid pericardial window, for pericardial effusion, 936
Subxiphoid pericardiostomy, for pericardial effusion, 936
Sucralfate, for radiation-induced mucositis, 615
Suction-assisted lipectomy, for lymphedema, 652
Suggestive linkage, 198
Suicide gene therapy, 518
Sulindac, for colorectal cancer prevention, 1488t
Sunitinib maleate (Sutent, SU22348), 452, 478
  congestive heart failure due to, 991
  for GISTs, 2041
  hypothyroidism due to, 1017
  for renal cell carcinoma, 1625, 1630
Sunscreens, for prevention of skin cancer, 381
Superficial ablative therapy, for cervical cancer, 1758
Superficial spreading melanoma (SSM), 1230–1232
Superficial venous thrombophlebitis (SVT), 708
Superior hypogastric blocks, 574

Superior mediastinum, 1380
Superior mesenteric artery, 1499
Superior mesenteric vein resection, for pancreatic cancer, 1604–1605
Superior sulcus tumors, 1331
Superior vena cava (SVC), anatomy and physiology of, 803–804, 804f
Superior vena cava obstruction (SVCO)
  anatomy and pathophysiology of, 804, 804f
  in children, 805
  clinical features of, 805, 806t
  diagnostic approach to, 806–808, 807b, 807t
  etiology of, 804–805
  historical perspective on, 803
  imaging studies of, 805–806, 806f
  treatment of, 808–812
    chemotherapy in, 809
    radiotherapy in, 808–809, 809t
    stents in, 810–812, 810f, 810t
    supportive measures in, 812
    surgical, 809–812
Superior vena cava (SVC) syndrome, 803–812
  anatomy and pathophysiology of, 803–804, 804f
  central venous catheter–related, 805
  clinical features of, 803, 805, 806f, 806t
  etiology of, 803–805, 805t
  evaluation of, 803, 805–808, 807b, 807t
  histologic diagnosis of, 806, 807b
  imaging studies of, 805–806, 806f
  treatment of, 803, 808–812
    chemotherapy in, 809
    radiotherapy in, 808–809, 809t
    stents in, 810–812, 810f, 811t
    supportive measures in, 812
    surgical, 809–812
  due to upper-extremity deep venous thrombosis, 695, 705
Superior vena cava (SVC) thrombosis, 695, 705
Supervised clustering, in breast cancer, 1880
Supportive therapy
  for acute lymphocytic leukemia, 2196
  for superior vena cava syndrome, 812
Suppressor of cytokine signaling (SOCS) proteins, 27
Supraglottis, cancer of, 1215–1216, 1216t
Suprasellar tumors, signs of, 1082
Supratentorial glioma(s), 1091–1105
  clinical considerations with, 1091
  genetics of, 1094–1095, 1095f
  imaging of, 1094, 1094f
  pathology of, 1091–1094, 1092f, 1093f
  prognosis for, 1094, 1097–1098
  stereotactic biopsy of, 1095–1096
  treatment of
    approach to, 1097, 1097b
    chemotherapy for, 1100–1103, 1100t, 1101f, 1102f, 1103t
    in elderly patients, 1103–1104
    new approaches to, 1104–1105
    quality of life after, 1104
    radiation therapy for, 1097–1100, 1097t, 1099t
    surgical, 1095–1097, 1097b
Suprefact (buserelin), 462
Surgical approach, to adrenal gland, 1283–1286, 1284f–1285f
Surgical cure, 413, 414t
Surgical cytoreduction, 414
  for ovarian cancer, 1831–1832, 1831t, 1847
Surgical decompression, for spinal metastases, 820–822, 821f, 822t
Surgical margins, for melanoma, 1238
Surgical oncologist
  roles of, 408–412, 408t, 415b
    in diagnosis, 411
    in multidisciplinary management, 412
    in prevention and screening, 409–411, 410t
    in staging, 411–412, 412t
  training of, 409, 409t
Surgical pathology, 233–238
  fine-needle aspiration in, 237
  future directions for, 237–238
  historical background of, 234
  immunohistochemistry in, 235–237, 236f
  intraoperative consultation in, 235, 235b
  staging in, 234
  tumor classification in, 234
  tumor grading in, 234–235
Surgical pathology report, 234–235
Surgical risk, 413, 413t
Surgical thromboprophylaxis, 709
Surgical treatment, 407–415
  of acoustic neuromas, 1114
  adequate margins of resection in, 413, 414t
  of adrenocortical carcinoma, 2116
  of anal cancer, 1560–1561, 1561t, 1566
  anesthesia for, 407–408
  antisepsis for, 408
  of brain tumors, 1085–1087
  of breast cancer
    breast conservation, 1906–1908, 1907t, 1927–1929
    for ductal carcinoma in situ, 1906
    mastectomy as, 1914–1916
    reproductive effects of, 1001
  of carcinoid tumor, 1291
  of cerebellar hemangioblastomas, 1115
  of cholangiocarcinoma, 1589
  of chordomas and chondrosarcomas, 1116
  of colorectal cancer, 1477, 1502–1509
    age as factor in, 1508
    bowel preparation for, 1502, 1502b
    complications of, 1508
    with involvement of adjacent organs, 1505
    laparoscopically assisted, 1508
    lymph nodes in, 1504
    for malignant polyp, 1505, 1506f
    margins in, 1497–1498
    minimally invasive, 1507
    with obstruction, 1504–1505
    with ovarian involvement, 1507
    with perforation, 1505
    restoring continuity in, 1503–1504
    surveillance for recurrence after, 1477–1478, 1509–1511, 1510b
    with synchronous metastatic disease, 1505–1507
Surgical treatment (*cont.*)
  of colorectal cancer (*cont.*)
    technique for, 1502–1503, 1502f, 1503f
    with tumors of appendix, 1509
    with uncommon tumors, 1508–1509
  for debulking, 414
  of desmoid tumors, 2044
  in elderly, 1039, 1045
  emergency, 414
  endocrine complications of, 1014
  of endometrial cancer, 1804–1806, 1805b, 1806t
  of esophageal cancer
    optimizing outcome of, 1409
    with preoperative chemoradiation, 1403–1405, 1404t, 1410–1414, 1411t, 1413t
    with preoperative chemotherapy, 1404t, 1405, 1409–1410
    as sole modality, 1403, 1404t, 1406–1409, 1406f, 1407f
    survival after, 1408–1409
  of Ewing's sarcoma, 1987–1992
    current guidelines for, 1987–1992, 1988f–1991f
    with radiation therapy, 1986–1987
    resection of "expendable" bone in, 1987, 1988f
  future directions for, 414–415
  of gallbladder cancer, 1582–1584, 1583t
  of gastric cancer, 1437–1440, 1438f
    for locally advanced disease, 1450–1451
    palliative, 1455
    relapse after, 1439–1440, 1440t
    survival after, 1439, 1439t
  of GISTs, 2040
  of glomus tumors, 1116
  of head and neck cancer, 1177, 1192–1193, 1192f
  of hepatoblastoma, 2114
  historical perspective on, 407–408
  of lymphoma in children, 2180–2181
  of malignant fibrous histiocytoma, 1994
  of melanoma, 1229, 1238–1241, 1243
  of meningiomas, 1110
  of mesothelioma, 1367, 1373–1375, 1374t, 1375t, 1378
  of metastases, 414
    to brain, 832–834, 832f, 833t
      vs. radiosurgery, 836, 837t
  of molar pregnancy, 1865
  of neuroblastoma, 2095
  of osteosarcoma, 1958–1974
    amputation as, 1962–1965, 1973, 2081
    arthrodesis as, 1973–1974
    arthroplasty as, 1974
    in children, 2081
    functional results of, 1973–1974
    for limb salvage reconstruction, 1965–1973
    limb-sparing, 1948, 1958–1959, 2081
    resection and distraction osteogenesis as, 1959, 1962f–1963f
    rotationplasty as, 1959, 1960f–1962f, 1974
  pain due to, 565
  for pain management, 572

Surgical treatment (*cont.*)
palliative, 414
of pancreatic cancer, 1602–1606, 1603f
of penile cancer, 1706–1707, 1707b, 1709
of pituitary adenomas, 1112
during pregnancy, 1049–1050

