to be certain that the type, frequency, and severity of such events is reasonable. Also, efficacy endpoints can be reviewed, following appropriate statistical guidelines, to satisfy ethical concerns. Much has been written about these subjects, and we discuss more details in the following sections.

Establishment of Procedures for Monitoring

Plans for monitoring and early stopping of accrual are another element of good trial design that can greatly alleviate problems in conducting studies. Researchers have an ethical obligation to learn about treatment differences as quickly as possible and to minimize the number of patients who are placed on a convincingly inferior treatment. By planning for early termination of accrual when unexpectedly large differences are observed, investigators can make a clinical trial more acceptable to other researchers and patients. A full discussion of sequential and group sequential methods for use in this context is beyond the scope of this chapter. These methods are now commonly implemented using well-described techniques.[48,49] Investigators can insure that monitoring methods are effectively implemented by having the accumulating data reviewed formally at intervals by a monitoring committee.

Repeatedly performing statistical significance tests on accumulating data increases the overall type I error. If 10 interim analyses were conducted with the conventional significance level of 0.05, the resulting overall type I error might be as high as 15%. This inflation of the type I error can be even higher if many interim looks at the data are performed. To compensate for this and control the type I error, investigators must prospectively plan the analysis points and the significance level for each analysis.

To control the overall type I error at 5%, each interim look should use a significance level smaller than 0.05. For example, in a clinical trial comparing response rates and two-sided testing for significance five times, a frequently used group sequential method[50] indicates that the analyses should be conducted with significance levels of approximately 0.0000075, 0.0013, 0.0085, 0.023, and 0.041, to control the overall type I error at the conventional 5%. Using this method, note that the final analysis is conducted using a significance level near, but less than, the usual 5%. Early in the trial, achieving statistical significance is more difficult.

Unplanned interim analyses may have undesirable properties and can pose serious problems in interpretation for researchers and regulators. Attempts have been made to alleviate this problem by retrospectively applying group sequential methods, although this has difficulties of its own. Another alternative for monitoring is the use of Bayesian statistical methods, which have much appeal to clinicians but have not gained as widespread use as other methods.[51] For a general discussion of monitoring alternatives, see Gail,[52] and for a practical discussion see DeMets[53] or O'Fallon.[54] In any case, the time to plan properly for trial monitoring is during the design phase of the study.

A second reason for terminating a trial early is when interim analyses demonstrate the near equivalence of the treatments and continuing the trial would be unlikely to demonstrate clinically significant differences. In this circumstance, early stopping has been based on conditional power calculations.[55] Using this technique reduces the size and length of trials that show no effect or treatment difference but still yields clinically useful information.

ANALYSIS

The exact procedures necessary for analyzing a clinical trial depend on the design and purposes of the study. For example, pharmacologic studies might require modeling and estimation of physiologic parameters in each patient to meet their objectives, whereas comparative trials usually require summaries of relative treatment effects and confidence intervals. Analyses for these differing types of studies seem to have very little in common. However, when we consider that all trials should inform us about the population being studied, the need for unbiased statistical estimation of clinical effects, and the need to summarize data in the most clinically useful form, much common ground is evident.

The approach we recommend to analysis and reporting emphasizes estimation rather than hypothesis testing.[29–31] Measuring and reporting clinical effects and associated estimates of variability (or confidence intervals) is more informative and useful than focusing attention on formal tests of statistical hypotheses and *P* values. A simple example should make the difference clear. Suppose a clinical trial is performed comparing two treatments, A and B, and the major outcome is survival. Investigators might perform a statistical hypothesis test comparing treatments A and B and report "survival on treatment A is significantly longer than on B ($P < 0.05$)." Alternatively, when emphasizing estimation, investigators might report the estimated hazard ratio (A vs. B) for death was 2.0 (95% confidence limits 1.5–2.3). In the first case, the reader is left only with a *P* value to summarize the data, whereas in the second case the treatment difference is described more completely. Some journals have adopted guidelines for reporting.[56] Our recommendations are similar in spirit to those. Although we have suggested some specific statistical methods and summaries for certain kinds of data, there are additional or alternative analytic procedures that should be adopted in special cases and we do not seek to limit analyses or reports. However, the basic concepts and approaches outlined here should prove to be helpful both clinically and statistically for correctness, lack of bias, completeness, and consistency. In this spirit we offer the following basic steps in the analysis of clinical trials (Table 22-4). We emphasize that these

Table 22-4 Basic Steps in the Analysis of Clinical Trials

1. Approach the trial as a test of treatment policy, not a test of treatment received. This is the "intent to treat'" principle.
2. Include all patients who meet the eligibility criteria.
3. Examine the data and correct errors.
4. Describe the population in the study.
5. Verify the comparability of treatment groups.
6. Estimate the effect of treatment and other prognostic factors on the major outcome (univariate analyses). Estimate confidence intervals.
7. Use standard statistical methods or models (e.g., linear, logistic, or proportional hazards regression), to re-estimate the treatment effect while adjusting for the following:
   - Statistically significantly imbalanced prognostic factors
   - Strong or influential prognostic factors, whether imbalanced or not
   - Any prognostic factor for which it is important to demonstrate convincing control
8. Consult the biostatistician concerning special methods to address secondary clinical questions. Any analyses not protected by the randomization should correspond to clinical hypotheses stated as study objectives. Control prognostic factors.
9. Consider repeating steps 1–6 after excluding ineligible patients—that is, patients who are ineligible based on entry criteria.
10. Cautiously conduct exploratory or hypothesis-generating analyses:
    - Any analysis suggested by the data and not by hypothesis
    - Any analysis that excludes patients based on postentry criteria
    - Subset analyses

These final steps should never be the "primary" analysis.

steps are conceptual and do not necessarily occur in the order listed. Also, some steps are relevant only to randomized or comparative trials.

Intention to Treat

It is unfortunate that investigators conducting clinical trials cannot guarantee that the patients who participate will definitely complete (or even receive) the treatment assigned. Thus, a clinical trial can be viewed as a test of treatment policy, not a test of treatment received. Many factors contribute to patients failing to complete the intended therapy including severe side effects, disease progression, strong preference for a different treatment, and a change of mind. Many such factors are strongly correlated with outcome, which can render a strong bias if such patients are removed from the analysis.

From a clinical perspective, postentry exclusion of eligible patients is essentially an attempt to use information from the future. When selecting a therapy for a new patient, the physician is primarily interested in the unconditional probability that the treatment will benefit the patient. Because the physician has no knowledge of whether or not the patient will complete the treatment intended, inferences that depend on events in the patient's future (i.e., adherence to therapy) are not helpful to that goal. In other words, adherence is both an outcome of the trial as well as a potential predictor. These two roles of adherence cannot be disentangled by removing patients from consideration. Consequently, the physician will be most interested in clinical trial results that include all patients who were assigned to the therapy.

To be certain that the trial results closely reflect the effect of the treatment, the eligibility criteria should exclude patients with characteristics that might prevent them from completing the therapy. For example, if the therapy is lengthy, perhaps only patients with good performance status should be eligible. If the treatment is highly toxic, only patients with normal function in major organ systems will be likely to complete the therapy.

Following on these considerations, the most important analysis includes all patients registered or randomized on the trial regardless of postentry events. This analysis is the intention-to-treat analysis. It is possible to exclude patients who were retrospectively found not to meet the eligibility criteria—that is, those who were mistakenly placed on study—without creating bias. Ideally, such patients would not have gone on study because they would have been found to be ineligible. However, only eligibility or pre-entry criteria should be used to make such exclusions. If patients are excluded on the basis of "evaluability" or other postentry criteria, the possibility of bias increases. Evaluability criteria are outcomes, no matter how well defined clinically. If we exclude subjects based on outcomes, the potential for bias is great.

Examination of the Data

The first practical step in any analysis is to look at the data. This includes examining lists and other simple tabulations that might highlight incorrect data values. Many problems in analyzing clinical trials can be prevented by correcting errors that become apparent in this way. This is also a step that knowledgeable investigators can perform quickly but very efficiently. With the widespread use of computers and automated analysis procedures to manage clinical information, it is possible to produce results from clinical studies without carefully examining the data. This is unfortunate, because even a cursory examination of raw data by a technically knowledgeable person can detect many errors of importance to the analysis.

Some of the errors that are amenable to detection by inspection include (1) incorrectly missing data (patient had level measured but not recorded in the database), (2) incorrect decimal points (80 recorded instead of 8.0), (3) failure to convert numerical codes for special values, (calcium becomes 99 instead of "missing"), (4) out-of-range or impermissible values (0.0 recorded instead of 8.0), (5) mislabeled variables (age is mistaken for calcium and vice versa), and (6) coding and recoding errors (0 should mean normal and 1 should mean abnormal, but values are reversed).

Inspection of the data is particularly important for small or single-investigator studies in which the data management techniques are not subject to regular quality control procedures as might be the case in multi-institutional cooperative group studies. Errors in small studies can be particularly influential. Many times, small studies are recorded entirely on paper with transcription to a computer at a later time, creating another opportunity for errors. Other times, data are stored on computers using convenient but unsophisticated software such as spreadsheets rather than database management programs that permit validation and checking. Fortunately, the quantity of data from such small studies is often very amenable to checking by inspection. It is embarrassing, frustrating, and bad for morale to have to ask that analyses be repeated because data errors were discovered late.

Description of the Study Population

Clinical trials are studies of particularly well-defined and often relatively small cohorts. Although the eligibility criteria define a target population of particular interest, the patients actually accrued on a trial may differ because of chance or subtle institutional characteristics. Investigators will want to describe the observed cohort, particularly with regard to important prognostic factors. Simple population measures and summary statistics usually suffice for this purpose. This process is also both a byproduct of and valuable in error checking.

Verification of the Comparability of Treatment Groups

In reports of many randomized studies, the first table presented is often intended to show the comparability of treatment groups. Actually, a lack of statistically significant differences between the treatment groups does not guarantee the absence of influential imbalances but only demonstrates the effectiveness of randomization. Even so, this is important, because readers will have increased confidence in the validity of the findings if imbalances are either absent or detected and controlled in the analyses. Although we will take note of any statistically significant differences between groups, nonsignificant imbalances in strong prognostic factors can influence treatment comparisons. This is discussed more completely in the later section on deciding when to adjust. Second, and conversely, statistically significant imbalances are not necessarily influential; the imbalance may occur in an inconsequential factor. For the clinician comparing groups, the magnitude of the difference is more important than the *P* value.

Estimation of Treatment and Prognostic Effects

As mentioned previously, some outcomes that are likely to be useful in oncology trials are group averages (or differences between group averages), probability of response (or odds ratios), and hazards (or hazard ratios). We omit discussion of methods for group averages, because they are well known and focus on dichotomous outcomes and event times. These outcomes have similarities with respect to their summary statistics and presentation. Odds ratios are useful summaries of data to describe the effects of dichotomous variables. For example, differences in the probability of response might be described by an odds ratio. Similarly, hazard ratios are useful for describing differences in risk of failure over time. For example, differences in recurrence or survival curves might be described by a hazard ratio.

To illustrate these and other aspects of the estimation of clinical effects, we consider simulated data from a hypothetical randomized trial comparing two treatments (A and B) for solid tumors. Simple randomization was used in this study, with 101 patients on treatment A and 99 patients on treatment B. Data on response to

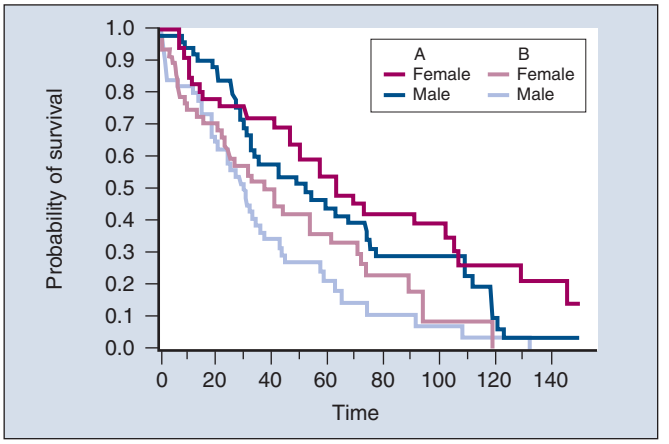

Figure 22-1 • Survival by treatment group and sex on a hypothetical clinical trial.

treatment were collected as an example of a dichotomous outcome, and patients were followed for survival as an example of an event time endpoint. Differences in response and survival attributable to sex are also thought to be important. Nonparametric estimates of survival for subgroups defined by treatment-sex combinations are shown in Figure 22-1.

The advantage to using simulated data, aside from convenience, is that the "true" treatment and covariate effects are known. In this case, the true treatment effects were a 4-fold odds of response and a 2-fold risk of death in favor of treatment A. For sex, the odds of response was 2-fold and the risk of death was 1.5-fold, both in favor of females. Response and survival were independent of one another. In what follows, the estimated effects will differ from these values because of random variation.

Odds and Hazard Ratios

The simulated-response data for the two treatment groups are shown in Table 22-5. The estimated response rate (probability) on treatment A was 0.376 compared with 0.182 on treatment B. The odds of response for treatment A is

$$\text{odds}_A = P/(1 - P) = 0.376/0.624 = 0.063$$

A more useful quantity for judging the relative effect of treatment on response is the odds ratio. The estimate of the overall odds ratio for group A versus group B, ORd_{AB} is

$$\text{ORd}_{AB} = (38 \times 81)/(18 \times 63) = 2.71$$

Because the odds of response on treatment A are almost threefold higher than on treatment B, this might be a clinically important difference. The decision to use the odds ratio of A versus B (or vice versa) is purely a matter of convenience. The data relating sex and response are shown in Table 22-6.

In treatment group A, the odds ratio for males versus females is 0.395/0.920 = 0.429. In group B the corresponding ratio is 0.707.

Table 22-5 Responses on Treatments for Solid Tumors

Treatment	Response	No Response
Group A	38	63
Group B	18	81

Table 22-6 Example of Odds Summary Data

Group	Sex	No. of Patients	No. of Responses	Response Odds
A	Males	53	15	.395
	Females	48	23	.920
	Overall	101	38	.603
B	Males	51	8	.186
	Females	48	10	.263
	Overall	99	18	.222

Thus, it seems that male subjects are less likely to respond than female subjects, and this is explored further later in the analysis.

For event time endpoints, the quantities of interest are the number of events in the groups and the total follow-up or exposure time (in years; Table 22-7).

The total exposure time is obtained by summing all follow-up times without regard to censoring. This represents the aggregate time at risk for the group. Thus, the estimated overall hazard of death in group A, l_A, is

$$l_A = 70/5614 = 0.012 \text{ per person-year},$$

and for group B, is

$$l_B = 77/3434 = 0.022 \text{ per person-year}$$

From these data we would conclude that the risk of death following treatment B is higher and that this difference might be of clinical importance. Here also, sex seems to influence the risk of death. The estimated hazard ratios for males versus females are 1.27 and 1.37 on treatments A and B. The effect of sex will be explored later in more detail.

This example has shown the utility of odds and hazard ratios in summarizing clinical effects. The next section will illustrate additional utility for confidence intervals.

Confidence Intervals

Informally, a confidence interval is a region in which we are confident that a true parameter or effect lies. Although this notion is not too misleading, confidence intervals are really probability statements about an estimate and not about the true parameter value. A 95% confidence interval indicates the region that would contain the true parameter value 95% of the time if we repeated the experiment. In other words, given the estimates resulting from a series of experi-

Table 22-7 Example of Hazard Summary Data

Group	Sex	No. of Patients	Exposure Time	No. of Deaths	Hazard
A	Males	53	2768	40	.014
	Females	48	2846	30	.011
	Overall	101	5614	70	.012
B	Males	51	1632	42	.026
	Females	48	1802	35	.019
	Overall	99	3434	77	.022

ments, the true value will fall within the 95% confidence regions 95% of the time.

The value of confidence intervals is that they convey both the magnitude of the estimated clinical effect and a sense of its precision. In many cases, simple hypothesis tests are analogous to the confidence interval. Also, when summarizing results from several studies, estimates and confidence intervals are more useful than *P* values.

Continuing with the preceding example of the randomized clinical trial, we first consider confidence intervals for the probability of response. Using the methods already discussed, an approximate 95% confidence interval for the probability of response on treatment A is

$$0.36 \pm 1.96 \times \sqrt{[0.376(1-0.376)/101]}$$
$$= 0.376 \pm 0.094 = [0.282 - 0.470]$$

Similarly, an approximate 95% confidence interval for response on treatment B is 0.182 ± 0.076 = [0.106 − 0.258]. Because of the large sample size and the intermediate size of the probabilities, these intervals are close to those that would be obtained by using exact binomial methods, which are [0.282 − 0.478] and [0. − 0.272] for groups A and B, respectively.

For odds and hazard ratios, calculating confidence intervals on a log scale is relatively simple. An approximate confidence interval for the log odds ratio for A versus B is

$$\log\{2.71\} \pm Z_a \times \sqrt{1/63 + 1/38 + 1/81 + 1/18}$$

where Z_a is the point on normal distribution exceeded with probability $a/2$ (e.g., for $a = 0.05$, $Z_a = 1.96$). This yields a confidence interval of [0.35–1.65] for the log odds ratio or [1.41–5.21] for the odds ratio. Because the 95% confidence interval for $\hat{o}R_{AB}$ excludes 1.0, the difference is "statistically significant." The statistical test of the null H_0:$\hat{o}R_{AB} = 1.0$ is rejected with significance level $P = 0.003$.

A similar method can be used for the hazard ratio. An approximate confidence interval for the log hazard ratio is

$$\log\{1.83\} \pm Z_a \times \sqrt{1/77 + 1/70}$$

This yields a confidence interval of [0.264–0.911] for the log hazard ratio or [1.30–2.49] for the hazard ratio. Again, the confidence interval excludes 1.0, indicating a statistically significant difference in the death rates between the groups ($P < 0.001$).

Problems with *P* Values

There are many circumstances in which *P* values are useful, particularly in well-designed hypothesis tests. However, *P* values have properties that make them poor summaries of clinical effects. In particular, *P* values do not convey the magnitude of a clinical effect. The size of the *P* value is a consequence of two things: the magnitude of the estimated treatment difference and its estimated variability (which is itself a consequence of sample size). Thus, the *P* value partially reflects the size of the experiment, which has no biologic importance. The *P* value also hides the size of the treatment difference, which does have major biologic importance.

Some investigators conclude things like "the effect might be statistically significant in a larger sample." This, of course, misses the point, because any effect other than zero will be statistically significant in a large enough sample. What the investigators should really be talking about is the size and clinical significance of an estimated treatment effect rather than its *P* value. In summary, *P* values only quantify the type I error and incompletely characterize the biologically important effects in the data.

To illustrate the advantage of estimation and confidence intervals over *P* values, consider a discussion over the prognostic effect of perioperative blood transfusion in lung cancer.[57–63] Several studies (not clinical trials) of this phenomenon have been performed because of firm evidence in other malignancies and diseases that blood transfusion has a clinically important immunosuppressive effect. Disagreement over the study results has stemmed, in part, from too strong an emphasis on hypothesis tests instead of accepting the estimated risk ratios and confidence limits. Some study results are shown in Table 22-8. Although the authors of the various reports came to different conclusions about the risk of blood transfusion because of differing *P* values, the estimated risk ratios adjusted for extent of disease seem to be consistent across studies. Based on these results, one might be justified in concluding that perioperative blood transfusion has a modest adverse effect on lung cancer patients.

Table 22-8 Summary of Studies Examining the Perioperative Effect of Blood Transfusion in Lung Cancer

Study	Endpoint	Hazard Ratio*	95% Confidence Limits
Tartter et al.[58]	Survival	1.99	1.09–3.64
Hyman et al.[59]	Survival	1.25	1.04–1.49
Pena et al.[60]	Survival	1.30	0.80–2.20
Keller et al.[61]	Recurrence		
	Stage I	1.24	0.67–1.81
	Stage II	1.92	0.28–3.57
Moores et al.[62]	Survival	1.57	1.14–2.16
	Recurrence	1.40	1.01–1.94

*All hazard ratios are transfused versus untransfused patients and are adjusted for extent of disease.

Adjustments

Not all clinical trial statisticians agree on the need for adjusted analyses in clinical trials. However, many investigators believe that the difference in estimated treatment effects before and after adjustment often conveys useful knowledge. Furthermore, nonrandomized studies, such as cohort studies, are invariably analyzed with adjustment for confounders or prognostic factors. The same kinds of systematic errors that can arise in observational studies can arise in clinical trials by chance. This seems to provide a firm rationale for examining the results of adjusted analyses.

One of the principal advantages of using statistical models to help analyze trial results is the straightforward generalization to multiple regressions suitable for adjusted analyses. Using these methods, investigators can estimate the treatment effect while adjusting for prognostic factors. One should consider adjusting for variables that meet any of three criteria: (1) prognostic factors that are statistically significantly imbalanced between the treatment groups, (2) strong or influential prognostic factors, whether imbalanced or not, (3) to prove that a particular prognostic factor does not artificially create the treatment effect.

The philosophy underlying adjusting in these circumstances is to be certain that the observed treatment effect is not due to confounding. The effects of clinical interest with adjustment are changes in relative risk parameters rather than changes in *P* values.

Regression Methods

Regression is an unfortunate historically anomalous name for a very important statistical method. A more descriptive name might be statistical modeling of multiple effects. In any case, the essential idea is to relate an outcome of interest to one or more predictor variables using a statistical model. The theoretical components of the model are its deterministic form (structural equation), probabilistic form (how it models errors), and parameters (biologic constants), whereas the empirical components are the observed data. If the model is approximately correct, it should predict the observed data well

Table 22-9 Logistic Regression Models Illustrating Adjusted Treatment Effects

Model	Variable	Odds Ratio	95% Confidence Limits	*P* Value
1	B vs. A	0.368	0.19–0.71	0.003
2	Male vs. female	0.542	0.29–1.01	0.055
3	B vs. A	0.358	0.19–0.69	0.002
	Male vs. female	0.520	0.27–0.99	0.046

provided we choose appropriate parameter values. Conversely, we can choose those parameter values that make the predictions and observations (data) close in some well-defined way. This latter sense is the way in which most statistical models are used. Trustworthy fitting methods exist, such as maximum likelihood, to estimate the best parameter values.

If the model has been constructed so that the parameters also correspond to clinically interesting effects, it yields a way of estimating the influence of several factors simultaneously on the outcome. In practice, models also provide a means for obtaining confidence intervals, testing hypotheses, and even revising the model itself.

Statistical models such as logistic regression for dichotomous outcomes and survival regression for event times are likely to be useful both for estimating odds and hazard ratios and performing multiple regression adjustments. Provided the assumptions of these models are met, they can provide estimates of the appropriate relative risk parameter(s), confidence limits, and *P* values.

We return to the hypothetical randomized clinical trial outlined previously, in which sex seemed to influence response rate and survival. For response, an appropriate statistical model is the logistic regression model, the results of which are shown in Table 22-9.

Models 1 and 2 show the overall odds ratios, confidence limits, and *P* values for treatment and sex considered individually. Model 3 shows the joint effects of sex and treatment group on response. When the effect of treatment is taken into account, females are seen to have a higher response odds. Because the estimated odds ratios don't change very much after adjustment, this suggests that sex and treatment have nearly independent effects on response. For the survival endpoint, the results of proportional hazards regression models are shown in Table 22-10.

The estimated hazard ratios are quantitatively similar to those determined previously and show a higher risk for males. Differences are due to different methods of calculation. The effect of treatment controlling for sex is significant. The adjusted hazard ratios (model 3) also suggest independent effects for sex and treatment on survival time.

Table 22-10 Proportional Hazards Regression Models Illustrating Adjusted Treatment Effects

Model	Variable	Hazard Ratio	95% Confidence Limits	*P* Value
1	B vs. A	1.91	1.36–2.66	<0.001
2	Male vs. female	1.32	0.95–1.82	0.100
3	B vs. A	1.92	1.37–2.68	<0.001
	Male vs. female	1.34	0.96–1.85	0.083

Special Methods

Frequently, special analyses are needed to address specific clinical questions or secondary goals of the trial. In some prognostic factor studies, special regression models may be needed, such as time-dependent covariate models, to account correctly for the effects of predictors that change over time. Other examples of situations that may require sophisticated analytic methods are repeated longitudinal measurements, Bayesian methods, nonindependent observations, and accounting for restricted randomization schemes. Aside from the lack of software for many needs, extra care is required to be certain that the assumptions of the analytic methods are met.

Repeat Analyses

Although we have tried to be firm about the value of the intention-to-treat analysis, there are circumstances in which one would like to know if the exclusion of some patients on the basis of clinical criteria affects the results. One such situation is the exclusion of ineligible patients in a randomized trial. Actually, exclusions based on eligibility criteria do not violate the intention-to-treat principle. However, investigators may sometimes feel the need to exclude eligible patients. One can consider repeating steps 1–6 after doing so. Provided the fraction of patients excluded is small, say 5%, and affect both treatment groups (if the trial is comparative), it is likely that the results will agree with the intention-to-treat analysis. This is as much an argument not to exclude patients as it is to allow exclusions.

Data Exploration

Clinicians generally need very little encouragement to conduct exploratory analyses of their data. By exploratory analyses, we mean those that do not follow directly from the design of the experiment. Such analyses are neither automatically inappropriate nor wrong. However, the conclusions derived from these analyses can be unreliable. Therefore, they should serve only to generate hypotheses to be tested more rigorously in the future. Reasons why exploratory analyses may be unreliable include the following:

- A comparison suggested by the data and not by prior hypothesis is likely to have a type I error larger than the nominal *P* value. This occurs because investigators have a tendency to only test those differences that are large, most of which are probably due to chance.
- An analysis that excludes patients based on postentry criteria (responses) will probably produce biased results.
- Subset analyses are likely to be influenced by uncontrolled prognostic factors.
- Investigating large numbers of subsets can lead to "significant" differences purely by chance (i.e., inflated type I error).

By relying on estimation of clinical effects rather than unplanned tests of statistical hypotheses, the utility of these exploratory analyses might be increased. Investigators might be less likely to misinterpret the results or to exaggerate their clinical utility. In any case, these types of exploratory analyses should never be the primary analysis of a clinical trial.

PUBLICATION AND INTERPRETATION

As with analysis, the most informative summaries and amount of detail to report from a clinical trial will depend largely on the nature of the clinical hypotheses being studied. This section will outline basic reporting guidelines (Table 22-11) that follow an estimation and confidence interval approach and that should be helpful for reporting many types of clinical trials. These guidelines should also be useful for reviewing and interpreting published reports of trials and prognostic factor analyses. Reports of clinical trial results may be subject to constraints that analyses are not. For example, reports often

Table 22-11 Ten Concepts in Reporting

1. Report all clinically relevant descriptions of the trial population including patients who met the eligibility criteria but chose not to participate.
2. Describe those patients who were retrospectively found to have failed the eligibility criteria and those patients who failed to complete the assigned treatment.
3. Report all statistical methods and assumptions made.
4. For univariate analyses, report estimated treatment effects (log odds ratios or hazard ratios), confidence intervals, and significance levels of tests of no treatment effect (*P* values).
5. Report adjusted estimates of treatment effects, confidence intervals, and *P* values.
6. When no treatment effect is found, do not report the power of the study. Instead use point estimates and confidence limits.
7. Report any differences between "intention-to-treat" analyses and "eligible patient" analyses.
8. Results with strong biologic or clinical justification and *P* values near 0.05 could be called "statistically significant."
9. Results without biologic or clinical backup or those that seem contradictory should be reported but interpreted with caution.
10. Represent exploratory or hypothesis-generating analyses accurately.

require a consensus among investigators and must undergo an imperfect editorial process before publication. We can offer little help here in navigating these difficulties except to suggest a certain minimal content and structure.

Description of the Study Population

Clinically relevant descriptions of both the study and target population should be reported. It may also be important to describe patients who met the eligibility criteria but chose not to participate in the trial, when this information is available. The need for this might arise when patients from a large group are asked to participate, but many refuse. As pointed out previously, it may be difficult to generalize from these situations. For nonrandomized designs, even detailed descriptions of the study group may not provide a convincing basis on which to make comparisons with other studies. Thus, comparison is not the motivation, but thoroughness is.

Treatment and Eligibility Failures

As mentioned previously, it is acceptable to perform statistical analyses on only the subset of eligible patients, even when eligibility is corrected in retrospect. This does not create bias in the estimate of relative effects within the trial. Investigators should report those patients who were retrospectively found to have failed the eligibility criteria as well as those patients who failed to complete the assigned treatment.

There are situations in which a large fraction of patients complete the assigned therapy but may receive additional therapy not specified by the protocol or design of the trial. For example, patients with esophageal cancer may undergo resection and chemotherapy, and have a variety of second-line treatments if signs of disease progression or recurrence are observed. If some of these latter treatments are active, the results of an initial treatment comparison based on recurrence or survival may be skewed. In fact, in general, it is difficult or impossible to use the statistical information in studies that permit "crossovers" either to new treatments or to the other treatment arm. One cannot exclude these patients but can use only the information up to the time of stopping the assigned treatment.

Statistical Methods and Assumptions

Readers should be made aware of any assumptions made in both the design and analysis of a clinical trial. For a discussion of some practical issues, see DerSimonian and associates.[27] The assumptions and limitations of many common statistical procedures are well understood by clinicians. However, the readers of clinical trial reports should be convinced that the data analyst has verified all important assumptions and reported the methods in detail for less well-known statistical procedures. Examples of assumptions that are often made in analysis, often violated by the data, and also likely to be consequential are distributional assumptions underlying the *t*-test or other statistical hypothesis tests, error distributions in linear regression analyses, and proportionality of hazards in life table regressions. For example, the *t*-test assumes that the distributions being compared are normal with equal variances. It can yield incorrect results when either of these assumptions is false, particularly if distributions are not symmetric. Proportional hazards regression models most often assume that the effects of predictors is to multiply a baseline risk and that the multiplicative factor is constant over time. Although the model is robust to departures from this assumption—that is, it will often yield the correct estimates of relative risk and significance levels anyway—it is helpful to validate the assumptions.

Univariate Analyses

It is likely that the data analyst will test the effect of all potentially important prognostic variables on the major outcomes. For these univariate analyses investigators should report estimated treatment effects (odds ratios or hazard ratios), confidence intervals, and significance levels of tests of no treatment effect (*P* values). This does not preclude presenting other displays of univariate analyses (e.g., survival curves or 2×2 tables) if these analyses are especially relevant. However, the investigators should keep in mind that univariate analyses, particularly in uncontrolled studies, are subject to confounding. Consequently, these analyses should probably not be emphasized or presented in excessive detail.

Adjusted Analyses

In a randomized trial, the univariate comparison of treatment groups is a simple and valid summary. However, many investigators attempt to show that the treatment effect is not due to any measured confounders by using adjusted analyses. The best style of reporting multivariate analyses is the same or similar to that for univariate effects. However, the adjusted analyses reported are usually selected from a larger set of less informative or preliminary results. As an example, consider a life table regression model attempting to predict time to cancer recurrence. The "best" (most predictive but parsimonious) model might be built using a step-down procedure from a large set of potential prognostic factors. Each step in the analysis need not be reported, but the final model is a major objective of the analysis.

For multiple regression analyses, investigators usually report adjusted estimates of treatment effects, confidence intervals, and *P* values. Not all prognostic factors retained in multiple regression models must be "statistically significant." It is often useful to keep nonsignificant effects in a multiple regression model to demonstrate convincingly that the treatment effect persists in their presence.

Negative Findings

When no statistically significant treatment effect or difference is found, the power of the study is sometimes called into question. However, the absence of a significant difference is not the same as evidence of no effect. Because clinical effects are measured by risk

ratios rather than *P* values, the preceding guidelines emphasizing estimated treatment differences rather than hypothesis tests are important. Helpful advice regarding negative clinical trials is provided by Detsky and Sackett.[64,65] Power calculations performed after the study is completed are rarely, if ever, helpful.

Effect of Patient Exclusions

Although we have emphasized the value of the intent-to-treat principle and related analyses, in practice, many exploratory analyses will be done. Investigators should report any differences between intention-to-treat analyses and eligible patient analyses. If subset analyses are performed, discrepancies between these and the major analyses of the clinical trial should be reported.

What Is Significant?

The *P* value should not be the only criterion for "significance." Results with strong biologic or clinical justification and *P* values near 0.05 are "statistically significant." When biologic justification is strong, effect estimates are large, and confidence intervals or *P* values indicate significance near conventional levels, it seems appropriate to label these results as "statistically significant." Conversely, results with no biologic or clinical justification or those which seem paradoxical should be reported and interpreted with caution, even when *P* values are smaller than 0.05. There is no way to separate type I errors from truly significant results, except to rely on additional evidence and biologic rationale. It is wise to report cautiously results that seem not to make sense.

Exploratory Analyses

Exploratory or hypothesis-generating analyses should be only informally reported. They should not be emphasized as the primary findings of a clinical trial unless supported by the design and a priori hypothesis.

BIOINFORMATICS AND CLINICAL TRIALS

Bioinformatics, a yet developing field, focuses on the interaction between computer science and biology. Medical informatics, an established field, focuses on the interaction between computer science and clinical medicine. Although these are separate fields, the emerging need to correlate genotypic with phenotypic information has created a need to bring both disciplines together to support genomic medicine. The large amounts of genetic, genomic, and proteomic data offer opportunities for new research targets, with novel therapies for established diseases being developed. These innovative approaches, however, cannot be sustained without effectively dealing with the vast amounts of data generated in the laboratory. Equally important is the integration of clinical data generated by medical records with genomic information. Biomedical informatics is an emerging discipline that aims to create a common conceptual information space in which to further the discovery of novel diagnostic and therapeutic methods in support of genomic medicine.

Genomic technologies will revolutionize drug discovery and development; that much is universally agreed upon. The high dimension of data from such technologies has challenged available data-analytic methods; that much is apparent. Researchers have been hard at work marrying the latest technologies with drug design to more closely examine whether a drug is having any biologic impact (clinical trial), what the effect is (measure of endpoint), when it stops working (onset of resistance), and what can be done about it (alternate therapies). Gene therapy, cancer-killing viruses, and new drugs highlight a few of the novel approaches to cancer treatment. The emergence of promising new molecular targeted agents and new technologies for screening and early detection through the application of bioinformatics has prompted new opportunities in biostatistics for clinical trial designs and analysis that integrate therapy and prevention endpoints.

Cancer has long been understood to be a genetic disorder, and the growing sophistication of genetic resources and tools are contributing greatly to the fight against it. Well before the Human Genome Project, classic cytogenetics revealed gross deletions, amplifications, and rearrangements in cancer cells, which changes can now be analyzed at base-pair resolution with technologies including single-nucleotide polymorphisms and comparative genomic hybridization-based genomic arrays. Expression studies that were done one gene at a time are now conducted across the entire transcriptome with 1.5 million feature expression arrays, and can be used to evaluate the changes wrought by epigenetic therapeutics such as histone deacetylases. Genes that are involved in cancer and carcinogenesis include tumor suppressor genes and oncogenes, often found in regions that are respectively deleted or amplified. All are important to our understanding of cancers, and many may be targets for prevention or cure. A therapy target is a gene whose expression can be changed by treatment. Tumor suppressor genes make good targets as some that have been turned off by epigenetic silencing can be turned on with treatment.

All of these advances provide a wealth of data and potential therapeutic targets that will require evaluation through clinical trials; this, in turn, has prompted a re-evaluation of set standards and procedures, such as those discussed in this chapter. What is needed is not so much ways to analyze expression per se but rather effective ways to channel the new technologies' flows of copy-number (deletion and amplification regions) and expression (treated/untreated fold-change) data into a manageable stream of candidate treatments and genes, and at the same time, new methods to appropriately evaluate the treatments' outcomes for the targets they are intended. In this section we highlight two previously discussed basic concepts, endpoint definition and monitoring, within the context of the impact of the genomics era on them and in particular, cancer vaccines as they represent a premier example of the translation of genomic information from bench to bedside.

DESIGN

Conventional oncology drug development paradigm is to investigate four phases, discussed previously in this chapter: phase I to determine safety and dose, phase II to evaluate effectiveness and look for side effects, phase III to verify effectiveness, and phase IV for postmarketing surveillance. With cancer vaccines, for several reasons, there is no clear delineation of such phases, calling for the development of a different paradigm. First, there are typically little to no serious toxicity risks and no proof for a linear dose-response relationship and thus no need for conventional dose escalation to establish the maximum tolerable dose. Dose and schedule are not determined through escalation based on toxicity. Cancer vaccines are not metabolized, and thus, there is no need for conventional pharmacokinetics. Many cancer vaccines are designed to address one tumor type, and thus, there is no need for mixed tumor trials for target selection. Conventional short-term response criteria (e.g., response criteria in solid tumors, RECIST) are not efficiently applicable to cancer vaccines (discussed in detail later), and historical control comparisons on response rate are not useful, because proof-of-principle endpoints should reflect biologic activity, including immunogenicity. There have been discussion and working groups formed to instead propose the development of a proof-of-principle trial followed by an efficacy trial, with proposed endpoints based on evidence of "signal of activity" of the vaccine.

Clinical Endpoint

In general, an endpoint is a measure to determine whether a therapy is working or not. In cancer vaccines the general goal is to develop a therapy that targets cancer cells, and thus, an examination of tumor response (as opposed to patient response) to therapy seems quite

reasonable. Unlike other vaccines and passive therapeutic modalities (e.g., chemotherapeutic agents and radiation therapy), targeted therapies, including cancer vaccines and other immuno-based treatments, initiate a dynamic process of activating the host's (patient's) own immune system; as such, there is potential for patient response to the therapy under consideration, as well as postvaccination therapies.

Ongoing therapeutic cancer vaccine trials have yet to show evidence of vaccines initiating a patient's immune system to shrink tumors, yet patients who receive these vaccines tend to live longer and respond better to subsequent treatment, prompting a question of whether we are looking at cancer vaccine trials the wrong way. Are we appropriately measuring "response to therapy"? To address this question, it is important to understand the process underlying therapeutic cancer vaccines.

Unlike preventative vaccines, such as those designed to protect against the flu, cancer vaccines are administered to treat an existing condition or disease. Such vaccines fall under one of two general types: (1) cell-based, created using cells from the patient's own immune system that have been activated to the presence of cancer antigens and delivered back to the patient along with additional proteins that facilitate immune activation, or (2) vector-based, wherein an engineered virus (vector) is used to introduce cancer proteins and other molecules to stimulate the immune system. In either case both approaches are designed to mount and prepare the patient's immune system into attacking existing tumor cells.

In their review, Schlom and coworkers[66] examine two cell-based vaccines, Sipuleucel-T (Provenge) and GVAX, in addition to three trials using an engineered pox-virus vector. Although their review article focuses on prostate cancer vaccines, the researchers consider these trials as examples of ongoing progress in similar vaccine therapies for lymphoma, melanoma, pancreatic, lung, and other types of cancer. According to their review of five prostate cancer vaccine trials, Schlom and colleagues[66] offer evidence that patients who receive vaccines may respond better to subsequent chemotherapy or hormone treatment, leading to improved patient survival. However, the endpoints of these trials were not long-term survival but a reduction in tumor size. With this endpoint, such vaccines may be deemed ineffective and abandoned, because the primary endpoint (tumor size reduction) was not achieved, despite their real therapeutic value in prolonging patient survival. The data prompt the rethinking of clinical vaccine trial design and in particular, the current approach to measuring cancer vaccine effectiveness. In this case, it may seem more reasonable to think of the effectiveness of a therapeutic vaccine in terms of the response of the patient, rather than the response of the tumor. Although RECIST standards work well to evaluate therapies that are toxic to tumors, such as radiation therapy or chemotherapy, they are less capable of measuring more subtle systemic effects of immune response. With this in mind, patient response to therapy may be long-term, in which case other markers as surrogates for patient response to a vaccine's "signal of activity" may be considered. In particular, the pursuit of molecular biomarkers and their appropriate use as surrogate endpoints in clinical trials is emerging with advances in cell biology, genetics, microbiology, and other fields.

Surrogate Endpoint

The demand for new and improved biomarkers is a reflection of the emerging drug development due in part to genomic advances that led to a better understanding of the disease processes. One example of such progress in measuring biomarkers to guide therapeutic development is the potential use of human immunodeficiency virus plasma RNA load (viral load) in AIDS. There are many new ways to discover drugs in light of gene target discoveries. The use of molecular targets to design new chemical compounds has provided many new candidates for testing, resulting in a pressing need for more efficient ways to design trials. The identification of highly precise and accurate biomarkers could allow the testing of more candidate drugs, reduce the number of patients required to conduct trials, expand on our capacity to predict adverse events, and potentially improve regulatory decision making. In oncology in particular, we are entering an era of sophistication in making more precise diagnoses and more informed choices about therapy. Biomarkers of immune system function and viral replication, such as CD4 cell counts and human immunodeficiency virus viral load, have helped in the initial evaluation of new AIDS therapies, which have subsequently been demonstrated to extend life and improve its quality.

To understand the link between a biomarker, clinical endpoint, and surrogate endpoint, we must first clarify their definitions. A biomarker (or biologic marker) is a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention. A clinical endpoint is a characteristic that reflects patients' responses (e.g., how they feel, function, or survive). These endpoints are distinct measures of disease characteristics that reflect the effect of a therapeutic intervention. A surrogate endpoint, in brief, is a biomarker intended to substitute for a clinical endpoint. Although all surrogate endpoints are biomarkers, not all biomarkers are surrogate endpoints, and in fact, only a very few biomarkers may be considered for use as surrogate endpoints. For a biomarker to be considered as a surrogate endpoint, it is required to predict clinical benefit based on epidemiologic, therapeutic, pathophysiologic or other scientific evidence. Additionally, the utility of a biomarker as a surrogate endpoint requires demonstration of its accuracy (the correlation of the measure with the clinical endpoint) and precision (the reproducibility of the measure).

One approach to establish the link between a biomarker and clinical endpoint is to estimate the proportion of treatment effect that is accounted for by the surrogate endpoint for which there are several ways to make this determination.[67] Strictly speaking, if a surrogate endpoint is to be valid as a clinical endpoint, the biomarker must be able to account for all of the effects of the intervention on the clinical outcome (endpoint). In practice, however, it may be too much to ask of a single biomarker to fully capture all of a treatment's effect. To this end, the use of multiple biomarkers representing various components of complex disease pathways may yield surrogate endpoints that are more comprehensive in the ability to assess effects of therapeutic interventions.

A timely example of such a need for multiple biomarkers lies in cancer vaccine trials, where "signal of activity" of a vaccine may be defined in terms of three characteristics: clinical response, biologic activity, or immune response. For biologic activity, potential measures may include regulatory T-cell activity or immune response against target cells, or molecular response (MRD). An immune profile may be assessed by sequential samples collected over time points (e.g., baseline, follow-up visits) to assess reproducibility of assay results. As for clinical activity, there is no current mandate to demonstrate clinical activity with conventional oncology endpoints in proof-of-principle trials, and thus, typically no end-stage patients, so a homogeneous population is selected. As for surrogate endpoints in trials with cancer vaccines, molecular response is being considered. Cancer vaccines are expected to work best in MRD populations. Molecular markers that allow uniform assessment of MRD and the impact of a vaccine on the target disease may function as a measure of biologic and/or clinical activity. Some examples include CML, with a well-defined chromosomal abnormality (BCR-ABL) that is detectable by reverse transcriptase–polymerase chain reaction (RT-PCR), and acute myeloid leukemia, wherein multiple heterogeneous chromosomal abnormalities are not present in all patients, requiring an array of markers to determine biologic activity.

Monitoring

To control patients' responses to therapies and maintain proper doses, monitoring is necessary. The advent of the genomics era has

prompted the potential use of molecular endpoints for monitoring patients' responses to therapy. To gain a better perspective on this issue, in this section, we revisit concepts introduced earlier in this chapter for monitoring within the context of CML.

Historically, studies of CML therapies have used cytogenetic responses, the different phases of CML, remission, and even death to monitor treatment response and ascertain treatment efficacy. These endpoints carry the greatest weight in clinical practice, because observed differences in them signify tangible differences in treatment benefit. The effectiveness of molecular targeted therapy, such as tyrosine kinase inhibitors (TKIs) at helping patients with CML to achieve a MRD but not eradicating the disease, has prompted consideration of combination therapies in treating CML. Thus, as therapy for CML improved, the low rate of disease progression has made it impractical to use clinical events as primary endpoints in trials of short duration. On the other hand, the ability to measure the amount (number of transcripts) of the hallmark gene in CML patients, *bcr-abl*, has made it possible to compare expression with received treatment, which is a more sensitive marker for therapies than cytogenetic response, and is able to detect MRD. Almost all CML therapy trials now incorporate this molecular assay as part of monitoring treatment response, yet *bcr-abl* as a marker for some clinical event is not accepted by the US Food and Drug Administration (FDA) for product registration for agents other than TKIs, with no formal guidelines on its use.

Although quantitative PCR testing of *bcr-abl* in patients with CML has become the predominant molecular monitoring technique for CML therapy, with correlations established with the probability of relapse, it is regarded as a risky endpoint from a regulatory perspective, with no absolute guidelines for monitoring. The difficulty with using changes in *bcr-abl* transcripts as a marker to evaluate treatment response is that the assay itself has issues of lower detection limits and large variability. These issues are particularly seen in CML patients with MRD, an ever-increasing patient pool, due to the effectiveness of TKIs. Devising a monitoring strategy for CML patients is thus a challenge ideally suited for a comprehensive statistical approach, requiring the development of models fully informed by current biomedical knowledge, efficient inference that extracts maximal information, and a design that combines the population with individual data.

A marker endpoint is considered a good surrogate for a clinical endpoint if treatment effects on the marker reliably predict treatment effects on the clinical endpoint. For this condition to hold, the marker (1) must be correlated with the clinical outcome and (2) must fully capture the effect of the treatment on the clinical endpoint.

Whereas most candidate markers typically adhere to the first condition, the second is more stringent, resulting in many markers as partial mediators of treatment response. Data now exist to support the importance of achieving molecular milestones when treating patients with TKIs. Newly diagnosed CML patients treated with the particular TKI, Gleevec, who achieved a 3 log reduction in *bcr-abl* transcripts at 12 months following its initiation, have been shown to improve in their progression-free survival as compared with patients who did not reach a 3 log decrease. This and related observations have led many investigators to use endpoints based on *bcr-abl* testing, although their surrogacy for a clinical endpoint has not been fully examined and validated. Within the context of understanding the significance of improving on Gleevec's clinical success with new combinations, there are two critical issues that must be broached. The first is the determination of whether additional reductions in PCR levels are of clinical importance (e.g., is a 3 log reduction as informative as a 4 log reduction or undetectable values?) and to translate such reductions into additional progression-free survival. The second requires ongoing modifications and enhancements of the molecular assay measuring *bcr-abl*. Disease burden measures at or near the assay's limit of detection seem to have large sample-to-sample variability. A criterion of "undetectable" as an endpoint can be confounded by sample handling, because undetectable values can be due to low-quality RNA or poor RNA yield and further, the limit of detection is sample- and run-specific.

The ability of a trial to answer the posed clinical question depends on whether the marker endpoint is indeed a surrogate for the clinical outcome of interest. There is a clear need for guidelines on the use of *bcr-abl* transcript changes as a molecular endpoint to monitor and assess treatment response. Molecular techniques will play a large role in monitoring the progress of CML and in reassessing therapeutic strategies. Many groups are at work to create standards that can be used to cross-validate results from individual laboratories, with their focus on creating a standardized assay that is universally accepted and used. Alternative strategies have been to create a series of statistical models whose results will be used to devise a monitoring strategy for implementation to achieve standardization of results. The potential use of molecular endpoints for monitoring of patients' response to therapy will have tremendous impact, especially with the advent of new efficient drugs and combination therapies, because results from clinical trials will be obtained faster than with a clinical endpoint, and in turn, clinicians will be able to adapt the new treatment faster.

Future Directions

The advances made in cancer biology have provided us with a better fundamental understanding of cancer but with yet slow progress in translating such knowledge into medical practice. As a result, the American Association for Cancer Research (AACR) together with the FDA and National Cancer Institute (NCI) have formed the AACR-FDA-NCI cancer biomarkers collaborative to facilitate the use of valid biomarkers in clinical trials and ultimately in evidence-based oncology and cancer medicine. Research is under way to find new ways of exploring the use of biomarkers in cancer detection and treatment that will, in turn, require a new generation of clinical trials that modernize the processes and methods used to evaluate safety and efficacy for evaluation of novel, gene-based therapies without sacrificing high standards.

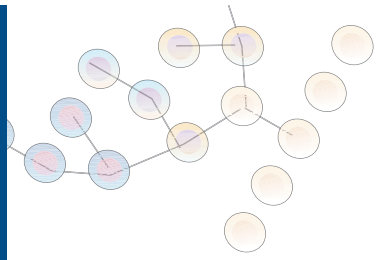
SUMMARY AND CONCLUSIONS

In developing new cancer treatments, investigators are often interested in treatment effects and differences that are about the same size as the variability or the bias that is a part of all clinical studies. The only solution for making valid inferences in the face of these potential errors is to properly design, conduct, and analyze clinical trials. There are a small number of important design considerations to help control bias and random errors including the use of randomization, blinding, stratification, minimizing postentry exclusions, adequate sample size, and planned interim monitoring.

Clinical trials have limitations, partly because of the rigor required to implement them. Investigators contemplating the use of these important scientific tools should focus most efforts on the design aspects of the study and concern themselves little with analysis. This is because most of the serious errors that can be made when performing clinical trials can be prevented or minimized by correct design. In this regard, consultation with an experienced clinical trial methodologist early in the design stage of an investigation will be of enormous benefit.

When analyzing and reporting the results of clinical trials, investigators should follow a simple approach. The purpose of a trial is to estimate an effect or treatment difference, which if present would have clinical utility when treating new patients. Procedures or methods that do not facilitate estimating and reporting the treatment effect with precision and without bias are likely to mislead investiga-

tors. Often in clinical trials, investigators are interested in estimates of odds or hazard ratios between treatment groups.



These ideas suggest that the most useful results from clinical trials will be estimated risk ratios and their confidence limits. Especially in oncology studies, where disease progression, recurrence, and death are of interest, estimates of risk difference are very relevant. Hypothesis tests and associated *P* values, though often (or exclusively) reported, are of lesser utility because they do not fully summarize the data. These recommendations are similar to those in many journals.

Despite some technical disagreement among statisticians regarding the need for adjusted analyses for imbalanced prognostic factors, we believe that it is wise to see if treatment effects change after accounting for imbalances. When this occurs, it seems likely that it will be of clinical interest. Although we discourage analyses that exclude any patients who meet the eligibility criteria, some circumstances will require that this be done (e.g., when a patient refuses to participate after randomization). Investigators should report, and emphasize as primary, those analyses that include all eligible patients.

23 Structures Supporting Cancer Clinical Trials

Jeffrey S. Abrams, Michaele Christian, and James H. Doroshow

SUMMARY OF KEY POINTS

- Cancer clinical trials provide the evidence on which sound oncology practice is based.
- Fewer than 5% of adult cancer patients participate in cancer clinical trials.
- Providing greater access to clinical trials has been a major goal of the National Cancer Institute, cancer centers, and patient advocacy groups.
- There are now many opportunities for physicians in private practice to participate in clinical trials sponsored by the National Cancer Institute and/or the biopharmaceutical industry.
- Successful participation in clinical trials includes the following clinical components:
  - The attitude and commitment of the physician
  - Sufficient preparation and infrastructure
  - Trained staff, including at least some of the following:
    Clinical research nurse
    Clinical research associate
    Pharmacist
  - Affiliation with an institution or network that provides the protocol and scientific and administrative support, such as the following:
    Cooperative group
    Cancer Trials Support Unit
    Cancer center network
    Biopharmaceutical industry network
    Research institution
  - Access to an authorized Institutional Review Board
  - Access to adequate laboratory facilities to process protocol-required specimens
  - Adherence to good clinical practices
  - Accurate and timely data reporting
  - Proper maintenance of primary source documentation
  - Adequate preparation for on-site audits
  - Adequate extramural financial support
- Many organizations now provide access to clinical trials and/or provide the necessary training and certification; relevant Web sites are included in this chapter.

INTRODUCTION

Modern oncology practice is founded on results from thousands of clinical trials conducted over the last four decades; thousands more clinical trials are ongoing at any given time and provide the evidence base for the rapidly changing therapeutic practices of this specialty. Motivations for the decision by an oncologist to participate actively in this extensive system of medical and scientific inquiry range from the ability to offer patients state-of-the-art treatments available through well-designed clinical trials, to the personal satisfaction and benefits that can be achieved from participation in this process. The commitment of time and resources necessary to participate effectively in such clinical research, and sometimes the unfamiliarity with clinical research requirements and procedures, prevent many oncologists from taking part. It has been estimated that only 3% to 5% of adult cancer patients in the United States are treated while taking part in clinical trials, with even lower rates of participation in many other countries. The lack of patient participation has been due, in part, to inadequate understanding of the clinical trials process. Fortunately, owing to intense publicity and educational programs by both patient advocacy groups and clinical trials organizations and widespread access to clinical trials information on the Internet, a growing number of patients now expect that available clinical trials will be included in the discussion of options for the treatment of their cancers. The purpose of this chapter is to describe some of the requirements, resources, and structures that are available to enable practicing oncologists to participate in clinical trials and to discuss the responsibilities that come with such participation. Numerous opportunities now exist for practicing physicians and their patients to participate in cancer clinical trials, including treatment, prevention, and cancer control trials, whether conducted by the National Cancer Institute (NCI), cancer treatment institutions, or the biopharmaceutical industry. Widespread access to the Internet has revolutionized communication and made it possible to provide regulatory information, educational and training materials, data forms, and documents online. A wide array of resources is now available to assist physicians and their staffs in placing their patients on clinical trials.

NATIONAL CANCER INSTITUTE–SPONSORED CLINICAL TRIALS ACTIVITIES

The NCI supports the development of over 100 agents (many in collaboration with pharmaceutical and biotechnology companies) and has an extensive clinical trials system that encompasses treatment, prevention, and cancer control studies. More than 800 trials are active at any given time, and several hundred new trials open each year. In the treatment area, the NCI has programs for early therapeutics development (primarily phase I and II trials), including many sites with grants and contracts to complete these early trials. The NCI also supports a large program of Clinical Trials Cooperative Groups that conduct later-phase trials, predominantly pilot studies and phase III trials. Phase III trials are conducted nationally, and participation in them is now possible even for oncology physicians who are not Cooperative Group members. Clinical Trials Cooperative Groups funded by the NCI (Box 23-1) provide a standing mechanism for performing large-scale multicenter treatment and prevention trials.

Over the years, this system has supported an experienced cadre of clinical researchers, biostatisticians, and research support staff who can respond to new clinical discoveries by organizing definitive phase III clinical trials. Because of their size and complexity, these trials require extensive infrastructure support to manage the necessary regulatory and data-reporting tasks. Although these Cooperative Group trials have provided a significant proportion of the evidence on which oncology practice is based, public advocacy for more rapid progress, increasing fiscal pressures on medical practice, and the accelerated pace of drug discovery caused the NCI to review and restructure aspects of its clinical trials program in 1998 and again in 2005. The major goals of these restructuring efforts were to increase access to NCI trials for patients and their physicians; to eliminate barriers to participation in clinical trials; to improve the coordination and cooperation among the functionally diverse elements of the NCI's clinical trials program, including relationships with industry and the U.S. Food and Drug Administration; to improve the prioritization process for developing clinical trials leading to increased scientific quality; to enhance the standardization of tools for clinical trial design and data capture; and to increase operational efficiency so that trials could be executed in a more timely manner.

From the mid-1980s to the mid-1990s, accrual to Cooperative Group treatment trials reached a plateau at about 20,000 patients annually. Whereas the pediatric groups consistently enrolled about 70% of all cancer patients, the adult groups were able to accrue only fewer than 2% of all cases. Phase III trials in the adult groups took an average of 4.5 years to enroll patients and an additional 3 to 4 years of follow-up before a result was known. This approximately 8-year cycle before potential treatment advances could be confirmed was clearly too long. It therefore became imperative to enable more rapid accrual to clinical trials.

Surveys among physicians and the public found that the obstacles to accrual in adult oncology were multifactorial (Table 23-1).[1–5] With these barriers in mind, the NCI undertook the extensive review of the clinical trials system noted previously, involving a wide range of stakeholders that included Cooperative Group and Cancer Center leaders, patient advocates, representatives from the FDA and the pharmaceutical industry, and government staff. The detailed reports of these reviews are available online from the 1998 review (http://ctep.cancer.gov/forms/ArmitageReport.pdf) and from the 2005 review (http://integratedtrials.nci.gov/ict/ctwg_report_June2005.pdf from 2005). Several pilot projects were developed from the 1998 restructuring effort that were aimed at modernizing the clinical trials regulatory and data collection systems, opening access to trials to more patients and investigators, and simplifying the role of local institutional review boards in multi-institutional clinical trials. New opportunities were created for community physicians to participate in a broad array of clinical trials, and new tools were created to enable this. Two major initiatives, the Cancer Trials Support Unit and the Central Institutional Review Board, are now integral parts of NCI's clinical trials system and are described next.[6]

Table 23-1 Barriers to Clinical Trial Participation

Physician Related	Patient Related
• Inadequate funding for data management personnel	• Doctor never discussed or offered
• Burdensome regulatory requirements	• Unaware of trials as option
Institutional Review Board	• Concerns about insurance coverage
Informed consent	• Fear of receiving placebo
Conflict of interest	
• Inadequate reimbursement	
• Lack of time	
• Resistance by third-party payers	

Cancer Trials Support Unit

The Cancer Trials Support Unit (CTSU) is designed to facilitate one-stop online access to a broad menu of predominantly phase III trials by a national network of NCI investigators. The network investigators include not only members of Cooperative Groups, but also physicians in practice with no group affiliation. They can access the CTSU menu of treatment trials from the public Web site (www.ctsu.org). The menu consists primarily of Cooperative Group phase III trials, although selected internationally led phase III trials, Cooperative Group phase II trials, and some trials led by U.S. cancer centers are also available. The scientific leadership for each study remains within the organization that developed the trial, but patient enrollment can come from any network physician across the country. By providing more physicians and their patients the opportunity to choose from a broader menu of trials, the CTSU promotes faster accrual to individual trials, allows increased access and broader treatment options to more patients nationwide, and renders trials involving uncommon cancers more feasible. Although the clinical trials menu is the most visible aspect of the CTSU, another major function of the CTSU is its centralized regulatory database. For all Cooperative Group members and nonmember physicians in the network, the CTSU maintains important demographic information about their sites or practices, including Cooperative Group(s) and academic/practice affiliation(s), Office for Human Research Protection assurance numbers for their sites, Institutional Review Board (IRB) approvals for specific protocols, and conflict of interest forms for investigators. This enables physicians, nurses, and clinical research associates to register once annually instead of having to register for each group or trial in which they participate. Initiated in 2002, the Regulatory Support System requires that investigators complete a 1572 investigational drug form once yearly, along with a supplemental information form and a conflict of interest form.[7] Nurses and clinical research associates who participate in group trials also register once annually online (registration is available at https://iapps-ctep.nci.nih. gov/ctepar/main.htmlfiReset). Information from this registration database is accessible to all Cooperative Groups, as the CTSU Web-based system is shared and maintained in a coordinated manner with all the Cooperative Group operations offices. Centralizing regulatory data has reduced the workload for investigators in the field,

consolidated duplicative work, and allowed Cooperative Group staff to partially offload this activity to the CTSU and focus instead on protocol development and analysis.

Cancer Trial Support Unit Trial Services

The CTSU maintains a public Web site that provides patients with information about all the clinical trials on the menu.

The widespread availability of Internet access in physicians' offices has made it possible for the CTSU to make the necessary documents, forms, and tools readily available. For physicians and their staffs, a password-protected members site contains the information that is needed to enroll a patient in one of the trials on the menu. Online access is provided to the protocol, case report forms, adverse event reporting forms, NCI pharmacy forms, site registration documents, patient enrollment documents, and education and training materials. Informed consent documents with Spanish translations are also available. In addition, detailed IRB application packets can be downloaded so that the process of obtaining local IRB approval is much less time consuming.

Regardless of which organization is leading a protocol on the CTSU menu, the CTSU manages site registration, protocol eligibility checks, and treatment randomization, obviating the need to interact with multiple different Cooperative Groups to treat patients on a variety of different protocols. Local site registrars can verify online that their site has successfully completed all the registration requirements for a specific protocol. In addition to the documents that are needed to conduct the study, the CTSU provides abstracted Time and Events Calendars and Protocol Schemas to assist medical staff with protocol adherence, a PowerPoint slide presentation to help physicians promote the trial, and patient education materials that provide information about both clinical trials in general and the specific trial under consideration. Physicians can also obtain quarterly accrual reports by study and by site and can order copies of investigator brochures when trials involve experimental drugs.

Data collection has been standardized on CTSU trials across all different Cooperative Groups and across diseases, to the extent possible, to facilitate ease of reporting, data sharing, and exchange. This has been possible because of the development of Common Data Elements (CDEs) through a project that NCI began several years ago in collaboration with the Cooperative Groups. For each disease, there now exists a set of commonly defined terms and values that are used to report information in a uniform manner. CDEs have now been developed for all the diseases that are treated in phase III studies by the adult groups and are currently being developed for pediatric and phase I and II trials. Currently, data collection is done by using paper case report forms. However, following an extensive evaluation, an electronic remote data capture system that will help to standardize the entire NCI Cooperative Group clinical trials system is on the verge of adoption. This effort, performed in conjunction with the larger NCI-wide bioinformatics initiative (caBIG, the cancer bioinformatics grid), will help to standardize clinical trials reporting not only for the Cooperative Groups but for all clinical trials supported by the NCI. The common CDE vocabulary system has also made rapid development of electronic case report forms more feasible. With the increasing availability of electronic data reporting for group trials, speed and data accuracy should improve owing to real-time data queries, thereby reducing time-consuming follow-up queries that currently arise weeks to months later when patient information is less readily retrievable.

The CTSU also manages two additional tasks: auditing and research reimbursement. Trials performed via the CTSU are audited in a fashion similar to other Cooperative Group trials (see the section entitled "Quality Assurance and Audits") to verify data accuracy and quality by comparing the primary record with the research forms that the site submits. Given that sites may now participate in trials led by multiple groups, the CTSU patient charts are simply added to a scheduled audit when a group is visiting a member site, to avoid burdening sites with multiple Cooperative Group audits. Depending on the number of CTSU accruals at a site, the audit team is sometimes supplemented with members from other groups or CTSU staff to ensure sufficient expertise. Similarly, the CTSU has used existing contractual relationships between groups and their members to forward payments to group members who have participated in trials via the CTSU. Physicians who are not group members are supported via direct contracts and are paid by the CTSU directly.

Cancer Trial Support Unit and Cooperative Group Interactions

The introduction of the CTSU was the first major structural change to NCI's multicenter trials system since its inception more than 50 years ago. The CTSU has assumed a major role as a support structure that complements the work of the Cooperative Groups. The CTSU is not a scientific structure and does not develop or analyze the studies that it supports. Rather, all the data that it receives are passed on to the group that is leading the trial for analysis. By reducing the duplicative administrative work that was traditionally done at each Group Operations Office and by offering more clinical trials to each group member, the CTSU allows the groups to focus on their prime missions: developing important clinical trial questions and analyzing these trials rigorously.

CENTRAL INSTITUTIONAL REVIEW BOARD

Background

In NCI-sponsored multicenter trials, the identical protocol is carried out at many sites, averaging about 100; each site requires its own local institutional review board (LIRB) to conduct an initial full-board review and subsequent annual reviews, adverse event reviews, and amendment reviews. These multiple IRB reviews create a largely redundant, time-consuming workload at these sites, compounding the ever-mounting pressures on the nation's IRB system, which have been well documented.[8] To provide an idea of the scope of the duplicative effort that occurs, consider that NCI has more than 8000 registered investigators at more than 1500 sites. On average, there are 160 ongoing phase III trials and 30 new trials entering the NCI system annually, resulting in approximately 16,000 IRB reviews (3000 initial reviews) conducted each year.[9] In addition, investigators often mention that the amount of time, paperwork, and (more recently) funding required of them to obtain IRB approval is a serious barrier to opening trials. These factors provided the impetus for the NCI to develop a new, centralized approach to human subjects protection for its large, phase III trials program.

Customarily, central institutional review boards (CIRB) models were instituted when LIRBs were lacking. In these cases, for-profit central IRBs contract their services to institutions without IRBs and maintain close contact with the sites by sending staff for frequent visits, thereby fulfilling the Office for Human Research Protection requirement that the IRB of record have knowledge of the local context. By contrast, LIRBs exist throughout the NCI system, and this fact led NCI to use a model in which responsibility is shared between the CIRB and LIRB. The CIRB provides the initial full-board review and then transmits its decision and detailed minutes of the meeting to the LIRB participants via a confidential Web site. These sites have the option to perform a facilitated review, whereby a LIRB chair (or a designated subcommittee) can review the CIRB documents rapidly, determine whether or not there are local issues that should be addressed, and then expeditiously approve the protocol, without the need for a full-board review at the local level. If facilitated review is accepted by the local site, then the CIRB becomes the IRB of record for that protocol. This means that the CIRB will perform the continuing annual reviews, adverse event reviews from

all sites participating in the trial, and the amendment reviews. This process relieves the LIRB of the burden of review for these multicenter trials, but the LIRB still has the responsibility to review adverse events that occur at the local site (but can now view them in the context of the overall adverse event review provided by the CIRB). The LIRB also retains responsibility for the medical and ethical conduct of the investigators and their staffs at their institution. To formalize this division of responsibility, a written agreement is signed by the LIRB when it joins the CIRB Initiative (available at http://www.ncicirb.org).

NCI's CIRB is composed of a distinguished panel of oncology physicians, nurses, and patient representatives and includes a pharmacist, an ethicist, and a lawyer. Recently, a pediatric CIRB was initiated. The two NCI CIRBs review all phase III studies from the Adult Cooperative Groups as well as any phase III trials that have been opened in the CTSU and trials from the Children's Oncology Group. Unlike most LIRBs, the CIRB is focused exclusively on cancer trials and has sufficient time and expertise to review each protocol in detail. In addition, compared with LIRBs, the CIRB by design has more leverage to request changes in the protocol and informed consent, as NCI requires that studies obtain CIRB approval before they can open.

This new model for human subjects protection in multicenter trials is now utilized by over one third of all major NCI-designated Cancer Centers and many other university medical centers. A major goal will be a significant reduction in review workload for LIRBs while preserving their role as the primary overseers of the actual conduct of the research at the local site. Patients and investigators should benefit from the ability to open trials rapidly using this mechanism and from the greater availability of trials that should result.

Clinical Trials Working Group Initiatives

The Clinical Trials Working Group proposed 22 initiatives to improve the NCI's clinical trials system in 2005. Although it is early in the implementation of these recommendations, several activities have already entered into their pilot phase of development. To facilitate coordination of the entire NCI clinical trials enterprise, a new Federal Advisory Committee-approved advisory group reporting to the NCI director, the Clinical Trials Advisory Committee, has been initiated with a specific charge to monitor the implementation of the Clinical Trials Working Group recommendations and to provide oversight for NCI's clinical trials program. This committee has already taken up a review of the funding guidelines for the NCI-supported Cooperative Groups, Cancer Centers, and Specialized Program of Research Excellence program with the goal of providing clear incentives for these major NCI research programs to work harmoniously in the clinical trials arena. To enhance the scientific quality of the clinical trials that are supported by the NCI, the initial disease-specific scientific steering committees called for in this report have been formed. Their function is to coalesce investigators in both translational and clinical science supported by the NCI with community-based clinical trialists and patient advocates to develop a broad consensus around scientifically outstanding clinical trials that are likely to reach their accrual goals in a timely fashion.

To assist in the process of standardizing the clinical trials infrastructure for NCI-supported investigations, the caBIG workspace for clinical trials has been expanded, and the caBIG has begun work on the creation of a comprehensive database of the clinical trials that are funded by all NCI funding mechanisms. A public-private partnership group has also been formed to develop commonly accepted clauses for clinical trial contracts to reduce the lead time that is needed to open studies. Finally, initial studies have been conducted to investigate the major process roadblocks to timely clinical trial initiation.[10] These investigations will undoubtedly lead to additional recommendations to streamline the clinical trials process further.

OTHER NATIONAL CANCER INSTITUTE–SPONSORED STRUCTURES SUPPORTING CLINICAL TRIALS

Although the CTSU, the CIRB, and the national scientific steering committees represent new mechanisms to reduce barriers and facilitate broader clinical trials participation by practicing oncologists, advocates, and translational scientists, a number of other important mechanisms provide additional options for support and participation (Fig. 23-1).

Clinical Trials Cooperative Groups

Physicians who wish to be more actively involved in the intellectual and scientific aspects of clinical trials and who can commit to accruing at least 5 to 10 patients per year to group studies, should seriously consider joining a Cooperative Group. Most groups have an affiliate program that allows community sites to partner or affiliate with a main member who assumes a number of the management and monitoring responsibilities for the affiliate. Procedures for joining can be found on the groups' Web sites (see Box 23-1). Affiliate members attend the semiannual meetings of the groups and are actively involved in the scientific agenda, protocol development, and publications of the group. In addition to intellectual satisfaction, career development, and networking opportunities, members have access to

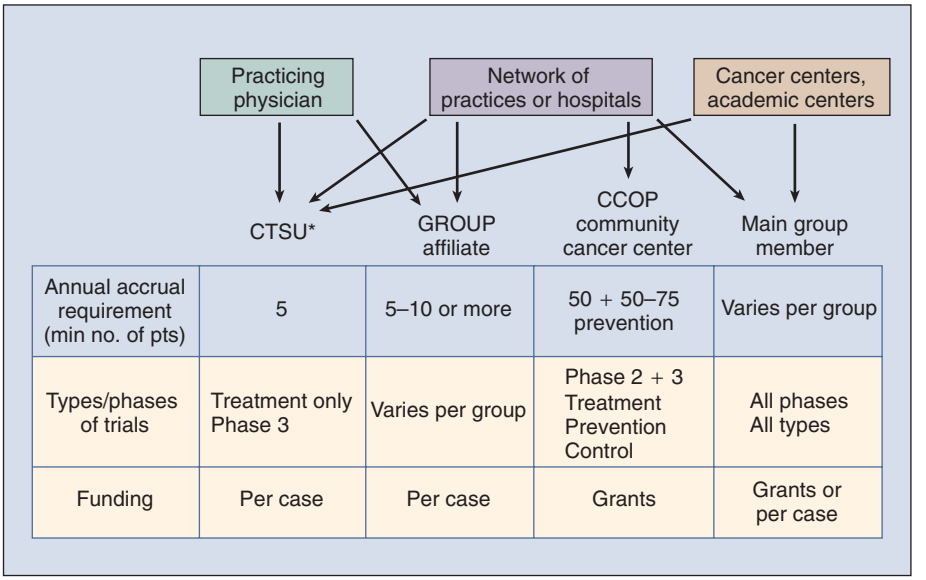

Figure 23-1 • Mechanisms for participating in NCI-sponsored clinical trials. *All members (affiliate, CCOP, main) have access to the CTSU menu of trials regardless of whether or not they are members of the group leading the trial.

a broader array of clinical trials for their patients, including phase I, phase II, and pilot trials that are not available on the CTSU menu and therefore are not accessible to nonmembers. Cooperative Groups also provide training and networking opportunities for research staff, including research nurses and clinical research associates, at group meetings and in other venues.

Community Clinical Oncology Program

For practices or groups or networks of practices that already have research experience and that can commit to enrolling significant numbers of patients in clinical trials, NCI grant funding through the Community Clinical Oncology Program (CCOP) mechanism offers many opportunities. CCOPs must document the ability to enroll 50 patients in cancer treatment studies plus 50 to 75 patients in prevention studies and/or trials focused on symptom management and cancer control. The grants provide important up-front funding to enable sites to hire critical staff from the start to support the substantial patient accrual that is required. In addition, special minority-based CCOPs are funded and provide additional support for groups or networks that serve predominantly minority populations. Minority-based CCOPs strive to increase cancer prevention and control activities in minority and underserved communities in addition to increasing access to clinical trials for minority patients. The CCOP program, funded by the NCI's Division of Cancer Prevention, has been in existence since 1983 and now funds over 50 research sites in 34 states. Details on these programs can be found on the Division of Cancer Prevention's Web site (http://www3.cancer.gov/prevention/ccop/).

Children's Oncology Group

Tremendous strides have been made over the past 50 years in the treatment of childhood cancers, transforming a once-fatal disease of children into a highly curable one. This success has been due in large part to the participation of large numbers of children with cancer in clinical trials. It is estimated that some 70% of children who are diagnosed are entered into clinical trials, and this has been a key factor in the rapid progress that has been made. In March 2000, four NCI-sponsored pediatric groups—the Children's Cancer Group, the Pediatric Oncology Group, the Intergroup Rhabdomyosarcoma Study Group, and the National Wilms' Study Group B—agreed to consolidate their efforts and formed the Children's Oncology Group. The Children's Oncology Group has more than 230 member institutions, which include all major U.S. universities and teaching hospitals, as well as sites in Europe and Australia. Individual practices seeking affiliate membership can receive information at http://www.childrensoncologygroup.org.

National Cancer Institute Cancer Centers Program

NCI-designated Cancer Centers exist in nearly every state and are funded by NCI to support a broad research infrastructure, including the personnel and physical resources to conduct a variety of clinical trials. While serving as tertiary referral centers, the Cancer Centers increasingly have recognized the desirability of forging links with community practitioners. The resultant research networks enable Cancer Centers to complete trials more quickly while providing practitioners and their patients with access to new drugs and techniques at an early stage of their development. These partnerships are flourishing in some areas of the country, and the model is likely to be replicated widely. For more information about Cancer Centers in your area, consult http://www3.cancer.gov/cancercenters.

Phase I and II Early Therapeutics Development Networks

The NCI supports a network of individual academic institutions and academic consortia to support the conduct of phase I and early phase II clinical trials, often performed with pharmacokinetic and correlative pharmacodynamic studies. These institutions enroll approximately 2000 patients per year in clinical trials, often first-in-human studies, that often set the standard for the further investigation of individual new agents or combinations of investigational agents by the Cooperative Groups or by industry. A major feature of this network is the expertise of the investigators and their institutions in blood and tumor sample acquisition, pharmacokinetic assay development and monitoring, and the development of pharmacodynamic assays.

National Community Cancer Centers Program

The NCI has very recently launched a new pilot program, the National Community Cancer Centers Program, to encourage collaboration between private practice medical, surgical, and radiation oncologists and large community hospital systems to explore ways to share information related to cancer care and expand and standardize the collection of blood and tissue specimens for cancer research. The program will also extend other NCI initiatives in the area of clinical trials and reduction of health care disparities. The major goal of this program is to provide access to research-based cancer care to a broader range of hospitals and clinics where most patients are treated.

BIOPHARMACEUTICAL INDUSTRY–SPONSORED CANCER CLINICAL TRIALS

During the first decades of the development of the field of medical oncology, there was relatively little industry participation in cancer therapeutics development. In part, this was a reflection of the complexity of therapeutics development in the field during a period when the lack of a sufficiently detailed understanding of cancer biology prevented a fully rational basis for new drug development. This relative lack of industry involvement, coupled with the significant public health problem presented by cancer, was responsible for the development of the large NCI-sponsored clinical trials apparatus described in detail in this chapter. The past decade, however, has seen a significant increase in biopharmaceutical investment in cancer discovery research and a parallel increase in both the extent and sophistication of industry sponsorship of clinical trials for the development of new cancer therapeutics. Hundreds of new agents are currently in different stages of clinical evaluation by the industry, either alone or in cooperation with the National Cancer Institute or similar organizations in other parts of the world.

Purpose and Nature of Industry-Sponsored Clinical Trials

The primary goal of therapeutic agent investigation by the biopharmaceutical industry is the evaluation of promising agents for eventual registration and commercialization. Because registration of a new cancer drug requires the demonstration of safety and efficacy for the new agent in the context of currently available therapy for the cancer being treated, the spectrum of clinical trials sponsored by industry often overlaps with the range of trials conducted by the Cooperative Groups. Furthermore, there is a long tradition of industry providing investigational agents for the conduct of clinical investigations through NCI-sponsored mechanisms, and there are many examples of new agents or indications that have received FDA approval on the basis of NCI-sponsored clinical trials. Ethical considerations regarding human investigation and expectations regarding adherence to standards for the conduct of clinical trials do not differ between NCI-sponsored and industry-sponsored clinical trials; therefore, the fundamental processes of conducting clinical trials are similar in both cases. Despite these similarities, however, there are some differences between industry trials and those sponsored by NCI.

Particular Characteristics of Industry-Sponsored Trials

Biopharmaceutical development proceeds in a heavily regulated environment, with detailed regulations from various government agencies covering the spectrum of activities ranging from those related to preparing an agent for first entry into humans, through the years of clinical investigation in patients, to postapproval restrictions on public discussion regarding possible uses of the agent for indications other than those for which the drug was approved. As a result of the requirements of working in such an environment, corporate clinical investigations tend to be focused on the "clinical development plan," the specific plan of clinical trials that will produce an appropriate evidentiary base to allow for regulatory review of the safety and efficacy profile of the agent. During the investigational phase of an agent's life cycle, therefore, companies might restrict the general availability of the agent to individual investigators for clinical study. This perceived need for containment and control can lead to tension between the investigative community and the industrial sponsor. Other potential sources of tension in the interaction between companies and investigators relate to the investigators' perceptions of the need for independence and objectivity in the conduct of multicenter trials. Historically, for example, many companies have generated phase III protocols internally, although usually with considerable input from both external advisors and regulatory bodies. The trial would be conducted by company personnel, and authorship would be conferred on the principal investigator of the largest accruing site. Increasingly, a new model is emerging in which a recognized expert is appointed as the principal investigator; this individual has a much greater role in the design, monitoring, and eventual analysis and publication of the trial than might have been the case historically. Similarly, recent years have seen the almost universal adoption of independent Data and Safety Monitoring Committees for late-stage clinical trials to oversee safety-related information as it emerges from the ongoing trial and to make recommendations to company staff about appropriate actions.

Impact of Globalization on Pharmaceutical Development

Pharmaceutical products increasingly are marketed globally, and large multinational pharmaceutical companies, therefore, need to conduct clinical development from a global perspective. Clinical trials with investigational agents with which the FDA is involved are being conducted in over 75 countries. This tendency toward global development has been greatly accelerated by the International Committee on Harmonization process, which facilitated standardization of many of the activities that are involved in preparing agents for clinical investigation, conducting those investigations, and then preparing the information for registration. Now a single set of standards exists for the conduct of industry-sponsored trials worldwide. Attempts are therefore made to harmonize the development process to produce a globally accepted drug registration package to the greatest extent possible.

Models for the Conduct of Industry Clinical Trials

Biopharmaceutical industry sponsors usually produce the investigational agent in their own facilities, as they anticipate eventually being responsible for the commercial production and distribution of the agent. They also can conduct the series of required clinical trials directly using their own clinical trials personnel, which may include internal company physicians, statisticians, monitors, data managers, quality assurance auditors, and the rest of the required infrastructure, such as company standard operating procedures, company information system support, and drug distribution apparatus. Alternatively, drug sponsors may utilize a contract research organization to perform the actual clinical trials. In fact, for large development programs, it is not unusual for large companies to coordinate clinical trials programs using a mixture of both internal and externally acquired resources. Contract research organizations are companies in the business of conducting clinical trials. Over the last decade, following the explosion in growth of biopharmaceutical clinical investigation, a large number of such companies have been created, some capable of conducting global trials. The actual arrangement—direct or indirect—that a drug sponsor uses for a particular clinical trial is important to the investigator and staff at the clinical trial site, because it determines the predominant source of interactions and contact during the actual conduct of the trial.

Different models exist, as well, for investigator participation in clinical trials with industry. Traditionally, pharmaceutical sponsors have dealt either with individual investigators or with individual institutions, as in the case of academic centers. Clinical trial contract budgets have included direct trial-related costs such as performing additional laboratory studies that are not being done as part of usual medical care plus direct site-related costs associated with the time spent on the trial by the various participating staff and indirect costs for institutional overhead. Recent years have seen the emergence of consortia of investigators (sometimes under the rubric of a Site Management Organization) or consortia of institutions presenting themselves to companies as clinical trial entities, often linked by a single central IRB and often offering the advantage of working under a single negotiated contract. In addition, individual academic centers sometimes have formed networks of oncologists within their referral area for the purpose of presenting themselves as more efficient entities for interaction. New models continue to evolve. These new models make it easier for companies to engage the several hundred sites that are required to conduct major phase III registration-directed trials in a much more efficient manner.

Good Clinical Practice and Other Issues

One area of drug development that has been the focus of International Committee on Harmonization activities is the development of good clinical practice guidelines for the conduct of clinical trials. Good clinical practice describes international ethical and scientific quality standards for designing, conducting, recording, and reporting trials that involve the participation of human subjects. The very useful and informative document "ICH E6 Consolidated Guidance for Good Clinical Practice for Industry" (available at http://www.fda.gov/cder/guidance/index.htm) represents a summary of good clinical practice guidance for the generation of clinical trial data that are intended for submission to regulatory authorities. This document comprehensively summarizes the responsibilities of IRBs, investigators, and sponsors, as well as issues regarding the clinical protocol, investigator's brochure, and the documents that are essential in the conduct of a trial. Although investigators participating in an industry-sponsored clinical trial can expect help in the preparation of the required documents, it is important that they understand their responsibilities both to their patients and to the industry sponsor within the context of a global registration program.

Recent concerns regarding investigator conflict of interest in new drug development have led many institutions to develop policies regarding the extent of financial involvement by investigators in companies sponsoring trials in which the investigators are participating. Industry sponsors have also developed conflict-of-interest policies. In addition, as part of drug approval submissions in the United States, companies must now provide financial disclosure statements from individual investigators who are participating in the registration-directed trials.

Changing Nature of Oncology Trials: Impact on Infrastructure

The same explosion in understanding cancer biology that has led to the increase in the number of new agents under development brings with it a realization that the most appropriate tests of those biologi-

cally targeted agents are clinical trials in which the patients who participate have tumors that are biologically appropriate for the agent. For example, imatinib administered to all newly diagnosed patients with any form of leukemia would have a response rate much lower than that in the biologically appropriate group of newly diagnosed patients with chronic myelogenous leukemia; selection of patients with chronic myelogenous leukemia allows for a focused development program leading to rapid initial registration. The same considerations can logically be extended to matching any biologically directed agent with any cancer patient population and argues strongly for more complete biologic characterization and continued monitoring of patients entering cancer clinical trials. Regardless of whether such characterization is prospective or retrospective in clinical trial design and analysis, it can be expected that the increased need for collection of peripheral blood for germline DNA studies; plasma for proteomics studies; fresh tumor tissue for DNA, RNA, and/or protein studies; and tumor tissue blocks for DNA or immunohistochemical studies or for specialized imaging studies will all place new demands on the infrastructure that is required to conduct trials. These requirements will also introduce new challenges for quality control on sample collection and storage and will increase the resource requirements for trials. It is also likely, however, that such clinical trials will become much more informative. The potential exists in the future for smaller, more definitive trials in more biologically homogeneous groups of patients than is possible with the classic histopathology that is currently used to characterize patients; this potential should lead to more effective and well-tailored treatments.

Challenges to the Conduct of Industry Oncology Clinical Trials

Numerous challenges exist both to the oncologist who wants to participate in the clinical trials process and to the corporate sponsor that wishes to conduct such registration-directed trials. From the individual oncologist's perspective, the bureaucratic hurdles that are associated with the clinical trials administration process can appear daunting, particularly when added to the responsibilities of using investigational agents in patients. Acquiring sufficient trained personnel to conduct such trials is a challenge. Unless participation in a particular trial is part of a broader commitment to the clinical trials process with supportive infrastructure in place and experience in the conduct of several simultaneous ongoing trials, successful participation is unlikely. For these reasons, oncologists who are already participating in Cooperative Group trials through one or another mechanism already have in place some of the required infrastructure for the local conduct of industry-sponsored clinical trials. The corporate sponsors of oncology drugs that are undergoing development face their own challenges and uncertainties. Cancer drug development traditionally has been a high-risk field. Many agents fail in late-stage development, a time when significant time and resources have already been expended. Although it is hoped that the kind of increased linkage of biologic study with therapeutics development will eventually make this whole process more predictable, the development of new cancer drugs remains an expensive and high-risk activity. Development is carried out through a clinical trials process that remains highly inefficient and lacking in standardized information collection, systems, and processes and without many biological markers to aid in decision making early enough in the clinical trials process to decrease risks in development. Continued improvements in efficiency and productivity of the clinical trials system remain a high priority in order to accelerate the delivery of effective new agents to patients.

EXPECTATIONS OF CLINICAL RESEARCH SITES

Staffing is foremost among the critical components for an effective research practice listed in Box 23-2. The number and precise composition of the necessary staff depend on the number of patients who are enrolled in clinical trials and the nature of the practice. In some settings, in which the number of patients in studies is small, one good research nurse can perform many of the required functions. At more active sites, research nurses, clinical research associates, and research pharmacists perform separate functions. For budgeting purposes, for example, it is often estimated that one full-time clinical research associate can handle 25 new patients and up to 50 patients in follow-up in a year. Some of the structures that support clinical trials participation, such as the CCOP program, provide substantial up-front funding to support salaries for the necessary staff in return for a commitment to substantial accrual. Many others, including the CTSU and the Cooperative Groups, provide a small amount of funding when each patient is accrued. The latter approach allows sites to introduce clinical research into their practices at a more gradual pace.

Box 23-2. COMPONENTS OF AN EFFECTIVE RESEARCH PRACTICE

- The presence of committed physicians who are willing to devote the time and energy necessary to conduct clinical research and to accept conscientiously the significant responsibility inherent in the conduct of human research.
- The availability of suitably trained staff (preferably an experienced research nurse) with enough time to assist in screening patients for protocol eligibility and for following patients on protocol treatment.
- The availability of suitable staff to administer the required treatments in the protocol-prescribed manner; increasingly, this might include administration of a wide range of potential therapeutics including, but not limited to, more conventional intravenous chemotherapy and, in some cases, radiation.
- Adequate and committed pharmacy capabilities to handle and account for investigational agents if these are part of the protocol treatment.
- Adequate data management staff to handle the data-reporting requirements for patients who are being treated on protocols.
- Access to an Institutional Review Board (IRB) with Office for Human Research Protections assurances to approve the protocol and monitor the progress of the research.
- Access to suitable laboratory facilities to complete the studies that the protocol requires.
- Willingness to comply with certain federal regulatory requirements, including adequate privacy procedures and training in human subjects protection (available as an online course through NIH at http://cme.cancer.gov/c01/).

Quality Assurance and Audits

Because the accuracy of the data that are collected on clinical trials is critical to the validity of the conclusions from the trials, all clinical trials organizations include quality assurance and audit programs. Although these are structured somewhat differently depending on the mechanism of participation (industry conducting the most frequent and extensive audits), all such programs have certain features in common. All send queries to the site when discrepancies or suspected errors are noted in submitted information, and all compare data that are submitted from the sites to the primary medical or research record for verification at on-site audits. NCI audits are typically conducted every 3 years and review a sample of patients enrolled on a variety of protocols. In addition to verifying data accuracy and protocol adherence, informed consents are reviewed, as are adverse event reporting compliance, pharmacy practices, and timeliness of required

IRB submissions and approvals. Preparation for audits is time consuming for the sites, as all relevant records, including laboratory studies and films (computed tomography, magnetic resonance imaging, etc.) required to document tumor measurements and response verification, must be gathered for the audit team. Some participants consider this work onerous; however, audits fulfill an important educational role in addition to ensuring the quality of the data and clinical trial procedures at participating sites. Data quality initially became a concern when clinical trial participation moved beyond academic sites to community practices. A number of evaluations in the 1980s, however, documented the ability of community sites to perform at a level comparable to that of academic institutions in terms of data quality, protocol adherence, and patient outcome.[11,12] Indeed, over 30% of the accrual to adult Cooperative Group trials now comes from community practices in the CCOP, and additional accrual comes from Cooperative Group affiliates, predominantly community sites.

As was noted previously, although regulatory standards regarding the conduct of clinical trials impose similar overall expectations, for its own reasons industry monitoring is both more extensive and frequent than the usual cooperative group monitoring. The basic tenet of monitoring for both industry-sponsored and NCI-sponsored clinical trials is similar: the need to verify data accuracy by comparing case report forms, whether submitted by paper or electronically, with source data in the patient's medical record. The sponsor-assigned clinical trial monitor will visit the site regularly, educate the involved staff about the goals and particular details of the protocol, and then track the progress of protocol-related activities throughout the conduct of the trial. Monitoring responsibilities include confirmation of appropriate local IRB review, investigator registration via completion of the FDA 1572 form, the existence of timely informed consent documents for each patient, inspection of drug accountability records, confirmation of timely and complete submission of serious adverse events reports, and ensuring appropriate and timely handling of amendments. These activities all fall within the responsibility of the clinical trial monitor, whether the monitor is provided directly from the company sponsor or through a contract research organization. Furthermore, regardless of whether the clinical trial is conducted directly by its own organization or by a contract research organization, biopharmaceutical companies often conduct their own quality assurance audits and monitoring associated with the trial, to further ensure the integrity of the submitted data. The intensity of clinical trial monitoring tends to increase as clinical trials mature and the data management group prepares to officially "lock" the database before the conduct of prespecified analysis and reporting activities. The intensity of quality assurance auditing also increases for a particular clinical trial when it has been identified as part of a New Drug Application or Biologic Licensing Application for drug registration with the FDA. Monitoring and data management activities are evolving with the widespread introduction of electronic data collection and submission systems that are replacing traditional paper-based case report form approaches.

Educational and Training Tools

As has been described previously, participation in clinical trials adds many complexities to care of cancer patients and can require that physicians, nurses, and other office staff acquire new and different skills. Fortunately, because of the widespread interest in clinical trials in the cancer community, there are many resources for gaining information about clinical trials and for acquiring the necessary skills. Professional societies are a good source for educational programs and materials, and some, such as the Oncology Nursing Society (http://www.oncc.org/), the Society of Clinical Research Associates (http://www.socra.org/), and the American Society of Health-System Pharmacists (http://www.ashp.org/), actually offer certification programs that can serve as important career development incentives to office staff. The American Society of Clinical Oncology (http://www.asco.org) also has a very useful Web site with links to a variety of sites that provide information about available clinical trials and detailed information about chemotherapy agents for physicians and nurses. NCI-sponsored Cooperative Groups provide regular educational activities for physicians, statisticians, nurses, and data managers who participate in their trials. Furthermore, the biopharmaceutical industry sponsors a wide range of educational activities that are conducted by both academic institutions and professional societies (e.g., the American Society of Clinical Oncology and the American Association of Cancer Research) about the clinical trials process in general and about the responsibilities of the individual clinical investigator.

The NCI's home page (http://www.cancer.gov/) provides a gateway to the many Web sites at the NCI and provides links to many other useful sites. It contains extensive information about cancer in general and cancer statistics, as well as detailed information about clinical trials with direct links to the Physician Data Query (PDQ). PDQ (http://cancer.gov/cancerinfo/pdq/) is a database maintained by the NCI that provides a comprehensive listing of NCI-sponsored clinical trials, along with extensive and detailed listings of trials (including international trials) that are submitted voluntarily by cancer centers, private hospitals, and the pharmaceutical and biotechnology industries. The PDQ search engine allows searches by geographic location and site or investigators, as well as by tumor type, stage, and other relevant categories, and it provides contact information to facilitate patient referral when appropriate. In addition, PDQ provides detailed information about the treatment of many cancers, as well as information on screening, prevention, genetics, and supportive care. Useful information on insurance coverage for patients on clinical trials, including the coverage offered by specific insurance carriers, can also be obtained from www.cancer.gov.

The NCI site also provides a link to the Cancer Therapy Evaluation Program, which coordinates NCI-funded clinical trials in treatment across the country. The Cancer Therapy Evaluation Program Web site contains detailed information related to the conduct of clinical trials, including the following:

- Human research protections and the required online course for all research teams conducting NIH-funded research
- The Investigators' Handbook and other tools for protocol development
- Information on data-reporting requirements and on the monitoring and auditing of clinical trials

The Web site of the Division of Cancer Prevention (http://www3.cancer.gov/prevention/) provides similar information on the conduct of cancer prevention and control studies. Other NCI resources include the Cancer Information Service (1-800-4-CANCER), a telephone service that provides information in both English and Spanish, answers many patient questions, and refers callers to other resources when appropriate.

CONCLUSION

Although the involvement of oncologists in clinical trials introduces additional complexities to their practice of oncology, it also provides substantial benefits to all participants and ultimately contributes to the goals of improving cancer treatment and prevention. A growing number of clinical practices have been able to integrate active clinical research into their activities successfully. To help facilitate this participation, the NCI began a small pilot in 2002 to allow sites without Cooperative Group affiliation to join Group-led trials directly via the CTSU.[13] A number of sites became involved successfully, and the NCI developed a number of tools that are now available through the CTSU. These tools include IRB submission packets, protocol calendars, and summaries, among others (Box 23-3). It is envisioned that the availability of a central IRB nationally and an electronic data reporting system will eliminate critical barriers and will make it easier

for community physicians to participate. Similarly, the biopharmaceutical industry continually seeks interested, conscientious physicians to participate in its trials. The shortage of such physicians creates a potentially serious limitation on the rate of development of new treatments for cancer. Surveys that have been done under the auspices of the Coalition of National Cooperative Groups suggest that the attitude of the treating physician is perhaps the most critical factor in patient enrollment in clinical trials.[2,5] With the right attitude, an increasing number of resources and tools are now available to make access to clinical trials a reality for many more patients, with the potential to benefit both themselves and future patients with cancer.

24 Economic Analysis of Cancer Treatment

Charles L. Bennett and Karen A. Fitzner

SUMMARY OF KEY POINTS

- Cancer care accounts for the largest number of dollars spent on any medical condition in the United States.
- Cancer accounts for 10% of all Medicare expenditures.
- Fewer than half of the states have passed legislation mandating coverage of clinical trials.
- Cost-benefit, cost-effectiveness, cost-utility, and cost-identification analyses are the main methods for evaluating the economics of clinical interventions.
- Empirical studies have found that results of cost-effectiveness studies are associated with pharmaceutical versus not-for-profit funding, although quality is not.
- Few economic studies have been incorporated into clinical trials sponsored by the National Cancer Institute (NCI).
- To date, only seven NCI-sponsored clinical trials have included economic assessments.

CANCER CARE IS EXPENSIVE

The costs of treating patients with cancer contribute substantially to the United States' $1.6 trillion annual health care spending. In fact, the economic burden of cancer is the largest imposed by any medical illness. The high expense associated with cancer is related to a number of factors, including an increase in the prevalence of cancer as people live longer, the high rate of comorbid medical illness in cancer patients, and high costs associated with diagnosis, treatment, and end-of-life and palliative care as new, more expensive treatments become available. The direct costs of cancer care (spent for prevention, screening, diagnosis, treatment, and palliation) accounted for $61 billion in 2002.[1,2] Pharmaceutical costs, which have been growing rapidly, account for a large amount of cancer-related expenditure.[3]

Cost is a major determinant of the type and intensity of cancer care, particularly related to reimbursement of high-tech and high-cost procedures and pharmaceutical products for cancer patients.[4] The physician has a large role in determining the medical costs incurred by individual patients. Medical costs are categorized as (1) direct medical costs; (2) direct nonmedical costs, that is, amounts spent for caregivers and travel; (3) indirect costs, that is, the economic value of lost productivity due to illness, disability, and death (mortality); and (4) intangible costs, that is, costs associated with pain, suffering, and grief. Although several studies have evaluated the direct costs of various types of cancers, few include estimates of direct nonmedical, indirect, and intangible costs. Pilot studies indicate that these costs may be as high as 75% of the total cost of cancer care.[5,6]

In 2006, the most costly cancers for men were prostate cancer followed by lung and colorectal cancer; for women, the most costly cancers were breast cancer followed by colorectal and lung cancer.[7] In addition to considering total costs, it is important to consider the benefit (or value) provided by the intervention in exchange for the amount expended. The number of articles addressing cost-effectiveness of cancer treatments has increased dramatically in the past few years, a large number of these studies addressing supportive care agents.[8–10] Oncologists, insurers, and policymakers increasingly are addressing questions of costs, cost-effectiveness, and quality of life. Many changes have been made in this area since the late 1990s, particularly in relation to the costs of clinical studies. Previously, the national mandate to evaluate the effectiveness of health care, including cancer care, was designed to incorporate cost-effectiveness assessments. The U.S. Healthcare Research and Quality Act of 1999 gave a mandate to the Agency for Healthcare Research and Quality to focus on evidence-based technology assessments, which could then be incorporated by relevant people in the medical community into guidelines produced by physicians or medical societies. Unfortunately, cost considerations are not addressed explicitly in the current mandate. A few of the assessments will, however, provide information that may be applicable to cost-effectiveness analyses that can be conducted by others.

Clinical Trials and Their Reimbursement

The costs of cancer clinical trials have become an important issue related to cancer treatment over the past decade. Findings from pilot studies of about 1300 patients in phase II/III clinical trials estimate that costs ranged from 10% lower to 23% higher for clinical trials in comparison to control groups that received standard medical care.[8–14] On the basis of these findings, nearly half of U.S. states, Medicare, and several private insurers now cover the costs of patient care in "qualifying" clinical trials. Because of economic and other considerations, federal policies were not supportive of clinical trial reimbursement during the 1990s; Medicare excluded coverage of routine costs of care associated with clinical trial participation on the basis that such treatment was experimental or investigational.[10] However, a 1993 review found that Medicare was being billed millions of dollars for patients who received care in clinical trials.[12] The U.S. General Accounting Office estimated that Medicare had paid 50% to 90% of routine patient care costs in clinical trials because fewer than 4% of claims for clinical trial costs incurred by Medicare beneficiaries

were denied and oncologists often submitted bills for components of complex treatments without specifying the procedure itself.[14]

In the late 1990s, there were several unsuccessful proposals, such as the Medicare Cancer Clinical Trial Coverage Act and the Medicare Cancer Clinical Trial Demonstration Act, that would have allocated considerable funds to cover cancer clinical trials sponsored by the National Institutes of Health, the Department of Defense, and the Department of Veterans Affairs. Following years of lobbying by individuals, patient groups, health care workers, and organizations who were concerned about reimbursement denials of clinical trial costs and the low rates of accrual to clinical trials, a 2000 executive order authorized Medicare to cover the costs of any cancer clinical trial that satisfied qualifying criteria. Medicare has paid routine care costs (e.g., office visits and lab tests) for patients enrolled in federally funded clinical trials since 2000. The Centers for Medicare and Medicaid Services revised its National Coverage Determination for off-label use in cancer clinical trials in early 2005. Medicare now pays for both routine and nonroutine costs associated with the patient's care as well as the off-label use of some anticancer drugs.[15–17]

At the state level, the question put before some state legislatures has been whether insurance barriers to clinical research are best removed through voluntary action of health insurers or formal legislation. As of December 2006, 22 states had passed laws mandating coverage of patient care costs associated with treatment provided in specified categories of cancer clinical trials.[18] In the mid-1990s, Rhode Island became the first state to legislate insurance coverage for phase II clinical trials. Since then, Georgia mandated insurance for selected pediatric cancer trials in 1998, and Maryland and Virginia mandated insurance for cancer trials conducted in in-state academic institutions in 1999. Maine requires managed care organizations and private insurers to cover trials approved and funded by the NIH, a NIH-sponsored cooperative group or center, or the U.S. Department of Health and Human Services. Louisiana requires coverage of Phase II, III, and IV clinical trials that are approved by entities such as the Food and Drug Administration (FDA), the Department of Defense, the Veterans Administration, and the Coalition of National Cancer Cooperative Groups. The New Jersey Association of Health Plans agreement is unique in that all private insurers in a single state have voluntarily agreed to provide cancer clinical trial coverage. These coverage mandates are important because without third-party coverage, most patients are unable to bear the cost of participating in a clinical trial.

Today, public payers and several large private health insurers reimburse for medical care costs associated with clinical trials. Concern over variable scientific quality has led many state legislatures to limit reimbursement to trials funded by federal agencies. Moreover, many states have mandated clinical trial coverage by private and public payers for cancer trials but not for other medical conditions. This is in part due to the national infrastructure surrounding cancer trials, which is the most established and comprehensive of any disease clinical trials.

Economic Assessments in Cancer Care

Economic issues in cancer care are paramount in planning for optimal use of scarce resources and in responding to the increased economic pressures faced by the health care system. Physicians and health policymakers need to make judgments on the effectiveness and cost-effectiveness of cancer care based on explicit assessments of the costs and benefits of alternative management strategies. In other words, payers want assurance that expensive treatments are cost-effective. To understand the financial impact of alternative cancer management strategies more clearly, it is essential to understand the basic terminology of economic studies in health care: costs, benefits, cost-effectiveness, cost utility, and cost minimization. It also is important to explain the methods that policymakers and oncology researchers use when they evaluate the costs of cancer care.

When Are Economic Assessments Likely to Be Helpful (or Unhelpful)?

Assessments of the costs of cancer care can be considered when significant resources are being used, when resource considerations have a direct impact on patient care, and when resource allocation decisions are likely to be made.[19] Economic analyses also help to identify the most efficient option when two or more clinically efficacious interventions are available. Examples of situations in which a large amount of resources are used include use of supportive care agents such as antiemetics, erythropoietin, granulocyte colony-stimulating factor (GCSF), and genetic predictors. Resource considerations played a prominent role in the decision to support high-dose chemotherapy with stem cell transplantation for breast cancer before reports of unfavorable results were received from several randomized clinical trials. Economic analyses are unlikely to be helpful in cases in which a treatment works well but only a small number of individuals are affected, thereby limiting the overall cost impact. For example, advanced testicular cancer routinely is treated with chemotherapy. The cure rate is high, but the number of cases is fewer than 10,000 per year. Similarly, data have been collected on the economic implications of high-dose chemotherapy with stem cell transplantation for breast cancer, but they will not be useful to policymakers because this procedure has not been found to be clinically effective.

Types of Economic Analyses

Economic evaluations provide information on the value of an intervention or therapy in relation to its costs when compared to a competing alternative when, ideally, the alternative is the current standard of care. Economic evaluations of cancer interventions can range from decision analytic models to retrospective database comparisons to analyses conducted alongside clinical trials. However, all of the economic analyses of clinical interventions can be grouped into four categories based on the measure of effectiveness used in the analysis: cost-benefit (costs and benefits are measured in the same terms, usually monetary), cost effectiveness (costs measured in monetary terms, effectiveness in clinical terms), cost utility (costs measured in monetary terms, utility measured in terms of utility), and cost identification (costs measured in monetary terms, no effectiveness measurement).[20]

Cost-benefit analysis compares the incremental cost of a medical intervention with its incremental benefit, with both terms measured in monetary units. Therefore, interventions with positive net benefits, in which the value of the incremental benefits is greater than the incremental costs, are cost-beneficial compared to the alternative. In theory, cost-benefit analysis allows for the comparison of health interventions with other programs or interventions from non–health care sectors that may be competing for the same dollars. That is, with a cost-benefit analysis, a government could compare whether to spend monies on a new after-school program for children or use the same monies to fund a breast cancer screening program. However, difficulties in valuing all the relevant factors (e.g., years of life lost and quality of life) in monetary terms limit the use of cost-benefit analysis.

More commonly, economic evaluations in cancer care involve cost-effectiveness analysis. Cost-effectiveness analysis provides information about the value of an intervention or therapy in relation to its costs compared to a competing alternative when effectiveness is measured in clinical terms. The analysis compares two or more interventions and provides information about the differences in costs and effects between comparators. The results are summarized into a ratio that provides the results in terms of the costs per unit of effect. This ratio is referred to as the incremental cost-effectiveness ratio, because it is assessing incremental differences between alternative treatments. Because it is a cost-effectiveness analysis, the denominator of the ratio is valued in natural units, such as years of life, and is calculated by finding the difference in the effectiveness measure between the

alternatives. For example, many cost-effectiveness analyses in cancer treatments report the incremental cost per year of life saved.

Cost-utility analysis is a subset of cost-effectiveness analysis in which the measure of effectiveness is a utility or value. Utilities provide a measure of overall quality of life and are applicable across different types of cancer. The measure is intended to incorporate both positive and negative aspects of treatment. The utility is combined with information on survival to estimate quality-adjusted life years, which are used as the measure of effectiveness in cost-utility analyses. Thus, cost-utility analyses provide an estimate of the cost per quality-adjusted life year gained. In principle, this method can be used to compare the value of screening programs to new chemotherapeutic agents to gauge the relative value of an alternative.

The final type of clinical economic analysis used in cancer studies is cost identification. This technique reports the total types and amounts of resources used in providing medical care, without formal assessments of the clinical benefits of the treatment. This technique is an integral part of the other economic evaluations in that it provides the cost estimate used in the numerator. However, with this method, the benefits are not compared formally among alternatives.

It is important to emphasize that in all types of economic analyses, the way monetary units are assigned to treatments can make important differences. Specifically, costs differ markedly from charges.[21] Costs represent the true opportunity cost of a resource, whereas charges represent the amount that is billed for that resource. There might be little connection between costs and charges, charges typically being much greater than the actual costs. Therefore, it is important to be aware of whether costs or charges are being used to derive the economic estimates.

CANCER COSTS: ESTIMATES FROM MEDICARE POPULATIONS

Total medical care expenditures for oncology account for 10% of all Medicare expenditures.[22] Medicare Part A covers inpatient cancer care. Cancer-screening services are covered for cervical, breast, colorectal, and prostate cancer, and many types of chemotherapy and related treatments are covered under Part B. As of 2006, Medicare Part D provides a drug benefit that covers cancer drugs but requires significant financial contribution from patients who have prescription expenses more than $2,250.[23] In the future, prescription drug data will also be captured via Medicare Part D.

Recent studies have incorporated economic analyses for various cancers experienced by the Medicare population.[1,2,24] Costs have been evaluated for the initial phase, the primary course of therapy, and any adjuvant therapy, continuing care, including surveillance activities for detecting recurrences and new cancers, and the terminal care phase. Data for these analyses derive from the linked Surveillance Epidemiology and End Results (SEER) and Medicare database that includes detailed financial and clinical data elements for cancer patients who received care in 11 geographic regions of the country (see http://seer.cancer.gov). The database provides detailed information for inpatient services (Part A) and payments for outpatient services (Part B). The Medicare-SEER cost files were generated by reviewing monthly cost files for each cancer patient identified in the SEER database. Prices are adjusted using the Medicare per capita index and Medicare-based price indices that account for differences in health care purchasing power over time and location. These data are used to provide estimates of national expenditures according to type of cancer and gender.

Quality Assessment of Economic Analyses

Controversy exists over the quality of economic analyses of medical treatments and has led to the development of grading systems for economic evaluations.[25,26] The quality of the data and the models that are used in these analyses are the major determinants of the results. Additional items that are considered in the quality of economic evaluations include the objective and perspective of the analysis, data sources, type of comparison, handling of uncertainty, the time horizon of the analysis, and the discount rate. Other important considerations are the outcome measure that are used in the analysis, measurement of costs, measurement of effectiveness, and the overall transparency of the analysis (i.e., were the assumptions explicitly stated?).

Study sponsorship is gaining attention as concern has been raised over the potential for conflict of interest to bias the research, affect the design, and skew the interpretation of economic analyses of medical therapies.[27–29] The newness of pharmacoeconomics research and its potential effects on pharmaceutical company revenue make it particularly vulnerable to financial conflicts of interest. Researchers have examined the effects of conflict of interest on pharmacoeconomic research in breakthrough areas in oncology, such as hematopoietic colony-stimulating factors, antiemetics, and taxanes oncology. Published articles were classified according to qualitative conclusion, quantitative result, timing of study initiation, and funding source.

The first study found correlations between funding source and qualitative cost assessment, timing of study initiation, and discrepancies between qualitative conclusions and quantitative results. Favorable conclusions were reached by 81% of the pharmaceutical company-sponsored studies and 48% of the nonprofit-sponsored studies ($P < 0.009$). All of the studies that reached unfavorable conclusions had been sponsored by nonprofit organizations. Although nearly one fourth of the studies gave qualitative conclusions that overstated their quantitative results, this was not significantly greater for pharmaceutical company-sponsored studies than for nonprofit-sponsored studies.[27] More than 80% of economic studies funded by all sources were conducted after favorable clinical trial results were known. The findings of the study demonstrated a strong association between pharmaceutical company sponsorship and favorable economic assessments. Although there is no evidence of bias in individual articles, the results raised concerns about potential bias in pharmacoeconomic studies. Unfavorable cost profiles probably are underreported, and qualitative overstatements about the cost-effectiveness of new agents are not uncommon.