Testicular cancer, 1713–1740
  brain metastases of, 1734
  classification of, 1714–1718, 1715t, 1716f–1717f
  clinical manifestations of, 1718
  contralateral, 1737–1738
  cryptorchidism and, 411
  cytogenetic aberrations in, 260t
  diagnosis of, 1713, 1718–1719, 1719f
  differential diagnosis of, 1713, 1718
  epidemiology of, 1713–1714
  etiology of, 1714
  hereditary, 176t
  histology of, 1714–1718, 1715t, 1716f–1717f
  late consequences of, 1737–1740
  molecular biology of, 1714
  natural history of, 1715, 1717f
  radiologic evaluation of, 1721
  recurrence of, 1737, 1738
  reproductive effects of, 1000–1001
Testicular cancer (*cont.*)
  risk assessment for, 1719–1721
    with advanced disease, 1730, 1731t
    with relapsed or refractory disease, 1737
    with residual masses after chemotherapy, 1734–1736
    with stage I disease, 1722–1725
    with stage II disease, 1728
  second malignant neoplasms with, 1031, 1739–1740
  staging of, 1713, 1721, 1722t, 1723t
  therapy for, 1721–1740
    for advanced disease, 1729–1737, 1730t
      with brain metastases, 1734
      with extragonadal disease, 1733–1734
      good-risk, 1730–1732
      poor-risk, 1732–1733, 1734f
      with residual masses after chemotherapy, 1734–1736
      risk assessment and, 1730, 1731t
    primary, 1713, 1721–1734
    for relapse or refractory disease, 1737, 1738
    salvage, 1736–1737
    second- and third-line, 1713, 1734–1737
    for stage I nonseminoma, 1724–1727, 1727f
      adjuvant chemotherapy in, 1725–1726
      adjuvant radiation therapy in, 1725
      retroperitoneal lymph node dissection in, 1725, 1726f
      risk assessment and, 1724–1725, 1724f, 1724t
      surveillance in, 1726–1727
    for stage I seminoma, 1722–1724, 1727f
    for stage II nonseminoma, 1728–1729, 1728f
    for stage II seminoma, 1727–1728, 1728f
    toxicities of, 1738–1739
  tumor markers for, 279, 1719–1721, 1720t
Testicular function
  chemotherapy effects on, 1003, 1004
  radiation effects on, 1002
Testicular germ cell tumors (TGCTs). *See* Testicular cancer.
Testicular sperm extraction, 1008
Testicular ultrasonography, 1718–1719
Testis(es)
  chemoprotection of, 1007
  form and function of, 1000
  metastases to, 1718
  radiation tolerance dose of, 435t
Testosterone, 1000
  and prostate cancer, 377
Testosterone replacement, for reproductive dysfunction due to cancer therapy, 1007b, 1008
Tet-off, 16
Tet-on (reverse tTA), 17
1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA), with monoclonal antibodies, 537
Tetracycline, for pleurodesis, 931
Tetracycline (tet) regulatory system, 16–17
Tetracycline response elements, as targets for gene therapy, 521–522

Tetraplegia, rehabilitation for, 582–583
TFE3 gene, in renal cell carcinoma, 2101
TFE3-ASPL fusion product, in renal cell carcinoma, 2101
TFEB gene, in renal cell carcinoma, 2101
6-TG (thioguanine), 479
TGCTs (testicular germ cell tumors). *See* Testicular cancer.
TGF-β (transforming growth factor β), in tumor microenvironment, 86
TGF-β (transforming growth factor β) receptor, in intracellular signaling, 23, 28
Th1 responses, anticarcinogenic effect of, 88, 89f
Thalidomide (Thalomid), 453, 479
  for cachexia, 595
  for Kaposi's sarcoma, 1065
  for melanoma, 1245
  for multiple myeloma, 2333–2335
    newly diagnosed, 2332t, 2333–2335, 2334t
    in patients not eligible for transplantation, 2336
    relapsed, 2338–2339
    results of, 2333–2335, 2334t
  for myelodysplastic syndrome, 2243–2244, 2244t
  neurotoxicity of, 951
  for primary myelofibrosis, 2274
  venous thromboembolic disease due to, 695–696
THE (transhiatal esophagectomy), 1407
TheraCys (bacillus Calmette-Guérin), 461
  for bladder cancer, 1641
Therapeutic abortion, 1058
Therapeutic index, 433
Therapeutic prevention, 366
Therapeutic response, tumor markers for prediction of, 280
Thermochemotherapy, for retinoblastoma, 2111
Thiazide diuretics, hyponatremia due to, 751–752, 756
Thiethylperazine, as antiemetic, 605
Thioguanine (Tabloid, 6-TG, aminopurine-6-thiol hemihydrate), 479
Thiopropazate, as antiemetic, 605
Thiotepa (TESPA, triethylenethiophosphoramide, TSPA), 479
  hyperpigmentation due to, 631
Thomas, Lewis, 79b, 223
Thoracentesis, 1379
  for pleural effusion, 928, 930
Thoracic radiation therapy (TRT)
  fractionation of, 1352, 1352t
  for lung cancer
    non-small cell, 1332, 1337, 1337t
      adjuvant, 1335
      neoadjuvant, 1336
    small cell, 1351–1353, 1351f, 1352t
  pulmonary toxicity of (*See* Radiation pneumonitis)
Thoracoabdominal approach, left, for esophagogastrectomy, 1407–1408
Thoracoscopy, for pleural effusion, 929
Three-dimensional conformal radiation therapy (3D-CRT), 440, 441f
  for prostate cancer, 1672–1673, 1672f, 1673f
Thrombocythemia, essential, 2267–2270
  diagnosis of, 2268–2269, 2268b, 2268t, 2269f
  diagnostic criteria for, 2269t
  incidence of, 2267
  pathogenesis of, 2267–2268
  pregnancy with, 2270
  risk stratification for, 2267t
  treatment of, 2268t, 2269–2270, 2269t
Thrombocytopenia, 682–683, 683f
  anticoagulation therapy with, 697–698
  heparin-induced, 697
  in myelodysplastic syndrome, 2237
  X-linked, 226
Thrombocytosis, 683
  in essential thrombocythemia, 2268, 2268t
Thromboembolic disease, venous. *See* Venous thromboembolic disease (VTE).
Thrombohemorrhagic risk factors, in polycythemia vera, 2266, 2267t
Thrombolytic therapy, for pulmonary embolism, 707
Thrombophlebitis
  migratory, 708
  superficial venous, 708
Thromboplastin time, partial, in acute lymphocytic leukemia, 2195t
Thrombopoietin (TPO), 682–683
Thrombopoietin (TPO) receptor agonists, 683
Thromboprophylaxis, 708–711
  with central venous access device, 709–710
  during chemotherapy, 710
  for hospitalized cancer patient, 710–711
  in surgical patient, 709
Thrombosis, due to erythropoiesis-stimulating proteins, 680
Thrombospondin(s) (TSPs), inhibition of angiogenesis by, 107
Thrombospondin-1 (TSP-1), in carcinoma of unknown primary, 2063
Thrombotic occlusion, central venous access device–associated, 710
Thrombus, of central venous access device, 787–788, 788t, 789b
Thymic carcinoid, 1384, 1384f
Thymic carcinoma, 1384
Thymic large B-cell lymphoma, 2178, 2179
Thymic tumors, 1382t
Thymidylate synthase (TS), in colorectal cancer, 1512, 1519
Thymoma, 1367–1368, 1381–1384
  classification of, 1381–1382
  clinical manifestations of, 1382–1383, 1383f
  differential diagnosis of, 1368
  epidemiology of, 1367–1368, 1382
  pathogenesis of, 1381
  pathology of, 1382, 1382f
  staging and evaluation of, 1368, 1382, 1382t
  treatment of, 1368, 1383–1384
Thyroid
  radiation tolerance dose of, 435t
  substernal, 1380–1381
Thyroid ablation, 1018
Thyroid cancer, 1271–1281
  anaplastic, 1273f, 1274, 1279f
  classification of, 1271–1274, 1273f, 1273t
  clinical presentation of, 1271
  diagnosis of, 1271, 1274–1276, 1275t
  etiology of, 1272
  familial
    medullary, 182
    nonmedullary, 1272
  follicular, 1273–1274, 1273f
  Hürthle cell, 1274
  imaging of, 302, 303f
  incidence of, 1271, 1272
  lymphoma as, 1274
  medullary, 1273f, 1280–1281, 1280f
    familial, 182
    in MEN-2, 1289
  papillary, 1272–1273, 1273f
    hereditary, 177t
  postirradiation, 1280
  during pregnancy, 1056
  prognosis for, 1273–1274
  radiation-induced, 1024, 1272
  radionuclide therapy and, 1032
  staging of, 1274t, 1275t
  treatment of, 1271, 1276–1281
    chemotherapy for, 1280
    radiation therapy for, 1276–1279, 1277f–1279f
    surgical, 1276, 1277f
    TSH suppression for, 1279–1280
Thyroid disorders
  due to biologic agents, 1016–1017
  due to bone marrow transplantation, 1015–1016
  chemotherapy-induced, 1015–1016
  after cranial or spinal irradiation, 1089
  evaluation and treatment of, 1013, 1017t, 1018
Thyroid hormone replacement, 1018
Thyroid nodule, diagnosis of, 1275–1276, 1280, 1280f
Thyroid transcription factor-1 (TTF-1), 1317
  in carcinoma of unknown primary, 2064–2065
Thyroid tumors, radiation-induced, 620
Thyroidectomy, for thyroid cancer, 1276, 1277f, 1281
Thyroiditis, acute radiation, 1015
Thyroid-stimulating hormone (TSH), recombinant human, for thyroid cancer, 1279
Thyroid-stimulating hormone (TSH)-secreting adenomas, 1112, 1112t, 1113
Thyroid-stimulating hormone (TSH) suppression, for thyroid cancer, 1279–1280
Tibia
  Ewing's sarcoma of, 1987, 1989f
  proximal, osteosarcoma of, 1952f, 1971–1973
TICE (bacillus Calmette-Guérin), 461
  for bladder cancer, 1641
Tijuana, Mexico, alternative medicine cancer clinics in, 557