The second study addressed variations in study quality when the 44 pharmaceutical and not-for-profit-funded cost-effectiveness studies of the six breakthrough drugs in oncology were compared.[28] Investigators rated specific aspects of study reporting based on criteria from the U.S. Public Health Service Panel on Cost-effectiveness in Health and Medicine. Dissemination strategies were evaluated by using impact factor scores from the Science Citation Index. Operational aspects of pharmaceutical manufacturer–sponsored study reporting were better overall than were those associated with nonprofit-sponsored studies with respect to the following criteria: The results were more likely to be reported based on data obtained from randomized clinical trials or detailed cost models (90% versus 70%); to include descriptions of the source of cost differences (90% versus 79%); to state whether the study was carried out from a societal, governmental, or insurer perspective (70% versus 42%); and to indicate clearly the time period over which costs were evaluated (65% versus 50%). Nonprofit-sponsored studies were more likely than pharmaceutical-sponsored studies to report the generalizability of the findings to other clinical settings (58% versus 35%), to include statements on the statistical significance of the findings (38% versus 20%), and to clearly outline the cost per unit and data sources for the cost analyses (67% versus 45%). Most studies were published in low-impact-factor, peer-reviewed journals, and journal impact factor scores were similar between pharmaceutical- and nonprofit-sponsored studies. Overall, the study found differences in study reporting but not in types of journals where studies were published. These results, particularly with respect to differences in generalizability, may account in part for the finding that pharmaceutical manufacturer-sponsored studies were less likely to report unfavorable conclusions.

Strategies for Conducting Economic Analyses in Oncology

Because economic assessments are potentially useful as secondary endpoints in clinical trials of new cancer therapies or technologies,[19] cost analyses have been proposed alongside pivotal trials or new technologies. These are appropriate when investigational therapies are resource-intensive or when new technologies or treatments are likely to be used by large numbers of cancer patients. In most cases, these analyses are associated with phase III clinical trials, although inclusion in phase II trials can facilitate the collection of pilot data that can assist in study design for phase III trials. Phase IV studies also are possible sources of data for clinical and economic analyses. Estimates of the potential difference in costs between treatment arms can be helpful to coverage determinations.

The perspective of the economic analysis varies in many of the reported cost-effectiveness analyses. Most commonly, the perspective is that of the third-party payer; however, the societal perspective should also be considered.[21] Many clinical trials report economic data that are based on a "modified" societal perspective; that is, direct medical costs are quantified as societal costs, while direct nonmedical and productivity costs are not evaluated. Data collection can be prospective or retrospective. Prospective studies allow for timely assessment of clinical and economic outcomes at the end of the study. Detailed information on direct medical, direct nonmedical, productivity, and intangible costs can be obtained if careful planning is done before the study begins. Retrospective economic assessments are far less costly to conduct, but they include information on only a limited perspective (generally the third-party payer perspective).

The time interval from randomization to follow-up can influence the findings of the economic analysis, if follow-up is short. Ideally, the time horizon should be the same for the clinical and the economic analysis and should allow for realistic outcome measurement. Some economic analyses consider intermediate outcomes (e.g., response rate); other cost analyses are based on a review of final outcomes (e.g., survival in months or years). In either case, the outcomes should be identified prospectively. Despite increasing discussion about methodologies and practical approaches to including economic analyses in randomized clinical trials, remarkably few of these assessments have been reported in the literature. The National Cancer Institute (NCI)–sponsored Cooperative Trials Groups reported only one prospective and six retrospective economic analyses.[30–35]

One can argue that cost data should be considered as important as clinical data and should be subjected to quality control assessments. Most of the literature related to cost analyses in cancer has been based on retrospective assessments of clinical trials, and these retrospective reviews generally have been funded by the pharmaceutical industry. Combining economic studies and clinical trials requires targeted funding, staff, and cooperation between clinical and economic researchers and analysts. Few independent nonprofit groups have the funds to supported economic analyses. Hence, concerns exist about researcher independence. One privately funded economic assessment of autologous stem cell transplant studies for breast cancer, for example, did not reveal the economic findings until after the clinical trial results were reported as negative. The savvy reader of economic analyses needs to think about the sponsor of a study and that group's motivation for undertaking a study and reporting its findings.

Economic Analyses Conducted by Cancer Clinical Trials Groups

During the 1990s, the NCI supported efforts to integrate economic analyses into cancer clinical trials.[19,20] In 1994, the NCI sponsored a conference with representatives of cancer centers and cooperative groups that addressed the importance, appropriateness, and

Table 24-1 Completed Economic Analyses Conducted by National Cancer Institute-Sponsored Clinical Trials Groups

Study	Treatment Arms	Effectiveness Time Frame	Economic Time Frame	Method	Outcome
Radiation Therapy Oncology Group 90-03 and 91-04[37]	Brain metastases; head and neck cancer	Not measured	Months	Cost estimation	90-03 costs estimated well; 91-04 costs not estimated very well
Eastern Cooperative Oncology Group 1490[35]	GM-CSF vs placebo for older	Weeks	Weeks	Cost minimization	GM-CSF was cost saving, and adults with AML decreased infections
Southwest Oncology Group 9031[33]	GCSF vs placebo for adults with AML	Weeks	Weeks	Cost minimization	GCSF did not add additional costs and decreased hospital stay
Southwest Oncology Group 9509[30]	Vinorelbine + cisplatin vs paclitaxel + carboplatin for non–small cell lung cancer	Months	24 months	Cost minimization	Cisplatin + vinorelbine is less costly
Children's Cancer Study Group[32]	GCSF vs placebo for children with leukemia	Weeks	Weeks	Cost minimization	GCSF did not add additional costs and was associated with shortened duration of neutropenia
Pediatrics Oncology Group[36]	GCSF vs control for children with leukemia	Weeks	Weeks	Cost minimization	GCSF did not add additional costs and was associated with shortened duration of neutropenia
Children's Cancer Study Group 1881, 1882, 1891, 1901, 1922, 1941[31]	Acute leukemia—various treatments	Years	Months	Cost effectiveness	Delayed intensification, augmented therapy, and dexamethasone therapy cost-effective vs treatment of first relapse

AML, acute myelogenous leukemia; GCSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte macrophage colony-stimulating factor.

complexity of these evaluations. The next year, the American Society of Clinical Oncology (ASCO) established a Health Outcomes Working Group, which was charged with developing specific guidelines for implementing economic evaluations in cancer clinical trials.[20] In 1996, the NCI and ASCO convened a second meeting, attended by experts from the NCI-sponsored cooperative groups, NCI staff, and experts in the field of health economics, to consider the practical implementation of economic evaluation in cancer clinical trials. In 1998, a workbook that served as a developing guide designed to be used as practical reference for subsequent economic analyses of cancer clinical trials was published.[17] The first articles describing economic analyses alongside clinical trials conducted by the NCI-sponsored cooperative groups were published in 1997.

Table 24-1 provides information on seven NCI-sponsored studies that have been published to date. The following summary considers some of these real-life examples of the methods and operational considerations researchers face when conducting cancer clinical trials. The first cost-effectiveness study of an NCI-sponsored cooperative group trial was reported in 1997 by investigators who were affiliated with the Children's Cancer Study Group.[32] The clinical trial evaluated the clinical and cost-effectiveness of GCSF as an adjunctive therapy for children with acute lymphoblastic leukemia. The study randomized 164 children and found a reduction in the duration of neutropenia (5.3 versus 12.7 days) and duration of hospitalization (6 versus 10 days). Cost-minimization analyses indicated that GCSF did not add additional costs. Clinical and economic data were obtained directly from the clinical trial participants.

The second economic analysis of an NCI-sponsored cooperative group trial was reported in 1999 by investigators who were affiliated with the Eastern Cooperative Oncology Group.[35] The randomized clinical trial evaluated the clinical effectiveness of the hematopoietic cytokine, granulocyte macrophage colony-stimulating factor (GM-CSF), as an adjunctive therapy for people 55 years of age or older who were receiving induction chemotherapy for acute myeloid leukemia. Patients receiving GM-CSF experienced a 72% reduction in severe infections, four fewer days with an absolute neutrophil count lower than 500 cells/mL, but no significant difference in the duration of hospitalization compared to the group taking the placebo. Decision analytic modeling was used to analyze the costs of GM-CSF use during induction therapy. Clinical probabilities of acquiring an infection were obtained from the clinical trial data; hospital costs per day for infected and uninfected patients were obtained from billing data from seven sites participating in the clinical trial. The significant improvements in rates of severe infections were associated with an estimated $2310 in cost savings per patient. The reduction in costs was particularly evident among individuals who received two cycles of induction chemotherapy. The study was conducted over a six-month period, with funding for the study provided by the pharmaceutical manufacturer.

A retrospective economic analysis of a randomized clinical trial conducted by the former Pediatrics Oncology Group[36] compared the costs of inpatient supportive care for pediatric patients (age 1 to 22 years) with T-cell leukemia and advanced lymphoblastic lymphoma. Patients received either GCSF ($n = 45$) or no GCSF ($n = 43$) following induction and two cycles of maintenance therapy. During maintenance therapy, the patients receiving GCSF had significantly fewer days to an absolute neutrophil count above 500 cells/μL and a trend toward fewer days of hospitalization. The study found that the total median costs of supportive care were similar for all patients in the study. Data on resource utilization were tabulated from case report forms, and costs were derived from national data on hospitalization costs, average wholesale prices of pharmaceuticals, and patient billing information from a single institution. The four-month study was conducted with support from the Cooperative Clinical Trial Group and the pharmaceutical supplier of the study drug.

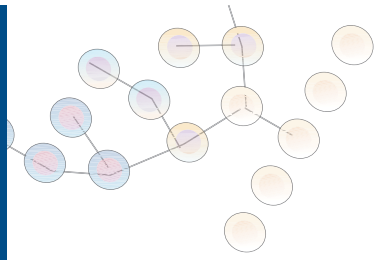
In 2001, the Radiation Therapy Oncology Group (RTOG)[37] initial pilot study addressed four aims: (1) measurement of radiation therapy treatment costs for patients treated in different arms of two randomized controlled clinical trials, (2) comparison of measured costs to those predicted by an economic model, (3) examination of the distribution of costs among patients treated on the same arm, and (4) assessment of the feasibility of retrospective data collection effort. The RTOG selected two phase III clinical trials to evaluate in this pilot effort. The first study, RTOG 91-04, compared standard treatment to a total dose of 30 Gy with a second arm of accelerated hyperfractionation to a total dose of 54.4 Gy for cancer patients with brain metastases. The second study, RTOG 90-03, was a phase III study of patients with squamous cell carcinomas of the head and neck who received either standard fractionation to a dose of 70 Gy, hyperfractionation to a dose of 81.6 Gy, accelerated fractionation with a split to a total dose of 67.2 Gy, or accelerated fractionation with a concomitant boost to a total dose of 72 Gy. Expected quantities of procedure codes and relative value units associated with Medicare billing efforts were modeled. The median and mean relative value units were within the range predicted by an economic model for all arms of the head and neck cancer study but were above the predicted range for the brain cancer study. Some of the researchers encountered considerable difficulties in collecting the retrospective economic data, suggesting that prospective data collection might be the better strategy for economic analysis of RTOG studies. Clinical trials with complex treatment protocols, such as the head and neck cancer study, appeared particularly difficult to include in retrospective economic analytic efforts.

Nonfinancial metrics can be reported. One study, for example, reported on the feasibility of using duration of hospitalization as a surrogate for cost and event-free survival as a measure of effectiveness to estimate cost-effectiveness ratios of various treatment regimens evaluated in clinical trials of children with acute lymphoblastic leukemia.[26] Metrics included marginal cost-effectiveness estimates of the number of days per patient for delayed intensification and for augmented therapy and relapse-adjusted "savings" associated with augmented therapy (16 days) and with dexamethasone-based therapy (82 days). The study was supported by grants to the office of the cooperative group's chairman and indicated that retrospective economic analyses were feasible, provided that the economic analyses focused on duration of hospitalization.

Researchers affiliated with the Southwest Oncology Group conducted the first prospective economic analysis of a randomized clinical trial conducted by an NCI-sponsored cooperative clinical trial group.[30] The clinical trial included patients who were randomized to receive cisplatin plus vinorelbine versus carboplatin plus paclitaxel. The findings from this study indicated that prospective economic analyses could be conducted alongside randomized clinical trials, although these efforts did require external funding and committed resources from the statistical operations center of the cooperative clinical trial group.

This review of the design, outcome metrics used, and sponsorship of these studies is instructive in identifying potential opportunities and obstacles for future research. Most studies were based on retrospective economic analyses. Funding sources were diverse, most of the analytic efforts being supported by pharmaceutical suppliers.

CONCLUSIONS



U.S. health care expenditure on cancer care is greater than expenditure for any other illness. It is important to consider both the clinical benefit and the economic value provided by cancer treatment interventions, particularly during their development. Economic tools (cost-benefit, cost-effectiveness, cost-utility, and cost-identification analyses) can provide such information. Despite increases in coverage for patients in "qualifying" clinical trials by Medicare, several private insurers, and many U.S. states, few robust economic analyses have been conducted in trials sponsored by the NCI. Clinical trials that incorporate cost analyses can contribute to an understanding of

the value of an intervention and can do so from a variety of perspectives.

Costs of cancer care can be evaluated in a variety of clinical settings. Economic considerations have important practical implications for oncologists and should be addressed for most new cancer treatments and procedures. Continuing economic pressures facing the health care system in the United States serve as an important reminder of the importance of unbiased cost analyses, particularly for cancer treatments. Despite nearly universal support for economic information, the paucity of cost-effectiveness analyses, especially studies that are not funded by the pharmaceutical industry, is particularly worrisome. Policymakers and physicians strive to make informed decisions about rational allocations of cancer resources. Economic data, if properly obtained, can assist in these decisions.

25 Use of Epidemiology in Oncology

Siobhan Sutcliffe, Kala Visvanathan, and Elizabeth A. Platz

SUMMARY OF KEY POINTS

Epidemiology is a design and analytical method used to investigate disease occurrence in human populations. Epidemiology encompasses several different design approaches, including randomized trial and observational approaches; this chapter focuses on observational approaches.

- Epidemiologic methods can be used to address a wide range of hypotheses in biomedical research, including translational and clinical hypotheses generated in oncology.
- To determine the optimal epidemiologic approach for addressing questions in oncology, research questions should be restated as testable hypotheses.
- Elements in the design of studies using observational epidemiologic methods should include the following:
  - Defining the target, source, and study populations
  - Defining the endpoint of interest (e.g., development of disease or recurrence of disease)
  - Defining the factor of interest (e.g., exposures, markers of susceptibility, markers of biological pathways influenced by both genetic and nongenetic factors, characteristics of premalignant lesions, cancer cells/tumors, and surrounding tissues)
  - Choosing the most appropriate study design, the prospective cohort or derivative designs, or the case-control study
- Testing a hypothesis usually involves comparing the occurrence of the endpoint in two or more groups that differ on a factor of interest.
  - Measures of occurrence of an endpoint in a study using the cohort design include the cumulative incidence (risk), which conveys the probability of the endpoint, or the incidence rate, which conveys how fast the endpoint is occurring in a population at risk.
  - Comparing the endpoint occurrence between two groups may involve comparing survival curves or quantifying the magnitude of the difference in the endpoint occurrence using ratio measures such as the *cumulative incidence ratio*, *rate ratio*, or *hazard ratio*, collectively known as the *relative risk* of the endpoint in cohort studies, or the odds ratio in case-control studies.
- The design, statistical analysis, and inference of an observational epidemiologic study should be motivated by temporality and comparability considerations.
  - *Temporality* means that the factor of interest must necessarily precede the occurrence of the endpoint. Lack of temporality can lead to the false conclusion that a factor caused an endpoint or that the factor has predictive capability for a future endpoint.
  - *Comparability* means that the only difference between two or more groups being contrasted is the factor of interest. Lack of comparability can lead to selection bias, observation bias, and confounding, all of which can lead to false conclusions.
- After considering alternative explanations for an epidemiologic finding (selection bias, observation bias, confounding, and chance variability), investigators still cannot conclude that the observed association reflects causation. In epidemiology, any given research question must be evaluated many times using different designs and study populations, and usually by independent investigators.
  - Each epidemiologic study design has a different potential for each type of bias.
  - In general, prospective cohort studies and derivative designs provide stronger evidence for a causal association than case-control studies because they maintain temporality and are less susceptible to selection and observation biases. Although both prospective studies and randomized trials are likely to have the correct temporal sequence, evidence from trials usually trumps evidence from prospective studies because randomization reduces the likelihood of selection bias and confounding.
  - Different study populations may have different characteristics that influence the likelihood or extent of unmeasured or residual confounding.
  - Chance variability is possible in any study.
- When considering whether an observed association between a factor and endpoint is causal, some investigators find it useful to think about the nine "aspects" of an association that Sir Austin Bradford Hill described: strength, consistency, specificity, temporality, biological gradient, plausibility, coherence, experiment, and analogy.
  - Temporality is highlighted in this chapter because it is the only aspect of an association necessary for causality; the other aspects do not rule in or rule out the potential for an association to be causal.
- Obtaining correct inferences from observational epidemiologic studies in oncology hinges on the appropriate study population, design, and analysis, all of which require epidemiologic thinking. For this reason, a multidisciplinary research team that includes collaborators from clinical science, basic science, biostatistics as well as epidemiology is optimal for addressing the complex translational and clinical questions posed in modern oncology.

EPIDEMIOLOGY

Epidemiology is a design and analytical method used to investigate disease occurrence in human populations. Although traditionally used to test hypotheses about disease causation, epidemiologic methods also can be used to address a wider range of hypotheses in biomedical research, including translational and clinical hypotheses generated in oncology. Epidemiology encompasses several different design approaches, including experimental (randomized trial) and observational approaches, but this chapter focuses on observational approaches. To motivate the use of epidemiology in oncology, two hypothetical translational and clinical research questions are posed and used to illustrate concepts and approaches throughout this chapter:

1. *Prognosis:* Basic scientists recently have identified a protein expressed to a greater extent in high- than low-grade prostate tumors and not expressed in normal adjacent epithelium. This protein can be measured in tissue using a newly developed sensitive technique. To help identify which men with prostate cancer should receive adjuvant therapy following prostatectomy, investigators would like to know whether high expression of this protein predicts prostate cancer recurrence after prostatectomy independent of known prognostic characteristics.
2. *Therapeutic effectiveness:* Researchers have determined that a gene encoding a particular P450 metabolic enzyme enhances the action of a chemotherapeutic agent currently being evaluated in combination with standard therapy for treatment of non-Hodgkin's lymphoma. To help determine which patients with non-Hodgkin's lymphoma may benefit most from this new chemotherapeutic agent, investigators would like to know whether a particular haplotype in the gene that encodes the P450 metabolic enzyme predicts overall survival after treatment with the chemotherapeutic agent in combination with standard therapy.

STATING RESEARCH QUESTIONS AS HYPOTHESES TESTABLE USING EPIDEMIOLOGIC METHODS

To determine the optimal epidemiologic approach for addressing translational and clinical research questions in oncology, the research questions should be restated as testable hypotheses. Stating a research question as a testable hypothesis involves determining which groups should be compared. For instance, the *prognosis* and *therapeutic effectiveness* research questions can be restated as testable hypotheses as follows:

Prognosis: To test whether patients with high expression of the tissue marker are more likely to recur after prostatectomy than patients with low expression of the tissue marker.

Therapeutic effectiveness: To test whether patients with non-Hodgkin's lymphoma with a particular haplotype are more likely to survive than patients without the haplotype after treatment with the new chemotherapeutic agent in combination with standard therapy.

ELEMENTS IN THE DESIGN OF STUDIES USING EPIDEMIOLOGIC METHODS

Defining the Target, Source, and Study Populations

Once the research question is defined and stated as a testable hypothesis, the population (*source population*) from which study participants (*study population*) will be drawn can be identified. In selecting the source population, investigators should be cognizant of all patients who may benefit from the results of the study (*target population*), beyond those included in the study (Fig. 25-1).

In the cancer center setting, several source populations from which the study population can be drawn typically are readily available (*convenience sample*): patients seeking screening and risk reduction options because of elevated risks of specific cancers; patients referred because of signs or symptoms suggestive of cancer; patients presenting with newly diagnosed cancer for treatment or a second opinion; patients under surveillance during and after completing treatment; and patients seeking salvage or palliative care for recurrence. For the two hypothetical research questions, possible source populations might be the following:

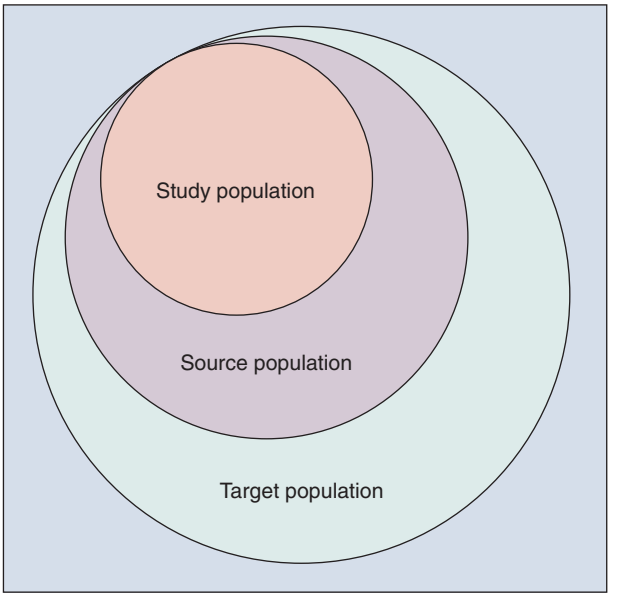

Figure 25-1 • Relationships among study, source, and target populations.

Prognosis: Patients newly diagnosed with prostate cancer eligible for prostatectomy.

Therapeutic effectiveness: Patients with non-Hodgkin's lymphoma eligible to receive the new chemotherapeutic agent.

Although they provide a good start, these definitions of the source population still are too broad. The source population should be narrowly defined with respect to person, place, and time. Doing so reduces the heterogeneity among individuals under study to help investigators draw sound inferences. For the two hypothetical translational and clinical research questions, the source populations can be more narrowly defined as follows:

Prognosis: Men newly diagnosed with clinical stage T1c or T2 prostate adenocarcinoma who underwent radical retropubic prostatectomy between 1993 and 2002 at one academic hospital and for whom resected prostate tissue was collected and stored.

Therapeutic effectiveness: Adult men and women newly diagnosed with diffuse large B-cell lymphoma randomized to the new chemotherapeutic agent arm of a multicenter clinical trial evaluating the efficacy of this agent in combination with standard therapy. All trial participants were required to have a histologically confirmed diagnosis of diffuse large B-cell lymphoma according to the World Health Organization Lymphoma Classification, to be less than 60 years of age, to be CD20-positive, and to have at least two risk factors according to the Age-Adjusted International Prognostic Index. Participants were enrolled in 2000 and followed for 5 years.

The study population typically is a subset of the source population. Reasons for not including all individuals from the source population in the study include feasibility issues, such as assay cost and throughput; patient willingness to participate; and availability or

completeness of medical records and biologic specimens. For instance, in the *prognosis* example, the investigators may have intended to enroll all men with early-stage prostate cancer treated by radical prostatectomy from 1993–2002. However, some men may have chosen not to participate and, therefore, were not included in the study population, although they were included in the source population. Alternatively, the investigators may assemble the study population in 2007 by searching the medical records for men who underwent prostatectomy for early-stage prostate cancer between 1993 and 2002. Some of these men may no longer have archived prostatectomy specimens and, thus, cannot be included in the study population, despite being in the source population.

In the *therapeutic effectiveness* example, the source population is the group of participants consented and randomized to the new chemotherapeutic agent arm of the trial. At the outset, participants may have been asked to provide consent for both randomization to treatment and collection of blood specimens for genetic testing, including testing for the new clinical research question. In this case, the source and study population are one and the same. Alternatively, the new clinical research question may have been posed subsequent to the start of the trial. In this case, the investigators would have had to approach participants at a later trial visit to collect blood specimens for genetic testing. The study population might then differ from the source population because some participants might not have consented to this new correlative study or some might no longer have been participating in the trial because of death or other reasons for withdrawal. Investigators should always consider reasons for differences between the source and study population, as these may affect the results of the study (see section on Comparability).

As stated earlier, when selecting the source population, investigators always should be aware of the target population. For the two hypothetical translational and clinical research questions, possible target populations might be the following:

Prognosis: Men newly diagnosed with clinically organ-confined prostate cancer.

Therapeutic effectiveness: Adult men and women less than 60 years of age newly diagnosed with CD20-positive diffuse large B-cell lymphoma with at least two risk factors according to the Age-Adjusted International Prognostic Index.

Although study populations should be representative of the target population when estimating the occurrence of disease or factor in the target population (e.g., Americans living with cancer in 2007), the source and study populations do not necessarily have to be representative of all patients in the target population when addressing translational or clinical research questions that involve comparing the experiences of two or more groups.

For instance, in the *therapeutic effectiveness* example, members of the study population may be more likely to be white, younger, and healthier, on average, than members of the target population. This difference might arise because members of different groups may choose to participate to differing extents even when effort is made to recruit adequate proportions of each group. Given this difference, an important question to consider is whether findings from the study population will apply to the broader target population. For example, if the new chemotherapeutic agent trial is conducted primarily among white, younger, and healthier patients and it is known that white individuals have a higher frequency than non-white individuals of the haplotype that produces a version of the P450 enzyme that enhances the action of the new agent, would the finding that white patients with the haplotype are more likely to survive after treatment than white patients without the haplotype also apply to non-white patients? All else being equal, it might be expected that the findings would apply; what might differ is the percentage of patients in a particular racial or ethnic group who have the beneficial haplotype and who would thus benefit from treatment with the new agent. Of course, if all else is *not* equal, then the findings might not apply perfectly. For example, if non-white patients tend to have more comorbidities for which they are simultaneously prescribed other medications that compete for activation by the enzyme, then the new agent might be less effective in non-white patients with the haplotype than in white patients with the haplotype. Thus, the gain in survival with the haplotype would appear to be lower in non-whites than in whites. Note that in this example the new agent might still be equally as effective in white and non-white participants with the haplotype who do not have comorbidities, and less effective, but equally so, in white and non-white participants with the haplotype who have comorbidities and are taking the same array of drugs activated by the enzyme.

Therefore, the message is: Before embarking on a study, contemplate the likely generalizability of the findings to other groups of patients beyond those who are most likely to participate in a translational or clinical research study. Then, at the minimum, collect adequate information to characterize the study population so that differences between the participants and the target population are known, and, optimally, design the study and enroll members of the target population so that differences in findings among key segments of the target population may be determined directly.

Defining the Endpoint of Interest

Once the study population is defined, a detailed definition of the endpoint of interest (*case definition*) should be developed. Depending on the translational or clinical research question, a wide range of endpoint definitions is possible in oncologic research. These include cancer-specific endpoints, such as cancer diagnosis, which can be further divided by stage (e.g., localized versus advanced stage), histology, or expression of specific receptors; cancer recurrence or progression; or cancer-specific death. Other possible endpoints include diagnosis of second cancers, death from all causes, or short- and long-term complications of treatment among cancer survivors (e.g., cognition, peripheral neuropathy, or neutropenic sepsis). Optimally, the case definition should be narrow and specific to limit the endpoint spectrum to only those relevant or believed to be relevant to the factor of interest. For the *prognosis* and *therapeutic effectiveness* examples, the endpoint definitions might be as follows:

Prognosis: Prostate cancer recurrence as defined by a rise in serum prostate-specific antigen (PSA) concentration >0.2 ng/mL on two consecutive tests, metastasis, or death from prostate cancer as the underlying cause.

Therapeutic effectiveness: Death from diffuse large B-cell lymphoma as the underlying cause.

Although the endpoint definition ideally should be narrowly defined, investigators tend to use broader endpoint definitions to increase the number of cases. In doing so, however, they may include more cases not related to the factor of interest. In the *prognosis* example, if the tissue marker is expressed only in those cases that have the potential to metastasize and cause death, then the case definition—serum PSA concentration >0.2 ng/mL on two consecutive tests, metastasis, or death from prostate cancer as the underlying cause—is a *sensitive* case definition; the investigators are unlikely to miss cases that ultimately will metastasize and result in death. On the other hand, this case definition is not very *specific*; many of the men who only have PSA recurrence might never develop metastases or die from their prostate cancer.

The undesired effect of a heterogeneous population of cases, which increases the opportunity for including cases that are not related to the factor of interest, is that the association between the factor and the endpoint will be diluted. One way to investigate the possibility of a heterogeneous case mix is to perform separate analyses by characteristics of the endpoint, for example, by PSA recurrence only or by metastasis and death from prostate cancer, or, more generally, by tumor histology, tumor-node-metastasis stage, differentia-

tion status, location in the organ, size, and known molecular markers (e.g., estrogen/progesterone receptor positivity in breast cancer, *BCL/ABL* translocation in chronic myelogenous leukemia).

Defining the Factor of Interest

As for the endpoint of interest, the factor of interest in oncologic research also can be wide-ranging, and does not need to be limited to a simple dichotomy of exposed and unexposed. Depending on the translational or clinical research question, the factor of interest can be the following:

- Exposures, whether measured in a participant's environment (e.g., air pollution, cigarette advertisements); as the participant's behaviors and their extent (e.g., pack-years of cigarette smoking, frequency of intake and dose of selenium from the diet and supplements, cancer screening uptake and frequency, frequency and dose of prescription medications, or reproductive history); or in the participant's blood or target organs (e.g., biomarkers of internal dose of selenium or DNA damage caused by ingestion of heterocyclic amines formed in charred meat)
- Markers of susceptibility, whether measured as germline genetic variation, inherited epigenetic variation (e.g., imprinting), or, possibly, family history of cancer as a surrogate for susceptibility
- Markers of biological pathways influenced by both genetic and nongenetic factors (e.g., age at menarche and menopause, circulating sex steroid hormones, or tissue cytokines)
- Characteristics of premalignant lesions, cancer cells/tumors and surrounding tissues (e.g., altered protein/receptor expression, gain or loss of CpG methylation, chromosomal aberrations, or telomere shortening) among other attributes of the individuals, their tissues, their cancers, and their environments.

In the two hypothetical translational and clinical questions, definitions of the factors of interest might be as follows:

Prognosis: Expression of the tissue marker in foci of prostate adenocarcinoma as detected by image analysis. A composite measure of immunohistochemical staining intensity and the proportion of cells staining positive is used. For possible future use in the clinic, the distribution of the composite measure is dichotomized as high versus low expression.

Therapeutic effectiveness: Carrying no copies versus at least one copy of the specified haplotype that is known to encode a catalytically more active version of the P450 enzyme. Germline DNA extracted from peripheral blood lymphocytes is used to determine haplotypes.

Note that for these particular examples, the factors of interest have been dichotomized for greater ease of description in later analytic sections, although more complicated expressions of the factors could be used (e.g., tissue marker—continuous expression or none, low, medium, high expression; haplotype—0, 1, or 2 copies).

In defining the factor of interest, investigators must consider the most relevant and feasible measure of the factor (*factor definitions*) in relation to the endpoint. For the *prognosis* and *therapeutic effectiveness* examples, the definitions of the factors of interest are relatively straightforward because the investigators can measure the most relevant factors directly at the most relevant times relative to the endpoint. In the *prognosis* example, the investigators are interested in testing whether patients with high expression of the tissue marker in the tumor are more likely than patients with low expression to have recurrences after prostatectomy. The most relevant factor of interest in this case is expression of the tissue marker in the cancer at the time of prostatectomy. In the *therapeutic effectiveness* example, the investigators are interested in testing whether patients with diffuse large B-cell non-Hodgkin's lymphoma with a particular haplotype are more likely to survive than patients without the haplotype after treatment with the new chemotherapeutic agent in combination with standard therapy. In this case, the most relevant factor of interest is a particular haplotype in the gene encoding one of the P450 enzymes. The time at which haplotypes are determined is less important because germline haplotypes remain the same throughout life.

Although the factor definitions for the hypothetical examples were relatively straightforward, there may be other situations in which the factor of interest is much more difficult to define. As an example, in a prognostic study of prostate cancer, the investigators may be interested in testing whether obesity is related to prostate cancer recurrence. However, deciding which is the most relevant measure of obesity (e.g., self-reported or measured/calculated weight, body mass index, waist-to-hip ratio, or percent body fat) and the most relevant and feasible time to measure obesity (e.g., at the time of prostatectomy, in the 10 years before prostatectomy, or in adolescence) may be difficult.

For instance, the most feasible factor for the investigators to measure might be body mass index calculated from self-reported weight and height at the time of prostatectomy, but the most relevant factor for prostate cancer prognosis might be the amount of adipose tissue at the time of prostatectomy. If the investigators choose to use the most feasible factor, then they may observe a weaker association between self-reported body mass index and prostate cancer recurrence than if they had used percent body fat depending on how well self-reported body mass index correlates with the amount of adipose tissue at the time of prostatectomy.

As a more extreme example, if the most relevant factor is the amount of adipose tissue during adolescence (at the time of prostate maturation), but the investigators choose to use the most feasible factor, then they may not observe an association between self-reported body mass index at the time of prostatectomy and prostate cancer recurrence if self-reported body mass index is not correlated (or not sufficiently correlated) with the amount of adipose tissue during adolescence. The investigators might then conclude that obesity is not associated with prostate cancer recurrence, even though obesity during adolescence might be important for prostate cancer prognosis. Therefore, the investigators must carefully consider the factor definition in relation to the proposed hypothesis. Defining and assessing the factor is an art, and may involve trade-offs in feasibility, accuracy, and relevance.

Design Considerations for Causal Inference: The Cohort Study

The typical goal of studies using epidemiologic methods, including translational and clinical studies, is to evaluate whether a factor is causally related to an endpoint of interest. Important considerations in drawing causal inferences include assessment of temporality and comparability.

Temporality

For a factor to be causally related to an endpoint of interest it must necessarily precede the occurrence of the endpoint; that is, *temporality* must be established. This is accomplished in experimental designs, whether in the laboratory or in a clinical trial, by randomly assigning a factor to laboratory animals or human participants, respectively, who do not currently have the endpoint of interest, and then observing these animals or participants over time for endpoint development. Therefore, in these designs it is clear that the factor preceded the endpoint. By contrast, in observational studies, investigators do not assign the factor to study participants. Rather, the investigators measure the existing factor status. Optimally, to establish temporality, the investigators measure the factor in individuals who have not yet experienced the endpoint of interest, but who are at risk for the endpoint, and then they follow those individuals over time for endpoint development. This design is called the *prospective cohort study* (Fig. 25-2). *Prospective* indicates that the factor status and its assessment predate the development of the endpoint. *Cohort study*

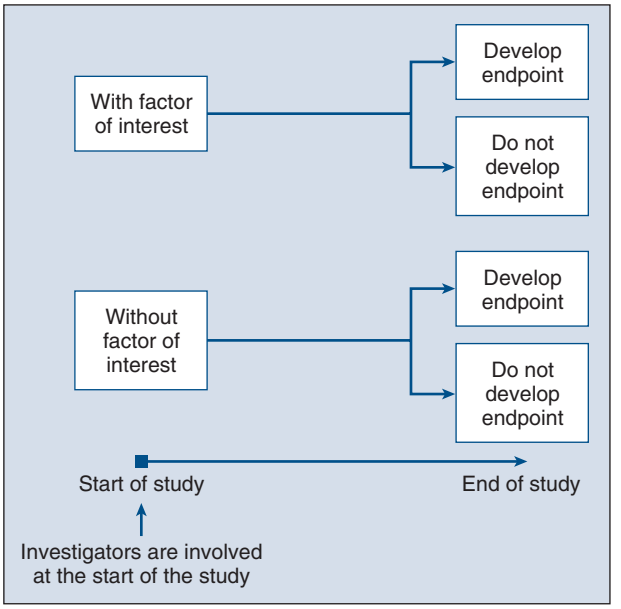

Figure 25-2 • Schematic of the prospective cohort study.

denotes follow-up of a specified group of initially endpoint-free individuals over time for endpoint development. In a simple analysis of the data from a prospective cohort study, the investigators compare the extent of occurrence of the endpoint in those with and without the factor. The prospective cohort study is the gold standard observational design. Returning to the two hypothetical translational and clinical questions, the prospective cohort design is illustrated as follows:

Prognosis: Cohort members are enrolled at the time of prostatectomy. Expression of the marker is assessed in foci of prostate adenocarcinoma from tissue resected at prostatectomy. Cohort members are followed through 2006 (maximum follow-up of 14 years) for recurrence. The frequency of recurrence is compared between those with high and low expression of the tissue marker (Fig. 25-3A).

Therapeutic effectiveness: Cohort members are trial participants randomized to the new chemotherapeutic agent arm. Presence or absence of the haplotype is determined from peripheral blood lymphocytes collected at the start of the trial. Patients are followed through to the end of the trial for death from diffuse large B-cell lymphoma. Survival is compared between those with and without the haplotype. Note that, although the parent study is a randomized clinical trial (of the efficacy of a new chemotherapeutic agent in combination with standard therapy versus standard therapy alone), this example question is not itself investigated using the randomized trial design because participants are not randomized to the factor of interest—haplotype for the gene encoding the enzyme (Fig. 25-3B).

As an alternative to the prospective cohort study design, the investigators may instead identify a cohort of individuals and reconstruct their past factor status using pre-existing records or specimens. This design is called the *retrospective cohort study* (Fig. 25-4). In this case, *retrospective* denotes that the factor status predates endpoint development, but the assessment of the factor postdates endpoint development. Otherwise the approach is the same as in a prospective

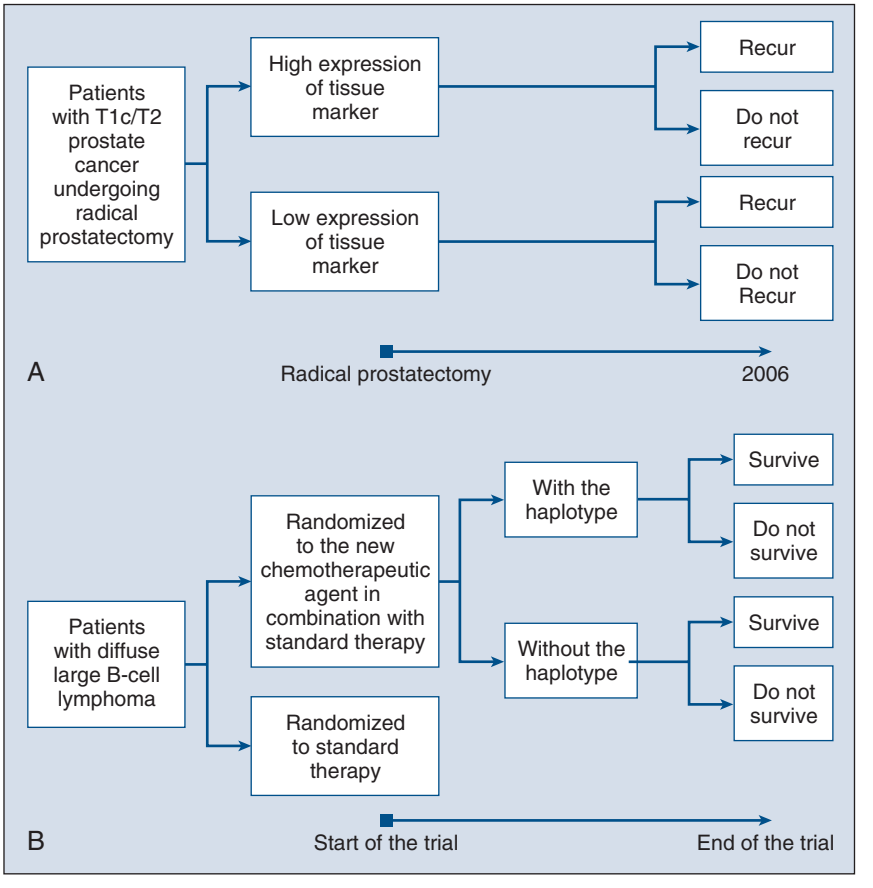

Figure 25-3 • **A,** Schematic of the hypothetical *prognostic* research question as a prospective cohort study. **B,** Schematic of the hypothetical *therapeutic effectiveness* research question as a prospective cohort study.

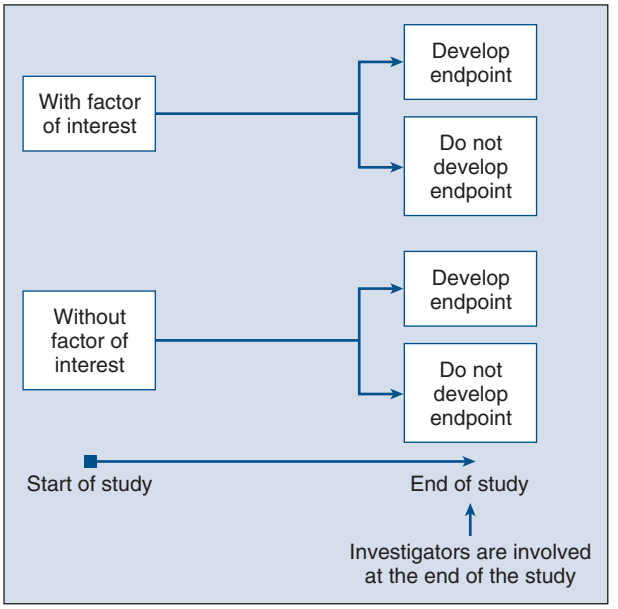

Figure 25-4 • Schematic of the retrospective cohort study.

cohort study. Returning to the hypothetical translational and clinical questions, the retrospective cohort design is illustrated as follows:

Prognosis: The investigators assemble the study population in 2007 by searching the medical records for men who underwent prostatectomy for clinically organ-confined prostate cancer between 1993 and 2002.

Therapeutic effectiveness: After the trial has finished, the investigators identify all participants in the new chemotherapeutic agent arm of the trial, and search each site of the multicenter clinical trial for blood specimens archived at the first visit of the trial.

Although the distinction may seem subtle, the major difference between the prospective and retrospective designs is the position of the investigators relative to factor assessment and follow-up for the endpoint of interest—whether the investigators (1) assemble the cohort and collect information on the factor or samples in which the factor status will be assessed at the start of follow-up, or (2) assemble the cohort sometime after the start of the follow-up and attempt to reconstruct the factor status at the time of the start of follow-up using existing records or samples. The retrospective cohort design may not be optimal because of uncertainties in factor assessment, including incomplete or missing medical or other records, and missing or degraded samples in which the factor status would have been assessed. For example, in the *prognosis* study, prostate tissue from some cohort members might no longer be available because it has already been used for other tissue studies.

A further problem with factor assessment in retrospective cohort studies is that the extent of uncertainty in the factor assessment may differ according to whether or not a participant experienced the endpoint. Say, for instance, in the *therapeutic effectiveness* example that blood specimens were not saved from the first visit of the new chemotherapeutic agent trial. In this case, investigators would have to collect blood samples from participants at a later date in the trial to determine the haplotype status of each participant. Although not consistent with the typical retrospective cohort study design, this approach still maintains temporality because germline haplotypes are present from the time of conception and are invariant throughout life and, therefore, must have preceded the endpoint of interest. However, by collecting blood at a later date in the trial, the investigators may still have introduced a distortion (*bias*) into the results of the study.

For example, suppose that absence of the haplotype is associated with shorter duration of survival after recurrence compared with presence of the haplotype. At the time of blood draw partway through the trial, proportionally more participants without the haplotype (a fact not yet known to the investigators) who had recurrences would not be able to provide a blood specimen because they had already died as opposed to those with the haplotype who had recurred, whereas there would be no difference in the ability to obtain a blood specimen from those who had not yet recurred among those with and without the haplotype. Thus, this differential inclusion of participants by both haplotype and death could then make it appear as though the haplotype were not as protective for death from lymphoma after treatment, not associated with death from lymphoma at all, or even associated with an increased risk of death from lymphoma, depending on the extent to which participants without the haplotype who died were excluded from the study because haplotype status could not be determined. For this and other reasons, investigators should think very carefully about the implications of reconstructing a cohort and its factor status to avoid biased results. Differential inclusion of participants by both the factor of interest and the endpoint of interest, as illustrated in this example, is called *selection bias*, a topic that will be discussed in the next section of the chapter.

Comparability

Another major consideration when drawing inferences from translational and clinical studies that use epidemiologic methods is *comparability* of the two (or more) groups being contrasted. To help think about comparability, consider laboratory animal experiments: the researcher has complete control over the groups being contrasted and, therefore, can make the groups as similar as possible on all aspects except for the factor of interest. The laboratory researcher typically selects genetically identical animals, assigns the factor (or treatment) to half of the animals but otherwise feeds and handles the animals in exactly the same manner, and then euthanizes the animals after a certain length of time to assess the endpoint of interest. The only difference between the two groups being contrasted is the factor of interest; that is, the two groups are comparable save the factor. When coupled with temporality (i.e., the factor/treatment was given before the endpoint occurred), comparability allows the laboratory researcher to conclude that the factor was the cause of the endpoint.

Trialists attempt to accomplish a similar objective in randomized clinical trials by assigning participants to the treatment (or other intervention) group or placebo (or standard of care) group through a random process. This process helps to ensure that participants in the treatment and placebo groups have similar distributions of known and unknown inherent and modifiable characteristics, including those related to disease incidence or prognosis. Although randomization cannot ensure comparability, the larger the number of participants randomized, the more likely it is that the two groups will have similar distributions of known and unknown characteristics. This level of comparability allows the investigators to conclude that the treatment was the likely cause of any observed differences in the occurrence of the endpoint between the two groups.

Had the investigators not used a randomized design, they would not have been able to reach such a strong conclusion about the relation between the treatment and the endpoint. If the investigators had not randomized participants, but instead had allowed patients or their oncologists to choose whether or not to take the new treatment, sicker patients (i.e., those already more likely to die of their cancers) might have been more likely to select the new therapy over the standard of care in the hope that cure might be more likely. In this case, patients receiving the new therapy would not have been comparable to patients receiving the standard of care with respect to disease prognosis. If these two groups had been compared with respect to the occurrence of the endpoint (e.g., death from cancer), as might be the case in a prospective cohort study, then the new treatment would have appeared to be less efficacious than it should. This bias is called

selection bias or *confounding by indication*. Selection bias occurs when enrollment or inclusion of individuals with and without the factor (e.g., those who selected the new treatment and those who selected the standard of care) is differentially dependent on their likelihood of developing the endpoint of interest (e.g., on their likelihood of dying from cancer).

Just as randomization helps to equalize the two groups being contrasted on disease incidence or prognosis, it also helps to equalize the two groups on all other known and unknown characteristics that also could alter the relation between a factor and an endpoint. For instance, in the preceding example, if the investigators had not randomized participants to the new treatment or standard of care, but instead had allowed them to select their treatment, patients or their oncologists might have selected treatment based on cost, rather than (or in addition to) disease prognosis. If oncologists only prescribed the new treatment to patients with higher socioeconomic status whose health insurance would be more likely to cover the cost of the expensive new treatment, and if patients with higher socioeconomic status were less likely to die from their cancer because of better diet, less adverse health behaviors, and greater access to adjuvant therapies, then the new treatment would have appeared to be more efficacious than it should simply because of differences in socioeconomic status between the two groups. In this case, socioeconomic status is called a *confounder*. Simply defined, confounders are factors that are (1) correlated with the factor of interest; (2) associated with the endpoint; and (3) not steps in the pathway in how the factor of interest influences the endpoint. In the preceding example, socioeconomic status is a confounder because it is (1) correlated with treatment; (2) associated with death from cancer; and (3) not a step in the pathway between treatment and death from cancer because it is unlikely that treatment influenced socioeconomic status, which then influenced death from cancer.

For reasons of both *selection bias* and *confounding*, randomized trials are the gold standard design for testing interventions, whether medications, devices, screening and diagnostic tests, other medical procedures and surgeries, or behavioral interventions. However, there are, of course, many circumstances in which a randomized trial would not be ethical, such as when a screening test is already in routine clinical practice, but was never formally tested for efficacy, or when the factor of interest is believed to be harmful. In addition, not all factors of interest in oncology are amenable to randomization because they are inherent characteristics of individuals or are otherwise nonmodifiable, such as family history of breast cancer, or age at menarche. In these cases, the cohort study may be an ethical alternative, and with proper design and analytic consideration, should provide sound inferences. Selection bias can be reduced in cohort studies by restricting the extent of disease among participants (e.g., by limiting the source population to a single stage at diagnosis) or by collecting detailed information on extent of disease at the start of the study, so that it may be taken into account in the statistical analysis (e.g., *adjusting* on stage at diagnosis, see the section on Comparing Two Groups: Measures of Association). Selection bias also is much less likely in cohort studies in which the baseline study population is free of a diagnosis of the endpoint of interest (e.g., a cohort of men and women who do not currently have a cancer diagnosis) as is typically the case in *etiologic studies* (i.e., studies seeking to identify the causes of an endpoint of interest). Selection bias also is less likely in prospective cohort studies than in retrospective cohort studies (see the illustration of selection bias in the retrospective cohort example of therapeutic effectiveness under the section on Design Considerations for Causal Inference: The Cohort Study).

Confounding can be minimized in cohort studies by collecting or measuring information on potential confounders, such as socioeconomic status, at the start of the study. These confounders can then be taken into account in either the design phase (e.g., by restricting to one level of the confounder—high socioeconomic status) and/or the statistical analysis of the study (by adjustment; see the section on Comparing Two Groups: Measures of Association). However, even with forethought, investigators may not always be able to anticipate all confounders or may not measure them perfectly. In such cases, residual confounding may be present and may still explain any observed associations.

Returning to the two hypothetical translational and clinical questions, randomized trials addressing the prognostic ability of the tissue biomarker or the difference in therapeutic effectiveness of the new agent by the enzyme haplotype are not feasible. Both the tissue biomarker and the haplotype are nonmodifiable characteristics of the patients' tumors or the patients themselves. Therefore, these questions are optimally addressed in cohort studies. Comparability in these example cohort studies is discussed here:

Prognosis: Patients whose prostate tumors have high and low expression of the tissue marker are made comparable with respect to a known prognostic factor, clinical stage at diagnosis, in the design phase of the study by restricting patients to only those with clinical stage T1c or T2 disease. In the conduct of the study, information is collected on pathologic stage and grade and other key prognostic factors so that they may be taken into consideration in the analysis to make those patients with high and low expression of the marker even more comparable on likelihood of recurrence. At the time of prostatectomy, demographic, anthropometric, and behavioral characteristics also are collected. These potential confounders can be taken into consideration in the statistical analysis. This level of comparability will allow investigators to determine the independent prognostic value of the tissue marker.

Therapeutic effectiveness: Although this study is embedded in a randomized trial of a new chemotherapeutic agent, the research question about the metabolic enzyme haplotype does not take advantage of the randomization. Only one arm of the trial is used: patients randomized to the new agent in combination with standard therapy. Therefore, comparability of those with and without at least one copy of the haplotype must be carefully considered. Patients with and without the haplotype are comparable with respect to histologic type of non-Hodgkin's lymphoma by design because only patients with diffuse large B-cell lymphoma were included in the trial. Participants also were required to be less than 60 years of age and to have at least two risk factors according to the Prognostic Index, making them more comparable on age and prognosis. Age, specific prognostic factors, and potentially confounding factors collected as part of the parent trial can be taken into consideration in the analysis to make those with and without at least one copy of the haplotype even more comparable on likelihood of survival with non-Hodgkin's lymphoma. This level of comparability will allow the investigators to determine the independent predictive capability of the haplotype for survival after treatment with the new agent.

Another possible source of lack of comparability common to both experimental and observational designs is *observation bias* or *information bias*. This bias occurs when the accuracy of observing the endpoint differs between those with and without the factor. One possible source of observation bias in both experimental (including randomized trials) and observational designs is differential loss-to-follow-up (i.e., loss-to-follow-up that is differential with respect to the likelihood of the endpoint of interest) between those with and those without the factor.

For example, a new complementary cancer treatment is being tested against placebo for improvement in quality of life after cancer treatment. Quality of life is assessed at the start and then again at the end of the trial. Suppose that the new treatment improves quality of life in some patients, but in many other patients quality of life dramatically declines because of an adverse response to the treatment. Those in the complementary treatment arm who experience the adverse response are much less likely to continue participating in the trial than those whose quality of life improves. In the placebo arm in which many fewer patients have dramatic declines in quality of life,

the likelihood of continued participation to the end of the trial is only slightly lower among those whose quality of life does not improve compared with those whose quality of life does improve. This bias would make the complementary treatment appear more efficacious than it is simply because patients receiving the treatment who experienced a decline in quality of life are under-represented in the analysis.

Another possible source of observation bias is detection bias or medical surveillance bias. This bias occurs when those with and without the factor of interest are surveyed for the endpoint to different degrees. For example, in a prospective study of obesity and prostate cancer recurrence, if urologists suspect that obesity may indeed increase the risk of recurrence, they might monitor obese men for a postprostatectomy rise in PSA more often than they monitor nonobese men. Thus, it may appear as though obesity is associated with earlier prostate cancer recurrence simply because obese men are monitored more frequently for recurrence.

In summary, comparability between those with and without the factor of interest is a major consideration in drawing causal inferences in studies using epidemiologic methods. To enhance comparability, investigators should think carefully about selection bias, confounding, and observation bias in the design, conduct, and analysis of their study.

Other Cohort Design Considerations

So far, the cohort design has been described as a single study population divided into those with and without the factor and then followed for the endpoint of interest. This approach of a cohort formed from a single study population is desirable because it helps to ensure that the two groups being contrasted are from a relatively homogeneous population with similar methods of factor, confounder, and endpoint assessment to enhance comparability between the two groups.

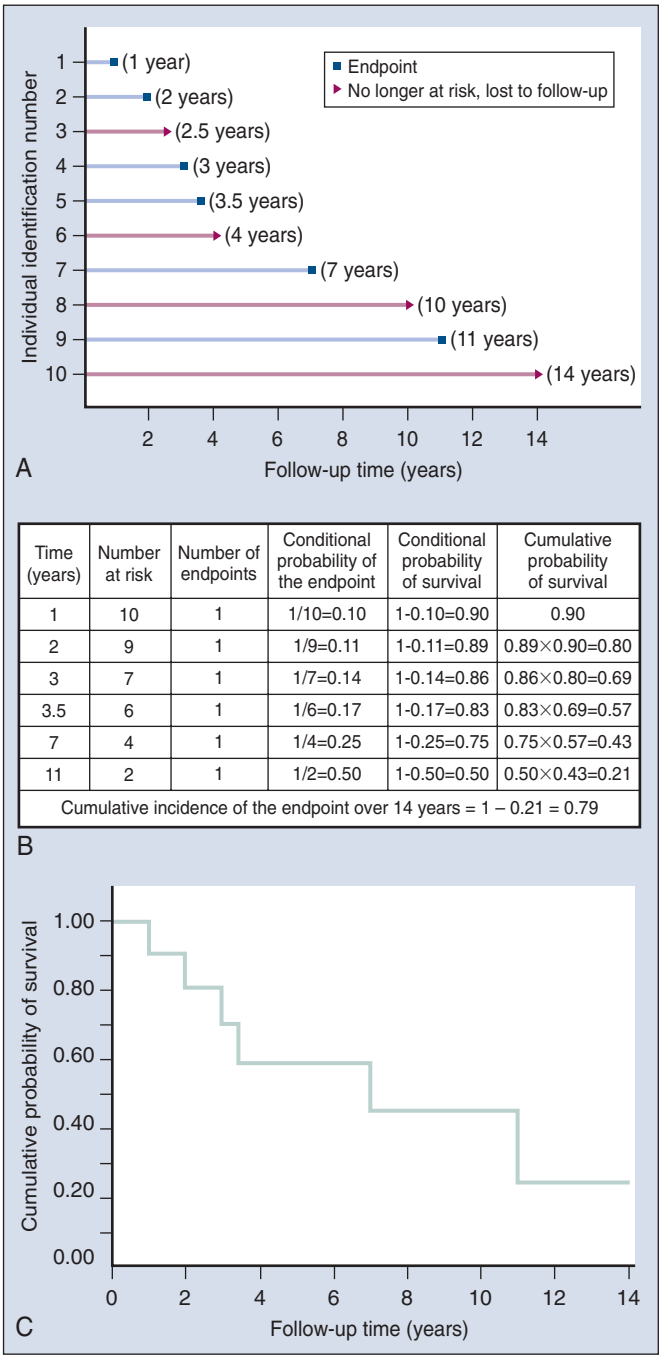
However, sometimes investigators cannot identify groups of participants with and without the factor of interest from the same population, and must resort to comparing groups from different populations. The classic example comes from cancer etiology studies in the occupational setting, in which all members of the study population have the factor of interest, such as employment at a large factory that manufactures a particular chemical. To get a sense of the risk experience the employees would have had if they had not been exposed to the chemical, an external unexposed comparison group is needed. One possible comparison group is employees at a factory that does not manufacture the particular chemical, but is otherwise similar to the factory that does manufacture the chemical. Another comparison group could be the entire population of the country in which the factory is located, if the risk of the endpoint (e.g., cancer) is known for that particular country. In using a national comparison group, investigators assume that the general population in that country is not exposed to the factor of interest and is otherwise comparable to the exposed group. This latter assumption should be carefully considered, for reasons such as the fact that workers tend to be healthier on average than the general population because they are able to work (*healthy worker effect*).

In the context of oncology, one setting in which investigators might need to use an external comparison group is in the introduction of a new cancer treatment before it is ready to be tested in a clinical trial. In this case, investigators might use a *historical comparison* group—a group of patients who were treated using the standard of care earlier in calendar time—to contrast with the current group of patients treated with the new surgical or pharmacologic cancer therapy. However, again care should be taken when comparing these two groups because of differences in the case mix and other patient characteristics over time (*secular trends*).

Statistical Analysis of Cohort Studies

Measures of the Occurrence of an Endpoint

The fundamental measure of occurrence of an endpoint (e.g., development of disease or recurrence of disease) in a study using the cohort design is the probability of the endpoint, called the *cumulative incidence* or *risk*. Most simply defined, the cumulative incidence is the number of new endpoints that occur during a particular time interval divided by the number of individuals at risk at the start of follow-up in a cohort study (or clinical trial). The numerator typically only includes new or *incident* endpoints, not existing or *prevalent* cases. In oncology, investigators usually are most interested in the first occurrence of an endpoint (e.g., cancer diagnosis or cancer recurrence). The denominator only includes those able to experience the endpoint (e.g., women who have had a hysterectomy are not at risk for endometrial cancer and would not be included in the denominator when estimating the cumulative incidence of endometrial cancer), and all of the endpoints must have arisen from among individuals at risk in the denominator. As an example of a cumulative incidence calculation, if 100 men and women were enrolled in a cohort study and 25 died by the end of 5 years of follow-up, then the cumulative incidence of death would be 25/100 or 0.25 over 5 years. The range of values for the cumulative incidence is 0 if none of the at-risk individuals experience the endpoint and 1 if all of the at-risk individuals experience the endpoint. The time interval over which the cumulative incidence is estimated must be specified: a 0.25 (or 25%) risk over 1 month is substantially larger than a 0.25 risk over the lifetime.



This simple cumulative incidence calculation assumes that all participants enter follow-up at the same time; follow-up time can be expressed as calendar time, age, or time on study (e.g., time since mastectomy irrespective of calendar year or age). It also assumes that follow-up only ends because of occurrence of the endpoint or end of the study (*administrative censoring*). In other words, participants who do not experience the endpoint of interest are assumed to remain at risk for the endpoint of interest (e.g., not die from another disease) and to remain under follow-up (e.g., not stop participating in the study) until the end of the study.

Rarely do all participants remain under follow-up until the end of the study. Some individuals may die of something other than the endpoint of interest. Others may choose not to continue participating or are withdrawn by the investigators. All of these individuals are considered lost to follow-up. In this case, the simple cumulative incidence calculation is not appropriate; the estimate will be too small because the at-risk denominator presumes that all participants were followed for the full study period.

One appropriate method to estimate cumulative incidence when there is loss-to-follow-up is the Kaplan-Meier method. This method allows all of the time during which an individual is at risk and under follow-up to be used, even for participants not observed for the full study period. The first step of the Kaplan-Meier method is to align all participants with respect to follow-up time (e.g., time since mastectomy). Then, at each time that an endpoint occurs, the probability of the endpoint is calculated among only those individuals who survived until the time of that particular endpoint (*conditional probability of the endpoint*). Lack of survival until the time that a particular endpoint occurs may be due to having already experienced the endpoint, no longer being at risk for other reasons (e.g., death from another cause). The group of individuals still at risk at the time each endpoint occurs is called the *risk set*. The next step in the Kaplan-Meier method is to calculate the probability of surviving to the time that each endpoint occurs for each of the risk sets (1 – conditional probability of the endpoint; *conditional probability of survival*). Then, the cumulative probability of survival up to the time of each endpoint is calculated as the product of the conditional probability of survival at the time of each endpoint and the cumulative probability of survival to the time of the prior endpoint.

The cumulative probability of survival over the entire follow-up period is the cumulative probability at the time of the last endpoint. The cumulative incidence over the entire follow-up period can then be calculated as the complement of the cumulative probability of survival over the entire follow-up period (1 – cumulative probability of survival; Figs. 25-5A and B). The cumulative probabilities of

survival at each time an endpoint occurs can be plotted against follow-up time to obtain the Kaplan-Meier survival curve (Fig. 25-5C). Note that survival curves may be generated for endpoints other than death; survival merely means not having had the endpoint of interest and still being at risk and under observation. Survival is assumed to be constant (flat line on the graph) until an endpoint occurs, at which time the cumulative survival drops to the value for the next interval. Direct examination of the Kaplan-Meier curve can show whether survival is constant or changes over follow-up time. In Figure 25-5C, the change in cumulative survival over the first 5 years is greater than the change in cumulative survival in subsequent years as shown by the difference in the steepness of the curve in the first 5 years compared with later years. The Kaplan-Meier curve also can be used to estimate such measures as median survival time by determining the time at which half of the population has experienced the endpoint of interest.

Time (years)	Number at risk	Number of endpoints	Conditional probability of the endpoint	Conditional probability of survival	Cumulative probability of survival
1	10	1	1/10=0.10	1-0.10=0.90	0.90
2	9	1	1/9=0.11	1-0.11=0.89	0.89×0.90=0.80
3	7	1	1/7=0.14	1-0.14=0.86	0.86×0.80=0.69
3.5	6	1	1/6=0.17	1-0.17=0.83	0.83×0.69=0.57
7	4	1	1/4=0.25	1-0.25=0.75	0.75×0.57=0.43
11	2	1	1/2=0.50	1-0.50=0.50	0.50×0.43=0.21
Cumulative incidence of the endpoint over 14 years = 1 – 0.21 = 0.79					

B

Figure 25-5 • Use of the Kaplan-Meier method to calculate the cumulative incidence of the endpoint and to plot the survival curve. **A,** Time at risk for 10 hypothetical individuals. **B,** Calculation of the cumulative probabilities of survival and incidence for the 10 hypothetical individuals. **C,** Kaplan-Meier survival curve for the 10 hypothetical individuals.

Two assumptions are made when using the Kaplan-Meier approach. The first is that individuals who do not experience the endpoint and do not survive until the next endpoint time have a similar risk of the endpoint as individuals who remain under follow-up. If this assumption is violated, then the estimated cumulative incidence will be incorrect. The second assumption is that no change in the background risk occurs over the accrual period (e.g., secular changes in the risk of cancer death might occur if there is a stage shift due to implementation of a new screening test and if this early detection followed by appropriate treatment produces longer survival than if not detected early). If this problem is present, then separate Kaplan-Meier estimates and curves should be presented for different intervals of accrual time.

Other methods of estimating cumulative incidence are available. For example, if the time that the endpoint occurs cannot be pinpointed, as may happen when cancer recurrence is detected on a blood test performed every 6 months, then the actuarial or life-table method may be used. The actuarial method is similar to the Kaplan-Meier method, except that the times of detection of the endpoints are binned into time intervals. For instance, in this cancer recurrence example, the endpoints would be binned into 6-month intervals (see Gordis[1] for further details).

Another measure of endpoint occurrence more typically used by epidemiologists is the incidence rate. When death is the endpoint, the incidence rate of death is usually called the *mortality rate*. The incidence rate conveys how fast the endpoint is occurring in a population at risk. It is used when follow-up for some participants begins later than for others or when some participants are not followed for the full study period. The incidence rate is calculated as the number of new endpoints divided by the person-time at risk. Like the cumulative incidence, the numerator is the number of incident endpoints. The denominator is the sum of the amount of time that each individual is at risk for the endpoint and is under follow-up. In Figure 25-6, individual 1 contributes 1 person-year at risk before he develops the endpoint of interest, individual 3 contributes 2.5 person-years at risk before she stops participating in the study, and individual 10 contributes 14 person-years at risk by the end of the study. Together, these 10 individuals contribute 58 person-years at risk to the denominator of the incidence rate. Whereas the cumulative incidence requires a separate specification of the relevant time period over which it applies, time is inherent in the calculation of the incidence rate. Person-time at risk may be expressed in any unit of time—years, months, weeks, seconds—although person-years are most often used for cancer incidence, recurrence, and death. The incidence rate may range from 0 per person-time if no endpoints occur during follow-up to infinity per person-time if one or more endpoints occur during the briefest instant of follow-up.

As for the calculation of cumulative incidence, several assumptions are made in calculating the incidence rate. The first two assumptions are the same as for the cumulative incidence: (1) individuals who do not experience the endpoint and do not survive until the next endpoint time have a similar risk of the endpoint as individuals who remain under follow-up; and (2) no change in the background risk occurs over the accrual period. A third assumption in calculating the incidence rate is the equivalence of person-time at risk over time and across individuals; that is, 1 person-year contributed by individual 10 during the first year of follow-up is the same as 1 person-year contributed by individual 10 during the last year of follow-up. Likewise,

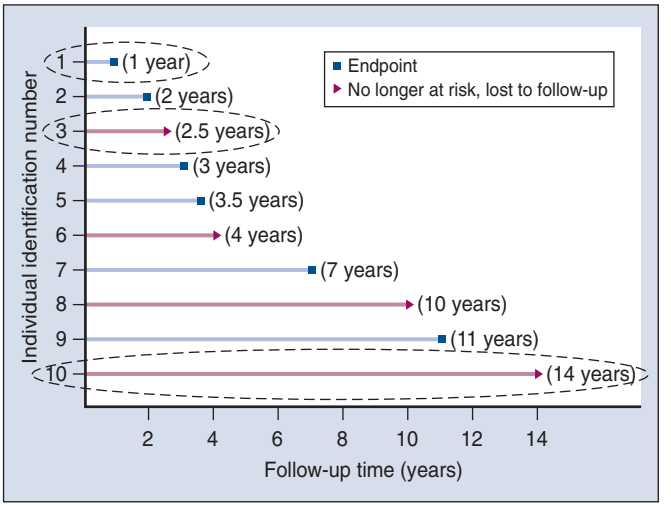


Figure 25-6 • Time at risk for 10 hypothetical individuals. Individual 1 contributes 1 person-year at risk before he develops the endpoint of interest; individual 3 contributes 2.5 person-years at risk before she stops participating in the study; and individual 10 contributes 14 person-years at risk by the end of the study.

any year contributed by individual 5 is the same as any year contributed by individual 7. When this equivalence does not hold, for example when the incidence rate differs by age or calendar time and/or by characteristics of the participants, then separate incidence rates should be calculated by categories of age, time, or participant characteristics.

A third measure of endpoint occurrence is the *hazard*, which is defined as the instantaneous occurrence of the endpoint among those still at risk. Although commonly calculated as part of a ratio (*hazard ratio*), the hazard itself is calculated very rarely because of complexities involved with the calculation.

When should the cumulative incidence versus the incidence rate be presented as the measure of endpoint occurrence? It depends on the goal of the research. If investigators would like to generate information useful for communicating to patients (e.g., What is the likelihood that my cancer will recur after I am treated?), then the cumulative incidence might be the most useful measure. When communicating this measure to patients, oncologists also should make it clear that the cumulative incidence is not specific to any one particular patient, but instead refers to the average cumulative incidence in a group of patients with similar characteristics. The incidence rate typically is calculated in the context of etiologic studies. The risk and the rate are mathematically related, and with certain assumptions, the cumulative incidence can be estimated from the observed incidence rates (see Rothman[2] for further details).

Comparing Two Groups: Measures of Association

Testing a hypothesis usually involves comparing the occurrence of the endpoint in two or more groups that differ on a factor of interest. One approach is to compare the survival curves generated from the Kaplan-Meier method between individuals with and without the factor of interest. The statistical test used to determine whether the survival curves are likely different from each other is called the *log-rank test*.

Sometimes investigators would like to know more than merely whether or not the survival experiences between the two groups differ. Instead, they may want to quantify the magnitude of this difference. If the endpoint experiences of the two groups are expressed as cumulative incidences (calculated from the Kaplan-Meier or other methods) or rates, then either the ratio or the difference of these measures may be calculated. Ratio measures include the *cumulative incidence ratio*, *rate ratio*, or *hazard ratio*, collectively known as the *relative risk* (RR) of the endpoint. The RR is calculated as follows:

Cumulative incidence ratio =
(cumulative incidence in group 1)/(cumulative incidence in group 2)

Rate ratio = (incidence rate in group 1)/(incidence rate in group 2)

The hazard ratio rarely is calculated directly because, as stated in the previous section, individual hazards are difficult to calculate.

The order of the two groups being compared in the calculation of the RR has direct bearing on its interpretation. Typically, in studies using epidemiologic methods, investigators are particularly interested in the endpoint experience in one group, the group with the factor of interest, as compared with a second group, the group without the factor of interest. In this case, the investigators would calculate the RR as follows:

RR = (occurrence of the endpoint in the group with the factor)/
(occurrence of the endpoint in the group without the factor)

Alternatively, investigators might be interested in comparing those without the factor of interest to those with the factor. The choice of which group belongs in the numerator of the ratio and which belongs in the denominator depends on the statement of the research question. For instance, in the *prognosis* example, the investigators asked whether high expression of the tissue marker is associated with greater prostate cancer recurrence; thus, they would calculate the RR as the cumulative incidence of prostate cancer recurrence in patients with high expression of the tissue marker divided by the cumulative incidence of prostate cancer recurrence in patients with low expression of the tissue marker. If the cumulative incidence were higher among patients with high expression than among patients with low expression, then the RR would be greater than 1 and the magnitude of the RR would indicate how many times higher the cumulative incidence of recurrence was in those with high expression than in those with low expression of the tissue marker (i.e., it would indicate the *strength of the association*). If contrary to the hypothesis, the cumulative incidence were lower among patients with high expression than among patients with low expression, then the RR would be less than 1 and the magnitude of the RR would indicate how many times lower the cumulative incidence of recurrence was in those with high compared with low expression. The RR is unitless and can range from 0 to infinity.

Measures of the difference in the occurrence of the endpoint include the *cumulative incidence difference* and *rate difference*, collectively known as the *risk difference*. The risk difference is calculated as follows:

Cumulative incidence difference = (cumulative incidence in group 1) − (cumulative incidence in group 2)

Rate difference = (incidence rate in group 1) − (incidence rate in group 2)

As for the RR, the order of the two groups also is important in the interpretation of the risk difference. Typically, investigators calculate the risk difference as the occurrence of the endpoint in the group with the factor of interest minus the occurrence of the endpoint in the group without the factor of interest. The cumulative incidence difference and rate difference have the same units as the cumulative incidence and rate, respectively. The cumulative incidence difference can range from −1 to 1, while the rate difference can range from minus infinity to positive infinity.

Whereas the RR often is calculated in studies using epidemiologic methods, the risk difference is calculated less often. It usually is calculated only when the factor has been identified as a likely cause of the endpoint and when the absolute size or burden of the endpoint attributable to this factor is of interest. For this reason, the risk difference also is known as the *attributable risk*. Another way to interpret

the attributable risk is the extent of occurrence of the endpoint that would have been avoided in individuals with the factor if they had never experienced the factor. Note that a high RR does not necessarily imply a high attributable risk. If, for instance, the cumulative incidence in those with the factor is 1 in 10,000,000 people over the lifetime and the cumulative incidence in those without the factor is 1 in 100,000,000 people over the lifetime, then the RR is 10 (large), but the attributable risk is only 9 in 100,000,000 over the lifetime (small). Sometimes the *population attributable risk percent* is reported as a measure of a population's excess burden due to some members of the population having the factor of interest. Another way to view this measure is the proportion of the occurrence of the endpoint that would have been avoided in a population if individuals with the factor had never experienced the factor. The population attributable risk percent is calculated as the cumulative incidence (rate) in the total population minus the cumulative incidence (rate) in those without the factor all divided by the cumulative incidence (rate) in the total population.

As alluded to in the discussion of comparability, it may be necessary to take potentially confounding factors into account in the estimation of the RR or the risk difference. Two main statistical approaches may be used: stratification or adjustment. *Stratification* involves estimating the RR or risk difference in categories of the potential confounder known as *strata*. Within each stratum of the confounder, all individuals have the same confounder status, and thus the stratum-specific association between the factor of interest and the endpoint is independent of the confounder. If an unconfounded summary estimate of the RR or risk difference is desired, then the summary estimate can be calculated as the weighted average (often using Mantel-Haenszel weights) of these independent stratum-specific estimates. Note that age-standardization, which is used routinely to adjust cancer incidence and mortality rates for confounding by age (because different populations may have different age structures), is merely a form of stratification with weights derived from a specified standard population, such as the 2000 U.S. Census Population as used by the National Cancer Institute's Surveillance, Epidemiology, and End Results Program (*http://seer.cancer.gov/*) or the World Standard Population as used by the World Health Organization (Globocan: *http://www-dep.iarc.fr/*).

Another statistical method that takes confounding into account is adjustment using regression techniques. Detailed descriptions of regression models can be found in biostatistics textbooks. Briefly, choice of the appropriate regression model is determined by the nature of the endpoint of interest. For instance, is the endpoint binary? This often is the type of endpoint studied in oncology (e.g., cancer diagnosis or cancer recurrence). Currently, there are no straightforward methods for modeling the cumulative incidence ratio when some participants are lost to follow-up, and thus it is difficult to calculate an adjusted estimate of association. If, instead, the rate ratio or the hazard ratio is the desired measure of association, then either Poisson regression or Cox proportional hazards regression, respectively, can be used to calculate adjusted estimates. The Cox model circumvents difficulties in directly estimating individual hazards by allowing the unmeasured hazard in those without the factor to vary from moment to moment, and then assuming that the ratio of the hazards in those with and without the factor is constant, allowing it to only estimate the hazard ratio.

Design Considerations for Causal Inference: Alternative Prospective Designs

Nested Case-Control Study

So far, this chapter has discussed only the cohort approach to addressing research questions. However, sometimes it is not feasible to evaluate the factor status of each participant in the cohort study, for example, when the factor is assessed using an expensive or labor-intensive method.

In this case, alternative prospective epidemiologic designs can be used that maintain the correct temporal sequence between the factor and the endpoint, but use a smaller sample size—the nested case-control study and the case-cohort study. In these designs, all individuals in the cohort must still be followed for the endpoint of interest, and material—either biological (e.g., blood specimen) or physical (e.g., paper medical records)—from which to ascertain the factor must be collected before the endpoint occurs. In the nested case-control study (Fig. 25-7), all individuals who develop the endpoint of interest (or a random sample of these individuals) are selected as *cases*. Then, at each time that a case occurs, one or more individuals are randomly selected from the *risk set*, which consists of those who have not yet developed the endpoint and who are still at risk and under follow-up. These individuals are called *controls*. Only these cases and controls are then tested for the factor of interest.

Looking at Figure 25-7, at the time that individual 1 recurs, individuals 2 through 10 are still at risk of recurrence and under follow-up. Individual 9 is randomly selected to be the control. At the time that individual 4 recurs, individuals 5 through 10 are still at risk of recurrence and under follow-up. Individual 6 is randomly selected to be control. This method of control sampling is called *incidence density sampling*. Note that an individual who later becomes a case may be sampled earlier as a control for another case (individual 9). Additionally, the same individual may be sampled as a control for more than one case. Individual 9 could have been sampled as a control for both case 1 and case 4.

To help illustrate why this sampling approach is correct, consider how in the Kaplan-Meier method the conditional probability of the endpoint is estimated at each endpoint time as the number of cases divided by the number of individuals still at risk and under follow-up; that is, each individual contributes to the estimate of the conditional probability at each time that an endpoint occurs, including individuals who later become cases. In the nested case-control study, each control is sampled from the risk set to reflect the risk of the members of the risk set. As in the Kaplan-Meier method, each individual still at risk and under follow-up has the opportunity to be sampled each time an endpoint occurs.

To enhance the statistical ability to adjust for confounding, control subjects often are sampled such that they have characteristics similar to the cases, a process called *matching*. In a nested case-control study with incidence density sampling of controls, cases and controls are necessarily matched on follow-up time by design. Note that statistical analysis of matched cases and controls should take into account

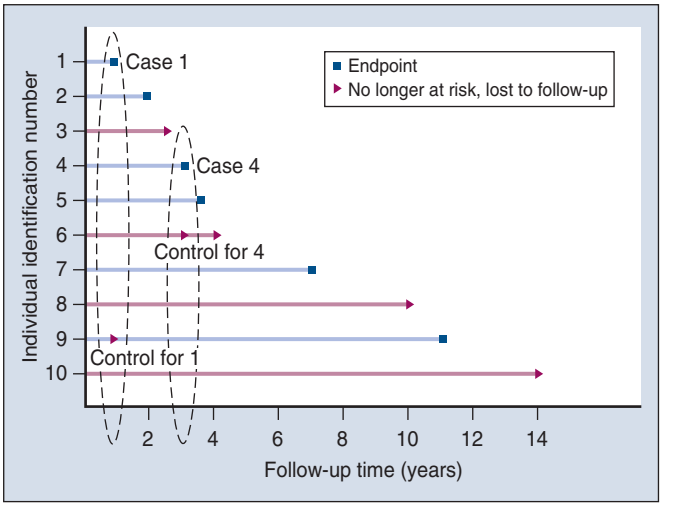

Figure 25-7 • Schematic of a nested case-control study within a prospective cohort of 10 hypothetical individuals. All cases are sampled. A subset of all possible controls is sampled using incidence density sampling.

the matched design (see section on Statistical Analysis of Case-Control Studies). Despite the incorrect common belief that matching itself enhances comparability and reduces confounding, not considering the matching in the analysis may produce a biased estimate of the association.

Rather than selecting controls from the risk set, it might be tempting to select controls from among individuals who never experience the endpoint of interest by the end of cohort follow-up (i.e., not matched on follow-up time). For two reasons, this approach is not optimal. First, because of the requirement that individuals sampled as controls remain free of the endpoint until the end of follow-up, they are less likely to include individuals who later become cases than incidence density sampled controls, who are required to be free of the endpoint only until the time of case diagnosis. Thus, if the factor of interest is associated with the endpoint, then the prevalence of the factor will be even lower (if the factor increases the risk or even higher if the factor decreases the risk) in controls selected from the end of follow-up than in controls selected at the time of case diagnosis. This lower prevalence of the factor results in an overestimation of the true rate/hazard ratio (see section on Statistical Analysis of Case-Control Studies).

The second reason that selecting controls at the end of study follow-up is not optimal is that, because controls are required to remain free of the endpoint until the end of follow-up, they also typically are required to remain alive for a longer period of time than cases who may die after their diagnosis. Therefore, if the factor of interest is associated with longevity, then investigators may observe an association between the factor of interest and the endpoint simply because controls are required to remain alive for a longer period of time than cases. This bias is called *survival bias*.

Case-Cohort Study

Another alternative to the prospective cohort design is the case-cohort design. It is used in the same settings as the nested case-control study, albeit less frequently, because in the past software to analyze data from this design was not readily available. In the case-cohort study (Fig. 25-8), the entire cohort is followed for the endpoint of interest, and material from which to ascertain the factor is collected before the endpoint occurs for all individuals. Then, individuals who develop the endpoint of interest (or a random sample of these individuals) are selected as cases. Next, a random sample (or random samples within categories of characteristics) of the entire cohort at the start of the study is selected and called the *subcohort*. All of the cases and all of the members of the subcohort are tested for the factor of interest. Looking at Figure 25-8, at the time that individual 6 recurs, individuals 7 through 15 in the subcohort are still at risk and under follow-up. Thus, individual 6 is compared to individuals 7 through 15, but not to individuals 1 through 5, who are not members of the subcohort. At the time that individual 1 recurs, individuals 7 through 15 in the subcohort are still at risk and under follow-up. In this case, individual 1 is compared with individuals 7 through 15. Thus, similar to controls in nested case-control studies, members of the subcohort in any given risk set are used to reflect the risk of all members in the entire cohort who would have been in that risk set. However, in contrast to the nested case-control setting, a greater number of individuals typically are used to reflect the risk set in the case-cohort setting than in the nested case-control setting.

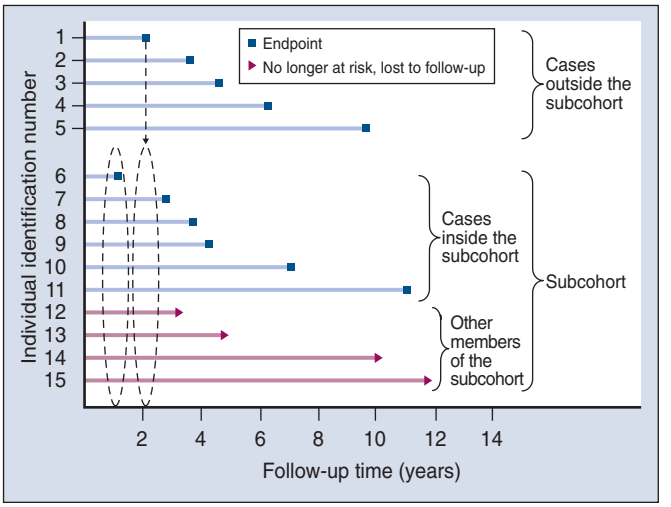

Figure 25-8 • Schematic of a case-cohort study within a prospective cohort of 10 hypothetical individuals. All cases are sampled. A subset of the entire cohort at baseline is sampled.

When should a case-cohort design be used instead of a nested case-control design? If investigators have several endpoints of interest, it might be more cost-effective to use a case-cohort design in which the subcohort can be used to reflect the risk experience of the entire cohort for multiple case groups rather than selecting a separate control group for each case group as would be done in a nested case-control study.

Statistical Analysis of Alternative Prospective Designs

Data from both the nested case-control and case-cohort approaches require special analytic techniques, conditional logistic regression, and Cox proportional hazards regression with a variance correction, respectively. The measures of association estimated from these data approximate the hazard ratio. Adjustment for potentially confounding factors in these models is done as usual.

Design Considerations for Causal Inference: The Case-Control Study

Thus far, all of the epidemiologic study approaches described have been variations on the cohort design. However, the cohort design often is not practical or feasible in oncologic research, for example when the source population is not enumerable, when the endpoint of interest is very rare, or when investigators do not have time to wait until enough endpoints have accrued in a cohort. For these reasons, investigators may choose to use the case-control design (Fig. 25-9). In this design, cases are individuals with the endpoint of interest, and controls are individuals who do not have the endpoint, but are at risk for its occurrence. Once cases and controls have been identified, the factor of interest is assessed at the time that the case or control is ascertained for the study. Thus, in contrast to prospective designs in which assessment of current or prior factor status is made before the case is diagnosed, in case-control designs, assessment of current or prior factor status is made *after* case diagnosis. Controls are used to obtain an estimate of the prevalence of the factor in the source population at risk for the endpoint.

In case-control studies, cases may be identified from several different sources: hospitals and clinics, community outreach screenings, and cancer and other state and national registries. Controls may be identified from those same sources, as well as from other types of registries, such as drivers, voters, population (e.g., in Scandinavia), and the Centers for Medicare and Medicaid Services (United States), or from a general population using mechanisms such as random-digit dialing. Two classic types of case-control studies have been defined: hospital (clinic)-based and population-based. In a hospital-based case-control study, cases and controls are sampled from the same practice, clinic, hospital, or medical care system. Typically, controls are individuals diagnosed with conditions other than the endpoint of interest that are thought not to be related to the factor of interest (i.e., the prevalence of the factor in the controls is expected to be the same as in the source population). This assumption can be difficult to prove, and, if incorrect, can lead to a biased estimate of the association between the factor and the endpoint. In a population-based case-control study, cases and controls are sampled from the same catchment area or the general population. For instance, cases may be

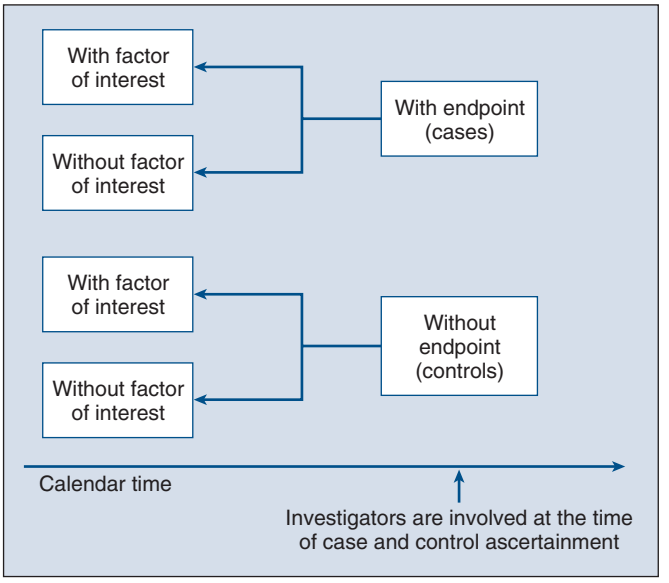

Figure 25-9 • Schematic of a case-control study.

sampled from a community hospital, and controls may be randomly sampled from the residents of the hospital's catchment area. Alternatively, cases may be sampled from a state cancer registry and controls may be sampled from residents of the state by random-digit dialing.

The factor of interest and its extent may be assessed using several possible methods. These include review of medical records, interview or administration of a questionnaire, or measurement of biological specimens, again at the time of ascertainment of the cases and controls.

As a simple illustration of the case-control design, consider a new hypothetical research question addressing second cancer risk:

To appropriately counsel women diagnosed with premenopausal breast cancer, oncologists would like to know whether these women have a higher risk of developing ovarian cancer than women not diagnosed with premenopausal breast cancer. If oncologists do not have access to a large cohort of women with information on breast and ovarian cancer diagnoses, then they may consider conducting a case-control study to address their research question in a faster and less expensive way than might be done if they developed a new prospective cohort study. In this case, the investigators would identify cases of ovarian cancer and controls without ovarian cancer and then ascertain the women's prior history of premenopausal breast cancer. Incident cases of ovarian cancer could be identified from the state cancer registry during a specified number of years, and controls free of a diagnosis of ovarian cancer could be identified from random-digit dialing of state residents who must have been residing in the state during the same time interval as the cases. Both cases and controls could then be sent a questionnaire asking them about their prior history of premenopausal breast cancer, and medical record information could be requested to confirm any reported diagnoses.

At first glance, the case-control design might appear simple and thus, straightforward to conduct. Oncologists have access to cases and "just need to find some controls." In fact, studies of this design require substantial forethought in sampling cases and controls and in assessing the factor of interest to avoid inaccurate results. Thinking back to the cohort design, two considerations for causal inference were described—temporality and comparability.

Temporality

In the case-control design, temporality cannot be ensured because the factor is determined at or after the occurrence of the endpoint of interest, rather than before the occurrence of the endpoint. For example, if investigators collect information about cases' and controls' recent history of the factor, they may not capture the relevant factor status because cases may have changed their factor status as a result of having experienced the endpoint (e.g., cases may change their diet near the time of recurrence due to prodromal symptoms). Likewise, high-grade tumors (cases) may have higher expression of a biomarker (factor of interest) in tissue removed at surgery than low-grade tumors (controls) because the tumor influenced the production of the factor, rather than the factor influencing the development of high-grade disease.

Comparability

In contrast to cohort studies, where *comparability* refers to similarity of those with and without the factor of interest, in case-control studies it refers to similarity of those with and without the endpoint of interest. Comparability encompasses similarity in (1) recruitment from the source population; (2) assessment of the factor of interest; and (3) assessment and handling of confounders. Pertinent to recruitment from the same source population, a classic problem in case-control studies is selection bias, which occurs when inclusion of individuals with and without the endpoint is differentially dependent on whether or not they have the factor of interest. Recall that selection bias in a cohort study occurs when inclusion of individuals with and without the factor is differentially dependent on their likelihood of developing the endpoint of interest. In a case-control study, selection bias can result from differences in the mechanisms and timing of selection of cases and controls. Selection bias can be induced unwittingly by the investigators or by mechanisms beyond the control of the investigators.

Ideally, controls should be sampled at the same time (or during the same interval of time) as cases (Fig. 25-10) to avoid differences in the factor experience of the source population over time. Time refers to the most relevant time axis, for instance, calendar time, age or time since cancer treatment. Looking at Figure 25-10, the source population can be visualized as an at-risk cohort, although the cohort is not enumerated and the cohort members are not observable during their entire time at risk. At the time that individual 5 develops the endpoint, individuals 2 and 8 are eligible to serve as controls because they have not yet developed the endpoint. Individual 8 might be selected as a control. Note how similar this diagram is to earlier diagrams of the Kaplan-Meier method and the nested case-control study design. To illustrate this sampling scheme, consider the second cancer example:

Cases are women recently diagnosed with ovarian cancer identified from a state cancer registry. At the time (i.e., calendar time) that each case is diagnosed, investigators select a woman who is the same age as the case (±2 years) and who has not been diagnosed with ovarian cancer to serve as the control from the female population of the state obtained through random-digit dialing. In this way, cases and controls are matched on both age and calendar time and, thus, should have a similar opportunity to develop premenopausal breast cancer and ovarian cancer.

Sometimes in oncologic case-control studies, controls are selected after ascertaining cases for practical reasons (Fig. 25-11). For instance, in the second cancer example, it may take investigators 10 years to identify a sufficient number of cases because ovarian cancer is a relatively rare cancer. Investigators may decide that it is too time-consuming and expensive to ascertain controls at the same time as cases. Instead, they may decide to sample controls after all of the cases have been ascertained. However, by sampling controls later in calendar time than cases, controls may not necessarily be sampled from the same source population as cases because time has elapsed. This sampling scheme may lead to at least two possible biases. The first is selection bias due to secular trends in factors or confounders not recognized, and therefore not measured, by investigators. For instance, in the second cancer example, if the investigators were not aware that

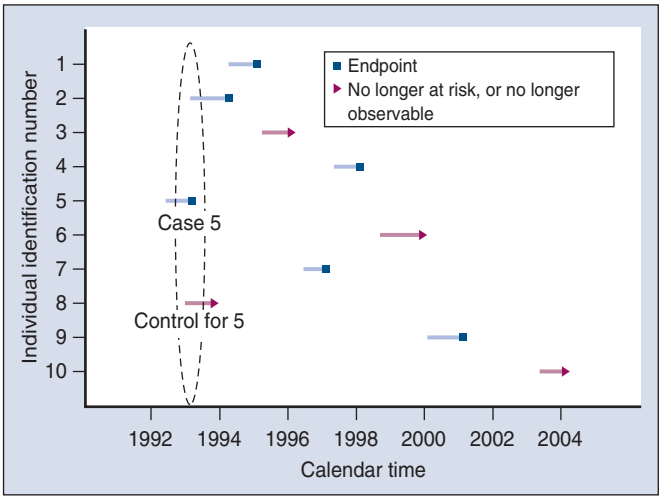

Figure 25-10 • Schematic of a case-control study in which controls are sampled at the same time as the cases.

a mammography campaign had been introduced into the state in the last 3 years of the study, they might observe a higher prevalence of prior premenopausal breast cancer among controls than among cases simply because controls would have been more likely than cases to be screened during the mammography campaign and to have occult breast cancer diagnosed before enrollment in the study.

A second example of selection bias related to sampling controls at a later date than cases is *survival bias*. This bias is the same as the one described earlier (see discussion of Nested Case-Control Study under Design Considerations for Causal Inference: Alternative Prospective Designs) and occurs when the factor of interest is associated with longevity, but not necessarily with the endpoint of interest. In this case, investigators may observe an association between the factor and endpoint merely because controls are required to remain alive for a longer period of time (i.e., to an older age) than cases.

Even if cases and controls are sampled at the same time, selection bias still may be introduced if cases and controls are recruited from different source populations. Consider the second cancer example redesigned as a hospital-based case-control study. Instead of selecting ovarian cancer cases from a state cancer registry and controls from the general population, investigators might decide to select cases and

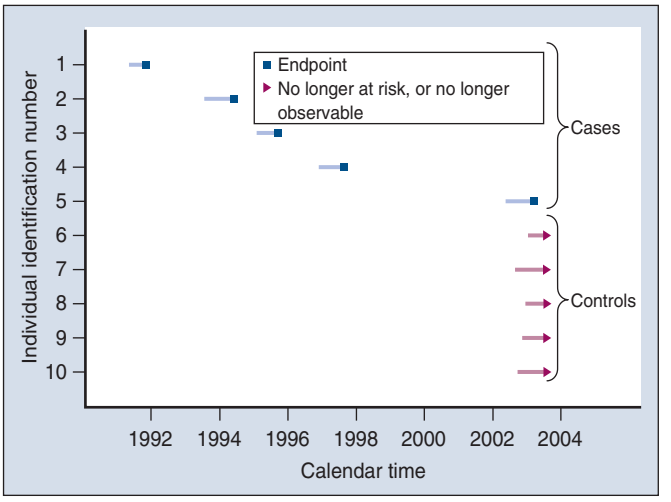

Figure 25-11 • Schematic of a case-control study in which controls are sampled after the cases.

controls from an academic medical center with a large high-risk ovarian and breast cancer clinic. Cases might be defined as women recently diagnosed with ovarian cancer at the high-risk ovarian and breast cancer clinic because it is a convenient source of ovarian cancer cases. Controls might be defined as similarly aged women attending the medical center for minor foot surgery. Cases and controls appear to be sampled from the same source population, namely, the same academic medical center. However, they actually are sampled from two different source populations: cases are sampled from a source population enriched with women with a prior history of premenopausal breast cancer because they are visiting the high-risk clinic, whereas controls are not enriched with women with a prior history of premenopausal breast cancer because they are not visiting the high-risk clinic. Therefore, even if premenopausal breast cancer truly is associated with subsequent development of ovarian cancer, the association will be incorrectly too large because cases and controls were sampled from two different source populations. A better choice of controls for these cases would be other similarly aged women attending the same high-risk ovarian and breast cancer clinic who have not been diagnosed with ovarian cancer.

Another example of selection bias is *detection bias* or *medical surveillance bias*. This bias occurs when those subjects with the factor of interest are more or less likely to be screened or investigated or otherwise more or less likely to have the endpoint detected than those without the factor of interest. In the second cancer example, physicians may screen women with premenopausal breast cancer more often for other types of cancer, such as ovarian cancer, than women without a diagnosis of breast cancer. If investigators do not take differences in ovarian cancer screening into account, then they may observe a higher prevalence of prior premenopausal breast cancer among cases than among controls simply because women with a diagnosis of premenopausal breast cancer are more heavily screened for ovarian cancer than women without a diagnosis of breast cancer.

A further example of selection bias is another form of *survival bias*. This bias occurs when those with the factor of interest have a different likelihood of being ascertained for the study than those without the factor, usually when the factor affects the likelihood of surviving long enough to be enrolled in the study (e.g., to complete a questionnaire or to collect biological samples). In the second cancer example, some women may be too sick or may have died from their ovarian cancer before investigators have the chance to mail them a questionnaire. In this case, only women who live a sufficiently long time after their diagnosis will be able to complete the questionnaire. Therefore, investigators may falsely attribute factors associated with shorter or longer survival following the endpoint to the development of the endpoint itself. Optimally, cases should be ascertained soon after they experience the endpoint of interest; enrolling incident rather than prevalent cases avoids this bias.

In addition to bias introduced in the process of case and control recruitment, bias also can be introduced at the time of factor assessment. This bias is called *observation bias*, and it occurs when the accuracy of assessing the factor of interest differs by case and control status. Sources of observation bias in case-control studies are plentiful. Two examples are given here. Cases may report their factor history more accurately than controls because they are seeking to explain their disease or are more willing to admit their factor history; this form of observation bias is called *recall bias*. One way to reduce the potential for recall bias is to blind cases and controls to the study hypotheses or to ascertain the factor status very soon after diagnosis to reduce the amount of time that the subject can contemplate his or her diagnosis. Recall bias is not the inability to accurately remember one's past factor history; this is merely poor recall. The key to recall bias is that the accuracy (or inaccuracy) of the recollection differs between those with and without the endpoint. Another example of observation bias is when an interviewer prompts cases more than controls, resulting in a more complete factor

history for cases. This form of observation bias is called *interviewer bias*, and can be minimized by blinding the interviewer to case-control status.

As in cohort studies, confounders also may contribute to lack of comparability, although, in this case, it is comparability between cases and controls. In case-control studies, confounders are handled in the same way as in cohort studies. To address confounders in a case-control study, investigators should collect information on potential confounders from cases and controls at the time of enrollment and then take these variables into consideration in the analyses (see the section on Statistical Analysis of Case-Control Studies). However, sometimes the distribution of these potentially confounding variables is very different between cases and controls, making it difficult to take these variables into account using statistical methods. One way to make the distributions of these potentially confounding variables more similar between cases and controls is to match controls to cases on these confounders and then analyze the data, taking into consideration the matching. Matching can be done at the individual level (*individual matching*), where each control is matched to one particular case on potential confounders (including time axes such as age), or at the group level (*frequency matching*), where controls are selected to have the same distribution of potential confounders as the entire group of cases. Matching enhances the ability to take these variables into account in the analysis, but, as noted previously, matching does not eliminate confounding. If cases and controls were matched on a true confounder and the data were not analyzed taking into consideration the matching, the results would be attenuated. The reason for this attenuation is that matching cases and controls on a third factor that is also correlated with the factor of interest (i.e., the confounder) makes cases and controls more similar on the factor of interest. Therefore, an analytic approach that focuses on the remaining differences between cases and controls is necessary.

Other Design Considerations In Case-Control Studies

Stated colloquially, the general principle guiding the design of case-control studies is: whatever investigators do to cases they must also do to controls. Stated more formally, selection of cases and observation of their factor and confounder status should be the same as selection of controls and observation of their factor and confounder status to reduce the possibility for selection bias, observation bias, and confounding.

There are very occasional exceptions to this statement. One is sampling of cases and controls from different source populations in studies of genetic variation and cancer. For example, in a study of polymorphisms (on chromosomes other than X and Y) in relation to testicular cancer, women could potentially be sampled as controls if they were sampled from individuals with the same racial and ethnic heritage as testicular cancer cases (to minimize confounding by race/ethnicity, i.e., *population stratification*), and if they were matched to cases on age (to minimize survival bias). Even though women are not at risk for testicular cancer, and thus are not in the same source population as cases, they could potentially still provide a valid estimate of allele frequencies in the source population that gave rise to the cases. However, investigators should still think very carefully about other potential differences between testicular cancer cases and female controls that might distort the relationship between polymorphisms and testicular cancer.

In contrast to the preceding example, blood bank donors, a convenient source of controls, may not provide a valid estimate of allele frequencies in the population that gave rise to the cases. Blood donors must meet very restrictive eligibility criteria, which may be related to their factor experience, such as susceptibility to infection, risk-taking behaviors, altruism, and so on. Therefore, in general, extreme caution must be taken in using controls that, from the outset, are clearly not from the source population that gave rise to the cases.

Statistical Analysis of Case-Control Studies

Due to differences in the design of case-control and prospective studies, data from case-control studies must be analyzed differently than data from prospective studies. In a case-control study, investigators decide how many cases and controls to sample. Typically, investigators do not select all possible cases and controls from the source population. More often, they select a sample of possible cases and controls, often with a greater sampling fraction for cases than controls. Therefore, even if lack of temporality were not of concern, cumulative incidences (or rates) could not be calculated from case-control data, because investigators set the number of cases relative to controls in the study. For example, in a source population that consists of 1000 people followed for 1 year, of whom 100 develop the endpoint and 900 do not (assuming no losses to follow-up), investigators might sample all of the cases (n = 100, 100% sampling fraction) and an equal number of controls (n = 100, 11% sampling fraction) for their case-control study. If investigators were to calculate a cumulative incidence based on these case-control data, the incorrectly calculated measure would be 100/(100 + 100) = 0.5 over 1 year, whereas the true cumulative incidence of the endpoint is actually 100/1000 = 0.1 over 1 year.

Instead of the cumulative incidence (or rate), the odds of the factor should be calculated in case-control studies in which cases and controls are not matched. The *odds* is the ratio of the probability of having the factor of interest divided by the probability of not having the factor:

$$\text{Odds} = P_F/(1 - P_F),$$

where P_F means the probability of having the factor and $1 - P_F$ means the probability of not having the factor.

The odds can range from 0 when the probability of the factor is 0 to infinity when the probability of the factor is 1. One odds is calculated for cases and another one for controls. Then, to determine the association between the factor of interest and the endpoint, the ratio of the two odds—or the *odds ratio* (OR)—is calculated as follows:

$$\text{OR} = [P_{F|case}/(1 - P_{F|case})]/[P_{F|control}/(1 - P_{F|control})]$$

To illustrate using the second cancer example, the probability of a prior history of premenopausal breast cancer is 15% or 0.15 in ovarian cancer cases and 0.08 in controls without ovarian cancer. The odds of prior premenopausal breast cancer in cases is thus 0.15/0.85 = 0.1765, and the odds of prior premenopausal breast cancer in controls is 0.08/0.92 = 0.08700. The OR then equals 0.1765/0.08700 = 2.03, suggesting a positive association between premenopausal breast cancer and ovarian cancer. A simpler way of calculating the OR is to multiply the number of exposed cases by the number of unexposed controls and then to divide by the product of the number of unexposed cases and exposed controls (Fig. 25-12). The OR is unitless and can range from 0 to infinity.

If cases and controls are individually matched, then the OR is calculated differently. Only pairs in which the case and its control differ on their factor status contribute information. These discordant pairs are used to calculate the matched OR, defined as the number of pairs in which the case has the factor and the control does not, divided by the number of pairs in which the case does not have the factor and the control does have the factor (Fig. 25-13).

Recall that controls should be sampled during the same calendar time as cases (see Fig. 25-10) but sometimes are sampled after the cases have been ascertained (see Fig. 25-11). If the former is done, then the OR is a direct estimate of the true rate/hazard ratio for the same reason as in the nested case-control study, assuming no selection bias, observation bias, or confounding. Note, though, that from an inferential perspective, the case-control study nested within a cohort is preferable to the case-control study in which the source population is not enumerated at baseline, because the factor is assessed

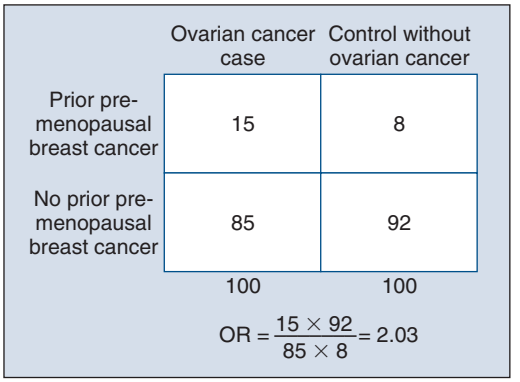

Figure 25-12 • Calculation of the odds ratio as the measure of association in the hypothetical *Second Cancer* case-control study.

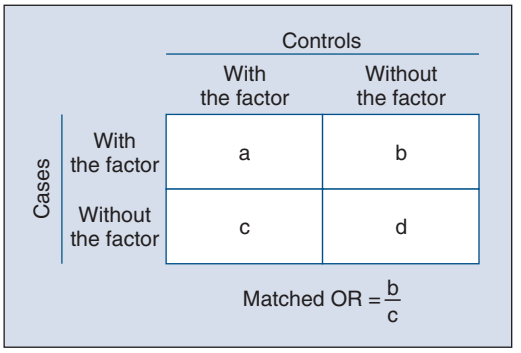

Figure 25-13 • Calculation of the matched odds ratio as the measure of association in a matched case-control study.

before the endpoint occurs, and the likelihood of selection bias is reduced.

When controls are sampled after cases in calendar time, the OR estimates the cumulative incidence ratio (assuming no selection bias, observation bias, or confounding), but only when the endpoint is uncommon in the source population (e.g., ovarian cancer in the second cancer example). Here is the logic:

The OR just described (i.e., the factor OR) is mathematically equivalent to the endpoint OR, which is defined as the odds of the endpoint among those with the factor divided by the odds of the endpoint in those without the factor:

$$\text{Endpoint OR} = [P_{D|F+}/(1 - P_{D|F+})]/[P_{D|F-}/(1 - P_{D|F-})]$$

where $P_{D|F+}$ means the probability of the endpoint among those with the factor and $P_{D|F-}$ means the probability of the endpoint among those without the factor.

The endpoint OR can be written as a function of the cumulative incidence ratio:

$$\text{Endpoint OR} = [P_{D|F+}/P_{D|F-}] \times [(1 - P_{D|F-})/(1 - P_{D|F+})]$$

or

$$\text{Endpoint OR} = \text{cumulative incidence ratio} \times [(1 - P_{D|F-})/(1 - P_{D|F+})]$$

When the endpoint is uncommon—for example, less than 10%—among those with and without the factor in the source population, then

$$1 - P_{D|F-} \cong 1 \text{ and } 1 - P_{D|F+} \cong 1$$

Thus,

$$\text{Endpoint OR} = \text{cumulative incidence ratio} \times [1 - P_{D|F-)}]/[1 - P_{D|F+}]$$

$$\approx \text{cumulative incidence ratio} \times 1$$

$$\approx \text{cumulative incidence ratio}$$

Except when the OR equals 1, the value of the OR is always further away from 1 than the value of the cumulative incidence ratio. For example, when the cumulative incidence ratio is greater than 1

$$P_{D|F+} > P_{D|F-} \text{ and } 1 - P_{D|F+} < 1 - P_{D|F-}$$

$$\text{So, } [1 - P_{D|F-}]/[1 - P_{D|F+}] > 1, \text{ and}$$

$$\text{Endpoint OR} = \text{cumulative incidence ratio} \cdot [1 - P_{D|F-)}]/[1 - P_{D|F+}]$$

Therefore, Endpoint OR is greater than the cumulative incidence ratio.

In this case, the OR suggests a stronger strength of association than the cumulative incidence ratio. If the cumulative incidence ratio had been less than 1, the OR would have been less than the cumulative incidence ratio, suggesting a stronger protective association. The more common the endpoint is in the source population (e.g., death from diffuse large B-cell lymphoma in the *therapeutic effectiveness* example), the greater is the overestimation of the cumulative incidence ratio by the OR.

If investigators wish to take potentially confounding factors into account, then the OR can be estimated by logistic regression for studies in which cases and controls are not matched, and by conditional logistic regression for studies in which cases and controls are matched. Detailed descriptions of these regression models can be found in biostatistics textbooks.

DRAWING INFERENCES FROM STUDIES USING EPIDEMIOLOGIC METHODS

Once the results are in hand, investigators must consider the ability to draw causal inferences—in other words, they must consider all possible explanations for their finding beyond cause. These alternative explanations may include selection bias, observation bias, and confounding, as well as chance variability.

Even if temporality and comparability were considered in the design phase of the study, error still may arise during the conduct of observational studies. For example, even if a rigorous definition of the source population and a rigorous approach to sampling from the source population were used, selection bias still is possible because participation is voluntary. The investigators always must be cognizant of these issues and should try to investigate how likely they were to have occurred and the extent to which they could have affected the results.

Chance variability pertains to the notion that only one sample of all possible members of the underlying population is studied. Assuming no selection bias, this sample should differ from the underlying population only in a random way. Thus, estimates of the measure of endpoint occurrence or association from this sample should differ from the true value in the full underlying population only in a random or nonsystematic way. Chance variability is reduced by studying a larger sample. Therefore, in the design phase of the study, investigators should consider the most appropriate sample size to optimize the statistical ability to detect an association if one truly exists. Sample size determination is based, in part, on the expected cumulative incidence or rate of the endpoint in those without the factor (cohort study), the expected prevalence of the factor among controls (case-control study), and/or the expected size of the association. In the analysis phase of the study, the extent of variability in the estimate of the measure of endpoint occurrence or association

should be quantified, usually with a confidence interval or *P* value. Investigators should then consider this variability when drawing inferences from the study. For instance, if the RR is > > 1, but the *P* is greater than 0.05 (the typical cut-point for statistical significance), is there an association or not? It depends: if the hypothesis were motivated by existing scientific evidence, then the conclusion from the study might be that the findings suggest an association, rather than that no association exists. Interpretation of association magnitudes and significance is an art; it is not dictated by simple rules.

After considering alternative explanations for an epidemiologic finding, investigators still cannot conclude that the observed association reflects causation. In epidemiology, any given research question must be evaluated many times using different designs and study populations, and usually by independent investigators.

Each epidemiologic study design has different potentials for each type of bias. If findings from studies that used different designs are similar, then this may provide evidence in favor of a causal association. If findings differ, then more weight should be given to studies that used designs that maintained temporality and were the least susceptible to bias.

In general, prospective cohort studies and their derivative designs provide stronger evidence for a causal association than retrospective cohort studies and case-control studies, because they maintain the correct temporal sequence between the factor and the endpoint and because they are less susceptible to selection and observation biases. Although both prospective cohort studies and randomized trials are likely to have the correct temporal sequence, evidence from randomized trials usually trumps evidence from cohort studies because randomization reduces the likelihood of selection bias and confounding.