TIL (tumor infiltrating lymphocyte) therapy, for melanoma, 1245
Time at risk, 351, 351f, 352f
Tinzaparin, for venous thromboembolic disease, 703
TIP regimen, for testicular cancer, 1730t
Tipifarnib, for myelodysplastic syndrome, 2251
Tirapazamine, as radiosensitizer, 432
Tissue banks, 200
Tissue microarrays, 9, 12f
Tissue-specific promoters, for gene therapy, 520, 521t
TKIs. *See* Tyrosine kinase inhibitors (TKIs).
TLR(s) (toll-like receptors), in multiple myeloma, 2324
TLR (toll-like receptor) agonists, cutaneous reactions to, 637
TLS. *See* Tumor lysis syndrome (TLS).
TME (total mesorectal excision), for rectal cancer, 1539, 1539f, 1545–1546, 1546f
TMPRAA2-ETV1 gene, 211t
TMPRSS2-ERG gene, 211t
  in prostate cancer, 1659
TMPRSS2-ETV4 gene, 211t
TMZ. *See* Temozolomide (Temodar, TMZ).
TNF (tumor necrosis factor) receptor, in intracellular signaling, 24, 28
TNF (tumor necrosis factor)-related apoptosis-inducing ligand (TRAIL)
  in apoptosis, 68, 74
  as molecular target, 487t
TNF-α (tumor necrosis factor α), in cachexia, 592, 594
TNFR (tumor necrosis factor receptor)-associated death domain (TRADD), in apoptosis, 68, 68f
TNFR1 (tumor necrosis factor receptor 1), in apoptosis, 68, 68f
TNM system. *See* Tumor, Node, Metastasis (TNM) system.
Tobacco, smokeless, and head and neck cancer, 1179
Tobacco smoke
  as avoidable cause, 362–363
  cancers caused by, 363
  carcinogens in, 129–130, 130t
Tobacco use. *See* Cigarette smoking.
Tobacco-specific *N*-nitrosamines (TSNAs), 1178–1179
α-Tocopherol. *See* Vitamin E.
Toes, melanoma of, 1238
Tolerance, 571t
  immune, 78, 79f, 81–83, 83f, 86–87
Toll-like receptor(s) (TLRs), in multiple myeloma, 2324
Toll-like receptor (TLR) agonists, cutaneous reactions to, 637
Tomosynthesis, 288
Tongue cancer, 1213, 1215
Tonicity, 749–750
Tonsil(s), cancer of, 1214–1215
Tonsillar herniation, due to brain tumor, 1080, 1081t
Topical therapies, for cutaneous T-cell lymphoma, 2416–2418
Topoisomerase I inhibitors, during pregnancy, 1053
Topoisomerase II inhibitors
  during pregnancy, 1006
  second malignant neoplasms due to, 1028
Topoisomerase inhibitors, cutaneous side effects of, 627t
Topotecan (Hycamtin, hycamptamine), 479–480
  for Ewing's sarcoma, 2090–2091
  for ovarian cancer, 1840, 1840t
  during pregnancy, 1053
  for small cell lung cancer, 1348, 1349t, 1350, 1354
Toremifene (Fareston), 480
Tositumomab (Bexxar, anti-CD20), 453
  for acute lymphocytic leukemia, 2207
  for lymphoma, 536, 536t
    follicular, 2384
Total mesorectal excision (TME), for rectal cancer, 1539, 1539f, 1545–1546, 1546f
Total vascular exclusion, for hepatic resection, 889
Touch preparations, 235
Toxoplasma gondii, 732–733
TP53 gene, 212t
  and adrenocortical carcinoma, 2116
  and breast cancer, 1875, 1879–1880
  and nonrhabdomyosarcoma soft-tissue sarcoma, 2105
  and rhabdomyosarcoma, 2102
TPF (true-positive fraction), 285–286, 285f
TPO (thrombopoietin), 682–683
TPO (thrombopoietin) receptor agonists, 683
Trabectidin (ET743, ecteinascidin 743)
  for liposarcomas, 2046
  for soft-tissue sarcoma, 2037
Tracheoesophageal fistula, radiation therapy with, 1415–1417
TRAcP-5b (tartrate-resistant acid phosphatase serum type 5b), as bone resorption marker, 853–854
TRADD (TNFR-associated death domain), in apoptosis, 68, 68f
TRAIL (TNF-related apoptosis-inducing ligand)
  in apoptosis, 68, 74
  as molecular target, 487t
Transanal endoscopic microsurgery (TEM), for rectal cancer, 1538
Transcription, 7–9, 10f
Transcriptional control, of gene therapy, 520, 521t
Transcriptional profiling, 9, 12f
  in breast cancer, 1880–1882, 1881f, 1882f
Transcription-coupled repair (TCR), 140, 143
Transcription-initiation complex, 10f
Transcutaneous electrical nerve stimulation, for pain management, 572
Transferrin shielding, in gene therapy, 524
Transformation zone, of cervix, 1748, 1748f
Transforming growth factor β (TGF-β), in tumor microenvironment, 86
Transforming growth factor β (TGF-β) receptor, in intracellular signaling, 23, 28
Transfusions
  for cytopenia, 684
  risks of, 684
Transgenes, 513, 514, 518
Transgenic mice, 15–17, 16f, 17f
Transhiatal esophagectomy (THE), 1407
Transient abnormal myelopoiesis, 2140
Transitional cell carcinoma (TCC), of bladder, 1636
Translational trials, 311, 311t
Translocations
  involving miRNAs, 219t
  as molecular targets, 486t
  in soft-tissue sarcomas, 2013
Transplantation
  hematopoietic stem cell (*See* Hematopoietic stem cell transplantation [HSCT])
  and infection, 732–733
  liver
    for cholangiocarcinoma, 1589
    for hepatocellular carcinoma, 1573t, 1574–1575
Transportation, rehabilitation for, 587
Transpulmonary chemoembolization, for pulmonary metastases, 882
Transpupillary thermal therapy (TTT)
  for retinoblastoma, 2111
  for uveal melanoma, 1147
Transrectal electroejaculation, 1008
Transrectal ultrasound (TRUS), for prostate biopsy, 1664–1665
Transsphenoidal approach, to pituitary adenomas, 1112
Transthoracic needle biopsy, 1381, 1381t
Transudates, 928
Transurethral resection (TUR), for bladder cancer, 1637, 1640, 1640f, 1642
Transurethral resection of the prostate (TURP)
  brachytherapy after, 1675, 1676
  three-dimensional conformal radiation therapy after, 1673
Transvaginal ultrasonography, for ovarian cancer screening, 1830
TRAP (tartrate-resistant acid phosphatase), in hairy cell leukemia, 2311
Trastuzumab (Herceptin), 453, 480
  for breast cancer, 42–43, 534
    early stage, 1920–1921, 1922t, 1923t
    with *HER2* mutation, 1880, 1920–1921
    metastatic, 1932
  cardiotoxicity of, 1921, 1923t
  congestive heart failure due to, 989–990, 1921
  for ovarian cancer, 1840
  during pregnancy, 1006, 1052t, 1054
Trauma, and soft-tissue sarcoma, 2011
Traumatic fractures, bone metastases vs., 849t
Traumeel S, for prevention of oral complications, 613
Treatment, economic analysis(es) of, 337–342
  by cancer clinical trials groups, 340–341, 340t
  indications for, 338
  quality assessment of, 339
  strategies for conducting, 340
  types of, 338–339

Treatment costs, 337–339
categories of, 337–339
estimation from Medicare populations of, 339–341, 340t
factors contributing to, 337
surrogate measures for, 341
Treatment effects, in clinical trials, 309–310, 317–319, 318f, 318t, 319t
Treatment failures, in clinical trials, 321
Tremor, grading of, 961t
Tretinoin (Vesanoid), 453, 480
for acute promyelocytic leukemia, 2228–2229, 2228b
fluid retention due to, 993
during pregnancy, 1057
Trichothiodystrophy (TTD), DNA damage in, 141t, 143, 144
Tricyclic antidepressants, for pain management, 574–575
Triethylenethiophosphoramide (thiotepa), 479
hyperpigmentation due to, 631
Trisenox. *See* Arsenic trioxide (Trisenox, As_2O_3).
Trismus, radiation-induced, 619–620
Troglitazone, for liposarcomas, 2046
Troponins, in anthracycline-induced cardiomyopathy, 987
Trousseau's syndrome, 708
TRT. *See* Thoracic radiation therapy (TRT).
True-positive fraction (TPF), 285–286, 285f
TRUS (transrectal ultrasound), for prostate biopsy, 1664–1665
TS (thymidylate synthase), in colorectal cancer, 1512, 1519
TSAs (tumor-specific antigens), 77–78, 79b
TSC1 gene, 212t
TSC2 gene, 212t
TSH (thyroid-stimulating hormone), recombinant human, for thyroid cancer, 1279
TSH (thyroid-stimulating hormone)-secreting adenomas, 1112, 1112t, 1113
TSH (thyroid-stimulating hormone) suppression, for thyroid cancer, 1279–1280
TSNAs (tobacco-specific *N*-nitrosamines), 1178–1179
TSP(s) (thrombospondins), inhibition of angiogenesis by, 107
TSP-1 (thrombospondin-1), in carcinoma of unknown primary, 2063
TSPA (thiotepa), 479
hyperpigmentation due to, 631
tTA, 16
TTD (trichothiodystrophy), DNA damage in, 141t, 143, 144
TTF-1 (thyroid transcription factor-1), 1317
in carcinoma of unknown primary, 2064–2065
TTG gene, 211t
t(3;8) translocation, constitutional, 176t
TTT (transpupillary thermal therapy)
for retinoblastoma, 2111
for uveal melanoma, 1147
Tuberous sclerosis, 174t
brain tumors in, 1078t
and renal cell carcinoma, 1616
Tumor(s), vs. self tissues, 77–78
Tumor cell DNA content, nomenclature for, 250t
Tumor cell growth, kinetics of, 450–451
Tumor cell hypoxia, anemia and, 680–681
Tumor cell kinetics, 2378–2380
Tumor classification, 234
immunohistochemistry in, 236–237, 236f
Tumor grading, 234–235
Tumor growth, aging and, 1041, 1041f, 1042t
Tumor hypoxia, and metastasis, 34–35, 35t
Tumor immune surveillance
evidence pro and con for, 78–80, 79f
importance of, 79b
innate immunity, epithelial immunity, and, 80–81, 81f
Tumor infiltrating lymphocyte (TIL) therapy, for melanoma, 1245
Tumor lysis syndrome (TLS), 759–763, 760t
clinical, 759, 760t
epidemiology of, 759
etiology of, 759
evaluation of, 759
grading of, 761t
laboratory, 759, 760t
with lymphoma in children, 2181
metabolic abnormalities associated with, 759, 760f
pathophysiology of, 760–762, 761f
prevention of, 762
risk factors for, 762, 762t
treatment of, 762–763, 762t, 763f, 763t
Tumor marker(s), 277–281
analytic considerations with, 280–281
for bone metastases, 846, 852–856, 856t
for breast cancer, 1916–1918, 1916t
for carcinoma of unknown primary, 2063
clinical applications of, 278–280
in diagnosis, 279–280
FDA-approved, 277–278, 278t
future directions for, 281
historical background of, 277
ideal, 277
at low levels, 272–273
methods for, 278
for monitoring disease, 280
for ovarian germ cell cancer, 1848
for pancreatic cancer, 1601
for prognosis/prediction of therapeutic response, 280
for screening and early detection, 278–279
for testicular cancer, 279, 1719–1721, 1720t
Tumor microenvironment
immunologic characteristics of, 78, 85–87, 85f
as selection pressure for metastatic tumor cells, 33–35, 34f, 35t
Tumor necrosis factor α (TNF-α), in cachexia, 592, 594
Tumor necrosis factor (TNF) receptor, in intracellular signaling, 24, 28
Tumor necrosis factor receptor 1 (TNFR1), in apoptosis, 68, 68f
Tumor necrosis factor receptor (TNFR)-associated death domain (TRADD), in apoptosis, 68, 68f
Tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL)
in apoptosis, 68, 74
as molecular target, 487t
Tumor, Node, Metastasis (TNM) system, 234, 411, 412t
for anal cancer, 1559, 1561t
for bile duct carcinoma, 1587t, 1588
for bladder cancer, 1638–1639, 1638t
for bone sarcomas, 1946, 1946t
for breast cancer, 1895, 1896t–1898t
for colorectal cancer, 1494–1498, 1495t
for cutaneous lymphomas, 2406, 2408t
for endometrial cancer, 1801
for esophageal cancer, 1405t
for gallbladder cancer, 1581–1582, 1582t
for gastric cancer, 1437, 1437t, 1458–1459
for hepatocellular carcinoma, 1572, 1572t
for lung cancer, 1324, 1325t
for melanoma, 1235t–1237t, 1236–1237
mesothelioma, 1371, 1373t
for penile cancer, 1705, 1705t
for prostate cancer, 1662t
for renal cell carcinoma, 1616–1618, 1617t, 1621
for small bowel tumors, 1470, 1471t
for testicular cancer, 1721, 1722t
for thyroid carcinoma, 1274, 1274t
for vulvar cancer, 1769, 1770t
Tumor profiling, 9–12, 12f, 13f
Tumor progression, barriers for, 34, 34f
Tumor staging. *See* Staging.
Tumor suppressor, retinoblastoma protein as, 52–54, 54f
Tumor suppressor gene(s), 208
in adult T-cell leukemia-lymphoma, 2427
cancer predisposition syndromes due to, 171
in cancer target conserved signaling pathways, 210–215, 211t, 212t, 213f, 214f
in carcinoma of unknown primary, 2063
mutations in, 208, 210, 212t
in nonmelanoma skin cancer, 1254–1255
promotion of apoptosis by, 70–71
somatic inactivation of, 213, 213f
Tumor suppressor inactivation, epigenetic mechanisms of, 208, 211–214, 213f
Tumor suppressor miRNAs, 219t
Tumor vaccines, 89, 89b
clinical trials for, 322–324
colorectal, 1525
lung, 1345–1346
melanoma, 517, 1242, 1245
prostate, 323, 1668–1669
for renal cell carcinoma, 1629–1630
Tumor vasculature, as target for gene therapy, 520
Tumor-associated antigens (TAAs), 1629
Tumor-associated macrophages (TAMs), in metastasis, 42, 42t
Tumor-associated promoters, for gene therapy, 520
Tumorectomy, for breast cancer, 1908
Tumorigenic cancer cells, 99–101, 99f, 100f, 101b