Different study populations (defined, for example, by country, race/ethnicity, or socioeconomic status) may have different characteristics that influence the likelihood or extent of confounding. If findings are the same across study populations, then this may provide evidence in favor of a causal association. If findings differ, reasons may include differences in unmeasured confounders or differences between study populations in the presence and prevalence of factors that might modify the association. At this point, investigators should think about possible reasons for differences across study populations and investigate these reasons in subsequent studies.

Chance variability is possible in any study. When the results from independent epidemiologic studies are not too heterogeneous, meta-analyses can be performed to generate a more stable (i.e., less variable) summary estimate of the association.

When considering whether an observed association between a factor and endpoint is causal, some investigators find it useful to think about the nine "aspects" of an association that Sir Austin Bradford Hill described in 1965[3]:

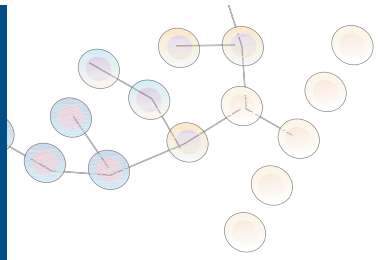
1. Strength: How big is the measure of association?
2. Consistency: Are findings from studies conducted using different designs in different populations similar?
3. Specificity: Is the factor only associated with the endpoint of interest, and is this the only factor that has been found to be associated with the endpoint of interest?
4. Temporality: Was the factor experienced before the endpoint occurred?
5. Biological gradient: Does the magnitude of the measure of association increase (or decrease) with increasing extent of the factor?
6. Plausibility and 7. Coherence: Is the association supported or refuted by the contemporary biologic literature?
8. Experiment: Does the magnitude of the measure of association decrease (or increase) after changing the factor status?
9. Analogy: Have associations between similar factors and similar endpoints been observed?

Temporality has been highlighted in this chapter because it is the only aspect of an association necessary for causality. The other aspects neither rule in nor rule out the potential for an association to be causal.

In light of all these considerations, the original *therapeutic effectiveness* example is now reexamined. The investigators observed that patients with 2 copies of the haplotype had 0.5 times the risk of death, and patients with 1 copy had 0.7 times the risk of death compared with patients with no copies of the haplotype. These results were statistically significant ($P < 0.05$).

What should investigators infer? They conducted a prospective cohort study in which haplotyping was performed using samples collected at the start of the study; hence, the correct temporal sequence was obtained. All individuals from one arm of the trial were included in the study; therefore, selection bias is unlikely to have been introduced into the study. All trial participants were followed actively and in the same manner for survival. Therefore, it is unlikely that the ability to observe the endpoint differed by haplotype (i.e., no observation bias). The investigators observed that the prevalence of the haplotype did not vary by any of the participant characteristics measured at the start of the study, including race or ethnicity; therefore, confounding also is unlikely. The strength of the association between the haplotype and survival is relatively strong, suggesting that confounding alone is unlikely to explain the association. Although the findings were statistically significant, chance cannot be ruled out as an explanation for the findings. This is the first study of this hypothesis, so there are no other studies to which to compare the findings. The RR of death decreased with increasing number of copies of the haplotype, demonstrating a biological gradient. The hypothesis was well motivated by scientific evidence that the P450 enzyme enhances the action of the chemotherapeutic agent, and that the haplotype of interest encodes a more active form of the enzyme. Findings from this study are analogous to those from a study that investigated genetic variation in a different metabolic enzyme with cancer survival after treatment with a different chemotherapeutic agent.

After contemplating all of these aspects of the study and its findings, the investigators might conclude that the findings are promising, but because the study is observational and the first to investigate this hypothesis, additional studies should be conducted before the findings can be translated into clinical practice. As already mentioned, a randomized trial of this research question is not possible because haplotype is an inherent characteristic of an individual. However, if, in the future, findings from this study are upheld in other studies, the next step might be to conduct a trial in which patients without the beneficial haplotype are randomized to either a drug that induces the P450 enzyme or placebo, concurrent with administration of the new chemotherapeutic agent.



FINAL THOUGHTS ON THE USE OF EPIDEMIOLOGIC METHODS IN ONCOLOGIC RESEARCH

This chapter has described epidemiologic methods for formally testing hypotheses pertinent to oncology and discussed their rationale. Epidemiology is a flexible method that can be applied to many different types of translational and clinical studies that do not necessarily have an etiologic or population-level focus. For instance, in the hypothetical *prognosis* example, the focus of the study appears to be on the measurement of a newly discovered tissue marker using an innovative technique. However, use of this innovative technique does not ensure correct inferences about whether or not the tissue marker predicts prognosis in the study population, nor its applicability to other populations, even if the technique is highly accurate. Obtaining a valid answer also hinges on choosing the

appropriate study population, design, and analysis, all of which require epidemiologic thinking. For this reason, a multidisciplinary research team that includes collaborators from clinical science, basic science, biostatistics, and epidemiology is optimal for addressing the complex translational and clinical questions posed in modern oncology.

26 Cancer Prevention, Screening, and Early Detection

Jason A. Zell and Frank L. Meyskens

SUMMARY OF KEY POINTS

Etiology and Pathogenesis

- Prevention of cancer is based on an understanding of the etiology and pathogenesis of the individual organ malignancies. The identification of at-risk individuals is based on familial/genetic and environmental influences.
- Smoking tobacco remains the number one cause of malignancy and accounts for about 30% of the mortality from cancer. The role of diet in cancer risk is substantial.
- Infections are an important component of cancer risk, and major etiologic agents for different organs include viruses (hepatitis B and C [hepatocellular], human papillomavirus [cervix and some oral cancers], Epstein-Barr virus [nasopharyngeal carcinoma]), bacteria (*Helicobacter pylori* [stomach]), and parasites (*Schistosoma haematobium* [bladder], *Clonorchis sinensis* [cholangiocarcinoma]).

Screening and Early Detection

- Effective screening and early detection techniques for cancer include visual examination (skin, cervical, and oral cancers), cytology (cervical cancer), mammography (breast cancer), and fecal occult blood, sigmoidoscopy, and colonoscopy (colorectal cancers).
- Screening for prostate cancer by serum prostate-specific antigen (PSA) measurement has been widely adopted, although its impact on overall survival remains uncertain. No successful method has been established for lung cancer screening.

Chemoprevention

- "Proof of principle" for the prevention of primary cancers has been established convincingly for breast cancer (tamoxifen and raloxifene), hepatocellular carcinoma (vaccination against hepatitis virus B), and cervical cancer (vaccination against human papillomavirus).
- Prevention or regression of various intraepithelial neoplasias has been demonstrated: actinic keratoses (diclofenac), oral leukoplakia (retinoids), cervical intraepithelial neoplasms (topical retinoic acid), adenomatous polyps (calcium, aspirin, celecoxib), and gastric dysplasia (anti-*H. pylori* therapy, antioxidants).
- Secondary aerodigestive cancers can be prevented with high-dose 13-*cis*-retinoic acid but at the price of unacceptable toxicity.
- An increased incidence of secondary lung cancers in smokers supplemented with β-carotene or 13-*cis*-retinoic acid demands particular caution in the development of chemoprevention agents.
- Unexpected cardiovascular toxicity demonstrated by selective cyclooxygenase-2 inhibitors demonstrated in colon polyp trials has led to a major concern about risk-risk in the evaluation of risk-benefit.
- Attempts to develop less toxic or low-dose combination interventions for all of the major cancers are being investigated.
- Useful resources for those interested in research in cancer prevention, screening, and early detection are provided.

INTRODUCTION

The guiding principles of this chapter and oncology should be that the best treatment of malignant disease is its prevention, and that the disease to be prevented is carcinogenesis, not cancer (Fig. 26-1).[1]

By the time a cancer is diagnosed, even with the advanced techniques now available, more than 90% of the biologic life of the tumor is over, and the best chance to control the malignant process has been missed. The extensive advances in our understanding of carcinogenesis at the molecular level in the past decade, the rediscovery of intraepithelial neoplasia as an early, recognizable precursor of many solid tumors that can be managed simply, and the well-defined successes of screening and early detection in reducing the morbidity and mortality from several major cancers, need to be brought to bear on the problem of malignancy in a concerted and widespread fashion, with clinical oncologists working closely with primary care physicians and subspecialists. Because fewer than 50% of cancers are cured, once established, and because gains in treatment effectiveness have been increasingly incremental and expensive, early detection and prevention of cancer should be pursued aggressively as a means to reduce morbidity and mortality.

Many major diseases of humankind have been controlled by the systematic application of prevention strategies, including morbidity and mortality from nutritional and infectious diseases and vehicular trauma.[1] Among chronic diseases, the incidence of cardiovascular disease has decreased markedly as smoking has declined, cholesterol and blood pressure lowered, and exercise encouraged. It is likely that these simple approaches have led to a greater overall benefit to health for the population than the effect of all intensive care units, but such direct comparisons are difficult to make. In general, appreciation of the role of prevention strategies in the overall management of cancer has been neglected by clinical oncologists, although health care planners and society as a whole are intensely interested in this topic.[2] Cancer prevention strategies can be considered at three different

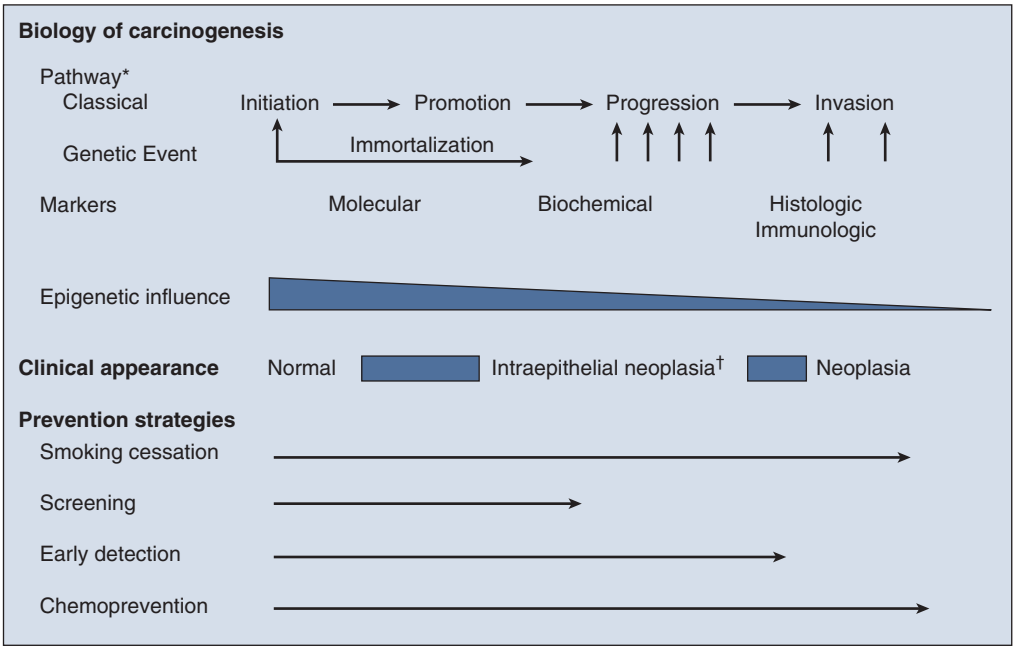

Figure 26-1 • Integration of the biology of carcinogenesis and prevention. *Hereditary alteration(s) or baseline polygenic representation provides the constitutive "set point" on which postzygote changes occur. †Precancer, premalignant lesion in general clinical parlance.

major levels: primary, secondary, and tertiary. This chapter will deal primarily with primary and secondary prevention and with tertiary prevention as represented by chemoprevention of second malignancies.

Normal, asymptomatic individuals are the population at which primary prevention is addressed. Major strategies for risk reduction include changes in diet, increased physical activity, tobacco awareness, decreased exposure to the sun, and reduced intake of alcohol. With the increasing identification of constitutive genetic alterations that predispose individuals to cancer, this group has been targeted for primary interventions such as prophylactic surgery.[3] Annual screening mammography in women older than 50 years of age and smoking cessation or chemoprevention in a group of asymptomatic smoking individuals are also examples of targeted primary prevention.

Secondary prevention is directed toward individuals with evidence of preneoplastic, clinically identifiable progression, but without frank malignancy. The phenomenon of intraepithelial neoplasia, also called preneoplasia or precancer, has become of widespread interest, and management of these lesions has the potential to abrogate the disease process early. Many organ sites have preneoplastic counterparts that should be amenable to early intervention (Table 26-1). Representative examples of this type of secondary prevention include suppression or reversal of oral leukoplakia, cervical intraepithelial neoplasia (CIN) or Barrett's esophagus and inhibition of polyp formation or progression (Fig. 26-2).

Tertiary prevention involves decreasing the morbidity of established disease. Chemoprevention of second malignancies is a good example of tertiary prevention. The distinction between primary, secondary, and tertiary prevention can sometimes become blurred. Further, tertiary prevention and adjuvant therapies can share many of the same goals. From the viewpoint of the clinical oncologist, probably the best way to look at prevention is as one more therapeutic modality for the management of cancer, directed at its control in the earliest stages. The observation that the addition of a retinoid after bone marrow transplantation markedly enhances the survival of children with refractory neuroblastoma represents an informative synthesis of a quaternary treatment approach and a tertiary prevention modality.[4]

Table 26-1 Common Clinical Precursors (Intraepithelial Neoplasia) of Cancer

Organ Site	Precursor	Method of Detection*
Oropharynx	Leukoplakia	Visual†
Skin	Actinic keratoses/moles	Visual†
Esophagus	Barrett's esophagus	Endoscopy
Colon	Adenoma (polyp)	Sigmoidoscopy, colonoscopy
Breast	LCIS, DCIS‡	Mammography, ultrasound, MRI
Cervix	Intraepithelial neoplasia	Colposcopy

*Cytology and/or biopsy is required in almost all cases before definitive therapy can be initiated.

†Elegant in situ optical spectroscopic methods are being developed to detect early preneoplastic changes, including enhancing the signals with fluorescent molecules.

‡Lobular and ductal carcinoma in situ.

Avoidable Causes

An extensive analysis of the topic of avoidable causes of cancer was performed over 2 decades ago by Doll and Peto[5]; these investigators concluded that 50% to 70% of all human cancers were preventable. No new data have emerged that would alter that overall estimate, although some of the specifics have changed.[6] The major avoidable risk factors can be broadly separated into four areas: tobacco, infectious, chemical (including hormonal), and diet.

Tobacco smoke is far and away the most important carcinogen to which humans are exposed on a routine basis. The morbidity and mortality from tobacco smoke is huge and represents the major preventable cause of all diseases, not just cancer, in modern and many undeveloped societies. It is estimated that more than 500 million smokers now living will die of tobacco-related illnesses.[7,8] What is generally not appreciated is the wide carcinogenic range of molecular

damage and the numerous organ sites affected by cigarette smoke.[9,10] In addition to the lungs, cigarette smoking contributes significant attributable risk to the development of cancers of the oropharynx (75%), bladder (50%), esophagus (50%), pancreas (25%), cervix (20%), kidney (15%), and bone marrow (10%). Cigarette smoke facilitates chromosomal instability and enhances transformation at all levels of cancer formation (initiation, promotion, progression), including adversely affecting the natural history of successfully resected early-stage lung cancer.[11] Although the incidence of cigarette smoking has fallen among males, in 1994 lung cancer surpassed breast cancer as the most common cause of death from cancer in females. Lung cancer incidence among females has increased from 1975 through 2003, although the rate of increase has declined since 1991.[12] Well-tested modules have been developed to assist health care workers, including physicians, in applying smoking prevention and cessation strategies.[7] Various forms of nicotine (gum, patch, inhalers, nasal sprays) and behavioral modulators (bupropion) have been effective in increasing the quit rate significantly at very low cost.[8]

The evidence for infectious involvement in human cancer has increased dramatically in the last 15 years (Table 26-2). Hepatitis and human papillomavirus (HPV) clearly play major roles in the development and evolution of hepatocellular and cervical carcinoma, respectively. Vaccines using various viral components as the target have recently been tested; results from these trials strongly suggest that liver cancer and cervical cancer are preventable.[13,14] In addition to the classical and long-recognized associations of the parasites *C. sinensis* to cholangiocarcinoma and *S. haematobium* to squamous cell carcinoma of the bladder, the bacterium *H. pylori* has now been accepted

Table 26-2 Cancers with an Infectious Etiology

Cancer	Agent	Major Mode of Transmission	Intervention
Hepatocellular carcinoma	Hepatitis virus	Maternal, oral	Vaccine
Gastric	*Helicobacter pylori*	Oral	Antibiotics
Cervix	Papillomavirus	Sexual	Vaccine

Several major cancers are of infectious etiology and can be eradicated by preventive intervention.

as an etiologic agent associated with gastric dysplasia, stomach cancer, and a rare type of lymphoma.[15] Early on, these diseases can be treated with antibiotics and the process reversed. Finally, it seems that viruses have a role in the evolution of some lymphomas (human T-lymphotropic virus-1, Epstein-Barr virus [EBV]). These findings all offer new approaches for primary and secondary prevention using standard and new microbiologic and immunologic approaches.

A number of chemicals are known to play a role in cancer causation, perhaps the most widespread being aniline dyes (bladder cancer), asbestos (lung, mesothelioma), and hormones (breast, prostate). The role of endogenous and exogenous hormones in cancer causation is complex and is considered in detail in the sections on breast, prostate, and gynecologic organ sites.[16] Some of the most intensely debated issues in medicine relate to this area. For example, is the overall health benefit of hormone replacement therapy (HRT) worthwhile? Results from the Women's Health Initiative (WHI) trial suggest not,[17] and long-term use of HRT is not recommended.

The question of the specific role of dietary components in cancer prevention remains largely unanswered. Many comprehensive reviews on the topic are available, and the overall recommendation to eat an abundant amount of fruits and vegetables has not changed in 20 years.[18] Ambitious campaigns such as the well-known "5-a-day for better health" campaign to encourage large-scale dietary changes continue.[19] The specific components responsible for the protective effects against cardiovascular disease and cancer remain unclear. The roles of macronutrients, fat, and fiber in prevention have been topics of much discussion. The general recommendation to reduce total calories and fat consumption and to increase fiber is a good one with regard to cardiovascular disease prophylaxis, but whether such a strategy affects cancer outcome remains unproven. Increasing epidemiologic data suggests that physical activity and basal metabolic index play critical roles, and several trials are underway to address these issues.[20]

There is growing evidence that changes in the insulin-like growth factor pathways play an important role in many aspects of lifestyle changes represented by a high basal metabolic index and its control.[20] With increasingly positive protective effects of physical exercise on cardiovascular disease being shown, there has been a renewed interest in the influence of physical exercise on malignant transformation and progression.[21] There has been a great deal of interest in micronutrients as preventive agents, but the results emanating from supplementation in well-done randomized clinical trials thus far have been disappointing.[22] Notable exceptions have included the report that supplementation with a modest dose of vitamin A (25,000 IU per day) can decrease the appearance of cutaneous squamous cell cancer of the skin in individuals with prior actinic keratoses and several trials showing that supplementation with a modest dose of calcium can decrease the subsequent prevalence of cancer polyps by 20%.[23–25]

Probably the most exciting diet-related development has been the identification of a wide range of potentially new and active chemoprevention compounds in food, such as protease inhibitors (soybeans), monoterpenes (citrus fruit oils), polyphenols (nuts), dithiolethiones (cruciferous vegetables), alliums (onion/garlic family), and many others.[26] The opportunity to genetically engineer foods to reduce the risk of heart disease and cancer is a topic of much scientific interest and commercial activity.[27] Nature created these molecules to deal with a hostile toxic environment, and figuring out how to use them for the prevention of cancer should be both scientifically interesting and clinically rewarding.

Screening and Early Detection

Strictly speaking, screening is limited to normal individuals. The science of screening identifies many pitfalls in the design, analysis, and interpretation of such trials, including length and lead-time biases and many others.[28,29] Beyond the technical issues involved in study design, three other requirements addressing implementation, analysis, and interpretation, must be met to demonstrate that a screening test is useful:

1. A test must be available that will detect cancer earlier than routine methods (e.g., clinical or self-examination).
2. There must be evidence that treatment at an earlier stage of disease will result in an improved outcome (decreased cause-specific morbidity or mortality).
3. There must be evidence of a total health benefit. For example, the benefits of early detection via screening that meets the aforementioned criteria must also outweigh the adverse risks of subsequent diagnostic and therapeutic interventions. In current screening trials, disease-specific vs. all-cause mortality, and risk-benefit have become increasingly important issues—particularly among older individuals.[30,31]

Fulfilling these requirements is difficult, and the issues specifically related to screening of different organ sites for precancers or cancers are discussed in those sections. Some generic comments are worthwhile. Enough evidence exists for a specific test for some organ sites that has been proven effective to recommend the routine adoption of screening (Table 26-3). Although the availability of cancer screening is generally increasing, usage is relatively low for some organ sites (e.g., colon) and among groups that lack health insurance or a usual source of care.[32] Many screening tests, however, are ineffective (e.g., routine chest roentgenograms in smokers being the most notable).

Also, a positive screening test may lead to aggressive intervention that could allow "cure" of the organ site disease but result in an overall increased morbidity or mortality that is not efficacious for a person's general health (e.g., radical prostatectomy for older individuals with a minimally increased PSA). Finally, screening for currently incurable malignancies (e.g., pancreatic cancer) offers new ethical dilemmas. If we have little to offer therapeutically, do we want to know the risk? Maybe, maybe not. Perhaps earlier prophylactic surgery might be able to affect the outcome in a few patients—for example, in families with early-onset pancreatic cancer.

Over the past few years, there have been rapid developments applying new imaging modalities for the purpose of cancer screenings. The United States Preventive Services Task Force now recommends screening with imaging techniques for breast cancer (mammography for women aged 40 to 70 years) and colorectal cancer (barium enema, fecal occult blood, endoscopy).[33] Cancer screening trials are ongoing for breast cancer (ultrasound, magnetic resonance imaging [MRI]), colorectal cancer (computed tomography [CT] colonography), liver cancer (ultrasound, CT), and pancreas (endoscopic ultrasound, CT, endoscopic retrograde cholangiopancreatography).[34] Major trials have completed accrual, including the Prostate, Lung, Colorectal and Ovarian (PLCO) trial and the National Lung Screening Trial. Mortality results from the PLCO are expected in 2015 and will assess the role of chest radiography (i.e., x-ray) in lung cancer screening, and transvaginal ultrasound for ovarian cancer screening. Mortality data from the National Lung Screening Trial are expected in 2009, to evaluate low-dose CT for lung cancer screening among high-risk adults.

The age of molecular diagnosis in screening is upon us and holds both promise and peril.[35] Novel functional and molecular imaging techniques for cancer diagnosis currently include measurements of tumor angiogenesis via dynamic contrast-enhanced (DCE)-MRI, DCE-CT with ultrasound, positron emission tomography (PET), and combinations of these techniques.[36] Diffuse optical imaging is another functional imaging technique that has emerged as an adjunct for cancer diagnosis. This noninvasive imaging method uses near-infrared light intensity to address tissue-specific changes between normal and tumor tissue (i.e., tissue hemoglobin concentration, tissue oxygen saturation) in vivo.[37] DCE-MRI, DCE-CT with ultrasound, and PET imaging have varying capabilities to profile microvessel density—a hallmark of angiogenesis—which is essential for tumor growth and invasion. However, even in the setting of cancer diagnosis, these methods are not

Table 26-3 Effectiveness of Major Screening Approaches for Cancer*

Organ Site	Test	Positive Level of Evidence†	Recommended
Breast			
Over age 50	Mammography	Strong	Yes
Age 40–50	Mammography	Fairly strong	Yes
Cervix	Papanicolaou‡	Strong	Yes
Colorectal			
Over age 50	Occult fecal blood	Strong	Yes
	Sigmoidoscopy	Strong	Yes
	Colonoscopy§	Fairly strong	Yes
Lung	Chest roentgenogram	None‖	No
Melanoma	Skin examination	Moderate	Yes
Prostate	Prostate-specific antigen	Moderate	Yes¶

*Listed here are organ sites for which sufficient data exist to make a judgment. Although no specific trial evidence exists, routine physical examination of the skin, oral cavity, testicles, and ovary/uterus is worthwhile, because treatment success is closely related to stage at diagnosis and effective treatment is available in most cases.

†The concept of level of evidence is a valuable approach—a quantitative approach that is presented in detail in the PDQ section of the NCI Web site (http://cancernet.nci.nih.gov/clinpolq/screening). A randomized trial with survival as an endpoint is at the top of the hierarchy, whereas anecdotal evidence by experts is at the lowest.

‡Screening should begin with the onset of sexual activity.

§Evidence also exists that colonoscopy with excisional biopsy is an effective therapeutic maneuver, but the cost of the procedure has precluded its general usage.

‖Several randomized trials of screening chest roentgenograms showed no effect on outcome. Spiral CT is currently being tested in a large national trial.

¶With careful follow-up and appropriate testing.

yet standardized.[36] Appropriate methods for incorporating these functional and molecular imaging techniques into screening trials must be considered, particularly in light of their associated high costs. Thus, the potential impact of such molecular and functional imaging techniques on cancer screening is great, though not yet realized.

Although early detection is, formally speaking, the evaluation of a symptomatic individual for cancer and is therefore different from screening, many of the caveats regarding evaluation of this approach are the same. The increasing ability to identify high-risk populations, either by phenotypic criteria or by genetic analysis, also tends to lead to a blurring of the classic division between screening and early detection. With the rapid advances in molecular diagnostics, routine genetic typing of individuals at risk for major tumor types should not be too distant in the future, and quantitation of that risk (a concept we proposed quite some time ago)[38] and its evaluation at the time of detection leads to real-world angst. Identification and referral of families at high risk for cancer susceptibility should be an increasing emphasis of clinical oncologists, but thus far, participation by oncologists has been low.[2,39] At the very least, the ability to downshift the stage of a disease at the time of detection should eventually lead to improved survival, because new treatment approaches emanate from causative understanding of a particular cancer. Proving this point, though, has been difficult for cancers of many organ sites.

The effectiveness of screening for the major types of cancer is summarized in Table 26-3 and is discussed in detail in the individual sections of this chapter. There are effective screening modalities for breast cancer, colorectal cancers, melanoma, and cervical cancers, whereas no compelling evidence exists for the value of screening for lung cancer. The effectiveness of PSA in screening for prostate cancer has been a subject of intense debate; we feel that the tide of evidence has turned and that the evidence supports the routine use of PSA screening over age 50 with thoughtful management and appropriate follow-up of abnormal values.

Carcinogenesis and Chemoprevention

Carcinogenesis

Advances in our understanding of the biology of carcinogenesis (cancer formation) have sharpened our thoughts about screening and early detection and provided a guide to thinking about risk assessment and chemoprevention.[40] Figure 26-1 serves as a useful general roadmap to reflect on these issues for all tumor types (see Shureiqi and colleagues).[41] The classical model of carcinogenesis divides cancer evolution into three major epochs: initiation, promotion, and progression. This classification has served as a useful heuristic model for which considerable experimental evidence has been developed. In the past 15 years, the genetic paradigm for the development of cancer has been elegantly articulated and experimentally confirmed for some organ sites. A series of steps in response to separate molecular events at the genetic level is a useful platform from which to understand carcinogenesis in human epithelial tumors. Almost all human cancers examined in any detail have shown evidence of several acquired molecular abnormalities. Although the "pathway" is different for each cancer, the tumor suppressor genes p53 and p16 seem to play a central role in many malignancies.[42,43] The expression of these abnormalities has allowed the development of markers that could serve as indicators of cancer risk or disease progression or possibly as surrogate endpoints for chemoprevention agent testing.[44]

Use of markers of carcinogenesis to assess the status of the disease relative to diagnosis and treatment and for assessment of chemoprevention effect is an important and complex issue.[45] The continued development and validation of markers will be critical to the intelligent management of early-stage cancer.[46] What also has become clear is that environmental phenomena (e.g., hormones, diet, carcinogens) can influence the expression of genetic changes. At one extreme of the paradigm is retinoblastoma, in which loss of a single gene inevitably results in an ocular tumor at a young age; however, most common solid tumors in adults seem to have underlying polygenic contributions, which can be affected by a large range of exogenous factors, even when a deleterious mutation such as *BRCA1* or *BRCA2* is present.

Chemoprevention

The idea of the chemoprevention of human cancer has been with us for nearly 3 decades, but only in the recent years have positive clinical trials validated the results of preclinical data and their potential for use in human beings.[47–50] Retinoids are a major group of compounds that have provided convincing "proof of principle" of

chemoprevention in humans, but in general they have been too toxic for widespread use and have not been adopted widely.[51] The overall results of some of the key randomized chemoprevention trials are summarized in Table 26-4 and are discussed in more detail in the individual organ site sections. Major problems in developing chemoprevention as a modality for cancer management have been the length and size of the trials required to show changes in a definitive endpoint.[52,53] Consequently, only the National Cancer Institute and a few large research groups have been able to marshal the resources to develop broad-based chemoprevention efforts. Another significant issue in the design of early trials was that many large studies evolved primarily from epidemiologic observations, with little experimental data available. Because the implementation of large phase III or IV chemoprevention trials is a 10- to 100-million-dollar exercise, political influences on the funding process have also been substantial.

An attempt to develop chemoprevention agents logically has been outlined, and systematic preclinical testing and evolution of sequential clinical trials are likely to avoid some of the mistakes of the past.[53,54] Several key elements are featured in this decision analysis process:

- Preclinical in vitro and in vivo testing against a battery of molecular targets and cellular and animal models
- Accurate identification of side effects and assessment of their importance
- Evidence of modulation of anticipated biochemical or molecular markers in the relevant tissue in short-term human trials
- A randomized 6- to 12-month study of multiple low doses of the candidate agent in a relevant patient/participant population, with careful identification of side effects and assessment of their importance, and evaluation of their biochemical, molecular, and/or histologic effects

In this regard we have performed a particularly informative series of studies in assessing topical all-*trans*-retinoic acid in cervical cancer prevention and difluoromethylornithine (DFMO) in colon cancer prevention,[55–57] whereas the M.D. Anderson group[58] has performed a series of important trials in aerodigestive cancers and the Arizona group has done the same for skin cancers.[59] Following this logical pathway of chemoprevention agent development assures that the probability of conducting a definitive phase III or IV study will be high and maximizes the chance for a successful outcome. Although the term "chemoprevention" has been widely used to describe chemical or dietary intervention to prevent or reverse cancer, it is a misnomer that is out of sync with the nosology used in other areas of medicine. Therapeutic prevention might be a better term—for example, cholesterol-lowering agents and antihypertensives to prevent cardiovascular diseases, prophylactic antibiotics to prevent infections, and many more. Risk-benefit of a drug in a prevention setting has always been a key issue, particularly of individuals at low risk. The unexpected increase of lung cancers and adverse cardiovascular events in two large trials in which β-carotene was administered called this issue into sharp focus in the mid-1990s.[60,61] Recently, a different level of risk has been appreciated, designated risk-risk. In several large trials, selective/specific COX-2 inhibitors markedly reduced the incidence of colonic polyps but at the price of increased serious cardiovascular events.[62,63] A careful analysis indicated that overall morbidity would be increased by using selective COX-2 inhibitors to reduce adenomatous colon polyps in individuals at low risk.[64] These important observations do not necessarily preclude using other nonsteroidal anti-inflammatory drugs (NSAIDs) that have more complex effects on the prostaglandin pathways (e.g., aspirin, sulindac); the results of other trials will help in this decision making, but the unexpected outcomes in the COX-2 inhibitor trials has clouded the field of chemoprevention for reduction of cancer incidence, particularly in

Table 26-4 Current Overall Status of Chemoprevention in Preventing Human Cancers*

Organ Site	Pretrial Level of Evidence	Agent	Status of Chemoprevention	Comment
Breast	Strong	Tamoxifen	Effective	One large trial, very positive; two smaller trials showed no effect. Overall long-term health benefits must be determined.
Cervix†	Strong	Multiple	Ineffective to marginal	Numerous phase III trials of several compounds have not substantiated phase II trials except for topical all-*trans*-retinoic acid.
Colon	Strong	Multiple	Mixed	Slight decrease (25%) in colon polyp recurrence by calcium or aspirin
Head and neck (secondary)	Moderately strong	13-*cis* retinoic acid	Effective but toxic	Follow-up trial at lower dose ineffective
Leukoplakia	Moderately strong	β-carotene	Promising	Single randomized trial needs confirmation.
Tertiary	Strong	13-*cis*- retinoic acid	Effective but toxic	Follow-up studies at lower doses in progress
Lung				
Primary	Strong	β-carotene	Ineffective	More lung cancers and increased higher overall mortality
Secondary (metaplasia)	Strong	Retinoids	Ineffective	Impressively negative
Prostate	Moderately strong	Finasteride	Accrual complete	Results indicate positive effects but are preliminary.
		SELECT‡	Ongoing	Results in 2010
Skin	Strong	Retinoids	Effective in some cases	Seems to depend on stage of cancer development and strength of agent
		Diclofenac	Effective	Causes regression of actinic keratoses

*Details are discussed in individual sections.
†Cervix, effects on regression of cervical intraepithelial neoplasia.
‡Selenium and vitamin E. Epidemiologic data from secondary analysis; experimental data moderate.

individuals at low risk. It is important to recall that the development of cardiovascular risk reduction trials met similar problems in the early days until effective and nontoxic agents were developed, and 20 to 30 years ago the regulatory burdens and the ethical bars were considerably lower.[65]

Although thus far most agents have been developed based on epidemiologic observations or carcinogen models in animals, increasing knowledge about the molecular basis of cancer progression in human tumors should result in the discovery and synthesis of highly specific drugs based on altered biochemical and signaling pathways.[66,67] The number of specific tumors for which prevention strategies could be reviewed is large. In this chapter we review the major organ sites (aerodigestive, colon, breast, prostate) and those sites (skin, ovary, cervix) in which sufficient evidence exists to suggest that preventive strategies currently have a role in clinical oncology. We also offer a few comments on less studied cancers (stomach, liver) that are extremely common outside the United States and Europe. With the rapidly increasing scientific understanding of the biologic basis for many tumor types and the recognition that screening, early detection, and chemoprevention should play a large role in the management of the carcinogenic process, we can anticipate that the list of therapeutic prevention strategies for intraepithelial neoplasia and possibly earlier manifestations of cancer will grow rapidly over the next few years.

AERODIGESTIVE MALIGNANCIES

Risk Reduction

Aerodigestive malignancies encompass a subset of cancers including those that arise from the oral cavity, pharynx, esophagus, and lung.[58] These organ sites have been grouped together, because they share a mucosal epithelial field that is directly subject to malignant transformation by the common toxin (tobacco), the major underlying etiologic agent for these malignancies. In addition to cigarette smoke, smokeless tobacco has also played an increasing contributory role in oral carcinogenesis, and oral cancer in the young adult has become increasingly common.[68] Alcohol also clearly plays a synergistic role with tobacco carcinogens in the development of oral and esophageal cancers, including second cancers.[69,70] Polymorphisms in the alcohol dehydrogenase gene involved with tobacco carcinogen metabolism may also play an important role in determining risk for head and neck and tobacco-related malignancies.[71] The identification of HPV in more than 50% of oropharyngeal and nearly 100% of laryngeal tumors has led to acceptance of the role of HPV in head and neck squamous cell carcinomas (HNSCCs) pathogenesis.[72,73] Compared with HPV-negative HNSCC tumors, which harbor tobacco-induced p53 mutations, HPV-positive HNSCC tumors have wild-type p53, which is inactivated by the viral oncoprotein.[73,74] Interestingly, HPV-positive HNSCC patients have a different clinical profile compared with HPV-negative patients: they are younger, less likely to ingest alcohol or use tobacco, and show equal gender distribution; the tumors show poorly differentiated and basaloid histology, but such patients have improved survival characteristics.[73,75] Progress in understanding the biology of tobacco-associated carcinogenesis in the past few years has been rapid, and molecular models of head and neck and lung cancers have been characterized to a substantial degree.[76] What is clear from cytogenetic genomic hybridization and other studies is that, although aerodigestive cancers share many similar changes early on (e.g., loss and gain of 3p and cyclin alterations), discrete subsets exist.[77] Because different genes are involved, this information should have a practical effect on the development of chemoprevention and other interventions.

In 2006 more than 230,000 cancers are expected to develop in aerodigestive sites, and 188,000 related deaths are anticipated in the United States.[78] Because it is estimated that the etiology of more than 80% of aerodigestive cancers is tobacco related, the cost to society of this legal carcinogen is extraordinarily high. The application of prevention strategies should have a favorable impact on decreasing morbidity and mortality from aerodigestive cancers; particularly important for the medical profession should be the adoption of proven, physician-facilitated smoking cessation methods.[7,8]

Screening and Early Detection

Oropharyngeal cancer occurs in a region of the body that is easily accessible to examination by a health care worker. The morbidity and mortality from oropharyngeal cancer is directly related to the stage at diagnosis, so effective screening and early detection should be worthwhile.[79] However, no definitive trial has demonstrated that an early detection program can downshift stage at diagnosis of oropharyngeal cancer or reduce mortality in a screened population. Nevertheless, an inspection of the oral cavity should be part of every examination in high-risk patients (smokers) and can be made efficacious by careful inspection of the soft palate, tongue, and floor of the mouth, where 90% of all squamous cell cancers occur.[80] The preneoplastic lesions, leukoplakia and particularly erythroplakia, should be identified and biopsy specimens obtained if necessary, because they represent early observable signs of squamous cell carcinomas with different prognoses (see Fig. 26-2A and B). In appropriately screened populations of high-risk smokers and drinkers over age 40, a detection rate of oral cancers as high as 1 cancer in every 200 individuals examined has been achieved.[81] A successful screening program can be mounted using health caseworkers; for example, in Sri Lanka, where oral cancer is a common malignancy, a sensitivity of 58% was obtained for 660 patients with suspected cancers.[82]

Recent advances in optical biology also suggest that screening using autofluorescent techniques may allow detection of premalignant changes before the clinical appearance of disease.[83] The strong association of HPV with oral cancers in young, nonsmoking individuals[72] and the success of screening techniques in detecting cervical intraepithelial neoplasia (see the discussion that follows) suggest that oral screening for HPV should be adopted for those who are sexually active. Established risk factors for HNSCC related to sexual behavior (i.e., history of genital warts, young age at onset of sexual activity, and a high number of sexual partners) indicate that this group is the same population at risk for genital HPV.

Routine screening of esophageal cancer in the United States has not been attempted to a significant degree, because it is relatively uncommon and therapeutic options are poor. In China and other Asian countries, however, the disease is much more common and found at high frequency in certain geographic locales. In these areas, screening and early detection using esophageal cytology are widely used, although the efficacy of these approaches has yet to be firmly established.[84]

Although lung cancer incidence among men has declined since the 1980s, the incidence for females has increased from 1975 through 2003 in the United States.[12] This trend may be changing, in that recent data indicate that the rate of increase among women has declined since 1991.[12] The issue of screening for lung cancer has been a long and complicated one, without a strong supporting evidence base. In the Mayo Lung Project (a large controlled trial designed to assess lung cancer screening with chest roentgenograms and sputum cytology among high-risk adults conducted in the 1970s and 1980s), chest x-ray imaging was noted to detect early-stage lung cancers, without leading to any difference in lung cancer mortality.[85,86] Furthermore, excess cases were noted in the intervention arm, leading to "overdiagnosis."[87] Four large randomized trials of screening chest x-rays in smokers have demonstrated no difference in survival between the randomized groups.[88] In subsequent chest CT screening trials at The Mayo Clinic, CT was shown to detect early-stage tumors, but with a high rate of false-positives (i.e., benign nodule detection). Recent support for lung cancer CT screening among high-risk individuals comes from the singular outcome analysis of a large trial in

which 85% of the screen-detected lung tumors were stage I at diagnosis, and 10-year overall survival was 88% for these stage I patients.[89] Although these observational findings are impressive, we must await the results of confirmatory randomized controlled prospective screening trials before making broad screening recommendations for lung cancer. Thus, the National Lung Screening Trial (CT imaging) and PLCO (chest x-ray) trials for lung cancer screening will serve as important validation studies to evaluate the efficacy of lung cancer screening among high-risk individuals.

Chemoprevention

Epithelial cancers of the upper aerodigestive tract and lungs are the most extensively studied system for chemoprevention in humans, and the results are the most negative. The natural history of the disease process has been studied extensively and provides a rich platform from which to conduct chemoprevention trials. Field carcinogenesis by tobacco carcinogens with its associated epidemiologic risk and characterized molecular changes is a straightforward concept that has guided the development of chemoprevention studies in this area.[46] The recent identification of molecular (e.g., DNA repair, telomerase), metabolic (e.g., cytochrome P450, alcohol dehydrogenase), and mutagen sensitivity profiles that predispose to aerodigestive cancers, acquired chromosomal abnormalities in the field and in the cancers, and alterations of several molecular parameters that predict responsiveness and unresponsiveness, have recently provided useful detail from which to consider the next generation of rational chemoprevention trials.[90] The identification of a variety of molecular changes during head and neck cancer progression, in addition to readily identifiable histologic precursors, has provided a biologic base for understanding the interaction of carcinogenesis and chemoprevention of this disease. Recent studies of the molecular changes that accompany the progression of lung cancer also provide a useful paradigm and platform from which to develop well-considered chemoprevention approaches.

Thus far, however, the results of primary, secondary, and tertiary chemoprevention trials of the lung have been disappointing (see Goodman[91]). Two large placebo-controlled, multiagent randomized trials in heavy smokers (more than 47,000 participants) have been negative and showed no beneficial effect of retinol (vitamin A) or α-tocopherol (vitamin E).[60,61] More disturbingly, these two large, randomized trials indicate that current smokers supplemented with oral β-carotene developed lung cancers at a rate 25% greater than the placebo group and also showed an increased overall mortality. Although these findings remain unexplained, possibilities that might help explain the adverse effect of β-carotene in these studies include the following:

- The formation of cyclic epoxides in the setting of tobacco carcinogens, inflammation, and high β-carotene concentrations
- The suppression of RAR-β, a major transcription factor important for differentiation in epithelial tissues
- Lowering of the concentration of other micronutrients that might be protective
- Stimulation of preneoplastic clones by enhancement of growth factor production
- Complex genetic polymorphisms that lead to alteration of tobacco carcinogen metabolism

Definitive secondary (metaplasia, atypia) and tertiary (second malignancy) chemoprevention trials that use a number of different retinoids and other compounds (folic acid, *N*-acetylcysteine) have also yielded negative results.[91,92] Treatment with anethole dithiolethione (an organo-sulfur compound) was shown in a randomized trial to reduce development of new bronchial dysplasia lesions and to slow progression of pre-existing disease in current or former smokers.[93] However, a randomized trial of inhaled budesonide in smokers with bronchial dysplasia indicated no effect of the active agent in the regression of bronchial dysplastic lesions or prevention of new lesions.[94] A modest decrease in p53 and BCL-2 protein expression in bronchial biopsy specimens was seen, as was a slightly higher rate of resolution of CT-detected lung nodules. Whether budesonide or anethole dithiolthione will be useful in managing preneoplastic lesions of the lung will require assessment in larger and longer trials.

Studies of secondary and tertiary chemoprevention of head and neck cancers have led to somewhat more encouraging results. Randomized trials have shown that isotretinoin causes regression of oral leukoplakia, though accompanied by substantial side effects.[95] Two randomized trials confirmed activity of β-carotene, although results from the later study were less convincing.[96,97] Several other, less toxic agents (retinol, 4-[hydroxyphenyl]-retinamide, and α-tocopherol) and selenium have also produced responses of premalignant lesions in phase II trials.[98] A randomized trial of the cyclooxygenase inhibitor ketorolac as an oral rinse was negative in patients with oropharyngeal leukoplakia.[99] A recently reported phase II trial of the complex retinoid fenretinide suggested activity for this compound in patients with retinoic acid–resistant oral leukoplakia.[100] We have demonstrated substantial potential activity of Bowman-Birk inhibitor (a soybean-derived compound) against oral leukoplakia.[101] The results of randomized studies for these latter two compounds have not yet been reported.

In a randomized phase III adjuvant trial of patients treated for head and neck cancer by local therapy, the synthetic retinoid 13-*cis*-retinoic acid (isotretinoin, Accutane) at a high daily oral dose (50 to 100 mg/m^2) led to a reduction in the incidence of second primary tumors, a difference that was maintained for more than 5 years.[102] The rate of second primary tumors was affected greatly by tobacco smoking status, with the efficacy of chemoprevention decreasing sequentially in current and former smokers as compared with nonsmokers.[103] The side effects in the 13-*cis*-retinoic acid trial were substantial at this dosage level, however. These results with 13-*cis*-retinoic acid were particularly significant in that a similarly designed randomized trial using another retinoid (etretinate) at a high dose showed no reduction of second primary tumors.[104] Therefore, the efficacy of low-dose isotretinoin (30 mg/day) to prevent second primary tumors after treatment of early-stage (I and II) head and neck cancer was tested in a randomized trial, with the hope that side effects could be decreased without losing efficacy. This strategy was unsuccessful, and no difference in the appearance of second malignancies in the placebo and treatment groups could be demonstrated; it is noteworthy that patients who continued to smoke had an increased rate of second primary tumors and death.[105]

The incidence of adenocarcinoma of the esophagus has been increasing over the past 2 decades. Gastroesophageal reflux has been identified as a risk factor leading to the development of a columnar-lined esophagus, called Barrett's esophagus, which progresses to adenocarcinoma via a metaplasia-dysplasia sequence (Fig. 26-2C). Both endoscopic resection and thermal or photodynamic ablation have been used to treat this condition,[106] but long-term benefit is unknown. Epidemiologic and clinical observations also suggest that NSAIDs and aspirin, by inhibiting COX enzymes, and proton pump inhibitors by decreasing gastric reflux[107] should be effective as chemopreventive agents, but randomized controlled trials proving this supposition have not yet been reported. Attempts to reverse or suppress these lesions with 13-*cis*-retinoic acid have been unsuccessful.[108]

Overall, these trials suggest that oral leukoplakia, but not bronchial metaplasia, can be reversed or suppressed by currently available chemopreventive agents. Thus far, "proof of principle" of chemoprevention in head and neck cancers has been achieved. However, large-scale phase III trials will have to show efficacy with a favorable risk-benefit profile before the strategy of chemoprevention can be adopted into standard medical practice for the management of aerodigestive cancers.

COLORECTAL CANCER

Screening for and early detection of colorectal cancers results in 5-year survival rates of 90% for colon cancer and 80% for rectal cancer, providing that diagnosis and treatment occur before the lesions have spread beyond the bowel to regional lymph nodes or distant metastatic sites. Unfortunately, more than 60% of patients still present with higher staged disease, leading to a lower overall 5-year survival rate of 65%.[78] In the United States, colorectal cancer affects 148,000 individuals annually and is responsible for more than 55,000 deaths per year, which is surpassed only by cancer deaths secondary to lung cancer.[78] These statistics highlight the critical importance of identifying individuals at risk for the development of colorectal cancer and of screening and early detection in its management. This section will discuss various risk factors, both modifiable (i.e., extrinsic risk factors) and not modifiable (i.e., intrinsic risk factors), that increase susceptibility for the development of colorectal cancer and will review current screening guidelines. This information can be used to design more effective preventive strategies, which could make use of genetic testing for individuals at risk and apply behavioral modification and chemoprevention.

Pathogenesis

Numerous epidemiologic, international, and experimental studies have evaluated various hereditary and environmental factors that lead directly or indirectly to the development of colorectal cancers. It is believed that colon cancer is the result of a complex series of genetic and epigenetic events that occur when environmental factors interact with an individual's inherited or acquired susceptibility.[42,109] This interaction produces somatic mutations that accumulate over time and lead to neoplastic transformation of normal colonic epithelium into premalignant adenomatous polyps (see Fig. 26-2D) and ultimately into invasive disease. The natural history preceding the development of cancer can progress through several decades. Adenomatous polyps, especially the villous subtype, are the premalignant lesions in more than 90% of colorectal cancers. The risk of malignant degeneration depends on the size of the polyp (increasing greatly in those greater than 1 to 2 cm in size), duration of its presence, number present at the time of the initial examination, and the histologic type.[110] Only adenomatous polyps seem to carry a premalignant risk; however, hyperplastic polyps are diagnosed more commonly in individuals with a smoking or drinking history, two predisposing factors for adenomatous polyp development.[111] The presence of hyperplastic polyps may warrant increased screening and prevention counseling, although further study of this issue is needed before definitive conclusions can be made.

Etiology

Heredity

Our understanding of the genetic and molecular alterations that precede the development of colorectal cancers has broadened and deepened over the past 10 to 15 years (Fig. 26-3).[112] This information has facilitated the identification of individuals who might benefit from early interventions with more vigilant screening, chemoprevention, or treatment. Based on studies of family histories, it is estimated that 20% to 30% of colorectal cancers have a significant hereditary component.[112] Thus far, however, genes associated with only two major syndromes—familial adenomatous polyposis (FAP) and hereditary nonpolyposis colon cancer (HNPCC)—have been identified clearly. Allelic deletions have been identified in patients diagnosed with these two autosomal dominant syndromes, FAP and HNPCC.[113–115] FAP accounts for only 1% of colon cancer cases per year and is associated with a deletion of the *APC* gene on chromosome 5 (band q21). These patients develop thousands of adenomatous polyps that tend to be evenly distributed throughout the colon and rectum by the second or third decades of life. If surgical treatment by complete colectomy is not done, affected individuals are at high risk to develop colon cancer by the age of 40. A highly specific mutation (T to A at nucleotide 3920) has been found in 6% of Ashkenazi Jews, and about 28% of Ashkenazim have a family history of colorectal cancer.[116] This mutation created a small hypermutable region of the gene, thereby indirectly causing predisposition.

The incidence of HNPCC was determined to be less than 1% of annual colon cancer cases in a large population-based study, although estimates of 5% are typically reported from nonpopulation-based studies.[117] Diagnosis requires that three or more relatives be diagnosed with colorectal cancer, representing at least two successive generations, and at least one relative must have been diagnosed before the age of 50.[115] One relative must be a first-degree relative of the proband patient. Patients tend to have cancers that arise in the proximal colon, and they also develop ovarian and endometrial cancers at a higher rate than the population at large. This syndrome is associated with defective DNA repair mechanisms, which lead to aberrant cell growth and tumor formation. These mutations occur on chromosomes 3 (hMLH1, 3p21) and 2 (hMSH2, 2p).[118,119] Based

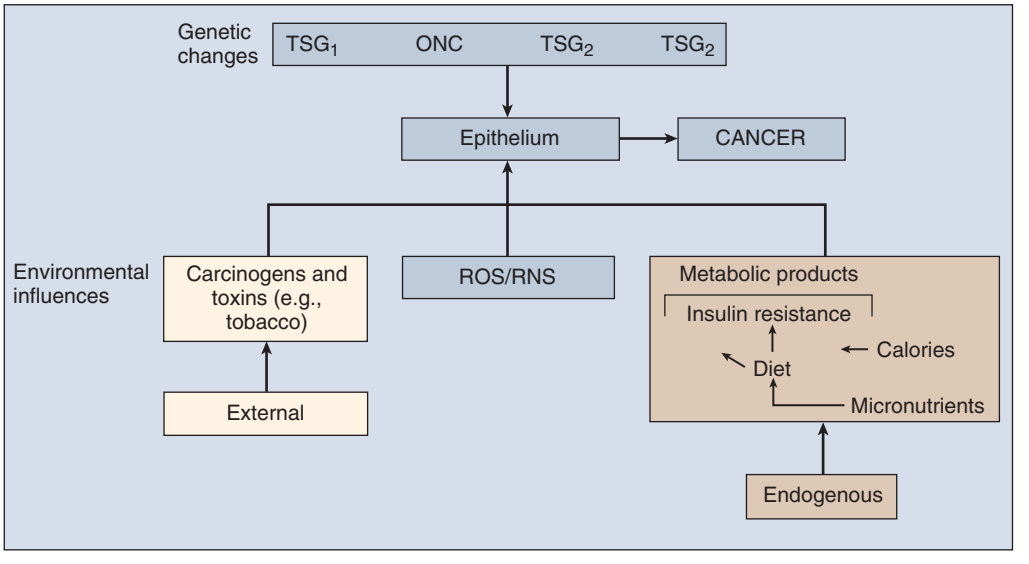

Figure 26-3 • Colorectal cancer results from inherited genetic predisposition and acquired molecular alterations interacting with environmental and endogenous toxins that are themselves modified by gene products. TSG, tumor suppressor gene; ONC, oncogene; ROS/RNS, reactive oxygen and reactive nitrogen species form from normal metabolic processes (endogenous) and from exposure to carcinogens and toxins (external).

on extensive experimental and clinical data, Vogelstein and colleagues[42,113] proposed that it is the progressive accumulation of mutations that ultimately lead to invasive disease. This proposal has been substantiated extensively, and mutations associated with colorectal cancers have been identified involving proto-oncogenes, tumor suppressor genes, and certain key regulatory enzymes, such as cytochrome P450 and acetyltransferase.[120–122] It has been suggested that colorectal cancers in adults develop through one of three different pathways (chromosomal instability, microsatellite instability, and CpG island methylator phenotype) and have different biologic behaviors.[109] The role of polymorphisms in metabolizing key molecules (including those present in the diet) is being examined closely and should provide a platform from which to understand gene-environment interactions. For example, polymorphisms in hepatic cytochrome P450 and acetyltransferase enzymes lead to rapid oxidation and acetylation of genotoxic compounds such as heterocyclic amines, which are present in processed foods.[122] Accelerated metabolism of these compounds increases an individual's risk of developing colorectal cancers threefold.

Diet

Although diet seems to play a significant role in colon carcinogenesis, the degree to which individual macronutrients and micronutrients contribute to the development of colorectal cancer has been elusive. In part, this difficulty stems from differences in design and methodology in studies that have been performed to evaluate this subject, including the type of dietary questionnaire administered, differences in cohorts such as age and ethnicity, confounding effects of other dietary components, selection and recall biases, sample size, and length of follow-up.

The majority of past evidence has demonstrated an increase in incidence and mortality rates from colorectal cancers in groups of people who consume a more "westernized" diet that is high in animal fat, total calories, and red meat but low in fiber and fruit and vegetable intake.[123] International and migrant studies have supported this observation. Recent studies, however, have indicated that the older evidence should be reconsidered. Large prospective cohort studies and several large randomized trials indicate that fiber does not seem to be protective nor fat contributory to colon cancer development.[124–126] In contrast, mechanistic considerations, metabolic studies, and epidemiologic studies suggest a strong protective effect of folate and an important role of insulin and insulin-like growth factors in colon cancer pathogenesis. Potter[109] and other researchers have done a particularly nice job in attempting to relate genetic changes, risk factors (including diet), and downstream molecules and pathogenesis.

Other Factors (Alcohol, Smoking, Exercise, Body Mass Index)

Primary prevention of colorectal cancer also requires that we understand factors other than diet that increase risk for colorectal carcinoma by initiating or promoting carcinogenesis. These include use of alcohol and tobacco, sedentary lifestyle, and the metabolic changes that proceed from these.[18,127]

Many studies have demonstrated a relationship between alcohol use and colorectal cancer and adenoma formation.[128,129] It is still uncertain whether alcohol directly initiates DNA damage or acts as a promoter on cells that already have undergone preneoplastic changes. A low-methionine or low-folate diet might contribute to a situation leading to adenomas and colorectal cancer, in that both methionine and folate are cofactors for DNA synthesis; lowered concentrations of these compounds leads to hypomethylation of DNA, which is a precursor to aneuploidy and loss of heterozygosity.[130] Various forms of a key enzyme, 5,10-methylenetetrahydrofolate reductase, which catalyzes the conversion of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, have also been identified.[131] Some mutations of this enzyme increase its activity, whereas others decrease it. Low activity leads to decreased methionine synthesis and antagonizes methyl group metabolism in DNA synthesis.[131] This theory gained some support in the U.S. Male Health Professionals Study.[111] An association was found between high alcohol intake and methionine-deficient diets, after controlling for intakes of fat, red meat, fiber, level of physical activity, body mass index (BMI), and multivitamin and aspirin supplementation. Alcohol might be particularly important for progression of large adenomas to tumors.[128] Avoiding excess alcohol, while increasing dietary folate and methionine, seems like a reasonable approach to decreasing risk for colon cancer. Several large studies are underway to test whether supplementation with folate can reduce adenomata development.

Cigarette smoking has been consistently associated with adenoma formation but less so with colon tumors, an observation that could be explained by the molecular nature of a subset of colon tumors in which microsatellite instability and/or p53-negative status is a prominent feature.[132] The Health Professionals Follow-up Cohort Study and the Nurse's Health Study observed more adenomas in individuals with a history of smoking than in those who did not smoke.[133] Analysis of the very large American Cancer Society Cancer Prevention II study indicates that 20% of colorectal cancers and 12% of deaths are associated with long-term cigarette smoking[134] (Fig. 26-4).

Physical inactivity and high BMI also increase one's risk for colorectal cancers. A prospective study found a significant inverse association between leisure-time physical activity and incidence of colon cancer in participants of the Nurse's Health Study.[135] An inverse association was also observed between physical activity and the development of large (>1 cm) adenomas in the distal colon. In this same study, more adenomas were observed in individuals with a high BMI. Obesity, and in particular abdominal adiposity, has also been associated with an elevated risk for adenomatous polyps and colon cancer.[136] Recently, two separate cohort studies have demonstrated that physical activity is associated with improved outcomes among resected colon cancer patients.[137,138] Increasing physical activity and maintaining lean body weight for the prevention of colorectal cancer probably has considerable merit for decreasing the incidence of polyps and colon cancer, as well as of other chronic diseases.

The mechanisms underlying these proposed effects are not clear, but a unifying hypothesis has been proposed recently and involves the sequential steps of consumption of excess dietary energy, development of insulin resistance, and increased circulating levels of insulin, triglycerides, and nonesterified fatty acids, which results in secondary colonic epithelial damage.[139] Thus, the beneficial effects of physical activity on colon cancer risk and outcomes represents the sum total of numerous cellular and molecular events. A goal of prevention research is to determine which molecular pathways are being affected by physical activity and to evaluate potential biomarkers in this process. However, validated mechanisms have been lacking. Epidemiologic evidence associating insulin, insulin-like growth factor-1, and insulin-like growth factor–binding protein levels with colorectal cancer incidence provides considerable support for the proposal that changes in diet and physical activity may affect key molecular events.[140]

Screening and Early Detection

Population-Based Data

A definitive amount of data has accumulated indicating that colorectal cancer screening for persons at average risk is effective and reduces colorectal morbidity; agreement on the best screening modality remains unsettled, however.[141] Cost-saving analysis even supports the use of universal colonoscopy over the long term, notwithstanding the considerable practical challenges and total cost in achieving this goal. Probably everyone over 50 years of age should be screened. Yet surprisingly, fewer than 50% of individuals who should be screened are evaluated by fecal occult blood tests (FOBT), digital rectal exams (DRE), and/or sigmoidoscopy.[32]

Conflicting recommendations from government and private agencies contribute to the confusion. In general, all groups advocate

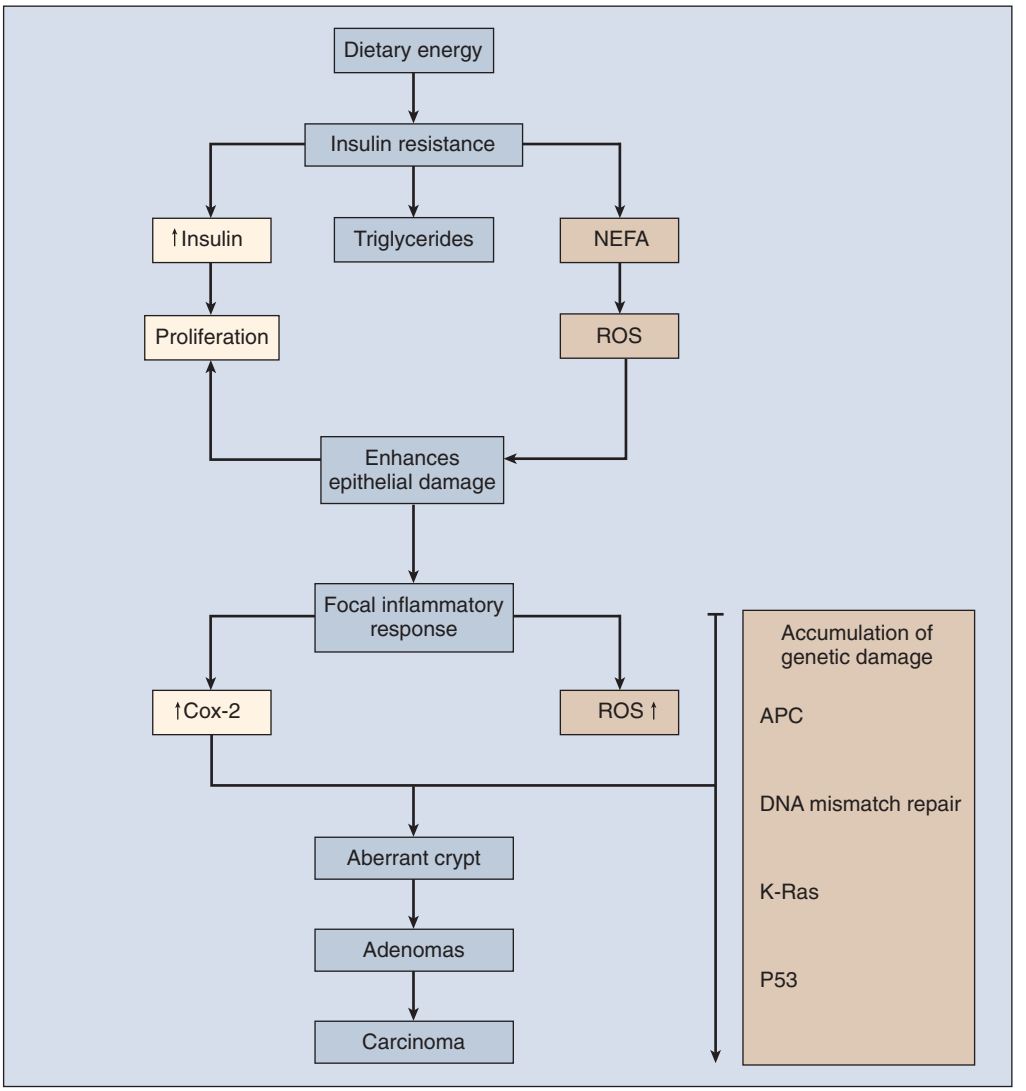

Figure 26-4 • The potential effect of diet on risk of colon cancer. NEFA, nonesterified fatty acids; ROS, reactive oxygen species.

screening in men and women beginning at the age of 50, because the incidence of colon cancer rises sharply between the ages of 50 and 55 and continues to double with each succeeding decade, reaching a peak by the age of 75. The American Cancer Society and the American College of Obstetricians and Gynecologists support yearly DREs beginning at age 40 and FOBTs performed yearly, once a person reaches 50 years of age. Sigmoidoscopy should occur every 3 to 5 years beginning at 50 years of age. Flexible sigmoidoscopy is superior to rigid sigmoidoscopy, because it allows the examiner to visualize up to 60 cm of bowel mucosa and is easier on the patient.

There are numerous studies validating the use of DRE, FOBT, and sigmoidoscopy as effective screening tools, providing regular screening is performed (to detect lesions in this disease with a long preinvasive phase).[142–144] This is particularly important with the FOBT, because reported sensitivities are low and range between 22% and 92%. Sensitivity is higher when at least three tests are performed on different days and the samples are rehydrated with hydrogen peroxide. To decrease false-negative results, which also increases the sensitivity of the test, patients should be instructed to avoid vitamin C and to eat a high-residue diet for several days before the test. The incidence of false positives is lowered when gastrointestinal irritants (e.g., aspirin, oral iron, and meat products) are not consumed a few days before the FOBT. In general, screened, asymptomatic patients have a positive test 4% to 6% of the time. Only 5% to 10% of these individuals have colorectal cancers, and an additional 30% have benign polyps.[145,146] The positive predictive value is only about 20%, so a positive test can be costly, because follow-up requires evaluation by sigmoidoscopy or colonoscopy. Randomized clinical trials have demonstrated a decrease in mortality by 15% to 33% with the regular use of serial FOBT, however.[143] Patients who received FOBT in conjunction with sigmoidoscopy in a Memorial Sloan-Kettering colon cancer trial had a significantly higher survival probability when compared with those who received sigmoidoscopy alone (70% vs. 48%, respectively).[143] This is an impressive result.

Regular screening with sigmoidoscopy among patients over 50 years of age both reduces mortality from colorectal cancer and prolongs survival.[147,148] Studies must be performed to clarify the optimal interval between screening and to develop recommendations for individuals at higher risk for adenomas or colorectal cancers. The early results of a "once-only" sigmoidoscopy at age 60, in which a high yield of adenomas was obtained, suggests that a less intense approach to screening could be a cost-effective strategy to prevent colon cancers.[149] Follow-up colonoscopy suggested that a significant number of proximal adenomas were present. The efficacy of screening

colonoscopy for adenoma detection was directly related to prolonged endoscope withdrawal time in a recent study, a finding that may influence patient management in the near future.[150] There is little doubt that screening colonoscopy is effective at identifying silent, large adenomas and colon cancers, but its cost effectiveness must be demonstrated; so must the optimal usage of fecal occult blood, sigmoidoscopy, and colonoscopy with regard to efficacy and cost. A particularly exciting approach is the identification of colon cancer-specific mutations in fecal DNA.[151] A study of the adenomatous polyposis coli (*APC*) gene, the initiating abnormality in most sporadic colon cancers, in the fecal DNA of normal individuals and patients with polyps shows considerable promise.[152] Although the specificity of this test was high (100%), the sensitivity was only 57%. However, integration of the test into the screening paradigm (perhaps with FOBT) as a low-cost, general screen is an important goal. The DRE should be included in all examinations, because it permits evaluation of the distal rectum and prostate. Its sensitivity has decreased, however, with the temporal shift to more proximal lesions in the colon.[149] Other tests, including double-contrast barium enema, have not been evaluated completely as screening tests and are more expensive than DRE, FOBT, and sigmoidoscopy. We feel that these modalities should be reserved for those patients with positive screening tests.

High-Risk Individuals

More frequent screening is recommended for certain postpolypectomy individuals and other individuals at increased risk for the development of adenomatous polyps or colorectal cancers.[153] One particularly important group includes those who have had previous treatment for a primary colorectal cancer. Recent analysis indicates that evaluation of this high-risk group has been inadequate. Proctosigmoidoscopy or colonoscopy should begin at age 10 for first-degree relatives of individuals with FAP and at age 25 for individuals with a strong family history suggestive of HNPCC.[154,155] Genetic testing for the mutated *APC* gene in peripheral mononuclear cells of patients with early onset of adenomatous polyps or in first-degree relatives of FAP-affected individuals will help to determine who needs closer surveillance.[156] Counseling about diet, chemoprevention, and lifestyle issues can be provided for individuals who test positive for the mutated *APC* gene. In addition, a colectomy should be considered if polyps are found.

Genetic testing for mutations in DNA repair genes should be performed on anyone whose family history is suggestive of HNPCC; counseling can then be provided for individuals who test positive.[157] A positive family history of colorectal cancer that does not meet criteria for FAP or HNPCC probably also warrants earlier screening, but definitive guidelines have not been established. A prospective study of approximately 120,000 men and women who underwent colonoscopy or sigmoidoscopy surveillance concluded that the age-adjusted relative risk for cancer was 1.72 with one first-degree relative with the disease, 2.75 with two first-degree relatives, and 5.37 with one first-degree relative who was under age 45 at the time of diagnosis.[158] It is estimated that as many as 25% of individuals with colon cancer have positive family histories. Baseline colonoscopy before age 50 seems to be a reasonable consideration among this group of patients with a positive family history.

Other high-risk conditions requiring close surveillance include individuals with a long-standing history of inflammatory bowel disease, a prior history of polypectomy or ureterosigmoidostomy, a personal history of ovarian, endometrial, or colon cancer, and finally anyone who has been treated for *Streptococcus bovis* bacteremia.[154,159–161]

Other Health Factors

In considering health care resources, other issues that affect the development of colon cancer should be considered. The role of estrogen replacement in the development of colon cancer and in other health parameters in postmenopausal women is of great importance. The results of the Nurse's Health Study suggested that current estrogen replacement in postmenopausal women can reduce the risk of colon cancer (relative risk = 0.65); this effect disappeared 5 years after discontinuation of estrogen replacement.[162] However, a detailed analysis of the group of postmenopausal women in the WHI trial who received estrogen plus progestin indicated that the colorectal cancers were diagnosed in a more advanced stage even though the number of colorectal cancers was reduced by 45%.[163] When reproductive factors were examined among women who were diagnosed with colon cancer in this study, oral contraceptive pill use and later age of menarche were also associated with a decreased risk. In another study, women who delivered more than five children, especially if they had a positive family history of adenomas, were at increased risk for the development of adenomas.[164] In this study, however, no association was found with age at menarche, menopause, first birth, or oral contraceptive pill use. Although estrogen plus progestin lowered the risk for colorectal cancer in the WHI trial,[163] these favorable results will have to be balanced against the increased risk for breast cancer and cardiovascular disease (see later discussion).

Chemoprevention

Despite the enormous amount of epidemiologic observations and experimental data that support a protective role of many dietary constituents against the development of adenomatous polyps and colorectal polyps, the results from definitive randomized trials have been modest, at best. Many micronutrients and dietary constituents have been studied. Trials using vitamins C, D, and E, and β-carotene as well as supplementation with fiber or lowering of dietary fat have been uniformly negative. Trials in which calcium has been supplemented have been modestly positive with a 25% to 35% reduction of adenomatous polyps demonstrated.[24,25] However, daily supplementation of calcium with vitamin D for 7 years had no effect on the incidence of colorectal cancer among postmenopausal women in the WHI.[165] These results suggest that calcium inhibits colon carcinogenesis at early but not late stages.

Additionally, in a double-blind, randomized, placebo-controlled trial of selenium supplementation for skin cancer prevention, a secondary analysis showed that the numbers of colon, prostate, and lung cancers were found to be reduced by 50% in the treatment arm.[166] The results of additional randomized trials are pending and should become available in the next 3 to 5 years.

Study of the effects of micronutrient supplementation on the formation of polyps and colorectal cancers is difficult, given the inherent complexity of carcinogenesis. Understanding how various dietary components inhibit carcinogenesis will be instrumental to the development of novel dietary-derived chemopreventive agents in the future. Factors such as type of micronutrient, dose, and duration of treatment, as well as cohort demographics (age and geographic location), and endpoints (polyp formation, or changes in the incidence and mortality of invasive cancer) are all important variables that will affect trial results. However, despite these difficulties in study design, analysis, and interpretation, we should not dismiss the large amount of epidemiologic evidence and supportive experimental data demonstrating that the consumption of diets rich in fruits and vegetables, but low in fat, have a lower incidence of bowel cancer and cancer in general.[167] Observational and animal studies suggest that reduction of caloric intake and moderate physical exercise should also decrease the risk of colorectal cancer.[168] Meat consumption—particularly red meat that has been processed, has been associated with increased risk of colorectal cancer in numerous epidemiologic studies. Substances in meat that have been implicated in colon carcinogenesis include the known carcinogens: heterocyclic amines (formed in meat during cooking), polycyclic aromatic hydrocarbons and N-nitroso compounds (both found in processed meats), and the amino acid arginine (i.e., a key substrate of the polyamine synthetic pathway).[169–172] Research from clinical trials should provide us with invaluable data

on which to base dietary and lifestyle recommendations for the prevention of colorectal cancer.

There are also abundant scientific opportunities to explore the role of nondietary chemoprevention compounds in controlling colorectal cancer based on substantial studies of colon carcinogenesis (see review[173]). Some of the more active nondietary compounds being studied include NSAIDs and DFMO. Mechanistic studies indicate that epithelial regeneration and focal inflammation may be important early changes in the pathogenic process,[139,173] so that the use of nontoxic antiproliferative and anti-inflammatory agents as chemoprevention agents has a strong rationale. These biologic features of colon carcinogenesis are also used to support a role for probiotics and prebiotics for the prevention of colorectal cancer.[174]

A considerable amount of experimental and epidemiologic evidence exists to support the use of NSAIDs to decrease the risk of colon cancer.[173] These compounds exert their antiproliferative effects on colonic cells through inhibiting prostaglandin synthesis by reversibly binding to cyclooxgenase as well as through several other newly discovered mechanisms. Laboratory studies have consistently demonstrated that NSAIDs can inhibit chemically induced and transplanted tumors in rodents. The interpretation of epidemiologic trials involving NSAIDs is challenging because of differences in design and methodology, including the particular agent chosen, the dose, frequency, and duration of use, and variable follow-up periods. Nevertheless, most case-control and cohort studies have demonstrated an association of a reduced risk of colon cancer with increased consumption of NSAIDs.

Analyses of subgroups of patients who routinely take these drugs—such as patients with rheumatoid arthritis (aspirin), inflammatory bowel disease (sulfasalazine), and FAP (sulindac)—have reported a decrease in either adenomatous polyp formation or the development of colorectal cancer. A particularly important study was the Nurse's Health Study, which used three consecutive questionnaires to determine the rate of colorectal cancer among women who consumed aspirin and compared these rates to women who reported no aspirin use.[175] After at least a decade of regular aspirin use, at doses similar to those recommended for the prevention of cardiovascular disease, aspirin consumption was found to reduce the risk of colorectal cancer substantially. Both celecoxib and sulindac have been shown to cause regression of polyps in patients with FAP.[176,177] Sulindac was not effective in preventing the development of new polyps in these patients, however.[178]

The results of several large randomized trials using NSAIDs have been reported.[168,179,180] Aspirin has uniformly reduced the recurrence of adenomatous polyps by 25% to 35% in patients at moderate risk with acceptable toxicity. Studies with COX-2 selective inhibitors have produced an unusual conundrum. Several randomized trials have demonstrated substantial benefit with a 40% to 50% reduction in recurrence of adenomas; however, cardiovascular events were markedly increased in the treatment arm.[62,63] These results have put a significant damper on the development of chemoprevention agents for cancer. Whether similar adverse results will be seen with less selective NSAIDs (e.g., sulindac) is unknown and awaits the results of ongoing trials.

DFMO has been found to be a potent inhibitor of carcinogenesis in experimental animal models by reducing the number and size of adenomas and carcinomas. This drug exerts its effects by irreversibly inhibiting ornithine decarboxylase, the first enzyme in the polyamine synthesis pathway. Suppressing intracellular pools of polyamines decreases cell growth and interferes with the process of carcinogenesis in essentially all animal models. We have reported the results of a long-term clinical trial, which serially measured the effects of different doses of DMFO on rectal mucosal polyamines over a 12-month time period and demonstrated consistent suppression without side effects.[57] Demonstration of a dose of a chemopreventive agent that has a substantial biochemical effect without producing clinical side effects is an important goal. Currently, we are studying the prevention of adenomas in patients that have undergone polypectomies for adenomatous polyps. DMFO will be given in conjunction with sulindac over a 3-year period, and its effect in reducing polyp recurrence is being studied in a randomized, placebo-controlled trial.

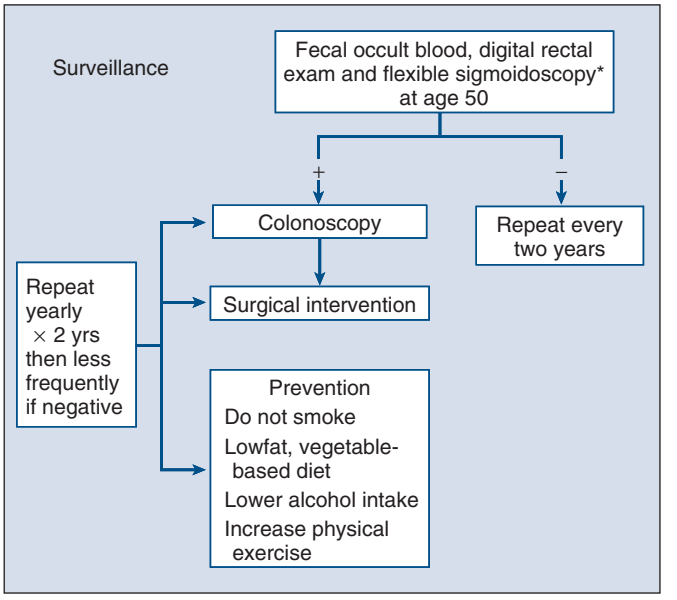

Figure 26-5 • Routine screening and early detection for colorectal cancer and its prevention. *There is a growing consensus that a colonoscopy should be performed at age 50 and all polyps removed. If negative, repeat about every 5 years. If positive, repeat in 3 years. If there is a familial tendency, start 5 years before age of youngest family member with disease.

The role of tertiary prevention in colorectal cancer has been little explored. As effective chemoprevention agents are developed, the group of patients who have been "cured" by standard therapy should become a focus of investigation, because the incidence of second primary colon cancers is high (about 25%).[181]

Integration of Prevention Activities

Several approaches exist to prevent the development of colorectal cancers. Successful primary prevention depends on public education and counseling about behavioral and dietary modifications that can be made to decrease an individual's risk, including increased physical activity and reduction of total calorie intake. In patients with adenomatous polyps, polypectomy is a useful preventive measure. Patients with FAP or HNPCC might require colectomies at a younger age to prevent development of cancer. New advances in genetic testing will help to select people who not only need closer surveillance but also might benefit from surgical treatment before cancer or premalignant polyps develop.

More vigilant screening in individuals at increased risk for the development of colorectal cancer is reasonable, but the appropriate screening tests, and the optimal interval between tests, require further clarification. More important, given that the majority of cancers occur in patients without a family history, everyone probably should be screened beginning at 50 years of age. Clinical applications of chemoprevention with DFMO, NSAIDs, and various micronutrients are still under development but may offer important alternatives for the future or as part of an overall approach to prevention (Fig. 26-5).

BREAST CANCER

The morbidity and mortality from breast cancer remains high despite significant advances in our understanding and management over the

last several decades. Therefore, prevention and early detection have become important challenges for the medical community. In addition to an enormous health benefit, several billion dollars would be saved annually if breast cancer were prevented and/or the disease were detected at an earlier stage. The widespread use of screening mammography, the increasing recognition that breast density is a major risk factor, the identification of high-risk individuals based on family history, the detection of deleterious mutations, and the "proof of principle" that tamoxifen and raloxifene can reduce the risk for breast cancer all anticipate more effective early management of this disease.

Etiology

Heredity

Primary prevention depends on our ability to identify individuals who are at increased risk for the development of breast cancer.[182] Although many risk factors cannot be changed, knowledge of their presence can be used to identify high-risk individuals. Age, socioeconomic class, geographic location, race, and ages of menopause, menarche, and first birth are examples of risk factors that are difficult to change but important to recognize. The incidence of breast cancer, like that of most cancers, increases with age. The majority of cases are diagnosed in women older than 40 years of age, with only 10% to 15% occurring in women younger than 40 years old and fewer than 5% occurring among women younger than 35 years of age. Affluent women and individuals born in colder climates or in the Western hemisphere also tend to have a higher incidence of breast cancer. White women have more breast cancers than black, Asian, Hispanic, or Native American women. It is of considerable interest that Hispanic and Native American women have many of the same demographic variables (obesity, high fat, and low vegetable diet) that are associated with a high incidence of breast cancer in whites, yet their incidence of breast cancer is less than half that of whites.[183] Determining whether this difference is genetically based or if it reflects some other protective dietary or environmental factor is an important issue to address. By identifying who is at higher risk for breast cancer, health professionals can then counsel this subgroup of women and their families about the risks for breast disease and various ways to modify these risks, and they can encourage enrollment into clinical trials aimed at studying novel approaches for breast cancer risk reduction.

The most important step in trying to discern who is at risk is to take a detailed personal and family history extending back at least three generations.[184] Nearly 25% of women diagnosed with breast cancer have a family history of the disease.[184] Recent advances in our understanding of the molecular biology of breast cancer have led to the identification of specific mutations that might help identify women with a hereditary predisposition to developing breast cancer and might help predict who will respond to adjuvant therapy. Medical records, including pathology reports, should be obtained whenever possible to help complete an accurate pedigree. Recall bias is a significant problem when constructing pedigrees and can profoundly influence how we counsel patients; therefore, it is important to collect documentation whenever possible. Family histories must be gathered from the maternal and paternal sides of the family. This latter step is often neglected and makes it impossible to counsel anyone in a meaningful way.

Although most cases of breast cancer are sporadic and a product of many genetic insults, approximately 5% are due to specific inherited germline mutations in the *BRCA1* and *BRCA2* tumor suppressor genes.[185] The estimated lifetime risk for breast cancer in *BRCA1* and *BRCA2* mutation carriers ranges from 55% to 85%, in comparison with the 13% lifetime risk for the general population.[185–187] Women with these mutations are also at increased risk for the development of a second breast cancer; *BRCA1* mutation carriers carry up to a 65% lifetime risk, and *BRCA2* carriers might share a similar risk.[187] Therefore, carriers of mutations in the *BRCA* genes and women with a personal or family history might benefit from prevention strategies and genetic counseling.

Genetic testing should be offered to individuals with a strong family history (breast or ovarian cancer in two or more generations), a history of multiple primaries (ovarian or breast, colon, endometrial), early age of onset of breast cancer (<35 years), or individuals of Ashkenazi Jewish descent, who carry a frequency of mutations in the *BRCA* genes estimated to be 2.2%.[185,186] Approximately one out of every 300 to 800 American women carries a *BRCA1* mutation; however, not every one of these women will develop breast cancer. This variable penetrance seen in *BRCA* mutation carriers highlights one of the dilemmas of genetic testing for *BRCA* gene abnormalities. Furthermore, a negative test might offer false reassurance, because it could represent a false negative. In addition, although a number of mutations in the *BRCA* genes have been sequenced, there are probably many more that we have not identified and for which we therefore cannot test. Practitioners should be aware of the uncertainty inherent in genetic testing for *BRCA* mutations and be prepared to counsel their patients accordingly.

Family history without a clearly defined genetic syndrome is also important in counseling women about their risks for developing breast cancer.[188,189] A woman with a first-degree relative with premenopausal breast cancer carries anywhere between a 1.8- and an 8.8-fold increased risk of developing a breast cancer in the future and is at high risk for harboring a deleterious mutation. This risk decreases to 1.2- to 4.0-fold in a woman who has a first-degree relative who developed breast cancer after menopause. Having a second-degree relative with breast cancer increases a woman's risk by approximately 1.5-fold.

Hormonal Factors

Women with a long lifetime exposure to estrogen are also more likely to develop breast cancer. The risk for breast cancer increases by 20% if menarche occurs before the age of 12.[190] Furthermore, women who experience a late menopause, are nulliparous, or deliver their first child after 30 are also at increased risk. An induced abortion does not result in an increased risk of breast cancer (Box 26-1).[191]

The subject of HRT and its role in the etiology and progression of breast cancer has been among the most intensely studied in medicine. Studies evaluating the role of hormone replacement in postmenopausal women have reported contradictory results—not surprising given that many of the studies evaluated different doses, preparations, follow-up times, and different age cohorts.[192–194] Results from the WHI study (i.e., the largest prospective randomized clinical trial to address the issue of HRT on breast cancer development), however, conclusively demonstrated an increased risk of invasive breast cancer (relative risk = 1.26) among those women taking estrogen plus progestin compared with placebo control subjects.[17] Additionally, the supplementation of postmenopausal women with estrogen plus progestin in the WHI trial led to increased mammographic density and breast cancer,[195,196] These findings have sparked an intense debate, with proponents of HRT advocating no change

Box 26-1. INDICATIONS FOR GENETIC TESTING IN BREAST CANCER*

- A first-degree relative with breast cancer before age 40
- Two or more relatives with breast or ovarian cancer at any age
- Three or more relatives with breast, ovarian, or colon cancer at any age

*The indications for genetic testing in breast cancer and in other cancers are in rapid evolution as the true risks become better defined and as prevention (e.g., tamoxifen) and early detection (e.g., mammography, MRI) strategies mature.

in prescribing habits and opponents vociferously advocating the opposite.

Compelling data in support of the aforementioned WHI results have emerged from recent epidemiologic reports indicating a sharp decrease in breast cancer incidence in 2003, particularly in estrogen receptor (ER)–positive tumors.[197,198] This time period represents the first year after results of the WHI trial were released, with a resultant immediate 50% decrease in HRT use. The rapidity of this observed decreased breast cancer incidence supports an effect of hormone therapy on progression of subclinical lesions. These reports from the California Cancer Registry and in the national U.S. Surveillance, Epidemiology, and End Results (SEER) registry have sparked a renewed debate about the role of HRT in early breast cancer development, because it represents the first significant decrease in breast cancer incidence in the United States in more than half a century.

In contrast, the preponderance of evidence suggests that the risk for breast cancer from oral contraceptive use is very low or nonexistent. An overview of 54 epidemiologic studies evaluating the role of oral contraceptives and breast cancer found the RR of current users to be 1.24 vs. no risk for women who had not taken them for 10 or more years.[199] Thomas[200] summarized the results of five cohort studies and found that the overall risk for ever-users to be 1.06. On the other hand, in a large, matched case-control study of *BRCA* mutation carriers use of oral contraceptives was associated with increased risk of breast cancer in *BRCA1* (overall risk = 1.20) but not in *BRCA2*.[201]

Oral contraceptives are used by more than 150 million women worldwide and offer a number of health benefits, including reduction in dysmenorrhea, fibrocystic breast changes, iron deficiency anemia, pelvic pain secondary to endometriosis, ectopic pregnancy, pelvic inflammatory disease, functional ovarian cyst formation, and the incidence of endometrial and ovarian cancers.[189] Women should be counseled that there could be a slightly increased risk of developing breast cancer, although some believe that the apparent increase is due to surveillance bias, because physicians examine women taking oral contraceptive pills more frequently. Supporting this viewpoint is the observation that women with breast cancer who have taken oral contraceptives in the past do not experience lower survival rates when compared with women who have not taken them. Based on these data, current prescribing practices for oral contraceptives should not be changed, although the special case of *BCRA* mutation carriers must be assessed carefully on an individual basis.[201]

Other risk factors associated with breast cancer, such as proliferative fibrocystic changes in the breast, sedentary lifestyle, and diet, may be used to design preventive strategies for the high-risk woman. Overall, typical or atypical proliferative fibrocystic changes of the breast are associated with a two- to fourfold increased risk for the development of breast cancer.[202] Because the clinical significance varies depending upon the degree of hyperplasia and atypia present, the Cancer Committee of the College of American Pathologists has replaced the term *fibrocystic disease* with *fibrocystic changes.* Possible treatment options for relieving symptoms related to fibrocystic changes include decreasing the consumption of foods rich in methylxanthines (e.g., chocolate, coffee, tea, and cola) or taking a supplement such as vitamin E, or medications such as danocrine, bromocriptine, or tamoxifen. Although consumption of these drugs has been shown to decrease fibrocystic changes in the breast, studies have not been done to evaluate whether these changes actually decrease the increased risk of breast cancer.

Diet

Numerous observational studies have reported on the role of diet in breast cancer development with disparate findings, whereas experimental studies are more definitive.[203–205] Many public health agencies advocate a low-fat, high-fiber diet to prevent breast cancer. Data linking diet to breast cancer come largely from international and migration studies. First-generation Japanese-American women and women who have recently migrated from Japan have risks for the development of breast cancer that approach those of Native American women.[206] Differences are seen among women from various countries as well; for example, women in Great Britain have age-standardized mortality rates of approximately 28 per 100,000 versus those of Japanese women of 6 per 100,000.[207]

The WHI study is the only randomized prospective study performed to address the role of diet in the development of breast cancer, in which women were randomized to low-fat diets or no dietary intervention.[208] In this randomized trial of a low-fat dietary intervention among postmenopausal women aged 50 through 79 years, the low-fat diet resulted in a nonsignificant 8% reduction in breast cancer incidence over an 8-year study period. However, secondary analysis revealed a benefit from the dietary intervention among women with baseline high-fat diets, and women who were strictly adherent to the intervention. Therefore, we consider these results to be promising, if not definitive data related to dietary modification of breast cancer risk. Initial data from the WHI study related to calcium–vitamin D supplementation compared to placebo among postmenopausal women revealed no reduction in breast cancer risk, although the incident breast cancers in the intervention group were smaller in size.[209]

Women of tall stature or who have high body fat and mass have higher rates of breast cancer than other women.[203–205] An increase in estrone and estradiol as BMI increases has also been documented.[210] The recognition that a hormone (leptin) produced by fat cells vigorously stimulates the growth of normal and malignant breast cells may provide an important biologic link to the phenomenologic observation.[211] Some animal studies, however, have shown that caloric restriction in general, rather than a low-fat diet per se, decreases risk of breast cancer. This effect of caloric restriction could underlie the observation that women who exercise have a lower risk of breast cancer. Another consideration is that women who exercise ovulate less frequently and therefore are not exposed to the higher levels of estrogen that normally occur in women who ovulate regularly.

Numerous epidemiologic studies suggest that alcohol has an effect on the development of invasive breast cancer. An extensive and detailed meta-analysis of the six largest prospective cohort studies addressing this issue showed that alcohol consumption was associated with a linear increase in breast cancer incidence for intakes less than 60 g/day (about two to five drinks).[212] The association was not modified by other factors, and higher alcoholic intakes (>60 g/day) were not associated with additional increased risk. Low dietary levels of selenium and antioxidants such as vitamins C and E, and β-carotene have been associated with breast cancer development and differences in survival.[213] β-carotene is the major provitamin A carotenoid and has differentiating and antiproliferative effects on a variety of cells, including mammary carcinomas. Levels of β-carotene have been analyzed in numerous studies and are lower in women with higher staged breast cancer and breast cancer in general. A case-control study from Europe, however, observed no differences in vitamin A or β-carotene levels between cases and control subjects.[214] Studies of soy intake in Singapore Chinese women are of great interest.[210,215] Soy intake was significantly associated with lowered plasma estrone and with more favorable mammographic patterns. Recently, there has been a great interest in gene-environment interactions and studies of micronutrients in relationship to metabolic pathways, and genetic polymorphisms are likely to be informative. Among women at high risk for breast cancer for other reasons (e.g., heredity), reducing alcohol consumption should be a straightforward way to reduce breast cancer risk.

Screening and Early Detection

Secondary prevention is aimed at detecting preinvasive lesions such as ductal carcinoma in situ, lobular carcinoma in situ, or early-staged breast cancers that have the potential to be cured with limited treatment. Screening tests include the breast self-examination, the clinical breast examination administered by health care professionals, and mammography. Successful implementation of wide-scale screening

programs that incorporate these techniques, followed by treatment of detected lesions, is probably responsible for most of the decline in the overall death rate from breast cancer that occurred among American women from 1989 through 1993.[216] This decline continues and probably represents both the increased use of mammography and the effectiveness of systemic adjuvant therapy. Currently, 5-year survival rates for localized breast cancers have increased to more than 98%.[78]

Although we encourage women to perform monthly breast examinations, a randomized trial indicated that this practice does not decrease overall mortality rates.[217] The most effective combination for decreasing the incidence of invasive disease is the clinical breast examination and mammography. The Breast Cancer Detection Demonstration Project showed that the sensitivity of the clinical breast examination and mammogram together was 70% to 80%, with sensitivity increased for older patients.[218] Although it is standard practice for a clinical breast examination to be performed annually, there has been a great deal of controversy surrounding the appropriate time to begin routine screening with mammograms. Randomized controlled trials of a large number of women on trials from several countries have unequivocally demonstrated a 40% decrease in mortality from breast cancer in women who have annual mammograms beginning at the age of 50.[219] Throughout the years, controversies have erupted regarding the magnitude of benefit from screening mammography. We continue to recommend the practice to women beginning at the age of 50 but encourage discussion of the risks and benefits associated with this procedure.

The opinion on routine screening in women between the ages of 40 and 49, however, is mixed.[220] Eight randomized controlled trials performed between 1963 and 1982 do not demonstrate a statistically significant difference in breast cancer mortality within 7 years after screening was initiated in women randomized to receive or not receive screening mammograms. A majority in a recent consensus panel used this information to state that there currently was not sufficient evidence to advocate routine screening mammography in women ages 40 to 49. Five of these trials, however, demonstrated a 16% decrease in mortality if follow-up continued for 10 years, prompting release of a minority report advocating routine screening in the 40 to 49 age group.[220] As the minority report highlighted, the goal of mammography is to detect preinvasive lesions, and 15% to 20% of breast cancers are now diagnosed as ductal carcinoma in situ or lobular carcinoma in situ in younger women. The minority report correctly pointed out that the risk from radiation during mammography screening was overemphasized. The U.S. Preventive Task Force has considered the issues carefully and recommends a screening mammography every 1 or 2 years for women aged 40 and older,[221] a position we favor. An important recent observation is that mammographic density is strongly associated with risk and is heritable.[222] This information should further target the premenopausal woman at higher risk for breast cancer; determination of the underlying genetic basis for breast density has now become of great interest, particularly in that the use of a postmenopausal hormone therapy was strongly associated with an increase in mammographic density in the Postmenopausal Estrogen/Progestin Interventions and WHI trials.[195,196]

New areas that are currently being evaluated for the enhancement of primary and secondary prevention strategies include digital mammography, DCE-MRI, DCE-CT with ultrasound, PET, optical scanning, ductal lavage for cytologies and molecular testing, nipple aspirates, and blood and urine assays for growth factors and autoantibodies to oncoproteins and to tumor DNA. Validated biologic markers of breast cancer risk and/or more sophisticated screening modalities might well increase our ability to detect lesions earlier in high-risk populations.

Chemoprevention

Successful therapeutic prevention for breast cancer has progressed faster than for any other malignancy.[223] Two compounds, tamoxifen and raloxifene, which are estrogen receptor antagonists, have been shown to reduce the incidence of primary breast cancer in women at high risk.[224,225] In a head-to-head randomized trial of tamoxifen and raloxifene, efficacy was comparable with a 50% reduction of breast cancers; the toxicity of raloxifene was considerably less than that of tamoxifen.[226] Based on the positive activity of anastrozole (an inhibitor of estrogen synthesis) in the adjuvant setting and its minimal toxicity,[227] a randomized trial of this compound versus raloxifene in women at high risk for breast cancer is now underway. Preclinical studies at our institution using a transgenic mouse model suggest that antiprogestational agents may be of particular benefit in *BCRA1*-positive breast cancers.[228] The pros and cons of chemoprevention for breast cancer were recently reviewed, and the overall conclusion was that it cannot yet be recommended for general usage but should be useful for reduction of risk among high-risk individuals.[229]

There are several other options for a woman who is at very high risk for breast cancer, including bilateral mastectomy or oophorectomy and lifestyle modification. Prophylactic bilateral mastectomies have been performed on some mutation carriers, but cases of breast cancer developing in the remaining breast tissue after subcutaneous and total mastectomies have been reported. In addition, such surgeries are dramatic procedures for a woman who has only a "probability" of developing breast cancer, and a decision analysis paradigm for these interventions is available.[230] No long-term data exist on the effect of these surgeries in increasing the life expectancy of mutation carriers, yet one meta-analysis reveals considerable global variation in the utility of prophylactic surgery among unaffected *BRCA1* and *BRCA2* mutation carriers.[231] Bilateral oophorectomy has been proposed as another option for premenopausal women who have completed their childbearing. Although castration has been shown to decrease the risk of breast cancer in young, nulliparous women, especially when it is performed before the age of 35, this remains a very controversial area in the management of breast disease. Secondary prevention can be accomplished by instructing these high-risk women about the importance of clinical breast examinations by a physician and screening mammograms, which should begin at a younger age, preferably at least 5 years earlier than the age at which the relative developed breast cancer. Observational studies and initial clinical trials suggest that moderate physical exercise and control of obesity may decrease the risk for breast cancer,[232–234] as has been suggested for colorectal cancer. Recently, several randomized interventional trials have been initiated to definitively address these issues.

PROSTATE CANCER

Etiology

The age-adjusted incidence of prostate cancer rose slowly from 1965 to 1985 for unclear reasons. Parallel with aging of the baby-boomer population, the prevalence has also markedly increased since the general recommendation in the late 1980s by the American Cancer Society and the American Urological Association of yearly screening for PSA after age 50. This recommendation led to widespread screening and a rapid increase in the incidence of prostate cancer that peaked in the early 1990s.[235] In the most recent national estimates using SEER data from 1999 through 2003, the age-adjusted incidence of prostate cancer was 165 cases per 100,000 individuals—the highest rate of any cancer type among men.[12] Major differences in the incidence of prostate cancer are observed across the major U.S. ethnic groups, with blacks having the highest incidence rates (243 per 100,000) and Asian-Pacific Islanders having the lowest incidence rates (104 per 100,000). Overall, 234,460 cases of prostate cancer are expected in the United States in 2006, along with 27,350 deaths—making prostate cancer the third deadliest cancer in men after cancer of the lung and colorectal cancer.[78]

Several factors—age, familial/genetic, environmental, and hormonal—seem to contribute to the development of prostate cancer.[236]

Prostate cancer shows a familial tendency that is currently not well defined, but at least one study suggests that 10% to 15% of cases could have a strong genetic component.[237] The loss of heterozygosity in certain chromosomes in prostate cancer suggests that a gene related to some prostate cancers will be found.[238] The existence of a locus in chromosome 1 (band q 24) that predisposes men to develop early-onset prostate cancer has been verified, but a gene has not yet been isolated.[239]

The androgen dependence of prostate cancer led to the interesting hypothesis that variations in transcriptional activity by the androgen receptor regulated by CAG repeats could determine risk. Subsequent findings, however, argue against such an association, although there may be specific underlying situations in which other genotype influences lead to such an effect.[240] Because these studies concentrate on identifying prostate cancer risk and most prostate cancers are not clinically significant, others have argued for identifying genotypes that are associated with clinically aggressive cancers that predict outcome (mortality). In this regard, a report documenting extensive mitochondrial mutations in primary prostate cancers might provide new insights into progression.[241]

Both epidemiologic and experimental data suggest that hormones, particularly testosterone, play a definitive role in the development of prostate cancer. In the rat model, testosterone induces prostate cancer, and in humans prostate cancer rarely occurs in castrated men.[242,243] Also, black men have a higher incidence of prostate cancer at all ages than white men, and Japanese men have the lowest incidence.[244,245] Whether this racial-ethnic variation in prostate cancer risk has a hormonal basis is still unclear, but a substantive amount of data supports this viewpoint.[245]

A high-fat diet and obesity may be associated with an increased risk of prostate cancer, but the studies to date have yielded inconsistent results.[246] One investigation suggests that the preadult hormonal milieu, as reflected in attained height and childhood obesity, could have a strong influence on prostate carcinogenesis.[247] Epidemiologic, animal model, and in vitro studies indicate that n-3 polyunsaturated fatty acids, lycopene, and selenium might also be important in the pathogenesis of prostate cancer.[248] Additionally, *GSTP1* has been proposed as a caretaker gene that serves to detoxify carcinogens associated with various lifestyle habits.[249]

Screening and Early Detection

The relative benefits and costs of screening for prostate cancer are currently among the most contentious issues in the medical community.[250–252] There are several major reasons why this controversy continues:

- All available first-line techniques (DRE and serum PSA) have high rates of false-positive results. This leads to a relatively low positive predictive value and the unnecessary workup of many normal individuals.
- The natural history of prostatic intraepithelial neoplasia (PIN), the probable precursor of prostate cancer, is highly variable, and the natural history of the disease cannot currently be predicted reliably in any one particular case or by any specific biologic or pathologic marker.
- The workup of abnormal screening tests is invasive, requiring several biopsies of the prostate.
- The treatment of prostate cancer produces significant morbidity and measurable mortality.
- The rate of false-negative results is also high, which can produce a false level of assurance about the reliability of the screening tests (Fig. 26-6).

These same five concerns regarding the use of PSA and DRE for screening also exist for their use for early detection purposes, but the consequences are mitigated somewhat, because individuals are by definition symptomatic on presentation.

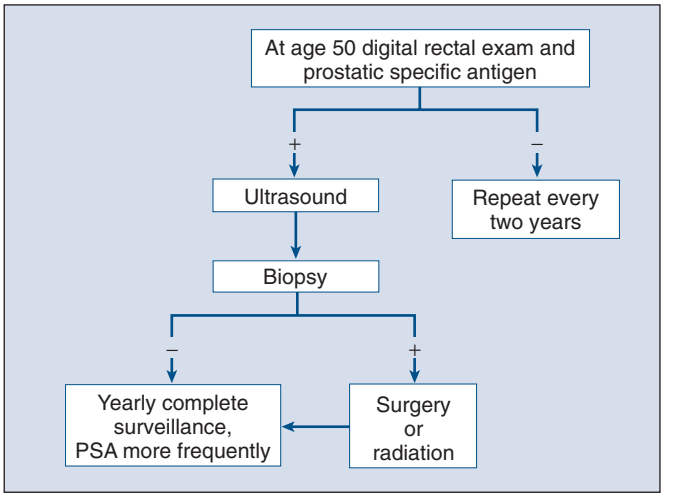

Figure 26-6 • Screening and early detection for prostate cancer.

The two most commonly used screening tests for prostate cancer are PSA and DRE, with transrectal ultrasound (TRUSP) reserved for patients with a positive PSA and/or DRE. Before the 1990s, yearly DRE after age 50 was the standard test used both for detection of prostate cancer and for screening. Although many primary care physicians use the DRE as part of a routine physical examination, assessment of its routine use indicates that DRE is performed in less than 50% of primary care encounters in which one would expect it to be done.[253]

A summary of the data indicates that the positive predictive value of DRE is relatively low (11% to 26%), whereas the negative predictive value (85% to 96%) is relatively high.[254] The most complete assessment thus far evaluated 811 unselected serial patients from 50 to 80 years of age who underwent DREs; 43 patients had a palpable nodule, and the positive predictive value of the 38 patients who underwent biopsy was 25%.[254] It is of great interest that 68% of the detected tumors were clinically localized, but only 30% were pathologically localized after radical prostatectomy. These data and other studies suggest that only about 20% to 25% of cases are localized at the time of a positive DRE; on the other hand, more than 25% of cases of prostate cancer are metastatic by the time a detectable palpable lump is detected on DRE.[254,255] Although the effectiveness of DRE is probably also significantly influenced by the skill of the examiner, the proper technique can easily be taught to health workers, is inexpensive, and is relatively noninvasive. Its usage as a primary screening tool, however, has not been widely adopted, probably because of its inconvenience. Whether routine screening by DRE alone can reduce mortality from prostate cancer is unknown. With the emergence of serum PSA as the screening test of choice, it is unlikely that the specific value of DRE in reducing prostate cancer morbidity and mortality per se will ever be demonstrated conclusively.

Annual measurement of serum PSA as a screening test for prostate cancer has been adopted widely following the initial 1993 recommendation of the American Cancer Society. At the current time, the professional community remains split over the question whether serum PSA should be recommended for routine screening in men older than age 50. The issues have been presented and analyzed extensively, and the same arguments that are used to discourage routine screening are used by others to recommend its widespread use. Estimates of overdiagnosis of clinically insignificant lesions have ranged from 15% to 84% in well-done investigations.[251,252]

Several studies have demonstrated that PSA screening results in a stage downshift and increases the detection rate of early-stage cancers.[256,257] The false-positive rate (25% to 50%) is high, however, resulting in a positive predictive value of PSA in screening studies of

about 30%. Because most of the studies have been done on symptomatic men, the positive predictive values in a true screening effort are likely to be lower (i.e., due to an expected lower prevalence of disease). In practical terms, this observation means that less than one-third of men with an elevated PSA will have biopsy-proven prostate cancer, and two-thirds will have a biopsy result that is negative for prostate cancer. Even if biologically aggressive tumors (and this is unlikely in most cases) were being identified (see the discussion later in this chapter), a large number of men would undergo unnecessary prostate biopsies with the attendant fiscal cost and morbidity.

Because the value of a "normal" level of PSA (<4 ng/mL) is influenced by several physiologic parameters, there has been a great interest in enhancing the specificity of the test. Techniques to improve the positive predictive value of PSA have included using age-adjusted reference ranges, PSA density (PSA level/size of prostate as measured by ultrasound), PSA velocity (change in PSA per unit of time), and ratio of bound to free PSA.[258,259] Although the validity of these strategies is currently unconfirmed, modeling has been important in determining the most effective use of tumor markers in other diseases, and it is likely that with enough time and information, the rate of false-positive results with PSA screening can be reduced. One way to reduce the false-positive rate is to combine PSA screening with DRE, and when appropriate, with TRUSP. A positive DRE increases the likelihood that a positive (i.e., abnormal) determination PSA is a true positive and therefore enhances the positive predictive value of the test. Additional evaluations with TRUSP should further increase the positive predictive value. The prostate component of the large, multicenter, randomized, controlled PLCO Cancer Screening Trial is expected to contribute significantly to our understanding of the value of PSA and DRE screening on mortality among men aged 55 to 74 years. In this study, the intervention arm receives screening examinations at scheduled intervals, but clinical management of these results are left to the individual study clinicians. However, such mortality data are not expected until the year 2015.

Initial reports addressing the rate of diagnostic procedures performed from the PLCO have emerged. At baseline through the year 2000, 4801 men with positive PSA (i.e., >4 ng/mL) or DRE were identified.[260] Among the 2717 men with elevated PSA, 64% received biopsy within 3 years, and among men with positive DRE and negative PSA only 27% underwent biopsy within 3 years. As might be expected, higher biopsy rates were noted for those with PSA above 7 ng/mL as compared with those whose PSA level was 4 to 7 ng/mL. Follow-up data regarding mortality, and also the positive predictive value for PSA, DRE, or both among different demographic strata are not yet available but are expected to assist greatly in our understanding of the utility of these commonly used screening tests.

The second major obstacle to the successful use of any screening modality for prostate cancer is that the biologic aggressiveness of PIN and early prostate cancer is not identified with high reliability by serum PSA. Progressive prostate cancer is a serious disease with high morbidity and mortality; however, not all prostate cancers are serious, and indolent behavior is more common than not. For example, about 30% of men over age 50 have histologic evidence of prostate cancer at routine autopsy, suggesting a prevalence of prostate cancer of about 9 million.[261] About 1.2 to 1.5 million of these 9 million men, or about 15%, will eventually die of their disease. Thus, most prostate cancers in the population are latent and do not progress to clinical adversity; therefore, an aggressive workup of an elevated PSA should not be a reflex action.

A third major consideration in evaluating PSA as a useful screening test is that the subsequent workup and treatment have a significant complication rate. Follow-up testing of an elevated PSA requires a repeat PSA, DRE, TRUSP, and biopsy. These are relatively safe procedures, but about 0.1% to 0.4% of the 20% of screened men who undergo biopsy experience infection or bleeding, and almost all experience considerable anxiety while waiting for the results.[262,263] The potential complications of treatment can be quite serious and include impotence, incontinence, and death from radical prostatectomy. Adverse outcomes of radical prostatectomy have been compared with watchful waiting in a randomized clinical trial. In this study, erectile dysfunction (80% vs. 45%) and urinary leakage (49% vs. 21%) were more common among patients who underwent radical prostatectomy; however, symptoms of urinary obstruction were improved (28% vs. 44%).[264] Radiation therapy is no less benign, but it carries a lower incidence of incontinence, a higher incidence of acute gastrointestinal complications, and a similar incidence of impotence.

A fourth major issue in PSA screening is the high rate of false-negative results. Numerous studies have demonstrated that many individuals (25%) with a normal PSA level have disease beyond the prostate.[265] Such results can lead to false reassurances and decreased follow-up when other factors suggest that a more aggressive workup might be reasonable. Several studies suggest that a rising PSA, even in the normal range, is a cause for concern and reason enough to biopsy.[266,267]

Although serum measurement of PSA has been widely adopted in men over age 50 as a primary screening tool for prostate cancer, its value in improving the overall health of men has not been shown to date. The equally important issue of whether screening does more harm than good also remains unanswered, because the natural history of prostate cancer is so variable.[265] Decision analysis has been used to determine the benefits and risks of age- and quality-adjusted survival, but the results remain inconclusive.[268,269] Other studies suggest that screening might have the potential to decrease survival, particularly in the older individual.[269] There is, of course, no lack of critics of this viewpoint.[270] What information is needed to resolve this difficult and important issue? Perhaps only a series of randomized trials can lay this question to rest, and to this aim, the prostate component of the PLCO Cancer Screening Trial may provide answers to these important questions. The results of a randomized trial involving more than 40,000 men in the city of Quebec have been reported, and those subjects with a regular PSA screening had a 60% decrease in mortality from prostate cancer after 7 years.[271] The conduct and interpretation of this type of trial is complex, and the results of several other large screening studies will have to be available before definitive recommendations about the value of routine screening PSA can be made.[272] These targeted trials, however, will provide only a general guide regarding population-based screening using serum PSA in men over age 50 as an approach to identify potential prostate cancers. The current consensus by the U.S. Preventive Services Task Force is that the evidence is insufficient to recommend for or against routine screening for prostate cancer using PSA.[272]

An equally important issue is this: How do we identify and distinguish a biologically aggressive tumor in any one individual from those that will remain latent for the life of the individual? This is a very difficult problem to study. Although the earliest features of prostate cancer pathogenesis remain obscure, recent studies of the biologic features of intraepithelial hyperplasia of the prostate and of the "normal" prostate in individuals with a strong family history could shed some light on this issue.[272–274] Recent studies of the cytogenetic and molecular alterations in high-grade PIN have indicated that loss of heterozygosity is prominent and that certain oncogenes are expressed.[274] Defining the biologic features of the preclinical phase of prostate cancer is critical to answer for innumerable reasons, not the least of which is to increase the effectiveness of PSA screening. In this regard, a large, randomized trial of men with T1b, T1c, or T2 prostate cancer demonstrated that radical prostatectomy was superior to "watchful waiting" in terms of disease-free survival but not in terms of overall survival.[275]

Chemoprevention

Although the development of rat prostate tumors has been studied for some time, this model system has been regarded as a poor one

for carcinogenesis of the human prostate. The development of transgenic models that simulate the human disease represents an improvement in this regard.[276] Epithelial changes, including PIN, were identified in the human prostate long ago, although only recently have the biologic (and clinical) implications of these changes been recognized. The importance of these alterations, the recognition of the analogous evolution of the process to other epithelial cancers (e.g., cervical, oral), and its association with a wide spectrum of biologic abnormalities has moved PIN into the forefront as the probable, but clinically uncommon, preneoplastic precursor of prostate cancer.[276] An impressive array of studies measuring various biologic and molecular parameters in PIN have been done, and various biologic changes associated with the progression of prostate cancer have been identified.[277] What should be done now is to relate these biologic findings to the clinical aggressiveness of PIN and/or the eventual outcome of clinically relevant (nonindolent) prostate cancer. To be able to do so will help guide the difficult decisions after detection of an elevated serum PSA in biopsy samples during the screening and/or identification of PIN and during the early detection process. Three major categories of chemoprevention agents are being currently considered: inhibitors of proliferation, hormonal modulators, and stimulators of differentiation.

Thus far, two definitive randomized trials have been launched. The results of a phase III study using the 5α-reductase inhibitor finasteride (thereby lowering levels of dihydrotestosterone, the active metabolite of testosterone) in a high-risk population has been reported. The incidence of prostate cancer was decreased about 25%, and the side effects were minimal.[278] However, conclusions about the overall benefit were compromised by the finding that the risk for higher grade tumors was increased in the treatment arm. Although a large number of explanations have been offered for these contradictory findings, the future of finasteride as a therapeutic agent for prostate prevention is uncertain.

A second trial uses selenium, vitamin E, or both. The rationale for the study was based on secondary analyses of several large intervention trials in which prostate cancer was not the target, although recently some supportive experimental data also have become available.[279,280] Accrual to this 2×2 factorial randomized trial (vitamin E, selenium) is ongoing, and results are anticipated in 2013. A large number of compounds are being investigated at the preclinical level, and a few have advanced to the phase I/II clinical level. Studies of fenretinide failed to show an effect on relevant surrogate markers, whereas DFMO was more successful.[273,281]

Two other relatively unexplored areas of chemoprevention research in prostate cancer should also be mentioned: PIN and familial risk. Just as understanding the biology of PIN will affect our screening and early detection decisions, PIN should also serve as a useful marker in chemoprevention studies. Although the heterogeneity of lesions will make interpretation of effect of an intervention a challenge, PIN represents an important parameter for advancing our knowledge of early prostate cancer carcinogenesis and its modulation by candidate chemoprevention agents. Several studies are in progress to use PIN as a screening tool for new chemoprevention agents including studies of biologic markers to determine risk.[282] The roles of family studies and genetics in identifying individuals at high risk for prostate cancer are in their infancy, but epidemiologic studies support the notion that genetic risk plays a role, and clinical studies support the observation that early prostate cancer in some individuals is highly aggressive, whereas in others it is indolent. Linking these two parameters should identify a population of individuals in whom screening, early detection, and chemoprevention agents should be intensively directed.

Advances in the systemic therapy of advanced prostate cancer have been slow in coming. In a real sense, advances in the management of prostate cancer have been minimal since the introduction of hormonal therapy more than 50 years ago. It is likely that the widespread use of screening and early detection with an appropriate follow-up will reduce the morbidity and mortality from prostate cancer in a substantial way and that effective chemoprevention will be developed, because the major biologic enhancer (androgens) of prostate cancer carcinogenesis is known.

SKIN CANCERS

Each year, more than $2 billion is spent to treat patients diagnosed with skin cancers, the majority of which are malignant melanoma and basal and squamous cell carcinomas. These figures underestimate the true cost, because many of these cancers are treated in physicians' offices, and nonmelanoma skin cancers are not routinely reported to tumor registries. An aging population, depletion of the stratospheric ozone layer, and increased recreational exposure to ultraviolet radiation (UVR) represent some of the factors that contribute to the development of over 1 million cases of nonmelanoma (basal and squamous cell carcinomas), 49,000 cases of melanoma in situ, and 62,000 cases of invasive melanoma diagnosed annually in the United States.[78] Understanding how these and other risk factors lead to alterations in key cellular processes like DNA synthesis and repair, oncogene activation, cell-cycle control, and apoptosis is the focus of intense research efforts aimed at designing novel preventive, diagnostic, and treatment strategies.[59] This section details the various primary, secondary, and tertiary preventive approaches for melanoma and nonmelanoma skin cancers. Incorporating these strategies into medical practice should decrease the incidence and mortality from skin cancer and should also decrease health care costs.

Etiology and Primary Prevention

Environmental

Successful primary prevention depends on the ability to identify individuals at risk for skin cancer and to use this information to educate both high-risk groups and the general population about various ways to reduce risk (Table 26-5). Many factors have been identified that increase an individual's risk for the development of melanoma and nonmelanoma skin cancers. Exposure to UVR is a major risk factor.[283] Not only is cumulative UVR exposure important in the development of skin cancers, but it is apparent that acute, intermittent exposure to UVR is carcinogenic.

The electromagnetic spectrum is composed of infrared, visible, and UV light; the latter is responsible for causing the cellular and architectural changes in the epidermis and dermis that lead to photoaging and skin cancer.[283] Although the UVR spectrum is broad, UVR-B (290–320 nm) and UVR-A (320–400 nm) are the only wavelengths that routinely reach the earth's surface, in that shorter wavelengths (UVR-C) are absorbed by the ozone layer. UVR-B is more potent than UVR-A in inducing neoplastic transformation in epidermal keratinocytes and melanocytes, which give rise to basal and squamous cell cancers, and melanoma, respectively. UVR-A, however, has been found to penetrate the skin more deeply and is the predominant wavelength emitted from artificial lamps found in tanning salons.[283] More than a million adolescent and young women frequent these facilities daily and expose themselves to up to five times the amount of UVR that is emitted from the sun at any given time. The role of UVR-A radiation in the development of skin cancer will increase as this industry continues to grow.

The mechanism of action of UVR on the skin has been studied extensively. Once photons penetrate through the stratum corneum, they are absorbed by cellular DNA and produce base substitutions in pyrimidines.[284] The substitution of thymidine for cytosine is pathognomonic for UVB-induced skin damage and is found in the tumor suppressor gene *p53* in more than 90% of squamous cell skin cancers.[285,286] Basal cell cancers also contain *p53* mutations.[287] Although UVR is regarded as contributing to the pathogenesis of melanoma, these types of mutations are uncommon, therefore raising the likelihood that the role of UVR is associative or complementary to the process. Normally, p53 acts to protect damaged cells by either

inducing cell-cycle arrest (so that mutated DNA can be repaired or excised) or by inducing apoptosis.[288] UVR-induced *p53* mutations disturb the cell cycle by inhibiting cyclin-dependent kinases, leading to uncontrolled cell proliferation. Cells with one mutated *p53* allele can undergo clonal expansion, and, if the other *p53* allele is mutated, neoplastic transformation occurs. Therefore, UVR could both initiate and promote carcinogenesis.[288] UV light might also have immunosuppressive effects by interfering with the ability of Langerhans cells to process antigens.[289]

Other risk factors that increase susceptibility for the development of skin cancers include skin complexion and response to sunlight, degree of freckling, ethnicity, gender, age, geographic location, presence of premalignant skin lesions, medical history of exposure to ionizing radiation or psoralen and UV therapy, chronic skin irritation (ulcers, inflammation, or trauma), or a personal history of a germatodermatoses (xeroderma pigmentosum, nevoid basal cell carcinoma syndrome, and familial dysplastic nevus syndrome), lymphoreticular malignancy, granulomatous diseases, or other immunosuppressed states such as organ transplantation in which development of multiple cutaneous squamous cell carcinomas is a major problem.

Health care providers should be aware of several premalignant dermatoses for the purpose of identifying individuals who are at increased risk for the development of skin cancers. The most common lesion, actinic keratoses (solar keratoses), has been reported to undergo malignant transformation to squamous cell cancer in 12% of patients.[290] Histologic evaluation of white patches occurring on mucous membranes, known as leukoplakia, is also important, because up to 20% could be dysplastic, with 3% to 6% becoming invasive cancers. Atypical and dysplastic nevi, large congenital nevi (>9 cm), and an increased number of moles are common precursor lesions of melanoma.[291] Chronic skin irritation from radiation (radiation dermatitis), chemicals (tar and arsenical keratoses), infrared light (thermal keratoses), and scars (scar keratoses) might also lead to malignant transformation. Any patient who is immunosuppressed (human immunodeficiency virus [HIV] diagnosis or transplant recipient) or who has a history of epidermodysplasia veruciformis or Bowen's disease (an intradermal carcinoma that often occurs on sun-exposed areas) should be considered for prevention protocols. Anyone who has a prior history of skin cancer is also at risk for a second primary cutaneous malignancy.[292,293] Patients diagnosed with thin melanomas (<75 mm in thickness; Breslow staging) were found to have a 4% chance of developing a second primary melanoma.[294] First-degree relatives of skin cancer patients also carry an increased risk.[292]

Recently, a risk model for melanoma risk has been proposed using data from a case-control study, based on similar methodologies developed by Gail for the breast cancer risk model developed nearly 2 decades ago.[295,296] This melanoma risk model incorporates subject responses to simple questions about complexion, history of blistering sunburn, and ability to tan, with findings on examination of the back describing the number of small and large nevi. This risk model captures attributable risk for melanoma development of 86% for men and 89% for women. Though promising, further risk models are still needed for individuals with a history of melanoma or nonmelanoma skin cancer, or persons with a first-degree relative with melanoma. Such models could identify high-risk individuals who could be referred for chemoprevention trials.[297]

Heredity

Several molecular abnormalities have been identified that could be responsible for the genetic instability preceding the development of invasive nonmelanoma skin cancers (Table 26-6). Defects in DNA repair genes, oncogenes, and tumor suppressor genes, as well as allelic losses in a number of chromosomes, have been described.[287] Mutations in the *Ras* oncogene have been shown to initiate epidermal skin cancers.[298] Mutations in DNA repair genes (xeroderma pigmentosum, for example) bring about an inability to repair UVR damage to DNA efficiently, leading to the development of melanoma and epidermal skin cancers.[299] DNA repair capacity might be particularly important for individuals with other strong risk factors, such as low tanning ability and the presence of dysplastic nevi.[300] There are numerous examples of specific chromosomal abnormalities in nonmelanoma skin cancers. Allelic losses have been found in 9p, 13q, 17p, 17q, and 3p in squamous cell cancers and in 9q in basal cell cancers.[298] Studies of keratinocyte transformation have also focused

on the UVR-mediated phosphatidylinositol 3-kinase and p38 mitogen-activated protein kinase pathways.[301]

The genes and genetics of melanoma have been summarized.[302] One autosomal dominant syndrome that markedly increases an individual's lifetime risk for melanoma is familial dysplastic nevus syndrome. Melanoma in one or more first-degree relatives and the presence of a large number of moles (between 10 and 100) are required to diagnose this syndrome.[303] Rearrangements or deletions of genes have been found to occur in chromosomes 9 and 10 in patients with familial melanoma, atypical nevi, or early melanoma lesions. Two cyclin-dependent, kinase, tumor suppressor genes have been isolated on chromosome 9 (p15, p16). Mutations in this region lead to uncontrolled cell proliferation, because the transition from G1 to S of the cell cycle is no longer inhibited.[304] The finding that the penetrance of one of these genes to frank melanoma is dependent on geographic variation emphasizes the role of environment in genetic expression[305] and the potential interaction of UVR and sunburn genotype.[306] Certain polymorphisms in the melanocortin-1 receptor gene have been shown to correlate with a reduced response to melanotrophin, the major natural hormone that regulates cutaneous pigmentation.[307] Other studies suggest that loss-of-function mutations in the *MCIR* gene sensitize human melanocytes to the DNA-damaging effects of UVR, which could increase melanoma cancer risk.[308]

The identification of frequent *RafB* mutations in both melanomas and benign moles is also of great interest and suggests that this alteration may be the initial molecular change leading to immortalization.[309] Once the significance of the genetic abnormalities in causing nonmelanoma and melanoma skin cancers is understood, we might be able to incorporate this information into new risk models to identify high-risk individuals who would benefit from prevention protocols and increased surveillance.

Preventive Measures

Numerous examples of primary preventive strategies exist. Protective clothing (hats, long sleeves, special fabrics approved by the U.S. Food and Drug Administration), behavioral modification (avoidance of peak sun from 10:00 AM to 3:00 PM, avoidance of sun tanning salons, and use of appropriate shading), and liberal application of sunscreens are three such examples.[310] There are two types of sunscreens: blockers and reflectors. Blockers such as paraminobenzoic acid absorb UVR-B only. Nonparaminobenzoic acid blocker sunscreens absorb both UVR-A and UVR-B. Reflectors such as zinc oxide completely reflect UVR light. The SPF, or sun protective factor, is a measure of the comparison of the minimal erythema dose with and without sunscreen and should be at least 15. Finally, sunscreens should not wash off easily when bathing or sweating.

The current role of sunscreens in preventing skin cancer is the subject of considerable controversy.[311] Randomized trials have demonstrated that sunscreen use encourages prolonged sun exposure.[312] Another randomized study, however, has shown a protective effect of sunscreen use against the development of squamous cell cancer and nevi.[313] Based on these findings, we probably can conclude that regular sunscreen application should be combined with protective clothing to reduce the long-term risk for the development of melanoma and nonmelanoma skin cancers.[283]

In Australia, which has the highest incidence of skin cancers, other approaches have been adopted, including the passage of laws for employers to provide sun protection for employees, distribution of free sunscreens, tree planting campaigns, and public shade structures. In the United States, the Federal Trade Commission requires that protective eyewear be worn in tanning salons. In addition, signed informed consents and signs about health risks of UVR exposure in tanning salons are required. Furthermore, in Texas an adult must accompany children attending tanning salons, and parental permission is mandatory for all minors. Attitude and behavioral modification of children (and their parents) informed by education and knowledge about sun exposure and skin damage/cancer is a reasonable goal and is most effective when started at a young age (Box 26-2).[314,315]

Box 26-2. USEFUL THINGS TO TELL YOUR PATIENTS ABOUT THE PREVENTION OF SKIN CANCER

- Avoid sunburns (know your skin type—do you burn easily?).
- Avoid tanning booths.
- Use sunscreens with high SPF.
- Stay covered.*
- Avoid outdoor recreation between 10 AM and 3 PM.
- Minimize sunlight exposure.
- Know your moles (and other skin lesions) and see a dermatologist promptly if they change or are new.

*A wet T-shirt has an SPF of 0; several companies now make clothes that are specifically treated to give a high SPF.

Screening and Early Detection

The following are essential for effective screening:

- An understanding of the four characteristics of skin lesions that are suggestive of premalignant or malignant changes (i.e., the ABCDs): asymmetry, border irregularity, color variegation, and diameter (6 mm or greater)
- Knowledge of important prognostic factors that should be recorded: anatomic location, ulceration, number of atypical lesions, presence of lymph nodes
- Familiarity with the types and indications for the particular type of biopsy: shave biopsy, incisional biopsy, excisional biopsy, punch biopsy
- Access to skilled pathologists who can comment on key histologic criteria such as thickness (Breslow staging), margins, ulceration, regression, satellitosis, angiolymphatic invasion, mitotic activity, precursor lesions, host response, and growth phase (radial vs. horizontal)

Screening for skin cancer, and in particular for melanoma, is supported by several criteria. Skin cancer is the most common cancer worldwide and is an important public health problem. Melanoma is second only to leukemia in terms of years of potential life lost, because it often affects younger people during the most productive periods of their lives.[315] Although basal and squamous cell cancers have a much better prognosis than melanoma, they cause considerable local disfigurement if not diagnosed and treated early. In addition, screening skin examinations are acceptable to both patients and health care providers. Premalignant cutaneous lesions tend to have a long latent phase, making early diagnosis and treatment possible with evidence that supports subsequent decreases in both incidence and mortality rates.[290]

Although no randomized, prospective studies evaluating the efficacy of screening for skin cancer have been conducted, nonrandomized studies support its practice. Thinner melanoma lesions (stages I and II) are diagnosed more frequently with routine screening and intensive education programs. The Sydney, Australia Melanoma Project demonstrated that widespread screening and education led to a decrease in the thickness of lesions from 2.5 mm to 0.8 mm, a decrease in the number of ulcerated lesions, an increase in the number of melanomas diagnosed in the radial rather than the vertical growth phase, and an increase in the 5-year survival rate to 94%.[316] A decrease in lesion thickness and an increase in the number of melanomas diagnosed were also confirmed in studies in Scotland and the United States.[316,317] Interestingly, a large skin cancer education and screening

demonstration project found that 80% of study participants did not have a regular dermatologist, 50% saw their physician only because of the free skin examination, and 80% were receiving their first skin examination. Another interesting population-based, case-control study investigated whether skin self-examination would reduce the incidence of melanoma.[318] Although only 15% of participants in the study cohort practiced skin self-examination, they found that skin self-examination was associated with a reduced risk of melanoma in general and a reduced incidence of more advanced disease in melanoma patients. The authors concluded that mortality from melanoma might be reduced by as much as 63% if regular skin self-examinations were performed.

New imaging technologies may play increasingly important roles in screening and early detection for skin cancers in the future. To this aim, diffuse optical spectroscopy represents an exciting new technology that is emerging. Recently, diffuse optical spectroscopy technology has been used via a hand-held probe with direct skin contact to define the optical properties of skin in vivo, including quantification of melanin, hemoglobin, and water concentrations.[319] Thus, the potential for noninvasive identification of malignant versus benign skin lesions is an anticipated application for this technology. However, the utility in accurately identifying malignant cutaneous lesions has not been described analytically, and the appropriate validation studies on melanoma and nonmelanoma skin cancers must be performed before widespread usage of this novel screening device can be recommended.

Challenges to effective screening examinations include the following:

- Lack of standardization of the examination and training that health care providers receive
- Lack of accurate reporting to tumor registries (for melanoma; nonmelanoma skin cancers are not reported at all)
- Inability to motivate certain high-risk groups (e.g., white males) to come in for examination
- An inability to screen adequately for the 1% to 2% of amelanotic cases of melanoma

One step toward overcoming these challenges has been to designate the months of May and June as free skin cancer screening months in the United States in an attempt to attract more people for evaluation.

Chemoprevention

Nonmelanoma Skin Cancers

Clinical trials investigating the use of β-carotene, 13-*cis*-retinoic acid, selenium, and NSAIDs have been performed on individuals with a history of nonmelanoma skin cancers. Results using vitamin A derivatives have been mixed, which most likely reflects the complex biochemical and molecular mechanisms underlying the prodifferentiation or promaturation changes that these compounds produce. Three randomized clinical trials did not find a decrease in the recurrence rates of basal or squamous cell cancers in individuals at high risk for new skin cancers. Levine and coworkers[320] found no beneficial effect when using isotretinoin or retinol in high-risk subjects with at least four prior basal cell or squamous cell cancers. The Isotretinoin–Basal Cell Carcinoma Study Group also demonstrated that isotretinoin did not prevent the recurrence of basal cell cancer in patients previously treated for basal cell cancer.[321] Finally β-carotene was not shown to prevent nonmelanoma cancers.[322] In contrast, in 2297 moderate-risk subjects with a history of actinic keratoses and at most two squamous or basal cell carcinomas, supplementation with a moderate dose of retinol (25,000 IU daily) reduced the incidence of squamous cell (but not basal cell) cancers by 25%.[23] In addition, patients with xeroderma pigmentosum develop fewer new skin cancers after receiving high-dose isotretinoin.[323] However, interest in the retinoids as preventive agents has waned, and it is unlikely that their usage will be adopted unless a new generation of nontoxic compounds can be developed.

Negative results have been produced in a large multicenter study involving selenium supplementation.[166] In this double-blind, randomized, placebo-controlled study, 200 μg of selenium daily did nor seem to prevent the development of future nonmelanoma skin cancers in patients with a history of basal or squamous cell skin cancer. A secondary analysis of the effect of NSAIDs in this trial on nonmelanoma skin cancer also suggested no effect for this class of agents.[324] Finally, NSAIDs have been found to prevent the erythema that occurs 6 to 12 hours after acute sun exposure. In a large, randomized trial, topical application of the COX-1 inhibitor diclofenac was superior to placebo in clearing actinic keratosis lesions, and this formulation has now been approved for clinical use, although recent concern about the cardiovascular toxicity of selective COX inhibitors leave its usage uncertain.[325] A small placebo-controlled study of 2-DFMO suggests that this compound might have comparable activity.[326] A comprehensive strategy for the development of chemoprevention drugs for nonmelanoma skin cancers has recently been described.[59]

Melanoma and Dysplastic Nevi

Topical β-all-*trans*-retinoic acid has been demonstrated to cause regression of dysplastic nevi[327,328]; however, the inconvenience of topical application has limited its usage.

The development of chemoprevention agents for melanoma has progressed slowly, although the development of a risk model for melanoma is an important first step, as is the development of an in vitro model for assessing the potential value of chemoprevention agents.[297,324] A great deal of new preclinical work has advanced our understanding of melanoma pathogenesis as well,[329] including a unique redox-based paradigm.[330] The recent development of a transgenic model that simulates the human disease is also an important advance and should lead to a more systematic development of chemoprevention drugs.[331]

Tertiary Prevention

Lifetime surveillance of patients who have been diagnosed and treated for skin cancer is an important component of prevention. Many studies have shown that laboratory and radiologic surveillance do not detect second primaries or recurrences beyond what is found on skin examination in patients with a history of melanoma. Patients with a history of melanoma should be evaluated every 6 months with skin and regional lymph node examinations. Particular attention should be paid to the scar of the previous excision site during these examinations. After 2 years of normal examinations, the interval between visits can be extended to 1 year. If an individual has any atypical moles, a positive family history for melanoma, or other poor prognostic factors, an evaluation (including cutaneous photography) every 3 to 6 months for the first 2 years (lengthening the interval between examinations only if the atypical moles are stable) is recommended. No recent findings have affected these general recommendations. Newer biomarkers are being explored to detect melanoma earlier, but thus far no validated successes have been reported.

Prevention of skin cancer depends on increasing the awareness of health care professionals and the public about the importance of early diagnosis and skin self-examinations. More research needs to be devoted to ways of motivating high-risk individuals to receive screening examinations. Public policy measures should be expanded and consideration given to other approaches, such as mandatory use of sunscreen and adequate clothing in daycare centers and public schools. The true measure of the various prevention strategies will come from studies of their ability to decrease both the incidence of and the mortality from skin cancers. Recent evaluations of the value of screening and early detection for cutaneous melanoma suggest that survival has been increased from 50% 30 years ago to over 85% today.

OVARIAN CANCER

Ovarian cancer will affect an estimated 20,180 women in the United States during 2006 and is the fifth leading cause of cancer mortality among women, after cancer of the lung, breast, colorectum, and pancreas.[78] Approximately 10% of ovarian cancers are associated with a *BRCA* mutation, whereas the remainder are sporadic.[332] The lifetime risk of developing ovarian cancer for the general population is approximately 1.5%.[333] Advanced-stage disease (spread beyond the pelvis or FIGO stage III/IV) is present in 70% of these women; this has led to a 40% overall 5-year survival rate with low 5-year survival rates for advanced-stage disease (stage III 5-year survival, 25.1%; stage IV 5-year survival, 11.1%).[334] Hence, most women who present with advanced disease die from their disease. Therefore, prevention of ovarian cancer is an important goal. Given that 90% of all ovarian cancers arise from the epithelial lining of the ovary rather than from the germ cells or sex-cord derivatives, preventive strategies outlined in the following paragraphs pertain to the prevention of epithelial cancers.

Primary Prevention and Risk Reduction

Epigenetic Factors

Several reproductive, environmental, and genetic factors could influence an individual's risk of developing ovarian cancer (Table 26-7). Advancing age is an important risk factor, in that data from SEER and the National Center for Health Statistics reveal that more than 48% of all cases of ovarian cancer occurred among women older than 65 years of age.[335]

Important protective reproductive factors include increased number of pregnancies, oral contraceptive use, and breastfeeding. Reanalysis of six large case-control studies involving 2768 incident cases demonstrated an overall risk of 0.66 in oral contraceptive users that continued to fall with duration of use; the effect was projected to persist for a lifetime after stopping.[336] Only a limited number of studies have examined the effect of HRT on ovarian cancer development. In the largest investigation reported thus far, a cohort study of 44,241 participants in the Breast Cancer Detection and Demonstration Project (329 cases of ovarian cancer), estrogen-only use (but not combined estrogen-progesterone) was associated with a modest increased relative risk of ovarian cancer.[337] No relationship between ovarian cancer risk and age of menarche, age of menopause, or duration of HRT has been observed in one large meta-analysis.[338] Conversely, increased risk was observed in nulliparous women who had a history of infertility. Critical analysis suggests that women with a history of infertility alone are at increased risk, and fertility drugs might not alter this risk further.[339] Tubal ligation, and to a lesser degree hysterectomy, are associated with decreased risk of ovarian cancer.[340]

A large prospective cohort study of 300,537 women (1511 deaths from ovarian cancer) showed that mortality rates from ovarian cancer were significantly increased in overweight and obese women who had never used HRT.[341] Other dietary factors, such as consumption of milk and selenium, might also modify an individual's risk for ovarian cancer, but the data are not convincing.

Finally, talc has been suggested as a possible factor leading to the development of ovarian cancer, in that epithelial ovarian malignancy shares similarities with mesotheliomas, and talc is structurally similar to asbestos, a proven cause of mesotheliomas. Cramer and associates[342] first reported this association in 1982 when they assessed genital exposure to talc in 215 white females with epithelial ovarian cancer and 215 matched controls. They reported that 92 of the patients (48%) regularly used talc, either as a dusting powder on the perineum or on sanitary napkins, compared with 61 controls (28.4%). A relative risk of 1.92 was associated with these practices in the women with ovarian cancer. In a follow-up study, researchers determined that the risk for ovarian cancer was highest in women who applied talc directly to the perineum or undergarments on a daily basis for more than 10 years.[343]

Genetic Factors

Approximately 10% of all epithelial ovarian cancers are related to genetic mutations (hereditary, familial, other rare syndromes). Women considered to have a hereditary ovarian cancer syndrome must have at least two first-degree relatives with histologically confirmed ovarian cancer. These individuals carry an overall lifetime probability of developing ovarian cancer of approximately 50%. There are three "hereditary" autosomal dominant syndromes, which include the site-specific ovarian cancer syndrome, hereditary breast and ovarian cancer syndrome, and HNPCC, Lynch II.[344] Together, these cancer syndromes account for 1% to 5% of the ovarian cancers that are diagnosed and generally occur 1 to 2 decades earlier than nonhereditary ovarian cancer.[345] The genetic linkage for the majority of the hereditary breast and ovarian cancer and the site-specific ovarian cancer syndromes has been found on the *BRCA1* and *BRCA2* loci on chromosome 17 (band q21). Specifically, the lifetime risk of developing ovarian cancers among *BRCA1* and *BRCA2* carriers is 15% to 60% and 15% to 28%, respectively.[346]

Women who report a family history of either a single first-degree relative and/or one or more non-first-degree relatives with ovarian cancer meet the definition of familial ovarian cancer syndrome. About 5% of diagnosed ovarian cancers fall into this category. Ovarian cancers can also occur as part of other rare, inherited, genetic syndromes such as Cowden's disease or Li-Fraumeni syndrome. Once individuals are identified with a familial or hereditary ovarian cancer syndrome, or a germline *BRCA* mutation carrier, primary preventive strategies can be implemented, including oral contraceptive pill use, risk-reducing salpingo-oophorectomy, and possibly dietary modification.

Prophylactic oophorectomy is a subject of substantial controversy. It has been estimated that 700 prophylactic oophorectomies might need to be performed to prevent one case of ovarian cancer.[347] A person's age, medical history, reproductive plans, and proximity to menopause must be considered when trying to make an informed

decision. In general, postmenopausal women or women older than 50 years are encouraged to undergo this procedure, because the risk of ovarian cancer increases with age. Women who are younger than 50 but older than 40 years of age should be counseled on the risks and benefits associated with surgical menopause and subsequent HRT, and on the risks of developing ovarian cancer based on their pedigree. There are two exceptions to these rules. One is the performance of prophylactic oophorectomies on women who are being operated on for a bowel cancer, because metastases are found in 25% of cases when the ovaries are carefully examined.[347] In addition, women with one of the three hereditary ovarian cancer syndromes, and also *BRCA1* or *BRCA2* carriers should strongly consider risk-reducing salpingo-oophorectomy at age 35 or at the completion of childbearing.[348,349] These women, however, should be counseled that they are still at increased risk for the development of intra-abdominal carcinomatosis, which is histologically similar to epithelial ovarian cancer but arises from the peritoneal lining. As mentioned, carriers of germline mutations in *BRCA1* and *BRCA2* genes should be counseled about the option of prophylactic risk-reducing salpingo-oophorectomy.[350] The recommendation is problematic, however, because there is heterogeneity in the type and number of mutations at the *BRCA* loci, which thus far has made it difficult to quantify an individual's risk of developing ovarian cancer. An interesting decision analysis study has been performed[351] to determine the effect of prophylactic oophorectomy on life expectancy in women with *BRCA1* and *BRCA2* mutations. On average, a 30-year-old woman would increase her life expectancy from 0.3 to 1.7 years after undergoing bilateral oophorectomies. The analysis suggested that a woman could delay oophorectomy until she was 40 years of age with minimal loss of life expectancy.

Screening and Early Diagnosis

Early detection of ovarian cancer has not contributed to an overall improvement in survival of gynecologic malignancies.[352] Effective screening for a disease requires that the disease of interest has a premalignant phase, a long preclinical phase, stage-dependent outcome, curative treatments that are acceptable and readily available, and a cost-effective screening test that demonstrates good sensitivity, specificity, and positive predictive values. Unfortunately, the premalignant condition that progresses to invasive ovarian cancer has not been well defined. In addition, once invasive ovarian cancers develop, the preclinical phase is asymptomatic, with the result that most women present with advanced disease. Survival is not only stage dependent but also grade dependent. Primary treatment is surgical and in general is curative only if disease is confined to the ovaries. The available screening tests (pelvic ultrasound, serum cancer antigen [CA-125] levels, and pelvic examinations) are acceptable to patients and physicians but suffer from decreased specificity secondary to unacceptably high false-positive rates. Furthermore, the likelihood that an individual has ovarian cancer after a positive test (positive predictive value) is too low for available tests to be used for mass screening. In addition, screening might actually increase morbidity and mortality, because surgical exploration is the only way to diagnose ovarian cancer definitively. A decrease in mortality from ovarian cancer will occur only if we can detect early-stage disease reliably, which is not possible given available screening tests. Currently, there is insufficient evidence to support routine screening with transvaginal ultrasound and serial CA-125 serum measurements.

Specific screening tests have been evaluated both individually and together in a variety of populations. Although the pelvic examination should be included in every annual physical examination, studies have shown that it is not extremely effective in diagnosing adnexal masses.[353] CA-125 is an antigenic determinant on a high-molecular-weight glycoprotein that is recognized by a monoclonal antibody (OC125).[354] It is expressed by 82% of ovarian carcinomas and in a percentage of other normal or pathologic conditions including pelvic infections, endometriosis, pregnancy, menstruation, pancreatitis, renal failure, hepatitis, peritonitis, and congestive heart failure. Even in early-stage disease, however, CA-125 can detect only 50% of stage I disease and 60% of stage II disease.[354] Therefore, a normal CA-125 in the setting of an abnormal examination should not keep the physician from performing other diagnostic studies or surgical exploration. The real value of this tumor marker is in a premenopausal or postmenopausal woman who has a pelvic mass, particularly in the postoperative period, to measure response to treatment and progression of disease (Box 26-3).

Box 26-3. PHILOSOPHY OF SCREENING AND EARLY DETECTION FOR OVARIAN CANCER

- No good test for screening is currently available.
- Concentrate on those patients with familial or heritable risk.
- Transvaginal ultrasonography and serum CA-125 are worth doing for selected patients.

Ultrasonography by itself is easy to perform, but like CA-125 measurements, it is not an acceptable enough screening test to warrant its general use. Currently, color flow imaging and measurements of pulsatility indexes are being coupled to transvaginal ultrasound to try to decrease the rate of false-positive results. Improvements in the ability to visualize both ovaries during a given examination might improve the accuracy of transvaginal ultrasound as a screening test. So might more accurate measurements of the morphologic variations that exist between ovaries, among patients, and during different periods of the reproductive life cycle of a woman.[354] Numerous studies have combined pelvic examinations, CA-125 serum measurements, and transvaginal ultrasound. Results from an ongoing National Cancer Institute–supported multicenter trial evaluating the utility of transvaginal ultrasound and serial CA-125 measurements in 74,000 women who have been randomized to either annual pelvic examinations with CA-125 measurements and pelvic ultrasonography or annual pelvic examinations without CA-125 or ultrasound evaluation will help direct future screening practices. Until improvements in test characteristics of the various screening techniques can be accomplished, multimodality screening for ovarian cancer is recommended only for women with a hereditary ovarian cancer syndrome or *BRCA1* or *BRCA2* mutation, although no specific studies are available to support this practice. Individuals with a strong family history that does not demonstrate an autosomal dominant inheritance pattern should be evaluated on a case-by-case basis.

Chemoprevention

Chemoprevention studies for epithelial ovarian cancer have not been performed, although the data for oral contraceptive pills suggest strongly that these agents would be effective. In addition, DePalo and colleagues[355] completed a preliminary analysis of women with T1-T2 breast cancer who were randomized to oral 4-hydroxy-fenretinamide or placebo. Six cases of ovarian cancer were diagnosed in the placebo group vs. none in the treated group ($P = 0.02$).[355] Long-term follow-up after the intervention phase has shown that no significant difference between the two groups was maintained once the intervention was stopped. Fenretinide and its derivatives continue to have considerable appeal, however, and further studies should clarify the role that this vitamin A derivative might play in the chemoprevention of ovarian cancer.[356] Studies in primates suggest a strong synergistic effect of oral contraceptives plus fenretinide on markers that should be associated with a reduction in ovarian cancer[357]; however, proving via a classical randomized trial whether ovarian cancer can be prevented will be difficult.

In conclusion, a great deal of work remains to be done both in establishing the etiology of ovarian cancer and in developing strategies to prevent its occurrence and reoccurrence, but the opportunities seem great.

CERVICAL CANCER

Prevention of cervical cancer is one of medicine's greatest accomplishments. The recent demonstration of an effective vaccine against HPV, the major etiologic agent of cervical cancer, suggests that this disease eventually could become a concern of the past.[358] The U.S. annual mortality rate for cervical cancer has decreased from 26,000 deaths in 1941 to an estimated 3700 deaths in 2006, which is impressive given the twofold increase in population in the United States during the second half of the 20th century.[78] Widespread usage of Papanicolaou smear screening is largely responsible for reduction of cervical cancer from the leading cause of cancer death in American women to an uncommon one. In fact, the incidence of cervical cancer has decreased by 70% since widespread screening began in the early 1940s.

Unfortunately, these favorable statistics cannot be generalized to other countries or to certain subgroups within the United States. Cervical cancer is still the number one killer of women in underdeveloped nations, with 500,000 cases still being diagnosed worldwide every year. Despite the tremendous resources dedicated to improved screening methodologies and identification of high-risk individuals, simple visual inspection of the cervix after acetic acid application is the most effective approach in underdeveloped countries, in terms of both cost and lives saved.[359]

Primary Prevention and Risk Reduction

Numerous risk factors for preinvasive and invasive cervical disease have been identified, some of which are modifiable and others not (Table 26-8). Age and race are nonmodifiable risk factors, whereas socioeconomic status and degree of immunosuppression (HIV-positive individuals, transplant recipients) are risk factors that are difficult to change. Other factors, such as sexual and behavioral risk factors—including a high number of sexual partners for a woman or her partner; early age at first coitus, pregnancy, or marriage; history of sexually transmitted diseases; HPV infection; contraceptive choice; nutritional status; tobacco smoking; and frequency of Papanicolaou smear screening—are modifiable risk factors, and areas for strategic prevention efforts.

Cervical cancer is a sexually transmitted disease. Many of the epidemiologic and behavioral risk factors are direct and indirect surrogate markers for infection with HPV. Recently the National Institutes of Health has released a consensus statement that cervical cancer is largely preventable if young people modify their sexual behavior and decrease their exposure to HPV, which is the most important risk factor for the development of preinvasive and invasive cervical disease.[360] More than 100 types of this double-stranded DNA virus exist, with approximately 50 types found in the epithelial cells of the genital tract. HPV is further subclassified into high-, intermediate, and low-risk types. For example, HPV 16 and 18 are high-risk types and have been found in many high-grade, preneoplastic, and invasive cervical lesions. In contrast, HPV 6 and 11 are low-risk types and are generally found in condylomata accuminata (genital warts) or low-grade cervical lesions. Almost 90% of invasive cervical cancer specimens and more than 75% of high-grade cervical lesions have measurable titers of HPV detected by available molecular biologic techniques (hybridization or the polymerase chain reaction).[361]

Table 26-8 Risk Factors for the Development of Cervical Cancer

Infection with the human papillomavirus (HPV)
Age, race, and socioeconomic status
Degree of immunosuppression (e.g., HIV positivity, transplant patients)
Sexual activity*
Tobacco smoking

*Sexual behavior is probably largely a surrogate for the risk of exposure to HPV.

The mechanism of action of HPV oncogenesis is related to viral production of the E6 and E7 proteins that bind and inactivate tumor suppressor genes such as *p53* and *Rb* (E7) in cervical cells.[362,363] This, in turn, could lead to neoplastic transformation. HPV DNA has been found to integrate into host chromosomal DNA in many high-grade dysplastic and invasive cancer cervical specimens but not in the majority of low-grade cervical cancer precursor lesions. In the latter, the HPV DNA tends to exist in an unintegrated, circular form known as an episome. Molecular epidemiologic studies suggesting that different HPV 16 variants have different oncogenic potential could partly explain the wide geographic variation of CIN and cervical cancer in similarly infected populations.[364]

In general, women with cytologic or histologic evidence of HPV DNA should be counseled that they are at increased risk for the development of cervical disease, even though it is difficult to provide definitive risk assessments. In addition, Koutsky and associates[13] performed two large prospective studies of women who had a normal Pap smear and found that those who tested HPV-positive had a 10- to 15-fold chance of developing a cytologic lesion compared with those who were HPV-negative.[13]

Clearly, not everyone with cytologic evidence of HPV will progress to developing a preneoplastic cervical lesion, and even fewer will progress to invasive disease. Investigators have detected HPV DNA in 6% of women of reproductive age with healthy cervixes.[365] The presence of HPV DNA in women with normal Pap smears might be as high as 40%, however, and it is estimated that approximately 10 to 20 million women in the United States have detectable HPV DNA.[366,367] Although numerous experimental, clinical, and epidemiologic studies have established a definitive role for HPV in the development of cervical cancer, other factors such as age, contraceptive method, smoking history, degree of immunosuppression, and nutritional status probably play a role in the progression and neoplastic transformation of HPV-infected cervical cells.

The grade of the cervical lesion also influences the risk of a cervical lesion progressing to invasive cancer. Many prospective studies have documented the percentage of the different grades of squamous intraepithelial lesions that will progress to higher grade lesions.[368] Estimates indicate that it could take approximately 10 years, on average, for a preinvasive lesion to progress to an invasive cancer. Sixty percent of low-grade lesions spontaneously regress on their own without treatment, in comparison with 30% of high-grade cervical lesions. It is estimated that anywhere from 35% (CIN 2) to 56% (CIN 3) of high-grade lesions will persist.[368] Therefore, the higher the grade of the lesion, the more likely it will either persist or progress. These wide ranges suggest that other factors play a significant role in determining the eventual outcome of premalignant cervical lesions.

Differences in incidence and mortality rates of carcinoma in situ and cervical cancer have been reported across different ethnic groups. Although socioeconomic factors might be substantially responsible for the discrepancies, African Americans and Mexican Americans, especially if they do not speak English, are more commonly diagnosed with cervical cancer and ultimately will die more frequently than white women.[369] The age-adjusted incidence rates for blacks are 14 per 100,000, compared with 7.8 per 100,000 for white Americans.[370] Subsequent data from the National Institutes of Health, however, revealed that the difference in incidence of cervical

cancer between blacks and whites is disappearing, which suggests that efforts to target this high-risk group are succeeding.[360] This is not the case for Hispanics, because approximately 1.6 million Hispanic women remained unscreened in the United States.

Different methods of contraception might have different effects on the development of cervical disease. Barrier methods of contraception have been found to significantly decrease an individual's risk of developing cervical cancer (relative risk ≈ 0.4).[371] Conversely, a weakly positive association has been observed between oral contraceptive use and the development of cervical disease.[372] It is difficult to conclude definitively that oral contraceptive use increases a person's risk for cervical disease because of important confounders such as sexual behavior and HPV infection.[373]

Evidence strongly implicates smoking as an independent risk factor in the development of cervical disease.[374] It has been estimated that smokers have a 4.5-fold increased risk of carcinoma in situ as compared with matched controls.[375] In a 10-year prospective study of cervical dysplasia, tobacco smoking was associated with a two- to fourfold increased risk of CIN 3 and invasive cervical cancer in those women also infected with oncogenic HPV.[376] In addition, a significant dose-response relationship has been observed in women who smoked more or for longer periods of time.[374] Elevated levels of nicotine and cotinine have been found in the cervical mucus of smokers, which could alter local defense mechanisms (such as Langerhans cells) and/or be mutagenic themselves, leading to transformation of HPV-infected cervical cells.[377]

The relationship between immunosuppression and neoplasia is strong and has been documented in several ways. Studies of renal allograft patients have demonstrated a 4- to 16-fold increase in cervical dysplasia, a 2- to 9-fold increase in HPV infection, and a marked increase in synchronous cervical, vulvar, vaginal, and anal lesions.[378] The HIV epidemic has created a large population of immunosuppressed patients at risk for the development of cancer in general. In 1993, cervical cancer was added to Kaposi's sarcoma and non-Hodgkin's lymphoma as an acquired immunodeficiency syndrome–defining malignancy based on published reports describing the development of more aggressive cervical cancers in HIV-infected women.[379] It was observed that HIV-infected women, though still asymptomatic from their disease, presented with more advanced cancers, of higher grade, and at a younger age than what was expected in the immunocompetent population.

Screening and Early Detection

The Pap smear is considered to be medicine's most successful screening test. Although it has never been subject to a randomized controlled clinical trial, this diagnostic test has been in widespread use since Drs. Traut and Papanicolaou published their findings in 1941.[380] International and regional surveys have documented decreases in both the incidence and mortality rates from cervical cancer among clinics that have widely adopted Pap smear screening. Scandinavian countries have reported reductions in mortality rates from cervical cancer by 30% to 80%, depending on the country, the duration of the screening program, and frequency of screening (Iceland, 80% reduction; Finland, 50%; Sweden, 34%).[381] Canada and the United States also have experienced similar reductions in both incidence and mortality rates. The Pap smear is an effective screening test because it can detect disease early—at a stage when it can subsequently be managed by available and effective treatments (Fig. 26-7). In addition, the Pap smear is cost effective and acceptable to both physicians and patients. Currently, 50 million Pap smears are performed annually in the United States.

Despite the profound impact that the Pap test has had on decreasing the incidence of cervical cancer by facilitating early detection of preinvasive lesions, its validity has been questioned periodically. General misperceptions by the media, public regulatory agencies, plaintiffs, physicians, and the community at large exist regarding the role of this screening test.[382]

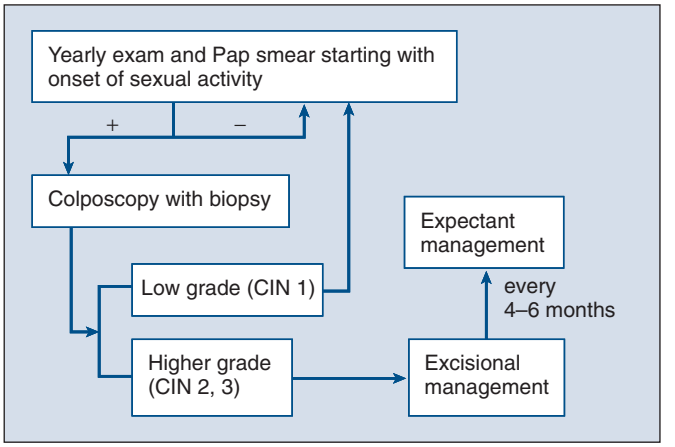

Figure 26-7 • Routine screening and early detection for cervical cancer and its prevention.

Several problems have arisen regarding the Pap smear as a screening tool. A great deal of media attention has focused on screening errors that have occurred in "Pap mills," where technicians were paid according to the number of slides they could screen. Studies have reported that the false-negative rate ranges between 5% and 20% in good laboratories, suggesting that the overall sensitivity is approximately 80%. Many of the false-negative results are actually due to sampling errors rather than to screening or interpretation errors. In sampling errors, abnormal cells are either absent or unidentifiable because of inappropriate technique, unsatisfactory equipment, or difficult patient examination, making it hard to obtain a satisfactory sample. Interpretation errors occur when the health care provider fails to fill out the patient history on the cytology requisition or cytotechnologists are supervised inadequately.

New technologies to improve the accuracy of the Pap smear are emerging, but there are some concerns that these tests might be too costly for high-risk patients who need them the most (low-income, minority, or elderly women). If this new technology improves the sensitivity of testing sufficiently, however, there ultimately might be a positive cost-benefit effect through the prevention of cervical cancer. A detailed analysis of the costs and benefits of different strategies to screen for cervical cancer in less-developed countries has been presented.[383] Compared with no well-organized screening, all strategies saved lives, at costs ranging from $121 to $6720 per life year saved, and they reduced mortality by as much as 58%. The simple approach of visual inspection of the cervix after applying acetic acid with appropriate follow-up was highly cost effective ($524 per life year saved and 83% reduction in mortality) and could be a more reasonable approach in less well-developed countries or certain hard-to-reach populations in the United States.

Current screening guidelines of the American College of Gynecologists and the American Cancer Society include annual Pap smear and pelvic examinations for any woman who is sexually active and/or 18 or more years of age. After three consecutive normal Pap smears and examinations, a "low-risk" patient may increase the interval between screenings from 1 year to 3 years. A high-risk individual is anyone who has had two or more sexual partners in her lifetime, intercourse before 20 years of age, a relationship with a male with multiple sexual partners, history of an abnormal Pap smear or gynecologic cancer, or anyone who is immunosuppressed. Most American women should probably be considered to be at high risk and therefore should undergo yearly Pap smear screening until sexually inactive.

Conventional Pap smear screening has proven to be extremely effective. The success of this test and future screening modalities depends on realistic expectations about screening tests, continued quality assurance, improved sampling of cervical tissue, and the incor-

poration of newer technologies with a view to improving the accuracy of screening and interpretation of Pap smears. Successful implementation, however, must be cost effective and lead to further declines in the incidence of and mortality from cervical cancer. Follow-up rates for abnormal Pap smears, particularly among underserved populations, remain another barrier for successful implementation of this important test. An attempt to improve the follow-up rates for severely abnormal Pap test results in underserved populations has been performed in the setting of a randomized controlled trial.[384] Patients in the single-visit intervention arm were required to wait in the clinic until the Pap smear results were available, and then large-loop electrosurgical excision procedure was performed immediately for severely abnormal results. This single-visit intervention resulted in a higher proportion of patients with abnormal Pap results receiving a full course of therapy within 6 months as compared with those in the usual-care study arm (88% vs. 53%), with a higher rate of follow-up at 1 year (63% vs. 21%). These results demonstrate that a single-visit cervical screening program was feasible among patients in an underserved population. Adoption of such a program could help narrow the gap in cervical cancer rates for underserved and minority populations. The challenge of the next decade will be for cervical cancer screening to optimize the medical outcomes and economic costs in general and in special high-risk populations.[385]

Chemoprevention

The goal of chemoprevention of cervical disease is to prevent or delay the development of cervical cancer and its precursor lesions by interrupting or preventing the process of carcinogenesis at the cellular level. The cervix is ideally suited for clinical studies that evaluate the process of carcinogenesis, because it is easily accessible for evaluation by Pap smear and colposcopy, and in general, abnormal cervical cells progress from low-grade lesions (HPV-positive cells and CIN 1) to high-grade lesions (CIN 2, CIN 3, carcinoma in situ) over an extended period of time.

Numerous experimental and epidemiologic trials have implicated HPV in the etiology of cervical cancer, and several large randomized trials have demonstrated spectacular efficacy (100% effectiveness) of an HPV vaccine in individuals who are sexually naive and/or HPV unaffected,[13] an effect that has been sustained over the long term.[14] Based on these results, a vaccine effective against a range of common subtypes has been approved for administration to young girls.[386,387] Epidemiologic studies of diet have suggested that low intake of several nutrients is associated with cervical cancer; however, the results of supplementation trials thus far have been almost uniformly negative, notwithstanding the experiences with topical retinoic acid and positive results from a recent randomized trial of celecoxib in which a favorable effect on high-grade dysplasia was demonstrated.[388–390] The eventual role of supplementation in late stages of the disease remains unconfirmed; clearly, continuation of smoking has an adverse effect,[391] an observation that remains important for overall cancer control.

INTERNATIONALLY IMPORTANT CANCERS

Hepatocellular carcinoma (HCC) and stomach cancer are the number one and two causes of death from cancer worldwide.[392] With the increasing influx of Asian immigrants, these diseases have become more common in the United States as well. Over the past several years, important advances related to their control have become evident, and therefore a brief review of these findings is presented. An excellent review recently has become available.[393] The major risk factor for HCC is exposure to hepatitis B or C virus, which is typically transmitted vertically (i.e., mother to child) in Asian countries and horizontally (i.e., intravenous injection, sexual contact, blood transfusion) in the United States.[393,394] Contributory risk factors include hepatotoxins such as aflatoxin, excess alcohol exposure, and smoking, as well as male gender.[393,395] Numerous studies have demonstrated that vaccination can prevent the development of HCC caused by hepatitis B.[395,396] Likewise, interferon treatment seems effective in interrupting or slowing the processes that lead to HCC initiated by hepatitis C.[397] A large phase III randomized controlled trial addressing HCC screening is currently underway to evaluate the optimal screening interval (3 months versus 6 months) for liver ultrasonography or CT among cirrhotic patients.[398]

Chemoprevention agents also seem to be effective in populations at risk for HCC due to hepatitis C infection. A randomized trial of a cyclic retinoid has shown that this compound reduced development of a second primary HCC by one-third, but this study has not been repeated or confirmed.[399] A phase III randomized trial of an anti-hepatitis C vaccine is underway, and a unique trial of supplementation with *S*-adenosylmethionine to prevent progression has recently been initiated at the University of California, Irvine. Overall, advances in microbial oncology have led to a great deal of progress in understanding the etiologic basis of HCC and in developing strategies for its eradication and prevention.

Our basic understanding of the etiologic origin of stomach cancer has been affected greatly by a paradigm shift, and the recognition that *H. pylori* infection is central to gastric carcinogenesis in humans has been critical to the development of new prevention strategies.[400] Although individual susceptibility, lifestyle issues, and diet all play a role in the pathogenesis of gastric carcinoma, attributable risks for *H. pylori* range as high as 73%.[401] There now exists a full-fledged attempt to prevent gastric cancer by appropriate screening in high-risk populations followed by *H. pylori* eradication.[401,402] Epidemiologic data are supportive of a protective role for fruit and vegetable consumption. Two large randomized trials suggest that *H. pylori* treatment interferes with the progression of gastric preneoplasia and gastric cancer[403,404] although a definitive trial is needed to prove the latter issue. Supplementation with antioxidants in both trials failed to add benefits to eradication of the bacterium.

Rational approaches to the early detection and prevention of the microbial origin of HCC and stomach cancer are now established. Concerted public health efforts should lead to screening and their eradication.

Nasopharyngeal carcinoma (NPC) is uncommon in the United States but has a high incidence in China and Southeast Asia, due to increased susceptibility to EBV.[405] In the endemic regions NPC is typically undifferentiated carcinoma (World Health Organization [WHO] type 3), whereas in the United States the majority of patients have the keratinizing squamous cell carcinoma (WHO type 1) NPC subtype. The WHO type 1 NPC subtype histologically resembles typical HNSCC and is more commonly associated with tobacco exposure and alcohol consumption. Nearly all type III NPC tumors involve latent EBV infection, whereas EBV infection is absent from type I NPC tumors in nonendemic regions; furthermore, survival is improved for type III NPC as compared with type I NPC.[406] Although the majority of type I NPC patients in the United States are Caucasian, Asian ethnicity within type I NPC has been shown to be an independent prognostic factor for improved survival.[407] This may be related to a higher proportion of EBV-positive type I tumors among U.S. Asians, or genotypic differences such as overexpression of epidermal growth factor receptor 1, which has been associated with poor survival in NPC and HNSCCs.[408–410] Recent advances in molecular targeted therapeutics of HNSCC involving epidermal growth factor receptor small molecule inhibitors and monoclonal antibodies have emerged.[411] Based on the findings and toxicity profile of agents in such therapeutic trials, opportunities may present for a targeted approach to prevention strategies for NPC and HNSCC among selected patients.

USEFUL RESOURCES

For those interested in cancer prevention, particularly useful resources include the *Journal of the National Cancer Institute* and the *Cancer*

Epidemiology Biomarkers and Prevention journal, and publications from the International Agency for Research on Cancer (http://www.iarc.fr/). This latter entity publishes a continuing series on early detection and prevention that represents an invaluable and critical analysis of current controversies. A particularly important Task Force Report from the American Association for Cancer Research on chemoprevention drug development recently has been published.[412] Useful Internet sites include

27 Nicotine Dependence: Current Treatments and Future Directions

Caryn Lerman, Robert A. Schnoll, and Freda Patterson

SUMMARY OF KEY POINTS

Prevalence and Impact
- Approximately one in five American adults are current smokers.
- Smoking accounts for one third of all cancer deaths.

Current Treatments
- Nonpharmacologic treatments include behavioral counseling (e.g., identifying triggers, managing withdrawal), quit lines, and self-help material (e.g., booklets and video).
- These approaches are popular but yield relatively low quit rates.
- The FDA-approved pharmacologic treatments, including nicotine replacement therapies (NRTs; i.e., transdermal patch, gum, nasal spray, inhaler, and lozenge) and bupropion, have been shown to double smoking cessation rates as compared to placebo.
- Varenicline, a new FDA-approved medication, has efficacy superior to that of NRTs and bupropion.

Smoking among Cancer Patients
- Approximately one half of cancer patients continue to smoke after diagnosis, even though tobacco use can heighten risk for a second primary tumor and diminished quality of life.
- Few studies have examined predictors of continued smoking among cancer patients, and even fewer trials of smoking cessation treatments have been conducted among cancer patients.

Barriers to Cessation Treatment in Clinical Oncology
- Physicians have limited time to address smoking among cancer patients, and patients may possess unique psychological characteristics that undermine their ability to quit smoking.
- Systems-level changes and tailored treatment approaches might be needed to lower the rate of persistent tobacco use among cancer patients.

Future Directions
- Research is needed to identify new medications for nicotine dependence and to evaluate these approaches with cancer patients.
- Pharmacogenetics research might help to guide the tailoring of treatments for subgroups of smokers to enhance efficacy and reduce toxicity.

INTRODUCTION

Despite several decades of research to identify new approaches to treat nicotine dependence, about 21% of adults in the United States are regular smokers, suggesting that the Healthy People 2010 objective of reducing U.S. adult smoking to 12% will not be attained.[1] Each year, cigarette smoking causes more than 400,000 premature deaths in the United States and 4.2 million premature deaths around the world from cancer, cardiovascular and respiratory diseases, and perinatal conditions.[1] Tobacco use accounts for at least 30% of all cancer deaths in the United States, and smoking has been causally linked to lung, head and neck, esophageal, pancreatic, bladder, kidney, cervical, endometrial, and gastric cancer and acute myeloid leukemia.[2] Furthermore, persistent tobacco use among cancer patients increases risk for disease recurrence, second-primary tumors, adverse reactions to therapy, diminished quality of life, and reduced survival.[3] Despite these data, 46% to 75% of cancer patients report smoking at the time of their diagnosis, and close to one half of these patients continue to smoke during and following medical treatment.[4]

This chapter provides an overview of the state of the art in smoking cessation treatment. First, we provide an overview of nonpharmacologic and pharmacologic treatments for nicotine dependence and highlights factors that affect treatment response. Second, we review the epidemiology of tobacco use among cancer patients, studies of predictors of tobacco use in this population, and studies of smoking cessation interventions with cancer patients. Third, physician and health care system and patient barriers to smoking cessation are discussed, and methods for overcoming these barriers are suggested. Fourth, we briefly review public policy initiatives that are used to reduce cigarette consumption, such as advertising bans, taxes on cigarettes, and smoke-free policies. We conclude with a brief discussion of potential new pharmacologic treatments for nicotine dependence as well as novel treatment approaches, including pharmacogenetics research. Some material in this chapter was adapted from an earlier publication.[5]

CURRENT TREATMENTS FOR NICOTINE DEPENDENCE

There are two general classes of treatments for nicotine dependence: nonpharmacologic and pharmacologic (Fig. 27-1). In the following sections, we describe these treatment approaches, with an emphasis on efficacy data and moderators of treatment response.

Nonpharmacologic Treatments

Nonpharmacologic smoking cessation treatments such as self-help interventions and behavioral counseling are the preferred mode of

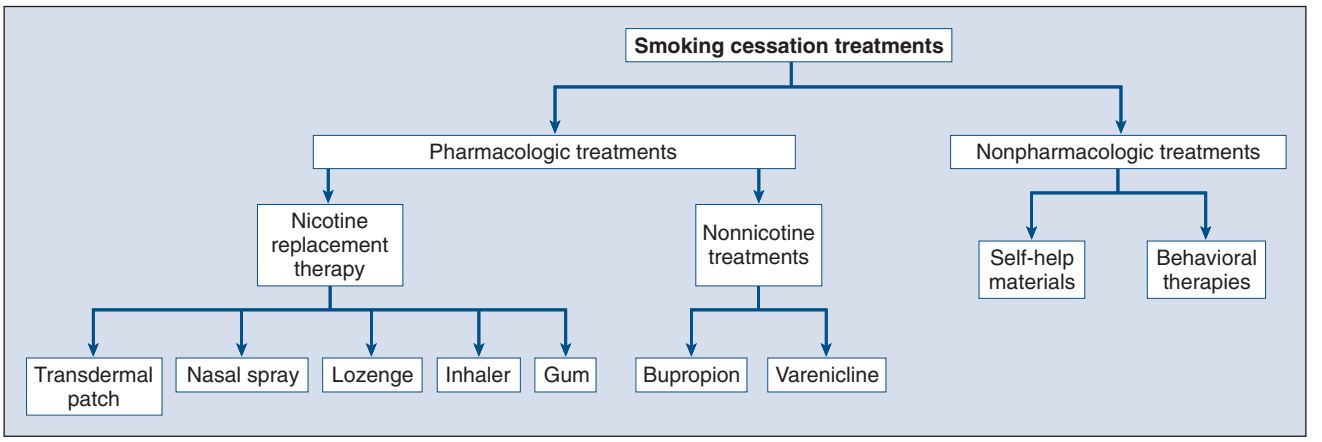

Figure 27-1 • Overview of FDA-approved available smoking cessation treatments.

treatment for most smokers.[6] These include informational booklets, audiotapes and videotapes or DVDs, and Internet-based programs that are designed to help smokers quit on their own.[7] Behavioral therapies include elements of nicotine fading, quit date contracting, management of smoking triggers, and relaxation techniques delivered either in a group or individual context.[7] The efficacy of these approaches is reviewed in the following discussion.

Self-Help Materials

Self-help smoking cessation interventions are reported to produce quit rates in the range of 4% to 11%[8] and are significantly more effective than no intervention at all.[9] Multimodal, more intense interventions are more effective than are single-modal, less intense interventions, while tailoring materials to individual characteristics has also been demonstrated to be a potentially effective strategy to enhance self-help quit rates. For example, in a sample of 300 treatment-seeking smokers, those who received computer-generated, tailored mailed feedback had significantly higher quit rates 1 year following the target quit date than did those who received standard advice (25% versus 10%, respectively).[10] The Internet has emerged as another vehicle through which self-help smoking cessation interventions can be delivered, with over 10 million Internet users in the United States searching for quit smoking information in 2004 and an estimated 75% self-reporting as current smokers.[11] Although only a small number of studies have evaluated the efficacy of Internet-based cessation approaches, one study did report that, at 3 months after the target quit date, a tailored, Internet-based cessation intervention produced a quit rate of 24% versus 5% in the control condition ($P < 0.05$).[12] These data are consistent with other preliminary work showing the efficacy of Internet-based cessation interventions;[13] however, more controlled trials in this area are needed before this approach can be considered a primary mode for the delivery of nicotine dependence treatment programs.

Behavioral Therapies

Behavioral therapies for smoking cessation include elements of nicotine fading, quit date contracting, management of smoking triggers, and relaxation techniques and have been reported to produce quit rates of 7% to 20%.[14,15] In one 3-month cognitive-behavioral smoking cessation program that provided participants with instruction and guidance on nicotine fading, quit date contracting, relaxation strategies, trigger management, and relapse prevention, end-of-treatment quit rates of 17.2% were reported as compared to 5.6% in the educational control condition.[16] No significant differences in individual versus group-based programs have been found.[17]

Telephone-based cessation counseling has become increasingly available in the United States, with 36 states providing quit lines for treatment-seeking smokers.[18] The efficacy of proactive telephone counseling (i.e., the cessation counselor initiates the call) has been well demonstrated,[19] producing 12-month quit rates in the range of 7% to 10%, the higher quit rates being achieved by recipients of more frequent calls.[20,21] Reactive telephone counseling (i.e., the patient initiates contact) such as that provided by state quit lines and hot lines has also been shown to be efficacious.[19,22] However, there is limited literature on the efficacy of statewide smoking cessation hot lines at this time.

Pharmacologic Treatments

FDA-Approved Nicotine Replacement Therapies

Five nicotine-replacement therapies (NRTs) have been approved by the U.S. Food and Drug Administration (FDA) for treating nicotine dependence: transdermal patch, gum, nasal spray, inhaler, and lozenge (Table 27-1); a sixth NRT, the sublingual tablet, is used only in Europe.[23] NRTs treat nicotine dependence by (1) ameliorating withdrawal symptoms that characterize initial physical and psychological reactions to cessation, such as irritability, restlessness, depressed mood, and poor concentration; (2) reducing the experience of nicotine craving on cessation and limiting possible weight gain (for gum and the patch); and (3) providing a safer way to experience the neurobiological and psychophysiologic effects of nicotine. NRTs are tolerable and safe and almost double quit rates compared to placebo (pooled OR = 1.77, 95% CI: 1.66 to 1.88).[24] Indirect[24] and head-to-head[25] comparisons indicate comparable efficacy between NRTs. However, NRTs do not provide nicotine as effectively as cigarettes do or adequately mimic the behavioral ritual of smoking. Furthermore, at best, only one quarter to one third of smokers who use NRTs to quit smoking will remain successfully abstinent 6 months following treatment completion.[24,25]

Identifying factors related to NRT responsiveness, including characteristics of the NRT as well as characteristics of the smoker, may lead to methods for enhancing NRT efficacy. One study found no difference in quit rates when NRT was used for a longer duration;[26] however, large-scale placebo-controlled trials testing the effects of extended NRT use are needed. Other studies have examined the efficacy of higher-dose NRT; however, findings thus far have not been supportive.[27] Meta-analytic reviews of studies that evaluated combination NRT therapy versus a single NRT show that combination therapy is somewhat more effective (OR = 1.42, 95% CI: 1.14 to 1.76[24] versus OR = 1.9, 95% CI: 1.3 to 2.6).[28] However, studies

Table 27-1 FDA-Approved Medications for Tobacco Dependence

Medication	Recommended Duration and Dose*	Estimated Quit Rate† (95% CI) Number of Studies	Advantages	Disadvantages	Cost
Nicotine gum	Up to 12 weeks; 2 mg (for those who smoke <25 cigarettes/day; 4 mg (for those who smoke ≥25 cigarettes/day	17.4% (17% to 18%) 52 trials[24]	Treat oral behavioral ritual and cue-elicited craving; prevent weight gain	Adverse side effects and poor compliance	$4.00 to $5.00/day
Nicotine patch	Up to 10 weeks; dose duration varies by cigarettes/day	13.7% (13% to 15%) 37 trials[24]	Better compliance and nicotine replacement; few side effects	Does not treat cue-elicited craving	$2.50/day
Nicotine spray	Up to 6 months; 8 to 40 sprays/day	24% (20% to 28%) 4 trials[24]	Nicotine is rapidly absorbed; treat cue-elicited craving	Unpleasant side effects and poor compliance	$5.00 to $15.00/day
Nicotine inhaler	Up to 6 months; 6 to 16 cartridges/day	17% (14% to 21%) 4 trials[24]	Treat oral behavioral ritual and cue-elicited craving	Unpleasant side effects and poor compliance	$7.00 to $18.50/day
Nicotine lozenge	Up to 12 weeks; 2 mg (for those who smoke their first cigarette more than 30 minutes after waking) and 4 mg (for those who smoke their first cigarette within 30 minutes of waking)	17% (15% to 20%) 4 trials[24]	Good nicotine replacement; treats oral behavioral ritual and treats cue-elicited craving; few side effects	Compliance is unknown	$3.00 to $4.00/day
Bupropion	Up to 12 weeks; 300 mg/day; 150 mg per day for 3 days, then 300 mg/day from day 4 to end of treatment	19% (Range: 4% to 43%) 2 trials[28] 31 trials[40]	Good side effect profile; low abuse liability; prevent weight gain	Relatively more costly	$4.00 to $5.00 (300 mg)
Varenicline	Up to 12 weeks; 2 mg/day; 0.5 mg for days 1 to 3, 0.5 mg twice daily for 4 days, and 1 mg twice daily from day 8 to end of treatment	30% 2 trials[54,55]	Well-tolerated; reduces withdrawal and reinforcing effects of nicotine	Limited data	Unknown

*Recommendations are taken from the manufacturer of the agent and/or from Fiore[28].
†6-month or greater point-prevalence quit rates, biochemically verified.

in this area have not been entirely consistent.[29] More recently, one study found that using the patch for 2 weeks prior to quitting doubled the likelihood of 4-week continuous abstinence, compared to standard patch use.[30] Finally, since NRT efficacy may be related to how rapidly nicotine is delivered into the central nervous system,[31] studies have begun to investigate rapid-release NRT. Niaura and colleagues[32] found that rapid-release nicotine gum significantly reduced postcessation cravings compared to standard nicotine gum, suggesting the need for clinical trials of rapid-release formulations of NRT.

Likewise, a range of smoker characteristics can affect response to NRTs, suggesting that the tailored use of NRT for subgroups of smokers could improve NRT efficacy.[33] The level of nicotine dependence affects response to NRT, more dependent smokers showing higher quit rates when they receive higher doses of NRTs.[34,35] Lerman and colleagues[25] also found that smokers with low to moderate levels of dependence have higher quit rates with the patch, while those with high levels of dependence have higher quit rates with the nasal spray. Caucasian smokers and nonobese smokers also showed higher quit rates on the patch, whereas smokers from racial and ethnic minority groups and obese smokers showed higher quit rates with the nasal spray.[25] Last, gender may affect response to NRT. While early placebo-controlled trials of NRT reported lower efficacy for women than men, two meta-analyses[36,37] indicate that NRTs have equal efficacy for women and men. However, meta-analytic studies included trials that provided only partial outcome data, omitted some relevant trials, and might have had limited statistical power to examine gender differences in light of low absolute quit rates.[38] Furthermore, another meta-analytic study found that NRT was less effective for maintaining long-term cessation for women versus men.[39]

FDA-Approved Nonnicotine Pharmacologic Treatments

Bupropion SR (Zyban) is an antidepressant that reduces the uptake of dopamine and norepinephrine (see Table 27-1). A meta-analysis[40] of 31 placebo-controlled trials concluded that bupropion more than doubled the likelihood of cessation compared to placebo, up to 12 months from a quit date (OR = 1.94, 95% CI: 1.72 to 2.19). The exact mechanism through which bupropion treats nicotine dependence is not fully known; however, the efficacy of this medication is mediated, in part, by reduction of dopamine and norepinephrine uptake[41] and/or nicotinic receptor antagonist effects.[42] A second mechanism may involve the drug's ability to prevent or diminish postcessation negative affect and weight gain, which are frequently cited as causes of relapse among smokers[43,44] Nevertheless, upward of three quarters of smokers who use bupropion to quit smoking do not achieve long-term abstinence. Therefore, researchers have begun to examine factors related to bupropion response. Research in this area has assessed clinical depression and depressive symptoms as a

moderator of treatment response. To date, no clinical trial has formally examined the role of depression as a moderator of bupropion efficacy by using depression a priori as a stratification variable. However, trials that conducted post hoc analysis to address this issue have not supported the hypothesis that bupropion is more effective for depressed smokers.[45–47] Researchers have also examined gender as a moderator of bupropion response. With few exceptions, placebo-controlled trials indicate comparable efficacy of bupropion for women and men.[48,49] However, there is some indication that the use of bupropion to prevent relapse is less effective for women than for men.[50]

Varenicline (Chantix) is an α4β2 neuronal nicotinic acetylcholine receptor (nAChR) partial agonist (see Table 27-1). By activating α4β2 nAChRs receptors, which are expressed widely on dopamine and GABA neurons in the ventral tegmental area, varenicline attenuates nicotine's effect on dopamine release, while maintaining dopaminergic tone.[51] Varenicline's agonist function may minimize craving and withdrawal, while its antagonist properties may attenuate the reinforcing effects of nicotine, thereby reducing satisfaction from a "slip" cigarette and the likelihood of relapse.[52,53] The recent FDA approval for varenicline was based on the results from three clinical trials. The first two trials randomized 2,052 smokers to placebo, 300 mg bupropion, or 2 mg varenicline for 12 weeks and assessed quit rates up to 1 year following the start of treatment.[54,55] Assessment of continuous quit rates for the last 4 weeks of treatment (weeks 9 to 12) across the two trials at the end of treatment showed an advantage for varenicline (44%) compared to bupropion (30%) and placebo (18%). The continuous quit rate for varenicline at the 1-year follow-up diminished (22%), but it remained significantly better than those for bupropion (16%) or placebo (10%). In a third study,[56] smokers received open-label varenicline (1 mg b.i.d.) for 12 weeks; subjects who remained abstinent at the end of 12 weeks were randomized to 12 additional weeks of 1 mg b.i.d. varenicline or placebo. An assessment conducted 28 weeks from the end of the second 12-week treatment phase showed that extended varenicline use prevented relapse. Across all trials, adverse events and rates of discontinuation were similar for placebo and varenicline, indicating that varenicline is well tolerated.

Since varenicline is a relatively new treatment for nicotine dependence, little is known about moderators of treatment response. Gonzales and colleagues reported gender differences in therapeutic response.[54] Biochemically confirmed continuous abstinence rates for weeks 9 to 12 were equivalent for men and women (43% versus 46%, respectively). Furthermore, there were no gender differences in 12-month quit rates in varenicline-treated participants in a pooled analysis of data from the three trials.[57]

TOBACCO USE IN THE ONCOLOGIC SETTING

While numerous studies have documented the rate of smoking among cancer patients, few studies have examined predictors of smoking by cancer patients and cessation interventions for this population. Accumulating data show that persistent tobacco use following a diagnosis can increase the risk for a second primary tumor, shorten survival duration, exacerbate treatment-related side effects, and diminish quality of life.[3] These findings have sparked greater interest in addressing tobacco use in this population. In the following sections, we provide an overview of the research that has been conducted to date concerning tobacco use among cancer patients.

Smoking Rates among Cancer Patients

Given the etiologic role of smoking in cancer, it is not surprising that rates of tobacco use among certain subgroups of cancer patients exceed rates in the general population. The vast majority of studies in this area have concentrated on lung cancer patients and head and neck cancer patients.[4] However, studies have also evaluated smoking among cervical[58] and bladder[59] cancer patients and among survivors of childhood cancers.[60] Among head and neck cancer patients, prevalence rates of continued smoking range from 25% to 90%.[61–66] Among lung cancer patients, prevalence rates of continued smoking range from 29% to 63%.[67,68] Variability in rates is likely due to methodologic differences across studies, such as inconsistent follow-up intervals, divergent methods for assessing smoking, reductions in baseline smoking rates in the population over time, and differences between the samples in demographic or medical variables. Recent prospective studies that defined smoking as taking a single puff of a cigarette in the past 30 days have reported rates of continued smoking to be 25% to 48% for head and neck cancer patients[66,69–71] and 35% to 40% for lung cancer patients.[68,70] Last, persistent tobacco use has been documented among 69% of bladder cancer patients,[59] 40% of cervical cancer patients,[58] 20% of adult cancer survivors,[72] and 17% to 20% of survivors of childhood cancers.[73–76]

Factors Related to Smoking Cessation among Cancer Patients

Identifying factors that influence smoking behavior among cancer patients is essential for developing and implementing smoking cessation interventions for this population. In the next few sections, we review the available literature concerning demographic, medical, and psychological correlates of smoking cessation among cancer patients.

Demographic Variables

Studies that have assessed demographic correlates of smoking behavioral among cancer patients have yielded few consistent findings. For example, while older cancer patients and survivors were more likely to remain abstinent in several studies,[72,77] this relationship has not been replicated in other studies,[59,70,78] or the opposite result has been reported[74,79] Likewise, while higher educational achievement has been linked with greater abstinence by some,[74,77] this relationship has not been replicated by others,[59,70,71,78] and one study found the opposite relationship.[65] Furthermore, aside from one study that reported that female cancer survivors were more likely to quit smoking, gender has not been found to be a predictor of smoking cessation among cancer patients.[61,65,66,70,77,78]

Smoking history variables (e.g., amount, duration, and level of nicotine dependence) have also been evaluated as correlates of smoking behavior among cancer patients. Amount and duration of tobacco use have been associated with the likelihood of cessation among cancer patients by some studies[74] but not by others.[59,65] In contrast, several studies have shown that patients with a lower level of nicotine addiction show a greater ability to quit smoking.[66,70,78,79] Last, alcohol use has been examined as a correlate of smoking behavior, particularly among head and neck cancer patients, since many head and neck cancer patients abuse (or at least heavily use) alcohol.[80] Vander Ark and colleagues[71] found that heavy alcohol use was a significant predictor of continued smoking by head and neck cancer patients. Chan and colleagues[62] also reported that concurrent alcohol use predicted future smoking. However, this relationship was not found in other studies of head and neck cancer patients.[61,77,79]

Medical Variables

The relationship between disease-related variables and smoking among cancer patients has also been evaluated; however, few consistent findings have emerged. For example, higher rates of abstinence from tobacco use have been noted among head and neck cancer patients with a more advanced disease stage.[65] Similar results were reported in a study with bladder cancer patients.[59] However, several other studies with head and neck cancer patients and lung cancer patients have not replicated this result. Some studies have reported that multimodal medical therapy (e.g., surgery plus radiation) increases quit rates,[65,71] while other studies indicate that it is the pres-

ence of surgery that underlies higher cessation rates (compared to radiation alone[79]). Although this had not been as adequately studied, three studies indicate that as time elapses from the point of diagnosis, the risk of relapsing to smoking increases.[70,78,81]

Psychological Variables

Several studies have also examined psychological correlates of smoking among cancer patients. Head and neck and lung cancer patients who exhibit higher motivation to quit (typically assessed by using the stage-based measure derived from the transtheoretical model) show higher rates of smoking cessation.[66,79,82] Beliefs about smoking behavior have also been correlated with tobacco use among cancer patients. Christensen and colleagues[61] examined whether perceived control (i.e., believing that future health outcomes are affected by one's behavior) and self-blame (i.e., attributing the cause of the diagnosis to one's behaviors) influenced smoking behavior among head and neck cancer patients. A significant interaction effect was detected: A greater proportion of patients with high levels of self-blame *and* low levels of perceived control continued to smoke compared to patients with high levels of self-blame *but* high levels of perceived control (64% versus 25%, respectively).[61] Schnoll and colleagues[78] reported that head and neck cancer patients who report higher quitting self-efficacy (i.e., confidence in their ability to quit) are more likely to abstain from smoking, a finding that was also reported in a prospective study with head and neck cancer patients.[66] Risk perceptions concerning the adverse health effects of tobacco use may be particularly important to address among head and neck cancer patients. In a cross-sectional study, lower perceived risk (e.g., for disease recurrence) was related to a greater likelihood of continued smoking among head and neck cancer patients,[78] a result that was replicated in a prospective study.[70] Lower levels of quitting pros (i.e., advantages of quitting) and higher levels of quitting cons (i.e., disadvantages of quitting) and fatalistic beliefs (i.e., believing that there is no use in quitting) have also been associated with a greater likelihood of continued smoking;[78] higher levels of quitting cons, moreover, predicted persistent smoking and relapse prospectively.[70]

Several studies have shown that negative affect, typically measured by symptoms of depression and anxiety, predict smoking among cancer patients. Cross-sectional studies associated negative mood measured by self-report instruments (e.g., the Hospital Anxiety and Depression Scale) with smoking among head and neck cancer patients.[78,80,83] One prospective study reported that patients who lapsed to smoking were significantly more likely to report anxiety in the week prior to a lapse compared to patients who maintained abstinence.[66] A more recent prospective study, which followed a sample of head and neck cancer patients for 15 months, found that patients who continued to smoke had greater negative mood as compared to nonsmokers.[69]

Smoking Cessation Interventions for Cancer Patients

Despite the high rate of persistent tobacco use among cancer patients and the growing recognition of the adverse effects on clinical outcomes for patients who continue to smoke, relatively few randomized clinical trials have evaluated the efficacy of smoking cessation interventions for cancer patients (Table 27-2).

The first study, with 186 head and neck cancer patients, randomized patients to either "usual care" physician quit advice (e.g., risks of continued smoking and benefits of cessation) or an "enhanced" physician quit advice intervention that included expression of confidence in the patient's ability to quit, a written quit date contract, tailored self-help booklets, and booster advice to remain abstinent.[79] The results showed extremely high continuous quit rates (biochemically confirmed) for both conditions at a 12-month follow-up (usual care = 77%, intervention = 64%), in part owing to strong physician quit advice provided in both study conditions and the inclusion of patients who had not smoked for up to 1 year prior to study recruitment. In a second study, Stanislaw and Wewers[84] randomized cancer patients with various tumor sites to either a usual care or an intervention that consisted of three in-person behavioral counseling sessions and five follow-up phone contacts. At 5 weeks, the quit rate (biochemically confirmed) for the experimental group was 75% (9/12), compared to 43% (6/14) for the control group, although the small sample led to a nonsignificant comparison. In the third study, Griebel and colleagues[85] randomized cancer patients with various types of malignancies to either usual care or to a one-time smoking cessation consultation with an oncology nurse (plus five telephone booster calls).[85] After 6 weeks, 21% (3/14) of experimental patients exhibited cotinine-validated abstinence, compared to 14% (2/14) of the patients in the usual care condition. Again, the small sample size could have led to a nonsignificant comparison of quit rates.

More recently, Schnoll and colleagues conducted two randomized smoking cessation clinical trials with cancer patients. The first trial examined a cognitive-behavioral therapy (CBT), which addressed theoretically derived cognitive and emotional variables linked to tobacco use in this population (e.g., self-efficacy, risk perception[86]). Head and neck and lung cancer patients ($n = 109$) were randomized to either the theoretically based CBT intervention or a general health education (GHE) condition, and all patients received nicotine replacement therapy. Although high quit rates were detected in this trial, no significant difference in 30-day point-prevalence abstinence between the CBT and GHE conditions was detected at either 1-month (45% versus 47%, respectively) or 3-month (43% versus 39%, respectively) follow-up evaluation. The second trial examined the efficacy of a physician-based smoking cessation intervention for cancer patients.[87] Cancer patients ($n = 432$) were randomized to either usual care or a National Institutes of Health physician-based smoking intervention (i.e., the 5As). At 6-month follow-up, there was no significant difference in quit rates between the usual care (12%) and the intervention (14%) group, and there was no significant difference between the usual care (14%) and the intervention (13.3%) group at the 12-month follow-up.

Wakefield and colleagues examined the use of motivational interviewing for promoting smoking cessation among cancer patients.[88] In this study, 137 cancer patients were randomized to either a control group, consisting of quit advice, self-help brochures, and a referral to a quit line, or an intervention arm that included motivational interviewing, smoking cessation self-help booklets, and NRT. After 6 months, the quit rate for the intervention arm was 6%, compared to 5% for the control arm. In a trial of 796 childhood cancer survivors, patients were randomized to either a self-help arm (quit advice letter and self-help booklet) or an intervention arm that consisted of six phone-based counseling sessions from a childhood cancer survivor plus self-help material, and NRT. Quit rates were higher for the peer-counseling condition than for the self-help condition at 8 months (16.8% versus 8.5%) and at 12 months (15% versus 9%).[89]

Barriers to Smoking Cessation Treatment in Clinical Oncology

Quitting smoking following a cancer diagnosis can improve clinical outcomes for patients, and cancer patients exhibit uniquely high levels of quit motivation,[90] suggesting that this can be a teachable moment for smoking cessation. Unfortunately, a cancer diagnosis has been underutilized as a teachable moment for assisting patients to quit smoking.[3] To facilitate greater attention to promoting smoking cessation among cancer patients, barriers to cessation should be identified, including physician and health care system barriers and patient barriers.

Physician and Health Care System Barriers to Smoking Cessation

Because patients visit physicians or members of the health care team repeatedly and view health care professionals as valuable, credible,

Table 27-2 Overview of Smoking Cessation Interventions for Cancer Patients

Study Authors (Year)	Study Population	Study Design and Treatment Groups	Main Results
Gritz et al. (1993)[79]	*N* = 186 Newly diagnosed head and neck cancer patients	Randomized trial in which participants received either one session of "usual care" physician quit advice or an "enhanced" physician quit advice intervention + 6 booster sessions.	12-month follow-up (biochemically confirmed; *n* = 114) continuous abstinence rates: usual care = 77%; intervention = 64%. No significant difference in quit rates between groups.
Stanislaw and Wewers (1994)[84]	*N* = 26 Patients with various cancers undergoing surgery	Randomized trial in which participants were assigned to usual care or an intervention that consisted of three in-person sessions and five weekly phone calls.	5-week (biochemically confirmed) quit rates: experimental group was 75% (9/12) versus 43% (6/14) for the control group. Difference in quit rates was statistically significant ($P < 0.1$).
Griebel et al. (1998)[85]	*N* = 28 Patients with various cancers undergoing surgery	Randomized trial in which participants were assigned either to receive usual care or a one-time 20-minute, postoperative smoking cessation session with an oncology nurse + 5 weekly 10-minute booster phone calls.	6-week (biochemically confirmed) abstinence rate: 21% (3/14) for experimental group and 14% (2/14) for usual care recipients. Quit rate differences between groups not statistically significant.
Schnoll et al. 2005[86]	*N* = 109 Head and neck or lung cancer patients	Randomized trial that compared the efficacy of a cognitive-behavioral therapy (CBT) intervention with a general health education (GHE) intervention for smoking cessation among cancer patients. CBT participants received one in-person session and three telephone counseling sessions that were tailored to their barriers to cessation. GHE participants received general quitting advice. All participants received transdermal nicotine.	No significant differences in cessation rates between the CBT and GHE groups were observed at 1-month (45% versus 47%, respectively) or 3-month (43% versus 39%, respectively) follow-up.
Schnoll et al., 2003[87]	*N* = 432 Patients with various cancers	Randomized trial that compared the effectiveness of a physician-based intervention in which the AHRQ 5 A's was delivered versus usual care (brief quit advice).	No significant differences in cessation rates between the physician-based intervention and the usual care condition were observed at the 6-month (14% versus 12%, respectively) and 12-month (13% versus 14%, respectively) follow-up assessments.
Wakefield et al. (2004)[88]	*N* = 137 Patients with various cancers	Randomized trial in which participants were assigned to receive either brief quit advice control condition (brochure + referral to a quit-line; *n* = 63) or a motivational interviewing experimental condition (*n* = 74) in which they received specific cessation advice and booklets targeted to cessation for cancer patients via telephone and in-person counseling. NRT was provided to those who smoked >15 cigarettes per day.	At 3-month follow-up, 7% of the motivational interviewing and 6% of the control group recipients had biochemically confirmed abstinence. Differences in group quit rates were not statistically significant. Intervention group was significantly more likely than control group to report making a quit attempt (86% versus 62%, respectively).
Emmons et al. (2005)[89]	*N* = 796 Childhood cancer survivors who smoked	Randomized trial in which participants were assigned to either a self-help smoking cessation intervention (physician letter + cessation brochure) or a peer-delivered telephone counseling intervention (up to 6 phone calls tailored to individual's stage of change delivered over 7 months). NRT was also offered to counseling intervention group.	At 3-months follow-up, counseling group had significantly higher quit rates as compared to self-help group (11% versus 5%). At 12-month follow-up, counseling group still had higher quit rates (11% versus 7%, respectively), but differences were not statistically significant.

and reliable sources of health information, they generally adhere to physician advice.[91] Thus, the health care team is a critical resource for addressing patients' tobacco use. Recent national surveys, however, indicate that primary care physicians and nurses are not capitalizing on their opportunity to intervene with patients. A national survey of physicians indicated that while most physicians (75%) advise their patients to quit smoking, fewer than one third of physicians recommend pharmacotherapy "often or always," and fewer than one quarter provide referrals for cessation treatment programs "often or always."[92] Surveys with oncology nurses yield convergent data; about two thirds of nurses document patient smoking status, one third provide cessation advice, and one quarter recommend NRT.[93]

A number of barriers are likely responsible for a failure to fully capitalize on this opportunity. First, pragmatic limitations can make

it challenging for health care professionals to intervene with cancer patients who smoke. Physicians and nurses are extremely busy and have little extra time to provide comprehensive nicotine addiction treatment. Second, a lack of third-party reimbursement for treating nicotine dependence and the expense of ascertaining treatment outside of insurance coverage can undermine commitment from health care professionals to intervene with patients who smoke. Third, certain attitudes that health care professionals have about smoking can undermine the provision of adequate treatment, such as believing that patients are not interested in receiving nicotine dependence treatment, that treatment will be ineffective, that they lack the skills and confidence to intervene, and that it is not part of their professional role.[93,94] These beliefs, in part, stem from an additional barrier to effective treatment of nicotine dependence by physicians and nurses working with cancer patients, namely, the lack of adequate training for health care providers in methods for treating nicotine dependence.[95] Thus, lack of time, financial coverage, and adequate training and specific beliefs undermine the provision of adequate nicotine addiction treatment for cancer patients. Last, health care providers may view nicotine addiction as an acute condition, rather than a chronic illness, and therefore might not provide the sort of ongoing treatment that is required to help patients to quit smoking.

Patient Barriers to Smoking Cessation

Unique aspects of a cancer diagnosis and its treatment undermine effective smoking cessation. First, a cancer diagnosis can produce significant negative affect (i.e., symptoms of anxiety and depression),[96] which, in turn, can undermine the patient's ability to quit smoking. Likewise, ongoing medical treatment, financial pressures, and family strain or conflict can produce stress that undermines quit motivation or triggers relapse following successful cessation. Last, many patients exhibit a fatalistic attitude about quitting smoking (i.e., what is the use of quitting now since the patient has been diagnosed) and low quitting self-efficacy,[96] which diminishes patient commitment to quitting smoking. Second, since cancer patients might be unwilling to admit to smoking, it can be very difficult to ensure that adequate treatment is provided. Third, most cancer patients show very high levels of nicotine dependence and have been smoking for many decades,[96] making treatment more challenging. Last, many cancer patients experience treatment-related side effects that can make it difficult to utilize nicotine addiction treatments, including the nicotine lozenge or gum or bupropion or varenicline (e.g., difficulty with or an inability to swallow), or they might have medical conditions that prevent the use of pharmacotherapy.

Overcoming Barriers

Reducing the prevalence of tobacco use among cancer patients depends on successfully overcoming both physician and patient barriers to cessation. While physicians and health care professionals should not be expected to devote much time to treating nicotine dependence, they should be expected to assess smoking status, deliver cessation advice, and provide a prescription for pharmacotherapy and/or a referral to a local smoking cessation program as needed. Some professional organizations have revised clinical treatment guidelines for smoking cessation from the 5As to Ask, Advise, Refer (see www.askadviserefer.org/about.asp) in order to overcome practical constraints for health care providers. Additionally, systems changes, such as including smoking status as a vital sign within patient records, can facilitate easy and continual assessment of patient smoking status, along with chart reminders and incentives for identifying and referring patients for appropriate cessation treatment.

While many comprehensive cancer centers offer smoking cessation treatment services or access to treatment through clinical trials, economic barriers to access remain. However, many major insurance companies and many state Medicare and Medicaid programs now cover smoking cessation treatment, and upward of 30 states have free quit lines, in addition to national hot lines operated by the National Institutes of Health and the American Cancer Society. As such, assessing smoking status and providing quit advice, self-help material, and a treatment referral should be affordable for all facilities; therefore, all patients should receive at least this minimal level of smoking cessation intervention.

Training oncologists in clinical practice guidelines for smoking cessation (i.e., the 5As) enhances physician adherence to practice guidelines[87] and reduces patient smoking.[97] Additional research is needed to identify effective and affordable methods for training health care professionals in treating nicotine dependence. This training should prepare health care professionals to intervene with patients and address beliefs that might discourage compliance with treatment guidelines, such as low patient interest in receiving treatment and the adoption of a chronic disease model for nicotine dependence.

Last, as new smoking cessation treatment programs are designed for cancer patients, the efficacy of these programs could depend on the degree to which they are tailored to address the specific needs of cancer patients. Many cancer patients will require intervention components that address affective barriers to cessation (e.g., bupropion). In addition, supportive therapies and coping skills training programs might be needed for many patients to assist them in avoiding relapse when stressful events are encountered. Behavioral counseling might also need to address fatalistic beliefs or a critical lack of confidence in quitting smoking. Patients must also be made to feel safe and comfortable to share their smoking status, so interventions must be nonjudgmental and nonconfrontational (i.e., motivational interviewing). Finally, treatments might need to be relatively intense (e.g., combination pharmacotherapy) to address level of nicotine dependence and be continuously provided for an extended period of time. However, practitioners must consider potential treatment side effects and medical contraindications when selecting a particular treatment approach for patients.

PUBLIC POLICY EFFORTS TO REDUCE CIGARETTE CONSUMPTION

A variety of public policy initiatives, such as bans on tobacco advertising, increased taxation on cigarettes, and clean air laws that ban smoking in public places, have come to the fore as being important legislative tools to reduce cigarette consumption. A brief review of these approaches is provided here.

Tobacco Advertising

Exposure to tobacco advertising has been shown to promote experimentation and the development of a regular smoking habit among adolescents,[98,99] as well as continued smoking among adults.[100] Consistent with these data is evidence that national bans on tobacco advertising in countries such as Norway, Finland, New Zealand, and France resulted in a 14% to 37% drop in cigarette consumption.[101] Likewise, bans on tobacco advertising in the United States have correlated with a decline in cigarette consumption . However, there are concerns that partial tobacco advertising bans (e.g., banning only outdoor advertising) might serve to exponentially increase tobacco advertising through other venues such as print media, point-of-purchase advertising, and sponsorships, thus compromising the efficacy of this public health approach to reducing cigarette consumption.[102]

Tobacco Taxes

Excise taxes on cigarettes have been shown to reduce cigarette consumption,[103] federal level tax increases being more effective than increases at the state level.[103] Data also suggest that a 10% increase

in the price of cigarettes would equate to an 8% decline in smoking prevalence among low-income adults and a 4% decline among higher-income adults.[104] In a random-digit-dial telephone survey of 10,000 New York residents, almost half of respondents who smoked reported that they reduced the number of cigarettes they had smoked in response in an increase in cigarette prices;[105] this response was more pronounced among non-Caucasians, people with low incomes, and those without a high school education.[105] Collectively, these data support the use of increased cigarette taxes as a strategy for reducing cigarette consumption.

Smoking Bans

Given evidence that secondhand smoke increases cancer risk, bans on smoking in public places and workplaces are considered appropriate strategies to minimize the negative health effects from secondhand smoke.[106] Smoking bans in countries such as Ireland, Italy, Sweden, and New Zealand and 13 U.S. states have provided the opportunity to assess the health effects of smoke-free environments, and the results have been encouraging. Specifically, Farrelly and colleagues reported on saliva cotinine (an indicator of nicotine exposure) levels in a sample of New York hospitality workers before and after the smoking ban. Results showed a significant decline in nicotine exposure following the ban.[107] These data are consistent with those of a similar study conducted in Ireland.[108] With regard to any positive health effects from living in an area with a smoke-free policy, one study conducted in the town of Helena, Montana, showed a significant decline in hospital admissions for myocardial infarction for a 6-month period while the smoke-free policy was in place compared to the same 6-month period in the previous years when the smoke-free policy was not in place.[109] Notably, hospital admissions for myocardial infarction in the areas outside Helena where the smoke-free policy was not in place showed a nonsignificant increase.[109]

FUTURE DIRECTIONS AND CONCLUSIONS

The potential increases in tobacco use worldwide, in combination with the suboptimal response to currently approved medications for nicotine dependence treatment, highlight the need to both develop more efficacious smoking cessation treatments and to improve the use of currently approved treatments. Toward this end, the identification of novel medications that mimic and/or attenuate nicotine's rewarding effects or reduce nicotine withdrawal is underway and most clearly demonstrated by the recent FDA approval of varenicline. There is also evidence for the efficacy of selegiline, fluoxetine, naltrexone, and mecamylamine in certain subgroups of smokers, although current data are limited or conflicting. In terms of improving the efficacy of currently approved treatments for nicotine dependence, research concerning smoker characteristics related to responsiveness to NRTs and the potential development of fast-acting NRTs could help clinicians to prescribe NRT (type, dose, and duration) based on the smoker's characteristics, thereby enhancing NRT effectiveness. Similarly, reduced NRT costs in conjunction with innovative marketing approaches to increase the appeal of, and access to, NRTs could significantly increase utilization of NRT products, in turn, broadening the impact of over-the-counter therapies on the population smoking rate. Finally, although the results from pharmacogenetic studies of treatments for nicotine addiction offer limited potential for individualizing patient care at this point, future research in this pioneering area might eventually lead to substantial breakthroughs for individualized treatments for nicotine addiction and additional significant reductions in the worldwide prevalence of smoking. Nevertheless, given the projections for substantial increases in the rate of tobacco use in developing countries and given the lack of resources in these countries to sustain the needed infrastructure for effective treatment for nicotine dependence, efforts must be directed toward the development of low-cost treatments that can be broadly disseminated. Low-cost treatments for nicotine dependence, coupled with innovative marketing of these treatments, should also be seen as a priority in developed countries to further the important advances that have been made thus far in reducing the rate of tobacco use over the past several decades. Partnerships between pharmaceutical companies and government agencies to develop, test, and market new treatments for nicotine dependence, as has been done with treatments for other medical illnesses and diseases, could be critical if additional significant reductions in the worldwide prevalence of smoking are to be realized.

28 Surgical Interventions in Cancer

John E. Niederhuber

SUMMARY OF KEY POINTS

- Surgeon is part of a multidisciplinary team.
- Surgeon is frequently the "entry point" for patients who are newly diagnosed with cancer.
- Surgeon must have knowledge of the biology and natural history of the cancer to be treated.
- Surgeon must be technically experienced in diagnostic procedures and operative interventions.
- Surgeon must have appropriate knowledge base in medical and radiation oncology.
- Patients treated in a multimodality setting have improved outcomes.
- Training of surgical oncologist must encompass the following:
  - Etiology and genetic predispositions of cancer
  - Prognostic factors and natural history of specific tumors
  - Understanding of how to provide cost-effective treatment
  - Skills to develop, conduct, and manage clinical trials
  - Guidance in management of advanced disease
  - Guidance in offering compassionate support
  - Guidance in determining and evaluating outcomes
- Surgical oncologist should be a participant in clinical trials, providing guidance in design and monitoring of quality control aspects of surgical intervention component as well as overall leadership design and implementation.
- Surgical oncologist should be an educational resource in the community.
- Surgical oncologist plays an important role in prevention and screening.

INTRODUCTION

Historically, surgery was the sole method used for treating cancer. However, with the introduction of ionizing radiation and the development of anticancer drugs, cancer therapy has rapidly progressed to involve the careful integration of an extensive array of therapeutic options in the treatment of both primary and recurrent tumors. As a result, the cancer surgeon no longer works alone but is part of a multidisciplinary team involved in the treatment of most solid tumors and in the design and implementation of clinical trials.

The surgeon must have a clear understanding of the biology of cancer and its natural history and must also be experienced in the technical procedures needed to accurately diagnose and appropriately resect primary cancers and, when indicated, locally recurrent and metastatic tumors. The cancer surgeon must also be prepared, in many cases, to function as the primary cancer care provider, or cancer-oriented "family physician," for the patient. The surgeon must provide for the patient a focus of treatment integration among the various cancer specialists. Cancer surgeons find that it is common for patients to call or visit them for advice about all aspects of their treatment, which often leads to a lifelong relationship of continued care and follow-up.

HISTORICAL PERSPECTIVE

In medicine, professional and public acceptance of a subspecialty has historically depended largely on accomplishment. The development of the surgical oncology subspecialty is no exception and has been intimately tied to the history of surgery. In fact, surgical treatment of cancer has been significantly responsible for the role of surgery in modern medicine. The earliest discussion of surgical treatment of tumors appears in the E.S. Papyrus (ca. 1600 BC), but it is believed to be based on earlier writings dating back to 3000 BC.[1]

Despite this early mention, surgery was primarily reserved for the treatment of abscesses and for managing trauma before the introduction of anesthesia. The few operations performed for tumors were amputations. Not only did patients suffer excruciating pain in the absence of anesthesia, but also, before the advent of antisepsis, the death rate from infection was extraordinarily high. As a result, few patients were willing to undergo such intense pain electively, with so little chance of survival. The development of anesthesia and the introduction of antisepsis made elective surgical techniques for the treatment of cancer much more acceptable, and rapid developments in cancer surgery began to occur during the second half of the nineteenth century as tumor-specific elective surgeries were undertaken and refined.[2,3]

Anesthesia

Some of the first "clinical trials" of ether anesthesia took place in the parlor of Crawford Long, a dentist practicing in Georgia during the early 1840s. Long is said to have invited his friends over for "ether parties" to enjoy a temporary "loss of Southern inhibitions." Long witnessed that his friends lost not only their inhibitions, but also pain sensation. He is said to have used ether anesthesia in his dental practice as early as 1842. Unfortunately, Long's use of ether was not brought to the attention of the medical public.

John Collins Warren is responsible for two significant benchmarks in oncologic surgical history. He published the first American work on tumors in 1838, entitled "Surgical Observations on Tumors

with Cases and Operations,"[4] and he was the surgeon in the first published account of the use of ether anesthesia for removal of a tongue cancer from Gilbert Abbott in 1846.[2] The anesthesia was administered by a dentist, William T. Morton, who had developed the technique. The operation involved excision of the submaxillary gland and part of the tongue.[5]

Antisepsis

Despite the advances made in anesthesia in the 1840s, sepsis remained a major barrier to successful surgery until Joseph Lister (subsequently Baron Lister), an accomplished surgeon, introduced the concept of bactericidal therapy with carbolic acid in 1867.[3] This was an outgrowth of Pasteur's theory that bacteria caused infection. Using carbolic acid as an antiseptic agent in conjunction with heat sterilization of instruments, Lister dramatically decreased the rate of postoperative fatalities. He also developed absorbable ligatures and the drainage tube; both represent significant advances for surgical management of wounds and incisions.

Lister was indirectly responsible for the introduction of the first ready-to-use surgical dressings in 1886. Robert Wood Johnson heard an address in 1876 by James Lister; as a result, he developed sterile dressings wrapped in individual packages suitable for immediate use without the risk of contamination.

Although the value of Lister's contributions was not recognized by his senior colleagues, they were quickly adopted by William Stewart Halsted,[6] the first professor of surgery at The Johns Hopkins Hospital. Halsted introduced the meticulous techniques of tissue handling during surgery and the antiseptic methods proposed by Lister to the United States. Halsted, who had a major interest in cancer, was strongly supported in his work by his close friend and colleague at Hopkins, Sir William Osler. Osler was a student of abdominal malignancies, and the collaboration of these two great American physicians represents one of the earliest occurrences of the multidisciplinary approach to cancer treatment.

SURGICAL ONCOLOGIST

Surgical oncology has emerged to play an increasingly important role in the treatment of cancer (Table 28-1). There are many reasons for this evolution of subspecialization within general surgery, but the most significant are: (1) the increasing complexity of multidisciplinary cancer care; (2) the opportunities for clinical and laboratory investigation of cancer biology; (3) the rapid increase in the number of medical and radiation oncologists, which threatens to diminish significantly the traditional role of the surgeon in coordinating the management of cancer patients (even those with early disease); and (4) the expectation of patients that surgeons have the latest information and newest treatment options.[7]

Coordinates multidisciplinary clinical care teams

Researcher
Facilitates laboratory research
Coordinates epidemiologic studies
Conducts clinical trials research
Develops novel approaches to education

Teacher
Ensures excellence in surgical care
Leads a multidisciplinary team to implement integrated oncology training

Today, the surgical oncologist is really a "cancer physician" who interacts with all other members of the cancer therapy team in a knowledgeable and confident manner (Box 28-1). This role requires a sound knowledge of cancer biology (including cancer prevention and the biology of metastasis), imaging technologies, chemical and biologic therapy, and radiation therapy.

In a 1996 address before the American College of Surgeons, Murray Brennan of Memorial Sloan-Kettering Cancer Center in New York stated, "In defining what might be considered the role of the surgeon in cancer care, there are at least seven important areas that I believe need to have renewed emphasis."[8] Brennan used his experience with soft-tissue sarcoma to illustrate the importance of the following performance objectives for the cancer surgeon: (1) understands etiology and genetic predisposition; (2) understands prognostic factors and natural history; (3) performs cost-effective treatment; (4) develops clinical trials; (5) guides advanced disease management; (6) guides compassionate support; and (7) evaluates outcome. Brennan's analysis of the cancer surgeon's role as a member of today's therapy team is an excellent real-life description of the responsibilities involved and the opportunities to provide real leadership in cancer care.

The surgical oncologist thus provides the leadership for cancer care, cancer research, and cancer teaching within the academic or hospital-based surgical community. This is an extremely important role, and it has become increasingly clear that programs that emphasize strong cancer leadership from surgical oncologists have developed solid research and clinical programs for patients seeking cancer treatment.

As part of the greater medical community, the surgical oncologist has the responsibility of introducing to the surgical community new information, new approaches to cancer diagnosis, and new approaches to therapy. The surgical oncologist is most often the one involved in the early stages of cancer diagnosis, an ideal position to provide significant institutional leadership in developing community interest in cancer prevention, including screening and early diagnosis.

In addition to local responsibilities, much ongoing work in national clinical trials depends heavily on surgical oncology leadership directed at establishing quality control of the surgical aspects of multidisciplinary protocols. Cancer surgeons have historically provided significant leadership in the conduct of clinical trials. Most noteworthy have been the National Surgical Adjuvant Breast and

Bowel Project (NSABP), initially under the direction of Bernard Fisher, and more recently, the American College of Surgeons Oncology Group (ACOSOG), originally led by Samuel Wells. Surgeons have also been active participants in several other cooperative groups. The success of these surgeon-sponsored clinical trials placed surgeons as significant contributors to the clinical trials agenda of these groups, and showed the importance of surgical involvement in designing clinical trials and maintaining control of the quality of surgery when it was part of the study. Standardizing and maintaining the quality of surgical intervention has proved especially important in evaluating studies of adjuvant therapy.

The surgical oncologist is an important member of the design team and is critical to providing education to participating surgeons about standards of care, technical guidelines for the operative procedure, and collection of data. The surgeon member of the team is also essential for reviewing the staging data submitted by participating surgeons as well as information provided by quality control reports. When surgery is part of the therapy being evaluated in a clinical trial, it must be performed in a uniform manner by surgeons specifically trained and competent to deliver the procedure in a quality manner.

Surgeons and Surgical Research

Surgeons have been somewhat notorious for the introduction of new surgical procedures and devices without evidence of a random assignment prospective evaluation. Perhaps it is the nature of what we do. We learn from the experience of repeated procedures, and from that experience comes new ideas we believe will improve patient outcomes. Though not wishing in any way to hinder this category of innovation, the surgical oncologist does find it necessary to hasten the introduction of evidence-based results in dealing with such new technologies to eradicate tumors, with lesser operative procedures (e.g., sentinel lymph nodes) and now with the various approaches to minimally invasive surgery.

Training in Surgical Oncology

Historically, training in surgical oncology occurred at the small number of large standalone cancer hospitals in the United States, primarily with the goal of preparing a select group of general surgeons to work as cancer specialists in university hospitals or at large medical centers.

During the 1970s there was more interest in developing the subspecialty of surgical oncology within academic surgery training programs and in obtaining board certification, as had been done for other oncologic subspecialties. This effort by several prominent cancer surgeons encountered considerable difficulties in the ensuing years, and surgical oncology has yet to achieve recognition as a board-certified subspecialty.

There are many reasons for this. First and foremost is that surgical cancer care in the community almost always falls to the general surgeon. Even in the university hospital setting, cancer surgery has not been the exclusive right of the surgical oncologist. The surgical oncologist, as a result, has always been viewed as somewhat redundant by general surgical colleagues. Furthermore, each of the boarded surgical subspecialties also deals with cancer treatment.

To address some of these issues, a conference was held at the National Cancer Institute (NCI) in 1979. It was the consensus of this conference that training in surgical oncology should involve a 2-year period after completion of a general surgery residency.[9] The committee charged a national organization, the Society of Surgical Oncology (SSO), with developing training guidelines and a review and approval process for identifying qualified training programs. Clearly, the hope of those involved was that expertise in surgical oncology could be increased in significant numbers and disseminated more broadly in the community practice arena, not just in academic centers. Further, it was hoped that the development of a number of university training programs would eventually lead to board certification. Guidelines established by the SSO in 2001 call for 12 months of training in the surgical management of cancer cases, with a minimum number of procedures established for specific anatomic categories. In addition to surgical cases, trainees must also gain experience in the other aspects of the multidisciplinary management of cancer. Nonsurgical experience is required in radiation oncology, surgical pathology, medical oncology, and supportive and rehabilitative care. Clinical research on human subjects is required, and participation in laboratory research is encouraged.[10] There are currently 14 approved surgical oncology fellowship programs.

The effort to enhance training in surgical oncology, broaden available training opportunities, and provide a measure of qualification or certification of competence has been supported and nurtured by the SSO, which was founded in 1940 as the James Ewing Society.[11] This society has become the leading academic oncologic society for surgeons around the world. In assuming this leadership role, the SSO has developed and disseminated optimal guidelines for the multidisciplinary care of patients with cancer, provided an important resource for continuing education through its annual meeting, initiated and supported a monthly journal (*The Annals of Surgical Oncology*), and actively stimulated cancer research.[12] The Society has willingly taken on the responsibility of evaluating and approving fellowship programs. It embraced the recommended guidelines proposed by the 1979 NCI Committee and, in 1982, approved the first three training sites.[13] In 1992, the World Federation of Surgical Oncology Societies was inaugurated and immediately worked to develop "standards of education, training, and practice" in surgical oncology.[14,15] These guidelines were published and are summarized in Table 28-2. It is through efforts of the SSO and the World Federation of Surgical Oncology Societies that excellent training opportunities now exist for a significant number of general surgery graduates. Standardization of the process of review and accreditation ensures that more well-qualified cancer surgeons will be available to serve as experts in cancer care within multidisciplinary teams. The SSO deserves much praise and credit for its untiring and expert leadership in the training of future surgical oncologists.

Although the SSO and other such organizations have taken on a leadership role in surgical oncology education, all surgical oncologists have an educational reponsibility and a role in teaching that should extend to their hospital staff, students, residents, fellows, colleagues, and the community. The surgical oncologist should have the capacity to develop effective training programs, laboratory research pro-

Table 28-2 Guidelines for Training of Surgical Oncologists in Europe

- Receive training to a high level of technical competence and attain the clinical skills needed to manage common and complex cancers.
- Receive training in the evolving understanding of tumor biology, mechanisms of spread of disease, and other oncologic principles.
- Understand the principles, scope, and limitations of different modalities of radiation therapy.
- Be conversant with the theoretical and practical applications of cytotoxic chemotherapy.
- Be prepared to study and evaluate evidence from clinical trials and thereby be in a position to propose new avenues of research and study, both in the clinical setting and in the laboratory.
- Be trained to be discriminating in the application of modern technology in the investigation and treatment of malignant disease.
- Be involved, as a member of a team, in each step of the decision-making process in planning the strategy for the patient's care.