Tumor–immune system interactions, active mediation by oncogenic pathways of, 84–85
Tumor-selective antigens, 78
Tumor-specific antigens (TSAs), 77–78, 79b
Tumor-specific promoters, for gene therapy, 520
TUR (transurethral resection), for bladder cancer, 1637, 1640, 1640f, 1642
Turcot syndrome, 174t
  brain tumors in, 1078t
TURP (transurethral resection of the prostate)
  brachytherapy after, 1675, 1676
  three-dimensional conformal radiation therapy after, 1673
Twist, in metastasis, 36, 36f
Two-hit hypothesis, 210, 213f
  for retinoblastoma, 2108–2109
Tykerb (lapatinib), 452, 497
  for breast cancer, 1880, 1921
  congestive heart failure due to, 990
Type I error, 310, 310t, 316
Type II error, 310, 310t
Typhlitis, 726–727
Tyrosinase, as target for gene therapy, 520
Tyrosine kinase inhibitors (TKIs), 452, 485–487
  for chronic myeloid leukemia, 324, 2284–2289
  cytogenetic analysis and, 249
  for head and neck cancer, 1208
  hypothyroidism due to, 1017
  for mesothelioma, 1378
  pulmonary toxicity of, 978
  for renal cell carcinoma, 1624–1625, 1630
Tyrosine kinase receptor mutations, in acute myelogenous leukemia, 2219

U

Ubiquitin ligases, 51–52, 51f
Ubiquitin-proteasome system, in genomic stability, 143
UCB (umbilical cord blood), hematopoietic stem cells from, 503, 504
  for acute lymphocytic leukemia, 2202
  for myelodysplastic syndrome, 2250
UCLA Integrated Staging System (UISS), for renal cell carcinoma, 1618, 1619, 1621
UCP-3 (uncoupling protein 3), in cachexia, 592
UE-DVT (upper-extremity deep venous thrombosis), 704–705
  diagnosis of, 700t, 704–705
  treatment of, 705
UH. *See* Unfractionated heparin (UH).
UKCCSG/MRC (United Kingdom Children's Cancer Study Group and Medical Research Council), on Ewing's sarcoma, 2089t
Ulcer(s), due to extravasation, 628, 628f
Ulceration, of melanoma, 1232, 1234, 1236, 1237f
Ulcerative colitis, and colorectal cancer, 1481, 1483
Ultrasonography (US), 289, 291t
  of breast, 1889–1892, 1890f, 1891f
  duplex, of deep venous thrombosis
    inferior vena cava and intra-abdominal, 707
    lower-extremity, 700–701
    upper-extremity, 704
  endorectal, of rectal cancer, 1536, 1536f
  endoscopic, of pancreatic cancer, 1599–1601
  esophageal, of esophageal cancer, 1406
  fetal exposure to, 1050
  of gestational trophoblastic disease, 1863–1864, 1864f
  of hepatocellular carcinoma, 1571
  intraoperative
    of brain tumors, 1085
    of hepatic metastases, 1491, 1492f
  of liver metastases, 298, 887, 888
  of pancreatic cancer, 1599, 1600f
  of prostate cancer, 296
  testicular, 1718–1719
  transrectal, for prostate biopsy, 1664–1665
  transvaginal, for ovarian cancer screening, 1830
  of Wilms' tumor, 2097–2098, 2098f
Ultrasound-guided liver biopsy, 1491, 1492f
Ultraviolet A (UVA) photochemotherapy, for cutaneous T-cell lymphoma, 2418
Ultraviolet B (UVB) phototherapy, for cutaneous T-cell lymphoma, 2418
Ultraviolet radiation (UVR)
  and basal cell carcinoma, 1255
    of eyelid, 1157
  as carcinogen, 130
  and melanoma, 1230, 1232
  and penile carcinoma, 1701–1702
  and skin cancer, 379–381
  and squamous cell carcinoma, 1257
    of eyelid, 1158
Umbilical cord blood (UCB), hematopoietic stem cells from, 503, 504
  for acute lymphocytic leukemia, 2202
  for myelodysplastic syndrome, 2250
Uncal herniation syndrome, due to brain tumor, 1080, 1081t
Unconventional medical therapy (UMT). *See* Complementary and alternative medicine (CAM).
Uncoupling protein 3 (UCP-3), in cachexia, 592
Undifferentiated carcinoma
  of endometrium, 1798
  of unknown primary, 2070
Undifferentiated spindle cell tumor, 1994
Undifferentiated uterine sarcoma, 1799
Unfractionated heparin (UH)
  cancer patient response to, 699
  for deep venous thrombosis, 703
  for pulmonary embolism, 707
  for thromboprophylaxis, 709
United Kingdom Children's Cancer Study Group and Medical Research Council (UKCCSG/MRC), on Ewing's sarcoma, 2089t
Univariate analyses, 321
Unsupervised clustering, in breast cancer, 1880
UPEP (urine protein electrophoresis), for multiple myeloma, 2328, 2329
Upper gastrointestinal tract infections, 726
Upper-extremity deep venous thrombosis (UE-DVT), 704–705
  diagnosis of, 700t, 704–705
  treatment of, 705
Uranium, and lung cancer, 131
Urate oxidase, for tumor lysis syndrome, 763
  with childhood lymphoma, 2181
Uremia, in tumor lysis syndrome, 761–762, 763t
Ureterosigmoidostomy, and colorectal cancer, 1024, 1484
Uric acid, in tumor lysis syndrome, 760, 761f
  with childhood lymphoma, 2181
Urinary diversion, after cystectomy, 1643, 1644f
Urinary incontinence
  due to brain tumor, 1081
  after radical prostatectomy, 1669
  rehabilitation for, 585, 586t
Urinary retention, due to brain tumor, 1081
Urine protein electrophoresis (UPEP), for multiple myeloma, 2328, 2329
Uromitexan (mesna), 474
Urothelial carcinoma. *See* Bladder cancer.
Ursodeoxycholic acid, for colorectal cancer prevention, 1488t, 1489–1490
US. *See* Ultrasonography (US).
USC (uterine serous carcinoma)
  molecular pathology and biology of, 1800
  pathology of, 1797, 1797f
Uterine sarcoma(s), 2043–2044
  carcino-, 1798, 1798f
  classification of, 1796t
  epidemiology of, 1795
  leiomyo-, 1798–1799
    molecular characteristics of, 2012t
    pathology of, 1798–1799, 1799f
    systemic treatment of, 1816, 2043–2044, 2046
  pathology and biology of, 1798–1799, 1799f
    molecular, 1800
  stromal, 1799, 1799f
  systemic therapy for, 1816
  undifferentiated, 1799
Uterine serous carcinoma (USC)
  molecular pathology and biology of, 1800
  pathology of, 1797, 1797f
Uterus, anatomy of, 1793–1794
UVA (ultraviolet A) photochemotherapy, for cutaneous T-cell lymphoma, 2418
UVB (ultraviolet B) phototherapy, for cutaneous T-cell lymphoma, 2418
Uveal melanoma, 1143–1147
  biopsy of, 1143
  classification of, 1143t
  clinical features of, 1143–1145, 1143f–1145f
  differential diagnosis of, 1145
  imaging of, 1143, 1143f
  metastasis of, 1144
  orbital extension of, 1144, 1145f
  pathogenesis of, 1143
  treatment of, 1145–1147, 1146b
    brachytherapy in, 1146, 1146t, 1147f
    chemotherapy and biologic therapy for, 1246–1247
    proton radiation therapy for, 443
UVR. *See* Ultraviolet radiation (UVR).

V
VAB-6 regimen, for testicular cancer, 1728, 1729, 1731, 1736
VAC regimen, for Ewing's sarcoma, 1985
Vaccine(s), 453
  cancer, 89, 89b
    clinical trials for, 322–324
    colorectal, 1525
    lung, 1345–1346
    melanoma, 517, 1242, 1245
    prostate, 323, 1688–1689
    for renal cell carcinoma, 1629–1630
  after hematopoietic stem cell transplantation, 730, 730t
  hepatitis B virus, 164
  human papillomavirus, 159, 164
Vaccinia viral (VV) vectors, 516–517, 517b
VACOP-B regimen, for diffuse large B-cell lymphoma, 2386
VAD regimen, for multiple myeloma, 2331–2333
Vaginal cancer, 1778–1783
  adenocarcinomas as, 1779, 1782–1783
  diagnosis of, 1778, 1780
  endodermal sinus tumors as, 1783
  epidemiology of, 1778–1779, 1779t
  etiology of, 1778, 1779
  melanoma as, 1783
  metastatic, 1778, 1783
  patterns of spread of, 1779–1780
  persistent or recurrent, 1782, 1783
  primary, 1778, 1779t
  prognosis for, 1782
  sarcomas as, 1783
  second malignant neoplasms with, 1030
  signs and symptoms of, 1780
  squamous cell, 1778
  staging of, 1778, 1780, 1780t, 1781f
  treatment of, 1778, 1781–1783
  verrucous, 1778–1779, 1779f
Vaginal intraepithelial neoplasia (VAIN), 1779
Vaginal metastases, of gestational trophoblastic disease, 1862, 1862f, 1869
Vaginal recurrence, of endometrial cancer, 1818–1819, 1818t
Vaginal stenosis, due to cervical irradiation, 1762
Valganciclovir, for cytomegalovirus, 728
Validated target, for molecularly targeted therapy, 488, 489t
Validity, clinical, 202
Valproic acid, for myelodysplastic syndrome, 2251
Vancomycin, for febrile neutropenic patient, 721–722, 722t
Vancomycin-resistant enterococcus (VRE), 724
Vanillylmandelic acid (VMA), with pheochromocytoma, 1286
Varenicline (Chantix), for smoking cessation, 399t, 400
Variability, chance, 358–359
Varicella zoster virus (VZV), 727
  with graft-versus-host disease, 731
  and transplantation, 732
    hematopoietic stem cell, 730
Varicoceles, 1718
Vascular access, surgery for, 414
Vascular access device(s), 779–789
  central lines as
    guidelines for, 782t
    percutaneous, 779–780
    surgically tunneled, 780, 780f
  choice of, 779–781, 780f–782f, 782t
  complications of, 786–788
  dressings for, 782t
  flushing of, 782t
  Groshong catheter as, 782t
  Hickman catheter as, 780, 780f
    guidelines for, 782t
    insertion of, 784, 785f
  infection due to, 727
  insertion of, 781–784
    complications of, 784
    introducer kit for, 784, 786f
    location for, 781–782
    for permanent Silastic catheter, 784, 785f
    preparation for, 782–783
    Seldinger technique for, 783, 783f
    technique for, 783–784, 783f–786f
    using veins in neck for, 783–784, 784f
  long-line central access (peripherally inserted central catheter) as, 780–781, 782t
  maintenance of, 782t, 789, 789b
  nonfunctioning, 788–789, 788t, 789b
  surgically implanted infusion/injection ports as, 780, 781f, 782f
    guidelines for, 782t
    placement of, 784, 786f
Vascular architecture, 108, 109f
Vascular cancer, predisposition syndromes for, 177t
Vascular compartment, 105–109
Vascular endothelial growth factor (VEGF)
  in angiogenesis, 107, 107t, 108f
  in ascites, 937
  in brain tumors, 1079
  in carcinoma of unknown primary, 2063
  in hepatocellular carcinoma, 1577
  in lymphangiogenesis, 112, 114f–115f
  in metastasis, 39
    to brain, 41
  as molecular target, 486t
  in movement of cells across vessel walls, 110
  in pleural effusions, 926
  in renal cell carcinoma, 1624–1629, 1625f, 1628f
  in vascular architecture, 108
Vascular endothelial growth factor (VEGF) blockade, by antiangiogenic agents, 118–120, 118f–119f
Vascular endothelial growth factor (VEGF) inhibitors, for non–small cell lung cancer, 1345
Vascular endothelial growth factor receptor (VEGFR)
  as molecular target, 486t
  as target for gene therapy, 520
Vascular permeability, 109–110, 111f
Vascular permeability factor (VPF), in brain tumors, 1079
Vascular sarcomas, 2015t, 2045, 2046f
Vascular stents, for superior vena cava syndrome, 810–812, 810f, 810t
Vascularization, 105–108
  cellular mechanisms of, 106–107, 106f
  molecular mechanisms of, 107–108, 107t, 108f
Vasculitis, paraneoplastic, 773
Vasculitis neuropathy, paraneoplastic, 773
Vasculogenesis, 106, 106f
  "postnatal," 106
Vasoactive intestinal peptide (VIP), tumors secreting, 1295f, 1297
Vasopressin, arginine. *See* Antidiuretic hormone (ADH).
VATS. *See* Video-assisted thoracoscopic surgery (VATS).
VBP regimen, for gestational trophoblastic neoplasia, 1868
VC (virtual colonography), for colorectal cancer screening, 297, 1484–1485, 1484f
VCR. *See* Vincristine (Oncovin, Vincasar, leurocristine, VCR).
Vectibix (panitumumab), 453, 476
  for colorectal cancer, 1525
Vector(s), 513–518
  ideal attributes of, 513
  nonviral, 517–518, 524
    antisense, 519
    via ballistic delivery (gene gun), 518

    via hydrodynamic gene delivery, 518
    via liposomes and virosomes, 518, 524
    nanoparticles as, 518
    via nucleic acid–based therapeutics, 518–519
    oligonucleotides as, 519
    plasmids as, 518–519, 518b
    ribozymes as, 519
    via RNA transduction, 518–519
    small interfering RNA as, 519
  retroviral, 514–515, 515f, 518b, 524
  targeting of, 523–524
  viral, 513–517
    recombinant adeno-associated virus as, 516
    recombinant adenoviral, 515–516, 515f, 516b, 523–526
    recombinant alphavirus (Sindbis) as, 517
    recombinant herpes simplex virus as, 516
    recombinant lentivirus as, 514–515
    recombinant Moloney murine leukemia virus as, 514, 514f
    recombinant pox (vaccinia virus), 516–517, 517b
VEGF. *See* Vascular endothelial growth factor (VEGF).
VeIP regimen, for testicular cancer, 1736
Velban (vinblastine), 480
  for gestational trophoblastic neoplasia, 1868
Velsar (vinblastine), 480
  for gestational trophoblastic neoplasia, 1868
Venacavograms, contrast, of superior vena cava syndrome, 806