Table 28-3 Common Predisposing Conditions and Associated Malignancies

Condition	Genes Tested	Associated Malignancy
Cryptorchid testis		Testicular
Chronic ulcerative colitis		Colon
Familial adenomatous polyposis	*APC*	Colon and rectum
Hereditary nonpolyposis colon cancer	*MSH2*	Colon and rectum
	MSH6	
	MLH1	
	PMS1	
	PMS2	
Family history of colon cancer		Colon and rectum
Multiple endocrine neoplasia Type 1	*MEN1*	Pancreatic islet cell, anterior pituitary
Multiple endocrine neoplasia Type 2	*RET* gene	Medullary cancer of the (types II and III) thyroid
Leukoplakia		Squamous
Family history of breast cancer	*BRCA1* and *BRCA2*	Breast and ovary
Family history of ovarian cancer	*BRCA1* and *BRCA2*	Ovary and breast

grams, treatment guidelines, clinical trials, and protocols. In addition, surgical oncologists must teach other surgeons and surgical residents how to incorporate oncology principles into their practice.

SURGEON'S ROLE IN CANCER MANAGEMENT

Prevention and Screening

The most effective weapons against cancer are prevention and early detection. Much of the debate about prevention has focused on the cost of delivering cancer prevention and screening services and the availability of enough adequately trained individuals to perform the appropriate screening test. Furthermore, the application of a screening test is a complex process (Table 28-3), and multiple layers of evaluation are needed to prove test efficacy. Clearly, a screening test must be applied at the right time and to the appropriate population to be effective. Moreover, the screening test itself is merely designed to identify a possible condition that needs further in-depth evaluation. For the surgeon, the effectiveness and cost of screening are directly related to the strategies used to address positive test results.

The level and quality of prevention and screening services may be increased through a greater consensus about goals for cancer prevention, better organization to provide these services more efficiently to large populations, and improvement of health education. Social problems like unemployment, poverty, and limited medical coverage for a large number of people have significantly influenced access to services, and in the poor regions of the world, screening is not even something to be considered. The agenda for the future in cancer prevention should include fundamental research, intervention research, program delivery, patient access through free choice, and surveillance and monitoring.[16,17]

Certain conditions, often congenital or inherited genetic traits, are associated with the subsequent manifestation of cancer. Genetic testing has made it possible to accurately identify the carriers of mutations that increase the risk of the occurrence of certain cancers. Genetic tests available include that for the *RET* proto-oncogene present in multiple endocrine neoplasia type 2 (MEN-2), for the *CDH1* mutation in hereditary diffuse gastric cancer, the *APC* gene in colorectal cancer, and the *BRCA1* and *BRCA2* mutations in breast and ovarian cancers. In patients in whom these syndromes are known to be present by occurrence or genetic testing, and in whom cancers are likely to occur in nonvital organs, it may become necessary to remove the organ to prevent possible malignancy. In these instances, the surgeon has a responsibility to inform and educate the patient about the condition and to alert the family to the hereditary nature of the disorder and its possible occurrence in other family members. The surgeon should also discuss the availability of genetic testing for family members at risk. Table 28-4 outlines some common predis-

Table 28-4 Ten Criteria for Cancer Screening Programs

1. Is the disease an important health problem?
   Probably yes
2. Is there effective therapy for patients with localized disease?
   Probably yes
3. Are treatment facilities for further diagnosis and treatment readily available?
   Probably yes
4. Is there an identifiable latent period or early symptomatic stage of the disease?
   Probably yes
5. Is there an effective screening technique?
   Probably yes
6. Are the tests acceptable to the screened population, particularly groups at increased risk for disease?
   Probably yes
7. Is the natural history of the disease, from its development to clinical manifestation, sufficiently known?
   Probably yes
8. Is there a generally acceptable strategy to identify patients who should receive treatment versus careful observation alone?
   Probably yes
9. Are the costs of screening acceptable?
   Probably yes
10. Does the treatment of early-stage disease have a favorable effect on prognosis?
    Probably yes

Adapted from Littrup PJ: Prostate cancer screening: Appropriate choices? Cancer 1994;74(Suppl):2016. © 1994 American Cancer Society, with permission.

posing conditions, genes associated with these conditions, and their corresponding malignancies.

As an example, 2% of adult women have a family history pattern that is associated with the *BRCA1* or *BRCA2* genes. For these women, the U.S. Preventive Services Task Force recommends referrals for genetic counseling and evaluation for *BRCA* testing.[18] The lifetime risk of developing breast cancer is 35% to 85 % for women with *BRCA* mutations as compared with a lifetime risk of 13.2% in the general population. The numbers for ovarian cancer are 10% to 50% vs. 1.7%. Prophylactic oophorectomy has been shown to reduce the ovarian cancer and breast cancer risk among such women by 83% and 70%, respectively.[19] Prophylactic mastectomy alone has been shown to reduce the breast cancer risk by 90% and in combination with oopherectomy, by 95%.[20] These are a number of options available for the patient, each with its own benefits and drawbacks. The surgeon plays a large role in informing the decisions of women at risk. The lethality of the disease, the risk of cancer, the efficacy of the screening tool, and the availability of effective surveillance options such as mammography in breast cancer, should all be considered in reaching a decision about prophylactic surgery. Even in the absence of an available genetic test, the same analysis can be applied to other high-risk patients.

Cryptorchidism is associated with a higher incidence of testicular cancer, which is often prevented by early prophylactic surgery. Patients with ulcerative colitis (with total and partial colonic involvement) are likely to have cancer of the colon if resection is not performed. The patient and surgeon must carefully balance the benefits and hazards of surgery with an understanding of the factors involved in determining increased risk (see Chapter 26).

Diagnosis

Evaluation for surgical cure should be based on a histologically confirmed diagnosis of a treatable cancer confined to local or regional tissues. The diagnosis of cancer cannot be proven without a biopsy, and biopsy should be repeated if the diagnosis is questionable. There have been remarkable advances in imaging technologies to improve the execution and outcome of selected biopsy procedures. Computed tomography (CT), ultrasonography, and magnetic resonance imaging are now frequently used to enhance needle guidance and placement. These techniques improve the accuracy and safety of needle placement along the target path, while avoiding injury to other structures. The use of three-dimensional stereotactic CT-guided biopsy is becoming increasingly widespread as a diagnostic tool. Stereotactic biopsy is appropriate for any lesion located in the brain stem, pons, or medulla.[21] This technology is also widely used to evaluate nonpalpable mammographically detected breast abnormalities. The use of these guidance techniques requires the surgeon to be familiar with the device and the approach.

Four techniques are currently in use for obtaining tissue for diagnosis:

1. Needle aspiration biopsy. This approach involves aspirating tissue fragments through a needle guided into an area in which disease is suspected. It can usually be performed using local anesthesia or, possibly, no anesthesia. Sampling can be guided by various imaging modalities, including CT and ultrasound. A study of the usefulness of CT-guided fine-needle aspiration in the diagnosis of malignancy in small pulmonary lesions showed 82% sensitivity, 100% specificity, and 88% accuracy.[22] The disadvantage of aspiration biopsy is that it seldom yields a sufficient specimen for histologic diagnosis. As a result, there is always a margin of error in individual cell analysis, even with an exceptionally skilled cytopathologist. Cytology has the disadvantage of being unable to distinguish between invasive and noninvasive cancers, so a more detailed histologic diagnosis is usually necessary.
2. Needle (core) biopsy. This technique entails the retrieval of a small core of tissue, using a specially designed "core-cutting" needle. This specimen is usually sufficient for histologic diagnosis of most tumor types. Like aspiration biopsy, this technique is relatively cost-effective and can usually be performed using a local anesthetic.
3. Incisional biopsy. This technique involves surgical retrieval of a small segment of a larger tumor for diagnosis. The advantage of the procedure is that it yields enough histologic material to provide analysis of tumor markers. It is also often possible to perform this procedure in an outpatient setting using local anesthesia. Incisional biopsies are particularly useful in the diagnosis of sarcomas, large tumors, and unresectable tumors, and when the preferred treatment is nonsurgical. The disadvantages of incisional biopsy include possible sampling errors, the risk of trauma to the tumor, the possible risk of tumor spread, and the need for excisional biopsy if no cancer is diagnosed. Precise technique is essential.
4. Excisional biopsy. This technique is total removal of all suspicious tumor tissue, with little or no margin. The circumstances of the procedure dictate the use of local or general anesthesia. This procedure is the most definitive diagnostic tool of the four described. It provides adequate treatment for nonmalignant tumors and involves minimal trauma to the cancer. It is necessary to perform excisional biopsy if the results of incisional biopsy or core needle biopsy are inconclusive. One of the disadvantages is that it is generally limited to small tumors (e.g., lymph nodes, parotid tumors). It also involves a deeper area of dissection, which necessitates wider margins.

The proper placement of a biopsy incision is vital. Misplacement can compromise subsequent surgical procedures, because the definitive operation will include excision of the surgical tract of the prior incisional or excisional biopsy. The evidence concerning tumor spread from incisional and excisional biopsy is inconclusive. However, the surgeon should take extreme care to avoid using contaminated instruments on new tissue planes and to secure proper hemostasis of biopsy sites to avoid the spread of tumor along tissue planes.

The biopsy technique selected should be appropriate for the suspected lesion and should yield an adequate tissue sample for proper histologic diagnosis. Orientation of the specimen, if applicable, should be marked clearly and carefully by the surgeon to facilitate proper histologic interpretation. Proper handling of excised tissue is the surgeon's responsibility and the surgeon must be knowledgeable regarding procedures required to provide optimal specimens for tissue banking. Although such banking procedures thus far have been ad hoc, the NCI has in place a set of First-Generation Guidelines for the biorepositories that it supports.[23] It is NCI's plan that to qualify for grant support, investigations must use tissue samples from NCI-accredited facilities.[24] Therefore, the surgeon is well advised to be familiar with these guidelines.

In addition to knowledge of such guidelines, it is also important for the surgeon to maintain a close relationship with the pathologist. They are able to provide guidance before staging procedures with regard to tissue requirements. Furthermore, if the patient has a pathologic diagnosis from an outside source, it is always necessary to have the diagnosis confirmed. It may even be necessary to obtain tissue blocks to prepare more slides, to perform more extensive cytologic marker studies, and occasionally, to perform additional biopsies to obtain a definitive diagnosis.

Staging

Staging is the classification of the anatomic extent of cancer in an individual. Specific stage groups categorize cancers of particular anatomic sites. Staging is essential in the treatment process and requires an understanding of the biology of cancer as well as the extent of disease. The tumor-node-metastasis (TNM) classification, detailed in Table 28-5, is the global standard in cancer staging.

Table 28-5 TNM Classification System

TNM SYSTEM

Describes the anatomic extent of disease based on assessment of three components

T	Primary tumor size and extent
N	Regional lymph node involvement
M	Distant metastasis absent or present

Primary tumor (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1, T2	Increasing size or local extension
T3, T4	Increasing extent of primary tumor

Regional lymph nodes (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1, N2, N3	Increasing involvement of regional lymph nodes

Distant metastasis (M)

MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis (may be further specified according to site of occurrence)

HISTOPATHOLOGY

Qualitative assessment of category of tissue or cell type based on appearance

Histopathology grade (G)

GX	Grade cannot be assessed
G1	Well differentiated
G2	Moderately well differentiated
G3	Poorly differentiated
G4	Undifferentiated

ADDITIONAL DESCRIPTIONS

cTNM (or TNM)	Clinical, increasing size or local extension
pTNM	Pathologic
rTNM	Recurrence of tumor after disease-free interval
aTNM	First determined at autopsy

STAGE GROUPING

0	Tis, N0, M0
I	T1, N0, M0
IIA	T0, N0, M0
	T1, N1, M0
	T2, N0, M0
IIB	T2, N1, M0
	T3, N0

From Rodary C, Flamont F, Donaldson SS: An attempt to use a common staging system in rhabdomyosarcoma: a report of an international workshop initiated by the International Society of Pediatric Oncology (SIOP). Med Pediatr Oncol 1989;17:210.

Over the past decade, there has been a move to using minimally invasive techniques for the staging of a tumor. For instance, although staging for pancreatic cancer has been traditionally done by CT, peritoneal spread of the disease is difficult to interpret by this method. A minimally invasive laparoscopy allows for such a determination and can help detect inoperable candidates.[25] One center's negative exploration rate was reduced from 65% to 24% after the introduction of staging laparoscopy in the treatment protocol.[25] In breast cancer, routine axillary dissection has been replaced by sentinel lymph node biopsy as the standard of care.[26] In validation studies for the procedure, accuracy rates ranged from 95% to 100%, yet carried significantly less morbidity than axillary dissection. Only patients with positive sentinel lymph nodes currently undergo the more extensive procedure. Sentinel lymph node biopsy is also now routinely used in the staging of melanoma and shows promise as a procedure in colorectal cancer.[27,28]

Recently, the role of molecular characterization of sampled lymph node tissue has been shown to demonstrate evidence of tumor when standard cytology and histology cannot. The importance of such findings remains to be demonstrated and certainly will vary depending on the tumor. Increasingly however, molecular characterization will determine therapy.[29]

Multidisciplinary Management

Although the management of cancer formerly involved surgery alone, most solid tumors, even very early cancers, are treated by more than one modality. This multidisciplinary approach to treatment requires the input and coordination of multiple specialists. To complicate matters even further, often more than one therapeutic option exists. This requires the specialists involved to agree on the treatment regimen to be followed.

Although the advances in multimodal therapy have changed the role of the surgeon in the diagnosis and treatment of cancer, the surgeon continues to be the primary care provider for most patients with cancer and frequently coordinates care with other oncology specialists including radiation and medical oncologists. Like the surgeon, the radiation oncologist provides an important modality of local and regional cancer therapy. Often, radiation therapy is used after surgery to improve local disease control rates, or even before surgery, to reduce tumor bulk or downstage the tumor. It is also increasingly common for radiation to be combined with simultaneous administration of chemotherapy or radiation sensitizer agents. The medical oncologist's responsibilities include administering and monitoring the patient's chemotherapy, hormone therapy, and in some instances, biologic therapy. Medical oncologists manage the toxicities of intravenous and oral anticancer therapy, and as a result, provide considerable supportive care, especially as new agents have been developed to better control nausea and fatigue.

It is important and beneficial to the patient that these various caregivers work in a coordinated and collaborative effort toward the optimum outcome. There is evidence that the multidisciplinary approach to cancer management leads to increased survival. A study in the United Kingdom examining standards of care in head and neck cancer[30] showed increases in 2-year survival for patients assessed in a multidisciplinary clinic. An earlier study also confirmed the benefits of multimodal management.[31] Patients with skeletal and soft-tissue sarcomas of the extremity were treated with preoperative intra-arterial doxorubicin and radiation therapy, radical surgical resection, and postoperative chemotherapy or chemoimmunotherapy, resulting in the preservation of a functional extremity in 13 of 14 patients. Seven of eight patients with stage IIIA and IIIB soft-tissue sarcomas that were managed with preoperative intra-arterial doxorubicin and radiation therapy followed by en bloc soft-tissue resection and six patients with bone sarcomas that were managed with preoperative treatment followed by bone resection and replacement with cadaver bone allografts remained free of disease for 4 to 34 months. The results of the combined-modality approach were significantly better than those obtained in patients managed with surgical resection alone or with a combination of surgery and another single modality, in terms of both short-term recurrence-free survival and salvage of a functional extremity.[31]

The surgical oncologist not only is involved with medical oncologists and radiation oncologists in developing the treatment plan but is also responsible for recognizing the need for input from other surgical cancer specialists in other surgical specialties (thoracic, urologic, plastic, head and neck, gynecologic, and orthopedic surgery) or the appropriateness of referring a patient to a clinical trial. Participation in clinical trials has been shown to be of enormous benefit

Table 28-6 American Society of Anesthesiologists Physical Status Classification

Class	Description
I	Healthy patient
II	Mild systemic disease, no functional limitation
III	Severe systemic disease, definite functional limitation
IV	Severe systemic disease that is a constant threat to life
V	Moribund patient unlikely to survive 24 hours with or without operation

From Miller RD: Principles and Practice of Anesthesia, 2nd ed. New York, Churchill Livingstone, 1986, with permission.

to patients. One study in patients with sarcoma noted that longer survival was associated with clinical trial participation in all age groups studied.[32] Although the clinical trials may lack a surgical component, the surgical oncologist can help to provide this benefit by keeping abreast of trials and enrolling eligible participants.

Advancing the development of multidisciplinary cancer care is a growing trend toward freestanding cancer care centers. The critical components of these centers are multidisciplinary cancer care, direct care and support services, a commitment to clinical trials, and a comprehensive program for quality assurance.[33] Comprehensive cancer centers affiliated with academic medical centers have an array of clinically focused investigations, including programs designed to test new therapies and research programs investigating the biology of cancer. These academic comprehensive cancer centers, some 61 supported in part by grants from the NCI, attract the elite of cancer clinician-scientists and basic scientists. As a result, patients receive better cancer care and greater support from experienced ancillary services. This translates into better quality of life as well as a longer life and greater hope for cure.

SURGICAL TREATMENT OF CANCER

Surgical Risk

Assessment of surgical risk is based on several factors. The physical status of the oncologic patient and the debilities that often accompany the disease process present specific challenges to the surgical team. Patients should undergo a complete evaluation before surgery, and any history of cardiac, pulmonary, hepatic, or renal disease should be documented. Emphasis should be placed on physiologic function rather than chronologic age. A study conducted at the Mayo Clinic in 1989 showed that patients 90 years of age and older tolerated the stress of a surgical procedure fairly well.[34] The physical status of the patients in the study was assessed using the American Society of Anesthesiologists Physical Status Classification (Table 28-6).

The performance scales most widely used by oncologic specialists are the Eastern Cooperative Oncology Group Performance Scale (ECOG-PS) and the Karnofsky Performance Status (KPS) rating. These performance scales are also useful to surgeons and anesthesiologists in determining operative risk. A comparison of the ECOG-PS and KPS ratings showed both methods to be valid prognostic indicators of functional status, but the ECOG-PS seemed slightly superior. If necessary, each can be converted to the other with sufficient accuracy.[35] These two classifications are outlined in Table 28-7.

Mortality caused by anesthetic complications is most often related to the physical status of the patient. Highly sophisticated techniques of anesthesia have increased the safety of major oncologic procedures, and many of these advances have their basis in modern cardiac surgery and in transplantation, especially liver transplantation. The choice of anesthetic technique and agent should be appropriate for both the procedure and the patient. For example, surgery in the lower abdominal area, lower extremities, or pelvis may be performed with general or spinal anesthesia, depending on the patient's health status. The risk to the patient who has evidence of congestive heart failure would probably be increased by the use of general anesthesia as opposed to spinal anesthesia. However, patients with a history of ischemic heart disease may become agitated during a surgical procedure in which they are awake, thereby causing myocardial stress. The surgeon should work closely with the anesthesiologist to ensure proper selection of anesthetic application. Epidural-assisted general anesthesia is frequently used for abdominal surgery and provides an opportunity for improved pain management during postsurgical recovery.[36]

The oncologic patient is a particularly challenging surgical candidate. Operative mortality is usually defined as mortality that occurs within 30 days of a major operative procedure. The operative mortality statistics for oncologic patients can be deceptive. For example, patients who undergo a palliative procedure have a very high operative mortality rate, even if the surgery is successful. The cancer surgeon is ultimately responsible for ensuring that surgical intervention is safely undertaken, with an awareness of the possible risks and complications.

Surgery for Primary Cancer

At times, the cancer surgeon alone will be responsible for patient outcome, whereas at other times a combination of therapeutic modalities may enhance the prospect of cure or quality of life. Surgery should always be extended or restricted with these considerations in mind. The cancer surgeon must think first as an oncologist and attempt to envision the entire course of a particular disease and its treatment. The ultimate approach for the patient is multispecialty consultation that develops a consensus-based optimized course of therapy in the context of available clinical trials (the tumor board concept).[37] If surgery is indeed the best treatment option, then the surgeon may act on that conclusion.[38]

Table 28-7 Eastern Cooperative Oncology Group Performance Scale and Corresponding Karnofsky Rating

ECOG-PS Grade	Description	Karnofsky Rating
0	Fully active, able to carry on all predisease activities without restriction	100
1	Restricted in physically strenuous activity, but ambulatory and able to carry out work of a light or sedentary nature (e.g., light housework, office work)	80–90
2	Ambulatory and capable of all self-care, but unable to carry out any work activities; up and about more than 50% of waking hours	60–70
3	Capable of only limited self-care; confined to bed or chair 50% or more of waking hours	40–50
4	Completely disabled; cannot carry on any self-care; totally confined to bed or chair	≤30

ECOG-PS, Eastern Cooperative Oncology Group performance scale.

Table 28-8 Adequate Margins of Resection

A complete margin of normal tissue around the primary lesion
Frozen sections used to evaluate tissue margins in instances of doubt
Complete removal of involved regional lymph nodes
Resection of involved adjacent organ
En bloc resection of biopsy tracts and tumor sinuses

Appropriate treatment of primary cancer varies with the individual cancer type and the area involved. The cardinal principle of surgical cure is total removal of neoplastic tissue. This involves avoiding implantation of loose tumor cells; minimizing iatrogenic, lymphatic, and vascular dissemination of cancer cells; and obtaining a complete margin of normal tissue around the primary tumor (Table 28-8).

As is the case for staging, minimally invasive procedures have been adopted for the treatment of several malignancies. The main benefits of laparoscopic procedures are a reduction in perioperative trauma, shorter hospital stays, and more rapid recovery. Laparoscopic procedures have been shown to be as effective as open surgery in cancers of the pancreas (lesions left of the portal vein), esophagus, liver, gynecologic malignancies, and colorectal cancer, among others.[39–42] The last has been the subject of debate, due to reports of port site metastases when the procedure was initially introduced.[42] However, later studies reported no increase in recurrence rates for laparoscopic procedures as opposed to open procedures.[43]

Laparoscopic procedures have been enhanced by the use of surgical robots that allow for three-dimensional viewing and greater control over the manipulation of surgical instruments. Robotic surgery has been utilized to enhance laparoscopic procedures in a variety of cancers.[42,44] The advantages afforded by robotic assistance in laparoscopic surgery have not generally been achieved in open procedures. However, there has been success in utilizing robotic assistance in prostatectomy.[42]

Surgical treatment is often combined with other modalities to improve outcome. To coordinate the appropriate care of the patient, the surgeon must fully understand the indications, risks, and benefits of using systemic and radiologic therapy, especially when the benefits of such modalities have been adequately studied in prospective clinical trials.

Surgery for Metastases

In many cases, patients in whom a single site of metastatic disease has been detected can undergo resection with a reasonable rate of success. Many patients with a limited number of metastases to sites such as the liver, brain, or lung can be cured by surgical resection. For example, published experience indicates that resection of colorectal metastases to the liver should be performed when: (1) the number of liver tumors is fewer than four, (2) extrahepatic tumor is not demonstrable, and (3) a tumor-free margin of at least 10 mm can be obtained. The 5-year survival rate is 30% to 40% when all of these criteria are met.[45] The current management of metastatic colorectal cancer is a good example of a more aggressive approach to recurrent disease where ablative procedures added to metastectomy have greatly extended the options (see Chapter 81). Resection of pulmonary metastases in patients with soft-tissue and bony sarcomas can cure as many as 30% of patients. The surgeon must consider several elements before undertaking surgery for metastatic disease. These include tumor histology; disease-free interval; tumor-doubling time; and the location, size, and extent of disease.

Surgery for Debulking

The results of experimental studies suggest that cytoreduction, or debulking of recurrent cancer, has important potential benefits. In the laboratory setting, reduction of the tumor increases the sensitivity of the remaining tumor to chemotherapy and radiation therapy by increasing the proportion of proliferating tumor cells, decreasing the number of therapeutic cycles necessary to eradicate the tumor, increasing cellular distribution of oxygen and nutrient within the tumor, and reducing the likelihood that resistant clones will develop.[46]

Evidence of human clinical benefit seems to be more limited. The benefits of cytoreduction are most dramatic when accompanied by effective chemotherapy or radiation; therefore, the value of cytoreduction has been acknowledged in pediatric solid tumors, lymphoma, and carcinoma of the ovary. Widespread application of cytoreduction, either alone or combined with other treatment modalities, lacks firm clinical support for common carcinomas.

Radiofrequency ablation (RFA) has also been used to some effect for debulking in patients with liver metastases, meeting selection criteria, of primary colorectal, breast and neuroendocrine tumors. Patients treated with RFA had longer median survival times than patients undergoing chemotherapy for the metastases.[47] Among primary tumors the use of RFA appears promising in hepatocellular carcinoma, renal cell carcinoma, and pulmonary neoplasia.[47]

Palliative Surgery

Palliative surgery is undertaken to relieve symptoms in the absence of cure. It is specifically designed to improve quality of life and must be undertaken with this in mind. Examples of palliative surgery include relief of intestinal obstruction, removal of tumors to control pain or hemorrhage, and introduction of a feeding jejunostomy to permit adequate nutrition.

Reconstructive and Rehabilitative Surgery

Quality of life is an important consideration in the care of the patient with cancer. The cancer surgeon has the unique responsibility to attend to the patient's cosmetic as well as curative surgical needs. Breast reconstruction after mastectomy, transfer of tissue after head and neck surgery, and lysis of contractures or muscle transposition to restore muscular function after radiation therapy are examples of techniques that offer the patient with cancer a higher degree of comfort and improved quality of life. Today, it is essential that the reconstructive surgeon be involved with the multispeciality team in planning the course of treatment so as to optimize reconstructive outcomes.

Vascular Access

Placement of short-term and long-term indwelling central venous catheters has become a common surgical procedure performed on cancer patients. These catheters provide venous access for chemotherapeutic infusion and withdrawal of blood. Several important developments in implantation technique and catheter design have decreased operative time and rendered this an almost exclusively outpatient procedure (see Chapter 52).

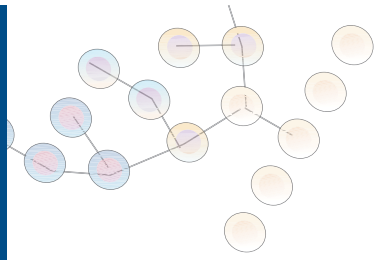
Surgery for Oncologic Emergencies

The patient with cancer presents a unique surgical risk. These patients are often neutropenic and thrombocytopenic, and have a high risk of hemorrhage and sepsis. The most common emergencies involve hemorrhage, perforation, intestinal obstruction, infection, or vital organ failure (see Chapter 53). When presented with an oncologic surgical emergency, the cancer surgeon must carefully assess the situation.

FUTURE DIRECTIONS

As evidenced throughout the preceding discussion, the role of the surgeon in the management of cancer, and therefore that of the

surgical oncologist, has continued to evolve and grow. Advances in cancer management demand an increasing supply of surgical oncology specialists who can fulfill a wide variety of functions in the rapidly changing environment of cancer care. The scope of these advances requires knowledge across several disciplines and an increased understanding of basic science, especially as it relates to the molecular and cellular processes of cancer development and metastases, and genetics. The completion of the Human Genome Project marked the start of a new era of molecular medicine. Already there are cancers that have been characterized by specific genetic defects, and patients characterized in terms of response to treatment by specific genetic variations. Such knowledge is being used to design highly specific and individual therapy. Greater understanding of the tumor microenvironment as well as the role that tumor stem cells might play in the initiation, metastasis, and recurrence of cancer has the potential to transform the treatment landscape even further.



For the cancer surgeon there will be a greater requirement to work in a multidisciplinary fashion in patient care. The cancer surgeon will need to play an increasing role in risk assessment, management of genetic screening, and cancer prevention. As a result, cancer surgeons must be well trained in the fundamentals of cancer biology, pharmacogenetics, and genetics. The cancer surgeon must possess experience and skills in the design and management of clinical trials, monitoring of adverse events, and statistical evaluation of endpoints. The types of cancer operations and the scope of surgical resection may also change as molecular techniques enhance oncologic treatment.[48]

The French philosopher Albert Camus said, "Real generosity toward the future lies in giving all to the present." Care of the patient with cancer is a complex process that requires devotion to the principle that each patient must be provided with the best treatment possible. Surgical oncology is a specialized core body of knowledge that is used to evaluate the best treatment and management options for each patient. The surgical oncologist attends to the future by providing leadership in education and research and forming meaningful partnerships with other oncologic disciplines to continue to provide the best possible patient care.

29 Basics of Radiation Therapy

Ricky A. Sharma, Katherine A. Vallis, and W. Gillies McKenna

SUMMARY OF KEY POINTS

Historical Perspective
- X-rays were discovered by Wilhelm Conrad Roentgen in 1895.
- Radioactivity was discovered and named by Henri Becquerel, Marie Curie, and Pierre Curie.
- Over the past 3 decades, major advances have been made in conformal external beam radiation therapy, brachytherapy, stereotactic irradiation, proton therapy, systemic targeted radionuclide therapy, and chemoradiation treatments.

Radiation Oncology Physics
- Several different types of ionizing radiation are used to treat patients; most cause low linear energy transfer (LET).
- Therapeutic x-rays (photons) and γ-rays are produced by linear accelerators or by radioactive decay.
- Radiation interacts with matter via several processes, of which the most important in clinical radiation therapy is Compton scatter.
- Megavoltage photons from linear accelerators have a skin-sparing effect, with the maximum dose deposited at depth.

Biological Effects of Radiation
- Direct and indirect damage to DNA in cells, particularly double-strand breaks, is believed to be the dominant form of radiation-induced cell kill.
- Irradiation causes diverse cellular responses that induce molecular mechanisms for DNA damage repair, cell cycle arrest, and cell death.
- The most commonly applied model of cell survival probability is the linear quadratic model, which uses α/β ratios to describe the surviving fractions.
- Cells may repair sublethal and potentially lethal damage after exposure to radiation.
- The radiosensitivity of cells changes as they progress through different stages of the cell cycle; cells are most radiosensitive in G2 and M phases.
- The response of cells to radiation is highly oxygen dependent, an effect expressed by the oxygen enhancement ratio (OER).
- Radiosensitizers, particularly systemic cytotoxic chemotherapy, aim to improve the therapeutic ratio by enhancement of tumor cell killing relative to normal tissues.

Clinical Application of Radiobiologic Principles
- Fractionation of radiation and altered fractionation schedules, such as accelerated hyperfractionated radiation therapy, make use of differences in the responses of normal and malignant tissues to irradiation in order to achieve higher therapeutic ratios.
- Radiation has varied effects on normal tissues, ranging from early effects such as skin erythema to late effects such as carcinogenesis.

Process in Radiation Treatment
- Process in treatment planning and quality control is essential to the safe and effective delivery of clinical radiation therapy.
- Three-dimensional conformal treatment planning and delivery has permitted escalation of dose and improved sparing of normal tissues.
- Radiation therapy is used in more than half of all patients with cancer, either as an adjuvant or neoadjuvant treatment in combination with surgery, as a definitive treatment alone or in combination with chemotherapy, as an organ-sparing therapy, or to palliate symptoms.

New Modalities in Radiation
- Brachytherapy delivers extremely high-dose radiation to tumor tissue with a much lower dose to surrounding normal tissues.
- Systemic targeted radionuclide therapy has been a significant advance in the treatment of hematologic malignancies and is being investigated for the treatment of solid cancers.
- Intensity-modulated radiation therapy (IMRT) uses multiple radiation beam intensities to try to improve the therapeutic ratio.
- Proton therapy has radiobiologic advantages over photon therapy, and it may be used to deliver high doses of radiation to tumors in close proximity to normal structures.

HISTORICAL PERSPECTIVE

In the closing years of the nineteenth century, many physicists were investigating the nature of electricity. It was known that if an electrical potential was placed across two separated platinum electrodes, a spark would leap between them. The British physicist William Crookes demonstrated that if the two electrodes were placed within a glass vessel that was then evacuated, as the vacuum increased the spark would at first be replaced by a glow that filled the whole vessel. As the vacuum was increased still further, a dark space would appear at the cathode electrode and would expand as the vacuum dropped until it filled the whole tube. The walls of the vessel would then begin to fluoresce. On November 8, 1895, while passing electricity through a high-vacuum Crookes tube, Wilhelm Conrad Roentgen noted the fluorescence of a nearby piece of paper painted with barium platinocyanide. Because he had wrapped the Crookes tube in heavy opaque

paper before beginning the experiment, he realized that this fluorescence of the paper could have been caused by a new, invisible type of ray that the tube was now emitting that was affecting both the shielded walls of the tube and the nearby piece of paper. Hence, the "x-ray" was discovered.[1]

Roentgen proceeded to study the intensity and the attenuation of x-rays. He proposed the inverse square law to describe the loss of intensity of the x-rays with the inverse square of the distance between the tube and the plate.[2] He also noted that he could see the shadow of the bones in his hand when it was placed between the Crookes tube and the fluorescent paper. This led to the first human x-ray film on December 22, 1895, when Roentgen placed his wife's hand between the x-ray tube and a photographic plate (Fig. 29-1).[2] Because the x-ray tube was a simple apparatus to replicate, many experiments using x-rays took place worldwide within a short time. This widespread experimentation resulted in rapid advances in the new field, particularly for diagnostic purposes in hospitals.

"Radioactivity" was discovered within a few years of the production of the first x-rays. As the Crookes tubes produced x-rays, the walls of the tube would fluoresce. Other substances were also known to fluoresce spontaneously, and it was thought that these substances might also produce x-rays. This possibility was investigated by Henri Becquerel,[3] who observed the darkening of photographic plates by uranium salts. From this phenomenon, he concluded that x-rays were emitted spontaneously and continuously from the salts. He reported the results of his experiments with uranium to Pierre and Marie Curie, who coined the term *radioactivity* to describe it. They set out to isolate in purer form the radioactive substances within uranium salts, and they reported the discovery of radium in 1898.[4]

The biologic effects of ionizing radiation were recognized very early. Unfortunately, scientists and other workers performing early radiation experiments experienced significant toxic effects. Initially, these side effects were primarily erythema of the skin from exposure to x-rays; the carcinogenic properties of x-rays became evident in later years. For example, Pierre Curie performed an experiment on himself in which he noted skin radiation changes and epilation after exposure to radium for only a few hours.[5] Reading of this, Alexander Graham Bell wrote to a colleague suggesting that if radium "sealed up in fine glass tube" were inserted "into the very heart" of a cancer, it might cause the tumor to regress.[6] Around this time, physicians at St. Louis Hospital in Paris began using radiation to treat patients with cancer. The first reported cure with radiation involved a patient with basal cell epithelioma in 1899.[7]

Figure 29-1 • First radiograph of his wife's hand, exposed by W.C. Roentgen on December 22, 1895.

Hope that further cures for cancer lay in radiation therapy was soon replaced by skepticism when recurrences and toxicities were noted. The early treatments often involved very large single exposures aimed at the complete eradication of tumors. These large exposures, together with the fact that the first x-ray machines were capable of producing only low-energy x-rays with poor tissue penetration, resulted in extensive skin toxicities and other complications. Therefore, only superficial sites were treated by the direct application of radium, with impressive results.[8] Eventually, physicians started to insert radium directly into deep-seated tumors, in the first forms of brachytherapy. Cervical cancer was treated using this method, with dramatic responses.[9] In fact, external beam radiation therapy might have been abandoned had it not been for the work of Claude Regaud and Henri Coutard, who used smaller doses of radiation in several treatments delivered over several weeks to overcome the acute toxicity induced by a large single fraction of radiation therapy.[10] Based on these pioneering studies, radiation oncology became a recognized medical field in 1922, when Coutard and Hautant reported that advanced laryngeal cancer could be cured without severe toxicities using fractionated treatments.[11] By 1934, Coutard had developed a fractionation scheme that remains the basis of radiation fractionation today.

In parallel with advances in the delivery of treatment, advances in measurements were achieved when the *skin erythema dose* (the dose of x-rays required to cause a light skin reaction) was replaced by a unit called the *roentgen* in 1928.[12] The roentgen, which was roughly the exposure received by placing 1 gram of radium at a distance of 1 yard for 1 hour, expressed the radiation exposure and allowed reproducible measurement and standardization of treatment dosages in different departments. It was calibrated by measurement of the ionization of air using ionization chambers. When higher-energy beams were developed, the size of the ionization chamber necessary to measure their effect became impossibly large, and the roentgen was replaced by a new unit, the *rad* (an abbreviation for *r*adiation *a*bsorbed *d*ose). The rad was a measure of the energy deposited per unit mass by all types of ionizing radiation. Biologic effects in tissue exposed to ionizing radiation depend on the energy deposited in the tissue rather than the amount of ionization that the radiation produces in air. One rad was defined as the deposition of 100 ergs per gram of absorbing material. As a general rule, the absorbed dose in soft tissue from 1 roentgen of intermediate-energy x-rays or gamma rays was roughly equivalent to 1 rad. With metric conversion to standard SI (Système International), the rad was replaced by the gray (Gy), a unit named after the British radiobiologist L.H. Gray. One gray is equal to 1 joule of energy absorbed per kilogram of mass. Energy absorbed is dependent on the material used; the material used for radiation therapy definitions is water. For materials with significantly higher atomic numbers than water (e.g., bone), the ratio of mass energy absorption coefficient depends on the energy of the radiation (see later section on Interactions of X-Rays with Matter). Clinical doses often are communicated as centiGray (cGy), equivalent to the older term 1 rad (i.e., 1 G = 100 rad = 1 joule/kg).

RADIATION ONCOLOGY PHYSICS

To understand the role of radiation therapy in curing and palliating disease, a full understanding of the particles and processes involved in the production and delivery of radiation is required. This section provides an introduction to the physical properties of radiation that are fundamental to the clinical applications of radiation.

Types of Radiation

Electromagnetic radiation is energy that is transmitted at the speed of light through oscillating electric or magnetic fields. A photon has wavelength λ, frequency ν, and energy $E = h\nu$, where h is Planck's constant (6.626×10^{-34} Joule seconds). The electromagnetic spec-

trum ranges from wavelengths of 10^5 m for AM radio waves to 10^{-12} m for x-rays and cosmic rays. Although electromagnetic radiation conventionally is described as waves, it also is valid to describe radiation in terms of photons ("packets of energy"). Because energy varies inversely with wavelength, x-rays have a much greater energy than do radio waves. This higher energy gives x-rays the property of being deeply penetrating, which makes it possible to use them therapeutically to treat internal tumors.

Clinical types of radiation therapy include teletherapy (e.g., treatment from a cobalt-60 source), external beam x-rays (from a linear accelerator), and brachytherapy (using a source of radiation inserted or implanted into the patient). X-rays and gamma rays differ only in terms of their production: gamma rays are produced within the nucleus from natural radioactive decay and x-rays are produced outside of the nucleus. In practice, x-rays are produced by machines such as linear accelerators (see the section on Radiation Production from Linear Accelerators) and gamma rays used in radiation therapy are produced by the decay of radioactive substances. There is no difference in their treatment effects. Radiation sources used in brachytherapy and systemic radionuclide therapy (see the section on Systemic Targeted Radionuclide Therapy) include radioactive nuclei that decay and emit positively charged alpha (α) particles, positively charged beta (β^+) particles, or negatively charged beta (β^-) particles (electrons), which may occur with emission of a gamma ray. Clinically, α and β particles do not penetrate deeply, so gamma rays and x-rays are used in external beam radiation therapy to deposit doses at depth.

X-rays, gamma rays, and electrons are termed *low linear energy transfer (LET) radiation* and must be distinguished from high LET radiation such as alpha particles or fast neutrons. LET is defined as energy transferred per unit track length of radiation, equivalent to how often a type of radiation causes ionizations in the tissue it is traveling through. The x-rays, gamma rays, and electrons commonly used in therapy are low-LET radiation, and are, therefore, sparsely ionizing, producing relatively few ionizations in the paths they travel through in the tissue. This is in contrast to high LET radiation such as neutrons (Fig. 29-2), discussed in more detail in the final section of this chapter.

Radiation Production

Radiation Production by Radioactive Decay

The nucleus contains protons and neutrons that usually have stable configurations. When these configurations are not stable, they undergo spontaneous disintegration to attempt to reach a more stable state. The disintegration of radioactive species is called *radioactive decay*. With these disintegrations, energy is released as a photon (gamma ray), which can be used for radiation therapy. The type of radioactive decay and type of particle emitted depend on the nuclear composition of the radioactive species.

The first radioactive species isolated by the Curies was polonium, with radium discovered shortly thereafter.[5] Since that time, many other radioactive species have been discovered and produced artificially. Today, the main use of radioactive species is in brachytherapy and systemic radionuclide therapy, although cobalt-60 units still are used for teletherapy. Radium was the most important implantation source used for more than 5 decades in the twentieth century. However, many properties of radium make it undesirable as a radioactive source for therapy. During its decay, radium produces radon gas, which is colorless and odorless but highly radioactive. Moreover, radium has a very long *half-life* (the time it takes for a radioactive substance to decay to half of its original strength). These qualities make it a significant hazard in the case of contamination. Hence, more suitable isotopes have replaced radium in clinical applications (Table 29-1). Cesium-137 is widely used for gynecologic brachytherapy implants. It has a lower-energy gamma ray than radium (i.e., it is less penetrating and easier to shield), and it has no gaseous daughter nuclei. Palladium-103, iridium-192, and iodine-125 are used for implantation in the body for brachytherapy treatments (see the section on New Modalities later in this chapter). Many of the isotopes used in brachytherapy emit low-energy gamma rays , resulting in a steep fall-off of dose for the surrounding normal tissues and posing no significant risk of radiation exposure for people in the patient's environment. Other isotopes such as strontium-90 or yttrium-90 emit β^- particles (electrons). The advantage of this type of radiation is that it deposits a dose very superficially, for example sparing the outer layers of the walls of arteries during intravascular brachytherapy.

Historically, cobalt-60 is a very important radioisotope because of its use in teletherapy. Cobalt machines were the first practical megavoltage machines, pioneered by the Canadian physicist H.E. Johns.[13] The radioactive decay of cobalt-60 releases gamma rays with energy of approximately 1.2 megavolts (MeV). Because the depth of penetration in tissue increases with increasing x-ray energy, this development allowed the delivery of higher doses of radiation therapy without having to limit the dose due to skin toxicity. This advance drove attempts to generate high-energy x-rays. For example, in the 1930s, St. Bartholomew's Hospital in London had a machine that produced

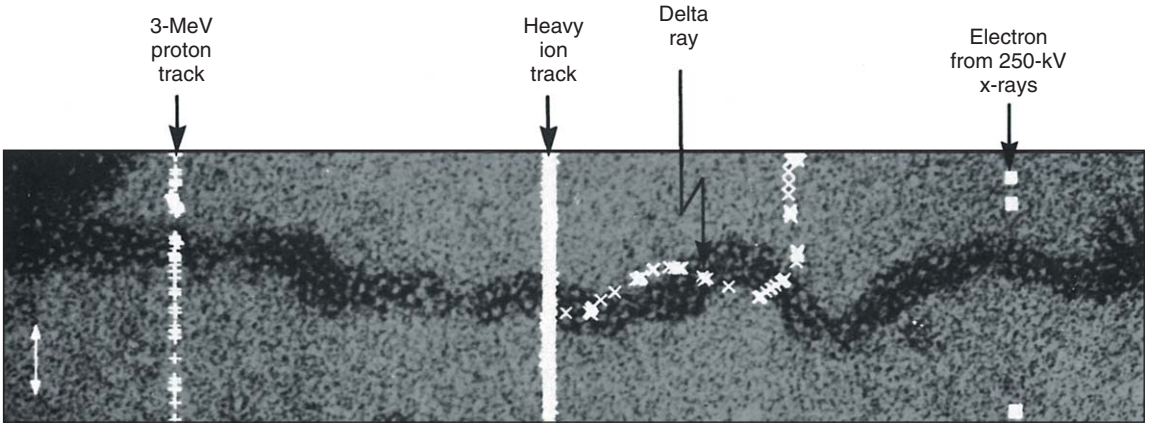

Figure 29-2 • Computer simulations of sections of charged-particle tracks produced by different types of radiation passing through a strand of chromatin. Each cross represents a single ionization of either the chromatin or the surrounding medium. *Right track*, low-linear-energy transfer (LET) 100 keV electron, typical of those produced by 250-kV x-rays. *Center track*, high-LET, high-energy iron ion that produces a dense column of ionization. Note the high-energy secondary delta ray coming out of the track. *Left track*, medium LET 3 MeV proton. The scale bar represents 50 nm. 1-MeV rays using an x-ray tube 30 feet long. These machines, however, had low output and small field sizes and were mechanically unreliable. Cobalt 60 machines were simple in design and highly reliable, so they revolutionized the practice of radiation therapy and were used for decades. Their skin-sparing effect made it possible, for the first time, to administer safely the doses of radiation required for treatment without the desquamating skin toxicity that had been the hallmark of kilovoltage radiation therapy. Over the past 3 decades, cobalt machines in the United States have been replaced largely by modern linear accelerators, which have the advantages of producing more sharply defined beams of a variety of different energies and the ability to deliver electrons or x-rays for therapeutic purposes. Linear accelerators also can be used with devices such as computer-controlled multileaf collimators, allowing dose delivery with much greater precision (see the section on Radiation Production from Linear Accelerators). Today, cobalt 60 is used primarily for palliative teletherapy or for stereotactic teletherapy to small malignant lesions in the brain and benign lesions such as acoustic neuromas or arteriovenous malformations. For *sterotactic radiation therapy* or *radiosurgery*, more than 200 narrow beams of gamma rays from a source such as cobalt 60 may be focused on one point, allowing tightly conformed doses of radiation therapy to be delivered as a single fraction or as multiple fractions. Alternatively, a linear accelerator may be used for x-ray production. The treatment requires extremely accurate immobilization of the patient, usually with a head frame or special mask. Lesions must meet stringent criteria to be considered amenable for stereotactic radiation therapy.[14]

Radiation Production from Linear Accelerators

Two processes can produce x-rays when electrons are directed at target atoms. The electrons can ionize the atoms by depositing sufficient energy so that an inner shell electron is ejected. The vacancy in the inner shell is filled by an electron from an outer shell, with the release of a photon called a *characteristic x-ray*. An alternative way of producing x-rays involves the interaction of an electron with the electromagnetic field of a nucleus. This interaction decelerates the electron, with the conservation of energy leading to the production of "bremsstrahlung" (braking energy) x-rays.

Although some centers continue to deliver external beam radiation therapy to skin cancers using a vacuum tube producing x-rays with a maximum energy of about 300 keV, most centers use linear accelerators for general radiation therapy. Modern linear accelerators (Figs. 29-3 and 29-4) use microwaves (with a frequency of ~3000 MHz) to accelerate electrons to very high energies. These electrons strike a target (usually tungsten) to produce a beam of x-rays, mainly by bremsstrahlung effects. The x-ray beam is "flattened" with a filter, so that the beam is uniform, and shaped with the collimators so that the field size is appropriate.

Another type of radiation therapy produced by linear accelerators is the electron beam. To produce an electron beam with a linear accelerator, the electrons strike a thin scattering foil that spreads out the electron beam to an area large enough to be used for treatment. Electrons are used to treat areas of superficial depth, for example, as definitive treatment of skin cancer or as a boost to the tumor bed of breast cancer.

Interaction of X-rays with Matter

X-rays can interact with matter via several different processes. The probability of each interaction type depends on the composition of the matter and the energy of the x-rays. These interactions cause some photons (x-rays) to be removed from the forward-moving x-ray beam, causing an effect called *attenuation*, which, in basic terms, is the loss of intensity and subsequent decrease in the deposition of dose as the beam reaches greater depths. Five possible interactions of x-rays with matter include (1) coherent scattering; (2) the photoelectric effect; (3) Compton scatter; (4) pair production; and (5) photodisintegration. The interactions most relevant to radiation therapy are illustrated in Figure 29-5.

Coherent Scattering

Also called classic scattering, coherent scattering occurs to low-energy x-rays. In coherent scattering, a photon is scattered from an electron, with a resultant change in direction but no change in energy. Only a negligible amount of coherent scattering occurs in therapeutic and diagnostic irradiation. Coherent scattering is important in processes such as x-ray crystallography.

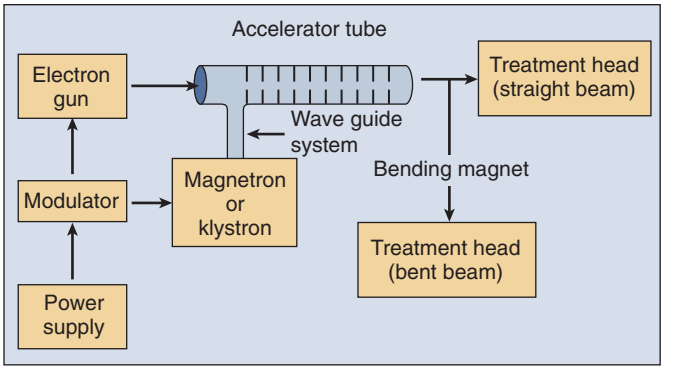

Figure 29-3 • Block diagram representing the mechanism of a typical medical linear accelerator. (From Leibel SA, Phillips TL [eds]: Textbook of Radiation Oncology. Philadelphia, WB Saunders, 1998, p 110.)

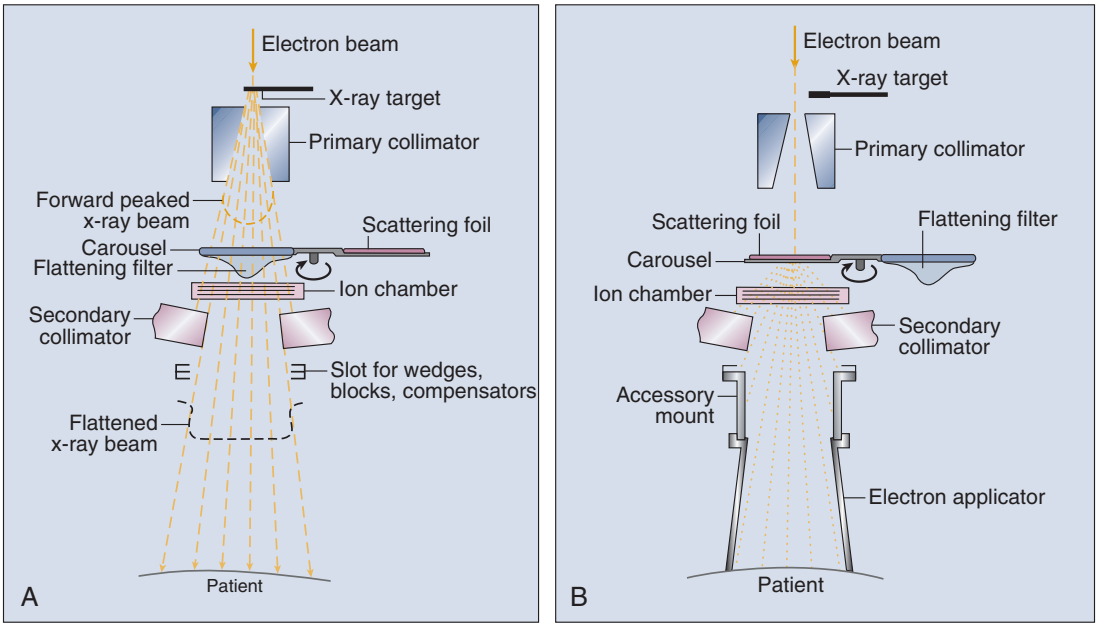

Figure 29-4 • Schematic diagram showing the basic components of the treatment head of a modern linear accelerator. **A,** Components in place for x-ray therapy. **B,** Components in place for electron therapy. (From Leibel SA, Phillips TL [eds]: Textbook of Radiation Oncology. Philadelphia, WB Saunders, 1998, p 100.)

Photoelectric Effect

The photoelectric effect first was described by Albert Einstein, and it was this contribution to physics that led to his Nobel Prize in 1921. In the photoelectric effect, a photon interacts with a tightly bound inner shell electron in the target tissue. Complete absorption of the photon's energy occurs, with the ejection of the electron from the orbit. The probability of a photoelectric interaction is highly dependent on the atomic number (Z) of the material through which the photon is passing. The photoelectric effect is very important in diagnostic radiology; it is the process that is the basis for the radiographic contrast between tissues (e.g., between bone and fat) in plain x-ray films and computed tomography (CT) scanning. With the exception of skin cancer treatment with superficial x-rays, the photoelectric effect is undesirable in radiation therapy. With higher energy x-rays delivered by linear accelerators, the contribution of the photoelectric effect is small to negligible.

Compton Scatter

Compton scatter is the most important interaction for energies within the range generally used for radiation therapy. In Compton scatter, a photon transfers energy to an electron of the target tissue, causing the ejection of this electron. In contrast to the photoelectric effect, however, the energy of the photon is not completely absorbed. Instead, it is scattered at an angle relative to the forward direction of the original photon. This secondary photon interacts with tissue again and again, ionizing and depositing dose with each interaction. These interactions and subsequent ionizations are responsible for the biologic effects on tissues during radiation therapy.

In contrast to the photoelectric effect, Compton interactions are less dependent on the atomic number (Z) of the tissue because these interactions tend to be with the loosely bound outer electrons in atoms, where the energy binding the electron to the atom is much less dependent on Z. This results in a fairly even probability of interaction (and, hence, a fairly even deposition of dose) throughout the different biologic tissues with which the x-rays interact in a patient.

Pair Production

Pair production occurs at high energies. It is the interaction of a photon with a nucleus, with the spontaneous disappearance of the photon and the production of an electron and a positron (a positively charged electron). Pair production becomes the predominant effect in biologic tissues at about 25 MeV. Because 25 MeV is above the range that is typically used in therapy, pair production plays only a small role in most cases.

Photodisintegration

At very high energies, x-rays can deposit so much dose into the nucleus of the target tissue that partial disintegration of the nucleus occurs, with emission of neutrons from the nucleus. Although this has little importance in the clinical interactions used in most radiation therapy, the production of neutrons is important when planning shielding around high-energy linear accelerators to protect patients and personnel from unnecessary exposure to radiation.

Deposition of Dose

As an x-ray beam passes through tissue, the region of rapidly increasing dose is known as the *build-up region*. This rapid increase occurs because of forward-moving photons interacting with electrons of the target tissue via the processes described previously. Because these electrons also are propelled forward but have a shorter course than the photons, there is an area at depth at which the number of electrons entering the plane of interaction from superficial interactions is exactly equal to the amount leaving the plane from interactions in that plane. This plane is termed the D_{max}, as it represents the depth of the maximum number of ionization events (Fig. 29-6). Beyond this point, as more interactions between the photon beam and tissue occur, fewer photons are available to travel forward and deposit dose at greater depths. This process is called *attenuation*. How a photon beam is attenuated (i.e., how much dose it deposits at depth) depends on qualities both within the beam and within the target tissue. The most substantial effect on

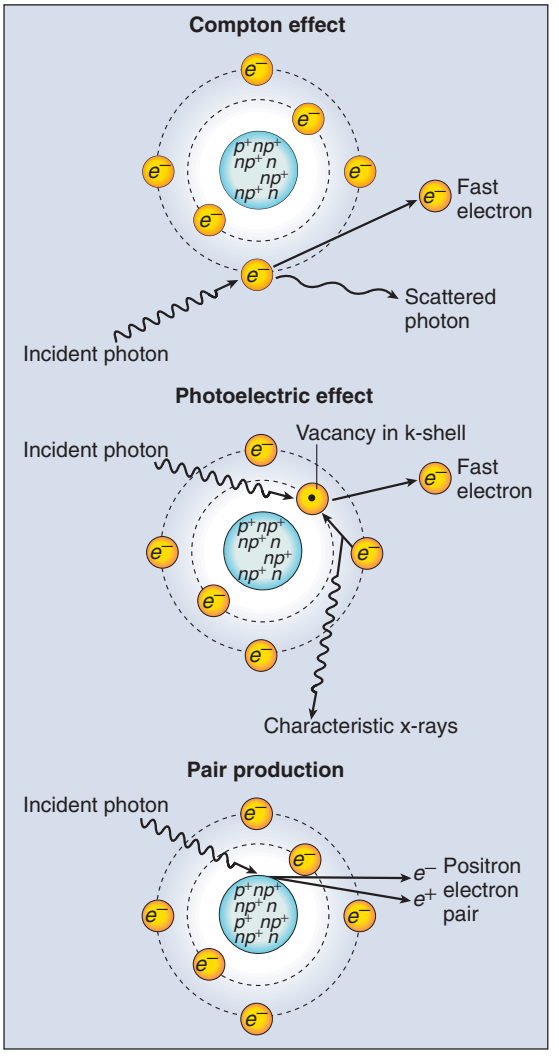

Figure 29-5 • The first step in the absorption of a photon of x-rays or gamma rays is the conversion of the energy of the photon into the kinetic energy of an electron or electron-positron pair. At higher energies, when the energy of the incident photon greatly exceeds the binding energy of the bound electrons in the atoms of the absorber, Compton scatter dominates. Part of the photon energy is given to the electron as kinetic energy, whereas the photon is deflected and has reduced energy.

At lower energies, when the binding energy of the bound electrons of the atoms of the absorber is not small compared to the photon energy, the photoelectric effect is most important. The photon disappears completely as it interacts with a bound electron. The electron is ejected with kinetic energy equal to the photon energy, less the energy required to overcome the electron bond. The vacancy caused by the removal of the electron must be filled by an electron dropping from an outer orbit, giving rise to a photon of characteristic radiation.

At sufficiently high photon energies, the photon might interact with the powerful nuclear forces to produce an electron-positron pair. The first 1.02 MeV of photon energy is used to create the rest mass of the pair, and the remainder is distributed equally between them as kinetic energy. (From Cox JD, Ang KK [eds]: Radiation Oncology: Rationale, Technique, Results, 8th ed. St. Louis, Mosby, 2003, p 5.)

depth dose from the photon beam itself is the beam's energy (Fig. 29-7).

Linear accelerators typically produce beam energies ranging from 4 to 18 MeV, and the dose deposited at depth increases with beam energy. Therefore, an 18-MeV beam would show more skin sparing and it would have a higher D_{max} than a 4-MeV beam. The depth dose is also affected by the size of the field of radiation used to treat the patient. With a larger field size, there is greater scattering of photons within the field during the interactions with electrons. This scatter effect leads to more interactions, which translates into a higher deposition of dose at depth. In other words, a dose given at a 10-cm depth from a photon beam that has a field size of 20 cm × 20 cm would be higher than the same photon beam with a field size of 5 cm × 5 cm. Many other factors go into the calculation of dose delivered at varying depths in a patient, including scatter from the collimators in the machine, blocks to shield normal tissue, and wedges and compensators (which are used to shape the photon beam). Another main modifier in the target tissue that affects dose at depth is the density of the tissue being treated. Lung, for example, because it is less dense than soft tissue, allows more photon transmission. Additionally, the inverse square law must be taken into account, particularly with

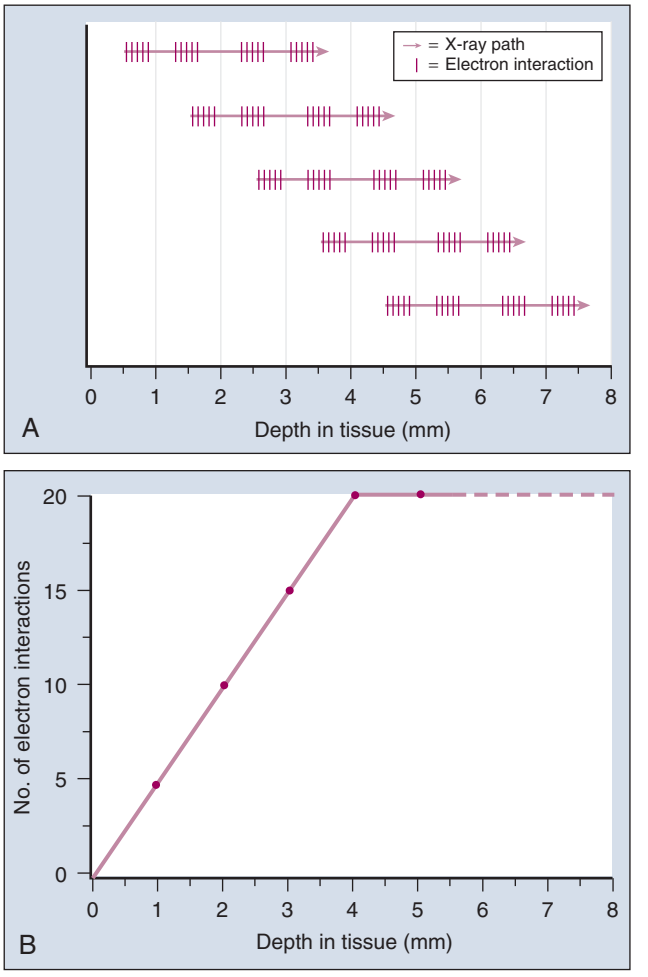

Figure 29-6 • **A,** Simplified explanation of the phenomenon behind skin sparing. Assume that x-rays interact with tissue and liberate electrons that can have subsequent ionizations along their tracks. In this example, the electrons have a range of 4 mm and an average of five interactions (*red lines*) for each millimeter of tissue traversed. **B,** We can then count the number of electron interactions and plot them on a graph. Note that the number of interactions increases with each millimeter of tissue until 4 mm of depth, where the number of interactions (20 in this case) reaches a maximum. If there were no attenuation of beam by tissue, this maximum number of interactions would continue to be observed at all depths. In reality, the intensity of the beam is attenuated by the tissue and, after the point of maximum dose, the number of interactions at greater depths will begin to decrease. (From Lichter AS: Radiation therapy. In Abeloff M [ed]: Clinical Oncology, 2nd ed. London, Churchill Livingstone, 2000, pp 423–470.)

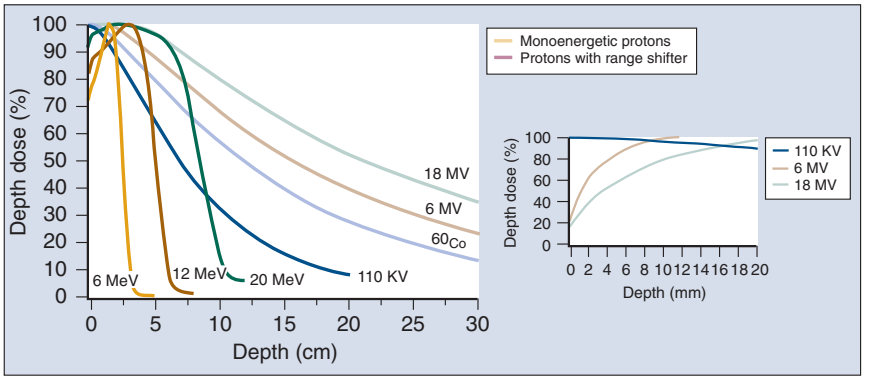

Figure 29-7 • Percentage depth-dose curves for a variety of radiation types used in clinical radiation therapy. These include x-rays and γ-rays (110 kV to 18 MV) and various energies of electrons (6 MeV to 20 MeV). The inset shows the pattern of absorption at shallow depths and provides an illustration of the skin-sparing effect of photons.

regard to the distance from the source to the skin. All of these factors must be taken into consideration when determining the dose being delivered to structures within the patient.

Electrons differ from photons in that electrons travel only a relatively short distance within tissue. They are very light particles compared with the nuclei of the target tissue with which they interact. Hence, they lose a large fraction of their energy as they travel through tissue, leading to much less skin sparing and the deposition of the majority of the dose superficially. Consequently, they are very useful for treatments in which the target of the radiation lies close to the surface of the patient, such as skin cancer, or close to the source of the electrons, such as brachytherapy implants.

BIOLOGIC EFFECTS OF RADIATION

Basic understanding of the physical properties of a radiation beam must be coupled with an understanding of how radiation interacts with biologic tissues to cause damage. Through the interaction processes described earlier, radiation deposits energy as it travels through a patient. These interactions set secondary electrons in motion that go on to produce further ionizations. This ultimately results in the breaking of chemical bonds and damage to molecules and structures within cells. If these broken bonds and subsequent damage occur to cells' critical structures, the most significant effect of the accumulation of radiation damage will be cell killing.

This section describes the complexities of this process. It should be noted that the deposition of radiation dose and the damage it induces are random, and its complexity depends on the type of radiation and the tissue being irradiated.

Interactions with Biologic Materials

Cellular kill occurs when critical targets within the cell are damaged by radiation and the cell is unable to repair that damage. Therefore, a radiation dose deposited near critical structures is statistically more likely to incur a biologic effect. A number of biologic molecules or structures are potential targets for radiation damage, and lively debate continues within the field as to whether there are multiple targets within the cell. Many circumstantial data indicate that DNA is a critical target for the biologic effects of radiation. Measurement of DNA damage after radiation closely correlates with cell lethality.[15,16] Cells that are inhibited from repairing DNA damage or that are naturally deficient in DNA repair enzymes show a distinct radiosensitivity.[17,18] Also, experiments in which the nucleus was irradiated selectively show that radiation caused cell death at a higher rate than did radiation of the cytoplasm.[19]

DNA damage can be termed direct or indirect (Fig. 29-8). If radiation is absorbed by the DNA itself, the atoms of the DNA can become ionized and damaged. This is termed the *direct effect* of radiation. Because the width of DNA is 1 to 4 nm, and there is relatively little DNA in the cell, direct damage must be a relatively rare event.[20] More commonly, water molecules surrounding the DNA are ionized by the radiation. The ionization of water creates hydroxyl radicals, hydrogen peroxide, hydrated electrons, and other oxygen free radicals,[21] all of which are highly reactive, capable of interacting with DNA and causing damage. This is termed *indirect damage*. Eighty percent of a cell is composed of water, suggesting that indirect damage to DNA is common.

Direct and indirect damage can break bonds in DNA. These broken bonds can result in the loss of a base or of the entire nucleotide, or in complete breakage of one or both of the strands of DNA. Single-strand breaks are repaired relatively easily using the opposite strand as a template. Therefore, single-strand breaks are not strongly related to cell killing, though they might result in mutation if the repair fidelity is not high. Chromosomal aberrations such as nondisjunctions and micronuclei are detectable in surviving irradiated cells, which may contribute to the clonal evolution of cancer. Double-strand breaks, on the other hand, are thought to be the most important lesion in determining cell kill.[22] In double-strand breaks, the chromatin is snapped into two pieces. It has been taught traditionally

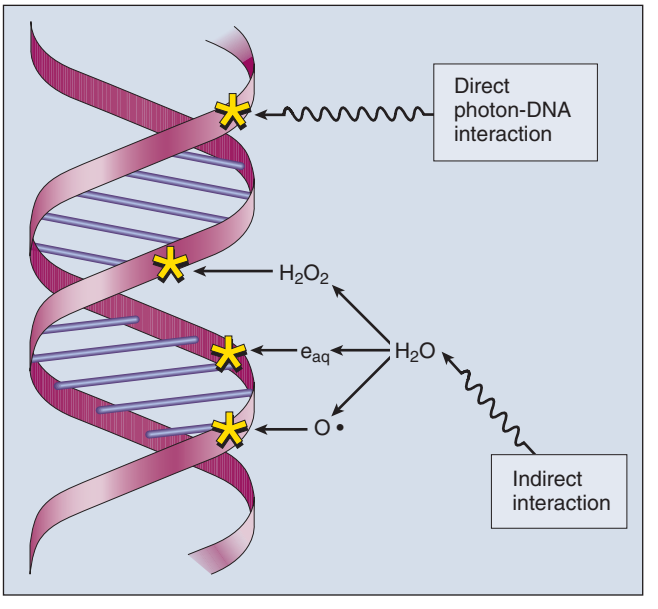

Figure 29-8 • Two types of interactions are possible between x-rays and DNA. In the direct interaction, an x-ray interacts with the DNA molecule itself. This interaction is relatively rare. In the indirect interaction, x-rays ionize water, and the reactive species that are created interact secondarily with DNA, causing damage and DNA strand breakage. (From Lichter AS: Radiation therapy. In Abeloff M [ed]: Clinical Oncology, 2nd ed. London, Churchill Livingstone, 2000, pp 423–470.)

that in an average cell, 1 Gy of low LET radiation causes damage to over 1000 bases in DNA, approximately 1000 single-strand breaks in DNA, and approximately 40 double-strand breaks. Because x-rays are sparsely ionizing, there can be random stochastic processes in regions within the cell where ionization events are much more densely clustered than in other areas. The free radicals produced also are thought to be clustered in discrete areas. Therefore, the multiple broken bonds and resultant DNA damage that occurs could be highly localized. The term *locally multiply damaged site*, or the *cluster hypothesis*, refers to this phenomenon, since they both suggest that it is these clustered regions of DNA damage that lead to clinically significant effects.[23,24]

Most investigators believe that the dominant form of lethal radiation-induced DNA damage is the double-strand break, which ultimately results in cell death if the cell is unable to repair the damage. Cells respond to double-strand DNA damage by invoking mechanisms that sense the damage and mechanisms that actually bring about repair. The earliest detectable event after exposure to ionizing radiation appears to be the phosphorylation of histone H2AX (i.e., the formation of "gamma-H2AX"), a reaction dependent on the ataxia telangiectasia mutated (ATM) protein.[25,26] Major factors that subsequently determine cellular fate include checkpoint proteins (such as ATM, ATR, CHK1, CHK2 and DNA-PK), cofactors and modulating factors that influence *p53* activation, and the success of DNA damage repair (Fig. 29-9).[27]

Two main modes by which cells accomplish repair of double-strand DNA breaks are generally recognized: homologous repair (HR) and repair by non-homologous end joining (NHEJ). In HR, either the undamaged homologous chromosome or the sister chromatid of a replicated chromosome is used as the template to fill in missing DNA sequences in the damaged chromosome. Consequently, HR is most efficient in late S or G2 phase, when the sister chromatids have replicated but not yet separated. The requirement for a template to which the damaged chromosome is matched ensures that HR has great fidelity of repair. Human tumor cells commonly arrest in G2 after double-strand DNA damage, a time when repair activities are detectable. It is, therefore, plausible that irradiation-induced G2 checkpoint delay allows more time for cells to accomplish HR and thereby survive radiation.[28] In contrast to HR, repair by NHEJ is less cell-cycle dependent. In NHEJ, the blunt ends of chromosomes severed by radiation or other agents are directly rejoined. Although repair by NHEJ might, in some ways, be more efficient than by HR, NHEJ lacks fidelity (i.e., it is considered mutagenic) because the template-free rejoining of blunt ends lacks the specificity of HR. In NHEJ, it is possible for the ends of different chromosomes to be rejoined, giving rise to chromosomal aberrations or potentially to the expression of dangerous fusion proteins. It is likely, therefore, that mutagenesis associated with radiation may be due in part to NHEJ.[29]

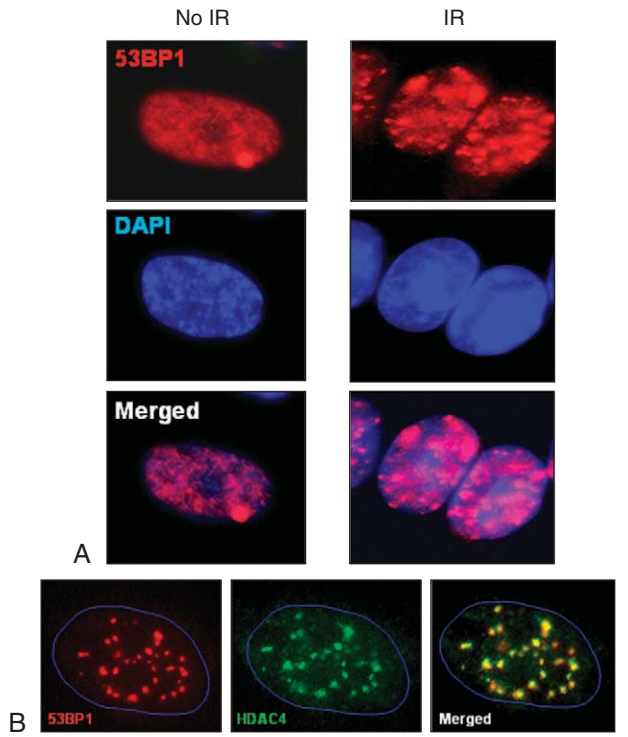

Figure 29-9 • Ionizing radiation induces nuclear 53BP1 foci. B53P1 is a protein that appears to act as a central mediator of several cellular pathways. **A,** 53BP1 protein localizes to nuclear foci at sites of double-strand DNA damage caused by ionizing radiation (IR). **B,** Recruitment of repair and chromatin remodeling factors at IR-induced 53BP1 foci. Bioactive proteins co-localize with 53BP1 at foci, including HDAC4 (shown), BRCA1, and Rad50/NBS. (Used with permission from Gary Kao, MD, PhD, University of Pennsylvania.)

If cells successfully repair DNA damage induced by ionizing radiation, they may resume proliferation. Alternatively, radiation may kill cancer cells by three pathways:

1. Inducing apoptosis by the intrinsic (p53-dependent) or the extrinsic pathway
2. Causing permanent cell cycle arrest or terminal differentiation
3. Inducing "mitotic cell death" from aberrant mitosis, resulting in mitotic catastrophe.

Apoptosis also is known as "programmed cell death." Dependent on the cell type, radiation damage triggers signaling cascades that may involve proteins such as ceramide, p53, MDM2, BAX, PUMA, NOXA, and FAS. The result is self-destruction of the cell. Cells undergoing apoptosis show very characteristic features as they die, including blebbing and fragmentation of the nucleus.[30] Radiation in the doses typically used clinically induce p53-dependent apoptosis in radiation-sensitive organs such as thymocytes and radiosensitive malignancies such as lymphomas, but apoptosis rarely is induced in tumors of epithelial origin.[31] Epithelial tissues and cancers of epithelial origin are more likely to undergo reversible or permanent cell cycle arrest, in which p53 may act as a survival factor for cells, or p53-independent mitotic cell death.[27]

Permanent cell cycle arrest and terminal differentiation also are effective endpoints by which radiation can effect cell kill. Cell cycle perturbations are seen characteristically after radiation exposure and were among the earliest observed biological effects of radiation.[32] Cells can show checkpoints or arrest in any phase of the cell cycle, although the best-described checkpoints with respect to radiation damage are the G1 and G2 checkpoints. Normal cells and cancer cells that retain normal p53 function arrest in the G1 phase of the cell cycle. This is a p53-mediated event.[27] One of the earliest effects seen after radiation damage in cells with normal p53 function is a rise in the intracellular level of p53 due to protein stabilization and decreased protein turnover. This, in turn, leads to an induction of p21, a potent cyclin-dependent kinase inhibitor, leading to blockage of the cells in the G1 phase of the cell cycle.[33] This is only one of the many known functions of p53. It also is involved in the regulation of gene expression, apoptosis, and angiogenesis, among other important cellular processes.[34] The cell cycle arrest induced by p53 often is transient but in some cases can lead the cell to exit the cell cycle permanently and undergo a process that resembles terminal differentiation. The pathways invoked are consequently reminiscent of *cellular senescence*, in which cells have lost the ability to cycle and proliferate.[35]

Many cancer cells, typically those with loss or mutation in the p53 protein pathway, have lost the ability to block in G1. These cells retain the ability to block in the G2 phase of the cell cycle. The G2 block is less well described at the molecular level than the G1 block,

but it also involves effects that regulate the activity of cyclin-dependent kinases that are specific to the G2 phase of the cycle.[34] G2 arrest is clearly related to cellular repair of radiation-induced DNA damage, in that cells that have lost the ability to arrest in G2 are exquisitely sensitive to DNA damage. Even in cells that re-enter the cycle after a G2 block, cell death can be seen subsequently. Such cell death can take several forms. Some cells fail in cytokinesis and form multinucleate giant cells. Some undergo mitotic catastrophe as they attempt to undergo mitosis. Others undergo delayed cell lysis, which, in some cases, may be a delayed form of apoptosis.

Both tumor cells and normal tissues differ in their sensitivity to radiation. In some cases, this is due to differential sensitivity to induction of apoptosis, but in others it is due to molecular mechanisms that are as yet poorly understood. A number of factors have been correlated with radioresistance, such as the presence of hypoxia, which could contribute to the poor prognosis of some tumors. It has been hypothesized that oxygen helps "fix" damage induced by radiation in such a way that the radiation is more lethal to the cancer cells.[36] The specific molecular pathways involved in this phenomenon have not been fully elucidated (see later section on Oxygen Effect).

Most radiobiologists currently think that radiation primarily causes cell death by double-strand DNA damage and that the inability of cancer cells to repair such damage with fidelity results in their death. Although it is clear that cells that lack the ability to repair some forms of DNA damage are extremely sensitive to radiation damage, it is less clear that altered DNA repair capacity contributes to increased resistance to radiation in common cancers.[17] Nevertheless, identifying proteins required to recognize and repair such DNA damage could provide potential targets for sensitizing cells to increase tumor cell kill by radiation.

Other factors that have been implicated in altered cellular sensitivity to radiation include a number of signal transduction pathways, including some that are known to be altered in cancer. For example, EGFR, Ras, and Raf have been implicated in altered cellular sensitivity to radiation, although the molecular mechanisms underlying their effects still are incompletely described.[37–39] Considerable interest also exists as to whether components of the tumor microenvironment might contribute to tumor sensitivity. In particular, persistent production of the cytokine transforming growth factor (TGF)-β1 is an early and consistent finding in tissues exposed to low and high doses of ionizing radiation.[40]

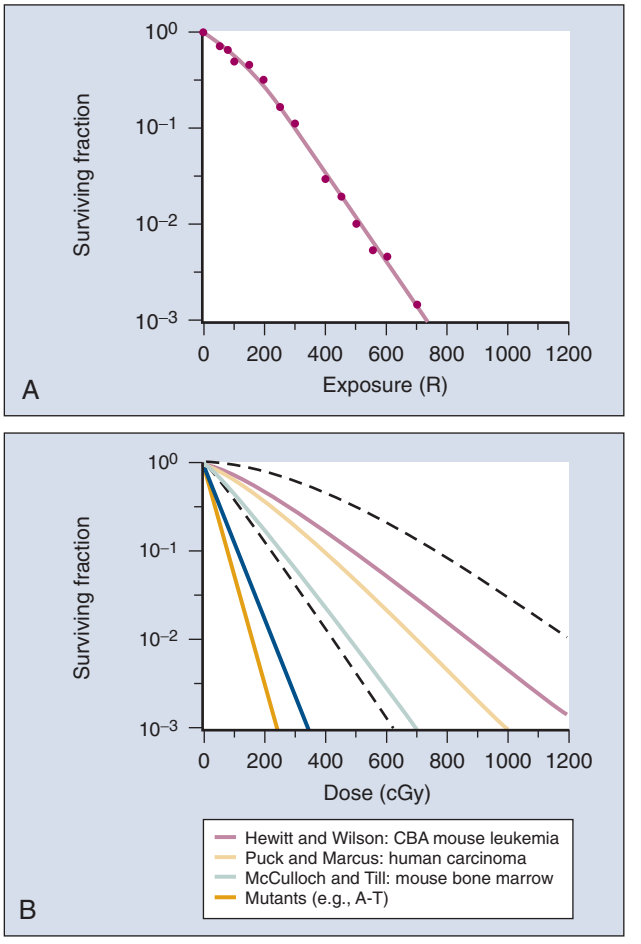

Figure 29-10 • X-ray or gamma ray dose-survival curves for mammalian cells. **A,** The first such curve, reported in 1956 by Puck and Marcus. Note that the dose is expressed in roentgens (R), which, for cells irradiated on the glass, must be multiplied by approximately 1.4 to give the dose in cGy. **B,** A range of survival curves for other mammalian cells. The dashed lines encompass the range for "wild-type" cells of various origins. The steepest curves show a range typical of hypersensitive mutants, such as cells from patients with ataxia-telangiectasia (AT). (From Leibel SA, Phillips TL [eds]: Textbook of Radiation Oncology. Philadelphia, WB Saunders, 1998, p 4.)

Cell Survival Curves

One of the central ideas of radiation biology is that the loss of reproductive integrity in long-term survival assays is important to our understanding of the response of a tumor or a normal tissue to radiation. When cells are exposed to lethal doses of radiation, they might not die immediately or within a few hours of treatment, or even sometimes within a single division of radiation. When cells have been observed by time-lapse cinematophotography after irradiation, it can be seen that some cells survive and go on to form colonies, and some die quickly. Others go through up to several rounds of abortive cell division before finally ceasing to divide and undergoing a variety of possible outcomes that might include terminal differentiation, formation of multinucleate giant cells, mitotic catastrophe, or delayed apoptosis.[41–43] Radiation biologists believe that it is the proportion of cells capable of forming a colony by sustained cell division that most accurately predicts the effects of a dose of radiation. Cell survival curves have been very important in radiation biology to estimate survival of tumor cells within a population with increasing doses of radiation.

The first cell survival curves were demonstrated in the 1950s, when Puck and colleagues[44] plotted the survival of irradiated HeLa tumor cells (Fig. 29-10). HeLa cells were the first continuously cultured human carcinoma strain, named after the patient who donated cervical cancer tissue. Cell survival curves usually are plotted with dose on a semilogarithmic scale. The most striking feature of these curves for low LET radiation is that the effectiveness of killing per unit dose increases with increasing radiation dose. At low doses, the survival curve starts out as a shallow line, with the surviving fraction being an exponential function of dose. At higher doses, the angle of the curve increases, representing more cell kill per increase in unit dose of radiation. Eventually, at higher doses, the curve tends to straighten again. In contrast, high LET radiation cell survival curves on a semilogarithmic plot are straight throughout, albeit with a steeper slope—i.e., survival is an exponential function of dose throughout. Survival curves contrasting low LET and high LET radiation are shown in Figure 29-11.

A number of mathematical models have been devised to attempt to describe the shape of the cell survival curves that are observed experimentally, with an initial shallower slope and eventual bending (the "shoulder") and a final, steeper slope. These include target models, lethal and potentially lethal damage models, and repair saturation models. Some of these have been based on simple mathematical modeling without any real attempt to model known molecular events involved in cell killing, whereas others have been based on

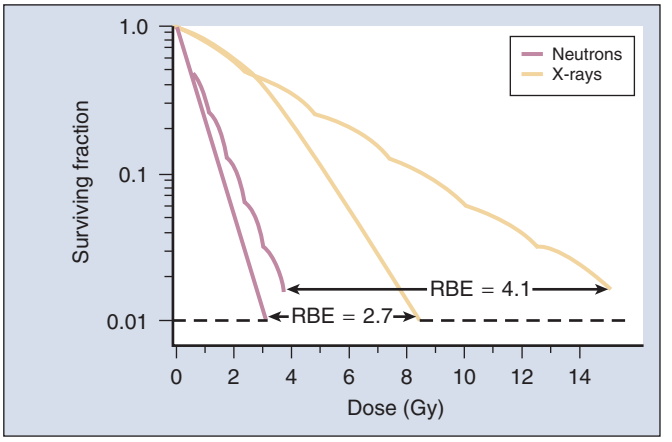

Figure 29-11 • The survival curve for x-rays (low LET radiation) is characterized by a broad initial shoulder, whereas for neutrons (high LET radiation), the survival curve has little or no shoulder. Consequently, the relative biological effectiveness (RBE) gets larger as the dose gets smaller. When a dose is fractionated, the RBE is larger for a given level of cell killing than if the dose is given in a single exposure because the large shoulder of the x-ray dose-response curve is repeated each time. (From Cox JD, Ang KK [eds]: Radiation Oncology: Rationale, Technique, Results, 8th ed. St. Louis, Mosby, 2003, p 45.)

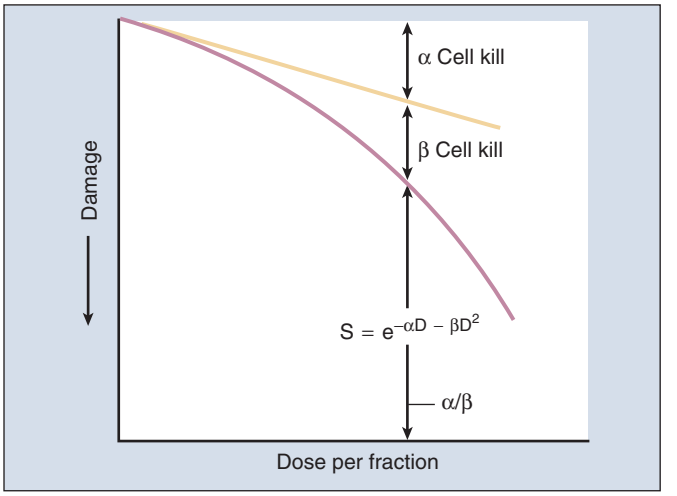

Figure 29-12 • Dose response curves for mammalian cells are adequately fitted by the linear-quadratic relationship, at least over the range of doses of concern in radiation therapy. The form of the equation is

$$S = e^{-\alpha D \beta D^2}$$

where S is the fraction of cells surviving a dose (D), and α and β are constants. Cell killing by the linear and quadratic term are equal when

$$\alpha D = \beta D^2.$$

This occurs when $D = \alpha/\beta$. (From Cox JD, Ang KK [eds]: Radiation Oncology: Rationale, Technique, Results, 8th ed. St. Louis, Mosby, 2003, p 14.)

attempts to model some of the known molecular events (e.g., chromosome breaks or DNA repair) that are involved in cell killing. All of the models can describe the shape of the survival curve to a first approximation. None do so perfectly, and none take into account all the events and all of the possible mechanisms involved in cell death. For a more detailed discussion of the limitations of each model, the interested reader is referred to one of the textbooks of radiobiology.[45]

One model that has been most influential on clinical practice is the *linear quadratic model*, because it is the model that best fits the behavior of cells after exposure to radiation doses within the range used in the clinic.[46] In their original thesis, Kellerer and Rossi proposed that radiation-induced cell killing resulted from two potential events, one with a linear relation to dose ($\exp[-\alpha D]$) and the other having a quadratic relation to dose ($\exp[-\beta D^2]$). This was expressed mathematically by the "alpha-beta" equation,

$$S = e^{-(\alpha D + \beta D^2)},$$

which was shown to fit most experimentally observed survival curves. S represents survival of a cell population after a dose, D (Fig. 29-12). For many cell types, the linear-quadratic model is useful in describing dose responses for a population of cells.

Derived from this model is the α/β ratio, obtained by manipulating the equation just described. A point on the survival curve can be defined at which the components of cell killing can be seen to be equal to each other—that is, $\alpha D = \beta D^2$, or $D = \alpha/\beta$. In other words, for a cell population there exists a dose of radiation where the linear (α) and quadratic (β) contributions to cell killing are equal. This dose is the dose equal to the ratio of α and β—the α/β ratio. The α/β ratio is specific to a cellular population and reflects the sensitivity of the cell to the two supposed types of damage. By this formulation, tissues that have an early response to radiation (skin, gut epithelium, and tumor cells) have a high α/β ratio. In other words, their survival curves stay straight for a longer period before the bend, with a higher contribution of single-event or α killing. Late-responding tissues such as spinal cord, kidney, and muscle have survival curves that bend earlier, with resultant lower α/β ratios (Table 29-2). These late-responding tissues have "shoulders" on their survival curves within the range of doses commonly used in radiation therapy.

This formulation led to the concept that altered fractionation schedules could be used to exploit this difference and treat tumor populations more effectively (with regard to damage to late-responding tissues, discussed in more detail later). This concept has resulted in several clinical trials of altered fractionation schemes, such as the concomitant boost technique for head and neck cancer and the CHART (continuous hyperfractionated accelerated radiation therapy) regime for lung cancer.[47,48] Altered fractionation schemes are described later in this chapter.

Table 29-2 Ratio of Linear to Quadratic Terms from Multifraction Experiments

Reaction Sites	α : β (Gy)
EARLY REACTIONS	
Skin	9–12
Jejunum	6–10
Colon	10-11
Testis	12–13
Callus	9–10
LATE REACTIONS	
Spinal cord	1.7–4.9
Kidney	1.0–2.4
Lung	2.0–6.3
Bladder	3.1–7.0

From Cox JD, Ang KK (eds): Radiation Oncology: Rationale, Technique, Results, 8th ed. St. Louis, Mosby, 2003, p 27.

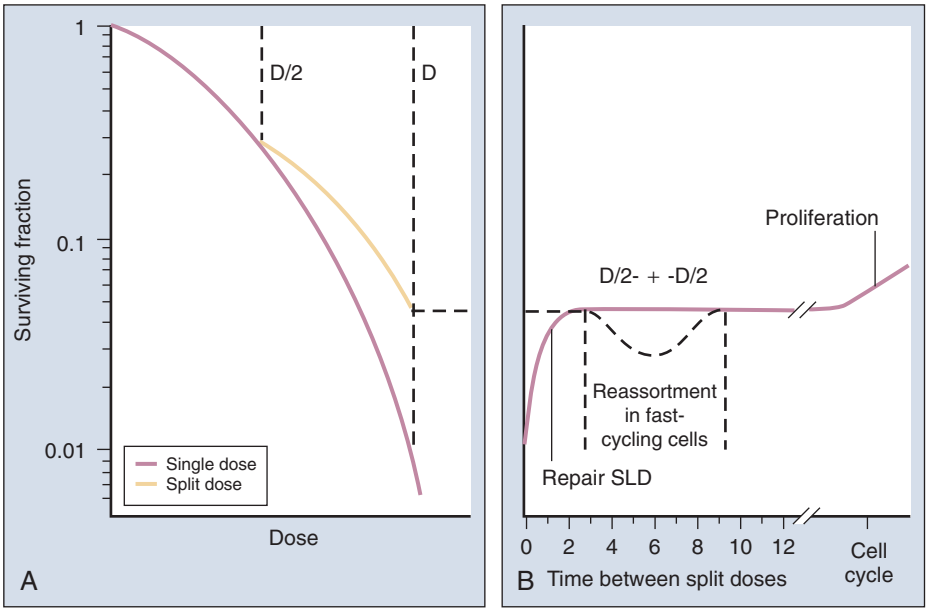

Figure 29-13 • **A,** Increase in cell survival observed when a dose of radiation is delivered in two fractions separated by a time interval adequate for repair of sublethal damage. When the dose is split into two fractions, the shoulder must be expressed each time. **B,** The fraction of cells surviving a split dose increases as the time interval between the two dose fractions increases. As the time interval increases from zero to two hours, the increase in survival results from the repair of sublethal damage. In cells with a long cell cycle, or cells that are out of cycle, cell survival cannot be further increased by separating the dose by more than two or three hours. (From Cox JD, Ang KK [eds]: Radiation Oncology: Rationale, Technique, Results, 8th ed. St. Louis, Mosby, 2003, p 24.)

Cellular Repair

Cells have complex mechanisms that are responsible for repairing radiation-induced damage. As described earlier, the shoulder on the cell survival curve is thought to relate to the cell's ability to repair DNA damage. One of the clearest demonstrations of the cell's ability to repair radiation damage is a phenomenon called *sublethal damage repair*. It has been observed that two doses of radiation given separated in time are less effective than the sum of the two doses given at the same time. The implication is that in the time interval between the first dose and the second dose, some of the damage from the first dose is repaired. Consistent with this conclusion is that the more closely the two doses are given in time, the more they resemble the effects of a large single dose, implying that repair has measurable kinetics.

Repair of sublethal damage was first reported in 1959 by Elkind and Sutton,[49] who noted that damage caused by radiation did not always produce cell killing and that this sublethal damage became lethal only when the total amount of damage had accumulated to a sufficient level. Since then, sublethal damage has been demonstrated in virtually every biologic system tested, predominantly by split-dose experimentation (Fig. 29-13).[50–52] It is important to remember that a correlation exists between cell kill and the production of asymmetric chromosomal aberrations (e.g., dicentrics and rings) from the interactions of double-strand breaks in the DNA. Therefore, sublethal damage repair can be interpreted as the repair of DNA damage that would have formed double-strand breaks by two separate hits (β killing). Because high LET radiation interacts almost without exception by α killing, sublethal repair is not considered relevant to the radiobiology of particle therapy.

Cellular repair of DNA lesions classified as "sublethal" is evidenced by the existence of the shoulder on the cell survival curve. Cells show increased survival with split-dose radiation because the shoulder of the survival curve must be repeated with every fraction. In other words, the shoulder of the survival curve represents the accumulation and repair of sublethal damage. Cells that have a broad shoulder that starts at low doses, with a resultant shallow initial slope, have a propensity for sublethal repair. These tissues, described as *late-responding tissues with low α/β ratios*, exhibit extensive sublethal repair and are spared preferentially by fractionation (Fig. 29-14).

A second type of cellular recovery after radiation, described in 1966 by Phillips and Tolmach,[53] is *potentially lethal damage repair*. This type represents radiation damage that may or may not lead to the killing of a cell, dependent on the cell's condition and environment in the period following irradiation. The researchers noted that cells that are not proliferating, either because they are out of the cell cycle due to contact inhibition or are being held in poor conditions that do not favor growth, show less killing after irradiation than the same cells did when dividing rapidly under optimal conditions. They postulated that resting cells had more time to repair DNA damage before re-entering the cell cycle than those cells that were dividing actively, thus potentially contributing to resistance to radiation therapy.

The extent of recovery from both sublethal damage and potentially lethal damage has been correlated with the repair of DNA and with the rejoining of chromosomal breaks.[54,55] Both processes increase the survival of a cell population with fractionated radiation schedules.

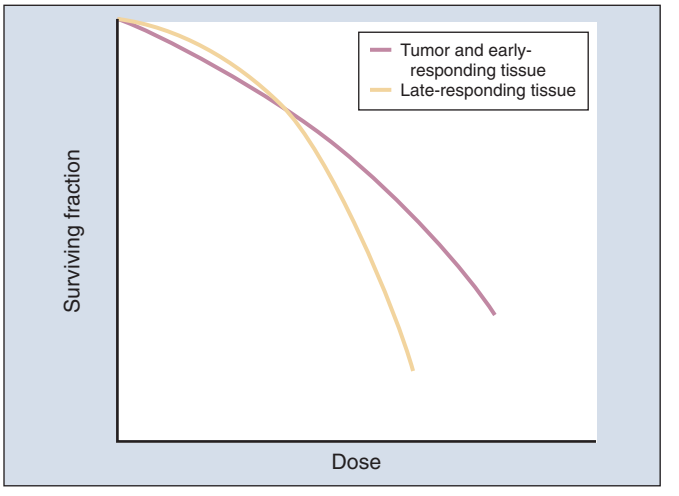

Figure 29-14 • The dose-response relationship for late-responding tissue is "curvier" than for early-responding tissue. The dose at which cell killing is equal by the linear and quadratic components is $\alpha : \beta$. This is about 2 Gy for late-responding tissues and 8 to 10 Gy for early-responding tissues. (From Cox JD, Ang KK [eds]: Radiation Oncology: Rationale, Technique, Results, 8th ed. St. Louis, Mosby, 2003, p 27.)

This can be manifested clinically either by an increase in normal tissue tolerance or by a decrease in tumor control. The time required for most sublethal/potentially lethal damage repair seems to be approximately 6 hours. If radiation therapy fractions are too closely spaced, unrepaired injury will accumulate between dose fractions, with the result that successive doses become more and more damaging to normal tissues. This factor should be borne in mind when designing fractionated courses of radiation to optimize tumor cell kill.

Dose Rate Effects

There is preferential sparing of late-responding tissues by fractionated radiation therapy due to sublethal damage repair. It should be kept in mind, however, that this sparing is relative to early-responding tissues. In other words, as a radiation dose is split and delivered over more than one treatment, the killing of cells within the tumor also decreases, although not by as much as late-responding tissues. When determining cell survival and toxicity (both early and late) of radiation therapy, other factors are involved. One of the most prominent of these factors is *cell repopulation*. As the total treatment time to deliver a dose of radiation lengthens, cells within a tissue have the ability to replenish, called *repopulation*. During a course of fractionated radiation therapy, the effects of sublethal repair and repopulation lead to diminished cell death with protraction of treatment times.

Dose rate effects can occur due to interfraction repopulation. In studies by Fowler and colleagues[56] using pig skin, it was shown that as overall treatment time was lengthened, additional radiation was required to elicit the same effect. Because both fraction size and fraction number were kept constant, this finding was believed to reflect the contribution of repopulation to the effect of the radiation.

Dose rate effects also have been demonstrated during each fraction of radiation. Bedford and Hall[57] demonstrated that the survival of cells increased as dose rate decreased from 7.3 Gy per minute to 0.1 Gy per hour. There also exists a dose rate below which reproduction of cells can continue despite continued radiation delivery. This threshold varies with tissue type, based on factors such as the sensitivity of the stem cells required to repopulate the cell population, the duration of the cell cycle, and the amount of adaptation that cells can undergo in response to radiation.[58]

The response to radiation injury and the survival of cells exposed to radiation are complex. Obviously, cell kill increases as radiation dose increases. Many other factors also contribute to survival, many of which are still not known. Early-responding tissues such as skin, mucosa, bone marrow, and tumor cells are likely to experience acute toxicities, which occur during the radiation course or within a few weeks thereafter. These tissues have stem cells for repopulation, which mature into functional cells. They exhibit rapid cell turnover from these stem cells. The intensity of the toxicity in these tissues reflects the balance between cell killing and the regeneration of cells from surviving stem cells. This balance depends primarily on accumulation of radiation dose. Larger fraction sizes are a factor in determining the severity of acute toxicities, with larger fraction sizes resulting in higher toxicity than smaller fraction sizes. The dependence on fraction size for acute toxicities is much more pronounced than for late effects. Moreover, dose rate has been shown to correlate with tumor cell kill and hence with the development of acute toxicity. One more very important parameter that corresponds with tumor cell kill and acute toxicity is the overall treatment time. As treatment time is extended, the development of acute toxicities decreases. It also has been demonstrated that long treatment times also reduce the likelihood of cure by virtue of reduced tumor cell kill because of the concept of *accelerated repopulation*, particularly beyond 4 to 6 weeks of treatment.[7]

In contrast to acute toxicities in early-responding tissues, late effects occur in late-responding tissues such as spinal cord, central and peripheral nerve tissue, heart myocytes, and kidney nephrons. Late effects often are of more concern to radiation oncologists than early effects, because they result in irreversible end-organ damage from radiation and, therefore, limit dose. Provided that sufficient time (generally agreed to be more than 6 hours) is allowed between fractions to allow for the complete repair of sublethal damage, classical late effects have no dependence on overall treatment time. An exception occurs if the treatment course is intense enough to cause such severe acute toxicities as to reduce the stem cells of early-responding tissues below a threshold; acute toxicity then can progress to chronic tissue injury, termed *consequential late effects*. Late-responding tissues usually are characterized by slow cellular turnover, with little repopulation during radiation treatments. Therefore, dose rate and overall treatment time play a minor role in the development of late toxicity. As stated previously, these tissues have a low α/β ratio, with the potential for significant sublethal damage repair between fractions. Hence, late-responding tissues are extremely sensitive to changes in dose per fraction.

Cell Cycle Effects

An important aspect of the effect of radiation on cells depends on their progression through different stages of the cell cycle.[59,60] With tumor cells, which have a high growth fraction, modulation of this factor is potentially of great importance. The radiosensitivity of cells changes as the cell progresses through the cell cycle, with cells in late G2 and mitosis being the most sensitive. Cells in mid- to late S phase and early G2 phase are the most resistant to radiation. Moderate sensitivity exists for those cells in late G1 and early S phase, and cells in mid G1 are moderately resistant.

These differences in sensitivity allow for preferential killing of cells in those stages that are sensitive to radiation, with a subsequent relative accumulation of cells in the resistant S phase of the cell cycle. This accumulation translates into relative radioresistance of the remaining cells to additional doses of radiation, if reassortment into other phases of the cell cycle through natural progression of cell division does not occur (Fig. 29-15).

Radiation also disrupts progression through the cell cycle. Doses of radiation cause blocks in the G2- to M-phase transition and in the G1- to S-phase transition. These delays are governed by cell cycle "checkpoint" genes, which are responsive to DNA damage and transmit feedback addressing the readiness of the cell to progress to the next phase of the cell cycle. The radiation-induced G1 block is p53 dependent.[27] Because most tumors in adults are mutant or otherwise deficient in p53, the G2 block might be the more important block in tumor response to radiation. The G2 block is dose dependent, averaging 1 to 2 hours per Gy with increasing doses.[60] The G2 delay also varies in time, depending on where the cell was in its cycle when it was irradiated. The delay is longest for cells irradiated in S and early G2 phase and shortest for cells irradiated in G1 phase.[60]

These variations in sensitivity with cell cycle changes could be related to the propensity of the DNA to be damaged or repaired in the various phases of the cell cycle. In late S and early G2 phases, repair of double-strand breaks by homologous repair is most efficient, compared with the G1 and early S phases (when a homologous chromosome is not available) and late G2 phase (when the chromatin is highly condensed and less accessible to repair).[61] Similarly, DNA is uncoiled at the beginning of the S phase, perhaps leading to increased susceptibility to radiation damage in this phase. The preferential susceptibility with respect to the cell cycle reiterates the importance of splitting the total radiation doses into fractions.

Fractionation

The biologic basis of fractionation in radiation therapy makes use of the "four Rs of radiobiology"—*r*epair of sublethal damage, *r*eassortment (redistribution) of cells within the cell cycle, *r*epopulation, and *r*eoxygenation.[45] Dividing the total dose into a number of smaller

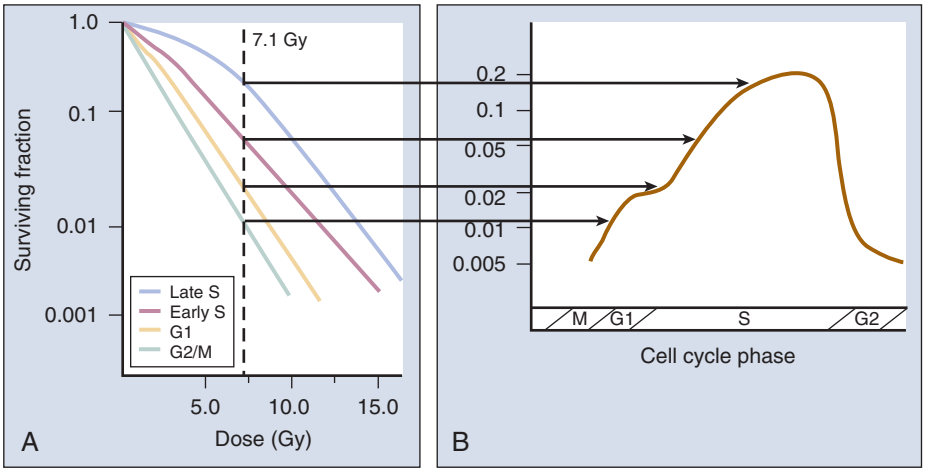

Figure 29-15 • **A,** Cell survival curves for populations of Chinese hamster cells irradiated in different phases of the cell cycle. **B,** Graphic illustration of how these radiosensitivity differences translate into age response patterns.

fractions allows for normal tissue sparing because of the repair of sublethal damage between fractions. Fractionating the therapy also allows for reassortment of tumor cells into radiosensitive phases of the cell cycle, with reoxygenation of the tumor cells causing them to be more radiosensitive. If too much time is allowed between fractions, repopulation or proliferation of the tumor cells can occur. Although this theory forms the basis for fractionated therapy, the reality is much more complex. Tumor populations and normal tissue represent a heterogeneous group of cells, all responding to the radiation and the fractionation scheme differently. Some general characteristics are presented in the following paragraphs.

Early-responding tissues include those tissues that are rapidly dividing and repopulating; these tissues are responsible for the acute toxicity seen with radiation therapy. The severity of acute toxicity reflects the rate of cell killing of early-responding tissues counteracted by regeneration by those tissues' surviving stem cells. This balance is based mainly on total treatment time. Prolonging overall treatment time spares the patient from the severity of acute toxicity, with short, intense treatment courses leading to severe acute toxicity. Severe acute toxicity can progress to consequential late effects.[62]

Late-responding tissues are responsible for the late toxicity from radiation therapy. These tissues are composed primarily of terminally differentiated cells with no stem cell population. Usually, therefore, there is no turnover of cells within a radiation treatment course and no opportunity for regeneration during treatment. In contrast to early-responding tissues, the overall treatment time has little importance in determining late toxicity. Instead, late toxicity depends mainly on total dose and dose per fraction.

These differences are seen by observing the dose-response relationships of the two types of tissue. Late-responding tissues have dose-response relationships that are more curved (i.e., with a larger shoulder) than those of early-responding tissues. In terms of the linear quadratic model, this translates into a higher α/β ratio for early effects (generally thought to be at ~10 Gy), compared with the ratio for late effects (thought to be at ~2 Gy). This has different consequences for each type of tissue. For early effects, the α/β ratio is large, meaning that the survival curve has an initial slope and no bend until higher doses. For late effects, the α/β ratio is small, with a short initial slope and a bend at low doses.[63] This creates a discrepancy between the two curves so that at certain doses, early-responding tissues (including many tumors) will be killed preferentially compared with late-responding tissues (see Fig. 29-14). As fraction upon fraction of radiation is given at these doses, the killing of tumor cells is much greater than that of cells of many normal organs, which are late responding. However, as fraction size increases, cells in late-responding tissues are killed in greater numbers. This explains the observation that late-responding tissues exhibit a much more marked change in survival with changes in dose per fraction. In other words, late-responding tissues are preferentially spared by dose fractionation.

The reason for the difference in these curves is not completely understood, although some possible explanations have been presented. The first deals with cell cycle-specific sensitivity. Cells are sensitive to radiation during mitosis and G2 phase and resistant to radiation during S and early G1 or G0 phases. Although this resistance eventually is overcome with high doses, late-responding tissues have many quiescent cells, hence incurring radioresistance as these cells rest in G0. On the other hand, tumor cells and early-responding cells reassort themselves into sensitive phases of the cell cycle, leading to radiosensitivity at smaller doses.

Another explanation of the differences in the dose-response curves relates to repair of DNA damage. Late-responding tissues have a greater capacity for sublethal repair than do early responding tissues, hence the lower α/β ratio and the shallower survival curve at low doses. Although late-responding tissues have a higher repair capacity than early-responding tissues, the repair kinetics themselves do not differ systematically between the two types of tissues.[64] Therefore, there is a minimum limit of time that is needed between fractions so that repair in late tissues can be completed. If this is not allowed, severe toxicity can result. This has been noted in studies that used fractionation schedules in which the interval between doses was less than 4.5 hours.[65] Although the explanation that these toxicities were due solely to incomplete repair has been questioned, most protocols now stipulate a minimum of 6 hours between fractions to allow for sufficient repair to take place.

Provided that sufficient recovery occurs between each fraction and the next, late radiation effects classically show no dependence on treatment course duration. In contrast, overall treatment time has a large effect on both acute toxicity in early-responding tissues and the cure of tumors. This implies that the tumors that show a decrease in curability with longer treatment times have rapid regeneration in response to the cell killing that occurs with radiation.

Altered Fractionation Schemes

All of the factors described so far must be taken into consideration when a fractionation scheme is being designed. The "standard" fractionation schedule differs in many parts of the world. In the United States, 1.8 to 2.0 Gy per day is the conventional fractionation. The standard of five fractions per week delivering a total dose of 9 to 10 Gy per week has evolved not as a biologically designed, optimal method for administration of radiation but rather from considerations such as the convenience of patients and staff, the availability of equipment, and financial constraints. Outside the United States, the same nonmedical constraints have dictated the development of

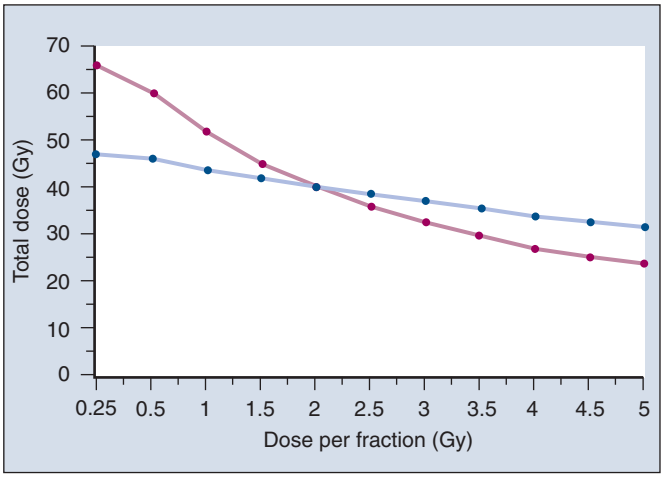

Figure 29-16 • Influence of fraction size on complications in early- vs. late-reacting tissues. The α/β ratio for the early tissue (*blue curve*) was set at 10 in this example; the α/β ratio for the late tissue (*red curve*) was 2.5. The tissues were presumed to have equal reactions to 40 Gy delivered at 2 Gy per fraction. Note that for equal reactions, the early-reacting tissue is far less dependent on fraction size. For large daily fractions, the late-reacting tissue will require substantial dose reduction to maintain equal clinical effects. Conversely, if fraction size is reduced, the late-reacting tissue will tolerate substantially higher doses of radiation. (From Lichter AS: Radiation therapy. In Abeloff M [ed]: Clinical Oncology, 2nd ed. London, Churchill Livingstone, 2000, pp 423–470.)

other fractionation regimens that may employ fewer fractions over a shorter time.