Venography
contrast, of deep venous thrombosis
inferior vena cava and intra-abdominal, 707
lower-extremity, 699–700
upper-extremity, 704
magnetic resonance
of brain tumors, 1085
of deep venous thrombosis
inferior vena cava and intra-abdominal, 707
lower-extremity, 701
upper-extremity, 704–705
Venoocclusive disease (VOD)
after bone marrow transplantation, 797–798, 798f
after hematopoietic stem cell transplantation, 507
Venous access, limited or compromised, for anticoagulant therapy, 698
Venous access device(s). *See* Vascular access device(s).
Venous flare reaction, 628, 628f
Venous phase computed tomography, of lower-extremity deep venous thrombosis, 701
Venous sinus thrombosis, due to brain tumor, 1081t
Venous thromboembolic disease (VTE), 693–711
cancer-related hypercoagulability and, 695–696, 695t
central venous access device–associated, 695, 705, 709–710
chemotherapy and, 710
deep venous thrombosis as
central venous access device–associated, 709–710
inferior vena cava and intra-abdominal, 707–708
lower-extremity, 699–704
diagnosis of, 699–702, 700t
treatment of, 702–704, 702b, 704t
upper-extremity, 704–705
diagnosis of, 700t, 704–705
treatment of, 705
diagnosis of, 694, 696–697
epidemiology of, 694
future prospects for, 711
idiopathic, 708
natural history of, 694–695
prevention of, 708–711
pulmonary embolism as, 705–707
diagnosis of, 705–706, 705t
treatment of, 707
recurrent, 696
risk factors for, 695–696, 695t
superficial thrombophlebitis as, 708
treatment of
challenges in, 697–698
inferior vena cava filters for, 708
low-molecular-weight heparins for, 699
Ventilation/perfusion (V/Q) lung scintigraphy, of pulmonary embolism, 696, 705–706
VEPA regimen, for adult T-cell leukemia-lymphoma, 2435
Vepesid. *See* Etoposide (Vepesid, VP-16).
Verrucous carcinoma, 1258
of penis, 1702–1703
of vagina, 1778–1779, 1779f
of vulva, 1777
Vertebral chordoma, 1998–2001, 2000f
Vertebral fractures, heparin-induced, 698
Vertebral metastasis. *See* Spinal metastasis(es).
Vertebroplasty, percutaneous, for spinal metastases, 823, 824f, 867
Vertical rectus abdominis musculocutaneous (VRAM) flap, for lymphedema, 653f
Vesanoid. *See* Tretinoin (Vesanoid).
Vesicovaginal fistulae, due to cervical irradiation, 1762
Vessel walls, movement of cells across, 110
Vestibular schwannomas, 1114–1115
Vestibular system, in vomiting reflex, 600, 600f
VHL gene. *See* von Hippel–Lindau tumor suppressor *(VHL)* gene.
Viagra (sildenafil citrate), 1008
Vidaza (5-azacytidine), 453, 460–461
for myelodysplastic syndrome, 2244t, 2245–2246
Video-assisted thoracoscopic surgery (VATS)
for non-small cell lung cancer, 1330
for pericardial effusion, 936
for pleural effusion, 929, 932
in pulmonary metastectomy, 876–877
Villoglandular carcinoma, of endometrium, 1797
VIN. *See* Vulvar intraepithelial neoplasia (VIN).
Vinblastine (Velban, Velsar, VLB, vincaleukoblastine), 480
for gestational trophoblastic neoplasia, 1868
Vinca alkaloids
neurotoxicity of, 948
during pregnancy, 1006, 1052t, 1053
Vincristine (Oncovin, Vincasar, leurocristine, VCR), 480–481
for gestational trophoblastic neoplasia, 1867–1868, 1868t
for hepatoblastoma, 2114–2115
neurotoxicity of, 948
for rhabdomyosarcoma, 2105
for soft-tissue sarcoma, 2035
for vulvar cancer, 1776t
for Wilms' tumor, 2098
Vinorelbine (Navelbine, 5'-noranhydrovinblastine, NVB), 481
for non-small cell lung cancer, 1340t, 1342
VIP (vasoactive intestinal peptide), tumors secreting, 1295f, 1297
VIP regimen, for testicular cancer, 1730t, 1732, 1736–1738
VIPoma, 1295f, 1297
Viral gene transfer vectors, 513–517
recombinant adeno-associated virus as, 516
recombinant adenovirus as, 515–516, 515f, 516b
recombinant alphavirus (Sindbis) as, 517
recombinant herpes simplex virus as, 516
recombinant lentivirus as, 514–515
Viral gene transfer vectors (*cont.*)
recombinant Moloney murine leukemia virus as, 514, 514f
recombinant pox (vaccinia virus), 516–517, 517b
Viral infections, 727–728
Viral tumors, treatment and prevention of, 163–164
Viral vector transfection, 453
Virilization, due to adrenocortical cancer, 1281
Virosomes, in gene therapy, 518
Virtual colonography (VC), for colorectal cancer screening, 297, 1484–1485, 1484f
Virus(es), 153–164
Epstein-Barr, 153–156, 155f
hepatitis B, 156–157, 157f
vaccine for, 164
hepatitis C, 160–161, 161f
human papilloma-, 157–159, 158f
vaccine for, 159, 164
human T-cell leukemia I, 159–160, 159f
Kaposi's sarcoma herpes-, 161–163, 162f
search for tumorigenic, 153
Visceral pain, 569t, 580
Viscum album, 553
Visual system, paraneoplastic syndromes of, 772
Vitamin A
for cancer prevention, 547
colorectal, 1487t
overdose of, 555
Vitamin A analogs, for cutaneous T-cell lymphoma, 2419
Vitamin B complex, overdose of, 555
Vitamin B_6, overdose of, 555
Vitamin C
for cancer prevention, 547
colorectal, 1486, 1487t
for cancer treatment, 553–554
megadose, 553–554
overdose of, 555
Vitamin D, for cancer prevention, 547
colorectal, 1486
Vitamin D analogs, 453
Vitamin D–linked hypercalcemia, 741
Vitamin E
for cancer prevention, 547
colorectal, 1486, 1487t
prostate, 379, 1661
for cancer treatment, 554
overdose of, 555
Vitamin K, overdose of, 555
Vitamin supplements, for colorectal cancer prevention, 1486–1489
Vitamin toxicities, 555
VLB (vinblastine), 480
for gestational trophoblastic neoplasia, 1868
VM-25 (teniposide), 479
for brain metastases, 838–839
VMA (vanillylmandelic acid), with pheochromocytoma, 1286
Vocational rehabilitation, 587

VOD (venoocclusive disease)
after bone marrow transplantation, 797–798, 798f
after hematopoietic stem cell transplantation, 507
Voiding dysfunction, rehabilitation for, 585, 586t
Voloxicimab, for renal cell carcinoma, 1627
Vomiting. *See* Nausea and vomiting.
Vomiting center, 599
Vomiting reflex, 599–600, 600f
von Behring, Emil, 532b
von Hansemann, David, 249
von Hippel–Lindau syndrome, 176t
brain tumors in, 1078t
cerebellar hemangioblastomas in, 1115
and renal cell carcinoma, 1614t, 1615, 1621
von Hippel–Lindau tumor suppressor *(VHL)* gene, 212t, 213
in cerebellar hemangioblastomas, 1115
in polycythemia vera, 2264
in renal cell carcinoma, 1615
von Recklinghausen's disease, and soft-tissue sarcoma, 2011t
Voriconazole-resistant molds, 726
Vorinostat (Zolinza), 453
for cutaneous T-cell lymphoma, 2420
VP-16. *See* Etoposide (Vepesid, VP-16).
VPF (vascular permeability factor), in brain tumors, 1079
V/Q (ventilation/perfusion) lung scintigraphy, of pulmonary embolism, 696, 705–706
VRAM (vertical rectus abdominis musculocutaneous) flap, for lymphedema, 653f
VRE (vancomycin-resistant enterococcus), 724
VTE. *See* Venous thromboembolic disease (VTE).
Vulvar cancer, 1766–1777
adenosquamous carcinoma as, 1776
of Bartholin gland, 1777
basal cell, 1777
and cervical cancer, 1766
classification of, 1767t
differential diagnosis of, 1766
epidemiology of, 1766
etiology of, 1766–1767
evaluation of, 1766
invasive squamous cell, 1768–1776
clinical features of, 1768
diagnosis of, 1769
recurrent, persistent, or metastatic, 1774–1776
routes of spread of, 1768–1769, 1769f
staging of, 1769t, 1770t
treatment of, 1766, 1769–1777
chemoradiation for, 1772–1773, 1773f, 1774t, 1775t
chemotherapy for, 1774–1776, 1776t
radiation therapy for, 1772–1774, 1773t–1775t, 1774f
surgical, 1770–1772, 1771f, 1771t, 1772f
vulvar dystrophy and, 1767
melanoma as, 1776–1777, 1777t
Vulvar cancer (*cont.*)
Paget's disease and, 1767, 1767f
pathology of, 1767–1769, 1767f, 1768f
sarcoma as, 1777
second malignant neoplasms with, 1030
verrucous carcinoma as, 1777
vulvar intraepithelial neoplasia and
classification of, 1767t
etiology of, 1766–1767
natural history of, 1768, 1768f
treatment of, 1769–1770
Vulvar dystrophy, 1767
Vulvar intraepithelial neoplasia (VIN)
classification of, 1767t
etiology of, 1766–1767
natural history of, 1768, 1768f
treatment of, 1769–1770
Vulvectomy, 1770, 1771f
Vumon (teniposide), 479
for brain metastases, 838–839
VV (vaccinia viral) vectors, 516–517, 517b
VZV. *See* Varicella zoster virus (VZV).