In the 1990s, more attention was paid to attempts to alter the customary fractionation protocols to provide schemes that could improve the therapeutic outcome, through either increased tumor sterilization or decreased normal tissue toxicity. These attempts were undertaken based on the knowledge that the effects of radiation on acutely reacting tissues (e.g., skin and mucosa) are different from those on late-reacting tissues (e.g., nerve and connective tissue).

The reactions in early-reacting tissues, which determine the patient's tolerance to treatment during the course of radiation, are time dependent. Because these tissues proliferate rapidly, prolonging the total time of therapy allows proliferation to take place and thus lessens the severity of the overall reaction. This is especially important in terms of breaks (days off) from treatment, particularly weekends, during which time a mucosal or skin reaction can heal substantially. Late-reacting tissues are not sensitive to overall treatment time, but they are very sensitive to fraction size. It is clear from a number of clinical studies that, given the same total dose, late reactions are worse when large fractions are used than with smaller ones.[66] This is understandable based on the shape of the cell survival curves for early- and late-reacting tissue. Late-reacting tissues have low α/β ratios, and their survival curves bend at higher doses, causing a substantial difference in cell kill with large rather than small fractions. With little proliferation to make up the difference, early-reacting tissues are extremely fraction-size dependent. If large fractions are used, the total dose must be lowered to achieve the same effect on long-term toxicity. Clinical examples of this effect are found most often in palliative regimens, in which 20 Gy in five fractions or 30 Gy in 10 fractions are given to bone metastases for the rapid relief of pain (Fig. 29-16). Although a few large fractions preferentially damage late-reacting tissues, a larger number of smaller fractions preferentially spares them.

The other side of this coin is tumor proliferation. If many small fractions are used and the time it takes to deliver a course of radiation is protracted, tumor proliferation could negate potential gains. When the aims are to take advantage of the sparing of late tissue damage and avoid having treatment last for too many days or weeks, treatment has been given with multiple fractions per day. Several alternative fractionation schemes are presented in Table 29-3. These schemes can be categorized according to two basic strategies: hyperfractionation and accelerated fractionation. In *hyperfractionation*, the fraction number is increased without altering the total treatment time. Although the dose per fraction is reduced, the total dose administered is larger, which allows for the safe escalation of dose with respect to late normal tissue toxicity, because the individual fraction sizes are quite small. An example of hyperfractionation is the treatment of head and neck cancer with 1.15 Gy twice daily (11.5 Gy per week). Following this schedule, instead of a typical 7-week course of treatment delivering 63 Gy at standard fractionation, 80.5 Gy is delivered in the same time period.[67] Several single-arm retrospective studies have reported results with hyperfractionated treatment of head and neck cancer that suggest benefit in terms of local control.[68,69] A large randomized trial in T2 and T3 oropharyngeal carcinoma showed a statistically significant (approximately 35%) increase in local control in the hyperfractionated group.[67] Although not all studies have shown an advantage for hyperfractionated regimes compared to conventional fractionation, overall the literature suggests that an advantage may exist for hyperfractionation in terms of local control of head and neck cancer (in the absence of concomitant chemotherapy).

In *accelerated fractionation*, the overall time of therapy (i.e., total number of days/weeks) is reduced. The number of fractions, fraction size, and total dose may or may not be reduced. The theoretical advantage is that a reduction in overall treatment time could counteract accelerated repopulation in the tumor. Based on the principles discussed previously, late effects should be similar to conventional fractionation, because the fraction size is standard (or reduced) and

the total dose is not increased. An example of accelerated fractionation is the British experience of continuous hyperfractionated accelerated radiation therapy (CHART) to treat non-small-cell lung cancer using 1.5 Gy three times daily for 12 consecutive days, delivering 54 Gy in 36 treatments in 1.5 weeks.[48] Another example of accelerated fractionation is the widely recognized scheme called the "concomitant boost" schedule for head and neck cancer, in which the first 36 Gy is given in four weeks at 1.8 Gy per fraction, and while that larger field continues to a total of 54 Gy, a smaller boost field is added as a second daily treatment for the last 2 to 3 weeks, bringing the total dose to 72 Gy in 6 rather than 8 weeks.[70] The results of a large randomized trial in patients with head and neck cancer showed a local control advantage for this technique.[47] To date, no overall survival benefit has been demonstrated for any altered fractionation schedule other than CHART.

One practical difficulty with hyperfractionated or accelerated schemes is the increased toxicity that can be seen in patients receiving concomitant chemotherapy (see the section on Radiosensitizers, Radioprotectors, and Concomitant Systemic Therapies). Combining chemo- and radiation therapy is becoming increasingly routine in the treatment of many cancers, for example, head and neck cancer and cervical cancer. Furthermore, these schemes, especially those that involve separation of doses in time, require the patient to come to the clinic more than once daily, which tends to be inconvenient for most patients. Therefore, many clinicians feel that these strategies must show an unequivocal benefit on overall survival to be worthwhile. Nevertheless, because of its simplicity and convenience, the concomitant boost technique has become an established and accepted technique worldwide for patients with many cancers, particularly head and neck cancer.

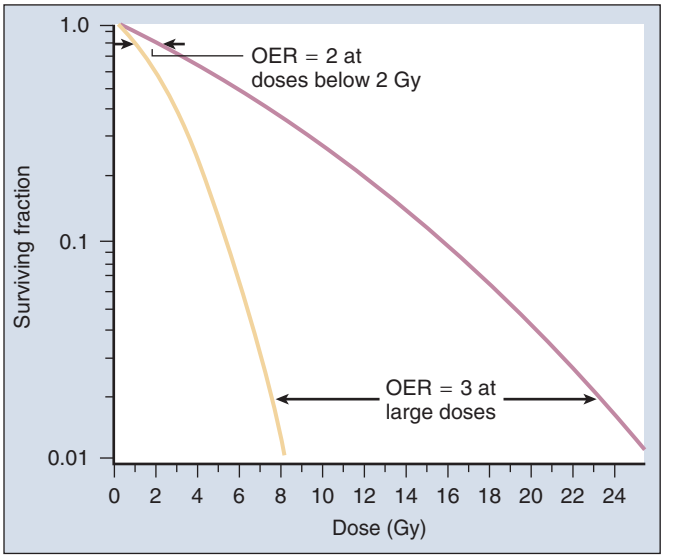

Figure 29-17 • Cells irradiated in the presence of molecular oxygen are more sensitive to killing by x-rays than cells that are hypoxic (deficient in oxygen). The ratio of doses that produce the same level of biological damage in the absence of oxygen and in the presence of oxygen is known as the oxygen enhancement ratio (OER). At high doses, the OER has a value of about 3; its value seems to be smaller (close to 2) at doses below 2 Gy. (From Cox JD, Ang KK [eds]: Radiation Oncology: Rationale, Technique, Results, 8th ed. St. Louis, Mosby, 2003, p 34.)

Oxygen Effect

Many agents have been observed to modify the responses of cells and tissues to radiation. One of the most extensively studied chemical modifiers is oxygen. The response of cells to ionizing radiation is strongly oxygen dependent, with well-oxygenated cells showing as much as threefold greater sensitivity to the killing effects of ionizing radiation than the same cells under hypoxic conditions.[45]

The effect of oxygen has been known for nearly a century. In 1912, Swartz noted a reduction of radiation effect if blood flow to an exposed area was reduced.[71] Although many suspected the modifying properties of oxygen, the oxygen effect was not demonstrated quantitatively until 1955.[72] This important discovery by Gray and Tomlinson had significant implications, because it became clear that tumors have a much higher proportion of hypoxic cells than do normal tissues. Many attempts have been made to circumvent this "built-in" radioresistance of tumor cells, but tumor hypoxia continues to be a problem in therapeutic radiation oncology.

The oxygen enhancement ratio (OER) is the ratio of hypoxic to aerated doses needed to achieve the same biologic effect. For x-rays, the oxygen enhancement ratio usually is between 2 and 3, becoming more pronounced at higher doses (Fig. 29-17). In other words, the presence of oxygen in cells increases cell killing by radiation. The mechanism behind oxygen's radiosensitizing effect is thought to lie in the process of indirect damage, which is DNA damage resulting from the production of free radicals from water molecules. These free radicals break chemical bonds and produce chemical changes, initiating the chain of events that result in the expression of biological damage. After DNA damage from free radicals occurs, the damaged targets usually are quickly repaired by a reduction reaction involving reducing species such as thiols and intracellular glutathione, which restores the target to its original condition. Oxygen inhibits this repair of free radical-induced damage by forming irreversible peroxides in the injured biomolecules, thus "fixing" the radiation damage.

Consistent with this explanation of oxygen's effect is the fact that oxygen need not be present at the time of radiation for sensitization to occur, but it must be present shortly thereafter. Oxygen could be added after the radiation to sensitize cells, provided the delay is no longer than 5 msec.[73] Also consistent with this theory is the fact that high-linear-energy transfer radiation has a lower oxygen enhancement ratio than does low linear energy transfer radiation.

The concentration of oxygen required for radiosensitization is remarkably small. Air has an oxygen concentration of approximately 155 mm Hg. Hypoxic resistance occurs at concentrations between 0 mm Hg and 20 mm Hg. By the time a 20-mm Hg concentration of oxygen is reached, the cell survival curve is similar to the curve obtained under fully oxygenated conditions. This is less than half of the partial pressure of oxygen normally found in tissues (~40 mm Hg). A concentration as small as 5 mm Hg results in a radiosensitivity halfway between hypoxic and fully oxygenated conditions. In practice, this means that hypoxia is not a major consideration for normal tissues; the minimum oxygen concentration to which most tissues will be exposed is at the level of venous blood (around 40–50 mm Hg), well above the borderline for the oxygen sensitizing effect. Some normal tissues (e.g., cartilage or skin) might contain borderline hypoxic cells.[74]

Although the oxygen tension of normal tissues is similar to that of venous blood (40 mm Hg), the oxygen tension within the cells themselves is heterogeneous. Some normal tissues contain a small percentage of cells that are borderline radiobiologically hypoxic. This percentage is amplified greatly in tumor tissues due to both chronic hypoxia and acute hypoxia. Chronic hypoxia (also termed *diffusion-limited hypoxia*) results from the propensity of tumors to outgrow their blood supplies. Tomlinson and Gray calculated the distance to which oxygen could diffuse in respiring tissues to be 100 to 180 μm.[72] Cells beyond this distance would be expected to be dead or dying, producing the observed areas of necrosis seen in tumors, but those on the fringe of this distance would make up a large hypoxic region of cells. Acute hypoxia, also known as perfusion-limited hypoxia, results from the transient closing of blood vessels within the tumors themselves. Other possible causes include changes in overall blood flow or decreases in red blood cell delivery. Like chronic hypoxia,

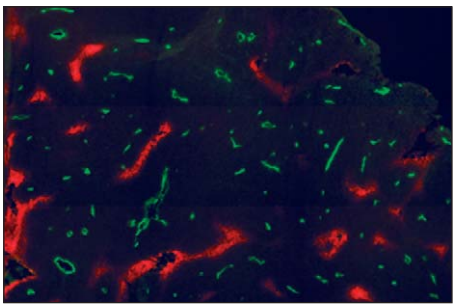

Figure 29-18 • Microscopic photo of a leiomyosarcoma of the extremity stained with EF-5, displaying the heterogenicity of hypoxia within the tumor. Green color corresponds to capillaries within the tumor. Red areas correspond to areas of hypoxia, which are at a notable distance from the blood supply. (Used with permission from Sydney Evans, VMD, University of Pennsylvania.)

acute hypoxia can create a substantial hypoxic population of cells within a tumor.[74]

These populations of hypoxic cells within tumors can significantly limit the efficacy of radiation therapy. Although cells within these hypoxic parameters retain properties of clonogenicity, they are protected from the killing effects of radiation because of the absence of oxygen to fix the radiation damage. Therefore, the presence of even a small population of hypoxic cells could limit the overall success of radiation therapy in clinical situations. It has been estimated that hypoxic fractions account for up to 50% of tumors, with 15% of all tumor cells, on average, being hypoxic (Fig. 29-18).[75]

Given that tumors contain hypoxic cells that greatly limit the success of radiation, how are clinical successes with radiation obtained? The answer might lie in the reoxygenation of tumor cells after radiation that has been observed in rodent tumors.[76,77] Reoxygenation occurs with both the chronic and acute mechanisms of hypoxia. In terms of chronic hypoxia, reoxygenation involves shrinking the tumors during a course of radiation therapy. As cells die from exposure to radiation, surviving cells that previously were beyond the range of oxygen diffusion are brought closer to a blood supply and then reoxygenate. This process is fairly slow, taking place over a period of days, depending on the rate of tumor regression. Reoxygenation also occurs in terms of the mechanism responsible for acute hypoxia. Assuming that blood flow resumes in areas of acute hypoxia, reoxygenation could take place within minutes or hours.

The process of reoxygenation is thought to be important in the practice of radiation oncology and again suggests the importance of using a protracted, fractionated course of radiation therapy. If human tumors reoxgenate as efficiently as animal tumors do, using multiple fractions could be sufficient to deal with the problem of hypoxic cell populations. Attempts at increasing the partial pressures of oxygen in tumors and using oxygen-mimetic chemicals to increase the sensitivity of tumor cells to radiation have yielded mixed results. A number of pharmacologic agents (e.g., 5-fluoro-etanidazole and pimonidazole) are being studied to allow more accurate assessment of the role of hypoxia in human tumors and cancer management.[78]

Radiosensitizers, Radioprotectors, and Concomitant Systemic Therapies

Although oxygen may be the most effective radiosensitizer, there are limitations to achieving levels of oxygen sufficient for sensitizing all tumor cells. Chemicals have been developed, therefore, to try to sensitize hypoxic tumor cells to kill by radiation. All have a similar electron affinity for the electrons produced by the ionization of biomolecules. The nitroimidazoles, including metronidazole, misonidazole, and etanidazole, represent molecules with such characteristics. Although these compounds are efficient radiosensitizers in animal model studies, clinical trials have shown them to have limited efficacy in humans,[74] for several possible reasons. As laboratory studies have continued to show encouraging results, diffusion into tissues seems to be the limiting quality in these compounds, just as it is for oxygen itself. In addition, severe side effects—most notably peripheral neuropathy—have been noted with some of these compounds at the drug concentrations required to produce radiosensitizing effects on tumors.[78] An additional problem is that in animal models (particularly rodent models), tumors grow rapidly and consequently might have more hypoxia. Also, tumors in animal models are more uniform than human cancers. The design adopted for the clinical trials of these compounds, particularly patient selection, also has been debated.

In response to the lack of efficacy seen with hypoxic cell radiosensitizers, other approaches have emerged to attack the hypoxia problem encountered in tumors. Tirapazamine is a prodrug that is activated to a cytotoxic molecule preferentially under hypoxic conditions.[79] Data suggest a synergistic effect when this compound is given with radiation. Clinical progress with tirapazamine has been slow, perhaps because of the severe nausea or muscle cramping experienced by some patients.[80] Clinical trials are underway with this drug and other prodrugs, such as AQ4N, which is selectively and irreversibly converted to AQ4 in hypoxic tumor cells where it acts as an inhibitor of topoisomerase II.[81]

Compounds that interact with DNA also may act synergistically with radiation. In 1960, it was found that pyrimidines could be halogenated and incorporated into DNA because the van der Waal's radius of chlorine, bromine, or iodine was similar to the size of a methyl group side chain on uridine and because a halogenated uridine would be recognized by DNA polymerase. Therefore, halogenated pyrimidines (e.g., uridine with a bromine atom replacing the methyl group [BUDR] or an iodine replacing the methyl group [IUDR]) could be substituted in DNA for a normal thymine.[82] DNA containing substituted halogenated pyrimidines is more susceptible to DNA double-strand breaks when exposed to ultraviolet light or ionizing radiation.[83] Although this finding relates to cell kill in preclinical models, in clinical trials to date, these compounds have not been shown to be efficacious.[84] It has been postulated that insufficient halogenated pyrimidines are incorporated into the DNA of tumor cells, resulting in inadequate radiosensitization.

Although the therapeutic ratio can be improved with radiosensitization, a therapeutic benefit in terms of the relative sparing of normal tissues could also be attained using *radioprotectors*. The most abundant radioprotectors are sulfhydryl-containing compounds. Cysteine was the first of these to be shown to protect against the effects of radiation, by Pratt and colleagues in 1948.[85] Since then, many other compounds have been found to be effective radioprotectors, the most efficient of which has a free SH group separated from the rest of the molecule. The mechanisms of the radioprotection afforded by sulfhydryl-containing molecules include free radical scavenging and hydrogen donation to facilitate DNA repair (Fig. 29-19). The radioprotector most commonly used clinically today is WR-2721 (amifostine), developed at the Walter Reed Institute of Research. It is converted to the active metabolite WR-1065 inside the cell and acts as a free radical scavenger. Given intravenously or subcutaneously, it has been demonstrated to be efficacious in reducing toxicity in head and neck cancers and lung cancer and its application is being tested in the treatment of other malignancies.[86]

Currently, the most widely used radiosensitizers are *chemotherapeutic agents*. Originally, the rationale for the combination of chemo- and radiation therapy was to attack two different problems, termed *spatial cooperation*. Whereas radiation would address local control issues, chemotherapy was thought to treat micrometastases located beyond the tumor bed. However, evidence of increased local control in patients receiving combined treatment is now considered evidence of chemotherapy's radiosensitizing effects, which have been demonstrated in many tumors. Examples include the use of platinum agents

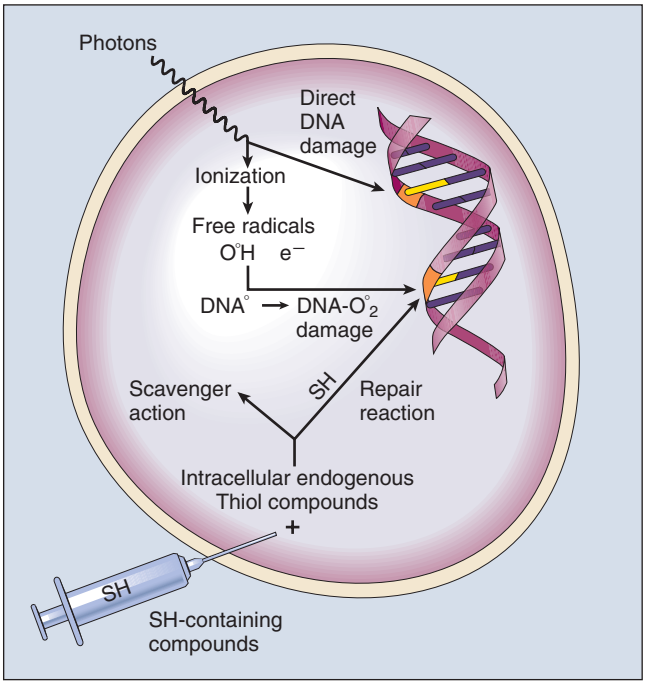

Figure 29-19 • Chemical protectors: competition model. There is a dual action to chemical radioprotection: (1) thiols and sulfhydryl compounds act as repair compounds; (2) they compete with free radicals (scavenging effect). (From Leibel SA, Phillips TL [eds]: Textbook of Radiation Oncology. Philadelphia, WB Saunders, 1998, p 50.)

in lung cancer, head and neck cancer, cervical cancer, rectal cancer, and bladder cancer; mitomycin-C in anal cancer; and 5-FU in esophageal, gastric, and pancreatic cancers (Table 29-4).[87–91] Although some of the improved outcomes in these studies are due to the elimination of micrometastases, improved local control from radiosensitization has been shown to be an important component. Recently a multicenter European–Canadian trial of patients with glioblastoma multiforme has reported improved local control and a significant improvement in overall survival with a combined modality approach using concomitant and adjuvant temozolamide chemotherapy with high-dose radiation therapy.[92]

Over the past decade, the emphasis of drug development in oncology has shifted toward new classes of molecularly targeted agents, particularly antibodies and small molecule inhibitors. It is increasingly apparent that many of these agents can act as radiation-specific sensitizers or protectors. Potential targets for radiosensitization include the following:

- Signal transduction pathways, for which targeting agents are in clinical trials (see later discussion)
- Pathways clearly involved in sensitivity to drugs and radiation, for which agents currently are in preclinical trials
- Investigation of the molecular mechanisms involved in the most highly conserved cellular responses to cytotoxic stress

The first large-scale-example of the clinical benefit that can be obtained by combining a molecularly targeted agent with radical radiation therapy is provided by cetuximab, an IgG1 monoclonal antibody directed against the ligand binding domain of the epidermal growth factor receptor (EGFR; see Chapters 34 and 72). Cetuximab enhances the cytotoxic effects of radiation in preclinical models of squamous cell carcinoma.[93,94] An international multicenter randomized controlled trial has demonstrated in the treatment of locoregionally advanced head and neck cancer that, compared to high-dose radiation therapy alone, concomitant high-dose radiation therapy plus cetuximab improves locoregional control and reduces mortality without increasing the common toxic effects associated with radiation therapy.[95]

CLINICAL APPLICATION OF RADIOBIOLOGIC PRINCIPLES

The goal of all investigations into the physical aspects and biologic principles behind radiation therapy is to attempt to increase the *therapeutic index*, which is defined as the tumor response for a fixed level of normal tissue damage.[96] Or, to restate it another way, the goal is to increase tumor cell kill and hence tumor control while maintaining normal tissue toxicity within a tolerable range. When discussing normal tissue toxicity, late effects that translate into end-organ damage usually are considered the dose-limiting toxicity.

All organs have a threshold for normal tissue toxicity. These thresholds, though, often lack rigidity and are poorly defined, because they depend on the interaction of many factors. The most important factors in terms of normal tissue tolerance and toxicity are total dose delivered and the volume of the organ exposed to this dose. It is not as simple to calculate this relationship for normal tissue as it is for tumors. When speaking in terms of tumor cure, the fraction of cells surviving determines the success of treatment, because a single surviving cell might suffice for regrowth of the tumor. For normal tissues, the tolerance depends heavily on the ability of stem cells to maintain a sufficient number of mature cells for proper organ function. This statement is an oversimplification, because the tolerance of an organ also depends on its structural organization, which some radiobiologists have termed *functional subunits*.[45,74,97] For example, consider the kidney and the spinal cord. If radiation permanently damages a number of nephrons, the end-organ function might not be affected as long as enough nephrons remain to maintain function. The functional subunits of the kidney, then, are said to be arranged in parallel. On the other hand, if one section of the spinal cord is damaged, the entire cord distal to the lesion will be disrupted. Organs such as the spinal cord, in which damage to one portion of the organ affects

Table 29-4 Example of Chemotherapy Agents That Sensitize Tissues to the Effects of Radition

Drug	Proposed Mechanism Enhancement	Clinical Use
5-Fluorouracil	Inhibits thymidylate synthase	Head and neck, gastrointestinal, bladder, anus
Platinum agents	DNA cross-linking and adduct formation	Head and neck, gynecologic, bladder, lung, anus
Mitomycin C	DNA cross-linking and adduct formation	Anus, bladder
Gemcitabine	Inhibits ribonucleotide reductase	Pancreas, head and neck, lung, bladder
Paclitaxel	Inhibits microtubule polymerization	Lung, gynecologic malignancies, head and neck
Temozolamide	Alkylation and methylation of DNA	Glioblastoma multiforme

the function of the entire organ, have what is called *serial functional subunits*.

Functional subunits have yet to be described for many organs, and the use of functional subunits to describe radiation tolerance of many organs remains theoretical. It is clear, however, that as the irradiated volume of an organ increases, the complications also increase. Although the volume of the organ that is exposed to radiation is important, this exposure might not be observed as toxicity if the total dose delivered remains below the dose that would damage the normal tissue in question. The concept of a threshold for total dose exposure becomes important as we attempt to escalate dose to increase tumor control. Clinical and preclinical data are consistent with the view that increased dose kills more cells, though few clinical trials have demonstrated this directly. Retrospective data have confirmed a dose response in the treatment of many clinical sites, including head and neck, Hodgkin's disease, high-grade glioma, non-small-cell lung cancer, prostate cancer, breast cancer, and cervical cancer.[98–103]

Therefore, the total dose to the tumor and the volume of normal tissue treated must be considered when designing a radiation treatment course. Success might be possible in any tumor, regardless of size and histology, if sufficiently high doses are used. Clinically, however, this consideration must be balanced against the toxicity that would result to normal tissue. To increase the therapeutic ratio, many of the radiobiologic and physical principles of radiation have been used, including tumor localization, choosing the optimal energy and radiation modality, manipulating the dose rate, fractionation schemes, and the use of radiosensitizers and radioprotectors or targeted therapies. All depend on accurate localization of the tumor and the precise delivery of radiation.

Effects of Radiation on Normal Tissue

The effects of radiation on normal tissue limit the doses of therapeutic radiation that can be administered safely. For some clinical presentations—for example, a responsive tumor (e.g., lymphoma) located in radiation-tolerant tissues such as the low neck—cure is possible without a major risk of serious complications. In other situations—such as the setting of advanced prostate cancer, where rectal complications can occur—cure is possible, but the risk of long-term complications cannot be dismissed. In still other situations—such as damage to normal brain tissue while treating high-grade gliomas—cure might not be possible without the risk of severe disability. Finally, an increase in the control rate in many clinical situations might be possible only at the expense of more complications unless ways can be found to increase the tumor dose without substantially increasing the dose to surrounding normal tissues. The latter concept underlies the increased use of interstitial implantation techniques and three-dimensional conformal dose delivery, discussed in detail later in this chapter.

It should be remembered that complication risk and chances of cure trade off against one another. Complications are an inherent risk of any medical treatment, and one must weigh the risks of failure to control the tumor against the advantage of local control associated with a complication. Consideration also should be given to whether a complication can be managed with other types of treatment, for example surgical transposition of the ovaries to reduce the chances of radiation menopause in a young female patient undergoing radiation treatment to the pelvis. Understanding the effects of radiation on normal tissues is critical to the proper use of this treatment modality in the context of a patient's treatment as a whole.

Acute Effects on Normal Tissues

The acute effects of radiation result from direct damage to parenchymal cells of organs that are sensitive to radiation. Traditionally, an *acute effect* has been defined as an effect seen during treatment and up to 3 months from the conclusion of therapy. A detailed discussion of this subject is beyond the scope of this chapter; it has been reviewed in other textbooks.[7,104] Table 29-5 summarizes the acute effects of radiation and their management.

Late Effects on Normal Tissues

Late effects are those that occur more than 3 months from the end of therapy. Virtually any organ or tissue that is treated can express a syndrome of late radiation damage. The mechanism of late tissue damage is likely to be multifactorial. Some radiobiologists believe that it is due to slow dropout of small vasculature, leading to organ cell loss, fibrosis, and eventual late organ failure.[105] Evidence for this viewpoint is supplied by morphologic studies of irradiated tissues, where decreased vascularity can be observed in virtually every tissue type.[105] Others believe that late damage is due in large part to direct damage to parenchymal cells. This theory is plausible, as organs have widely differing sensitivities to radiation, but there is little evidence

Table 29-5 Acute Effects of Radiation

Organ	Symptom/Sign	Management
Systemic	Lethargy, fatigue	Symptomatic
Skin	Erythema, dry desquamation, pruritus, moist desquamation	Observation; low-dose topical corticosteroids for pruritus; avoidance of occlusive dressings or clothing; aqueous creams
Oral mucous membranes/teeth	Mucositis, ulceration	Dental consultation pretreatment; rinse with sodium bicarbonate; fluoride treatment; viscous xylocaine and oral analgesics for pain; watch for and treat candidiasis
Esophagus	Esophagitis	Systemic analgesics; consider diagnosis of opportunistic inflection
Lung	Pneumonitis, cough	Observation in mild cases; prednisone in severe cases
Liver	Radiation hepatitis	Symptomatic management; prednisone in severe cases
Bowel	Cramping, diarrhea, nausea, vomiting	Antidiarrheal agents; sulcralfate; antiemetics; low-residue diet
Bladder	Frequency, urgency, dysuria, hematuria	Analgesia; antimuscarinics for bladder instability; alpha$_1$-blockers for obstructive symptoms in men
Rectum	Proctitis, bleeding, tenesmus	Symptomatic; corticosteroid suppositories
Hematopoietic	Lymphopenia, thrombocytopenia, anemia, cytopenia	Supportive; transfusions; aggressive treatment of infections

Table 29-6 Approximate Organ Tolerance Doses in Radiation Therapy Estimated from Preclinical and Clinical Data

Organ	Toxicity	Tolerance Dose (cGy)*
Brain	Necrosis	6000
Eye	Cataract	600
	Keratitis	5000
	Retinal damage	4500
Pituitary	Hypopituitarism	4500
Spinal cord	Paralysis	5000 (5-cm segment)
Skin	Necrosis	6000 (10 × 10 cm)
Salivary gland	Xerostomia	4000
Thyroid	Hypothyroidism	4500
Lung	Pneumonitis	2000
Heart	Peri-/paracarditis	4500
Esophagus	Stricture	6000
Liver	Hepatitis	3000
Stomach	Ulcer/hemorrhage	5000
Kidney	Nephritis	2000
Rectum	Ulcer/hemorrhage	6000
Ovary	Sterility/menopause	600
Testis	Sterility	200
Bladder	Contracture	6500

*Dose to whole organ at 200 cGy per fractron, 5% complication level.

to suggest that blood vessels in one part of the body are more or less radiosensitive than in any other part. Thus, if vascular damage were a final common pathway, then most organs should share similar radiation tolerance doses, and they do not.[106] In all likelihood, late damage represents a combination of vascular damage and direct organ cell depletion.[107,108] Table 29-6 provides a summary of organ tolerances to radiation.

Carcinogenesis

Because radiation causes damage to DNA and some of the damage is misrepaired, it is not difficult to conceive that a radiation-damaged piece of DNA could be misrepaired with a small but nonlethal mistake. Alternatively, a base in the DNA strand could be damaged in a manner that is nonlethal, but alters the base sequence. Such a change in the sequence of DNA bases is called a *mutation*, and some mutations can lead to malignant transformation of the cell. Thus, radiation would be expected to be a carcinogen, and decades of research have confirmed this fact. In fact, radiation probably is the most thoroughly studied carcinogen. Its ability to induce malignancy was first seen in the pioneers of clinical radiation research, many of whom lost limbs or their lives to multiple aggressive skin cancers caused by repeated exposure to x-rays. Over the years, a number of radiation-exposed populations have been studied, including radium watch dial painters and patients exposed to radiation for benign diseases. Five well-known examples of the latter are tuberculosis victims examined with multiple fluoroscopies over the course of many years, patients with postpartum mastitis whose breasts were irradiated, patients with ankylosing spondylitis who received spinal irradiation, children who received scalp irradiation for tinea capitis, and children treated with radiation to reduce thymic enlargement.[109–113] Two of the largest and most carefully studied populations exposed to ionizing radiation have been the survivors of the atomic bomb explosions from Japan during World War II and the survivors of the Chernobyl nuclear accident in the former Soviet Union in 1986.[114–116]

Several basic principles of radiation-induced carcinogenesis have been elucidated by studying these populations:

- Radiation-induced cancer appears several years after exposure, often 4 to 10 years later for radiation-induced leukemias and 10 to 30 years later for solid malignancies.[117]
- Leukemia is the most common primary tumor associated with previous radiation exposure, with relative risks of 30 or greater over that of the general population. The incidence of leukemia peaks 6 to 8 years after radiation exposure, after which time the incidence tails off.[118]
- Not all cancers can be associated with previous radiation exposure. Whereas thyroid and breast cancer are commonly associated, pancreatic and rectal carcinomas appear to have little association with previous radiation induction. No discernible pattern of organ sensitivity has been deduced.[119]
- Radiation induction of cancer is age sensitive. For example, radiation of breast tissue during the teens and 20s is more commonly associated with subsequent breast cancer than irradiation after age 50 years.[120]
- The age distribution of radiation-induced cancers is similar to the naturally occurring incidence pattern. This finding suggests that radiation facilitates the appearance of malignancy rather than being entirely causative of the problem.[121]
- There is a relationship between radiation dose and cancer induction. Cancers are induced with increased frequency as dose increases up to a point, after which increasing dose decreases the appearance of malignancy in both experimental and clinical situations (Fig. 29-20).[74] This is likely due to the amount of DNA damage being caused; at lower doses, cells can survive while sustaining nonlethal mutations, whereas at high doses, lethal mutations dominate. This finding implies that a high-dose therapeutic course of radiation should not induce large numbers of cancers in survivors. This

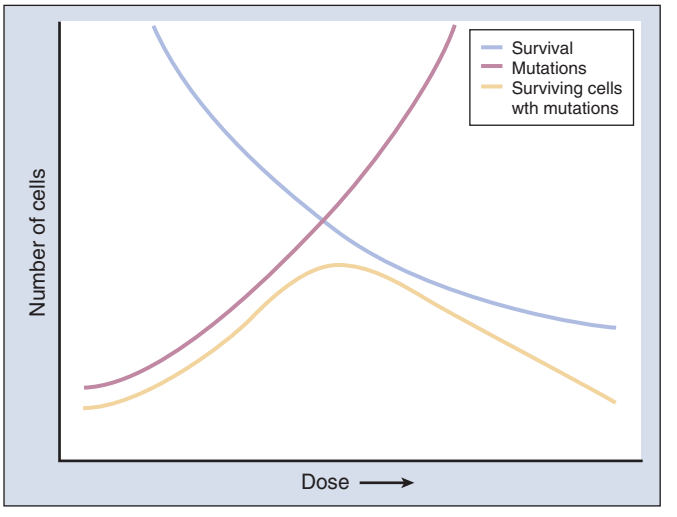

Figure 29-20 • Relationship between dose and viable mutations. As the dose increases, the number of mutations increases. As dose increases, however, survival of cells decreases. The composite, labeled "surviving cells with mutations," has a characteristic shape. Mutations increase up to a relatively low dose level and then begin to decrease. High-dose therapeutic radiation produces a very small number of secondary induced cancers. (From Lichter AS: Radiation therapy. In Abeloff M [ed]: Clinical Oncology, 2nd ed. London, Churchill Livingstone, 2000, pp 423–470.)

appears to be the case, although it should be emphasized that cancer induction from high dose radiation treatment has been clearly documented.[122]

Although low doses of radiation can cause cancer, it is not known whether any dose is so low as not to be dangerous—i.e., whether a threshold for adverse effects exists below which small doses of radiation have no biologic effects. Our information on radiation carcinogenesis comes from dosage data in the tens and hundreds of centigrays (cGy). We have little or no data from doses in the 1- or 2-cGy range, and even fewer data in the tenths of cGy range, which are the doses associated with many diagnostic x-ray exposures and with some population exposures relating to emissions from nuclear facilities, working with tracer doses of radionuclides, or visiting a patient with a radioactive implant in the hospital.[123] If a safe threshold were determined, it would make the public health aspects of radiation protection much less problematic. Currently, a conservative approach to radiation exposure is followed in most developed countries, although rules vary locally. In general, it is assumed that any radiation exposure is associated with risk in a linear fashion. Furthermore, population protection levels are calculated with an even more conservative concept of person-cGy, which implies that the same cancer risk will occur if one person is exposed to 1000 cGy that will occur if 1000 persons are each exposed to 1 cGy. From a biologic point of view, this type of calculation seems illogical, but it forms the basis of estimates for the amount of radiation to which the general population can be exposed with safety.[124] Overall, it is prudent to eliminate as much unnecessary radiation exposure as possible. On the other hand, medically necessary radiation in the form of diagnostic or therapeutic radiation can be more life saving compared to the risk of exposure and usually can be justified under even the most stringent estimates of carcinogenic risk of radiation.

PROCESS IN RADIATION TREATMENT

Radiation therapy is an important component of many patients' treatment regimens. It often is combined with surgery or chemotherapy for optimal treatment of cancer. After the patient has been evaluated and the decision to use radiation has been made, perhaps the most important step in a radiation treatment course is the design of the radiation treatment itself.

Treatment Planning

Successful treatment planning is imperative to the success of a radiation treatment course. Formulation of the management plan for an individual patient involves discussion among radiation oncologists, radiologists, pathologists, surgeons, physicians, nurses, and radiographers. The basis for the prescription of radiation therapy takes into account diagnostic studies, the limitations of radiologic studies, evaluation of tumor extent (staging), knowledge of pathologic characteristics of the disease, a clear definition of the goal of therapy, and consideration of appropriate and alternative treatment modalities. The optimal dose of irradiation depends on the volume to be treated, the anatomic location, the histologic type of the tumor, the stage, and the potential regional spread. The dose-limiting factor usually is one or more normal structures in the region. The patient's general condition must be evaluated initially, with periodic assessment of treatment tolerance during irradiation. The goal is to identify the full extent of the tumor and areas of possible spread. Several considerations must be taken into account when determining the volume to be treated. These considerations include the tumor histology; the extent of gross disease; regions of microscopic spread but no gross disease; whether the treatment is being given postoperatively or in an undisturbed tumor bed; and the tolerances of adjacent structures. A plan must then be devised to treat this entire region to the dose desired for each region while keeping the volume of normal tissue below its tolerance dose.

The process of designing a radiation field starts with *simulation*, which is used to map out the extent of disease and its relationship to other organs when the patient is in the treatment position. Once simulation has been performed, the treatment position cannot be altered without the risk of inaccurate treatment delivery. Initially conventional simulators were fluoroscopy units designed to mimic the geometry of the treatment machines. Fluoroscopy was used to outline the boundaries of the field, with plain film x-rays being taken to include the general outline of the area to be treated. Although fluoroscopic simulators still are in use, many three-dimensional (3-D) treatment planning systems now are available to permit more accurate or more conformal delivery of radiation treatment. 3-D treatment planning systems use CT data (in some cases, augmented by fusion with other radiologic modalities) to simulate radiation delivery. This can be accomplished in a variety of ways:

- The field can be set up by transferring CT data onto conventional simulation films.
- CT images can be transferred to a computer-based treatment planning system. The fields are designed using the CT-based planning system, with verification (i.e., checking the treatment position) performed by taking x-ray films on a conventional simulator.
- The third and most efficient method is to use a CT simulator to set up the radiation fields. The CT simulator combines the processes of obtaining CT images and field design. CT images of the patient are transferred directly to a computer system that allows the physician to outline the tumor volume and critical structures on individual CT slices. This, in effect, produces an accurate 3-D recreation of both the tumor that is to be treated and normal tissues that are to be avoided during the delivery of radiation.
- Additional data from magnetic resonance imaging (MRI) scanning or positron emission tomographic imaging can be fused with images obtained in the CT simulator in order to improve the accuracy of planning.

After the image data sets are obtained in any type of simulation, careful review of the clinical data must be done to delineate the tissue to be treated. The volume to be treated is defined as the *target volume* and is created by adding three components together.[125] First, the gross tumor volume (GTV) is delineated. The *gross tumor volume* consists of all known detectable disease, including any abnormal regional lymph nodes. This volume refers to the total volume of tumor detectable by diagnostic procedures such as CT or MRI scanning and endoscopic procedures. The *clinical tumor volume* (CTV) encompasses the gross tumor volume plus regions considered to harbor potential microscopic disease and other areas at risk for spread, such as draining lymphatic regions. The *planning target volume* (PTV) includes a margin around the clinical target volume to allow for internal target motion, other anatomic motion during treatment (e.g., respiration), and variations in treatment set-up. Finally, a margin must be added to account for the physical characteristics of radiation such as the penumbra (the edge of the beam where dose falls off rapidly). After a complete surgical resection with no residual detectable tumor and clear surgical margins, a GTV cannot be defined and the radiation oncologist will proceed directly to outline a CTV. Examples of 3-D treatment planning are shown in Figure 29-21.

The planning process also involves choosing the number of radiation beams required, the energy of these beams, the angles, and the weighting (i.e., proportion of total energy deposition) of these beams needed to deliver the required radiation dose to the tumor with optimal sparing of normal tissues. Beams also may be modified to improve the delivery of dose. After the plan has been designed by radiation physicists, *digitally reconstructed radiographs* are produced from CT data to represent the treatment fields. *Beam's eye views* also are valuable to the radiographers delivering the treatment, since they offer a radiographic representation of the orientation of each beam. The availability of 3-D treatment planning has allowed for much more complex plans in the attempt to increase the therapeutic ratio

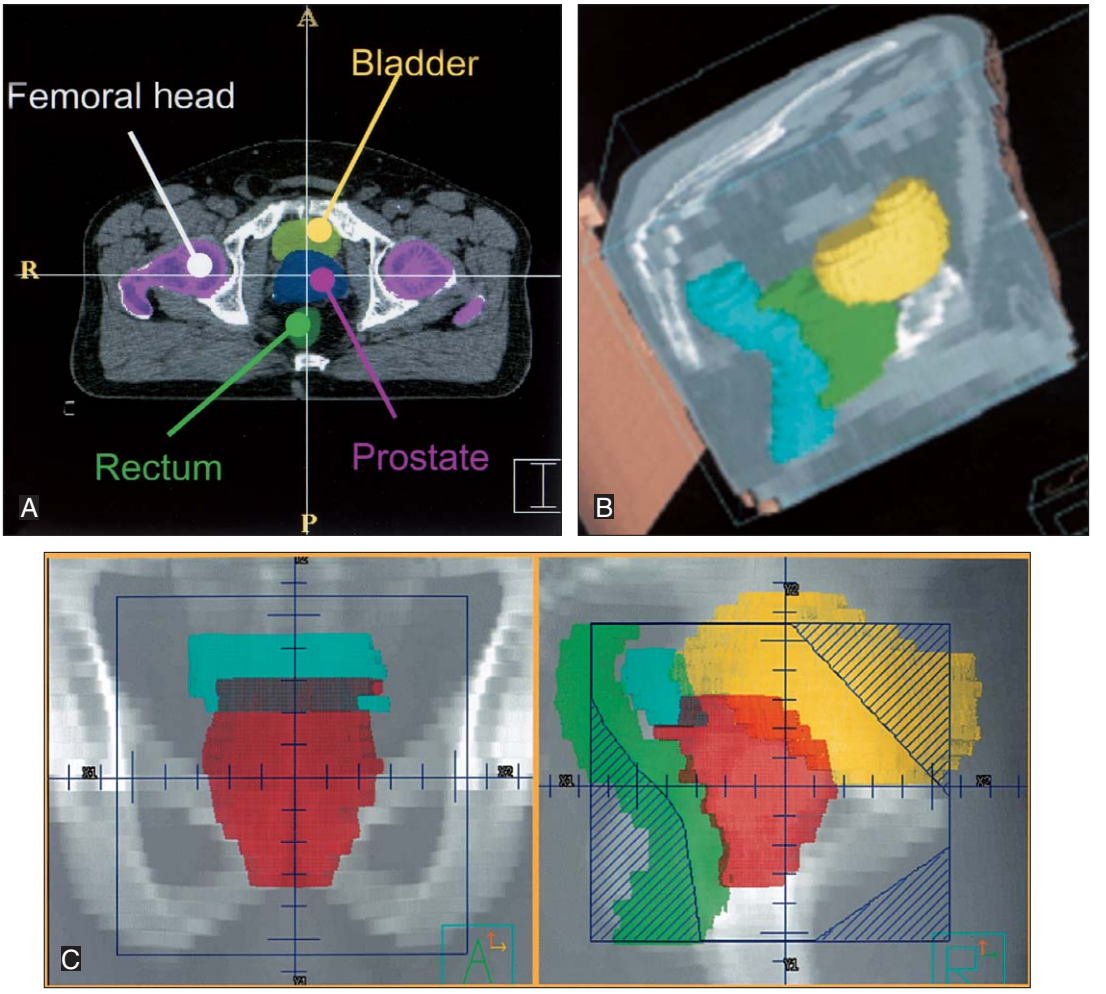

Figure 29-21 • **A,** Transverse CT scan of a male pelvis with simulated organs shown. **B,** Three-dimensional surfaces of the prostate (*green*), rectum (*blue*), and bladder (*yellow*) reconstructed from outlines drawn on CT images. **C,** Digitally reconstructed radiographs (DRRs) of conventional anteroposterior and lateral fields. Prostate is shown in red, seminal vesicles in blue, rectum in green, and bladder in yellow. (From Cox JD, Ang KK [eds]: Radiation Oncology: Rationale, Technique, Results, 8th ed. St. Louis, Mosby, 2003.)

via the design of radiation fields, as the doses to the tumor and normal organs can be evaluated accurately and three dimensionally. This evaluation process allows assessment of the possible toxicity that could result from the radiation treatment via the evaluation of a *dose volume histogram*, which shows the dose delivered throughout the volume of the tumor and each normal organ in the radiation field. Although usually it is unacceptable to treat an entire organ beyond its tolerance, there are circumstances when portions of an organ may be treated to close to or even beyond tolerance. A consideration is whether the organ in question is considered to have a serial or parallel structure (see previous discussion). In an organ with a serial structure, failure of any component of the organ will cause failure of the entire organ. An example of this might be the spinal cord, where taking any segment of the cord beyond cord tolerance will cause failure of everything downstream. In a parallel organ, however, such as the lung or kidney, the patient might be able to tolerate loss of part of the organ's function, provided certain volume considerations are not exceeded (Fig. 29-22).

Normal tissues can be shielded within radiation beams in various ways. The first shields or blocks were manually placed pieces of lead or depleted uranium that were inserted in the radiation field to shield the structures below them. Following the discovery of a low-melting-point alloy of lead with similar beam attenuating properties, it became possible to create complex blocks that followed the divergent properties of the beam to shield organs defined on the simulation films more accurately.[126] Blocks were custom made for each patient, taking into account the divergence of the beam from its source. A newer method of shielding available in modern linear accelerators involves the use of a *multileaf collimator* (MLC). The MLC system uses 1- or 0.5-cm "leaves" that actually are partitioned jaws of the collimator in the head of the treatment machine. These leaves can be moved in from the edges of the field to block the radiation field and effectively shape the beam as desired (Fig. 29-23).

Once treatment planning is completed, including verification of the treatment position if required, the patient begins the course of radiation therapy. Each day, the patient is positioned by treatment radiographers in the exact position in which the simulation and verification were done. To aid in positioning, immobilization devices are often used, such as foam knee supports, vacuumed bags for limbs, body casts, or perspex/thermoplastic head masks ("shells"). These are made prior to simulation and are kept for use throughout the entire radiation course. For young children (generally less than 4 years of age) or for any patient unable to keep still when left alone in the treatment room, general anesthesia may be required for simulation and for each fraction of radiation therapy. Most modern radiation treatments are *isocentric*, meaning that there is one point around

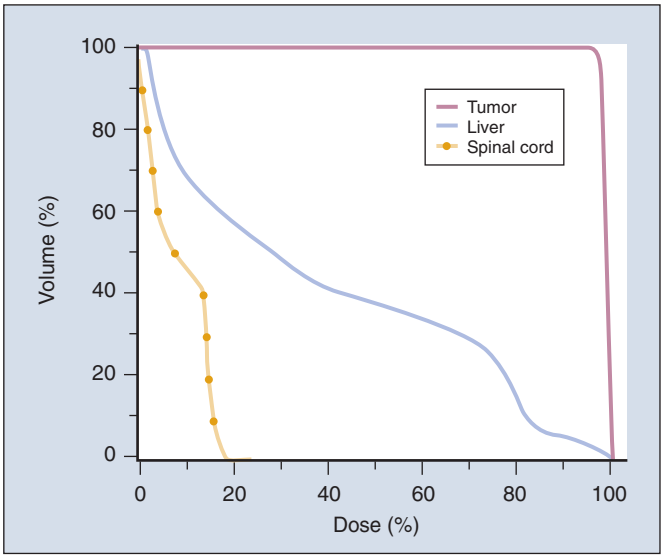

Figure 29-22 • Dose-volume histogram. The percentage of the volume of a structure receiving a percentage dose level or more is illustrated in this cumulative histogram. For the tumor, 100% of the volume receives 100% of the dose, which is the desirable situation. For normal structures, lesser doses are given. In this example, 40% of the liver received 40% or more of the dose, and 20% of the spinal cord received approximately 17% or more of the dose. A small portion of the liver received more than 90% of the prescribed dose, while no portion of the spinal cord received more than 20% of the prescribed dose. This plot is quite useful in presenting a large amount of complex three-dimensional dose-volume information in a fashion that can be assimilated quickly. (From Lichter AS: Radiation therapy. In Abeloff M [ed]: Clinical Oncology, 2nd ed. London, Churchill Livingstone, 2000, pp 423–470.)

which the treatment machine ("gantry"), the couch, and the collimator in the head of the treatment machine rotate. Laser lights in the simulator and the treatment room are used to assist in the positioning of the patient relative to the isocenter. The reproducibility of the patient's treatment position is monitored on a daily or weekly basis by the use of portal images taken from the treatment machine while the patient is in the treatment position. Because treatment machines produce megavoltage radiation, the quality of these images is inferior to those produced by diagnostic machines, which produce radiation in the kilovoltage range (see the section on Photoelectric Effect).

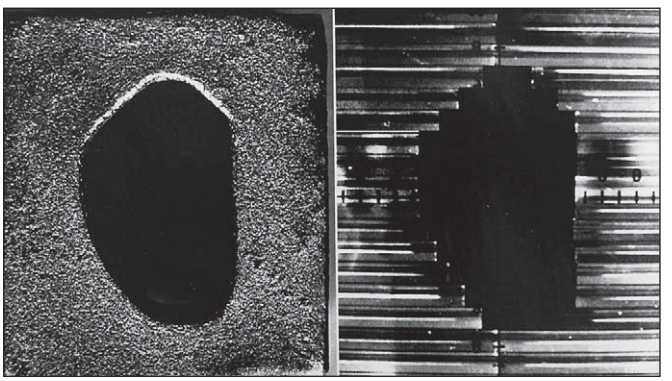

Figure 29-23 • Traditionally, radiation fields have been shaped by molding blocks made from a low-melting-point lead alloy (*left*). The same shape can be created within seconds using a multileaf collimator (*right*). Multiple pairs of thin leaves are each driven by their own motor. The desired shape of the field is entered into a computer that drives the leaf motors and creates the desired shape. (From Lichter AS: Radiation therapy. In Abeloff M [ed]: Clinical Oncology, 2nd ed. London, Churchill Livingstone, 2000, pp 423–470.)

Clinical Use of Radiation Therapy

Radiation is employed to treat cancer in most parts of the body. It can be used as definitive treatment (with or without chemotherapy) where radiation is the sole curative modality (Table 29-7). This type of definitive radiation therapy is used in place of a surgical procedure, and it is often referred to as "organ sparing" or "organ preserving." Examples include the treatment of laryngeal cancer, cervical cancer, and localized bladder cancer.[87,127,128] Brachytherapy also is used in this context (see later discussion). If the cancer is not eradicated completely by radiation therapy, or if it recurs, subsequent surgical resection is described as *salvage*.

Radiation also can be used prior to surgical excision ("neoadjuvant radiation therapy") or after a definitive surgical procedure ("adjuvant radiation therapy"), either to reduce the morbidity of surgery or to increase the likelihood of local and regional control.[129,130] The aim of combining treatments usually is to improve the chances of cure and to preserve organ function. Clinical examples of these strategies include the treatment of breast cancer and soft tissue sarcoma.

As described earlier in this chapter, chemosensitization of tissues to radiation can have a synergistic effect on tumor cell kill, thus increasing the therapeutic index. Such effects have been demonstrated in the treatment of head and neck cancer, small cell lung cancer, non-small-cell lung cancer, cervical cancer, bladder cancer, anal cancer, pancreatic cancer, glioblastoma multiforme, and esophageal cancer.[87–92,131] The most prominent examples of the importance of combining concomitant chemotherapy with definitive radiation therapy are improvements in survival that have been demonstrated by the addition of cisplatin to radical radiation therapy for locally advanced cervical cancer and locally advanced head and neck cancer.[87–89] According to two large multicenter phase III trials studying postoperative radiation treatment of locally advanced head and neck cancer, concomitant cisplatin chemotherapy improves local control and progression-free survival, but it is associated with increased morbidity.[90,132] The reader interested in the use of cisplatin or cetuximab in combination with high-dose radiation therapy for head and neck cancer is referred to Chapter 72. The risk of severe or fatal toxicity to normal tissues should be considered carefully when planning clinical trials of chemosensitization combined with novel approaches to radiation therapy, because fatalities have been reported.[133,134]

Worldwide, radiation therapy is the most widespread method employed to palliate symptoms related to tumor spread or growth.[7,135] The most common example of this clinical use is the treatment of bone metastases with hypofractionated (i.e., a small number of large fractions) courses of radiation therapy to provide rapid relief of pain. Although the feasibility depends on the dose previously delivered and normal tissues within the field, retreatment with radiation should always be discussed with the patient's radiotherapist to provide rapid palliation. Radiation remains the main treatment modality for the relief of symptoms in patients with progressive and incurable cancers. It often is employed to stop bleeding, to relieve obstruction (e.g., of airway, gut lumen), and to relieve pain. Some of the most gratifying experiences in radiation oncology come from the ability to relieve symptoms in patients with progressive cancer and to diminish their reliance on major opioids for analgesia. Further examples of improving a patient's quality of life with radiation therapy are early intervention for spinal cord compression caused by multiple myeloma or treatment of painful bone metastasis from prostate cancer. Radiation oncology in this manner epitomizes Osler's dictum, "To cure sometimes, to relieve often, to comfort always—this is our work."

Table 29-7 Postulated Inter-relationship of Biological Dose, Tumor Size, and Control by Irradiation

Total Dose (Gy)*	Histology	Size	Control (%)
50	Squamous	Subclinical (<10^6 cells)	95+
	Adenocarcinoma		
60	Squamous	<2 cm	85
		>4 cm	50
65	Squamous	2–4 cm	70
70	Squamous	2–4 cm	90
	Adenocarcinoma	>4 cm	60
75+	Squamous	>4 cm	90

*Approximation based on a minimum tumor dose of 2 Gy per fraction and five fractions per week.
From Cox JD, Ang KK (eds): Radiation Oncology Rationale, Technique, Results, 8th ed. St. Louis, Mo, Mosby, 2003, p 33.

NEW MODALITIES IN RADIATION

In addition to research directed at increasing the therapeutic ratio in radiation therapy, many of the largest advances in radiation oncology have resulted from improvements in the technology used to deliver radiation. Although it is not feasible to cover all the recent major advances in radiation therapy in this section, the basic principles are described for four modalities that have been adopted as important radiation treatments by large cancer centers.

Brachytherapy

Derived from ancient Greek word for "short distance" (*brachy*), the term *brachytherapy* refers to the placement of radioactive seeds or sources inside or next to a tumor. It is also known as *sealed source radiation therapy* or *endocurietherapy*. The seeds/sources deliver radiation directly to the tumor, potentially sparing surrounding healthy tissue better than external beam therapy or teletherapy.[135] If brachytherapy is used as an alternative to surgery, for example, in prostate or cervical cancer, it is described as "organ sparing." The radioactive sources are referred to as *sealed sources*, as opposed to systemic targeted radionuclide therapy (see the section on Systemic Targeted Radionuclide Therapy), in which the radioactivity is unsealed. Thin needles or hollow applicators often are used to insert sealed sources into the tumor. Interstitial, intracavitary, and intravascular brachytherapy currently are practiced.

Interstitial Brachytherapy

In interstitial brachytherapy, sealed sources are inserted into tissue, for example, the oral cavity, skin, or anus. The most common sealed source is iridium 192 wire. Iridium wire can be arranged using either the Manchester or the Paris systems; the latter was designed specifically to take advantage of the new nuclide.[136–138] The aim is to treat all parts of the target volume within 10% of the prescription dose. This form of brachytherapy can be further subdivided into two types: permanent, in which sealed sources remain inside the body; and temporary, in which the seeds are removed from the body after the treatment. Cancers treated with temporary implants include soft tissue sarcoma and squamous cell carcinoma of the oral cavity. In the treatment of prostate cancer, radioactive seeds (e.g., iodine 125) about the size of a grain of rice stay within the treatment area permanently. Some migration of the seeds may occur with time.

Intracavitary Brachytherapy

Intracavitary brachytherapy places the sources inside a pre-existing body cavity. The most common applications of this method are gynecologic, particularly for cervical cancer, although it also can be used in other cavitary structures such as the nasopharynx or rectum. The move to reduce the medical staff's radiation exposure led to the introduction of *remote afterloading* brachytherapy devices, in which hollow tubes are connected to a safe containing a small radioactive source welded to a wire that is driven out by a stepping motor to predetermined positions to deliver radiation treatment. The motor is engaged only when all staff have left the shielded room that holds the patient for the duration of the treatment. Over 50 different types of intracavitary applicators exist for remote afterloading.[136] Although *high-dose-rate* (HDR) brachytherapy, often using iridium 192, may be performed as an outpatient procedure, low-dose-rate (LDR) brachytherapy with cesium 137 requires hospital admission because of the length of continuous treatment.

Intravascular Brachytherapy

Intravascular brachytherapy places a catheter with the sealed sources inside a blood vessel, usually an artery. The most well-established application of this method uses strontium 90 as a treatment for coronary artery stenosis in ischemic heart disease. More recently, glass or resin microspheres containing yttrium 90 have been developed to treat hepatocellular carcinoma or liver metastases.[139]

Systemic Targeted Radionuclide Therapy

Systemic targeted radionuclide therapy involves the delivery of radioisotopes specifically to cancer cells. This can be achieved through the design of radiolabeled pharmaceuticals targeted against cell surface molecules that are differentially expressed in cancer compared to normal cells. The radiobiologic effects of these agents depend on the physical characteristics of the radionuclide, such as half-life and the nature of the particulate radiations that are emitted, and on the abundance and distribution of the target molecule within the tumor.[140] An important example of systemic radiation therapy is the use of ^{131}I-NaI to treat thyroid cancer and nonmalignant hyperthyroidism.[141] The success of this treatment is due to the selective uptake and concentration of iodine by the thyroid. This treatment has been used for over half a century, and hundreds of thousands of patients have received this therapy worldwide. Radioiodine therapy is remarkably safe; the only common side effect is hypothyroidism. An overview of long-term safety data suggests that the risk of developing thyroid cancer or other primary malignancies is not increased by radioiodine therapy.[7]

Delivering radioisotopes to cancers of other organs with similar precision has proved more challenging. The discovery of monoclonal antibodies (mAb) in the mid-1970s (see Chapter 34) gave rise to much optimism that, if directed against tumor-associated antigens, they could be used to deliver radioisotopes specifically to tumors.

After years of development and research, this treatment modality, called radioimmunotherapy (RIT), has come to fruition. The CD20 differentiation antigen, expressed by more than 95% of B cell lymphomas, is targeted by mAbs conjugated to iodine 131(^{131}I-tositumomab; Bexxar [GlaxoSmithKline]) and ytrrium 90-^{90}Y-ibritumomab tiuxetan; Zevalin [Biogen Idec Inc]). Both agents are approved for use in the treatment of relapsed low-grade or follicular B cell lymphoma, with an overall response rate of about 80%.[142] These drugs often are effective even in tumors that are resistant to treatment with a naked anti-CD20 antibody, rituximab. Other indications for RIT in the treatment of non-Hodgkin's lymphoma, such as in the adjuvant setting after chemotherapy and as preparation for stem cell transplantation, are being explored in clinical trials.[143]

In contrast to the successful treatment of hematologic malignancies, RIT of the common solid malignancies has been severely limited by toxicity to the bone marrow, poor tumor penetration, the significantly lower radiosensitivity of these malignancies compared to NHL, and the development of an immune response to the mAbs, which has restricted the ability to administer repeated treatments. Numerous phase I and II trials of radiolabeled antibodies directed against a variety of tumor-associated antigens have been conducted.[144] A few patients have achieved complete response, but more often partial or minor responses are reported. Some encouraging results have been reported in the setting of minimal residual disease, because small tumor deposits and micrometastases accumulate disproportionately high amounts of radioimmunoconjugates compared to larger tumors. Several research strategies are being pursued in an effort to improve the RIT of solid tumors.[145,146]

An important development in the field of systemic targeted radiation therapy has been the recognition that small peptides that are natural ligands of surface receptors might be used as vehicles for radioisotope delivery. This form of treatment has been called *peptide receptor radiation therapy*.[147] The low molecular weight of peptides results in efficient tumor penetration. Peptides are rapidly eliminated from the blood by renal excretion, which results in lower bone marrow toxicity and permits dose escalation. Peptide-directed radiation therapy using radiolabeled octreotide (a synthetic analogue of somatostatin) has been tested extensively in tumors that express somatostatin receptors.[148]

In general, β-emitters have been use for systemic radiation therapy. Since β particles have a track length of a few millimeters, not every cell within a tumor need be directly targeted. Adjacent cells will be irradiated through the so-called "crossfire" effect. Unfortunately, the crossfire effect also may result in the irradiation of normal cells and contributes to toxicity. For this reason there has been recent interest in isotopes that emit α-particles or Auger electrons.[149,150] These have much shorter track lengths and, therefore, if they can be accurately delivered to malignant tissue, are less likely to cause serious normal tissue damage.

Radioimmunotherapy now plays a central role in the treatment of non-Hodgkin's lymphoma. With further advances in the field, molecularly targeted radiotherapeutic agents are likely to be increasingly important in the treatment of cancer.

Intensity-Modulated Radiation Therapy

Radiation therapy is the earliest example of a targeted therapy for cancer: it aims to deliver a dose to tumor and to diminish the dose to adjacent normal structures. The concept of conformal radiation is not new. The first report of field shaping to conform to the shape of the tumor was published in 1959.[151] Remarkably, automated computer-driven treatment planning also was reported in the 1950s.[152] A great advance was made in the 1970s in making the computer and the conformal planning more three-dimensional by virtue of the development of the beam's-eye view display.[153] The beam's-eye view display is reconstructed from x-ray or CT data and provides a view from the source of the radiation beam. This technological advance, coupled with the development of the diagnostic CT scanner, led to the prospect of anatomy definition that had not been possible in radiation treatment planning and resulted in significant improvement in defining tumor volumes and critical structures.[154] In the late 1980s, 3-D radiation treatment planning systems began to be used more widely.[155] Significant additional technological advancements in 3-D treatment planning systems continue to be made to improve radiation therapy, particularly with regard to the integration of CT and MRI into the planning, verification and monitoring processes.

The goal of 3-D conformal radiation therapy is to shape the area of high dose to the tumor volume while minimizing the dose to the surrounding tissues. The high dose is delivered to the tumor volume using a set of fixed radiation beams, with normal tissue surrounding the tumor volume shielded from receiving the full dose of radiation. This shielding classically has been done with blocks made from Cerrobend, a lead alloy, which stop the transmission of photons to those areas desired to be shielded. The development of the linear accelerator offered the ability to deliver shaped uniform beams from multiple angles as it rotated around the patient. The introduction of the multileaf collimator, whereby the machine shaped the beams rather than requiring additional beam-shaping devices such as Cerrobend blocks, made conformal radiation therapy significantly easier and more widely available.

Because the leaves in a multileaf collimator are computer driven, it also is possible to move the leaves continuously during treatment. Treatment has thus become *four-dimensional* (i.e., in time and space), and allows the use of beams that are deliberately nonuniform to deliver varying doses to varying parts of the treatment field. The CT simulator allows the treatment to be simulated in virtual time rather than in real time, allowing the physicist and physician, assisted by sophisticated computer software, to evaluate dozens or hundreds of treatment plans to optimize the dose to the tumor. This technology forms the basis for intensity-modulated radiation therapy (IMRT).[156] IMRT involves variation in the intensity of the x-ray output from a linear accelerator and the use of multiple shaped treatment fields. Although the treatment can be delivered by standard modern linear accelerators, the planning process is significantly more labor intensive than conventional radiation therapy and requires the use of more sophisticated modeling software for optimization.[157]

Several IMRT delivery techniques are available, such as combining photon and electron beams, including serial tomotherapy, or using a conventional multileaf collimator (Fig. 29-24).[156,157] In tomotherapy, radiation is delivered in narrow slit beams, analogous to the techniques used for CT imaging systems.[157] Treatment is delivered to a narrow slice of the patient in an arc-type rotation. As the machine rotates around the patient, delivering radiation in an arcing manner, "beamlets" of varying intensity of radiation delivered are created by dynamic movement of the machine's multileaf collimator. In areas to which more dose is to be delivered, the leaves of the multileaf collimator are out of the field longer compared with those areas that require less deposition of dose. The end result of these interactions in serial adjoining axial slices is the conformal treatment that is desired. IMRT also can be done using static field techniques, where the beam moves to various fixed positions around the patient, but the multileaf collimator is used to vary the intensity of different parts of the beam during treatment of each field.

In these highly evolved treatments, optimization of these plans would not be possible without specialized computer software.[158] An important concept used for most IMRT is that of *inverse planning*, in contrast to the forward planning that is used for most conventional treatment planning. In forward treatment planning, the beam orientation, shape, size, modifiers, and so on are defined first, followed by the calculation of dose that results from this design. Changes to achieve better dose distribution are made by modifying the beam weighting, adding or subtracting beams, and so forth, until the desired dose distribution is achieved. In inverse treatment planning, the desired dose distribution is stated first, followed by computer

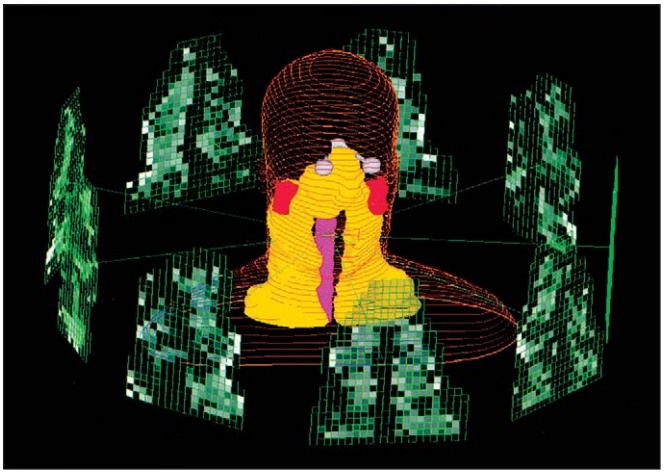

Figure 29-24 • Advanced form of 3-D IMRT, which is based on the use of optimized nonuniform radiation beam intensities incident on the patient. Shown are a 3-D view of the patient, the PTV, spinal cord, parotid glands, and the nine intensity-modulated beams (with gray levels reflecting the intensity value) used to generate the IMRT dose distribution.

optimization to adjust beam intensities to attempt to achieve that dose distribution. *Optimization* includes stating the dose that the tumor bed or areas at risk should receive, as well as limits of dose that normal tissues will be permitted to receive. These parameters are based on maximizing the probability of tumor control and minimizing the toxicity profiles of the various normal tissues and organs. Because normal tissues have different tolerances, different organs will have different thresholds. After the computer optimizes the dose distribution, the physician may choose what is deemed to be an optimal plan (Fig. 29-25).

Many clinical studies have verified that IMRT provides superior dose distribution over conventional 3D conformal radiation, although most of these studies have reported on small numbers of patients.[159–163] Since the goal of IMRT is to increase the therapeutic ratio, delivering a higher tumor dose relative to normal tissues, IMRT can be used to escalate the tumor volume to a higher dose while maintaining normal tissue toxicity at a tolerable level. Among the cancer sites investigated using IMRT to escalate total dose are non-small-cell lung cancer, head and neck cancer, intracranial tumors, and prostate cancer.[159–163] Alternatively, IMRT can be used to deliver conventional doses to the tumor bed, resulting in lower dose to normal tissues, with hopes of reducing toxicity. It is anticipated that favorable dose distributions should result in decreased toxicity,

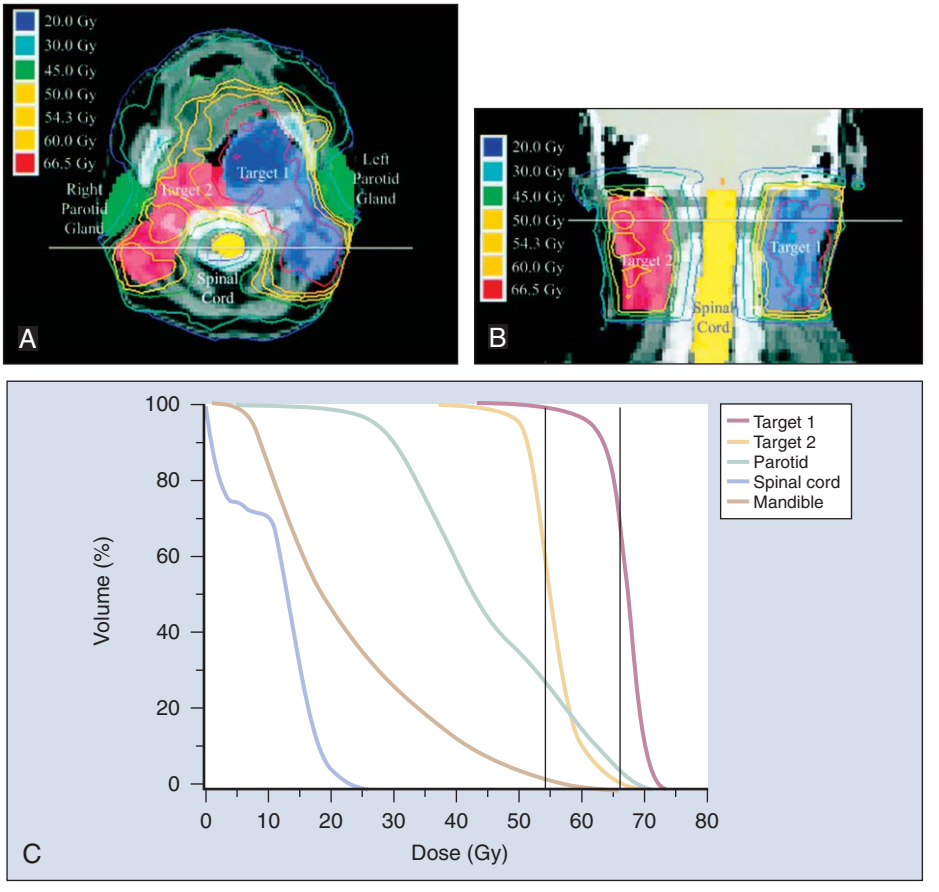

Figure 29-25 • Typical head-and-neck IMRT treatment plan showing conformal avoidance of the spinal cord and parotid glands, while simultaneously delivering multiple dose prescriptions (66.5 Gy and 54.3 Gy) to the two target volumes. **A,** Transverse cross-section. White line corresponds to the position of the coronal cross-section. **B,** Coronal cross-section. White line corresponds to the position of the transverse cross-section. **C,** DVHs of the target volumes and selected critical structures. Vertical bars indicate the prescription doses and highlight the increased dose heterogeneity often encountered as a consequence of conformal avoidance.

although no definitive study has yet demonstrated the clinical impact of IMRT in reducing toxicity to normal tissues. Because the dose distributions made possible by IMRT's planning and treatment delivery are superior to conventional conformal 3D plans, improvements in clinical outcomes are expected, although the long-term safety of IMRT remains to be demonstrated.

As with all technological advances, a number of potentially difficult problems with IMRT exist and need to be addressed.[164,165] With IMRT, it is much more difficult than with 3-D conformal therapy to verify that treatment has been delivered correctly to the patient and to keep a long-term record of that treatment. If there is organ motion—which is inevitable for every organ below the calvarium—then there is a possibility that the dose delivered may differ significantly from the dose planned and recorded, as planning was performed on static images. Finally, as more beams are added to the treatment and the daily treatment time increases, then, although less normal tissue will be treated to tolerance doses, the volume of normal tissue that receives some dose of radiation (e.g., scattered radiation), in fact, increases, as does the total-body dose of radiation. It remains to be seen how significant these problems will be over the longer term.

Particle Radiation Therapy

Particle beam therapy utilizes subatomic particles instead of x-rays or gamma rays to deliver the dose of radiation. The development and application of particle radiation therapy has been motivated by two main factors. One is the physical property that allows for precise dose localization and superior depth dose distribution with heavy charged particles such as protons. The other is the potential radiobiologic advantage of high-linear-energy-transfer (LET) particles. High-LET radiation deposits more dose along its path than conventional x-rays, which are low LET. This offers advantages for several potential reasons. Firstly, high-LET radiation is more damaging to hypoxic cells. Secondly, there is less repair of damage induced by high linear energy transfer radiation. Thirdly, damage from high-LET radiation is less cell cycle dependent.[74]

Neutron Therapy

Neutron radiation therapy first was applied in the late 1930s to attempt to increase killing of hypoxic cells.[166] Because there was little understanding of the high-LET and resultant high relative biologic effectiveness of neutrons, there were severe radiation sequelae with treatment.[167] It was not until the 1960s that clinical trials in neutron therapy were resumed, with adjustments in dose compensating for the high-LET and relative biologic effectiveness of neutrons.[168] Early trials failed to confirm the efficacy of neutron therapy, but because of the potential advantages of high-LET radiation, neutron therapy has been used widely in the attempt to control various tumors (Fig. 29-26). Approximately 30,000 patients have received neutron therapy worldwide, with mixed results.

The most quoted site said to show an advantage for neutrons over conventional photons was unresectable salivary gland carcinomas. Early single-institution studies indicated a therapeutic advantage of neutron therapy over photon therapy, prompting a phase III RTOG/MRC trial that showed a significant local control advantage of neutrons over photons (56% vs. 17%), but with no overall survival advantage due to distant metastases.[169] This advantage also has been shown more recently in both major and minor salivary gland tumors.[170]

Neutron therapy also has been investigated in soft tissue, osteogenic, and chondrogenic sarcomas. These tumors are thought to be radioresistant to conventional x-rays and responsive to neutron therapy.[171] Phase II data and single-institutional data show the pos-

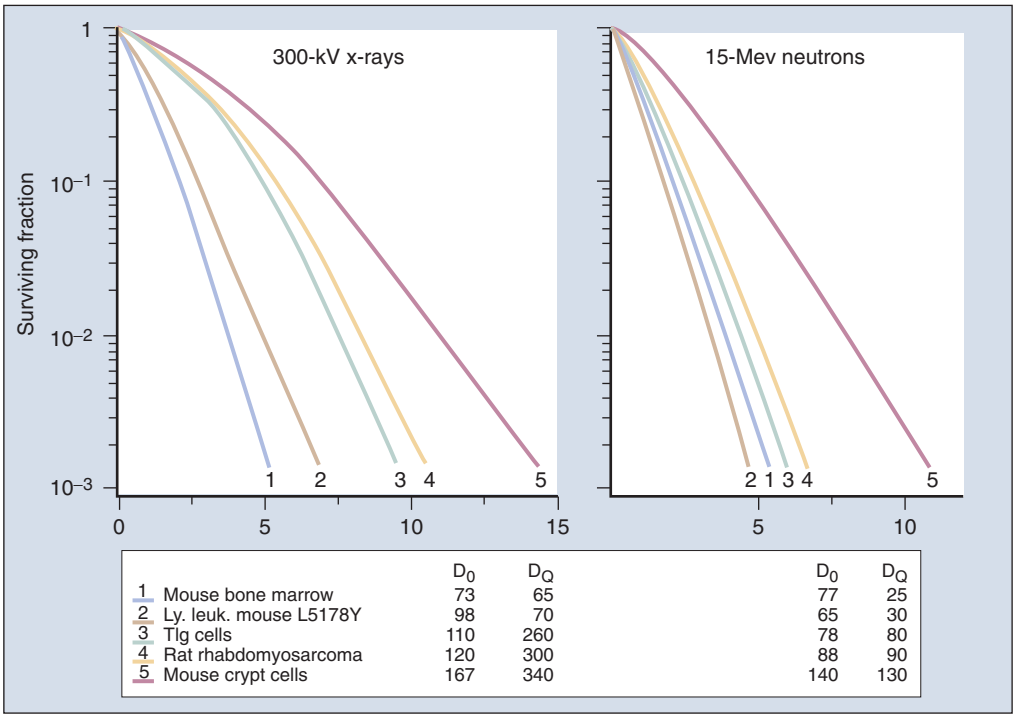

Figure 29-26 • Survival curves for various types of clonogenic mammalian cells irradiated with 300-kV x-rays or 15 MeV $d^+ \rightarrow T$ neutrons. *Curve 1*, Mouse hematopoietic stem cells. *Curve 2*, Mouse lymphocytic leukemia (Ly. leuk.) L5178Y cells. *Curve 3*, Tlg cultured cells of human kidney origin. *Curve 4*, Rat rhabdomyosarcoma cells. *Curve 5*, Mouse intestinal crypt stem cells. The variation in radiosensitivity between different cell lines is markedly less for neutrons than for x-rays. (From Cox JD, Ang KK [eds]: Radiation Oncology: Rationale, Technique, Results, 8th ed. St. Louis, Mosby, 2003, p 46.)

sibility of an advantage in unresectable sarcomas, though this has never been tested in a large-scale randomized clinical trial.[172,173]

Results of neutron therapy in head and neck cancer and in non-small-cell lung cancer have not been as encouraging. Phase III data from head and neck neutron therapy trials indicate higher toxicity with no definite advantage in terms of local control, regional control, or survival with neutrons.[174–176] Similarly, the results of studies done with neutrons in patients with non-small-cell lung cancer are inconclusive, showing no definite advantage with neutrons over conventional photons.[171]

Two randomized clinical trials have compared neutron therapy with photon therapy in patients with prostate cancer.[177,178] These studies show an advantage of neutrons in terms of locoregional control, with one study showing an overall survival advantage. Neither study showed an advantage in terms of disease-specific survival.

There are no active clinical studies involving neutron therapy. It is used selectively in certain specialist centers for inoperable tumors (e.g., salivary gland tumors, selected sarcomas) in which there is some evidence for its effectiveness and in which the dose distribution is superior to conventional radiation therapy. Given its potential for causing late toxicity[179] and because neutron therapy often produces dose distributions that are less desirable than charged particle therapy, interest in neutron therapy has waned.

Proton Therapy

Although protons have a slightly higher linear energy transfer than x-rays, they are not generally considered high-linear-energy transfer particles. Most of their their advantage over x-rays is achieved in their physical dose distribution. When a heavy, charged particle, such as a proton, passes through tissue, the dose it deposits increases slowly with depth, then reaches a sharp increase at its maximum depth of penetration. This is called the Bragg peak (Fig. 29-27). The maximum depth of penetration can be adjusted by varying the energy of the proton beam or by adding or removing compensating material placed in the path of the beam. In clinical use, the Bragg peak often is spread out in depth using specialized filters to achieve the dose deposition pattern desired, but still with the desirable sharp dose fall-off at the deep edge of the beam. Using multiple beams or varying compensators, it is possible to design a 3-D dose deposition that is precisely confined to the tumor volume with minimal dose to the surrounding normal tissue.

Most patients treated with proton therapy have had tumors in close proximity to critical structures.[180] The precise dose deposition patterns of protons made it possible to treat these tumors without crossing the threshold of critical toxicity of the surrounding normal structures (Fig. 29-28).

Uveal melanoma is a malignancy that had been difficult to treat with photons on account of toxicity to normal structures of the eye. Surgical enucleation traditionally has been the treatment of choice. Proton therapy has become an alternative treatment for uveal melanomas. Massachusetts General Hospital has reported a 10- and 15-year actuarial local control rate of 95%, using 70 Gy-equivalent doses. Enucleation was avoided in the great majority of patients, with only 2% to 10% (depending on size of the primary tumor) requiring subsequent enucleation.[180,181] This high rate of control also has been reported by the group at the Paul Sherrer Institute in Switzerland, with a 10-year local control rate of 95%.[182] Again, subsequent enucleation rate was low (8%), with a 15-year overall eye retention rate of 84%.[183] With these outcome data, all patients could be considered for what is basically organ-sparing treatment in the form of proton beam therapy.

Tumors of the paranasal sinuses also have been treated using proton beam therapy, with the precision of proton beams allowing dose escalation up to 76 Gy-equivalent. Using a combination of photons and protons after partial resection or biopsy, local control rates for T3-T4 tumors have been reported up to 85%, again with low toxicity.[180,184]

More commonly occurring tumors have also been treated with proton beam radiation therapy, with the high precision allowing for dose escalation in diseases that are difficult to control with conventional doses. A phase II study in 23 patients with glioblastoma multiforme was undertaken at the Massachusetts General Hospital with dose escalation up to 90 Gy-equivalent using proton beams. Such doses cannot be achieved with photons due to toxicity to critical brain structures. Median survival was 20 months, with a 3-year actuarial survival of 18%. Recurrence was seen in only one patient treated at the 90 Gy-equivalent dose level, but radiation necrosis was observed in 7 of the 23 patients treated.[185]

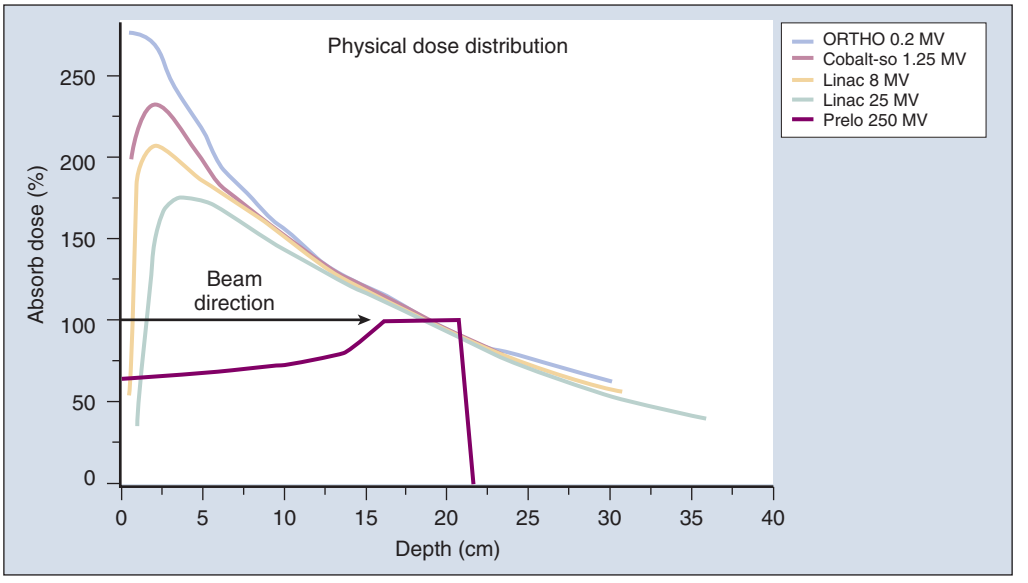

Figure 29-27 • Depth-dose distributions for a proton beam compared with other photon beams. The dose for the proton beam is limited for the entrance tissues, reaches a Bragg peak at the desired depth, then displays an extremely sharp fall-off.

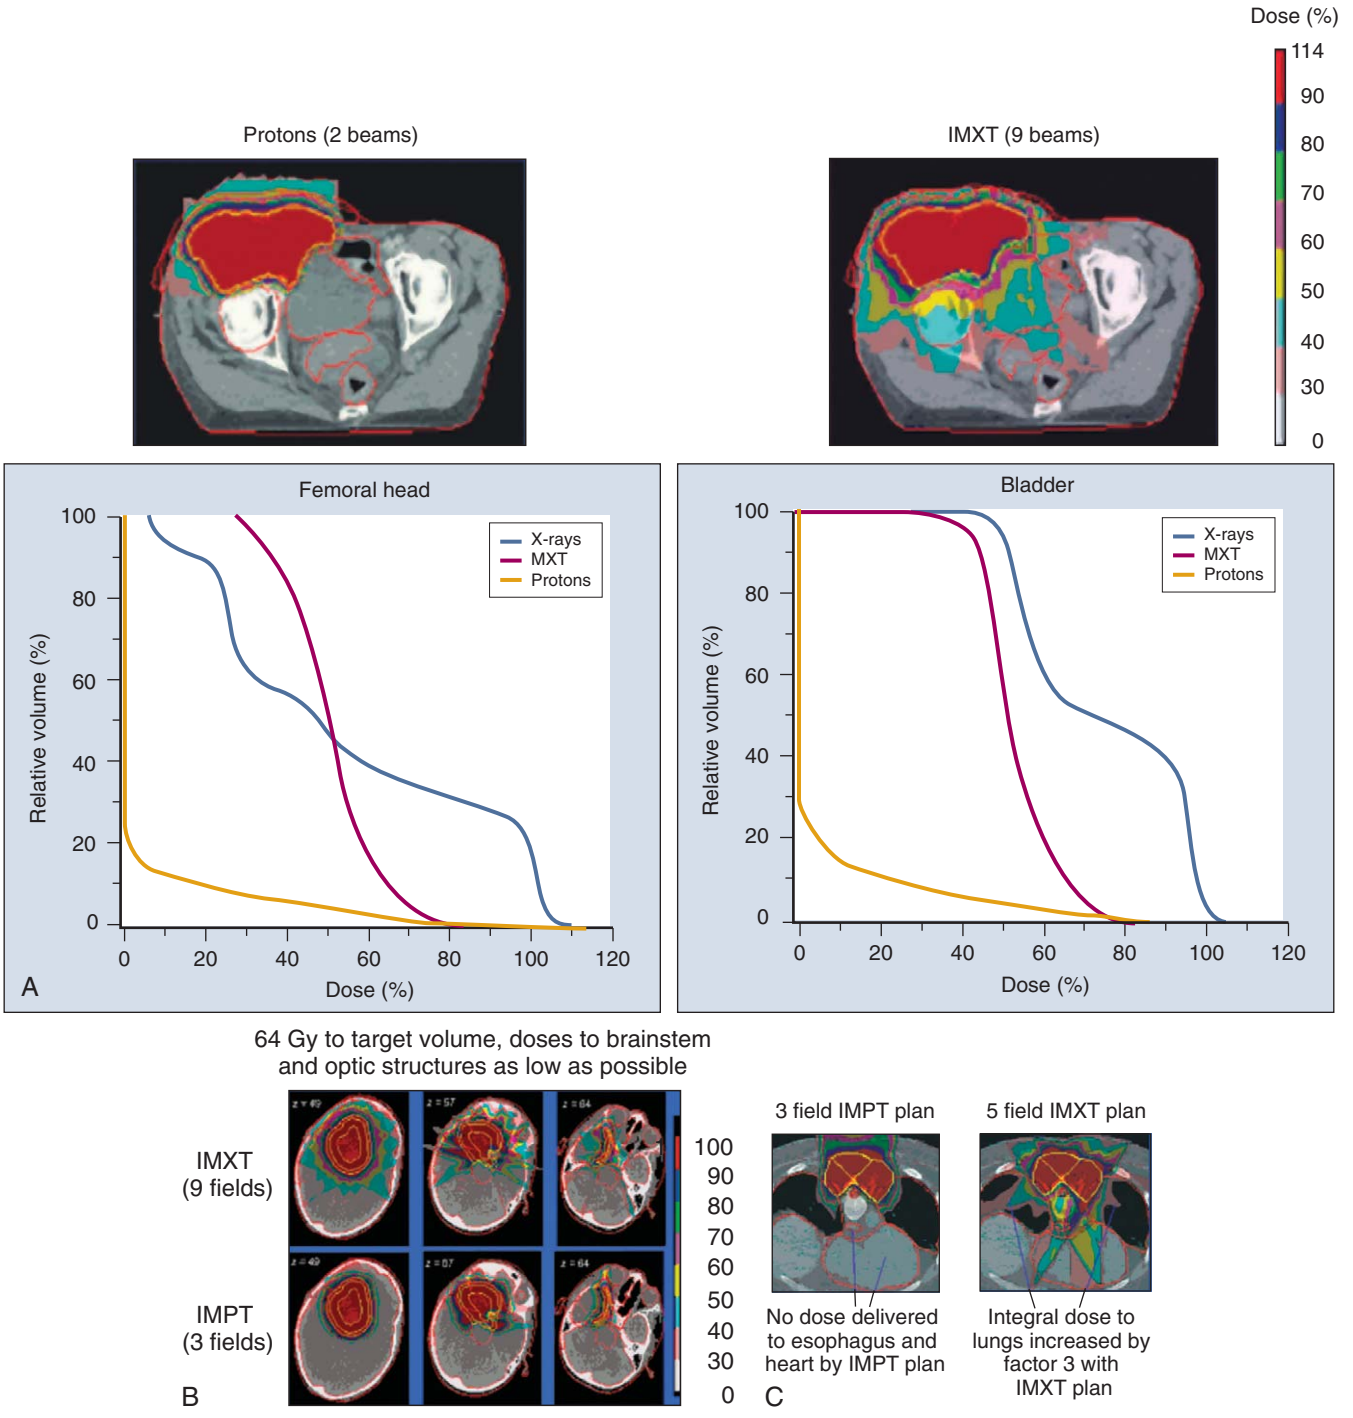

Figure 29-28 • **A,** Proton beam arrangement compared with a complex IMRT plan of nine beams for the treatment of malignant melanoma. Note the full coverage of the target volume with sparing of normal tissues. **B,** Proton beam arrangement compared with an IMRT plan for treatment of a pediatric meningioma. **C,** Treatment of a thoracic paraspinal chordoma requiring contouring of the dose distribution around the spinal cord, while continuing to provide full coverage to the target volume, more easily attained with proton beams than with a complex IMRT plan. (Used with permission from Anthony Lomax, PhD, Paul Scherrer Institute, Switzerland.)

Meningiomas are another type of CNS tumor that has been treated with protons. In a study of 46 patients with partially resected, biopsied, or recurrent meningiomas, a combination of photons and protons was used to deliver a median dose of 59 Gy-equivalent to the macroscopic tumor volume. The recurrence-free rates at 5 and 10 years were 100% and 88%, respectively. Eight patients, however, developed severe ophthalmologic, neurologic, or otologic long-term toxicity from radiation therapy.[186]

Prostate cancer is the only tumor in which dose escalation with protons has been tested against conventional radiation in a randomized trial.[187] Patients with T3 or T4 prostate cancer who received 50.4 Gy via photons to a pelvic field were randomized to receive either an additional 16.8 Gy with photons or 25.2 Gy equivalent with protons. There was no difference in overall survival, disease-specific survival, or local control between the two groups. Additionally, there was an increase in toxicity in the proton arm, owing to the

higher dose delivered to the rectum.[188] This study was done in the 1970s, prior to the recognition of the importance of volume considerations in determining rectal toxicity. More recent studies have demonstrated that sparing of the rectum during prostate irradiation can be achieved with proton therapy.[189]

The role of proton therapy is currently being studied in patients with prostate cancer, hepatocellular carcinoma, and non-small-cell lung cancer, and in combination with stereotactic radiosurgery (see previous discussion).[180,190–192] Proton therapy provides a further example of the application of technological advances in the field of radiation oncology (Box 29-1). Because it represents the optimal therapeutic ratio available in terms of dose delivery for many cancers, its availability as a standard treatment modality is anticipated to become more widespread.

CONCLUSIONS

Radiation therapy has progressed rapidly since the discovery of x-rays over 100 years ago. Understanding of the physical and biologic properties of radiation has led to great advances in the field of radiation therapy, making it possible to cure hundreds of thousands of patients worldwide and spare thousands more from the mutilating consequences of surgery. With the advent of computers and conformal 3-D treatment planning, the field of radiation oncology has advanced further in recent decades. The therapeutic index has been increased by dose escalation and more accurate shielding of normal tissues. Recent innovations such as systemic targeted radionuclide therapy, novel approaches to brachytherapy, and dose escalation with IMRT offer hope for further improvements in radiation treatments for patients with cancer. Clinical studies investigating these modalities and the strategic development of combination treatments, particularly with cytotoxic chemotherapy and molecular biology-based targeted therapies, will ensure continued advancement of the field of radiation oncology in years to come.

Box 29-1. TREATMENT STRATEGIES FOR CHORDOMA OF THE BASE OF SKULL

Tumors of the skull base are difficult to treat because of their location. The base of the skull involves and is surrounded by critical structures such as the brain stem, the optic chiasm, the optic nerves, the cranial nerve roots, the arterial circle of Willis, and the cervical spinal cord. Two primary malignant tumors that arise in the skull base are chordomas and chondrosarcomas, both of which can cause debilitating morbidity or even death due to the position in which they arise. Both types of tumor are difficult to treat, either with surgery or conventional radiation therapy, without the risk of leaving the patient with significant disability. These tumors require high doses of radiation if local control is to be achieved, and retreatment with radiation usually is not feasible without significant risk of morbidity.

Using a combination of 3-D conformal x-ray therapy and charged particle therapy (protons), a more desirable dose distribution can be achieved than that obtained using conformal megavoltage photon radiation alone. The Bragg peak (see Fig. 29-27) can be used to allow a steep fall-off of dose within a few millimeters of critical organs. In two reported series of patients with chordomas arising in this anatomic region, the application of this novel combination of radiation modalities has resulted in local control rates of 65% to 70%.* In these small series, median tumor dose was 70 Gy-equivalent (physical dose ×1.1—the relative biologic effectiveness for protons). A low incidence of long-term toxicities was reported.

30 Systemic Therapy

Carl E. Freter and Michael C. Perry

SUMMARY OF KEY POINTS

History of Drug Discovery

- The history of cancer chemotherapy and of the disciplines of medical oncology has been that of drug discovery.

Development of Combination Chemotherapy

- Virtually all of the curative chemotherapy regimens that have been developed for hematologic malignancies and for advanced solid tumors use combinations of active agents.
- Mathematical models describing tumor cell kinetics and tumor cell drug resistance have had a strong influence on the development of clinical regimens.
- A series of principles for the development of effective combination regimens was developed in the 1970s and continues to be used today.
- The concepts of alternating, non-cross-resistant chemotherapy, hybrid chemotherapy, dose-intense chemotherapy, and dose-dense chemotherapy have generated hypothesis-driven clinical research that has led in some cases to superior chemotherapy regimens.

Targeted Agents and New Directions in Drug Development

- New categories of agents include tyrosine kinase and multikinase inhibitors, differentiating agents, antiangiogenesis agents, monoclonal antibodies, gene therapy, and vaccines.
- An increasing number of these targeted agents are becoming established in standard therapy, often as part of combination chemotherapy regimens.
- Computer modeling and combinatorial chemistry are powerful new tools for drug development.
- The roles of pharmacogenetics, pharmacogenomics, pharmacoproteomics, pharmacokinetics, and pharmacodynamics are likely to become increasingly important in oncology.

Clinical Uses of Chemotherapy

- Adjuvant chemotherapy is the logical extension of the use of chemotherapy in patients who remain at high risk of recurrence after all clinically detectable disease has been eradicated (Box 30-1).
- In specific cancers, the application of chemotherapy prior to any other anticancer therapy (neoadjuvant therapy) can provide improved survival and/or organ sparing and preservation of function.
- The most common use of cancer chemotherapy is in the management of advanced and metastatic disease. Although curative for several advanced cancers, chemotherapy is largely palliative for metastatic disease.

Chemotherapeutic Process

- The choice of chemotherapy for a specific patient must take into account physiologic age, performance status, nutritional status, prior therapy, pharmacogenetics, and comorbid conditions.
- The principles of drug selection include the pharmacologic characteristics of the individual agents, the route of administration, and the toxicity profile.
- Information regarding individual chemotherapeutic agents is presented according to drug class, mechanism of action, dosage forms, drug interactions, pharmacokinetics and metabolism, indications, and toxicity.

INTRODUCTION

Systemic therapy is defined as chemotherapy, hormonal therapy, or targeted therapy. Although chemotherapy is a relatively recent addition to the therapeutic armamentarium for the treatment of patients with cancer, its role is expanding, and cytotoxic agents are used at some point during treatment for most patients with cancer. Historically, chemotherapy was used principally as therapy for metastatic cancer after failed local therapies, and it remains the treatment of choice for such patients. However, the evolution of cancer therapy over the past several decades has resulted in increased recognition of the important role that chemotherapy can play in the management of apparently localized and surgically resectable disease. This recognition has led to the development of other applications for systemic therapy designed to decrease postsurgical recurrences, when given as adjuvant therapy, or to allow more limited organ- and function-sparing surgical procedures when chemotherapy is given preoperatively or concurrently with radiation therapy. The recent addition of molecularly targeted therapies raises new possible therapeutic options.

Box 30-1. MANAGEMENT APPROACH: CANCERS THAT ARE TREATED EFFECTIVELY BY ADJUVANT CHEMOTHERAPY

Wilms' tumor
Osteosarcoma
Breast cancer
Colorectal cancer

Perhaps more than any other disease, cancer requires close interaction among medical specialties. As our knowledge of how to combine available therapies evolves and as the efficacy and specificity of available chemotherapeutic agents improve, chemotherapy will play an even greater role in improving both the survival and quality of life for patients with cancer.

HISTORY OF DRUG DISCOVERY

Paul Ehrlich coined the term *chemotherapy* in reference to the systemic treatment of both infectious diseases and neoplasia. Although the concept of treating cancers with drugs can be traced back several centuries, there were no examples of truly successful systemic cancer chemotherapy until the 1940s. Gilman and Philips[1] conducted the first clinical trial of nitrogen mustard in patients with malignant lymphomas at Yale University in 1942. The use of nitrogen mustard as a chemotherapeutic agent was suggested by the serendipitous findings of marrow and lymphoid hypoplasia in seamen who had been exposed to mustard gas after the explosion of a ship that contained material manufactured for use in chemical warfare in World War II.[2] This discovery supported previous evidence of a systemic lympholytic effect from alkylating agents of this type. The dramatic regressions of the lymphomas that were noted in this original study generated tremendous excitement for this new field of medicine, although enthusiasm was dampened by the fact that regrowth of tumor seemed inevitable. The results, initially published in 1946, could be said to mark the beginning of modern chemotherapy.

Other "experiments of nature" and the observations of well-trained scientists have yielded a number of other important leads, including the recognition by Farber and colleagues[3] of the importance of folates in cell growth in acute leukemia in children and the subsequent development of the first antifolate antimetabolites. This class of compounds produced perhaps the first examples of drug-induced cures of a metastatic cancer in gestational choriocarcinoma, and they remain in wide clinical use today.[4] For their recognition of the importance of nucleic acid synthesis to inhibition of cell growth and for the development of effective antipurine analogs for cancer and other diseases, Elion[5] and Hitchings were awarded the Nobel Prize for Medicine in 1988. Serendipity also played a role in the recognition of the potential of vinca alkaloids, epipodophyllotoxins, and platinum coordination complexes as chemotherapy agents.[6,7] This scenario has been repeated with sufficient frequency that drug discovery programs such as that of the National Cancer Institute have made extensive use of the approach of mass screening of both natural products and synthetic compounds to identify lead compounds with potent antitumor activity and unique mechanisms of action.

Screening is key to the process of drug development because it narrows the enormous number of candidate drugs to a more manageable number for further study and possible clinical evaluation. Traditionally, this screening system has used transplantable murine tumors to search for evidence of biologic activity.[8] Although this system identified a series of compounds for clinical trial, there was continued uncertainty regarding the relevance of these murine cell lines to human cancers. The current screening system employs a panel of human cancer cell lines grown in culture that represent the major histologic subtypes and sites of origins of human cancer. It is also possible, and probably important, to include cell lines that express various drug resistance phenotypes, such as multidrug resistance, to evaluate new agents against tumor cells that manifest these potentially clinically important cellular characteristics. It also has been possible to automate the testing of candidate drugs in this system so that high-volume screening can be maintained.[9] Because this screening system uses human cancer cell lines, it is hoped that it will identify agents that have unique promise against advanced solid tumors that would not be identified by using other methods.

This organized approach to random screening of large numbers of compounds must be complemented in the drug development effort, however, by attempts to exploit new therapeutic targets that are identified in ongoing basic cancer research. When a putative target is identified on the basis of its biologic significance in the cancer cell, this strategy suggests that the ability of potential therapeutic agents to interact with this target and to inhibit or modify its function should be evaluated as a primary screening procedure. This mechanism-based screening is often performed in simple cell-free systems in which the target and effector are isolated. Drugs that have been identified as promising candidates by this mechanism-based approach to drug development also require test systems that have been developed to validate their biologic activity in whole cells and experimental animal tumor models. Active new agents are needed for the treatment of all common human cancers. The ongoing work in drug development is crucial if our use of chemotherapy is to continue to improve and if its role in potentially curative therapy is to expand. A number of promising and novel strategies are undergoing clinical trials, including antiangiogenesis factors, drugs that affect intracellular signaling pathways, differentiating agents, agents that affect a cell's ability to undergo apoptosis, and gene-specific therapies such as antisense oligonucleotides and ribozymes. These approaches and others that will undoubtedly follow offer great promise for the future of cancer treatment.

DEVELOPMENT OF COMBINATION CHEMOTHERAPY

Chemotherapy initially involved the use of single agents that were associated with responses but almost universal disease progression and dose-limiting toxicity. The development of new agents quickly led to the birth of the concept of combination chemotherapy. However, single-agent therapy retains an important place especially in palliative therapy after initial combination chemotherapy fails. The principles of combination chemotherapy were developed both empirically and with a theoretical basis provided by the fields of tumor cell growth kinetics and drug resistance.

Tumor Cell Growth Kinetics

More than 30 years ago, Skipper and Schabel used a murine leukemia model to define the concept of logarithmic cancer cell growth with the corollary concept that a specific dose of a chemotherapeutic agent would produce an associated specific log cell kill that was independent of the number of cells in the tumor.[10] These studies established the important concepts of growth rate, tumor bulk (or cell number), and chemotherapy dose as determinants of therapeutic outcome. While appealing in its mathematical simplicity, pure logarithmic tumor cell growth is, in fact, the exception rather than the rule. This is particularly true in solid tumors, whose growth involves complex functions of heterogeneous growth kinetics, cell death, and development of cancer-promoting growth properties, including the capacity for invasion, metastases, angiogenesis, elaboration of growth factors, and development of mechanisms of chemotherapy resistance (see later discussion). Hence, most of the available data suggest that cancers generally do not grow with a constant doubling time.[11–15] In these cases, the data support a Gompertzian model of tumor growth and regression. In Gompertzian growth, the doubling time increases and the growth fraction of tumor decreases as the tumor becomes larger. Experimental models suggest that this observation is the result of decreased cell production rather than of increased cell loss in larger tumors.[16,17] A tumor theoretically responds to therapy depending on where it lies on the Gompertzian growth curve. In a patient with an advanced cancer and large tumor bulk, this model predicts a lower growth fraction and a lower fraction of cells killed by a given dose of therapy than would be the case with a smaller tumor. The Norton-Simon[18–20] model for the response of tumors to chemotherapy has used the concept of Gompertzian growth to explain clinically observed phenomena and to suggest treatment strategies. The Norton-Simon

model predicts that the log cell kill will be greater for very small cancers than for large cancers and favors, particularly for small tumors, multiple sequential agents at high doses and alternating regimens over more than one cycle to achieve optimum cell kill. The Norton-Simon model has also afforded useful insights into clinical cancer biology. For example, Gompertzian growth kinetics have clarified the rate of tumor regrowth from residual cells that remain after chemotherapy that fails to achieve a cure.[19,20] The increased rate of tumor cell growth that is seen when tumors are small will minimize the differences in survival among patients with advanced disease who achieved complete versus partial responses to systemic chemotherapy, because the residual tumor in the complete responders grows back faster.

Drug Resistance

The earliest experience with chemotherapy made it clear that cancers that are initially sensitive to chemotherapy unfortunately eventually become resistant. The process of bacterial mutation rates of resistance to bacteriophage killing, which was studied and mathematically modeled by Luria and Delbruck,[21] formed the conceptual basis for the Goldie-Coldman model, a mathematical model of genetic resistance of cancer cells to chemotherapy drugs. The Goldie-Coldman hypothesis mathematically describes the likelihood that drug-resistant cancer cells are present in a patient at diagnosis.[22] A fundamental tenet of the Goldie-Coldman model is that chemotherapy mutations that confer chemotherapy resistance occur in 10^3 to 10^6 cells, substantially lower than the limit of clinical detection, which is about 10^9 cells or a 1 cm^3 mass. Goldie and Coldman proposed that tumor cells could acquire drug resistance before drug exposure on the basis of the spontaneous mutation rate that is intrinsic to the genetic instability of a particular tumor. The likelihood that resistant cells are present can be modeled as a function of tumor size or the number of tumor cells and the spontaneous mutation rate of the cells. The predicted frequency of spontaneous mutation of $1 : 10^{-5}$ to $1 : 10^{-6}$ divisions in proliferative tumor cells is consistent with in vitro studies of this phenomenon.[23] Although this discussion has focused on this phenomenon as a means by which cells might acquire drug resistance, it is equally plausible that the same type of genetic events could lead to an increase in vascular invasion and local spread or to an increased tendency to develop systemic metastases.[24] Preclinical studies have demonstrated clearly that the development of the metastatic potential can be the result of genetic instability.[25]

The Goldie-Coldman model predicts that to overcome cancer cell drug resistance most effectively, (1) multiple active agents should be given over the shortest period of time as early in the growth of a cancer as possible, and (2) multiple agents that are given simultaneously will be more effective than sequential agents given at individually higher doses.

Principles of Combination Chemotherapy

Combination chemotherapy has developed both empirically and through the application of principles and predictions of cancer cell kinetics (Norton-Simon hypothesis), and drug resistance (Goldie-Coldman model), into the following principles for combination chemotherapy regimens (Box 30-2):

- All drugs must be active as single agents. The practice of adding an ineffective drug to promote biochemical synergy has rarely produced effective regimens.
- Drugs should be chosen for nonoverlapping toxicity. This spreads toxicity over multiple organ systems, allowing recovery for chemotherapy on schedule, and avoids damaging toxicity to any single organ.
- Drugs should be chosen for different or synergistic mechanisms of action. This achieves the attacking of multiple different cellular targets and the overcoming of resistance at any single target or biochemical pathway.

Box 30-2. MANAGEMENT APPROACH: PRINCIPLES OF COMBINATION CHEMOTHERAPY

1. Only agents that have been proven effective should be used.
2. Each agent used should have a different mechanism of action.
3. Each drug should have a different spectrum of toxicity and (ideally) of resistance.
4. Each drug should be used at maximum dose.
5. Agents with similar dose-limiting toxicities can be combined safely only by reducing doses, resulting in decreased effects.
6. Drug combinations should be administered in the shortest interval between therapy cycles to allow for the recovery of normal tissue.

- Drugs should be chosen that have different mechanisms or patterns of resistance. Cancer cells with resistance to one drug can be attacked by other drugs to which resistance has not developed.
- Drugs should be given according to the optimum dose and schedule. This allows maximum cell kill with a given drug dose and avoids unnecessary toxicity, drug resistance, and "kinetic" chemotherapy failure.
- Drug doses should be individually titrated to end-organ toxicity in individual patients. Reproducible standard toxicity criteria are used for individual organ systems (bone marrow, gastrointestinal, neurologic, dermatologic, etc.). This allows adequate recovery from toxicity to allow cyclic chemotherapy on schedule at the maximum tolerated dose.

Clinical application of the preceding principles has led to a number of concepts with testable hypotheses for the design of chemotherapy regimens. These have included *alternating non-cross-resistant chemotherapy, hybrid chemotherapy, dose-intense chemotherapy* (increased total dose of chemotherapy during a fixed cycle period), and *dose-dense chemotherapy* (increasing dose per unit time, generally by shortening cycle interval). Alternating non-cross-resistant chemotherapy involves the use of multiple active chemotherapy agents with different mechanisms of action organized into two different combination chemotherapy regimens administered on an alternating basis. The Goldie-Coldman hypothesis would suggest frequent alternation of these regimens (e.g., every second cycle), and this has been the general approach taken in prospective clinical trials that have examined this question. A more recent variation on this theme has been the development of hybrid regimens, in which elements of each regimen are administered during each cycle (e.g., on day 1 and day 8) rather than during every second cycle.

In small cell lung cancer, several chemotherapy regimens are available that have roughly equal antitumor efficacies, and alternating chemotherapy regimens have been studied frequently in this disease. Early trials of this strategy in extensive small cell lung cancer demonstrated minimal survival benefit from the use of alternating chemotherapy regimens and a short prolongation of the duration of initial remission in some studies.[26–29] Other studies have suggested that the benefits of using more than one chemotherapy regimen in small cell lung cancer might be more apparent in limited-stage disease, in which a survival advantage has been shown in several small studies.[30,31] In Hodgkin's disease, randomized trials of MOPP versus ABVD (doxorubicin, bleomycin, vinblastine, dacarbazine) versus MOPP alternated with ABVD have shown superiority of the alternating regimen and ABVD to MOPP alone in terms of both survival and complete remission.[32] A hybrid regimen of MOPP-ABVD has been shown to be superior to MOPP followed by ABVD.[33] In both cases, however, the testing of the hypothesis is clouded by the fact that in these cooperative group studies, the MOPP regimen consistently required significant dosage reductions. In metastatic breast cancer, studies with a similar design have failed to demonstrate an

advantage of alternating cycles of CMFVP (cyclophosphamide, methotrexate, 5-fluorouracil [5-FU], vincristine, prednisone) and VATH (vinblastine, doxorubicin, thiotepa, halotensin) to either CAF (cyclophosphamide, doxorubicin, 5-FU) or VATH alone.[34] Collectively, these data suggest that the use of alternating non-cross-resistant chemotherapy regimens is an acceptable, but still not mandatory, alternative therapeutic strategy for these diseases.