W

WAGR syndrome, 176t, 2096
Waldenström's macroglobulinemia, 2323, 2342–2343
diagnostic criteria for, 2325t, 2342
paraneoplastic sensorimotor neuropathy in, 773
prognosis for, 2342
treatment of, 2342–2343, 2385
Wallstent, for superior vena cava syndrome, 810, 810f
Warfarin, for venous thromboembolic disease, 703
Warfarin failure, 697, 703
Warren, John Collins, 407–408
Warthin, Aldred, 185
Warthin's tumor, cytogenetic aberrations in, 258t
WAS (Wiskott-Aldrich syndrome)
as cancer predisposition syndrome, 175t
lymphoma with, 225t, 226, 226t
tumor distribution with, 225t
WASP gene, 226
Watchful waiting, for prostate cancer, 1668, 1670f
Water regulation, 750
Water restriction, for ascites, 939
Water retention, hyponatremia due to, 752f
WBA (whole-blood hemagglutination) assays, for D-dimer, 702
WBC (white blood cell) count, in acute lymphocytic leukemia, 2195, 2195t, 2205
WBC (white blood cell) disorders, 681–682
WBRT. *See* Whole-brain radiotherapy (WBRT).
Web sites
on clinical trials, 329, 334, 335b
on complementary and alternative medicine, 556, 557b, 557t
Weight loss, due to pancreatic cancer, 1599
Wellcovorin. *See* Leucovorin calcium (Wellcovorin, citrovorum factor, folinic acid, FA, LV).
Well-differentiated tumors, 234
Wells, Samuel, 408
Werner's syndrome, 177t
DNA damage in, 141t, 148
immunodeficiency and cancer in, 229t, 230
mutation of caretaker genes in, 1254
and soft-tissue sarcoma, 2011, 2011t
WHI (Women's Health Initiative) trial, 374–375
Whipple procedure
for pancreatic cancer, 1602–1604, 1603f
for small bowel tumors, 1472
White blood cell (WBC) count, in acute lymphocytic leukemia, 2195, 2195t, 2205
White blood cell (WBC) disorders, 681–682
WHO. *See* World Health Organization (WHO).
Whole-blood hemagglutination (WBA) assays, for D-dimer, 702
Whole-body hyperthermia, for soft-tissue sarcoma, 2031–2032
Whole-brain radiotherapy (WBRT), 830–833
with chemotherapy, 838
for gliomas, 1098
portal image of, 830f
with radiosurgery, 834t, 835–836, 835t
randomized trials of, 830–831, 831t
response and local control with, 831
with surgery, 832–833, 833t
toxicity of, 831–832
Whole-liver irradiation, for liver metastases, 912, 912t, 913t
Wide excision, for breast cancer, 1906, 1908
Wilms' tumor, 2076, 2096–2100
anaplastic, 2097, 2097f, 2099–2100
bilateral, 2100
clinical manifestations and pattern of spread of, 2076, 2097
cytogenetic aberrations in, 258t
differential diagnosis of, 2076
epidemiology of, 2076, 2096
etiology of, 2076
familial, 2096, 2097
laboratory and radiologic evaluation of, 2097–2098, 2098f
pathology of, 2076, 2097, 2097f
recurrent, 2100
second, malignant neoplasms with, 1025, 1025f
staging of, 2076, 2099t
treatment of, 2076, 2098–2100, 2099t, 2100b
tumor biology of, 2076, 2096–2097
Wilms' tumor syndrome, 176t
Wireless capsule endoscopy, for small bowel tumors, 1470
Wire-localized excisional biopsy, of breast, 1893, 1894f, 1895f
Wisconsin Brief Pain Inventory, 568
Wiskott-Aldrich syndrome (WAS)
as cancer predisposition syndrome, 175t
lymphoma with, 225t, 226, 226t
tumor distribution with, 225t
Withdrawal, from opioids, 571t

Wnt
in intracellular signaling, 28, 29f
in metastasis, 36, 36f
in regulation of self-renewal, 97
Women's Health Initiative (WHI) trial, 374–375
Wood dust, as carcinogen, 133
World Health Organization (WHO), 234
World Health Organization (WHO) classification
of hematologic malignancies, 2131–2136, 2133t, 2134b–2135b
of lymphoma(s), 2373, 2373t
cutaneous, 2406, 2407t, 2413
Hodgkin's, 2355t
of myelodysplastic syndrome, 2239, 2240t
of myeloproliferative disorders, 2261
World Health Organization (WHO) Prognostic Scoring System (WPSS)
for gestational trophoblastic disease, 1865, 1866t
for myelodysplastic syndrome, 2242
Wound infections, after colon cancer surgery, 1508
WR-2721. *See* Amifostine (Ethyol, WR-2721, ethiofos).
WRN gene, 148, 230, 2011
WT1, 212t
in Wilms' tumor, 2096
WT2, in Beckwith-Wiedemann syndrome, 2096–2097

X
Xanthogranuloma, orbital, 1166, 1166f
Xeloda. *See* Capecitabine (Xeloda).
Xenograft models, of molecularly targeted therapy, 489
Xeroderma pigmentosum (XP), 1254
as cancer predisposition syndrome, 175t
DNA damage in, 141t, 143, 144
and skin cancer, 135
Xerostomia
in dying patient, 668
radiation-induced, 616–618, 617b
Xialine, for xerostomia, 617
X-linked agammaglobulinemia, 225t
X-linked CD40 ligand deficiency, 227
X-linked hyper-IgM syndrome (XHIM), 227
X-linked lymphoproliferative syndrome (XLP)
as cancer predisposition syndrome, 176t
and lymphoma, 226t, 227
X-linked severe combined immunodeficiency (X-SCID), 226, 226t
gene therapy for, 524–525, 525f
X-linked thrombocytopenia, 226
XP. *See* Xeroderma pigmentosum (XP).
X-ray(s), 283, 288, 291t, 419
bremsstrahlung (braking energy), 420
characteristic, 420
fetal exposure to, 1050, 1050t
interaction of matter and, 420, 422f
XRT (external radiation therapy). *See* Radiation therapy (RT).
X-SCID (X-linked severe combined immunodeficiency), 226, 226t
gene therapy for, 524–525, 525f

Y
^{90}Y microspheres, for liver metastases, 915
Yeast two-hybrid system, 13–14, 14f
Yohimbe bark, interactions with, 555t
Yolk sac tumors, histology of, 1716f–1717f, 1718f
Yttrium 90, 419
Yttrium-90 ibritumomab tiuxetan (Y-90 Zevalin), 453, 470
for follicular lymphoma, 2384
for lymphoma, 535–536, 536t

Z
ZAG (zinc α-glycoprotein), in cachexia, 592
Zanosar. *See* Streptozocin (Zanosar).
ZAP-70, in chronic lymphoid leukemia, 2297, 2298
ZD1839, for head and neck cancer, 1208
Z/EG double reporter system, 17f
Zevalin (ibritumomab tiuxetan), 453, 470
for follicular lymphoma, 2384
for lymphoma, 535–536, 536t
Zinc α-glycoprotein (ZAG), in cachexia, 592
Zinecard (dexrazoxane), 466
for cardioprotection, 989, 989f, 992b
Zoladex (goserelin acetate), 469–470
for prostate cancer, 1683–1684
reproductive effects of, 1002
Zoledronic acid (Zometa), 481
for bone metastases
of breast cancer, 861t, 862, 862f
of multiple myeloma, 863
of prostate cancer, 863, 864
of solid tumors, 864
for hypercalcemia of malignancy, 744–745, 746t
Zolinza (vorinostat), 453
for cutaneous T-cell lymphoma, 2420
Zollinger-Ellison syndrome, 1297
Zometa. *See* Zoledronic acid (Zometa).
Z-stent, for superior vena cava syndrome, 810, 810f
Zubrod scale, 457, 457t
zur Hausen, Harald, 157
Zyban (bupropion SR), for smoking cessation, 399–400, 399t