The Norton-Simon approach advocates a crossover strategy by which each active regimen is used for a longer period of time (i.e., several cycles) before switching to the alternative regimen. Theoretically, this approach accomplishes two important goals. First, it maintains the most dose-intense administration of each regimen by giving it during every cycle rather than during alternate cycles. Second, it addresses the heterogeneous populations of cells, killing the most sensitive, rapidly growing cells first and then treating the slower-growing, more resistant cells as efficiently as possible.

The concept of dose-dense chemotherapy received additional support with the recent publication of a Cancer and Leukemia Group B study in the adjuvant therapy of node-positive breast cancer.[35] A 2×2 factorial design was used, with patients randomized to receive concurrent adriamycin/cyclophosphamide followed by paclitaxel, each for four cycles, or sequential single-agent adriamycin, cyclophosphamide, and paclitaxel, each for four cycles. Patients were also randomized to receive their therapy at 3-week (standard) or 2-week (dose-dense) intervals. Growth factor support was added to the 2-week schedule. Dose-dense treatment improved disease-free survival and overall survival compared with the 3-week cycles. There were no differences in terms of outcome between concurrent or sequential schedules.

The lack of difference between sequential and concurrent therapies raises fundamental questions about the conventional wisdom of combination therapies always being superior to sequential single agents. Although the results might be drug- and disease-specific, the data are consistent with the Norton-Simon predictions that dose density would improve therapeutic results and that giving drugs in sequence while maintaining dose density would maintain efficacy and reduce toxicity.[35]

These concepts have not been definitively tested clinically, and the available results do not totally support either approach. A direct comparison of alternating and sequential chemotherapy in the adjuvant chemotherapy of breast cancer was conducted by using doxorubicin and the CMF (cyclophosphamide, methotrexate, and 5-FU) regimen.[35] In one arm of this study, patients received four courses of doxorubicin followed by eight courses of CMF; in the second arm, patients received two cycles of CMF alternating with one course of doxorubicin. This sequence was repeated four times, for a total of 12 cycles of chemotherapy. The total dose of all drugs was equal, but the patients in the first arm experienced significantly better disease-free and overall survival. In this case, the sequential approach was superior to the alternating schedule.

An intergroup trial involving patients with Hodgkin's disease came to a different conclusion.[33] In this study, a hybrid MOPP-ABV chemotherapy regimen was superior in terms of complete remission, failure-free survival, and overall survival, compared with the sequential use of MOPP followed by ABVD. Whether this study is a valid test of the concept or whether the results reflect the significant dose modifications in the MOPP arm remains unclear.

The Goldie-Coldman and Norton-Simon hypotheses have provided an important paradigm for hypothesis-driven clinical trials in cancer research. Taken together, the results of these trials have been limited by the lack of "ideal" drugs and combination regimens with which to test these hypotheses and perhaps the simplicity of these models in the face of the biological complexity of cancer. The study of drug resistance and tumor cell kinetics has provided important insights into the mechanisms of "chemotherapy failure." However, developing insights into cancer biology suggest that chemotherapy resistance and "kinetic failure" might not be the only mechanisms by which chemotherapy can fail. The existence of tumor stem cells that have different properties and chemosensitivity than their progeny,[36] for example, continues the challenge to develop effective chemotherapy based on hypothesis-driven clinical research.

TARGETED AGENTS AND NEW DIRECTIONS IN DRUG DEVELOPMENT

The term *targeted agents* has come to refer to a growing class of drugs that specifically target cancer cell-specific pathways on a molecular level, including gene expression, growth regulation, cell cycle control, apoptosis, and angiogenesis. The targeting of specific molecular pathways on which cancer cells are differentially dependent offers the attractive advantage of cancer-specific therapy with reduced toxicity to normal tissues. This disparate and growing group of drugs and treatment approaches includes small molecule tyrosine kinase and multikinase inhibitors, differentiating agents, angiogenesis inhibitors, monoclonal antibodies, proteosome inhibitors, histone deacetylase inhibitors, gene therapy strategies, and vaccines. The developing experience with kinase inhibitors, angiogenesis inhibitors, and monoclonal antibodies is that while they produce responses, they are generally not curative and are associated with the development of resistance. This has led to efforts to understand how best to combine these agents with more conventional chemotherapy agents to capitalize on the strengths of each.

Tyrosine Kinase and Multikinase Inhibitors

Basic oncology research has given us many important clues as to the molecules that drive the malignant phenotype. Although the basic defect is in the genome, the expression of that defect is manifested in how the cell interacts with its surrounding milieu, which can include other malignant cells, nearby normal cells, the extracellular matrix, and humoral factors. This interaction affects the cell via surface membrane receptors and second messengers within the cell. These second messengers affect gene expression and cell phenotype via kinase cascades (signal transduction pathways) that are specific to the receptor/second messenger system that is activated. Within these receptor/second messenger systems, many oncogenes are mutated proteins that confer abnormal cellular responses to malignant cells.

An important paradigm for drug discovery in oncology has been identifying recurrent specific chromosomal markers as guideposts to discovery of the biology of their associated genetic alterations in a specific cancer. This might then allow the development of molecularly designed therapy to correct or circumvent biologic changes sustaining the cancer phenotype. A striking example of this approach has been the development of the tyrosine kinase inhibitor imatinib to inactivate the constitutively expressed fusion protein BCR-abl, the biologic abnormality that drives CML, defined decades earlier by the Philadelphia chromosome.[37] Imatinib has subsequently been used to target c-Kit in gastrointestinal stromal tumors,[38] and the success of this approach has driven the development of a growing number of tyrosine kinase inhibitors, including dasatinib, a multikinase inhibitor that targets BCR-Abl, SRC-family kinases, c-kit, EPHA2, and PDGFR-beta, indicated for treatment of CML with resistance to prior therapy including imatinib and resistant Ph+ ALL.[39] Erlotinib, an oral tyrosine kinase inhibitor targeting the epidermal growth factor receptor, has been approved for treatment of non-small-cell lung and pancreatic cancers.[40,41] Sorafenib is an oral multikinase inhibitor that targets Raf, tumor signaling, and tumor vasculature and is approved in advanced renal carcinoma.[42] Sunitinib is another multikinase and angiogenesis inhibitor that is approved in renal cell and gastrointestinal stromal tumors.[43] Lapatinib, a tyrosine kinase inhibitor of HER2/neu and EGFR, has activity in HER2/neu-positive breast cancer progressing after trastuzumab-based therapy (see later discussion).[44] Other members of this family of small molecule kinase and multikinase inhibitors are in active clinical development.

Differentiating Agents

Several classes of compounds have potent in vitro and in vivo differentiating effects on the malignant cell phenotype. These include retinoids, vitamin D analogs, cyclooxygenase inhibitors, and hypomethylating agents. These agents do not eliminate the malignant clone or affect its genotype, but their continued application can cause regression of malignancy, and they might have a role in chemoprevention. All-*trans* retinoic acid represents an example of a targeted therapy that causes striking granulocytic differentiation of the leukemic cells in acute promyelocytic leukemia, in which the chromosomal translocation 15 : 17 results in the expression of an aberrant fusion gene involving the retinoic acid receptor PML-RAR-α.[45] 5-Azacytidine and decitabine are DNA hypomethylating agents that act to restore cellular differentiation in myelodysplastic syndrome and certain leukemias.[46] The COX-2 inhibitor celecoxib has activity in reducing polyps in familial adenomatous polyposis[47] and is being tested in other chemoprevention settings.

Angiogenesis Inhibitors

Solid tumors must stimulate the growth of new blood vessels, a process called *neovascularization,* to obtain oxygen, nutrients, and growth factors to be able to grow and successfully metastasize. Study of the molecular basis of tumor angiogenesis has led to important insights into tumor biology as well as targeted molecular strategies to inhibit tumor angiogenesis. An established agent is bevicizumab, a humanized monoclonal antibody that targets the angiogenic growth factor VEGF. Bevicizumab has modest single-agent activity but has been associated with survival prolongation when combined with conventional chemotherapy for lung, colon, and breast cancer.[48,49] Thalidomide and lenalidomide, established agents in multiple myeloma, have complex mechanisms of action, including inhibition of tumor necrosis factor-α, interleukin-6, basic fibroblast growth factor, and antiangiogenic activity through inhibition of vascular endothelial growth factor (VEGF).[50]

Monoclonal Antibodies

Malignant cells are vulnerable to treatments that are directed at unique antigens expressed on their surface. Monoclonal antibodies that are directed against growth factor receptors or other specific cancer cellular targets have increasingly established roles in therapy. Antibody binding to the surface of the malignant cell can lead to complement-mediated lysis, antibody-dependent cellular cytotoxicity, or signal transduction-mediated apoptosis. The monoclonal antibody can either be of murine origin or, through recombinant DNA techniques, be made partly human (chimeric) or nearly completely human (humanized). Rituxan, directed against the lymphoid cell surface marker CD20, is widely used in chemotherapy of lymphoid malignancies,[51,52] as well as in other settings for its immunosuppressive properties. Alemtuzumab, defined by the lymphoid marker CD52w against which it is directed, is approved for treatment of CLL. [53] Trastuzumab, a humanized monoclonal antibody against the HER2 protein, is established in treatment of HER2/neu-positive breast cancer.[54] Cetuximab, a recombinant human/mouse chimeric monoclonal antibody is directed against the extracellular domain of the human epidermal growth factor receptor (EGFR), and has activity in colorectal and head and neck cancers.[55,56] Panitumumab is another EGFR-directed monoclonal antibody that is indicated for treatment of patients with EGFR-expressing metastatic colorectal cancer that is resistant to conventional chemotherapy.[57] Monoclonal antibodies have also been used to "target" cancer cell antigens with attached cytotoxic moieties, including radionuclides, as in the case of anti-CD20 conjugates, I-131-conjugated tositumomab,[58] or yttrium-90-conjugated ibritumomab tiuxetan[59] for B-cell lymphomas. Immunoconjugates have also been constructed with biological toxins or antitumor antibiotics as in the case of the anti-CD-33-calicheamicin conjugate gemtuzumab ozogamicin for acute myelogenous leukemia.[60] Denileukin diftitox is an example of a recombinant fusion product with cellular binding and toxic moieties combining interleukin-2 and diphtheria toxin to inhibit cellular protein synthesis and induce apoptosis in the treatment of cutaneous T-cell lymphomas.[61]

Proteosome Inhibitors

The ubiquitin-proteosome pathway involves targeted proteolysis of "ubiquitin-tagged" intracellular proteins. Inhibition of the normal essential function of this pathway leads to disruption of multiple intracellular signaling pathways and programmed cell death. Bortezomib, the first approved drug in the proteosome inhibitor class, is a reversible inhibitor of the 26S proteosome, and an established agent in multiple myeloma and some non-Hodgkin's lymphomas.[50]

Histone Deacetylase Inhibitors

The family of histone deacetylases catalyzes the deacetylation of lysine residues on protein substrates including histones and transcription factors. Histone deacetylation is believed to control expression of oncologically relevant genes, including tumor suppressors, and genes involved in differentiation, proliferation, and cell cycle control. Inhibition of overexpressed histone deacetylases in cancer cells is thought to lead to cell cycle arrest and apoptosis. Vorinostat is an oral histone deacetylase inhibitor with activity against a spectrum of histone deacetylases with an indication for treatment of refractory cutaneous T-cell lymphoma.[62]

Gene Therapy

Treatment strategies incorporating specific ribonucleotide sequences come in many different varieties, such as antisense therapy (RNA). An example is the antisense oligonucleotide against bcl-2 RNA, oblimersen, being studied in CLL, melanoma, and other malignancies as a strategy to increase sensitivity to apoptosis with conventional chemotherapy drugs.[63] Other approaches that are under study include systemic viral vector transfection (RNA or DNA), DNA injection into tumors, and ex vivo transfected and selected tumor cells, immune cells, or bone marrow progenitors (DNA). Most of these techniques have demonstrated some effectiveness in animal models, and clinical trials are ongoing. No proof of efficacy has been shown, however, and the technical hurdles are still daunting.

Vaccines

Vaccine strategies to treat cancers have been used for more than 100 years. The principles of immune surveillance and tumor rejection have been well demonstrated in animal models and form the justification for human vaccine strategies. In the last 10 years, many human tumor antigens (and the humoral and cellular immune responses to them) have been characterized. To date, no convincing clinical evidence exists for sufficient efficacy of cancer vaccines, and the ability to correlate immune response to a vaccine and clinical effectiveness has been elusive. Recent advances in molecular immunology might hold the key to solving the puzzles of reinstating and measuring clinically relevant tumor immunogenicity. Several possibly effective cancer vaccines are currently in large phase III trials, which could lead to FDA approval. The recent approval of a vaccine against human papillomavirus to prevent HPV-associated cervical cancer represents the first application of a cancer prevention vaccine.

PHARMACOLOGIC APPROACHES

Drug Development

Although approximately 100 drugs are now in use to treat human cancers, the vast majority of cancers are not cured by chemotherapy. Since it no longer seems possible to identify one specific abnormality

between cancerous and normal cells, additional agents with different modes of action must be sought. Although some chemotherapeutic agents (e.g., 5-FU) have been designed rationally, others (e.g., cisplatin) have been found by chance. The National Cancer Institute is developing a chemical screening system that permits the identification of a compound of interest—a lead compound—that can then be modified or enhanced, and the interaction of the compound with its target (enzyme, growth factor, or oncogene product) can be characterized. Appropriate bioassays are required for each lead agent as it is developed.

A significant fraction of our currently available chemotherapeutic agents are either natural products or derived from natural products, which often have complex structures that complicate synthesis efforts. Problems commonly arise in supply of starting material, the development of drug synthesis methods, and successful formulation of the drug so that it is absorbed and distributed appropriately. The problems of chemistry compound the difficulty in bringing drugs to clinical trials.

Computer Modeling and Combinatorial Chemistry

The pioneering discoveries of the early days of chemotherapy have permitted the development of a paradigm for drug discovery that persists, with modifications, to the present day. This organized approach to random screening of large numbers of compounds, however, must be complemented in the drug development effort by attempts to exploit new therapeutic targets that are identified in ongoing basic cancer research.

The molecular basis for antineoplastic therapy has been rapidly being unveiled since the 1990s. For many chemotherapy agents, the molecules that are responsible for drug transport, binding, effector mechanism, detoxification, and efflux out of cells are known. Therefore, new and better agents that result in tumor cell death and clinical response can be designed to exploit these known targets. This effort requires powerful computer programs, advanced chemistry techniques, three-dimensional modeling capabilities, and nucleotide sequences of all the relevant target protein genes. With these tools in place, one can create new small or large molecules or modify existing molecules by the addition or subtraction of functional groups to direct the binding, specificity, inhibition, duration of action, and toxicity of these molecules on the basis of chemical interactions with the target molecules. This process is called *mechanistic drug development,* and it uses computer modeling to predict the chemical composition of the new drugs, whether they be small molecule inhibitors, peptides, proteins, or nucleotide sequences.

A related endeavor that is occurring in the pharmaceutical industry and elsewhere is called *combinatorial chemistry.*[64–69] This process tests for binding interactions between new compounds or molecules and known targets that result in the desired cellular and clinical effect. The target is usually placed on a solid phase, and the candidate molecule is tested for binding to this solid phase. Once specific binding is documented, this compound is then tested for in vitro and in vivo biologic modulation (inhibition or stimulation) of the target molecule function. From there, standard testing of preclinical and clinical activity can be carried out with existing or new methods.

This ongoing work in drug development is crucial if our use of chemotherapy is to continue to improve and if its role in potentially curative therapy is to expand. Standard approaches and mechanistically based drug development will continue in parallel, and many new agents will undoubtedly follow, offering great promise for the future of cancer treatment.

Pharmacogenetics

It is now clear that much of the variability in response to drugs is inherited. The genetically determined variability of drug response characterizes a research area known as pharmacogenetics. Phase III clinical trials frequently report grade 4 toxicities in various solid tumors and hematologic malignancies that have been traditionally regarded as an acceptable alternative to underdosing with ineffective therapy. Identifying genes and allelic variants of genes that affect response to cancer chemotherapy drugs holds great promise for more individualized therapy to avoid untoward toxicity as well as underdosing. One of the first clinically important applications of pharmacogenetics was the identification of single-nucleotide polymorphisms in the gene for the enzyme thiopurine methyltransferase, which is responsible for metabolism of the antitumor agents, 6-thioguanine and 6-mercaptopurine. Children with inherited thiopurine methyltransferase deficiency develop severe hematologic toxicity when exposed to such drugs, while those with high levels of the enzyme require higher doses to achieve the desired effect.[70] Identification of children with thiopurine methyltransferase polymorphisms has the potential to ameliorate toxicity and improve therapeutic outcome.[71] To be clinically useful, such a polymorphism needs to be identified as associated with a correctable untoward clinical outcome and be rapidly detectable with a sensitive, specific test of reasonable cost. Early in the clinical experience with irinotecan in colorectal cancer, an unacceptable early death rate attributable to diarrhea and neutropenia was observed.[72] This was identified as being due to a polymorphism in the gene that encodes uridine diphosphate glucuronosyltransferase 1A1, patients who were homozygous for UGT1A1*28 allele being at increased risk. A genetic test performed on genomic DNA from peripheral blood is available and recommended to screen such patients.[73]

While this patient-tailored approach to chemotherapy drugs is developing, the related fields of pharmacogenomics and pharmacoproteomics hold promise for large-scale genomic and proteomic screening for heritable variation in drug metabolism and other areas of cancer biology. Either technique allows the formulation of a pattern of phenotypic or genotypic expression of the cancer cell, from which patterns of gene expression and therapeutic targets can be discerned. For example, reverse-phase protein microarrays can be used to analyze patient biopsy specimens to measure hundreds of phosphorylated proteins in multiple signaling pathways relevant to the malignant phenotype.[74]

Pharmacokinetics and Pharmacodynamics

Pharmacokinetics is the relationship between plasma concentration of a drug and time and is concerned with the drug's absorption, distribution, metabolism, and excretion. It is what the body does to the drug. The interpretation of pharmacokinetic data is usually based on assessment of total plasma clearance, by measurement of either the area under the plasma concentration–time curve or the steady-state plasma concentration during a constant infusion. A critical issue is intersubject variability in clearance; here, several factors come into play, including saturation of the major metabolic or excretory sites, protein binding, and body size. The evidence for the use of body surface area in dosing oncology drugs is scarce, and other methods could be preferable.

Conversely, pharmacodynamics—the relationship between plasma concentration of the drug and its effects—is what the drug does to the body. Pharmacodynamics analyses have increasingly been incorporated into cancer drug development and complement pharmacokinetic studies, as pharmacodynamics, in conjunction with pharmacokinetics, permits a better prediction and understanding of effect, rather than evaluating plasma concentrations of unclear significance. To date, the influence of pharmacodynamics in oncology has been relatively limited, owing to the tendency to use combination chemotherapy for most malignancies and to the considerable heterogeneity of the cancer population. Many oncology patients are older and have comorbidities that could affect pharmacokinetic-pharmacodynamic variability; hepatic metastases could alter drug metabolism; and there is often a significant lag time between the last measured plasma concentration and the first major therapeutic or

toxic effect. The net result is that such studies are often not practical at the present time. This is a field of active investigation, however, and advances in this area might yield great benefits in tailoring treatment to the individual patient.

CLINICAL USES OF SYSTEMIC THERAPY

Adjuvant Therapy

Systemic therapy can be used in a number of ways in the treatment of cancer. The vast majority of cancer chemotherapy treatments or hormonal therapies are administered to patients with clinically obvious disease. The notable exception is adjuvant therapy, which uses chemotherapy or hormonal therapy for patients who remain at high risk of recurrence after the primary tumor and all evidence of cancer have been surgically removed or treated definitively with radiation. Despite an apparently successful resection of primary breast, colon, or other primary cancers along with the regional lymph nodes, patients can be prospectively identified who are at high risk of recurrence of their disease. These criteria might differ for each tumor, but in general, the degree of local extension of the primary tumor, the presence of positive lymph nodes, and certain morphologic or biologic characteristics of the individual cancer cells are important determinants of that risk. The need for effective adjuvant therapy is strongly emphasized by the fact that systemic therapy usually fails to cure these cancers once recurrence has taken place. The theoretical advantage of treating patients with small total body tumor burden is very compelling, but, in fact, some patients who will receive adjuvant therapy have already been rendered disease free by the local therapy and would be cured without it (Box 30-3).

The use of chemotherapy when the tumor burden is minimal avoids the problems of increasing tumor cell number, decreasing growth fraction, decreased vascular supply, hypoxia, tumor cell heterogeneity, and the likelihood of emergence of drug resistance, all of which occur with increasing frequency as tumors enlarge. Considerable experimental evidence suggests that cancers are most sensitive to chemotherapy during the early stages of growth. This increased sensitivity is believed to be the result of the high growth fraction and shorter cell cycle times, so a given dose of drug might exert a greater therapeutic effect than it would in a larger, quiescent tumor.[75]

The selection of the specific chemotherapy or hormonal therapy regimen to be used as part of adjuvant therapy for a particular cancer is based on objective response rates observed for patients with advanced cancers of the same type. These regimens should be selected carefully, as it is unrealistic to expect a chemotherapy regimen to be effective in preventing recurrences in the adjuvant setting if the regimen does not have a substantial response rate in advanced disease. The selection of patients for adjuvant therapy is based on the expected rate of recurrence for their initial clinical stage of cancer after local treatment alone. Initial demonstration of the efficacy of an adjuvant therapy regimen requires comparison with a control group that receives no therapy beyond local management in a prospective clinical trial. Historical controls are notoriously unreliable in this regard and are not adequate to prove efficacy.

The typical endpoints of systemic therapy—shrinkage of measurable tumor on physical examination or serial radiographic studies—are not available in this situation; in clinical trials of adjuvant therapy, relapse-free survival and overall survival are the principal measures of treatment effect. For an individual patient, there are no means to determine whether the adjuvant therapy and its resultant toxicity and expense have been beneficial or necessary.

This strategy of adjuvant therapy has been attempted in a wide variety of pediatric and adult tumors with some success, and the principles of adjuvant therapy strategy are well established. In the cases of breast cancer and colon cancer, the number of lives saved by the adjuvant therapy approach is significant because of the large number of affected patients, despite the modest differences that are seen between treated and control patients with current treatment programs.

Neoadjuvant Chemotherapy

A second strategy that acknowledges the presence of micrometastatic disease at sites remote from the primary tumor at diagnosis is that of neoadjuvant chemotherapy (Box 30-4).[76] As with adjuvant chemotherapy, treatment is directed at the possibility of systemic disease in patients with apparently localized disease, although in this instance, chemotherapy is administered before surgery is performed. This approach has several potential advantages over conventional postoperative adjuvant chemotherapy. First, neoadjuvant or preoperative chemotherapy provides earlier exposure of potential micrometastases to chemotherapy than is achieved with the standard adjuvant approach. If the advantages of early chemotherapy treatment that are observed in the laboratory are exportable to the clinic, this should be an optimal approach to the treatment of micrometastases. Second, an objective response to chemotherapy in the primary lesion provides important in vivo evidence that the therapy that is being used has antitumor activity and suggests that the tumor at remote subclinical sites will be sensitive as well. By contrast, if the primary lesion does not respond, the likelihood of success of the initial chemotherapy regimen in eradicating micrometastases would seem to be greatly diminished. Monitoring the response thus provides an early opportunity to consider alternative chemotherapy approaches. This approach has perhaps best been described for osteosarcoma.[77] Third, significant regression of the primary tumor might allow local management to be tailored to the individual patient. For example, surgery might be technically easier because of the reduced tumor bulk, a more conservative surgical procedure could be considered, or radiation therapy might be administered in lieu of surgery. The recent use of the aromatase inhibitors in locally advanced breast cancers is another example of the utility of this approach.

The latter two approaches could permit organ sparing and function preservation for some patients. In some situations, preoperative chemotherapy is administered concurrently with radiation therapy to

Box 30-3. MANAGEMENT APPROACH: PRINCIPLES OF ADJUVANT CHEMOTHERAPY

1. Effective chemotherapy must be available.
2. Known tumor should be removed by surgery.
3. Chemotherapy should be started as soon as possible postoperatively.
4. Chemotherapy should be given in maximally tolerated doses.
5. Chemotherapy should continue for a limited time period.
6. Chemotherapy should be intermittent, when possible, to minimize immunosuppression.

Box 30-4. MANAGEMENT APPROACH: CANCERS THAT ARE TREATED EFFECTIVELY BY NEOADJUVANT CHEMOTHERAPY

Soft-tissue sarcoma
Osteosarcoma
Anal cancer
Bladder cancer
Larynx cancer
Esophageal cancer
Locally advanced breast cancer

improve local disease control and to treat systemic micrometastases. For cancer of the anal canal and bladder cancer, this approach has allowed organ-sparing procedures for a high percentage of patients. It has also served as highly effective preoperative therapy for esophageal cancer and squamous cell cancer of the head and neck.

The potential disadvantages of the neoadjuvant approach are also very real. First, chemotherapy is being used as initial therapy for a group of patients with cancers that are potentially curable by surgery alone in a small percentage of patients. If chemotherapy proves ineffective and the cancer becomes unresectable during treatment, great harm could be done. Second, the use of preoperative chemotherapy could obscure the true pathologic stage of the cancer by altering tumor size and margins and converting histologically positive nodes to negative. The inaccuracy of clinical staging for many cancers makes it difficult to be confident that a homogeneous group of patients has been treated, and this fact might confound interpretation of results of clinical trials. Third, if a dramatic clinical response results in the performance of an inappropriately conservative procedure or poor patient acceptance of the recommended procedure and if the cancer then recurs, a significant disservice has been done to the patient.

Approximately seven types of cancers have been managed effectively by using neoadjuvant chemotherapy. In all cases, this "effectiveness" might not imply improved survival. In some cases, organ sparing or function preservation is routinely possible and is ample justification for the use of this approach.

Management of Advanced and Metastatic Disease

The most common use of systemic therapy is for the management of advanced or metastatic disease after failed local therapies or in treating disease for which no alternative therapy has been found. This is perhaps the sternest test for chemotherapy, as tumor volume is significant and patients are often physically compromised by the effects of their disease. It is this clinical situation, however, in which the activity of new anticancer agents and combination chemotherapy regimens are initially evaluated. In treating patients with advanced cancer, it is possible both to determine the antitumor activity of the therapy on an individual patient basis and to define the response rate for the therapy accurately by entering an appropriate number of patients with the same diagnosis and similar pretreatment characteristics in a clinical trial. The benefit of systemic therapy to patients can be inferred by the degree to which measurable or evaluable tumor responds to therapy.

Clearly, the most important measure of the efficacy of systemic therapy is the achievement of a complete response, defined as the disappearance of all radiographic and clinical evidence of measurable or evaluable tumor (Box 30-5). It is the necessary first step to achieving a clinical cure. The achievement of a complete response results in a significant decrease in or disappearance of disease-related symptoms and generally translates into a meaningful prolongation of survival, even for patients who ultimately relapse. Therapy can be said to be curative only when the complete response is maintained after treatment is discontinued. The clinical importance of a complete response is therefore measured by the disease-free or relapse-free survival time. Partial responses are defined as a 50% decrease in cross-sectional area of measurable tumor masses and also can result in symptomatic benefit for patients, although survival is rarely significantly prolonged. Continued administration of the chemotherapy regimen is usually required to maintain the partial response. Unless the regimen is extremely well tolerated, the cumulative effects of therapy might ultimately limit the benefit to the patient. The median duration of response among the complete and partial responders is often used as an endpoint in clinical trials of therapies.

Perhaps the greatest value to clinical investigators of documenting partial responses is in the evaluation of investigational new drugs, in which preliminary evidence for antitumor activity of new drugs is often first observed. New agents that produce partial responses in patients with advanced cancer in phase I or II trials might warrant further evaluation at earlier stages of disease or in combination with other active agents. Patients who have stable disease while receiving therapy—that is, responses that do not meet the criteria for either an objective response or progressive disease—are reported in some clinical trials, although the scientific value of this measure in evaluating therapy can be legitimately questioned. For individual patients who experience extended periods of stable disease and symptomatic palliation on treatment after a period of rapid progression, the clinician (and patient) might consider the therapy of value and continue it on that basis. The importance of this endpoint has increased as novel agents that are not truly cytotoxic, such as antimetastatic agents, differentiating agents, or agents that affect intracellular signaling, enter clinical trials. In these cases, it is possible that evidence of biologic effect will take a different form from that to which we have become accustomed with conventional cytotoxic agents.

Although objective responses, duration of survival, and cure rates have been our traditional systemic therapy endpoints, it has become increasingly clear that clinical researchers and clinicians caring for patients must consider other outcomes or endpoints also. These generally fall under the rubric of palliation of symptoms and improved quality of life.[78,79] Although these endpoints might be more subjective than the traditional ones, it is important that criteria for their evaluation be agreed on and that they be used routinely in clinical trials in which an improved cure rate is not a likely outcome. The palliative benefit to patients who do not have a curable disease is not well defined by our current criteria, and the addition of a semiquantitative means of assessing palliative benefit is critical.

Despite the obvious limitations of our current cytotoxic agents, chemotherapy is curative for several advanced human cancers. These diseases include gestational trophoblastic disease and several hematologic malignancies, but only one advanced solid tumor—germ cell cancer of the testis—can be said to be routinely curable with chemotherapy alone. Another group of cancers, such as small cell lung cancer and ovarian cancer, is occasionally cured with chemotherapy. The most common solid tumors, however—for example, cancers of the breast, lung, prostate, or gastrointestinal tract—when metastatic are not curable with current therapies. These diseases will provide the greatest challenge to the process of drug development and the practice of chemotherapy in the future and will continue to be the focus of active investigative efforts.

The reader is directed to the discussions of the management of individual cancers in Part III of this textbook, "Specific Malignancies." General principles regarding selection of systemic therapy and characteristics of specific drugs are discussed later in this chapter.

Box 30-5. MANAGEMENT APPROACH: CANCERS THAT ARE CURABLE OR OCCASIONALLY CURABLE WITH CHEMOTHERAPY ALONE

Cancers That Are Curable with Chemotherapy Alone
Gestational choriocarcinoma
Hodgkin's disease
Germ cell cancer of the testis
Acute lymphoid leukemia
Non-Hodgkin's lymphoma (some subtypes)
Hairy cell leukemia (probable)

Cancers That Are Occasionally Cured with Chemotherapy
Acute myeloid leukemia
Ovarian cancer
Small cell lung cancer (with radiation)

Box 30-6. MANAGEMENT APPROACH: REQUIREMENTS FOR CHEMOTHERAPY

1. Biopsy-proven residual or metastatic disease*
2. Indicator lesion*
3. Satisfactory performance score and nutrition
4. Patient capable of informed consent
5. Minimal bone marrow, renal, and hepatic function (occasionally pulmonary or cardiac function important)
6. Available monitoring and support functions

*Exception: adjuvant chemotherapy.

CHEMOTHERAPEUTIC PROCESS

The choice of chemotherapy as the treatment modality for a given patient has significant implications and requires a detailed knowledge of the patient and his or her medical problems and social and emotional background, a general knowledge of chemotherapy, a specific knowledge of the program to be used, and the availability of laboratory and support services (Box 30-6). The occasional therapist cannot expect to become an expert, any more than one can expect to become an accomplished chef simply by using a cookbook. Indicator lesions may be physical findings (e.g., lymphadenopathy, hepatomegaly, splenomegaly, subcutaneous nodules), radiologic abnormalities, or tumor markers in body fluids.

Patient Selection

Physiologic Age

Advanced age alone is seldom a valid criterion for excluding patients from chemotherapy. Nevertheless, age-related alterations (in addition to disease-related changes) in organ function suggest that aggressive (or even nonaggressive) programs could result in unacceptable toxicity. Examples of such changes include decreased bone marrow reserve with the possibility of enhanced myelosuppression, reduced renal function with the possibility of enhanced methotrexate or cisplatin toxicity, variable gastrointestinal absorption of oral chemotherapeutic agents, and altered drug metabolism by the liver, resulting in possible decreased effectiveness of chemotherapy.[80] Treatment decisions must also take into account the likelihood of benefit. The decision to treat acute granulocytic leukemia in an elderly patient, for whom toxicity is certain and the likelihood of benefit is small, is an example of a difficult situation.

Performance Score

Whether the Karnofsky or Zubrod scale is used, performance status or score (Table 30-1) correlates closely with survival in certain settings. This is most clearly expressed in non-small-cell lung cancer, in which each decrement of 10% in the Karnofsky score results in a measurable decrease in survival. The implication is that patients with Zubrod performance scores of 3 or 4 or Karnofsky scores of less than 30% are usually not candidates for chemotherapy unless the tumor is untreated and especially likely to respond.

Table 30-1 Patient Performance Score Using Zubrod and Karnofsky Scales

Zubrod	Karnofsky (%)	Definition
0	100	Asymptomatic
1	80–90	Symptomatic, fully ambulatory
2	60–70	Symptomatic, in bed <50% of day
3	40–50	Symptomatic, in bed >50% of day, but not bedridden
4	20–30	Bedridden

Nutrition

Although maintenance of usual body weight might be impossible in the setting of advanced malignancy, the ingestion of 1500 to 2000 calories daily is necessary to permit a satisfactory chance of tumor response. This is best accomplished through oral intake, if possible, using supplemental sources as necessary. If the patient cannot ingest enough calories, enteral or parenteral feeding should be considered.

Obesity

Chemotherapy in the massively obese patient carries a potential risk of overdosage if the patient's actual weight is used, whether dosing is on a milligram-per-kilogram basis or according to body surface area. There are no guidelines for this situation, and the pharmacokinetics of antineoplastic drugs in obese patients are poorly understood. It has been suggested that when patients are to be treated with curative intent, they should receive full-dose intensity, using body surface area calculated on actual body weight or on ideal body weight, with dose escalations if tolerated.[81] Patients who are to receive palliative therapy can more safely be given doses based on ideal body weight.[82]

Prior Therapy

In breast cancer, in spite of positive estrogen/progesterone receptors, failure to respond to a hormonal manipulation decreases the likelihood of a response to subsequent hormonal treatment. Similarly, in virtually all malignancies, failure to respond to a first chemotherapy program lessens the probability of a response to second-line therapy, often because of the development of multidrug resistance.

Organ Function

Altered end-organ function (bone marrow, renal, hepatic, cardiac, pulmonary) could eliminate the use of some chemotherapeutic agents entirely or require dose modification.[83] To avoid undue toxicity, it is essential to know the process of drug disposition and metabolism in this setting. Most oncologists find it useful to determine baseline bone marrow function by peripheral blood counts, hepatic and renal function by chemistry profiles, and (occasionally) cardiac function by echocardiography and gated pool cardiac scans or pulmonary function by chest radiography and spirometry.

Coexisting Illnesses

Other nonneoplastic illnesses might modify the choice of chemotherapeutic agents, even if they do not eliminate the rationale of the use of chemotherapy. For instance, congestive heart failure rules out the possibility of the cardiotoxic drug doxorubicin, and severe chronic obstructive pulmonary disease should eliminate the use of the pulmonary toxin bleomycin. Similarly, diabetes might be aggravated by the use of corticosteroids.

Pharmacogenetics

The evolving field of pharmacogenetics has revealed that unexpectedly severe toxicity from 5-FU could be due to a deficiency of dihydropyrimidine dehydrogenase.[84] The prevalence of this enzyme deficiency in the general population is unknown, as is the impact of the heterozygous state on susceptibility to 5-FU toxicity. Similarly, determination of acetylator phenotype as defined by caffeine metabolism can accurately predict the extent of acetylation of amonafide, a DNA-intercalating agent.[85] Determination of acetylation phenotype can thus be used to modify drug dosing to prevent excess toxicity.

Principles of Drug Selection

Single-agent therapy has largely been replaced by combination chemotherapy when cure is the goal of treatment. There are, however, circumstances in which single agents can be used with curative intent. These include methotrexate or dactinomycin in choriocarcinoma and interferon, pentostatin, or cladribine (chlorodeoxyadenosine) in hairy cell leukemia.

Combination therapy is now the standard for the treatment of many disseminated or metastatic diseases and is curative in some.[86] Unfortunately, most of these diseases are relatively uncommon hematologic or pediatric malignancies, and the more common neoplasms of adults, such as cancers of the colon and rectum, lung, or breast, once metastatic, are seldom cured.

Chemohormonal therapy is the use of chemotherapeutic agents and hormonal agents, such as prednisone in the MOPP combination program, or prednisone with vincristine and daunorubicin in the treatment of acute lymphocytic leukemia (ALL). The inclusion of tamoxifen after cytoxan and doxorubicin in the chemotherapeutic program for breast cancer is another example. Biologic response modifiers, such as interferon or interleukin-2, are used singly or in combination with chemotherapeutic agents.

Differentiating agents, the newest class of anticancer therapies, are currently represented by just one compound, all-*trans*-retinoic acid, which is effective in acute progranulocytic leukemia.

Route of administration has been usually a straightforward decision. Most chemotherapeutic agents are given intravenously, eliminating problems of compliance and absorption. Many of the hormonal agents and some chemotherapeutic agents, such as alkeran, chlorambucil, myleran, 6-mercaptopurine, and 6-thioguanine, are given by the oral route. More recently, oral etoposide and capcitibine, an oral form of 5-FU, have been added to the armamentarium of oral cytotoxic drugs. Absorption could be enhanced if these drugs are taken on an empty stomach. Methotrexate can be given orally, intravenously, intramuscularly, or intrathecally. Interferon and interleukin-2 are usually given subcutaneously. Some chemotherapeutic agents can be instilled in body cavities to treat effusions, as in the example of bleomycin to treat pleural effusions. Continuous infusion therapy offers a potential advantage for cell cycle-specific drugs, such as antimetabolites, in which prolonged exposure might increase cell kill. Cytosine arabinoside is most effective in the treatment of acute granulocytic leukemia, for example, when used as a continuous infusion over 7 days.

Venous access must also be considered, and intravenous therapy might not be feasible if this cannot be established. Fortunately, the development of subcutaneously implanted venous access devices (central or peripheral), multilumen external catheters, and peripherally inserted catheters (PIC lines) has permitted the use of chemotherapy in many circumstances in which this was not possible previously.[87]

Drug programs, including dose, should be extracted from published articles and modified according to the patient's end-organ function (Table 30-2).

Table 30-2 Dose Modifications for Chemotherapy (% of Dose to Be Given)

HEMATOLOGIC TOXICITY

	Granulocytes/Total WBC

5.0		Omit	Omit	Omit	Omit	Omit

5-FU, 5-fluorouracil; NC, no change; SGOT, serum glutamic-oxaloacetic transaminase.

Dose Modification Guidelines

Drug doses are routinely modified for decreases in blood counts and for changes in renal or hepatic function. Individual protocols should be consulted for possible modifications. Table 30-2 outlines commonly used guidelines for dose reductions. The occurrence of certain toxicities, such as neurotoxicity from the vinca alkaloids or mucositis from methotrexate, is also used as an indication for reduction in dose or cessation of the drug.

Response Criteria

Complete response implies disappearance of all measurable or evaluable disease, signs, symptoms, and biochemical changes related to the tumor for at least 4 weeks, during which time no new lesions may appear. Partial response implies a reduction of greater than 50% in the sum of the products of the perpendicular diameters of all measurable lesions (compared with pretreatment measurements) lasting at least 4 weeks, during which no new lesions may appear and no existing lesion may enlarge. For hepatic lesions, a reduction of greater than 30% in the sum of the measured distances from the costal margin at the midclavicular line and at the xiphoid process to the edge of the liver is required. Stable disease is a less than 50% reduction or a less than 25% increase in the sum of the products of the two perpendicular diameters of all measured lesions and the appearance of no new lesions for 8 weeks. Progression or relapse is defined as an increase in the product of two perpendicular diameters of any measurable lesion by more than 25% over the size that is present at entry into the study, or, for patients who respond, over the size at time of maximum regression, or the appearance of new areas of malignant disease (usually excluding central nervous system metastases). A two-step deterioration in performance status, greater than 10% loss of pretreatment weight, or increasing symptoms in and of themselves, do not constitute progression. Their appearance, however, should initiate a new evaluation for disease extent.

Follow-up

Adjuvant therapy is usually given for a set number of cycles, such as six cycles (or months) of chemotherapy after a modified radical mastectomy or lumpectomy for stage I or II breast cancer. For other situations, such as metastatic disease, it is common to reevaluate the patient after two to three cycles (months) of therapy to determine its effectiveness. If therapy has clearly produced a response (using the criteria discussed previously) and is tolerable for the patient, it is usually continued for a set number of cycles or for two courses past a complete response (to eliminate any remaining microscopic tumor). If the disease has progressed during this interval, therapy is discontinued, and a reevaluation is undertaken. Stable disease after therapy represents the most difficult clinical situation that is encountered. If the patient can tolerate the therapy in terms of side effects, then a mutual decision to continue is reasonable, with the realization that eventually, progressive disease will be seen.

CHEMOTHERAPEUTIC AGENTS

The information about the agents in the following list is taken from multiple sources, but the latest information from the manufacturer should be sought before initiating therapy.[82,88–93] Unless otherwise specified, all chemotherapeutic agents are capable of producing some degree of nausea and/or vomiting with administration and myelosuppression, alopecia, and mucositis and/or diarrhea after treatment. Because most agents are also harmful to the gonads and fetus, these toxicities will not be spelled out. Administration of chemotherapy during pregnancy is warranted only in special circumstances and requires a particularly high level of expertise.[94] The increasing incidence of second malignancies as a late complication following successful chemotherapy should also be noted.

Alemtuzumab (Campath)
- Drug Class: Recombinant humanized monoclonal antibody that targets the CD 52 antigen present on most normal and malignant B- and T-cell lymphocytes. This results in antibody-dependent cellular toxicity and complement binding, then apoptosis and activation of T-cell-induced cytotoxicity.
- Dosage Form: 30-mg vial.
- Drug Interactions: None.
- Pharmacokinetics/Metabolism: Metabolic fate unknown.
- Toxicity: Anaphylactoid reactions. Immunosuppression with decreased CD4 and CD8 counts with resulting increase in opportunistic infections. Myelosuppression. GI toxicity: nausea, vomiting, diarrhea. Constitutional symptoms.
- Indications: Food and Drug Administration (FDA) approved for treatment of relapsed or refractory B-cell chronic lymphocytic leukemia and refractory T-cell prolymphocytic leukemia.
- Dosing: 30 mg/day IV infusion three times weekly for up to 12 weeks.

Altretamine (Hexalen)—Hexamethylmelamine, HMM
- Drug Class: Alkylating agent.
- Dosage Form: 50-mg capsules.
- Drug Interactions: Metabolism may be slowed by cimetidine or enhanced by Phenobarbital.
- Pharmacokinetics/Metabolism: Well absorbed by mouth, metabolized in the liver. Elimination half-life 4 to 13 hours. Metabolites largely excreted in the urine.
- Toxicity: Myelosuppression is dose limiting. Leukopenia, thrombocytopenia, nausea, and vomiting are common. Neurologic toxicity, including confusion, lethargy, weakness, and sensory changes, is common.
- Indications: FDA approved for refractory ovarian carcinoma.
- Dosing: 4 to 12 mg/kg/day in divided doses for 3 to 6 weeks or 150 mg/m^2/day for 14 days each cycle; higher doses have been used.

Amifostine (Ethyol)—WR-2721, ethiofos
- Drug Class: Cytoprotectant; free-radical scavenger.
- Dosage Form: 500 mg of powder in vial.
- Drug Interactions: Not known to decrease the effectiveness of any cytotoxic drug but not yet adequately studied.
- Pharmacokinetics/Metabolism: Poorly absorbed in the GI tract. After IV infusion, the drug is metabolized to inactive forms in the plasma. Metabolites are cleared in the urine.
- Toxicity: Transient hypotension is dose limiting. Nausea, vomiting, and somnolence are common. Sneezing, hypocalcemia, and flushing can be seen.
- Indications: FDA approved for pretreatment with cisplatin. Useful as a bone marrow, kidney, and nerve cytoprotectant. Useful with other alkylators as well. Also FDA approved as a radiation protectant to reduce xerostomia.
- Dosing: 740 mg/m^2 IV infusion over 15 minutes given 15 to 30 minutes before the cytotoxic agent or radiation. Lower doses and subcutaneous administration have also been used.

Anagrelide (Agrylin)
- Drug Class: Inhibitor of platelet aggregation with an exploitable side effect of thrombocytopenia, for which the mechanism is unclear.
- Dosage Form: 0.5-mg capsules.
- Drug Interactions: Sucralfate may decrease absorption.
- Pharmacokinetics/Metabolism: Good oral bioavailability; maximum plasma concentration occurs after 1 hour. The plasma half-life is 1.3 hours. The drug is metabolized extensively in the liver. Metabolites are excreted in the urine.
- Toxicity: Other than thrombocytopenia, common toxicities include hypotension, headache, and palpitations. Rare toxicities include anemia, arrhythmias, angina pectoris, and congestive heart failure.

Indications: FDA approved for treatment of essential thrombocytosis as an orphan drug.
Dosing: 0.5 mg four times daily or 1 mg twice daily.

Anastrazole (Arimidex)
Drug Class: Nonsteroidal aromatase inhibitor; blocks estrogen production selectively.
Dosage Form: 1-mg tablets.
Drug Interactions: None noted.
Pharmacokinetics/Metabolism: Well absorbed from the GI tract, with maximum plasma levels achieved within 2 hours. Terminal elimination half-life is 50 hours. The drug is extensively metabolized in the liver and is eliminated in the urine as metabolites and 10% unchanged drug. Despite hepatic and renal clearance being important, no adjustments are needed for abnormal function of these organs due to the wide therapeutic index of this drug. Eliminated in the urine as metabolites and 10% unchanged drug.
Toxicity: The drug is very well tolerated. Asthenia, headache, and hot flashes occur in fewer than 15% of women. Diarrhea, abdominal pain, anorexia, nausea, and vomiting occur in 10% or fewer. Thrombophlebitis has been reported.
Indications: As adjuvant therapy of breast cancer and for treatment of postmenopausal women with breast carcinoma who have progressed on tamoxifen therapy.
Dosing: 1 mg PO every day. Higher doses are no more effective.

Arsenic Trioxide (Trisenox)
Drug Class: Novel arsenical differentiating agent.
Dosage Form: Ampules containing 10 mg of drug in 10 mL solution.
Drug Interactions: None known.
Pharmacokinetics/Metabolism: Half-life of this compound is unknown. It is methylated in the liver and eliminated in the urine.
Toxicity: The "differentiation syndrome" is dose limiting and includes leukocytosis, fever, dyspnea, chest pain, tachycardia, hypoxia, and sometimes death. Corticosteroids seem to benefit this syndrome. QT prolongation is common. Common side effects include rash, pruritus, headache, arthralgias, anxiety, bleeding, nausea, and vomiting. Liver and renal toxicity are uncommon.
Indications: FDA approved for relapsed acute promyelocytic leukemia.
Dosing: 0.15 mg/kg/day in 100 to 250 mL of D5W until remission, not to exceed 60 doses, then up to 25 doses over five weeks for consolidation starting 3 to 6 weeks after achievement of remission.

L-Asparaginase (Elspar)—colaspase
Drug Class: Naturally occurring enzyme derived from *Escherichia coli* or *Erwinia carotovora* that cleaves the amino acid asparagine, which is an essential amino acid required by rapidly proliferating cells.
Dosage Form: 10,000-IU vial of lyophilized cake.
Drug Interactions: None noted.
Pharmacokinetics/Metabolism: Not orally bioavailable. After IV or IM injection, the drug is metabolized intravascularly by proteolysis. Elimination half-life of 8 to 30 hours. No excretion is required.
Toxicity: Hypersensitivity can be life threatening, requiring anaphylaxis precautions and a 2-unit test dose. Coagulopathy is common and requires monitoring. Nausea, vomiting, abdominal cramps, anorexia, elevated liver function tests, and transient renal insufficiency are common. Lethargy, somnolence, fatigue, depression, and confusion are seen, as are pancreatitis and fever.
Indications: FDA approved for acute lymphoblastic lymphoma (ALL); also used in AML, late-stage chronic myelogenous leukemia (CML), chronic lymphocytic leukemia (CLL), and non-Hodgkin's lymphomas.
Dosing: After a 2-unit intradermal test dose, an IM dose of 6000 to 10,000 IU/m^2 every 3 days for nine doses, or 1000 IU/kg/day IV over 30 minutes for 10 days, has been used.

PEG-Asparaginase (Oncaspar)—pegaspargase
Drug Class: Naturally occurring enzyme, covalently linked to polyethylene glycol to reduce immunogenicity, slow metabolism, and prolong half-life. The enzyme cleaves the amino acid asparagine, which is an essential amino acid required by rapidly proliferating cells.
Dosage Form: 750 IU/mL in a 5-mL vial No reconstitution or dilution necessary.
Drug Interactions: None noted. Can reduce effectiveness of methotrexate if given beforehand, due to inhibition of cell division.
Pharmacokinetics/Metabolism: The drug is not absorbed by the GI tract. When given by IM injection, it has an elimination half-life of approximately 5 days and is not detected in urine or bile. Metabolized completely, clearance not dependent on renal or hepatic function.
Toxicity: Although less immunogenic that the non-PEGylated form, hypersensitivity and anaphylaxis can still occur. Toxicities similar to those of the non-PEGylated forms are seen, including elevated liver enzymes, coagulopathy, hypercholesterolemia, pancreatitis, hyperglycemia, fever, chills, anorexia, lethargy, confusion, headache, seizures, and azotemia.
Indications: FDA approved for treatment of ALL, and, like asparaginase, is also used for other leukemias and non-Hodgkin's lymphomas.
Dosing: 2,500 IU/m^2 IM every 14 days with other chemotherapy agents for induction or maintenance.

Azacitadine—NSC-102816 (investigational)
Drug Class: Antimetabolite, cytidine analog; incorporated into nucleic acids, causing interruption of or errors in transcription and replication of DNA.
Dosage Form: 100-mg vial of lyophilized powder: 100-mg vial diluted to 20 mL in sterile water, and then rapidly diluted to a final concentration of 0.2 to 2 mg/mL in normal saline or 5% dextrose in water.
Drug Interactions: None noted.
Pharmacokinetics/Metabolism: Not orally bioavailable. When administered by IV infusion, the drug is activated inside cells to the triphosphate form. It is deaminated in the liver. The elimination half-life is 3 to 6 hours. Parent drug and metabolites are excreted in the urine.
Toxicity: Myelosuppression is dose limiting. Leukopenia can be prolonged. Nausea and vomiting are common and can be severe. Diarrhea is common; stomatitis is rare. Hepatic enzyme elevation and liver function compromise are common. Transient azotemia is seen. Lethargy, confusion, and coma have been reported.
Indications: Investigational agent for AML.
Dosing: 150 to 300 mg/m^2/day for 5 days every 3 weeks, or 150 to 200 mg/m^2 twice weekly for several weeks.

Azacytidine (Vidaza)
Drug Class: Antimetabolite. 5-AZA induces hypomethylation of DNA, which may either induce apoptosis or restore normal function. At higher doses, it acts as a cytidine analog.
Dosage Form: 100-mg vial of lyophilized powder: 100-mg vial diluted to 20 mL in sterile water, and then rapidly diluted to a final concentration of 0.2 to 2 mg/mL in normal saline or 5% dextrose in water.
Drug Interactions: None noted.
Pharmacokinetics/Metabolism: Not orally bioavailable. Metabolized by the liver and excreted in urine. Elimination half-life of 4 hours.

Toxicity: Myelosuppression is dose limiting. Leukopenia, thrombocytopenia, and transient elevation of liver function tests are common; nausea and vomiting and abdominal pain are common.
Indications: Myelodysplastic syndromes.
Dosing: 75 to 100 mg/m^2 for 7 days; repeated every 4 weeks for 4 to 6 cycles.

Azathioprine (Imuran)
Drug Class: Purine analog antimetabolite, which is converted to 6-mercaptopurine in vivo.
Dosage Form: 50-mg tablets and 100-mg vials of lyophilized powder.
Drug Interactions: Azathioprine may inhibit the anticoagulant effects of warfarin. Allopurinol blocks the xanthine oxidase-mediated metabolism of azathioprine, requiring reduction of dose for patients taking allopurinol. Angiotensin-converting enzyme inhibitors may exaggerate the myelosuppressive effects of azathioprine.
Pharmacokinetics/Metabolism: Azathioprine has good oral bioavailability and is rapidly converted to mercaptopurine in the blood compartment. The parent drug and thiol metabolites have a half-life of about 5 hours, but the metabolism of active forms is very rapid, with virtually no azathioprine detectable in urine after a dose. Metabolism occurs in blood and liver. Inactive metabolites are excreted in the urine.
Toxicity: Myelosuppression is expected and dose limiting. Due to chronic dosing of this drug, the effects on leukocytes, platelets, and to a lesser extent red cells are slow in onset and usually rapidly reversible. A rare metabolic disorder called thiopurine methyltransferase deficiency results in extreme sensitivity to this drug in affected persons. Nausea and vomiting are common but usually mild and transient during chronic therapy. Opportunistic infections are uncommon. Diarrhea, fever, myalgias, skin rashes, and interstitial pneumonitis are rare. Secondary malignancies have been reported. This drug should not be used during pregnancy or nursing.
Indications: FDA approved for renal transplant recipients and for rheumatoid arthritis. Also used in some hematologic malignancies.
Dosing: Chronic dosing for the preceding indications is in the range of 1 to 3 mg/kg/day. Higher doses, using the intravenous formulation, are used in the immediate post-transplant period.

Bacillus Calmette-Guérin (TICE BCG, TheraCys)—BCG
Drug Class: Immunostimulant/vaccine; induces a cellular immune response at the site of instillation.
Dosage Form: Freeze-dried powder in vials, 27 mg/vial, supplied with diluent.
Drug Interactions: Immunosuppressive drugs may block the reaction to BCG and also make the patient more prone to clinical infection from viable BCG organisms.
Pharmacokinetics/Metabolism: BCG is a live, attenuated bacteria culture, and as such, it does not enter the body in viable form in any quantity. Therefore, it has no detectable pharmacokinetic fate. In rare cases, however, a clinical infection can result from treatment, indicating invasion of the body at the site of administration into the systemic circulation.
Toxicity: Urinary symptoms predominate, including dysuria, hematuria, hesitancy, urgency, frequency, and secondary infection. Other toxicities include fever, chills, malaise, myalgias/arthralgias, anorexia, nausea, vomiting, and anemia. Clinical mycobacterial infection is rare and generally seen only in immunocompromised patients.
Indications: Intravesical instillation is FDA approved for noninvasive bladder cancer after removal of papillary tumors. Also used for some experimental vaccine programs as an adjuvant to the vaccine.
Dosing: 81 mg per treatment, in 53 mL total volume, instructions as previously given. Given once weekly for 6 doses and then at 3, 6, 12, 18, and 24 months after the induction.

Bevacizumab (Avastin)
Drug Class: Recombinant humanized monoclonal antibody that binds to all human forms of vascular endothelial growth factor (VEGF), preventing binding to it receptors.
Dosage Form: 100-mg and 400-mg vials of lyophilized powder: 100-mg vial diluted to 20 mL in sterile water and then rapidly diluted to a final concentration of 0.2 to 2 mg/mL in normal saline or 5% dextrose in water.
Drug Interactions: None noted.
Pharmacokinetics/Metabolism: Administered by IV infusion. Half-life is 20 days. The fate of parent drug and metabolites is unknown.
Toxicity: Most common: asthenia, pain, nausea/vomiting, diarrhea, anorexia, stomatitis, dermatitis, hypertension, proteinuria. Infusion-related reactions are rare. Hemoptysis, hemorrhage, delayed wound healing, gastrointestinal perforations; increased risk of thromboembolic events can be severe or fatal.
Indications: FDA approved for metastatic colorectal cancer, breast cancer and non-small-cell lung cancer.
Dosing: 5 to 15 mg/m^2/day IV every 3 weeks.

Bexarotene (Targretin)
Drug Class: Synthetic retinoid, differentiating agent.
Dosage Form: 75 mg capsules.
Drug Interactions: No formal studies done. Drugs which inhibit cytochrome P450 3A4 such as ketoconazole, erythromycin, and gemfibrozil expected to increase plasma levels and half-life of bexarotene. Known to decrease plasma levels of tamoxifen with concomitant administration.
Pharmacokinetics/Metabolism: Good oral bioavailability increased by a high-fat meal. Metabolized in the liver to oxidative metabolites by cytochrome P450 3A4, glucuronidated, eliminated in the bile.
Toxicity: Hyperlipidemia is dose-limiting and should be monitored while on therapy and treated as appropriate. Pruritus, leukopenia, diarrhea, fatigue, headache, and liver function test elevation can also be dose limiting. Rash, edema, fever, chills, and nausea are uncommon. Excessive bleeding and back or abdominal pain are rare.
Indications: FDA approved for treatment of cutaneous T-cell lymphoma (mycosis fungoides) refractory to at least one prior therapy.
Dosing: 300 mg/m^2/day orally, dose adjusted for toxicity.

Bicalutamide (Casodex)
Drug Class: Nonsteroidal antiandrogen.
Dosage Forms: 50-mg tablet.
Drug Interactions: Bicalutamide may enhance the anticoagulant effects of warfarin.
Pharmacokinetics/Metabolism: Bicalutamide is well absorbed after oral administration. It is highly protein-bound. It undergoes conversion to inactive metabolites in the liver via oxidation and glucuronidation. It has a terminal half-life of several days. Parent drug and metabolites are excreted in the urine and feces.
Toxicity: Constitutional symptoms predominate, including hot flashes, decreased libido, depression, weight gain, edema, gynecomastia, early disease-site pain (flare reaction), and constipation. Nausea, vomiting, anorexia, diarrhea, and dizziness are uncommon. Dyspnea, anemia, fever, and rashes are rare.
Indications: FDA approved for stage D2 prostate cancer, in combination with a luteinizing hormone–releasing hormone (LHRH) agonist agent.
Dosing: 50 mg by mouth daily, in combination with an LHRH agonist agent.

Bleomycin (Blenoxane)—Bleo
- Drug Class: Antitumor antibiotic; causes DNA strand breaks directly in normal and neoplastic cells.
- Dosage Forms: Available as 15-unit (15-mg) vials of lyophilized powder.
- Drug Interactions: None noted.
- Phamakokinetics/Metabolism: Bleomycin is not orally bioavailable. After an IV infusion, it has an elimination half-life of 3 to 5 hours. Bleomycin is incompletely metabolized by intracellular aminopeptidases. It is excreted in the kidney as unchanged drug and metabolites.
- Toxicity: Pulmonary toxicity, including reversible and irreversible fibrosis, is dose limiting. Other common toxicities include fever, chills, rash, exfoliation, and anorexia. Nausea, vomiting, myelosuppression, anaphylaxis, and mucositis are rare.
- Indications: FDA approved for germ cell tumors, Hodgkin's disease, and squamous cell cancers; used off-label for melanoma, ovarian cancer, and Kaposi's sarcoma. Also used as a sclerosing agent for malignant pleural or pericardial effusions
- Dosing: After 1 to 6 hours of observation following a 2-unit IV test dose given over 15 minutes, the full dose can be given. The usual dose is 10 to 20 units/m^2 IV, IM, or SC one to two times per week, or 15 to 20 units/m^2/day as a continuous infusion over 3 to 7 days. As a sclerosing agent 60 units is generally used.

Buserelin (Suprefact)—HOE 766
- Drug Class: LHRH agonist; shuts off luteinizing hormone and follicle-stimulating hormone secretion, thereby resulting in chemical castration.
- Dosage Form: Available as vials for injection at 1 mg/mL and as an intranasal spray in a 10-mL canister.
- Drug Interactions: May cause pain flares in bone metastases if not given with a direct hormonal antagonist.
- Pharmacokinetics/Metabolism: Intravascular and extravascular proteolysis.
- Toxicity: Flare reactions as noted previously, which can be prevented. Castration symptoms such as hot flashes and decreased libido common. Other nonspecific symptoms include headache, nausea, vomiting, diarrhea, constipation, and weakness.
- Indications: FDA approved for prostatic cancer.
- Dosing: 500 μg SC tid for the first week, then 200 μg/day, or intranasally 800 μg tid followed by 400 μg tid.

Busulfan (Myleran)—BSF
- Drug Class: Alkylating agent.
- Dosage Form: 2-mg scored tablets (an IV form is not yet widely available).
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: Excellent oral bioavailability, with peak levels in serum occurring at about 1 hour. Elimination half-life of 2.5 hours. Metabolized partially in liver. Parent drug and metabolites excreted in the urine.
- Toxicity: Myelosuppression, partly chronic and cumulative, is dose limiting. Other common toxicities include nausea, vomiting, anorexia, mucositis, hyperpigmentation, and elevated liver function tests (or veno-occlusive disease of the liver at transplant doses). Neurologic toxicity, including blurred vision, dizziness, and confusion, and interstitial lung disease are less common.
- Indications: Regular-dose therapy in CML (FDA approved) and polycythemia vera. High-dose therapy in bone marrow transplant.
- Dosing: Regular dose: 4 to 8 mg/day. High dose: 8 to 16 mg/kg total dose.

Capecitibine (Xeloda)
- Drug Class: Oral antimetabolite prodrug.
- Dosage Form: 150-mg and 500-mg tablets.
- Drug Interactions: Capecitibine increases the half-life, area under the curve (AUC), and prothrombin time effect of warfarin. Maalox, when given immediately after capecitibine, increases the oral bioavailability of capecitibine.
- Pharmacokinetics/Metabolism: Readily absorbed by the GI tract, metabolized in vivo to fluorouracil in the liver by carboxylesterase and cytidine deaminase, and then in turn in the peripheral tissues and tumor tissue by thymidine phosphorylase. Capecitibine appears to produce higher levels of fluorouracil in tumor tissue than in normal tissues, probably because thymidine phosphorylase is expressed at higher levels in most tumor tissues.
- Toxicity: Myelosuppression and palmar-plantar erythrodysesthesia are dose limiting. Diarrhea, fatigue, stomatitis, and hyperbilirubinemia are uncommon. Nausea, vomiting, and rash are rare.
- Indications: FDA approved for metastatic breast cancer and metastatic colorectal cancer. Used also in head and neck squamous cell cancer.
- Dosing: The approved dose and schedule is 1250 mg/m^2 every 12 hours for 14 days every 21 days. Dose reductions are often required. Treatment delays are sometimes required. Other doses and schedules have been used.

Carboplatin (Paraplatin)—Carbo, CBDCA
- Drug Class: Atypical alkyator; produces intrastrand and interstrand cross-links in DNA via association bonds with the platinum molecule, leading to DNA strand breakage during replication.
- Dosage Form: Available as powder in glass vials: 50, 150, and 450 mg/vial.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: Carboplatin is not orally bioavailable. It is rapidly cleared from the bloodstream after IV infusion, with a terminal half-life of 2.5 hours. It is cleared largely as unchanged drug by the kidneys.
- Toxicity: Myelosuppression, especially thrombocytopenia, is dose limiting. Nausea and vomiting are mild. Renal and neuronal toxicity are rare.
- Indications: FDA approved for ovarian cancer and used extensively in testicular cancer, squamous cell cancers of the head and neck and cervix, and lung cancer.
- Dosing: Dosing can be done on a per-meter-squared basis or through several formulas that take into account renal function and desired level of thrombocytopenia (such as Calvert's formula). Typical doses with normal renal function are in the 300- to 500-mg/m^2 range as an IV infusion.

Carmustine (BiCNU)—BCNU, bis-chloronitrosourea
- Drug Class: Alkylator agent in the nitrosourea class. Cell cycle-independent mechanism.
- Dosage Form: 100-mg vial of carmustine powder and 3-mL vial of ethanol.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: Poorly available by the oral route. After an IV infusion, the drug is rapidly taken up by tissues, including the CNS. Extensively metabolized in the liver. The serum half-life is only 15 to 20 minutes. The parent drug and metabolites are cleared by the kidney.
- Toxicity: Myelosuppression, which is slow in onset and cumulative, is dose limiting. Nausea and vomiting are common and can be severe. Hyperpigmentation and renal toxicity can be seen. Interstitial lung disease, including fibrosis, is rare but can occur with any dose. Transplant doses can cause severe liver toxicity and more frequent lung toxicity.
- Indications: FDA approved for brain tumors, multiple myeloma, Hodgkin's disease, lymphoma. Also used for breast cancer, melanoma, stomach cancer, colon cancer, and liver cancer.

Dosing: Single-agent dose is 150 to 200 mg/m^2 every 6 weeks. For transplant, the dose is as high as 600 mg/m^2, along with other drugs.

Carmustine impregnated wafer (Gliadel)—polifeprosan 20 with carmustine implant.
- Drug Class: Novel delivery mechanism for classical nitrosourea alkylating agent.
- Dosage Form: Each individually packaged, sterile wafer contains 7.7 mg of carmustine.
- Drug Interactions: None known.
- Pharmacokinetics/Metabolism: More than 70% of the copolymer degrades by 3 weeks. Gliadel wafers produce minimal systemic exposure to carmustine. The copolymer itself is biodegradable, but metabolites of the polymer have no known or expected pharmacologic implications.
- Toxicity: None.
- Indications: FDA approved for adjuvant treatment of recurrent glioblastoma multiforme. Being tested in the setting of initial resection.
- Dosing: Up to eight wafers are placed in the resection cavity at the time of craniotomy and operative resection.

Cetuximab (Erbitux)
- Drug Class: Monoclonal antibody.
- Dosage Form: IV.
- Drug Interactions: None known.
- Pharmacokinetics/Metabolism: A recombinant humanized monoclonal antibody targeted against the epidermal growth factor receptor. It competitively inhibits growth factor binding and inhibiting autophosphorylation and cell signaling. Metabolism is poorly understood. Half-life is 5 to 7 days with minimal clearance by kidneys or liver.
- Toxicity: Infusion reaction, characterized by rapid onset dyspnea, fever, chills, urticaria, flushing, angioedema, and hypotension is seen in 40% to 50% of patients. Acneiform rash is common. Constitutional symptoms. Hypomagnesemia. Interstitial lung disease is rare.
- Indications: Metastatic colorectal cancer, head and neck cancer in combination with radiation.
- Dosing: 400 mg/m^2 IV, followed by 250 mg/m^2 weekly.

Chlorambucil (Leukeran)
- Drug Class: Alkylating agent. Cell cycle independent.
- Dosage Form: 2-mg tablets.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: Excellent oral bioavailability; maximum plasma level at 1 hour. Elimination half-life of 1 to 2 hours. Extensively metabolized in the liver to active and inactive metabolites, which are excreted via the kidneys.
- Toxicity: Myelosuppression is dose limiting and universal, and it can be cumulative. Nausea, vomiting, and diarrhea are mild and uncommon. Sterility and alopecia occur in a minority of patients. Pulmonary fibrosis and neurologic side effects are quite rare.
- Indications: FDA approved for CLL and low-grade lymphomas. Also used for Waldenstrom's macroglobulinemia, multiple myeloma, hairy cell leukemia, and rarely in some solid tumors.
- Dosing: 16 mg/m^2/day for 5 days every 4 weeks, or 0.4 mg/kg every 2 to 4 weeks, or 0.1 to 0.2 mg/kg/day for 3 to 6 weeks.

Cisplatin (Platinol)—cDDP, DDP, cisplatinum, *cis*-diamminedichloroplatinum (II)
- Drug Class: Atypical alkyator; produces intrastrand and interstrand cross-links in DNA via association bonds with the platinum molecule, leading to DNA strand breakage during replication.
- Dosage Form: Lyophilized powder in sealed vials of 10 and 50 mg, and as a 1-mg/mL solution in bottles of 50 and 100 mg/bottle.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: Poor oral bioavailability. After IV infusion, rapid distribution to tissues takes place, and the drug is over 90% protein bound. While the distribution half-life is less than 1 hour, the terminal half-life is 60 to 90 hours due to tissue retention. Not extensively metabolized. Elimination is via the kidneys.
- Toxicity: Nephrotoxicity is dose limiting for an individual dose, while neurotoxicity, especially painful peripheral neuropathy, is dose limiting for cumulative doses. Myelosuppression is mild. Nausea and vomiting are common but manageable, and anorexia and diarrhea are common. Cumulative ototoxicity is also common. Chronic renal magnesium and potassium wasting is common and sometimes not reversible. Elevated liver transaminases can be seen, while alopecia and cardiac conduction abnormalities are rare.
- Indications: Used for almost every class of solid tumor and lymphoma. FDA approved for testicular and ovarian cancer and transitional cell carcinoma.
- Dosing: Cisplatin can be given all in one IV infusion or given daily as an IV infusion for several days for each cycle. Daily divided doses are somewhat better tolerated. The total dose per cycle ranges from 80 to 160 mg/m^2. Continuous infusion can also be used. Dose should be reduced for a creatinine clearance below 60 mL/min. Adequate renal perfusion and urine output are critical for minimizing renal toxicity; therefore, prehydration and adequate post-treatment hydration are used, usually with normal saline with or without mannitol, potassium, and magnesium, along with the cisplatin. Cisplatin 100 to 200 mg/m^2 is also used intraperitoneally for ovarian cancer.

Cladribine (Leustatin)—chlorodeoxyadenosine, 2-CdA
- Drug Class: Antimetabolite, purine analog; cytotoxic to dividing and nondividing cells via disruption of DNA function.
- Dosage Form: 1-mg/mL solution in 20-mL vials.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: Not orally bioavailable. After IV administration, it has a distribution half-life of 36 minutes and an elimination half-life of 7 hours. Resistant to adenosine deaminase. Chemical conversion to the active form takes place intracellularly in all cells that have deoxycytidine kinase activity. Further information on metabolism and excretion is not available.
- Toxicity: Renal toxicity is dose limiting, but at the typical doses used, myelosuppression is most prominent, including universal lymphopenia and common neutropenia and thrombocytopenia. Fever is common, while nausea and vomiting are rare and mild, and neurologic reactions are rare.
- Indications: FDA approved for hairy cell leukemia. Also used in chronic and acute leukemias, lymphoma, and mycosis fungoides.
- Dosing: For hairy cell leukemia, the dose is 0.1 mg/kg/day for 7 days as a continuous IV infusion, as a single treatment or repeated once. Other doses have ranged from 0.1 to 0.3 mg/kg/day for 5 to 7 days. Can also be given subcutaneously.

Clofarabine (Clolar)
- Drug Class: Antimetabolite.
- Dosage Form: IV 20-mL vials.
- Drug Interactions: None known.

Pharmacokinetics/Metabolism: Purine nucleoside antimetabolite. Metabolized intracellularly to the 5′ monophosphate metabolite and then phosphorylated to active triphosphate form. Inhibits DNA synthesis by decreasing deoxynucleoside triphosphate pools by inhibiting ribonucleotide reductase. Incorporates into DN, inhibiting DNA repair. Negligible hepatic metabolism. Most of drug is excreted unchanged in the urine.

Toxicity: Myelosuppression. Nausea and vomiting. Hepatobiliary toxicity. Cardiac toxicity (decrease in ejection fraction and tachycardia). Capillary leak syndrome.
Indications: Relapsed or refractory acute lymphoblastic leukemia in children.
Dosing: 52 mg/m^2 IV over 2 hours daily for 5 days, repeated every 2 to 6 weeks.

Cyclophosphamide (Cytoxan, Neosar)—CTX, CPM, Cy
Drug Class: Prototypical alkylator drug. Cell cycle independent.
Dosage Form: 25-mg and 50-mg tablets for oral use, and vials of powder in 100-, 200-, 500-, 1000-, and 2000-mg sizes for IV administration.
Drug Interactions: None noted.
Pharmacokinetics/Metabolism: 75% oral bioavailability; peak serum levels occur approximately 1 hour after administration. Activated by hepatic enzymes and metabolized to inactive forms in the liver as well. Elimination half-life is 3 to 10 hours. Parent drug and metabolites are excreted in the urine.
Toxicity: Myelosuppression is dose limiting, leukopenia being most significant. Nausea and vomiting are common and can be chronic with oral administration. Hemorrhagic cystitis is uncommon with standard doses but is common with doses over 2 g/m^2. Other toxicities of high-dose therapy include syndrome of inappropriate secretion of antidiuretic hormone, pulmonary fibrosis, and hemorrhagic myocarditis. Secondary malignancies are rare but well documented.
Indications: FDA approved for many malignancies and used for even more. Most commonly used for breast carcinoma, non-Hodgkin's lymphoma, ovarian carcinoma, and testicular cancer.
Dosing: Doses range from 50 mg/m^2 for 14 days every 28 days, to standard IV doses of 600 to 2000 mg/m^2 once every 21 to 28 days, to transplant doses of 60 mg/kg IV for 2 days.

Cytarabine (Cytosar-U)—AraC, cytosine arabinoside
Drug Class: Antimetabolite; incorporated into DNA during replication, leading to strand termination. This drug is S-phase specific.
Dosage Form: Comes in 100-mg through 2000-mg vials of powdered drug.
Drug Interactions: None noted.
Pharmacokinetics/Metabolism: Parenteral bioavailability only. After an IV dose, it is rapidly distributed into tissues, where it is converted to AraC triphosphate and rapidly deaminated in the blood. It has an elimination half-life of 2 to 3 hours. Eliminated through the kidneys.
Toxicity: Myelosuppression, often severe and prolonged, is dose limiting. It affects all lineages. Nausea, vomiting, anorexia, mucositis, and diarrhea are common. Skin erythema with exfoliation is common. Keratitis and conjunctivitis are common. Hepatic inflammation and elevation of liver function tests are common. Flu-like syndrome with fever is common. Neurologic toxicity, mostly central with ataxia being predominant, is common and usually mild, but it is dose dependent and may leave permanent dysfunction. It is more common with intrathecal administration. Pulmonary infiltrates after administration are uncommon but can be fatal. Cardiac complications are rare.
Indications: AML, ALL, and non-Hodgkin's lymphoma. Intrathecal use in acute leukemia.
Dosing: Doses range from 100 mg/m^2/day for 7 days as bolus or continuous infusion to 3 g/m^2 every 12 hours for 3 days. Doses less than 500 mg/m^2 are considered standard, while doses of 1 g/m^2 or more are considered high. The intrathecal dose is generally from 12 mg total dose up to 30 mg/m^2, given intermittently during systemic treatment.

Cytarabine, liposomal (DepoCyt)
Drug Class: Novel liposomal preparation of an antimetabolite for extended exposure to cancer cells in the cerebrospinal fluid.
Dosage Form: Vials containing 50 mg of drug in aqueous liposomal solution.
Drug Interactions: Minimal systemic exposure after intrathecal administration. Drug interactions are not considered clinically important.
Pharmacokinetics/Metabolism: After intrathecal administration of liposomes, peak levels of cytarabine occur in the CSF at 5 hours, and the half-life of cytarabine in the CSF is 100 to 200 hours. Cytarabine and metabolites eventually enter the plasma compartment, where they are eliminated in the urine.
Toxicity: Chemical arachnoiditis is common and dose limiting. Headache and back pain are the major clinical manifestations. Myelosuppression is common but usually mild. Fever, nausea, and vomiting are uncommon. Neurologic side effects are also uncommon.
Indications: FDA approved for treatment of lymphomatous meningitis. Appears to active in leukemic meningitis and carcinomatous meningitis, but published experience is limited.
Dosing: 50 mg intrathecally via spinal needle or Ommaya reservoir over 1 to 5 minutes every 14 days for up to 9 doses and then every 28 days for up to 4 doses.

Dacarbazine (DTIC-Dome)—DTIC, DIC, imidazole carboxamide
Drug Class: Atypical alkylator; methylates guanine bases preferentially. Non-cell cycle dependent.
Dosage Form: Vials of lyophylized drug containing 100, 200, or 1000 mg.
Drug Interactions: None noted.
Pharmacokinetics/Metabolism: Not orally bioavailable. After IV administration, the drug is activated by demethylation by microsomal enzymes in the liver and further metabolized to inactive forms. The elimination half-life is 3 to 5 hours. Active and inactive metabolites are largely excreted in the urine.
Toxicity: Myelosuppression is dose limiting. Nausea and vomiting are severe without aggressive antiemetic therapy. Fever is common, and flu-like syndrome is uncommon, as are diarrhea, stomatitis, alopecia, rash, or significant liver or renal toxicity.
Indications: FDA approved for the treatment of malignant melanoma and Hodgkin's disease; also used for adult sarcomas and neuroblastoma.
Dosing: Given by intravenous piggyback in doses of 375 to 1450 mg/m^2 every 2 to 3 weeks or 50 to 250 mg/m^2/day for 5 to 10 days every 3 to 4 weeks.

Dactinomycin (Cosmegen)—actinomycin D, ACT-D
Drug Class: Antitumor antibiotic, inhibits transcription by complexing with DNA.
Dosage Form: Available in vials of 0.5 mg of lyophilized drug.
Drug Interactions: None noted.
Pharmacokinetics/Metabolism: Poor oral bioavailability. After an IV dose, the drug is widely distributed except to the cerebrospinal fluid. It is metabolized in the liver. It has an elimination half-life of 30 to 40 hours. Dactinomycin and its metabolites are excreted in both bile and urine.
Toxicity: This drug is a moderate vesicant. Myelosuppression is dose limiting. Nausea, vomiting, skin erythema, acneiform lesions, and hyperpigmentation are common, while mucositis, diarrhea, and anorexia are uncommon. Hepatitis, ascites, fever, and hypocalcemia are rare.
Indications: FDA approved for Wilms' tumor, Ewing's sarcoma, rhabdomysarcoma, uterine carcinoma, germ cell tumors, and sarcoma botryoides; also used for other sarcomas, melanoma, acute myeloid leukemia, ovarian cancer, and trophoblastic neoplasms.
Dosing: 1 to 2 mg/m^2 every 3 weeks or continuous infusions of 0.25 to 0.6 mg/m^2/day for 5 days every 3 to 4 weeks.

Darbopoetin alfa (Arenesp)
Drug Class: Erythropoietic growth factor, modified recombinant DNA peptide product.

Dosage Form: Vials containing 25, 40, 60, 100, 150, 200, 300, and 500 μg of drug in 1 mL of either albumin or polysorbate aqueous solution.
Drug Interactions: No formal drug studies have been done. Exogenous testosterone and erythropoietin products used together could cause polycythemia.
Pharmacokinetics/Metabolism: After subcutaneous administration, absorption into the bloodstream is slow and dose limiting. Peak concentration occurs at approximately 30 hours and half-life in the bloodstream is 30 to 90 hours. Metabolic fates and routes of elimination have not been formally studied.
Toxicity: Polycythemia can occur and thus hemoglobin must be monitored during therapy. No other form of dose limiting toxicity is known. Either hypertension or hypotension are common. Headache is uncommon. Cardiovascular events including myocardial infarction, arrhythmia, or stroke are uncommon but can be serious. Fever, edema, or pain are rare.
Indications: FDA approved for anemia caused by cancer chemotherapy for nonmyeloid malignancies and anemia associated with chronic renal insufficiency.
Dosing: For anemia and renal insufficiency, the indicated dose is 0.45 μg/kg SC or IV once weekly, titrated upward to achieve the target hemoglobin level of 12 g/dL. For anemic cancer patients receiving chemotherapy, the recommended dose is 2.25 μg/kg SC once weekly, again with slow upward titration as needed to achieve a specific hemoglobin goal. Every other week and every 3 week doses are currently under evaluation.

Dasatinib (Sprycel)
Drug Class: Anthracycline antitumor antibiotic, intercalating agent.
Dosage Form: 20-mg vials of powdered drug for reconstitution.
Drug Interactions: None noted.
Pharmacokinetics/Metabolism: Not orally bioavailable. After IV bolus, the drug is widely distributed and is metabolized in the liver to active and inactive metabolites. The elimination of the parent drug is 18 hours, and that of the active metabolite daunorubicinol is about 25 hours. Elimination of parent drug and metabolites is via the biliary and renal routes.
Toxicity: Daunorubicin is a vesicant. Precautions are necessary. Myelosuppression is dose limiting. Alopecia, nausea, vomiting, and stomatitis are common. Diarrhea, rash, elevated liver function tests, and transient arrhythmias are uncommon. Dose-related cardiomyopathy is uncommon below cumulative doses of 400 to 500 mg/m^2.
Indications: FDA approved for AML and ALL.
Dosing: Given as a single IV injection daily for 1 to 5 days. Total dose per course up to 150 mg/m^2. A typical dose would be 45 mg/m^2/day for 3 days.

Daunorubicin, liposomal (Daunosome)
Drug Class: Novel liposomal preparation of the anthracycline DNA intercalating agent daunorubicin which modifies the pharmacokinetics and toxicities of the drug.
Dosage Form: Single-use vials containing 50 mg of daunorubicin in an aqueous liposomal solution at a concentration of 2 mg/mL.
Drug Interactions: Significant interactions of liposomal daunorubicin and other drugs have not been observed.
Pharmacokinetics/Metabolism: Daunorubicin liposomes have a small volume of distribution after IV administration but are rapidly cleared from the plasma compartment into peripheral tissues with a half-life of about 4 hours. Low levels of metabolites are detected in the plasma, likely due to slow distribution of parent drug from the peripheral tissues to the liver for metabolism. Metabolic fates are the same as for the conventional drug.
Toxicity: In general, this agent has a milder side effect and toxicity profile that conventional daunorubicin. Myelosuppression is mild but still dose limiting. An acute syndrome of back pain, chest tightness, and flushing can occur uncommonly during administration, which can usually be treated symptomatically. Other cardiac side effects are rare. Skin rashes are rare. Nausea, vomiting, and alopecia are rare.
Indications: FDA approved for treatment of AIDS-associated Kaposi's sarcoma. Some experience in other solid tumors.
Dosing: 0 mg/m^2 IV infusion over 60 minutes every 2 weeks, with reduction and delay for significant myelosuppression.

Decitabine (Dacogen)
Drug Class: Antimetabolite.
Dosage Form: Oral.
Drug Interactions: None known.
Pharmacokinetics/Metabolism: Inhibits DNA methyltransferase, causing hypomethylation of DNA. This may induce apoptosis or restore normal function to genes that control cellular differentiation and proliferation. Deaminated by cytidine deaminase, found in liver, granulocytes, gut, and blood. Elimination half-life is 30 minutes.
Toxicity: Myelosuppression. Nausea, vomiting, abdominal pain. Constitutional symptoms. Elevated liver functions, blood sugar, low serum magnesium, low serum potassium. Respiratory toxicity.
Indications: Myelodysplastic syndromes.
Dosing: 15 mg/m^2 by continuous infusion over 3 hours, every 8 hours for 3 days, repeated every 6 weeks for a minimum of 4 cycles.

Denileukin diftitox (Ontak)
Drug Class: Recombinant DNA peptide fusion product combining interleukin-2 and a diphtheria toxin, allowing relative specificity of diphtheria toxin toward interleukin-2 receptor-expressing cells.
Dosage Form: Vials of 300 μg in 2 mL frozen aqueous solution.
Drug Interactions: None known.
Pharmacokinetics/Metabolism: After IV administration, the plasma half-life of denileukin diftitox is about 80 minutes. Radiolabeling studies show that the drug accumulates in the vasculature, liver, and kidneys, but its specific metabolic fates are unknown. Antibodies against the drug have been shown to slow its clearance.
Toxicity: Denileukin diftitox has a broad range of toxicities similar to other peptide biologic response modifiers, with hypotension and other manifestations of vascular leak syndrome being dose limiting. Fever, chills, edema, rash, fatigue, headache, nausea, vomiting, anorexia, and diarrhea are common. Dyspnea, cough, arthralgias, myalgias, and pharyngitis are uncommon. Infections associated with drug administration are common. Arrhythmias and significant neurologic, hepatic, or renal complications are rare.
Indications: FDA approved for recurrent cutaneous T-cell lymphoma (mycosis fungoides).
Dosing: 9 or 18 μg/kg/day for 5 days as an IV infusion over at least 15 minutes, repeated every 21 days.

Dexamethasone (Decadron)—Dex, DXM
Drug Class: Corticosteroid that has pleiotrophic properties in various body tissues. Directly toxic to benign and malignant lymphocytes. Potent anti-inflammatory action.
Dosage Form: Tablets ranging from 0.25 to 6 mg are available, as well as an oral solution at 0.1 mg/mL and a solution for injection at 4 to 24 mg/mL.
Drug Interactions: Drugs that induce hepatic microsomal enzymes can enhance the metabolism of dexamethasone and decrease its effectiveness. This includes phenytoin, tegretol, and dilantin.
Pharmacokinetics/Metabolism: Well absorbed by the GI tract. Metabolized in the liver. Elimination half-life is 3 to 4 hours.

Elimination of metabolites is primarily renal, with some biliary component.
Toxicity: Toxicities are shared with other corticosteroids and include leukocytosis, hyperglycemia, mood changes, euphoria, insomnia, increased appetite, weight gain, dyspepsia, exacerbation of peptic ulcer disease, cataracts, adrenal suppression, edema, and osteoporosis.
Indications: Used for many purposes in oncology and hematology patients, including treatment of multiple myeloma, CLL and ALL, non-Hodgkin's lymphoma, immune thrombocytopenic purpura, and hemolytic anemia. Also used to alleviate symptoms from brain or spinal cord metastases and other metastatic sites where edema and inflammation exist. Used as an adjunctive antiemetic medication as well.
Dosing: Oral and parenteral dosing are equivalent. Dosage for acute indications or active treatment involves total daily doses of 16 to 40 mg, sometimes with an initial "bolus" dose of up to 100 mg. Tapering treatments will decrease down to 1 to 2 mg/day. As an antiemetic, 10 to 20 mg is the standard dose.

Dexrazoxane (Zinecard)—ADR-529, ICRF-187
Drug Class: Iron-chelating agent that serves as a free-radical scavenger/cytoprotectant.
Dosage Form: Lyophilized powder, 500 mg/vial, with diluent.
Drug Interactions: None noted.
Pharmacokinetics/Metabolism: The drug is not bioavailable by the oral route. After an IV dose, distribution in the body is widespread and rapid. Metabolism is predominantly hepatic. The terminal half-life is 3 to 4 hours. Parent drug and metabolites are excreted by the kidneys.
Toxicity: Dexrazoxane appears to worsen slightly the leukopenia induced by doxorubicin. Mild nausea and vomiting are common, fever, stomatitis, fatigue, anorexia, and hypotension are uncommon. Seizure, respiratory arrest, deep venous thrombosis, and significant liver toxicity are rare.
Indications: FDA approved as an "orphan drug" to prevent doxorubicin-induced cardiomyopathy.
Dosing: Administered just prior to a dose of doxorubicin as a 15- to 30-minute infusion at a dose of 500 to 1000 mg/m^2.

Docetaxel (Taxotere)—RP-56976
Drug Class: Docetaxel is a semisynthetic taxane, a class of compounds that inhibit the mitotic spindle apparatus by stabilizing tubulin polymers, leading to death of mitotic cells.
Dosage Form: 20- and 80-mg vials at a concentration of 40 mg/mL in polysorbate 80 solvent.
Drug Interactions: Docetaxel given concurrently with cisplatin has been reported to increase the incidence and severity of peripheral neuropathy.
Pharmacokinetics/Metabolism: The drug has poor oral bioavailability. After a 1-hour infusion, docetaxel is widely distributed and has a triphasic elimination course, with a distribution half-life of 4 minutes, an elimination half-life of 1 hour, and a terminal half-life of 18 hours. The extent and by-products of metabolism are not well known. The main excretion route is biliary.
Toxicity: Myelosuppression is universal and dose limiting. Alopecia is also universal. Edema and fluid accumulation, including pleural effusions and ascites, are common and can be dose limiting. Fluid accumulation is partially preventable with corticosteroid treatment before and after each cycle of docetaxel. Mild sensory or sensorimotor neuropathy is common. Mucositis and diarrhea are common and usually mild. Hypersensitivity reactions are uncommon and can largely be prevented through premedication with corticosteroids and antihistamines. Rash and elevated liver function tests are uncommon.
Indications: FDA approved for metastatic breast cancer and first and second line non-small-cell lung cancer. Clinical experience is increasing in ovarian cancer and other epithelial neoplasms.
Dosing: The standard dose is 100 mg/m^2 IV over 1 hour every 3 weeks. Higher doses and other schedules have been used.

Doxorubicin (Adriamycin, Rubex)—Adria, hydroxydaunorubicin
Drug Class: Anthracycline antitumor antibiotic, intercalating agent.
Dosage Form: Available in vials of lyophilized powder containing 10 to 150 mg of drug and as vials of 2-mg/mL solution in 10- to 200-mg vials.
Drug Interactions: None noted.
Pharmacokinetics/Metabolism: The drug has poor oral bioavailability. After an IV dose, it is widely distributed in tissues and is 70% protein bound. It is metabolized in the liver to active and inactive forms. It has an elimination half-life of 18 hours or more. Most of the drug and metabolites are excreted through the biliary route.
Toxicity: Doxorubicin is a potent vesicant, and extravasation precautions are a must. Myelosuppression is universal and usually dose limiting with each individual cycle. Cardiotoxicity is common and can be dose limiting, though usually subclinical. Chronic, cumulative cardiomyopathy is expected when total dose exceeds 400 to 500 mg/m^2. This toxicity can be lessened by the addition of dexrazoxone or by longer infusions. Acute cardiac effects, including arrhythmias, are less often seen and are unpredictable. Nausea and vomiting are common but manageable. Diarrhea and stomatitis are common but usually mild. Alopecia, rash, and hyperpigmentation are common.
Indications: FDA approved for a variety of cancers and used for many more. Most commonly used for breast carcinoma, adult sarcomas, pediatric solid tumors, Hodgkin's disease, non-Hodgkin's lymphomas, and ovarian cancer.
Dosing: Standard doses range from 60 to 90 mg/m^2 IV as a bolus or continuous infusion over 48 to 72 hours every 3 to 4 weeks. Weekly and biweekly schedules are also used, with lower doses. Doses are usually reduced for elevated bilirubin levels.

Doxorubicin, liposomal (Doxil)
Drug Class: Novel liposomal preparation of the anthracycline DNA intercalating agent doxorubicin.
Dosage Form: Vials of 20 mg in 10 mL and 50 mg in 25 mL of doxorubicin in aqueous liposomal dispersion.
Drug Interactions: No formal drug interaction studies have been conducted. No important drug interactions have been reported.
Pharmacokinetics/Metabolism: The parent drug, doxorubicin, is metabolized in the liver and excreted primarily in the bile. Significant levels of the principal metabolite doxorubicinol, have not been observed with the liposomal preparation, likely due to the slow distribution of free doxorubicin to the liver. Half-life of the liposomes in the plasma compartment is approximately 55 hours.
Toxicity: Myelosuppression is mild but dose limiting. Palmar plantar erythrodysesthesia is common and can occasionally be severe and dose limiting. Stomatitis and nausea are common but usually mild. Alopecia is uncommon. Acute infusion reactions including chest pain, back pain, dyspnea, and wheezing can occur uncommonly.
Indications: FDA approved for recurrent metastatic ovarian cancer and AIDS-related Kaposi's sarcoma. Also used commonly in metastatic breast cancer and multiple myeloma.
Dosing: 50 mg/m^2 IV infusion over 1 hour for ovarian cancer, 20 mg/m^2 IV infusion over 30 minutes for Kaposi's sarcoma.

Epirubicin (Ellence)
Drug Class: Anthracycline DNA intercalating agent.
Dosage Form: Vials of 50 mg in 25 mL or 200 mg in 100 mL of aqueous solution.

Drug Interactions: Additive toxicities with other cytotoxic drugs should be expected. Cardiac toxicity of epirubicin can be enhanced when used with other drugs that can temporarily or permanently impair cardiac function. Cimetidine increases the AUC of epirubicin and should be stopped before starting epirubicin.

Pharmacokinetics/Metabolism: Epirubicin is metabolized primarily by the liver. The parent drug and metabolites are glucuronidated and are excreted in the bile much more than via renal clearance. Doses should be reduced for patients with mild to moderate hepatic dysfunction. Severe hepatic dysfunction is a contraindication for using epirubicin. Half-life of plasma levels is about 30 to 35 hours after IV administration.

Toxicity: Myelosuppression is universal and dose limiting. Alopecia is expected. This drug is a vesicant, and precaution must be taken to avoid extravasation into soft tissue around veins. Nausea and vomiting are common but usually manageable. Stomatitis is common. Fatigue is common. Detectable cardiac dysfunction is uncommon to rare. Secondary leukemia is rare.

Indications: FDA approved for adjuvant therapy after optimal surgical treatment of localized breast cancer with involved axillary lymph nodes.

Dosing: 100 to 120 mg/m^2 by intravenous infusion every 3 to 4 weeks. Usually combined with cyclophosphamide and 5-fluorouracil.

Erlotinib (Tarceva)

Drug Class: Targeted agent.

Dosage Form: 25-mg, 100-mg, 150-mg tablets.

Drug Interactions: Drugs that stimulate or inhibit liver CYP3A4 enzymes. Warfarin.

Pharmacokinetics/Metabolism: Inhibits the tyrosine kinase domain of the epidermal growth factor receptor, leading to inhibition of EGFR autophosphorylation and signaling.

Toxicity: Acneiform rash. Diarrhea. Interstitial lung disease.

Indications: Second- or third-line therapy of non-small-cell lung cancer. Pancreatic cancer, in combination with gemcitabine.

Dosing: Lung cancer: 150 mg/day. Pancreatic cancer: 100 mg/day.

Erythropoietin (Epogen, Procrit)—EPO, epoitin alpha

Drug Class: Hematopoietic growth factor. Stimulates erythrocytic precursors.

Dosage Form: Vials of 2000, 4000, and 10,000 units in solution.

Drug Interactions: Erythropoietin may temporarily decrease the effectiveness of heparin when the two drugs are given simultaneously. Oral aluminum-containing antacids may decrease the effectiveness of erythropoietin.

Pharmacokinetics/Metabolism: This peptide must be given parenterally. After IV or subcutaneous dosing, it is detectable in plasma for 24 hours. It is distributed to a volume approximating the total blood volume. It is degraded by proteolysis within the blood compartment. Half-life ranges from 4 to 27 hours. Onset of therapeutic effect takes at least 7 days. Excretion of intact peptide is negligible.

Toxicity: Hypertension is common but usually mild and not dose limiting. Injection site pain is common but mild. Flu-like syndrome and diaphoresis are uncommon. Nausea and vomiting are rare. Seizures have been reported in dialysis patients receiving the drug. Iron deficiency anemia can occur after prolonged therapy, and concomitant iron administration may increase the effectiveness of erythropoietin. Hematocrit values should be monitored closely while on therapy to prevent polycythemia and hyperviscosity.

Indications: The oncology indication is chemotherapy-induced anemia that is symptomatic. Also used for anemia of chronic renal failure and human immunodeficiency virus (HIV)-associated anemia.

Dosing: Starting doses of 150 units/kg SC three times per week were recommended, with increases up to 300 units/kg if there is suboptimal effect after 6 to 8 weeks, although 40,000 units weekly with increases to 60,000 units is the most commonly used program.

Estramustine (Emcyt)

Drug Class: A conjugate of estrogen and an alkylating moiety, estramustine appears to work through estrogen-binding proteins to kill malignant cells through a nonalkylator mechanism, perhaps by inhibition of microtubules.

Dosage Form: 140-mg capsules.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Well absorbed by mouth, subject to hepatic metabolism, with a terminal half-life of about 20 hours. Excretion route is not clearly delineated.

Toxicity: Nausea and vomiting are common and dose limiting but diminish over time. Headache, edema, decreased libido, and impotence are common. Gynecomastia and breast tenderness can be seen. Rash, alopecia, myelosuppression, hepatic toxicity, and thromboembolic events are rare.

Indications: FDA approved for the treatment of prostate cancer. Not used commonly for any other types of cancer.

Dosing: The usual dose for prostate cancer is 15 mg/kg/day, which is typically given as 420 mg PO tid for most men.

Etoposide (Vespid)—VP-16, epipodophyllotoxin; also available as etoposide phosphate (Etopophos)

Drug Class: Plant alkaloid; topoisomerase II inhibitor. Partially cell cycle dependent.

Dosage Form: Etoposide comes in oral form as 50-mg capsules and in parenteral form as 100-mg multidose vials in solution at 20 mg/mL. Etoposide phosphate is available in 100-mg single-dose vials as lyophilized powder.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Etoposide phosphate is rapidly converted to etoposide after IV infusion. Etoposide itself is extensively protein bound, is metabolized in the liver, and has an elimination half-life of about 10 hours. About 50% of oral etoposide is absorbed via the GI tract, requiring oral doses to be twice as high as parenteral doses. Excreted both unchanged in the urine and as metabolites in the bile.

Toxicity: Myelosuppression, primarily leukopenia, is universal and dose limiting. Nausea and vomiting are common with PO administration but rare when the drug is given IV. Stomatitis and diarrhea are rare with normal doses but common with high doses. Alopecia is mild or absent. Hepatic toxicity and neurologic effects (peripheral neuropathy and CNS changes) are rare. Hypotension can occur with rapid administration of etoposide but does not occur commonly when etoposide phosphate is infused over 5 minutes. Secondary AML has been reported after etoposide.

Indications: FDA approved for germ cell tumors and SCLC. Also used for lymphomas, AML, brain tumors, non-SCLC, and as high-dose therapy in the transplant setting for breast cancer, ovarian cancer, and lymphomas.

Dosing: Etoposide can be given either over several days or at lower doses over many days. Typical doses are 50 to 120 mg/m^2/day for 3 to 5 days given IV. Oral doses are generally twice the IV doses. A typical protracted oral course would be 50 mg/m^2/day for 21 days given every 28 days. Transplant doses up to 1200 mg/m^2 over 1 to 3 days have been used.

Exemestane (Aromasin)

Drug Class: Hormonal agent, steroidal aromatase inhibitor.

Dosage Form: 25-mg tablets.

Drug Interactions: In spite of the fact that exemestane is metabolized by cytochrome P450 3A4, ketoconazole does not affect its half-life or AUC, and no other drug-drug interactions have been identified.

Pharmacokinetics/Metabolism: After oral administration, approximately 40% of exemestane is absorbed from the gastrointestinal tract. Absorption is increased by a fatty meal. It is highly protein bound in the plasma. Exemestane is metabolized in the liver by cytochrome P450 3A4 and aldoketoreductase. Metabolites are eliminated equally in urine and feces.

Toxicity: Though generally well tolerated, exemestane is expected to cause or exacerbate hot flashes or intermittent flushing in some women. Fatigue and mild nausea are common. Vomiting, headache, and dyspnea are uncommon. It is teratogenic and should not be used in premenopausal women.

Indications: FDA approved for treatment of estrogen-responsive metastatic breast cancer in postmenopausal women who have progressed on prior hormonal therapy.

Dosing: 25 mg orally once daily after a meal.

Filgrastim (Neupogen)—G-CSF

Drug Class: Hematopoietic growth factor, relatively specific for the granulocyte lineage.

Dosage Form: Available in single-use vials of 300 and 480 μg, in solution.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: After a bolus SC injection, peak plasma levels of filgrastim occur in 2 to 6 hours, while the elimination half-life is generally 7 hours or less. Metabolism is via proteolysis in the blood compartment. The intact molecule is largely absent from bile or urine.

Toxicity: Mild bone pain is common. Low-grade fever, myalgias, arthralgias, and transient hypotension are uncommon, as are hyperuricemia and elevations of lactate dehydrogenase and alkaline phosphatase. Leukocytosis leading to hypoxia or capillary leak syndrome has been reported. Anaphylaxis or allergic reaction are rare.

Indications: FDA approved for minimization of granulocytopenia after myelosuppressive chemotherapy. Also used to speed recovery of granulocytes in the setting of neutropenic fever after chemotherapy, for myelodysplastic syndromes, for congenital agranulocytosis, for cyclic neutropenia, and for mobilization of peripheral blood stem cells from patients or donors for transplant.

Dosing: Starting dose is 5 μg/kg/day until neutrophil recovery (discontinue the drug after an absolute neutrophil count of 10,000 or greater has been achieved), although generally either the whole 300 μg or 480 μg vial is used. For post-transplant or high-dose chemotherapy applications, 10 μg/kg/day is the typical dose. There is no known maximum dose.

Floxuridine (FUDR)—FdUR, fluorodeoxyuridine

Drug Class: Pyrimidine nucleotide analog, antimetabolite. Cell cycle dependent.

Dosage Form: Available in 500-mg vials of lyophilized powder.

Drug Interactions: Leucovorin will enhance the toxicity of floxuridine.

Pharmacokinetics/Metabolism: After infusion into the hepatic artery, the drug is phosphorylated to the active monophosphate form and incorporated into cells. Further hepatic metabolism to inactive forms is rapid. The elimination half-life is 30 minutes. Metabolites are cleared by the kidneys.

Toxicity: When given as a bolus, myelosuppression is dose limiting, while diarrhea and stomatitis are the dose-limiting toxicities of the more common protracted infusions. Other GI toxicities, all rare, include nausea, vomiting, anorexia, gastritis, cramping, enteritis, and duodenal ulcers. Liver toxicity, usually a cholestatic picture, is dose limiting with intrahepatic arterial infusions. Serious neurologic side effects, including ataxia and visual changes, are rare, as is fever.

Indications: FDA approved for regional (intra-arterial) treatment of GI adenocarcinomas metastatic to the liver. Sometimes used intravenously for the same tumors.

Dosing: Protracted intra-arterial infusions are generally given at 0.1 to 0.6 mg/kg/day until grade III toxicity, sometimes according to a circadian schedule. IV doses range up to 60 mg/kg/week by various infusion schedules.

Fludarabine (Fludara)—FAMP

Drug Class: Purine nucleotide analog antimetabolite. Only partially cell cycle dependent.

Dosage Form: Vials containing 50 mg each of lyophilized drug. Add 2 mL of sterile water to the vial to make a 25-mg/mL solution, and then dilute the desired dose further to a concentration of 0.04 to 1 mg/mL (depending on the infusion schedule).

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Fludarabine is available only by the parenteral route. After IV administration, the drug is metabolized to 2-fluoro-araA and widely distributed in tissues. It has an elimination half-life of 9 to 10 hours. The drug and metabolite are excreted primarily by the kidneys.

Toxicity: Neurotoxicity, including cortical blindness, confusion, somnolence, coma, and demyelinating lesions, is dose limiting, but the lower doses that are conventionally used rarely produce these side effects. At these doses, mild myelosuppression is the most common toxicity, cumulative lymphopenia being the most clinically important. Nausea, vomiting, and other GI toxicities are rare. Alopecia and rash are also rare.

Indications: FDA approved for the treatment of CLL. Also used for low-grade lymphomas and for AML.

Dosing: The standard regimen is 25 mg/m^2/day for 5 days by short IV infusion. Prolonged infusions have also been used.

5-Fluorouracil (Adrucil, Efudex)—5-FU

Drug Class: Pyrimidine antimetabolite; inhibitor of thymidylate synthase. Partially cell cycle dependent.

Dosage Form: Available in solution in 0.5- to 5-g ampules or vials at a concentration of 50 mg/mL.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Parental bioavailability only. After an intravenous dose, 80% of the drug is metabolized to the inactive dihydro-5-FU by dihydropyrimidine dehydrogenase in the liver. The rest of the drug is activated to fluorodeoxyuridine monophosphate in the target cells. The elimination half-life is about 20 minutes. Excretion is via the kidneys.

Toxicity: GI toxicities, primarily mucositis for bolus injections and diarrhea for prolonged infusions, are dose limiting. Rare patients with dihydropyrimidine dehydrogenase deficiency have excessive GI toxicity. Myelosuppression is generally less with continuous infusion schedules. Nausea and vomiting are uncommon and mild. Dermatitis and other cutaneous toxicities, including hand-foot syndrome, are common. Cerebellar ataxia and myocardial ischemia are rare.

Indications: FDA approved for colon, rectum, gastric, pancreas, and breast carcinomas and used for a wide range of other neoplasms in combination regimens. Used for intrahepatic arterial infusion for liver metastases from GI tumors; also used topically for various cutaneous neoplasms and disorders.

Dosing: IV dosing schemes include weekly bolus, 5 days of bolus every 28 days, 4 to 5 day continuous infusions. Doses range from 300 to 3000 mg/m^2/day depending on the dosing scheme and schedule.

Fluoxymesterone (Halotestin, Oro-Testryl)

Drug Class: Synthetic steroidal androgen. Antagonizes estrogenic effects in estrogen-dependent target cells.

Dosage Form: 2-, 5-, and 10-mg tablets.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: The drug is available by the oral route, is metabolized in the liver, and has an elimination half-life of about 10 hours. Route of excretion is unknown.

Toxicity: Androgenic effects predominate. Hirsutism, amenorrhea, hoarseness, acne, and increased libido occur in women; men may have gynecomastia. Mild edema is common. Liver abnormalities, including transaminitis, fatty change, cholestatic jaundice, and rarely carcinoma, are not uncommon. Polycythemia may occur.

Indications: FDA approved for the treatment of hormone-sensitive breast cancer and for hypogonadism in males.

Dosing: The total daily dose for breast cancer is usually between 10 and 40 mg, divided into two or three doses per day.

Flutamide (Eulexin)

Drug Class: Nonsteroidal antiandrogen.

Dosage Form: 125-mg capsules.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Good oral bioavailability, with peak plasma levels after an oral dose at 1 to 2 hours. The drug is metabolized to active and inactive forms in the liver. The elimination half-life is 8 to 10 hours. Parent drug and metabolites are excreted in the urine.

Toxicity: Generally well tolerated. Gynecomastia, galactorrhea, and impotence are common. Nausea, vomiting, diarrhea, mild myelosuppression, myalgias, and elevated liver function tests are rare.

Indications: FDA approved for prostate carcinoma.

Dosing: The standard dose is 250 mg PO three times daily. Often given in conjunction with an LHRH agonist such as leuprolide to create complete androgen blockade.

Fulvestrant (Faslodex)

Drug Class: Estrogen receptor antagonist.

Dosage Form: 250mg/5 mL and 125 mg/2.5 mL prefilled syringes.

Drug Interactions: None known.

Pharmacokinetics/Metabolism: Binds to the estrogen receptor (ER), leading to degradation and loss of ER from the cell. Peak plasma levels reached in 7 days, half-life is 40 days. Metabolized by the liver microsomal P4503A4 system and excreted primarily in the feces.

Toxicity: Constitutional symptoms, including hot flashes. Peripheral edema. Nausea, vomiting.

Indications: Estrogen receptor positive metastatic breast cancer in postmenopausal women.

Dosing: 250 mg IM monthly.

Gallium Nitrate (Ganite)

Drug Class: Heavy metal that antagonizes iron metabolism in tumor cells preferentially. Causes hypocalcemia by a similar mechanism.

Dosage Form: 500-mg vials (20-mL vials of a 25-mg/mL solution).

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: This drug is not metabolized and has an elimination half-life of about 5 hours. Cleared unchanged in the urine.

Toxicity: Renal toxicity, including glomerular and tubular defects, is dose limiting but partly preventable with adequate hydration during therapy. Hypocalcemia is expected and common and can be dose limiting. Nausea, vomiting, diarrhea, and anorexia are not uncommon. Mild myelosuppression, rashes, hearing loss or tinnitus, visual disturbances, and transient neurologic symptoms are rare.

Indications: FDA approved for the treatment of malignancy-related hypercalcemia. Also used for advanced bladder carcinoma.

Dosing: The standard dose and schedule is 300 mg/m^2/day for 7 days by continuous IV infusion in a volume of 1000 mL of normal saline.

Gemcitibine (Gemzar)

Drug Class: Antimetabolite. Gemcitibine is a nucleoside analog that exhibits cell cycle-dependent and S-phase-specific cytotoxicity, likely due to inhibition of DNA synthesis.

Dosage Form: Supplied as lyophilized powder in vials containing 200 and 1000 mg of drug.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Gemcitibine has poor oral bioavailability. After IV infusion, the drug is rapidly distributed and has a half-life of less than 2 hours. It is metabolized throughout the body to inactive forms. Parent drug and metabolite are excreted principally by the kidneys.

Toxicity: Myelosuppression, including anemia, is mild but dose limiting. Nausea and vomiting are mild but common. Diarrhea and edema are sometimes seen. Elevated transaminases are common, as is fever during drug administration. Hematuria and proteinuria are uncommon. Acute dyspnea and rash are uncommon. Paresthesias and CNS depression are rare.

Indications: FDA approved for advanced pancreatic adenocarcinoma, NSCLC, and metastatic breast cancer; extensively used in bladder cancer also.

Dosing: The usual dose in pancreatic cancer is 1000 mg/m^2 as an IV bolus weekly for up to 7 weeks, followed by a week of rest before another cycle is begun. Similar doses in combination with or without platinating agents are used for the other indications.

Gemtuzumab ozogamicin (Mylotarg)

Drug Class: Novel toxin-conjugated monoclonal antibody directed at myeloid lineage cells.

Dosage Form: Amber single use vials containing 5 mg of drug as a lyophilized powder.

Drug Interactions: No formal studies done, and no important drug interactions yet noted. Other medications that cause myelosuppression would be expected to worsen myelosuppression caused by gemtuzumab.

Pharmacokinetics/Metabolism: Gemtuzumab is given as a 2-hour IV infusion, after which the total calicheamycin (ozogamicin released from the antibody by hydrolysis) has a half-life of 45 hours for the first dose and 60 hours after the second dose. Metabolism of the toxin is hepatic. The elimination routes of the toxin and the antibody are unknown.

Toxicity: This peptide antibody linked to a toxin, given in a group of patients with poor prognosis who are often medically fragile, can have marked acute toxicities. These include somewhat common typical antibody infusion side effects, including fever, chills, hypotension, dyspnea, and wheezing, and other uncommon toxicities including tachycardia, renal insufficiency, hepatic compromise (including hepatic veno-occlusive disease), dizziness, headache, and rash. Leukopenia is expected and can be prolonged, causing a high risk of bacterial, fungal, and sometimes viral infections. Thrombocytopenia and anemia are common also. Nausea and vomiting and diarrhea are common. Serious coagulopathy or hemorrhage are rare.

Indications: FDA approved for relapsed AML.

Dosing: 9 mg/m^2 as a 2-hour IV infusion given once up front and then again in 14 days.

Goserelin Acetate (Zoladex)

Drug Class: LHRH that inhibits pituitary-gonadal axis function. This drug causes steroid hormone withdrawal from dependent tissues, including prostate cancer and breast cancer cells.

Dosage Form: 3.6-mg prefilled syringes.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: After the contents of the syringe are injected SC into adipose tissue, the depot of drug is slowly released over 28 days, peaking at 12 to 15 days. The elimination half-life is 4 hours, and the drug is not appreciably metabolized. Excretion in almost entirely by the urinary route.

Toxicity: Toxicity is mild. Endocrine side effects are most prominent and include hot flashes, diminished libido, impotence, gynecomastia, amenorrhea, and breakthrough vaginal bleeding. Other toxicities include flares of pain early during treat-

ment in sites of disease, local tenderness at injection sites, headache, nausea, depression, and elevated cholesterol levels.
- Indications: FDA approved for advanced prostate cancer; used also in metastatic breast cancer.
- Dosing: 3.6 mg SC usually in the abdomen, every 28 days.

Hydroxyurea (Hydrea)—hydrocarbamide
- Drug Class: Antimetabolite; inhibitor of ribonucleotide reductase, which converts nucleotides to the deoxyribose forms for DNA synthesis. Cell cycle dependent.
- Dosage Form: 500-mg capsules.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: After oral administration, the drug is well absorbed, and drug levels peak in the blood 2 hours after a dose. The elimination half-life is 2 to 5 hours. Metabolism to inactive forms occurs in the liver. Renal excretion is the route of elimination.
- Toxicity: Myelosuppression is common and dose limiting. Other toxicities include rash, headache, fever, and hyperuricemia. Nausea and vomiting are uncommon. Liver toxicity and serious neurologic toxicity are rare.
- Indications: FDA approved for CML; commonly used for other myeloproliferative disorders; also used occasionally for metastatic melanoma, refractory ovarian carcinoma, and squamous cell carcinoma of the cervix and the head and neck.
- Dosing: For CML, the dose is 1000 to 3000 mg/day; in solid tumors, the dose is either 80 mg/kg every third day or 1.25 g/m^2 every 8 hours for five doses once a week.

Ibritumomab tiuxetan—Yttrium-90 (Zevalin)
- Drug Class: Monoclonal antibody directed to the B-cell surface antigen CD20 linked to beta-emitting radionuclide yttrium-90.
- Dosage Form: Kits for preparation of either the In-111 (used for predicting drug distribution) or Y-90 (used for therapy) form of the drug include a vial containing 3.2 mg of the antibody in saline solution along with three other vials for mixing. Y-90 is sent with the Y-90 kit. Rituxan and In-111 must be ordered separately.
- Drug Interactions: None known. Formal studies have not been conducted.
- Pharmacokinetics/Metabolism: Optimal irbitumomab/Y-90 binding and clinical effect require pretreatment with unconjugated ibritumomab. The physical half-life of Y-90 is 64 hours, but the biological half-life of the agent in the body in terms of radioactivity detected is 30 hours. Metabolic and excretory fates of the radionuclide and antibody are not known.
- Toxicity: Ibritumomab/Y-90 should not be administered if the biodistribution of ibritumomab/In-111 is altered significantly. Antibody toxicities can include fever, chills, dyspnea, wheezing, urticaria, and rash. Radionuclide or total agent side effects include lymphopenia, and myelosuppression of other cell lines, which can be prolonged. Infection risk is increased accordingly. Nausea, vomiting, and diarrhea are uncommon, as are arthralgias, myalgias, or neurologic side effects.
- Indications: FDA approved for treatment of relapsed and/or transformed follicular B-cell lymphomas.
- Dosing: The first step of therapy is administration of a 250 mg/m^2 dose of rituximab, followed by a 1.6 mg/5 mCi dose of ibritumomab/In-111 as a 10-minute infusion; 9 days later, if biodistribution of the In-111-labeled product is normal, the same dose of rituximab is followed by a 1.6 mg/0.4 mCi/kg dose of ibritumomab/Y-90 as a 10-minute infusion.

Idarubicin (Idamycin)—4-demethoxydaunorubicin
- Drug Class: Anthracycline intercalating agent. Non-cell cycle dependent.
- Dosage Form: Lyophilized powder in vials of 5 and 10 mg.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: Idarubicin has poor oral bioavailability. After an IV dose, the drug is metabolized in the liver to active and inactive forms. The elimination half-life of the parent compound is 13 to 26 hours. Metabolites and some of the unchanged drug are almost exclusively excreted in bile.
- Toxicity: Myelosuppression is common and generally dose limiting for each dose. The cumulative dose-limiting toxicity is cardiomyopathy, but idarubicin is less cardiotoxic than daunorubicin or doxorubicin. Nausea and vomiting are common but usually mild. Diarrhea and stomatitis are sometimes seen. Idarubicin is a weak vesicant or irritant.
- Indications: FDA approved for the treatment of AML.
- Dosing: The standard dose as part of a "7 plus 3" regimen (with cytarabine) is 12 mg/m^2/day for 3 days for induction or reinduction/intensification. Other doses have been used.

Ifosfamide (Ifex)
- Drug Class: Classic alkylating agent. Non-cell cycle dependent.
- Dosage Form: Available in 1- and 3-g vials of powdered drug.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: After an intravenous dose, ifosfamide is activated by hepatic microsomal enzymes. It is then converted to inactive metabolites in the liver. The active form of the drug is the same as that for cyclophosphamide. The elimination half-life of the drug is 7 to 15 hours. The metabolites and some unchanged drug are excreted in the urine.
- Toxicity: Myelosuppression, hemorrhagic cystitis, and CNS toxicity are all fairly common and can be dose limiting. Hemorrhagic cystitis can largely be prevented by coadministration of the uroprotective agent mesna, and nausea and vomiting are minimized with modern antiemetic regimens. The CNS toxicity, including lethargy, stupor, coma, myoclonus, and seizures, is usually mild and completely reversible. It is worse with impaired renal function. Renal dysfunction, usually reversible, is also seen with ifosfamide. Hepatic toxicity, diarrhea, and rash are rare.
- Indications: FDA approved for the treatment of recurrent germ cell tumors. Used for many other tumor types, including adult sarcomas, lymphoma, Hodgkin's disease, breast cancer, and ovarian cancer.
- Dosing: fosfamide is generally given IV over 3 to 5 days with a total dose of 8 to 12 g/m^2/cycle, repeated every 3 to 4 weeks. It can be given as a short infusion each day or as a continuous infusion. Mesna is given IV concurrently, also by short infusion or continuous infusion. Hydration of greater than 3 L/day total, with saline or alkali solutions, is also recommended.

Imatinib mesylate (Gleevec)
- Drug Class: Specific receptor tyrosine kinase inhibitor, which selectively inhibits the tyrosine kinases of bcr-abl, c-kit, and PDGF receptors.
- Dosage Form: 100-mg capsules.
- Drug Interactions: Imatinib plasma levels are enhanced by ketoconazole, and imatinib increases the plasma levels of other drugs that are metabolized by cytochrome P450 3A4. Inducers of this enzyme such as phenytoin would be expected to lower the plasma levels of imatinib.
- Pharmacokinetics/Metabolism: Imatinib has good oral bioavailability, reaches peak serum levels in about 3 hours, and has an elimination half-life of 18 hours. It is metabolized in the liver by cytochrome P450 3A4 among other isoforms, with the demethylated metabolite showing activity similar to that of the parent drug. The parent drug and major metabolite are excreted primarily in the feces.
- Toxicity: Imatinib has no definite dose-limiting toxicity. Myelosuppression is significant in chronic myelogenous leukemia

(CML) but mild in gastrointestinal stromal tumors. Hepatotoxicity is common but usually mild. Liver function tests should be monitored closely during therapy. Fluid retention is common but usually mild, as are nausea, vomiting, and diarrhea. Rash and fever are uncommon.

Indications: FDA approved for treatment of CML in the frontline setting, in accelerated phase, and in blast crisis. It is also approved for the treatment of recurrent inoperable or metastatic gastrointestinal stromal tumors.

Dosing: Total daily doses of 400 mg to 800 mg, once daily, or divided.

Interferon-α (IntronA, Roferon)—α-interferon, IFN-α

Drug Class: Biologic response modifier, antiviral, immunostimulant.

Dosage Form: Available in vials of lyophilized powder or aqueous solution in quantities from 3 million to 50 million IU/vial.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: After parenteral administration, peak levels of IFN-α in the blood occur in 30 minutes to 8 hours depending on the route. The elimination half-life is 2 to 9 hours. IFN-α is catabolized throughout the body through proteolysis but primarily in the renal tubules. Excretion of intact drug is minimal and not significantly affected by organ function.

Toxicity: Constitutional symptoms are predominant side effects and are dose limiting in both the short and long term in lower dose schedules. Acute side effects include fever, chills, nasal congestion, diarrhea, and malaise. Chronic side effects include fatigue, anorexia, weight loss, and depression. Neutropenia and thrombocytopenia, both of which are transient, are dose limiting at higher doses. Anemia may also occur, albeit with more chronic administration. Cardiac toxicity, including congestive heart failure and arrhythmias, is rare and almost always reversible. Serious CNS toxicity, including delirium and psychosis, or peripheral neuropathies are also rare and reversible. Hypocalcemia and hyperglycemia can also occur.

Indications: FDA approved for nonmalignant conditions and malignancies including melanoma, CML, hairy cell leukemia, Kaposi's sarcoma, and cutaneous T-cell lymphoma. Also used in multiple myeloma and low-grade lymphomas.

Dosing: Dose depends on both the diagnosis and the brand or type of IFN-α. The doses for malignant conditions range from 2 million up to 30 million units/m^2 by the SC, IM, or IV route from three times per week to every day. Adjustments are made on the basis of patient tolerance and laboratory parameters.

Interleukin-2 (Proleukin)—aldesleukin, IL-2

Drug Class: IL-2 is a glycoprotein cytokine, previously known as T-cell growth factor, that stimulates antigen-specific and nonspecific T-cell and other lymphocyte subsets and also triggers an inflammatory cytokine cascade. Its antineoplastic effects are dependent on an intact immune system.

Dosage Form: Vials of lyophilized drug containing 18 million IU.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: IL-2 is available by the parenteral route only. It has an elimination half-life of 30 to 60 minutes. It is catabolized by proteolysis throughout the body. Negligible amounts of intact drug are found in urine or bile.

Toxicity: IL-2 has a wide range of moderate to severe toxicities that are both dose and schedule dependent. Toxicities tend to follow immediately after a bolus dose but gradually accumulate during a continuous infusion. Toxicities are higher for a given dose with continuous infusion as compared to bolus dosing. Capillary leak syndrome, which is dose limiting for most IL-2 administration schedules, results in hypotension, edema, pulmonary congestion, renal insufficiency, arrhythmias, diarrhea, and possibly some of the CNS and hepatic toxicity seen with IL-2. Transient myelosuppression or more prolonged anemia occurs commonly, as does transient hyperbilirubinemia, elevation of transaminases, and electrolyte imbalances. Other constitutional symptoms that occur with IL-2 include fever, chills, malaise, arthralgia/myalgias, erythroderma, nasal congestion/rhinorrhea, and nausea/vomiting. Other serious and less common toxicities include lethargy or delirium, angina pectoris, congestive heart failure, frank respiratory failure, and infections, particularly gram-positive bacteremia.

Indications: FDA approved for high-dose bolus treatment of metastatic renal cell cancer and metastatic melanoma. Also used at lower doses for metastatic melanoma and for maintenance treatment of acute myeloid leukemia.

Dosing: The FDA-approved dose for renal cell carcinoma and melanoma is a 600,000 to 720,000 IU/kg IV bolus every 8 hours for a maximum of 14 doses on days 1 to 5 and 11 to 15 every 6 weeks. Lower doses are more commonly used, especially continuous infusions of 3 million to 18 million IU/m^2/day for 96 hours. SC administration at similar daily doses has also been attempted with reasonable patient tolerance.

Irinotecan (Camptosar)—CPT-11

Drug Class: A semisynthetic camptothecin, which functions as a topoisomerase I inhibitor. Partly cell cycle dependent.

Dosage Form: Available in 100-mg vials as a 20-mg/mL aqueous solution.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Irinotecan is available only by the parenteral route. After IV administration, the drug is converted partially from the active lactone form to the inactive carboxylate form through hydrolysis. The parent drug is metabolized in the intestine, liver, and plasma. The active metabolite of irinotecan, SN-38, also exists in the lactone and inactive carboxylate form in equilibrium in plasma. SN-38 is inactivated by glucuronidation in the liver. SN-38 is responsible for the majority of antitumor activity attributed to the parent drug. The elimination half-life of irinotecan is 8 hours, while the elimination half-life of SN-38 is about 12 hours. Excretion of parent drug and metabolites is largely via the bile.

Toxicity: Myelosuppression, primarily neutropenia, is common and dose limiting. Diarrhea is also common and can be dose limiting. Diarrhea can occur as part of a cholinergic syndrome, along with cramping, nausea, and vomiting, during or immediately after drug administration or for several days after drug administration. Anticholinergics and antidiarrheals will curtail the immediate diarrhea and other GI symptoms partially but are less effective in treating the delayed diarrhea. Flushing, rash, and alopecia are common. Significant hepatic, renal, neurologic, or pulmonary toxicities are rare.

Indications: Irinotecan is FDA approved for refractory or recurrent metastatic colon cancer, and it has now been used in other malignancies, including lung cancer, ovarian cancer, and lymphoma.

Dosing: The recommended dosage for recurrent colon cancer is 125 mg/m^2 as a 90-minute IV infusion every week for 4 weeks, with this cycle repeated every 6 weeks. Other doses and schedules have been used.

Isotretinoin (Accutane)—13-cis-retinoic acid, 13-CRA

Drug Class: Isotretinoin is a retinoid derivative of vitamin A that binds to specific nuclear receptors and leads to changes in gene expression. This results in apoptosis or differentiation of many malignant or premalignant cell lines.

Dosage Form: 10-, 20-, and 40-mg capsules.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Oral bioavailability is about 25%, and the drug is highly protein bound in plasma. It is metabolized in the liver and has an elimination half-life of 10 to 20

hours. Parent compound and metabolite are excreted in both the urine and feces.

Toxicity: Isotretinoin is teratogenic and should not be given to women of childbearing age without adequate contraception. Mucocutaneous side effects are common and dose limiting and include xerostomia, stomatitis, conjunctivitis, dry skin, pruritus, cheilitis, rash, patchy alopecia, fragility of nails and skin, photosensitivity, and epistaxis. Other less common side effects include elevations in transaminases and bilirubin or frank hepatitis, hyperlipidemia, nausea, vomiting, anorexia, diarrhea, headache, fatigue, depression, and myalgias/arthralgias. Anemia and pseudotumor cerebri are rare.

Indications: FDA approved for acne vulgaris. Has shown some effectiveness in chemoprevention of aerodigestive malignancies. Ongoing studies are testing its chemopreventive potential in other malignancies.

Dosing: Daily oral doses of 0.5 to 4 mg/kg/day have been used in the chemoprevention trials for durations of 2 to 6 months.

Ketoconazole (Nizoral)

Drug Class: Oral antifungal agent that also acts as an androgen antagonist at high doses.

Dosage Form: 200-mg tablets.

Drug Interactions: Ketoconazole is a potent inhibitor of cytochrome P450 3A4 . As such, it increases the potency of other drugs that are metabolized by that enzyme isoform, including terfenadine, astemizole, cisapride, midazolam, triazolam, and loratadine and possibly cyclosporin, tacrolimus, methylprednisolone, and warfarin. Rifampin and isoniazid decrease the potency of ketoconazole. Ketoconazole has been reported to cause a disulfiram-type reaction when used with alcohol.

Pharmacokinetics/Metabolism: Ketoconazole has good oral bioavailability. Its level peaks in the plasma in about 2 hours. It has a terminal half-life of about 8 hours. It is metabolized in the liver to several inactive metabolites. The metabolites are excreted in the bile.

Toxicity: This drug is not strictly an antineoplastic drug and is generally very well-tolerated. Nausea, vomiting, headache, dizziness, fever, chills, impotence, gynecomastia, leukopenia, hemolytic anemia, urticaria, and anaphylaxis are all rare. Hepatic toxicity is also rare. It has been fatal in unusual cases. Administration with terfenadine and astemizole has resulted in prolonged QT interval, arrhythmias, and deaths in rare cases. Other potential drug interactions are possible, as listed previously.

Indications: FDA approved for fungal infections, primarily yeast infections. Used in doses of up to 1200 mg/day for androgen-dependent or -independent prostate cancer.

Dosing: As per preceding instructions, used alone or in combination with chemotherapy, including doxorubicin.

Lenalidomide (Revlimid)

Drug Class: Antiangiogenesis agent, immunomodulator.

Dosage Form: 5-mg, 10-mg capsules.

Drug Interactions: None known.

Pharmacokinetics/Metabolism: Mechanism of action not fully characterized. An immunomodulatory agent that inhibits angiogenesis in some cells. Inhibits bone marrow secretion of IL-6, VEGF, and TNF-α.

Toxicity: Myelosuppression. Diarrhea, rash, fatigue. Increased risk of DVT and PE.

Indications: Transfusion dependent anemia due to low or intermediate risk myelodysplasia with 5q deletion. Multiple myeloma.

Dosing: For MDS: 10 mg daily. For myeloma: 25 mg daily for 21 of 28 days.

Letrozole (Femara)

Drug Class: Nonsteroidal aromatase inhibitor.

Dosage Form: 2.5-mg tablets.

Drug Interactions: Studies have revealed no interactions between letrozole and warfarin or cimetidine. No other formal drug interaction studies have been done.

Pharmacokinetics/Metabolism: Letrozole has nearly 100% bioavailability, is metabolized in the liver, is glucuronidated, and is excreted by the kidneys. It has a terminal half-life of about 2 days. With daily administration, steady-state plasma levels are reached in 2 to 6 weeks.

Toxicity: This drug is generally well tolerated. Muscle aches and nausea are uncommon; hot flashes and fatigue are uncommon; weight change, urticaria, and dyspepsia are rare.

Indications: FDA approved for treatment of metastatic estrogen-responsive breast cancer in postmenopausal patients.

Dosing: 2.5 mg orally once daily.

Leucovorin Calcium (Wellcovorin)—citrovorum factor, folinic acid, FA, LV

Drug Class: Tetrahydrofolate derivative and enzyme cofactor for thymidylate synthase and other purine and pyrimidine synthesis steps. Leucovorin bypasses the dihydrofolate reductase step, which is inhibited by methotrexate and therefore can be used to "rescue" normal cells from the toxicity of methotrexate after high doses are administered. In addition, leucovorin potentiates the toxicity of fluoropyrimidines such as fluorouracil by strengthening the association of the drug with its target enzyme, thymidylate synthase.

Dosage Form: Tablets in 5- to 25-mg sizes, powder for oral solution, and as vials of powdered drug in 3- to 350-mg sizes.

Drug Interactions: Reduces the effectiveness and toxicity of dihydrofolate reductase inhibitors such as methotrexate.

Pharmacokinetics/Metabolism: Leucovorin has excellent bioavailability by the oral or parenteral route. It is oxidized in cofactor reactions throughout the body, and is also partly metabolized. It has an elimination half-life of 2 to 4 hours. Excreted in the urine.

Toxicity: Leucovorin is generally very well tolerated. It occasionally causes stomach upset or nausea, rash, diarrhea, and headache. Allergic reactions have been reported.

Indications: Used for rescue of high-dose methotrexate therapy for a variety of neoplasms and as a potentiator of fluoropyrimidine therapy in gastrointestinal malignancies, particularly colorectal cancer.

Dosing: For rescue from methotrexate, the usual dose is 10 to 25 mg/m^2 orally or IV every 6 hours starting up to 24 hours after the methotrexate, until methotrexate levels are less than 1×10^{-8} molar. When used to potentiate 5-FU, doses ranging from 20 to 500 mg/m^2, usually given IV, have been used, depending on the 5-FU dose.

Leuprolide Acetate (Leupron)—leuprorelin acetate

Drug Class: Gonadotropin-releasing hormone agonist, which serves to paradoxically shut down the pituitary release of gonadotropins with chronic exposure. This results in a dramatic decrease in gonadal estrogens and androgens and growth inhibition of hormone-dependent neoplasms.

Dosage Form: Available in vials for monthly administration (depot) containing 3.75 and 7.5 mg of powder, along with diluent and syringe. A multidose vial containing 2.8 mL of a 5-mg/mL solution along with syringes is also available for daily administration.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Leuprolide is bioavailable only by the parenteral route. After a SC injection, about 90% of the drug is eventually absorbed. The depot form of the drug is absorbed slowly over days, while the injectable solution is absorbed over several hours. The elimination half-life of the drug once in the serum is 3 hours. Metabolism and excretion are not well delineated but are clinically unimportant.

Toxicity: Usually well tolerated, but side effects can affect many systems, including endocrine (hot flashes, impotence, gynecomastia, breast tenderness, diminished libido, amenorrhea, atrophic vaginitis, increased cholesterol); GI (nausea, constipation, anorexia, diarrhea); hepatic (elevation of transaminases); dermatologic (rash, changes in body hair composition, pruritus); and neuropsychiatric (insomnia, depression, emotional lability, lethargy, memory loss). Significant cardiac toxicity is rare.

Indications: FDA approved for the treatment of hormone-dependent advanced prostate cancer. Also used for breast cancer and endometriosis.

Dosing: The usual dose for prostate cancer is 7.5 mg of the depot form by SC injection once every month or 1 mg of the injectable solution SC daily.

Lomustine (CeeNU)—CCNU

Drug Class: Nitrosourea alkylating agent. Cell cycle independent.

Dosage Form: Available as 10-, 20-, and 100-mg capsules.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Well absorbed after oral administration. Widely distributed in the body, including the cerebrospinal fluid. Metabolized extensively in the liver to active metabolites. Elimination half-life is 72 hours. Metabolites are excreted in the urine.

Toxicity: Myelosuppression is dose limiting and tends to be cumulative. Nausea and vomiting are common but usually mild to moderate. Anorexia is also common but short lived. Pulmonary fibrosis can occur with long-term administration. Other toxicities, including CNS effects, hepatic or renal dysfunction, and secondary leukemia, are rare.

Indications: FDA approved for primary brain tumors and Hodgkin's disease. Also used in melanoma, multiple myeloma, other lymphomas, and breast cancer.

Dosing: The recommended dose for brain tumors is 100 to 130 mg/m^2 orally every 6 weeks. Other doses and schedules have been used.

Mechlorethamine (Mustargen)—nitrogen mustard, HN2

Drug Class: Classic alkylating agent. Cell cycle independent.

Dosage Form: Vials of lyophilized powder containing 10 mg of drug.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Mechlorethamine is not orally bioavailable. After an IV dose, the drug is rapidly deactivated in the blood by reaction with biomolecules. It has an elimination half-life of 15 minutes and has no significant organ metabolism. Virtually no excretion of the drug is detected in urine or stool.

Toxicity: This drug is a powerful vesicant, so optimal extravasation precautions are a must, as well as rapid infusion. Tissue necrosis will occur if the drug extravasates, although sodium thiosulfate is a somewhat effective antidote. Vein discoloration and scarring are common. Nausea and vomiting are common, potentially severe, and often dose limiting. Myelosuppression is expected and also often dose limiting. Alopecia and infertility are often seen. Less common toxicities include anorexia, diarrhea, jaundice, tinnitus, and skin rash (common with topical treatment). Secondary leukemia and permanent hearing loss are rare.

Indications: FDA approved for a variety of hematologic malignancies and solid tumors but generally used less in the last decade. Still used for Hodgkin's disease and topically for cutaneous T-cell lymphoma.

Dosing: The standard dose for Hodgkin's disease as part of the MOPP regimen is 6 mg/m^2 IV over 1 to 5 minutes on day 1 and day 8 of a 28-day cycle. The topical form is usually a 10-mg/60-mL solution or 10-mg/dL ointment.

Medroxyprogesterone acetate (Provera, Depo-Provera)

Drug Class: Steroidal progestational agent.

Dosage Form: Available as tablets in sizes of 2.5, 5, and 10 mg, and as a suspension for depot injection as 100 or 400 mg/m.

Drug Interactions: The metabolism of medroxyprogesterone acetate may be enhanced by aminoglutethamide, leading to decreased effect for a given dose.

Pharmacokinetics/Metabolism: This drug has good oral bioavailability. It is metabolized in the liver to inactive metabolites and has an elimination half-life of up to 60 hours. Parent drug and metabolites are excreted in the urine and bile.

Toxicity: Toxicities are mostly constitutional and not dose limiting. They include menstrual changes, amenorrhea, gynecomastia, hot flashes, edema, weight gain, fatigue, acne, hirsutism, anxiety, depression, sleep disturbance, and headache. Nausea, significant skin reactions or allergy, jaundice, and thrombophlebitis are uncommon.

Indications: FDA approved for treatment of advanced endometrial or renal cell carcinoma. Also used occasionally for breast or prostate cancer.

Dosing: Loading doses of up to 1000 mg IM weekly and 400 mg IM every month have been used, while oral doses range from 100 to 300 mg/day. Much lower doses are used for gynecologic indications.

Megestrol Acetate (Megace)—megestrol

Drug Class: Steroidal progestational agent.

Dosage Form: 20- and 40-mg tablets and 40-mg/mL oral solution.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: The drug is well absorbed by mouth, is metabolized in the liver to inactive compounds, and has an elimination half-life of 15 to 20 hours. Parent drug and metabolites are excreted in the urine.

Toxicity: Toxicities are similar to those of other progestins as noted previously. They include menstrual changes, hot flashes, edema, weight gain, fatigue, acne, hirsutism, anxiety, depression, sleep disturbance, and headache. Urinary frequency can also occur. Nausea, vomiting, diarrhea, skin rash or allergy, jaundice, and thrombophlebitis are uncommon.

Indications: FDA approved for treatment of breast and endometrial carcinoma. Also used for renal cell carcinoma and for appetite stimulation in HIV disease and cancer patients.

Dosing: The standard dose for cancer treatment is 160 mg/day in divided doses or a single dose. The dose for appetite stimulation may be as high as 800 mg/day, which is where the concentrated oral solution is useful.

Melphalan (Alkeran)—l-PAM, l-phenylalanine mustard, l-sarcolysin

Drug Class: Classical alkylating agent. Cell cycle independent.

Dosage Form: 2-mg tablets and vials for injection at 50 mg/vial.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Melphalan has unpredictable GI absorption, is highly protein bound, and is rapidly autometabolized by hydrolysis in the plasma. It has an elimination half-life of about 2 hours. Ten percent to 15% is excreted as unchanged drug in the urine.

Toxicity: Myelosuppression is expected and is dose limiting. Recovery may be prolonged, and effects can be cumulative. Large doses may cause significant nausea and vomiting. Diarrhea and stomatitis are uncommon. Vein reactions including scarring may occur, but this agent is not known as a vesicant. Other skin reactions are uncommon, as are pulmonary fibrosis, vasculitis, infertility, alopecia, and secondary leukemia.

Indications: Used primarily for multiple myeloma, but also FDA approved for ovarian carcinoma. May also be useful in high-dose chemotherapy/transplant settings and in regional perfusion of extremities for melanoma and sarcoma.

Dosing: Doses for myeloma are typically in the range of 0.1 mg/kg/day for 2 to 3 weeks or up to 6 mg/m^2/day for 5 days every

6 weeks. Transplant doses (IV or PO) range up to 140 mg/m^2 total. Doses for perfusion are either 0.45 to 0.9 mg/kg or dosed for a certain concentration in the perfusate.

Mercaptopurine (Purinethol)—6-MP, 6-mercaptopurine
- Drug Class: Purine analog antimetabolite; predominantly S-phase specific.
- Dosage Form: 50-mg tablets. An IV formulation is investigational.
- Drug Interactions: Allopurinol inhibits first-pass metabolism of mercaptopurine in the liver by xanthine oxidase, and therefore dose reduction is required if allopurinol is also being given.
- Pharmacokinetics/Metabolism: 6-MP has good oral bioavailability, undergoes extensive first-pass metabolism in the liver, and has an elimination half-life of about 7 hours. Intact drug and metabolites are excreted by the kidneys.
- Toxicity: Myelosuppression is common and dose limiting. Nausea and vomiting occur occasionally but are usually mild. Diarrhea, anorexia, and stomatitis are less common. Headache and rash are uncommon. Fulminant hepatic toxicity is very rare, but lesser degrees of cholestasis and hepatitis are sometimes seen.
- Indications: Mercaptopurine is FDA approved for treatment of acute lymphoblastic leukemia. It is occasionally used for other hematologic malignancies. There is an investigational IV formulation that does not yet have clinical indications.
- Dosing: The usual dose is 70 to 100 mg/m^2/day for a defined period of days during induction or maintenance.

Mesna (Mesnex)—mercaptoethanesulfonate sodium, uromitexan
- Drug Class: Thiol uroprotectant; binds to and inactivates acrolein, the highly reactive metabolite of cyclophosphamide and ifosfamide, helping to prevent hemorrhagic cystitis.
- Dosage Form: Available as aqueous solution at a concentration of 100 mg/mL.
- Drug Interactions: Mesna does not decrease the effectiveness of cytotoxic drugs or radiation.
- Pharmacokinetics/Metabolism: Mesna has an oral bioavailability of about 50% and is usually given IV. After an IV dose, mesna is converted in the plasma to dimesna, is filtered by the kidneys, and is converted back into mesna in the urine. It has an elimination half-life of 1 hour.
- Toxicity: Mesna is usually very well tolerated. It has been described to occasionally cause nausea, vomiting, diarrhea, rash, fatigue, headache, hypotension, or arthralgias.
- Indications: FDA approved for use as a uroprotectant when administering ifosfamide. Also effective for high-dose cyclophosphamide.
- Dosing: The usual daily dose of mesna is 60% of the daily milligram amount of the ifosfamide, given by IV bolus before, 4 hours after, and 8 hours after the chemotherapy or as a continuous infusion with a loading dose before the chemotherapy. Mesna may be continued for up to 24 hours after the chemotherapy has been completed.

Methotrexate (Mexate, Folex, others)—MTX, amethopterin
- Drug Class: Antifolate antimetabolite; interferes with nucleotide synthesis by inhibiting dihydrofolate reductase. Cell cycle dependent.
- Dosage Form: 2.5-mg tablets, vials of powder for injection of 20 to 1000 mg/vial, and as a 2.5- and 25-mg/mL aqueous solution for injection.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: Methotrexate has good oral bioavailability at low doses. After oral or IV dosing, it is distriuted throughout the body water compartment. It will accumulate in "third-space" fluid compartments and exhibit prolonged toxicity and therefore should be used with caution, if at all, in patients with significant pleural or peritoneal fluid. The drug is minimally metabolized in the liver and has an elimination half-life of about 3 hours, and even low concentrations of drug after most of the drug is eliminated can contribute to significant toxicity. Therefore, dosing based on renal function is critical. Excretion of this drug is entirely renal.
- Toxicity: Myelosuppression is expected and is usually dose limiting. Stomatitis and diarrhea are common. Nausea and vomiting are uncommon. Renal toxicity is uncommon and usually reversible but can be severe. Many types of skin reactions can occur but are uncommon. Pulmonary fibrosis and hepatic fibrosis are rare. Encephalopathy is rare with moderate to low-dose therapy but is more common with high doses, intrathecal administration, or concomitant CNS radiation. It can be severe and permanent.
- Indications: FDA approved for a wide spectrum of malignant and nonmalignant diseases. Most often used for acute leukemias, lymphomas, breast cancer, bladder cancer, squamous cell cancers, and sarcomas.
- Dosing: For malignant conditions, doses up to 100 mg/m^2 are considered low dose, 100 to 1000 mg/m^2 moderate dose, and over 1000 mg/m^2 high dose. Moderate and high doses require leucovorin rescue. Doses can be given weekly or at longer intervals. IV infusions can be 30 minutes or longer, including 24-hour continuous infusions. Methotrexate is also commonly given intrathecally, usually as a 12-mg dose in 10 mL of preservative-free saline.

Mitomycin C (Mutamycin)
- Drug Class: Antitumor antibiotic; inhibits DNA and RNA synthesis.
- Dosage Form: Vials of powder in 5-, 20-, and 40-mg sizes.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: Poor oral bioavailability. After an IV dose, mitomycin C is rapidly metabolized to inactive forms in the liver, spleen, and kidneys, with an elimination half-life of about 1 hour. Parent drug and inactive metabolites are excreted in the urine.
- Toxicity: Mitomycin C is a vesicant; extravasation precautions are a must. Myelosuppression is expected and is dose limiting, with a white blood cell nadir at 4 weeks and full recovery at 6 to 7 weeks. Mild nausea, vomiting, anorexia, and fatigue are common. Uncommon toxicities include diarrhea, stomatitis, rash, fever, and renal insufficiency. Rare toxicities include veno-occlusive disease of the liver, hemolytic-uremic syndrome, and interstitial pneumonitis.
- Indications: FDA approved for adenocarcinomas of the stomach and pancreas. Also used commonly in breast cancer and lung cancer.
- Dosing: The usual dose is 10 to 20 mg/m^2 IV over 2 to 5 minutes every 6 to 8 weeks.

Mitotane (Lysodren)—o,p′-DDD
- Drug Class: Adrenal cortical cytotoxin.
- Dosage Form: 500-mg tablets.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: This drug has moderate oral bioavailability, with a peak plasma level about 4 hours after an oral dose. Significant therapeutic effect is not seen until up to 4 weeks of continuous usage. Mitotane is metabolized in the liver and has a variable elimination half-life (due to storage of the drug in adipose tissue) of up to 160 hours. Mitotane is eliminated in the urine and bile.
- Toxicity: Adrenal insufficiency is expected and must be abrogated with concomitant oral glucocorticoid usage (and sometimes mineralocorticoids as well). Anorexia, nausea, vomiting, sedation, and lethargy are common. Hypercholesterolemia and elevation of liver function tests are also common. Rash is seen frequently but is usually mild. Myelosuppression, diarrhea, fever, wheezing, changes in blood pressure, and flushing are

uncommon. Permanent CNS changes, retinopathy, nephrotoxicity, and hemorrhagic cystitis are rare.
Indications: FDA approved for adrenal cortical carcinoma.
Dosing: The initial dose is usually 1 g/day in four divided doses; this is increased up to 10 g/day as tolerated.

Mitoxantrone (Novantrone)—DHAD, dihydroxyanthracenedione
Drug Class: Anthracycline antitumor antibiotic.
Dosage Form: Vials of 2-mg/mL solution.
Drug Interactions: None noted.
Pharmacokinetics/Metabolism: Mitoxantrone has poor oral bioavailability. After an IV dose, it exhibits a large volume of distribution, undergoes metabolism in the liver, and has an elimination half-life of 24 to 37 hours. Mitoxantrone is eliminated through the bile.
Toxicity: Mitoxantrone is not a tissue vesicant. Myelosuppression, mostly limited to leukopenia, is expected and dose limiting. Nausea and vomiting are common but mild, stomatitis is common, and diarrhea and anorexia are less common. Elevated liver function tests are common, but significant hepatic toxicity is rare. Cardiotoxicity is uncommon and dose dependent. Pulmonary or neurologic toxicity is rare.
Indications: FDA approved for AML and prostate carcinoma. Also used for breast cancer, lymphoma, and hepatocellular carcinoma.
Dosing: For AML, the typical dose is 10 to 12 mg/m^2/day for 3 days by 30-minute infusion, along with AraC. For solid tumors, 12 mg/m^2 is given over 30 minutes every 3 to 4 weeks.

Nelarabine (Arranon)
Drug Class: Antimetabolite.
Dosage Form: IV.
Drug Interactions: None known.
Pharmacokinetics/Metabolism: A prodrug of deoxyguanosine analog 9-β-D-arabinofuranosylguanine (ara-G). After demethylation by adenosine deaminase to ara-G, it is converted to its active triphosphate form ara-GTP. Incorporation of ara-GTP into DNA inhibits DNA synthesis and function.
Toxicity: CNS toxicity is dose limiting, with somnolence, headache, dizziness, peripheral neuropathy, seizures, and coma, which may be severe and permanent. Myelosuppression. GI toxicities. Respiratory toxicity. Fatigue, fever, asthenia, blurred, vision, and edema.
Indications: Refractory or resistant T-cell acute lymphoblastic leukemia/lymphoma as third-line therapy.
Dosing: 1500 mg/m^2 IV over 2 hours days 1, 3, and 5 every 21 days.

Nilutamide (Nilandron)
Drug Class: Orally administered nonsteroidal antiandrogen.
Dosage Form: 50-mg and 150-mg tablets.
Drug Interactions: Inhibits activity of several cytochrome P450 isoenzymes and thus may increase the potency of several potentially toxic drugs such as warfarin, theophylline, and phenytoin. Caution and careful monitoring are advised during concomitant use of nilutamide with such medications.
Pharmacokinetics/Metabolism: Rapid and complete GI absorption has been demonstrated. Elimination half-life is about 45 hours. The drug is metabolized in the liver and eliminated in the urine.
Toxicity: Hot flashes, body hair loss, fatigue, loss of libido, and weight gain are common but usually mild. Loss of visual adaptation to the darkness is common but transient, and nausea and fever and dyspepsia are uncommon. Interstitial pneumonitis is rare.
Indications: FDA approved for treatment of metastatic prostate cancer.
Dosing: The usual dose is 300 mg once daily for 30 days followed by 150 mg daily.

Octreotide, Octreotide long-acting (Sandostatin, Sandostatin LA)—L-cysteinamide
Drug Class: Synthetic peptide analog of somatostatin; inhibits other GI peptide actions, such as serotonin, insulin, glucagon, and gastrin.
Dosage Form: Ampules containing 0.05, 0.1, and 0.5 mg in 1 mL of aqueous solution.
Drug Interactions: May interfere with insulin action, requiring increase in insulin dosage.
Pharmacokinetics/Metabolism: Not orally bioavailable but rapidly absorbed after SC administration. Metabolized by hydrolysis throughout the body. No active metabolites. Half-life of elimination is about 1.5 hours. Intact drug is cleared via the kidneys.
Toxicity: GI side effects are dose limiting and include abdominal pain, vomiting, loose stool, occasional fat malabsorption, bloating, and cholelithiasis. Elevations of liver function tests can also occur, but frank hepatitis is rare. Skin reactions, such as pain at the injection site or flushing, rash, or skin thinning, are sometimes seen. Constitutional symptoms, including rhinorrhea, xerostomia, sweating, throat discomfort, and vertigo, can be bothersome. Either hyperglycemia or hypoglycemia can occur. Cardiac side effects, including angina, congestive heart failure, and hypotension or hypertension, are uncommon. Anxiety, depression, fatigue, and anorexia are uncommon, and seizures are rare.
Indications: FDA approved for carcinoid tumors causing carcinoid syndrome and for vasoactive peptide-secreting tumors. Also used for refractory diarrhea, either cancer related or treatment related, in cancer patients.
Dosing: Doses from 50 μg twice a day to 1000 μg four times a day injected SC have been used. Continuous IV infusions or administration of drug in total parenteral nutrition solutions has also been used.

Oprelvekin (Neumega)—interleukin-11, IL-11
Drug Class: Recombinant polypeptide cytokine molecule; multiple cellular actions, including stimulation of megakaryocyte proliferation and platelet production from megakaryocytes.
Dosage Form: Vials containing 5 mg of lyophilized powder.
Drug Interactions: None noted.
Pharmacokinetics/Metabolism: Oprelvekin is available only by parenteral routes. With SC administration, it is absorbed into the circulation with a peak plasma concentration of 3 hours and has an elimination half-life of about 7 hours. This polypeptide agent is metabolized throughout the body by proteolysis. Excretion of drug is not substantial, owing to degradation.
Toxicity: Headache, fever, malaise, dyspnea, rash, conjunctival irritation, fluid retention, and edema are common during administration but are not usually severe. Oral thrush, dizziness, diarrhea, pleural effusions, and transient anemia are uncommon. Paresthesias, ocular hemorrhage, atrial arrhythmias, and exfoliative dermatitis are rare.
Indications: FDA approved for prevention of severe chemotherapy-related thrombocytopenia.
Dosing: 50 μg/kg/day SC injection until the postnadir platelet count is greater than 50,000/mm^3, starting 1 day after the completion of chemotherapy.

Oxaliplatin (Eloxatin)
Drug Class: New generation platinating agent. Disrupts DNA via intrastrand and interstrand cross-links with two strong platinum association bonds in the molecule, which induces apoptosis beyond a certain level of DNA damage in malignant cells.
Dosage Form: Clear glass single-use vials containing 50 mg or 100 mg of drug as a lyophilized powder.
Drug Interactions: No drug-drug interaction studies have been done, and no interactions have yet been identified. Expected

additive toxicities with other antineoplastic agents and neurotoxic drugs. Nephrotoxic drugs may slow clearance of oxaliplatin.

Pharmacokinetics/Metabolism: Oxaliplatin has poor oral bioavailibility. After IV administration, rapid distribution into tissues occurs, as well as rapid spontaneous conversion via hydrolysis into active drug and metabolites. The terminal half-life is long (>300 hours) but represents minimal plasma levels of the hydrolyzed drug. Elimination of platinum metabolites is via the kidneys.

Toxicity: Neurotoxicity, in the form of a transient neuropathy with each dose and a persistent, cumulative typical sensory polyneuropathy, is very common and dose limiting. Myelosuppression is expected but mild and only sometimes dose limiting. Fatigue and nausea are common but mild. Diarrhea, stomatitis, edema, cough, hypersensitivity reactions, and extravasation injury are rare.

Indications: FDA approved for metastatic colorectal cancer in combination with 5-fluorouracil/leucovorin. Has been used as a single agent in this disease and is being studied in other malignancies.

Dosing: With 5-fluorouracil and leucovorin, the dose and schedule is 85 mg/m^2 IV every 2 weeks as a 2-hour infusion in 250 to 500 mL of D5W. As a single agent, the most studied doses are the same 2-week dose or 130 mg/m^2 IV every 3 weeks.

Paclitaxel (Taxol, Onxol)

Drug Class: Naturally occurring taxane molecule; inhibits depolymerization of tubulin in the spindle apparatus, thereby inducing apoptosis in dividing cells.

Dosage Form: Vials containing 30 and 100 mg of drug in nonaqueous solution.

Drug Interactions: Cisplatin administered before paclitaxel may enhance the myelosuppressive effect of paclitaxel. Coadministration of paclitaxel and doxorubicin may enhance the cardiotoxicity of doxorubicin.

Pharmacokinetics/Metabolism: Paclitaxel has poor oral bioavailability. After IV administration, the drug exhibits a large volume of distribution and undergoes metabolism in the liver. The elimination half-life is 15 to 50 hours. Excretion of drug and metabolites is predominantly via the bile.

Toxicity: Paclitaxel is an irritant or mild vesicant when extravasated into subcutaneous tissue. Myelosuppression, predominantly neutropenia, is expected and is dose limiting. Shorter infusions of the same dose produce less neutropenia. Mucositis is also very common, particularly with longer infusions. Peripheral neuropathy is common, usually mild, and increases with cumulative dose. Acute neuromyopathy is also common and occurs for several days after each dose. This syndrome may require opiate analgesics to control pain. Cardiovascular side effects, including hypertension, hypotension, premature contractions, and bradyarrhythmias, are common but rarely require intervention. Hypersensitivity reactions to paclitaxel, including urticaria, wheezing, chest pain, dyspnea, and hypotension, are common but are reduced in frequency and severity by premedication with corticosteroids and histamine$_1$ and histamine$_2$ antihistamines (the recommended regimen is dexamethasone 20 mg PO 12 and 6 hours prior to paclitaxel and diphenhydramine 50 mg and cimetidine 300 mg IV 30 minutes prior to paclitaxel). Alopecia, usually complete, is expected. Other toxicities are uncommon and include nausea, vomiting, diarrhea, liver toxicity, and interstitial pneumonitis.

Indications: FDA approved for salvage therapy in ovarian cancer and for breast cancer in both the metastatic and adjuvant settings. Used also in lung cancer, head and neck cancer, and bladder cancer.

Dosing: 135 to 250 mg/m^2 IV over 3 hours or 24 hours every 3 weeks. Weekly schedules and longer infusions have also been used.

Paclitaxel, Protein bound (Abraxane)

Drug Class: Taxane; an albumin-bound form of paclitaxel with a mean particle size of approximately 130 nanometers.

Dosage Form: 100-mg vial.

Drug Interactions: Potential interactions with substrates or inhibitors of CYP2C8 and CYP3A4.

Pharmacokinetics/Metabolism: Not studied in patients with hepatic or renal dysfunction.

Toxicity: Neutropenia, thrombocytopenia, anemia, hypersensitivity reactions, hypotension, cardiovascular events, dyspnea, cough, sensory neuropathy, arthralgias/myalgias, nausea/vomiting, asthenia.

Indications: Treatment of metastatic breast cancer after failure of combination chemotherapy or relapse with 6 months of adjuvant chemotherapy.

Dosing: 260 mg/m^2 IV over 30 minutes every 3 weeks.

Pamidronate (Aredia)—APD, aminohydroxypropylidene diphosphonate

Drug Class: Organic bisphosphonate; inhibitor of bone resorption by osteoclasts.

Dosage Form: Vials of lyophilized powder containing 30 mg of drug.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Pamidronate is available only by the parenteral route. After IV administration, the drug concentrates in the bone, spleen, and liver. Its metabolism is not well characterized. It has a terminal half-life of about 27 hours. Fifty percent of the parent drug is eliminated in the urine.

Toxicity: Pamidronate is usually quite well tolerated. Hypotension, syncope, tachycardia, and even atrial fibrillation have been reported uncommonly during the infusion. Hypocalcemia, hypophosphatemia, hypokalemia, and hypomagnesemia occur commonly but only rarely require intervention. Nausea, vomiting, and somnolence are rare.

Indications: FDA approved for malignancy-induced hypercalcemia. May lead to pain relief and even tumor shrinkage of bone metastases in multiple myeloma, breast cancer, and prostate cancer.

Dosing: 60 to 90 mg/m^2 IV over 24 hours, although the clinical experience with infusions of 1 to 3 hours is extensive. Treatment may be repeated every 1 to 3 weeks. Peak effect occurs 3 to 7 days after a dose.

Panitumumab (Vectibix)

Drug Class: Monoclonal antibody.

Dosage Form: IV.

Drug Interactions: None known.

Pharmacokinetics/Metabolism: A recombinant, fully humanized IgG2 kappa monoclonal antibody that binds to the epidermal growth factor receptor. Binds specifically to EGFR, competitively inhibiting ligand binding to the receptor. Steady-state levels are reached by the third infusion. Elimination half-life is about 7.5 days.

Toxicity: Rash, which may be severe. Diarrhea. Infusion reactions. Hypomagnesemia. Pulmonary fibrosis.

Indications: Previously treated EGFR expressing metastatic colorectal cancer.

Dosing: 6 mg/m^2 IV every 2 weeks.

Pegfilgrastim (Neulasta)

Drug Class: Long-acting (PEGylated) recombinant DNA granulocytic growth factor polypeptide.

Dosage Form: Syringes containing 6 mg of drug in 0.6 mL aqueous solution with a 27-gauge needle.

Drug Interactions: No formal drug interaction studies have been done.

Pharmacokinetics/Metabolism: PEGylation of filgrastim increases its half-life by decreasing renal clearance. After subcutaneous administration, half-life is between 15 and 80 hours, with biologic activity lasting much longer.

Toxicity: Toxicity and side effect profile is essentially no different than those of filgrastim. Bone pain is common and usually mild and treatable but can be dose limiting. Nausea, fatigue, weakness, and diarrhea are rare. Very rare instances of adult respiratory distress syndrome, sickle cell crisis, splenic rupture, and severe allergic reaction have been seen with the parent drug filgrastim.

Indications: FDA approved for prevention of severe granulocytopenia from cytotoxic chemotherapy for nonmyeloid malignancies.

Dosing: 6 mg SC after each chemotherapy cycle (generally used for a 3- or 4-week cycle duration).

Pemetrexed (Alimta)

Drug Class: Antimetabolite.

Dosage Form: 500-mg vials.

Drug Interactions: Salicylates and NSAIDS may decrease the renal excretion, increasing toxicity. Nephrotoxic drugs may also lead to decreased renal clearance. Thymidine rescues the toxic effects of pemetrexed.

Pharmacokinetics/Metabolism: Inhibits folate-dependent enzymes thymidylate synthetase, dihyrofolate reductase and glycinamide ribonucleotide formyltransferase which are involved in the de novo synthesis of thymidine and purine nucleotides, leading to inhibition of DNA and RNA synthesis and function. Metabolized intracellularly to its highly active polyglutamated form. Excreted in urine with 90% of drug unchanged.

Toxicity: Myelosuppression. Nausea, vomiting, diarrhea. Rash. Dyspnea and fatigue.

Indications: Mesothelioma and non-small-cell lung cancer.

Dosing: 500 mg/m^2 IV every 3 weeks. Note: All patients must be given folic acid and vitamin B12 supplementation to decrease toxicity, starting 1 week prior to therapy.

Pentostatin (Nipent)

Drug Class: Antimetabolite, purine antagonist.

Dosage Form: 10-mg vial.

Drug Interactions: Toxicity is increased with vidarabine, and fatal pulmonary toxicity has resulted from the concomitant use of fludarabine.

Pharmacokinetics/Metabolism: Enzyme adenosine deaminase, found in high concentration in lymphocytes, leading to accumulation of deoxyadenosine and deoxyadenosine triphosphate (dATP), which are cytotoxic to lymphocytes. Elevated dATP levels inhibit ribonucleotide reductase, which inhibits DNA synthesis and function. Undergoes little metabolism, and more than 90% of the drug is excreted in the urine with an elimination half-life of about 5 hours.

Toxicity: Myelosuppression. Increased risk of opportunistic infections. Hypersensitivity reactions. CNS toxicity. Ophthalmologic and otologic complications.

Indications: Hairy cell leukemia, chronic lymphocytic leukemia, cutaneous T-cell leukemia.

Dosing: 4 mg/m^2 IV every 2 weeks.

Plicamycin (Mithracin)—mithramycin

Drug Class: Antitumor antibiotic. Partly cell cycle dependent.

Dosage Form: Supplied as lyophilized powder in vials containing 2.5 mg of drug.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Available only by the intravenous route. After an IV dose, the drug is metabolized by the liver and has an elimination half-life of about 2 hours. Parent drug and metabolites are eliminated via the kidneys.

Toxicity: Plicamycin is a vesicant if extravasated into soft tissues. Hemorrhage, due to both thrombocytopenia and coagulopathy, is dose limiting. Other hematologic toxicities are uncommon. Nausea and vomiting are common but not severe. Stomatitis, diarrhea, and anorexia are less common. Rash is common, but severe cutaneous reactions, such as toxic epidermal necrolysis, are rare. Depletion of calcium, potassium, phosphate, and magnesium are expected but rarely require intervention. Renal toxicities, including proteinuria and azotemia, are uncommon. Elevated liver function tests and neurologic toxicity (including lethargy, weakness, anxiety, somnolence, and headache) are uncommon.

Indications: FDA approved for treatment of malignancy-induced hypercalcemia, and also for treatment of germ cell tumors. Also has been used for CML in blast crisis.

Dosing: The typical dose for germ cell tumors is 25 to 30 μg/kg/day IV infusion over 60 minutes for 8 to 10 days. For hypercalcemia, the same dose is given one to three times per week.

Prednisone (Deltasone, others)

Drug Class: Corticosteroid.

Dosage Form: Tablets in sizes from 1 to 50 mg and oral solution.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Prednisone has good oral bioavailability and is extensively metabolized in the liver, primarily to the active form of the drug, prednisolone. It has an elimination half-life of approximately 4 hours. Liver disease may decrease conversion to the active form, requiring use of prednisolone instead of prednisone. Routes of excretion are not well delineated.

Toxicity: Toxicity is mostly in the form of constitutional symptoms, including mood changes (depressive, anxious, or euphoric), insomnia, indigestion, enhanced appetite, weight gain, acne, and cushingoid features. Other side effects may be more serious but are less common. Hyperglycemia and increased stomach acid predisposing to ulceration occur acutely, while osteopenia, cataracts, skin atrophy, and adrenal insufficiency occur with prolonged use.

Indications: FDA approved for a wide variety of malignant and nonmalignant conditions. Used in oncology for lymphoid malignancies, for palliative care, and for management of side effects/toxicities.

Dosing: Lympholytic doses are generally in the range of 50 to 100 mg/m^2/day for 5 to 14 days. Higher or lower doses are also used, depending upon the indication.

Procarbazine (Matulane)—N-methylhydrazine

Drug Class: Alkylating agent. Cell cycle independent.

Dosage Form: 50-mg capsules.

Drug Interactions: This drug has monoamine oxidase inhibitory activity and therefore should not be taken with certain types of food, including beer, wines, fermented cheese, chocolate, and fava beans, or with certain medications, including ethanol, decongestants, tricyclic antidepressants, antihypertensives, antihistamines, narcotics, barbiturates, phenothiazines, or other monoamine oxidase inhibitors.

Pharmacokinetics/Metabolism: Well absorbed by the oral route, reaching peak plasma levels in 1 hour, with good distribution to the cerebrospinal fluid. Procarbazine is metabolized by the liver and has an elimination half-life of about 1 hour. Largely excreted in the urine.

Toxicity: Myelosuppression is expected and dose limiting, but anemia is uncommon. Nausea and vomiting are common and can be dose limiting as well. Rash, hives, and photosensitivity sometimes occur. Other side effects are uncommon and include anorexia, diarrhea, stomatitis, hypotension, tachycardia, syncope, flu-like syndrome, interstitial pneumonitis, CNS excitation including seizures, and secondary malignancies.

Indications: FDA approved for Hodgkin's disease, and may also be useful in non-Hodgkin's lymphoma, multiple myeloma, brain tumors, melanoma, and lung cancer.

Dosing: In Hodgkin's disease regimens such as MOPP, the dose is 100 mg/m^2/day for 14 days during each cycle.

Rituximab (Rituxan)
- Drug Class: Monclonal antibody directed against the B-cell surface antigen CD20.
- Dosage Form: Sterile vials containing 100 and 500 mg of antibody in aqueous solution (10 mg/mL).
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: Not available by the oral route, but when given IV, it is taken up by B lymphocytes and then degraded throughout the body by proteolysis, with a wide ranging serum half-life of 11 to 105 hours (mean 60 hours) with the first dose. There is no appreciable excretion of this polypeptide.
- Toxicity: Fever, chills, and malaise are common during administration, even with premedication with acetaminophen and diphenhydramine. Other infusion-related symptoms include nausea, vomiting, flushing, urticaria, angioedema, hypotension, dyspnea, bronchospasm, fatigue, headache, rhinitis, and pain at disease sites. These symptoms are generally self-limited, improve with slowing of the infusion, and resolve after infusion. Short-lived myelosuppression, abdominal pain, and myalgia are uncommon. Arrhythmias and angina pectoris are rare.
- Indications: FDA approved for relapsed or refractory low-grade or follicular, CD20-positive, B-cell lymphomas.
- Dosing: The recommended dose is 375 mg/m^2 by IV infusion (starting at 50 mg/hr and increasing to 400 mg/hr maximum) weekly for 4 weeks. Higher doses, more doses, and longer courses are being used in other lymphoid malignancies.

Sargramostim (Leukine, Leukomax)—granulocyte-macrophage colony-stimulating factor (GM-CSF)
- Drug Class: Cytokine; exhibits pleiotropic stimulatory effects on bone marrow progenitor cells.
- Dosage Form: Vials containing 250, 400, and 500 μg of lyophilized GM-CSF.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: Not available by the oral route but has similar bioavailability when given IV or SC. Degraded throughout the body, predominantly in the liver and kidneys, with an elimination half-life of 2 hours. No appreciable excretion of this peptide occurs.
- Toxicity: Constitutional symptoms, which tend to decrease over time, predominate at standard doses. Higher doses may cause capillary leak syndrome. Side effects include flushing, hypotension (or hypertension), dyspnea, fever, nausea, vomiting, fatigue, myalgias, bone pain, headache, and skin rash. Thrombocytopenia may also occur. Fluid retention and edema rarely occur at standard doses. Progression of myelodysplastic syndrome has been documented in patients on GM-CSF.
- Indications: FDA approved for the treatment of myelosuppression after ABMT. May be useful to minimize myelosuppression after standard-dose chemotherapy or to shorten the course of neutropenic fever. Immunostimulatory properties of GM-CSF are still being investigated.
- Dosing: 250 μg/m^2/day for 21 days or 5 μg/ kg/day for 10 to 14 days.

Sorafenib (Nexavar)
- Drug Class: Targeted agent: Multikinase inhibitor.
- Dosage Form: 200-mg tablets.
- Drug Interactions: The AUC of doxorubicin is increased by 21% with concomitant use of sorafenib.
- Pharmacokinetics/Metabolism: An oral multikinase inhibitor that interacts with multiple intracellular (CRAD, BRAF) and cell surface kinases (KIT, FLT-3, VEGFR-2, VEGFR-2, and PDGFR-β. May inhibit angiogenesis. Metabolized in the liver. Drug and metabolites are excreted primarily in the feces.
- Toxicity: Skin toxicity with rash and hand-foot syndrome. Nausea, vomiting, anorexia, diarrhea. Asthenia, pain, arthralgias. Hypertension. Bleeding events, especially in anticoagulated patients. Cardiac ischemia. Myelosuppression.
- Indications: Advanced renal cell carcinoma.
- Dosing: 400 mg twice daily.

Streptozocin (Zanosar)
- Drug Class: Alkylating agent. Cell cycle independent.
- Dosage Form: Vials containing 1 g of lyophilized streptozocin.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: Streptozocin is bioavailable only by the IV route. It is metabolized primarily in the liver and has an elimination half-life of less than 1 hour. Parent drug and metabolites are excreted in the urine.
- Toxicity: GI side effects (nausea, vomiting, and cramping) or nephrotoxicity (glomerular and tubular damage) are common and potentially dose limiting. Myelosuppression is less often dose limiting. Elevated liver function tests can occur occasionally but are rarely clinically significant. Fever, delirium, and depression occur rarely. Streptozocin is an irritant if extravasated into perivenous soft tissue.
- Indications: FDA approved for metastatic islet cell carcinoma and may also be useful for advanced carcinoid tumor, pancreatic carcinoma, and Hodgkin's disease.
- Dosing: The usual dose is 500 to 1000 mg/m^2/day by IV bolus for 5 days every 4 weeks.

Sunitinib maleate (Sutent)
- Drug Class: Receptor tyrosine kinase inhibitor.
- Dosage Form: 50-mg tablets.
- Drug Interactions: Medications that inhibit or induce CYP3A4; St John's wort.
- Pharmacokinetics/Metabolism: Inhibits multiple receptor tyrosine kinases. Inhibits PDGFRα and PDGFRβ, VEGFR1–3, stem cell factor receptor, FLT-3, CSF-1R, and the neurotrophic factor receptor. This inhibition inhibits tumor growth and metastases. Metabolized in the liver with elimination primarily in the feces. Half-life is 40 to 60 hours for the drug and 80 to 110 hours for its primary metabolite.
- Toxicity: Cardiotoxicity-usually reversible. Bleeding event, epistaxis most common. Hypertension. Myelosuppression. Nausea, vomiting. Rash. Liver function test alterations.
- Indications: Advanced renal cell carcinoma. Second-line therapy for gastrointestinal stromal (GIST) cell tumors.
- Dosing: 50 mg daily for 4 weeks, with a 2-week rest.

Tamoxifen (Nolvedex)
- Drug Class: Nonsteroidal antiestrogen; cytostatic effects on estrogen-dependent and nondependent malignant cells.
- Dosage Form: 10-mg tablets.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: Tamoxifen has good oral bioavailability, is metabolized in the liver, and has an elimination half-life of about 7 days. Neither tamoxifen nor its major metabolite is found in the bile or urine.
- Toxicity: Tamoxifen is usually very well tolerated. Constitutional symptoms are most prevalent and usually dose limiting. Hot flashes, sweating, mood changes, weight gain or loss, and stomach upset are most common. Nausea, vomiting, diarrhea, and constipation are less common. Menstrual changes, including significant vaginal bleeding, are uncommon. Venous thromboembolism, myelosuppression, and retinopathy are rare.
- Indications: FDA approved for the treatment of breast cancer, generally in postmenopausal patients or those with estrogen receptor-positive tumors. The same dose has been approved for chemoprevention of breast cancer in high-risk individuals. Higher doses are used for melanoma and pancreatic cancer.
- Dosing: The standard dose for breast cancer is 10 mg PO bid (or 20 mg once a day).

Temozolomide (Temodar)
- Drug Class: Atypical alkylator (semiselective DNA methylator) drug sharing the same active metabolite as dacarbazine, MTIC but, unlike dacarbazine, is spontaneously converted to MTIC and also penetrates the blood-brain barrier effectively.
- Dosage Form: Capsules containing 5 mg, 20 mg, 100 mg, and 250 mg of temozolomide.
- Drug Interactions: Coadministration with valproic acid results in decreased oral bioavailability of temozolomide by a minor amount. No other drug interactions have been identified.
- Pharmacokinetics/Metabolism: Temozolomide had good bioavailability, enhanced by an empty stomach. After absorption into the bloodstream, it is spontaneously converted to the active moiety MTIC. Peak plasma concentrations occur in about 1 hour. The elimination half-life is about 1.8 hours. Parent drug, MTIC, and other metabolites are eliminated in the urine.
- Toxicity: Myelosuppression is expected and dose-limiting. It may be cumulative. Nausea is common but generally mild and treatable. Headache and fatigue are common. Rash or other cutaneous reactions are uncommon. Infections are common in this population, and some are probably caused by immunosuppression that is known to occur with temozolomide.
- Indications: FDA approved for treatment of recurrent high-grade astrocytomas. Used commonly for other gliomas and also for metastatic melanoma.
- Dosing: 200 mg/m^2 PO on an empty stomach daily for 5 days on a 28-day cycle. Other doses and schedules have been used with similar clinical results.

Teniposide (Vumon)—VM-26, PTG
- Drug Class: Inhibitor of topoisomerase II; similar in action to etoposide.
- Dosage Form: Vials of 10-mg/mL solution containing 50 mg of drug.
- Drug Interactions: Metabolism of teniposide is increased by inducers of liver microsomal enzymes such as phenobarbital and carbamazepine.
- Pharmacokinetics/Metabolism: Teniposide is only available by the IV route. It is extensively protein bound in the plasma and undergoes near-complete metabolism in the liver. It has an elimination half-life of 5 hours. Metabolites are excreted in the bile and urine.
- Toxicity: Myelosuppression, predominantly leukopenia, is universal and dose limiting. Otherwise usually well tolerated. Nausea, vomiting, diarrhea, stomatitis, and anorexia are uncommon. Alopecia is generally mild. Elevated liver function tests can occur but are not usually clinically significant. Allergic reactions, hypotension, fatigue, seizures, somnolence, fever, renal insufficiency, and secondary leukemia are all rare.
- Indications: FDA approved for childhood ALL. Not used commonly for other malignancies, but does have activity against SCLC.
- Dosing: 100 mg/m^2 once or twice weekly or 20 to 60 mg/m^2/day for 5 days as a slow IV infusion (at least 30 minutes).

Thalidomide (Thalomid)
- Drug Class: Novel antiangiogenic and immunomodulating agent.
- Dosage Form: 50-mg tablets.
- Drug Interactions: Increases the sedative properties of barbiturates, chlorpromazine, and ethanol.
- Pharmacokinetics/Metabolism: While it has acceptable bioavailibility, thalidomide is slowly and incompletely absorbed from the GI tract. Metabolism appears to be via spontaneous hydrolysis, with an elimination half-life of about 6 hours. Exact quantification of elimination routes are unknown.
- Toxicity: Historical teratogenicity has led to required strict evaluation and monitoring for those taking thalidomide, called the S.T.E.P.S. Program. Strict procedures to prevent conception include barrier contraception for men, since the drug is present in semen of men who are taking it. Fatigue and peripheral neuropathy are the main toxicities and are dose limiting. Myelosuppression is uncommon and usually mild. Rash and headache uncommon.
- Indications: FDA approved for cutaneous leprosy. Used in oncology for multiple myeloma, renal cell carcinoma, metastatic melanoma, and malignant gliomas. Also used as a treatment for cachexia owing to its mild anabolic and appetite-stimulating properties.
- Dosing: Oncology doses range for 50 mg/day up to 1200 mg/day.

Thioguanine (Tabloid)—6-TG, aminopurine-6-thiol hemihydrate
- Drug Class: Purine analog antimetabolite. Cell cycle dependent.
- Dosage Form: 40-mg tablets.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: Thioguanine has modest but slow oral route absorption. It is almost completely metabolized in the liver and has an elimination half-life of up to 11 hours. Metabolites are excreted in the urine.
- Toxicity: Thioguanine is usually well tolerated. Leukopenia and thrombocytopenia are common and dose limiting. Nausea and vomiting, stomatitis, diarrhea, rash, elevated liver function tests, hyperuricemia, and renal insufficiency are uncommon.
- Indications: FDA approved for AML in all phases of treatment. May be useful in other leukemias. An injectable formulation does not yet have FDA approval.
- Dosing: The usual dose for leukemias is 2 to 3 mg/kg/day as part of an ongoing multidrug regimen.

Thiotepa (TESPA)—triethylenethiophosphoramide, TSPA
- Drug Class: Classical alkylating agent. Cell cycle independent.
- Dosage Form: Available as lyophilized powder in vials containing 15 mg of drug.
- Drug Interactions: None noted.
- Pharmacokinetics/Metabolism: With poor oral bioavailability, thiotepa is available only by the parenteral route. Extensive metabolism occurs in the liver, and the drug has an elimination half-life of 2 to 3 hours. Metabolites are excreted in the urine.
- Toxicity: Myelosuppression, predominantly leukopenia, is expected and dose limiting and may be cumulative. Nausea, vomiting, anorexia, stomatitis, and diarrhea are uncommon. Infertility, fever, and angioedema or urticaria are uncommon. Second malignancies such as acute leukemia are rare. With high-dose therapy and bone marrow rescue, stomatitis and cognitive impairment can be severe. Intravesical administration leads to predominant urinary symptoms, including pain, hematuria, hemorrhagic cystitis, and rare ureteral obstruction.
- Indications: FDA approved for the treatment of breast and ovarian carcinoma, as well as Hodgkin's disease and non-Hodgkin's lymphoma. Used for intravesical therapy of superficial bladder cancer and may also be used for intracavitary and intrathecal administration. Used in the transplant setting for ovarian and breast carcinoma.
- Dosing: The usual dose is 12 to 16 mg/m^2 IV over 10 minutes every 1 to 4 weeks. In the transplant setting, doses up to 900 mg/m^2 have been used. The bladder instillation dose is 30 to 60 mg once weekly for 4 weeks. The intrathecal dose is 1 to 10 mg/m^2 one to two times per week.

Topotecan (Hycamtin)—hycamptamine
- Drug Class: Semisynthetic camptothecin molecule; an inhibitor of topoisomerase I, which is required by cells for both transcription and replication.
- Dosage Form: 5-mg vials of lyophilized powder.
- Drug Interactions: None noted.

Pharmacokinetics/Metabolism: No oral form of this drug is available. After IV administration, the drug is not extensively metabolized, and it has an elimination half-life of about 3 hours. A significant portion of the drug is excreted unchanged in the urine.

Toxicity: Myelosuppression, especially leukopenia, is expected and dose limiting. Thrombocytopenia and anemia are common but mild. Nausea, vomiting, and diarrhea are common but usually not severe. Headache, fever, fatigue, anorexia, malaise, and elevated liver function tests are also common. Hypertension, tachycardia, urticaria, renal insufficiency, hematuria, neuropathy, and mucositis are uncommon.

Indications: FDA approved for the treatment of refractory, relapsed ovarian carcinoma and for relapsed small cell lung cancer. Also used in myeloid leukemias.

Dosing: The standard dose for ovarian cancer is 1.5 mg/m^2/day for 5 days as a 30-minute infusion.

Toremifene (Fareston)

Drug Class: Nonsteroidal antiestrogen; cytostatic effects on estrogen-dependent and nondependent malignant cells.

Dosage Form: 60-mg tablets.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Toremifene has good oral bioavailability and is extensively bound to plasma proteins. It is metabolized in the liver to active metabolites and has an elimination half-life of about 5 days. Parent drug and metabolites are excreted in the bile.

Toxicity: Toremifene is usually very well tolerated. Hot flashes, nausea, sweating, dizziness, and fatigue are the most common side effects. Vomiting, diarrhea, anorexia, vaginal discharge, vaginal bleeding, and headache are less common. Venous thrombosis and pulmonary embolism are rare.

Indications: FDA approved for the treatment of postmenopausal or estrogen receptor-positive metastatic breast cancer.

Dosing: 60 mg PO every day.

Trastuzumab (Herceptin)

Drug Class: A genetically engineered humanized mouse monoclonal antibody directed against the her2/neu growth factor receptor that is overexpressed in many invasive breast carcinomas. Mechanism of action for clinical activity in breast cancer is unknown but may be complement mediated cell lysis, antibody-dependent cellular cytotoxicity, or induction of apoptosis.

Dosage Form: Vials of 440 mg.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Binding studies show strong binding to cells overexpressing her2/neu molecules. Very little else is known regarding the distribution and metabolic fates of this molecule. Half-life should be very short with minimal distribution outside the vascular compartment and minimal clearance by kidneys or liver (similar to other monoclonal antibodies and polypeptide agents).

Toxicity: Common toxicities include acute fever, chills, nausea, vomiting, and headache. Trastuzumab seems to worsen leukopenia, anemia, and diarrhea when given with chemotherapy compared to chemotherapy alone. Also, trastuzumab may have uncommon acute cardiotoxicity, which may add to the more common anthracycline-induced cardiotoxicity; therefore, the use of trastuzumab with doxorubicin is not indicated by the FDA.

Indications: FDA approved for her2/neu overexpressing metastatic or locally advanced breast cancer; has shown clinical benefit as a single agent and in conjunction with paclitaxel-based chemotherapy.

Dosing: Loading dose of 250 mg or 4 mg/kg by intravenous infusion followed by weekly intravenous infusions of 100 mg or 2 mg/kg for up to 10 weeks (or longer).

Tretinoin (Vesanoid)—ATRA, all-trans-retinoic acid.

Drug Class: A naturally occurring retinoid; induces differentiation and apoptosis of malignant promyelocytes in acute promyelocytic leukemia.

Dosage Form: 10-mg capsules.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: This drug has good oral bioavailability and a very short elimination half-life of about 40 minutes. It induces its own metabolism in the liver, leading to decreased levels and clinical effect with continued administration. No appreciable excretion of the parent compound is evident.

Toxicity: Tretinoin is teratogenic, so women of childbearing age who take this drug must be on optimal contraceptive measures. Leukostasis and hemorrhage due to leukocytosis are dose limiting but uncommonly life threatening if the drug is stopped. "Retinoic acid syndrome," although not common, can be dose limiting and consists of fever, chest pain, dyspnea, hypoxia, pulmonary infiltrates, and pleural/pericardial effusions. It can be lethal but improves with cessation of the drug and is treatable with corticosteroids. Dry skin, exfoliation, xerostomia, and cheilitis are common. Elevations in liver function tests and hyperlipidemias are also common. Headache is often seen, but pseudotumor cerebri or other neurologic occurrences are uncommon.

Indications: FDA approved induction therapy for acute promyelocytic leukemia. Also of benefit in the maintenance phase of this disorder and may have clinical activity in other hematologic malignancies.

Dosing: For induction, the dose is 45 mg/m^2/day PO for 30 to 90 days, depending on the clinical response.

Vinblastine (Velban, Velsar, others)—VLB, vincaleukoblastine

Drug Class: Vinca alkaloid; inhibitor of tubulin polymerization and thereby mitosis. G_2-phase specific.

Dosage Form: Vials of drug in solution (1 mg/mL), or lyophilized powder containing 10 mg of drug.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: Poor oral bioavailability. After an IV dose, the drug undergoes deacetylation in the liver to an active metabolite, followed by further metabolism. The elimination half-life is about 20 hours. Excretion is predominantly via the bile.

Toxicity: Vinblastine is a soft tissue vesicant, requiring extravasation precautions during administration. Myelosuppression, especially leukopenia, is expected and dose limiting. Anemia and thrombocytopenia are less common. Peripheral and autonomic neuropathy are less common than that observed with vincristine. Nausea and vomiting are uncommon, but constipation is more often seen. Acute reactions during administration, including dyspnea, wheezing, chest pain, tumor pain, and fever, are uncommon. Syndrome of inappropriate antidiuretic hormone secretion occurs rarely, as does angina pectoris.

Indications: FDA approved for multiple hematologic and solid neoplasms. Most often used for Hodgkin's disease, non-Hodgkin's lymphoma, germ cell tumors, and breast cancer.

Dosing: Typical doses are between 6 and 10 mg/m^2 by IV push every 2 to 4 weeks, combined with other drugs. Can also be given as a continuous infusion over 96 hours at a dose of 1.7 to 2.0 mg/m^2/day.

Vincristine (Oncovin, Vincasar)—leurocristine, VCR

Drug Class: Vinca alkaloid; inhibitor of tubulin polymerization and thereby mitosis. G_2-phase specific.

Dosage Form: Available as solution (1 mg/mL) in vials containing 1 to 5 mg of drug and in syringes containing 1 or 2 mg.

Drug Interactions: L-Asparaginase may decrease hepatic metabolism of vincristine.

Pharmacokinetics/Metabolism: Vincristine is bioavailable only by the IV route. It is metabolized by the liver. The elimination half-life is variable but usually greater than 10 hours. Parent drug and metabolites are primarily excreted in the bile.

Toxicity: Vincristine is a vesicant and should be administered with extravasation precautions. Neurotoxicity is dose limiting in the form of peripheral neuropathy, which is related to total cumulative dose. Autonomic neuropathy is less common, and CNS toxicity is rare. Myelosuppression is mild. Nausea and vomiting are rare, but constipation is fairly common. Acute cardiopulmonary or pain symptoms occurring during administration are uncommon. Transient elevation of liver function tests is sometimes seen.

Indications: FDA approved for Hodgkin's disease and other lymphomas, acute leukemias, rhabdomyosarcoma, neuroblastoma, and Wilms' tumor. Used for many other neoplasms as well.

Dosing: The usual dose is 0.5 to 1.4 mg/m^2 IV push every 1 to 4 weeks. A continuous infusion of 0.5 mg/m^2/day over 96 hours has also been used.

Vinorelbine (Navelbine)—5′-noranhydrovinblastine, NVB

Drug Class: Semisynthetic vinca alkaloid; inhibitor of tubulin polymerization and thereby mitosis. G_2-phase specific.

Dosage Form: Available as vials of 10-mg/mL solution.

Drug Interactions: None noted.

Pharmacokinetics/Metabolism: This drug has fair oral bioavailability but is currently available only as an IV preparation. It is metabolized by the liver and has an elimination half-life of about 24 hours. Excretion is predominantly in the bile.

Toxicity: Vinorelbine is a mild vesicant, requiring extravasation precautions. Myelosuppression, mostly leukopenia, is expected and dose limiting. Significant nausea and vomiting are uncommon. Neurotoxicity in the form of neuropathy is less common and milder than that seen with vincristine. Tumor pain during administration has been reported. Acute reaction such as dyspnea, chest pain, and wheezing have occurred during administration and may be prevented by premedication with corticosteroids.

Indications: FDA approved for the treatment of relapsed metastatic breast cancer and for NSCLC as a single agent or combined with a platinating agent.

Dosing: The recommended dose is 30 mg/m^2 IV over 20 minutes every week, with dose adjustments based on leukocyte counts.

Zolendronic Acid (Zometa)

Drug Class: Bisphosphonate inhibitor of bone metastases.

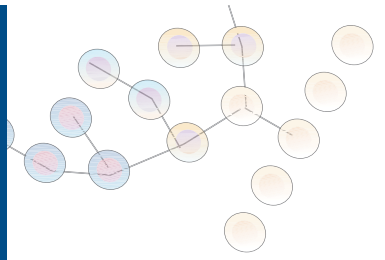
Dosage Form: Vials containing 4 mg of zolendronic acid in powder form.

Drug Interactions: No studies have identified interactions. Theoretical concerns include exacerbation of hypocalcemia if zolendronic acid is coadministered with aminoglycosides or thiazide diuretics. Also, zolendronic acid could exacerbate the renal effects of other nephrotoxic drugs.

Pharmacokinetics/Metabolism: Zolendronic acid is poorly absorbed by the GI tract and is therefore given as an intravenous infusion. It is not metabolized and is excreted by the kidneys. It has a plasma terminal elimination half-life of about 150 hours.

Toxicity: Zolendronic acid is generally well tolerated. The most common infusional side effect is fever, which is usually mild and treatable. Nausea and constipation are also common. Dyspnea, fatigue, diffuse pain, rash, and headache are uncommon. Renal insufficiency is uncommon and generally reversible after discontinuation of the drug, but it is more likely with higher doses than with the approved and recommended 4-mg dose.

Indications: FDA approved for treatment of hypercalcemia of malignancy and for prevention of pathologic fractures in multiple myeloma and solid tumors with known bone metastases.



Dosing: 4 mg IV injection over 15 minutes once monthly.

31 Principles of Molecularly Targeted Therapy: Present and Future

Anthony J. Murgo, Shivaani Kummar, Martin Gutierrez, Joseph E. Tomaszewski, and James H. Doroshow

SUMMARY OF KEY POINTS

- Molecularly targeted anticancer agents (MTAs) are those that selectively target specific molecular features of cancer cells such as aberrations in genes, proteins, or pathways that regulate tumor growth, progression, and survival.
- Molecular targets include the following: products of activating mutations and translocations, growth factors and receptors, aberrant signal transduction and apoptotic pathways, factors that control tumor angiogenesis and microenvironment, dysregulated proteins, DNA repair machinery, and aberrant epigenetic mechanisms.
- The development of MTAs requires innovative strategies that differ from those traditionally applied to nontargeted conventional chemotherapy.
- Successful development of an MTA depends largely on the importance of the target in controlling tumor cell proliferation and survival, a qualified assay to measure target modulation, and careful attention to patient selection.
- Primary objectives of clinical trials of MTAs differ from those used in trials of conventional chemotherapy. An important objective in phase I trials of MTAs is determination of a phase II dose based on optimal target modulation (i.e., a biologically effective dose) rather than on maximum tolerated dose. In addition, objective tumor response may not be an adequate endpoint for the efficacy evaluation of MTAs, because they may have antitumor effects that are more cytostatic than cytotoxic in nature. Progression-free survival may be a more appropriate endpoint.
- MTAs may be more effective when used in combination.
- Functional and molecular imaging plays an increasingly important role in the development of MTAs.

INTRODUCTION

Recent advances in cancer biology and synthetic chemistry have generated extraordinary opportunities for the development of molecularly targeted cancer therapeutics. Molecularly targeted anticancer agents (MTAs) are defined here as those that selectively target specific molecular features of cancer cells such as aberrations in genes, proteins, or pathways that regulate tumor growth, progression, and survival. In contrast, nontargeted therapeutics such as standard chemotherapeutic agents tend to be nonselective and thus produce considerable toxicity against normal cells. By identifying ways that cancer cells differ from normal healthy cells at the molecular level, scientists are now in a better position to exploit these differences to develop drugs that more effectively attack cancer cells while sparing normal cells. Consequently, an increasing number of MTAs are being developed with the goal of producing more effective and minimally toxic anticancer therapeutics. Furthermore, progress in the development of MTAs can shape cancer therapeutics into a more personalized form of cancer medicine. This chapter will review the principles of molecularly targeted therapy including strategies for preclinical and clinical development.

MOLECULAR TARGETS

There is an increasing number and assortment of molecular targets, broadly categorized according to genetic or functional properties including the following: products of activating gene mutations and translocations; growth factors and receptors; aberrant signal transduction and apoptotic pathways; factors that control tumor angiogenesis and the tumor microenvironment; dysregulated proteins; DNA repair machinery and aberrant epigenetic mechanisms (Table 31-1). Understandably, any such categorization of targets contains considerable overlap. For example, activation of the growth factor receptors epidermal growth factor receptor (EGFR) and HER2 can occur by a variety of mechanisms including altered transcriptional control, gene amplification, and activating mutations.[1,2] Similarly, platelet-derived growth factor receptor (PDGFR)-α and PDGFR-β are receptors for growth factors in many types of tumors but are also expressed in stromal tissue and play a role in angiogenesis.[3] In addition, abnormal expression of PDGFR-α and PDGFR-β can result from genetic abnormalities; activating mutations of PDGFR-α in some cases of gastrointestinal stromal tumor (GIST)[4] and chromosomal translocations resulting in the TEL/PDGFR-β fusion protein in chronic myelomonocytic leukemia.[5]

The most promising molecular targets are those solely responsible for sustaining tumor growth and survival. Agents that potently and selectively inhibit these critical targets are likely to have a major clinical impact. Probably the best example of a critical target is BCR-ABL in chronic myelogenous leukemia (CML). BCR-ABL is a fusion protein formed by the reciprocal translocation of chromosomes 9 and 22. Knowledge that this dysregulated tyrosine kinase played a causal role in the pathogenesis of essentially all cases of CML spurred preclinical studies that led to the development of a potent and selective ABL tyrosine kinase inhibitor, imatinib mesylate.[6] Subsequent clinical trials established imatinib mesylate as the first highly effective molecularly targeted therapy for CML and a prototype for the

Table 31-1 Tumor Targets

Validated*

Target	Disease Indication	FDA-Approved Agents(s)	Agent Type
CHROMOSOMAL TRANSLOCATIONS			
BCR-ABL	Ph+ CML, ALL	Imatinib mesylate, dasatinib	TKI
PML-RAR	Acute promyelocytic leukemia	All-*trans* retinoic acid	Retinoid
PDGFR-β	CMML, DFSP	Imatinib mesylate	TKI
SOMATIC MUTATIONS			
KIT	GIST	Imatinib mesylate, sunitinib malate	TKI
PDGFR-α	GIST	Imatinib mesylate, sunitinib malate	TKI
GROWTH FACTORS/RECEPTORS			
EGFR	Non-small cell lung cancer	Erlotinib	TKI
	Colorectal cancer	Cetuximab, panitumumab	Mo-Ab
	Head and neck cancer	Cetuximab	Mo-Ab
ErbB-2	HER-2 overexpressing breast cancer	Trastuzumab	Mo-Ab
		Lapatinib	TKI
ANGIOGENESIS			
VEGF	Colorectal cancer, non-small cell lung cancer	Bevacizumab	Mo-Ab
VEGFR	Renal cell carcinoma	Sunitinib malate, sorafenib	TKI
mTOR	Renal cell carcinoma	Temsirolimus	Rapamycin analogue
EPIGENETIC SILENCING			
DNA methyltransferase	Myelodysplastic syndrome	Azacitidine, decitabine	Pyrimidine analogue
Histone deacetylase	Cutaneous T-cell lymphoma	Vorinostat	Hydroxamic acid
DYSREGULATED PROTEINS			
Proteosome	Multiple myeloma	Bortezomib	26S proteasome inhibitor

Agents under Clinical Development

Target	Role of Target	Disease Indication	Examples of Agents in Clinical Development	Ref.
SOMATIC MUTATIONS				
FLT-3 (FMS-like tyrosine kinase-3)	Regulates cell cycle progression, proliferation, and survival	Acute myeloid leukemia	Sunitinib	90
			CEP-701	91
			MLN518	92
bRAF mutation	Effects cell proliferation and angiogenesis via amplification of signal transduction in RAS/MAPK pathway	Papillary thyroid carcinoma Melanoma	PLX4032	93

ALL, acute lymphoblastic leukemia; CMML, chronic monomyelocytic leukemia; DFSP, dermatofibrosarcoma protuberans; HIF-1α, hypoxia-inducible factor-1α; IGF-1R, insulin-like growth factor-1 receptor; IGFBP3, insulin-like growth factor binding protein-3; Mo-Ab, monoclonal antibody; mTOR, mammalian target of rapamycin; PARP, poly (ADP-ribose) polymerase; Ph + CML, Philadelphia chromosome positive myelogenous leukemia; TKI, tyrosine kinase inhibitor. TRAIL, tumor necrosis factor-related apoptosis-inducing ligand.

*Valid to the degree that agents directed against them have proven effective in the treatment of one or more disease indications bearing the target.

development of others in the class.[6–8] Imatinib mesylate is also a potent inhibitor of other tyrosine kinases including PDGFR and KIT, and it is highly effective in the treatment of GIST bearing activating c-*KIT* mutations, and in some GIST bearing activating *PDGFR* mutations.[4]

Unfortunately, the majority of human tumors, including the most common types, are genetically complex and do not have a single critical target. In addition, what may be a critical target in one type of tumor may be expressed but not be as relevant in another. Most tumor types have various genetic and molecular abnormalities driving their growth and survival. The existence of multiple abnormalities is one mechanism to explain resistance to molecularly targeted therapy and provides a rationale for treatment strategies combining two or more targeted agents.[9] However, recent information suggests cancer cells

may become "addicted" or physiologically dependent on the sustained activity of specific oncogenes for maintenance of a malignant phenotype and for survival**.** This dependence mechanism, termed oncogene addiction[10,11] (Fig. 31-1), is associated with differential attenuation rates of prosurvival and proapoptotic signals stemming from the oncoprotein, with predominant apoptotic signals resulting in cell killing. The latter process, termed "oncogenic shock,"[12] could explain the remarkably rapid clinical responses to tyrosine kinase inhibitors in some patients with solid tumors,[13] including those typically having complex molecular abnormalities. Other possible factors controlling sensitivity or resistance to molecularly targeted therapy include increased expression of the target due to gene amplification or transcription, emergence of resistant target gene mutations, and overexpression of multidrug transporter membrane proteins.[8,14]

There has been increased attention to the development of molecular therapy directed at factors controlling angiogenesis since approval by the United States Food and Drug Administration (FDA) of several agents that target vascular endothelial growth factor (VEGF) and its receptor (VEGFR). The VEGF pathway, involving the VEGF family of proteins and their receptors, is an important regulator of both physiologic and pathologic angiogenesis. Through its signaling pathways, VEGF/VEGFR activation contributes to increased vascular permeability, mobilization of bone marrow-derived endothelial cell precursors, degradation of the extracellular matrix, and endothelial cell division, differentiation, migration, and survival.[15,16] VEGF overexpression occurs in most types of cancers, including colorectal, gastric, pancreatic, liver, lung, breast, thyroid, genitourinary, and in glioma and other intracranial tumors, as well as hematologic malignancies.[17,18] In addition, VEGF overexpression is associated with tumor growth and clinical outcome in several of these tumor types.[17]

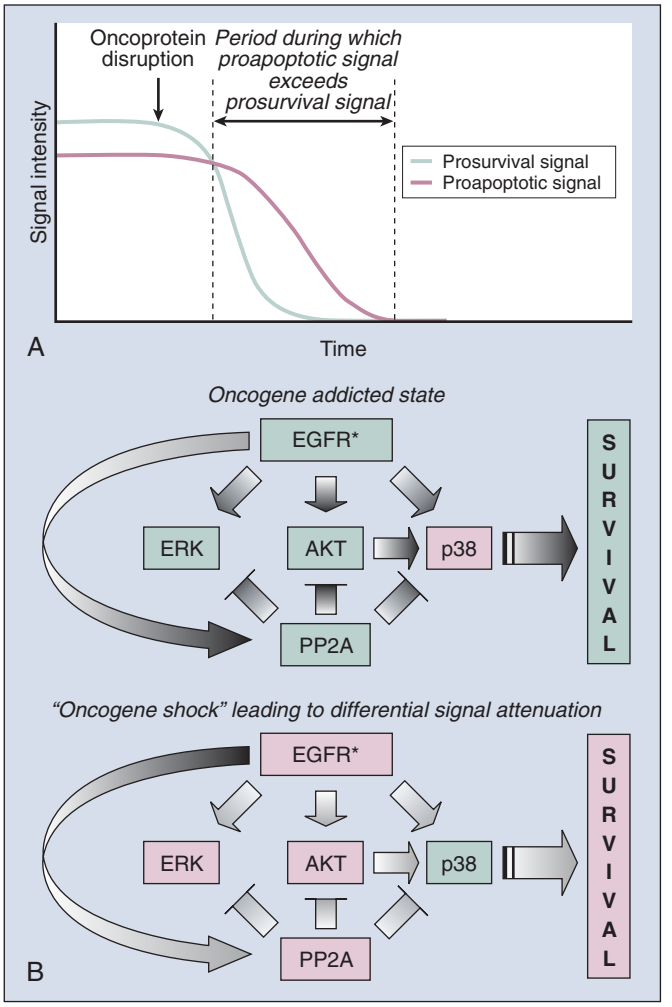

Figure 31-1 • Proposed model of oncogene addiction. **A,** Proposed role of differential signal attenuation in creating a temporal window during which apoptotic signals persist in the absence of prosurvival signals following acute oncogene inactivation to promote cell death. **B,** Proposed role of differential signal attenuation in the cell death response to acute inactivation of oncogenic EGFR (EGFR*) upon which a tumor cell has become dependent. The upper panel illustrates the oncogene "addicted" state in which cells survive, and the lower panel illustrates the shift in the balance of prosurvival and proapoptotic signaling shortly after EGFR inactivation. Red, "off"; green, "on." (From Sharma SV, Gajowniczek P, Way IP, et al: A common signaling cascade may underlie "addiction" to the Src, BCR-ABL, and EGF receptor oncogenes. Cancer Cell 2006;10:425–435.)

Potential therapeutic strategies to inhibit signaling through VEGF and VEGFR pathway activation include monoclonal antibodies directed against VEGF or VEGFR, tyrosine kinase inhibitors, and antisense strategies (antisense oligodeoxynucleotides, antisense RNA, small interfering RNAs). In 2004, the FDA approved bevacizumab, a humanized murine monoclonal antibody directed against VEGF, for treatment of metastatic colorectal cancer when used in combination with fluorouracil-based chemotherapy.[19] Subsequently, two small molecule tyrosine kinase inhibitors with activity against VEGFR, sunitinib and sorafenib, became FDA approved for the treatment of advanced renal cancer.[20,21] In addition, sorafenib is effective in the treatment of hepatocellular carcinoma,[22] a tumor against which standard cytotoxic chemotherapy has little or no activity. The experience with these agents established the VEGF/VEGFR pathway as a valid target for cancer therapeutics.

Mammalian target of rapamycin (mTOR) has also emerged as a validated target with the demonstration that the small molecule mTOR inhibitor, temsirolimus, is effective in the treatment of renal cell carcinoma.[23] This activity of temsirolimus is attributed to the downregulation of factors that control cell growth and angiogenesis such as hypoxia inducible factor-1 (HIF-1).[24] Several other strategies to inhibit HIF-1 are under development including the use of the chemotherapeutic agent topotecan, which at low doses administered for relatively long periods has been shown in in vitro and animal models to reduce HIF-1 protein production thus inhibiting angiogenesis.[25]

PRECLINICAL DEVELOPMENT OF MOLECULARLY TARGETED ANTICANCER AGENTS

The discovery and development of MTAs requires closely aligned laboratory and clinical research, integrating drug discovery, development, and clinical investigation. In such a cooperative setting, researchers can effectively take rational and iterative steps from target identification to clinical evaluation (Fig. 31-2; Table 31-2). A crucial early step in developing an MTA is target validation, defined as experimental evaluation of the role of a given gene or protein in cancer.[26,27] The process of target validation involves a variety of preclinical approaches, including genetic, cell-based, and animal models.[26,28,29] Validation and prioritization of molecular targets for therapeutic development depends on a variety of criteria taking into consideration chemical, biologic, clinical and practical factors (Table 31-3).[27] The fundamental goal is to provide evidence that the target is valid (affecting the target inhibits tumor growth, progression, or survival) and that making drugs that hit the target is feasible. The next major step in the development of MTAs is finding compounds directed against the target.

Empirical approaches traditionally used to screen for cytotoxic agents are not optimal for MTAs. Rather, screening for MTAs should be target based. The increasing number of potential targets and the

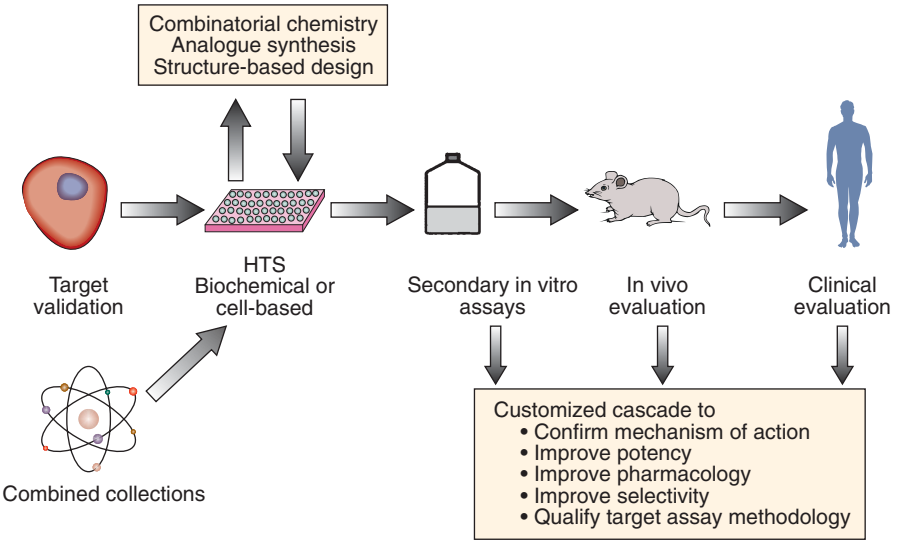

Figure 31-2 • Central role of high-throughput screening (HTS) in the mechanism-based drug discovery process. (With permission from Aherne GW, McDonald E, Workman P: Finding the needle in the haystack: why high-throughput screening is good for your health. Breast Cancer Res 2002;4:148–154.)

availability of sophisticated high-throughput screening technology provide tremendous opportunities to screen an enormous set of diverse small molecular compounds for promising therapeutics.[27] Furthermore, the availability of genetically engineered mouse models provides the opportunity to better screen compounds in vivo.[28,29] A more in-depth discussion of these important drug discovery tools and their implications to the molecularly targeted drug development process is beyond the scope of this chapter.

Optimal development of an MTA requires careful assessment of pharmacokinetic (PK) and pharmacodynamic (PD) effects in relevant nonclinical models before initiating clinical trials. Preclinical in vivo pharmacologic and toxicologic testing is required to establish starting dose and schedule for clinical trials, evaluate effects on normal host tissue, and help make predictions about serum and tissue levels required for target modulation as well as effects on tumor growth. At present most in vivo efficacy studies involve human tumor cell murine xenograft models.[30,31] However, xenograft models have limitations including the requirement for an immunocompromised host, and they are not an ideal method to simulate the complex relationship between tumor and microenvironment such as the angiogenesis process.[28] Moreover, xenograft models have not been very predictive of drug efficacy in cancer patients; activity in a particular histology in a xenograft tumor model does not closely correlate with activity in the same human cancer histology.[32] However, agents that have activity against a broad range of tumor types in xenografts have a better chance of clinical activity than those that do not. Major variables to consider in designing xenograft studies include the origin of the tumor, mutation status, site of implantation, size of the tumor at commencement of drug treatment, and dose and schedule of administration. Clearly, the future development of MTAs would benefit from more predictive in vivo models. Those based on target

Table 31-2 Steps in Discovery and Preclinical Development of Molecularly Targeted Therapy

Identify the molecular target against which an agent will be developed.
Validate the molecular target; confirm that affecting the target inhibits tumor growth/survival.
Screen for compounds that "hit" target (i.e., high-throughput screening).
Optimize compounds: select or modify structure to increase activity and selectivity while maintaining favorable pharmacologic drug properties.
Qualify assay methodology for drug-target effect, in in vitro and in animal models.
Evaluate lead drug(s) in vivo for efficacy and safety.
Prioritize and select drug candidate(s) for clinical testing.
Conduct necessary preclinical animal toxicology and pharmacokinetic studies to support investigational new drug status for first-in-human trial.

Table 31-3 Validation Criteria and Prioritization of New Targets for Drug Screening

High frequency of genetic or epigenetic deregulation of the molecular target or pathway in human cancer—indicates that the target or pathway is probably important in driving the disease.
Linkage of the deregulation to clinical outcome—strengthens case for causal involvement.
Evidence in a model system that the target pathway causes or contributes to the malignant phenotype—demonstrates a direct causal role in malignancy.
Demonstration of reversal of the malignant phenotype—provides greater confidence that modulation of the target by a drug will produce an anticancer effect.
Demonstration of "drugability" of the target (e.g., enzymes are generally much more druggable than are large-domain protein-protein interactions).
Availability of a robust, efficient biological test cascade to support the drug discovery program—to allow evaluation of lead compounds and to select a development candidate for preclinical toxicology testing and clinical trials.
Feasibility of establishing, validating, and running an affordable and robust high-throughput screen.
Potential for a drug design approach based on structural biology; such an approach, based on an x-ray crystallographic or nuclear magnetic resonance structure, can be highly complementary to a screening strategy.

Adapted from Aherne GW, McDonald E, Workman P: Finding the needle in the haystack: why high-throughput screening is good for your health. Breast Cancer Res 2002;4:148–154.

expression rather than histology promise better success, but this will require substantial additional testing.

CLINICAL DEVELOPMENT OF MOLECULARLY TARGETED AGENTS

Successful development of MTAs may require different strategies than those traditionally used for the development of conventional cytotoxic chemotherapeutic agents (Table 31-4).[33] Consequently, the discovery of an increasing number of molecularly targeted compounds has created major challenges in drug development, both for dose determination and efficacy evaluation. In animal models, many of these newer agents may show marked growth-inhibitory and antimetastatic effects without impressive tumor regression, properties commonly referred to as cytostatic. Although the specific effects of each class are dependent on the target or targets inhibited, in patients many are more likely to result in tumor growth inhibition rather than tumor regression. Pivotal clinical trials of sorafenib in renal cell and hepatocellular carcinoma, for example, substantiate the cytostatic properties of this small molecule VEGFR inhibitor, with results showing marked improvement in progression-free survival with minimal objective tumor response by RECIST criteria.[21,22]

Dose Determination

The primary objective of phase I trials of conventional cytotoxic agents is ordinarily to define maximum tolerated dose (MTD), under the assumption that the higher the dose the greater the antitumor activity (Fig. 31-3A). Thus, the dose recommended for phase II efficacy trials is typically the MTD. However, MTAs are generally less toxic and, because of their selectivity, may be effective at doses much lower than the MTD (Fig. 31-3B). MTAs act on highly specific targets differentially expressed or activated in cancer cells. Thus, they tend to spare normal tissue except at higher doses, resulting in a wide therapeutic index. Therefore, increasing the dose in a traditional phase I trial to the point of normal tissue tolerance (MTD) may be an irrelevant or nonachievable endpoint with an MTA. Rather, target inhibition may be a better endpoint, with the primary objective of determining the "optimal biologic dose," that is, the lowest dose that maximally inhibits the relevant target or pathway.[33–35]

Phase I trials intended primarily to determine a dose that optimally inhibits a target in tumor tissue usually involve pre- and post-treatment biopsies. However, the requirement for tissue biopsies is costly and hampers enrollment, because only patients with tumors

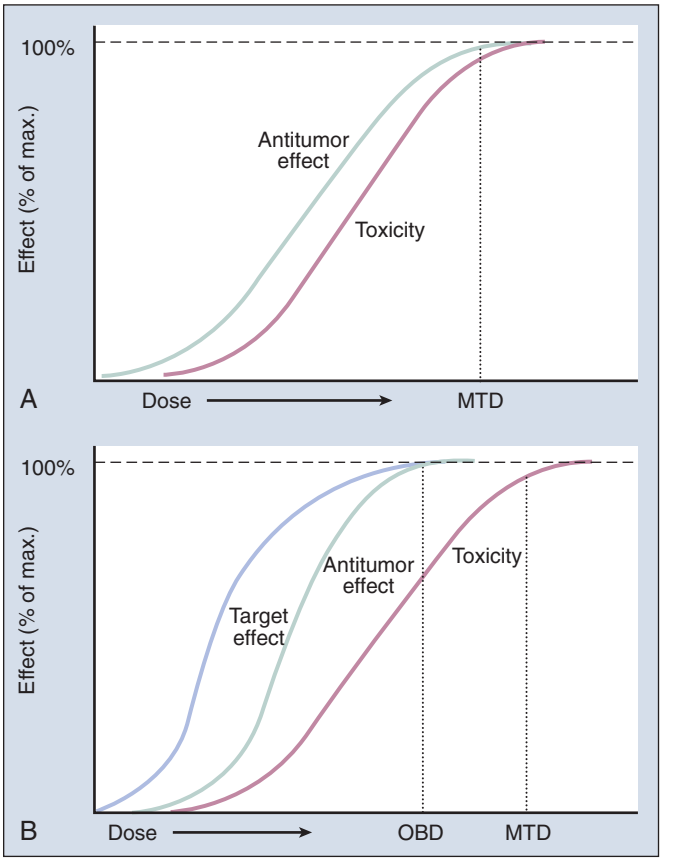

Figure 31-3 • **A,** Hypothetical dose-effect curves for the antitumor and toxic effects of a conventional nontargeted cytotoxic agent. The therapeutic index is narrow, with the maximum antitumor effect close to the maximal tolerable dose (MTD). **B,** Hypothetical dose-effect curves for the antitumor and toxic effects of an MTA. The therapeutic index is relatively wide, with the optimal biologic dose (OBD) antitumor dose occurring at a dose considerably lower than the MTD.

Table 31-4 Properties and Development of Nontargeted versus Molecularly Targeted Anticancer Agents

	Nontargeted Chemotherapy	Molecularly Targeted
Drug discovery	Empirical approaches; screening for compounds that inhibit tumor growth/survival	Target-based approaches; screening for compounds that hit tumor target
Antitumor effects	Cytotoxic; tumor shrinkage	May be cytostatic; growth inhibition
Host toxicity	Nonselective, toxic to many normal organ systems	Selective; depends on target(s) specificity; "off-target" effects
Therapeutic window	Usually narrow	Usually wider
Phase I primary endpoints	DLT and MTD; PK	Target inhibition and OBD; PK
Dosing	Intermittent	Intermittent or continuous
Phase II efficacy trial endpoints	Objective tumor response (tumor shrinkage)	Tumor response or progression-free survival
Phase II dose	Based on MTD	OBD
Patient selection	Histology	Target expression, if possible
Interval to clinical response	Relatively short (e.g., 4–8 weeks)	Variable

DLT, dose-limiting toxicity; MTD, maximum tolerated dose; OBD, optimal biologic dose; PK, pharmacokinetics.

accessible to biopsy are eligible, and not all otherwise eligible patients consent to the procedure. Therefore, in lieu of tumor biopsies, one strategy to evaluate target modulation and determine a biologically active dose is to use less invasive procedures involving target or biomarker assessment in surrogate tissue expressing the target, such as skin or peripheral blood mononuclear cells (PBMCs).[35–38] For example, demonstrating a "biologically effective dose" in PBMCs may serve as a guide in dose-finding trials. This approach was invaluable in the initial studies of the proteasome inhibitor bortezomib.[36] Because a sufficiently sensitive PK assay was not yet available, the study used PBMC proteasome levels as a bioassay surrogate. This turned out to be a successful method for dose determination pending a sensitive PK assay. Phase I trials could also use target modulation in surrogate tissue such as PBMCs to determine a dose level to start obtaining more invasive tumor biopsies, based on the premise that measurable effects in tumor tissue are not likely to occur at lower doses.[35]

However, this approach may not be adequate for dose determination with all types of molecularly targeted therapy. For example, a phase I trial of the alkylguanine DNA alkyltransferase depleting agent O^6-benzylguanine determined that substantially higher doses of the drug were required to inhibit the enzyme in tumor tissue as compared with PBMCs.[37] Thus, before relying on PBMCs or other potential surrogates for target effect in tumor tissue, authenticating studies should be done to directly compare the effects in the potential surrogate versus tumor tissue, preferably first performed in animal models and then confirmed in pre–phase I or phase 0 clinical trials.[39]

Another strategy to help define the optimal biologically effective dose is to incorporate into dose-finding trials noninvasive molecular and functional imaging, such as innovative magnetic resonance imaging (MRI) and positron emission tomography (PET).[40,41] Dynamic contrast enhanced MRI (DCE-MRI), which can measure tumor permeability and vascularity, may be a useful biomarker for dose determination in studies of angiogenesis inhibitors. For example, assessment of changes in tumor vascularity and permeability by DCE-MRI has been successfully used in phase I studies as a biomarker for defining pharmacologically active doses for small molecule tyrosine kinase angiogenesis inhibitors.[42,43] DCE-MRI is also applicable to the evaluation of early evidence of tumor responsiveness, a topic addressed later in this chapter.

Given the growing number of targeted agents in development and the complexities of determining a dose that yields optimal biologic activity based on target or biomarker inhibition rather than on toxicity, there is an increasing need for novel adaptive phase I trial statistical designs. One such design recommended for phase I trials of MTAs is based on the assumption that the target response in individual patients is a binary value (positive or negative) determined in each individual patient.[44] The goal of the design is to study a minimum number of patients to find a biologically adequate (rather than optimal) dose, with the intent to obtain sufficient data to move as quickly as possible from dose-finding to evaluating efficacy. Based on limited simulations, this type of design seems to perform adequately with only three or four patients treated at each dose level. The efficacy of this approach for dose determination for targeted agents warrants prospective evaluation in future clinical trials.[33,39,44]

However, to define a biologically effective dose it is essential to have a validated target (as defined previously) and a reliable and reproducible assay to evaluate for target inhibition. This is best accomplished by having a clear understanding of the dynamics and consequences of target inhibition, the degree of target effect required for tumor growth inhibition, whether the target must be inhibited continuously or intermittently, and the function of the target in normal cells. Thus, optimal clinical development of MTAs requires extensive preclinical studies, including better animal models that are predictive of eventual clinical effect and are applicable to thorough assay interrogation.[45] Following this, the drug and its effect on tumor (as evaluated by the assay) should preferably then be evaluated in first-in-human prephase I or "phase 0" studies before definitive phase I trials.[33,39]

In addition to the potential to start substantially earlier than traditional phase I trials, phase 0 trials provide a better opportunity to establish feasibility and qualify target assay methodology in limited numbers of human samples before embarking on studies that involve larger numbers of patients receiving higher and potentially toxic doses of the study agent (Table 31-5). Phase 0 trials characteristically involve rigorous preclinical development of assays for target modulation and PK analysis in advance of clinical investigation, and real-time analysis of patient samples incorporated into the clinical trial.

Table 31-5 Phase I versus Phase "0" Clinical Trials

	Phase I Trials	Phase "0" Trials
Primary endpoint	Establish maximum tolerated dose.	Target modulation or ability to image target of interest.
Dose escalation	Determine safety and toxicity.	Achieve desired systemic exposure or target modulation, allowing dose selection for future studies.
Preclinical biomarker studies	Not consistently performed before initiating the trial	Required to have plasma drug (pharmacokinetic) and preclinical biomarker (pharmacodynamic) assay development and assay qualification before the initiation of the clinical trial
Biomarker assays	Not performed consistently, most phase I trials do not emphasize pharmacodynamic markers	Biomarker assays and/or imaging studies are integrated to establish mechanism of action in actual patient samples.
Number of patients	Usually >20	10–15
Dosing	Multiple	Limited
Therapeutic benefit	None expected; however, tumor response is evaluated to permit continued dosing in case evidence of clinical benefit is found.	None
Tumor biopsies	Optional	Serial tumor biopsies required to evaluate drug effect on target(s)
Pharmacokinetic/ pharmacodynamic analysis	Samples are usually batched and analyzed at a later time point.	Real-time

Adapted from Kummar S, Kinders R, Rubinstein L, et al: Compressing drug development timelines in oncology using phase "0" trials. Nat Rev Cancer 2007;7:131–139.

Because these pilot prephase I studies involve a limited number of subjects and very limited drug exposure with no therapeutic intent, fewer preclinical toxicity data may be required for them to be initiated in accordance with the FDA guidance for Exploratory Investigational New Drug (IND) studies.[46] There are several types of studies that can potentially be conducted under the purview of an Exploratory IND. These include studies that provide important PK information (e.g., oral bioavailability), are designed to select the most promising lead agent from several candidates, determine whether a mechanism of action (e.g., target inhibition) observed in animal models can be observed in humans, and evaluate in vivo binding properties of novel imaging agents using extremely small doses of the test agent ("microdosing").

Another approach to determine an optimal dose of an MTA is to conduct a randomized phase II trial with a clinical response endpoint comparing two or more different doses. This approach may be necessary if dose-selection cannot rely on a biologic marker. However, if this design is to be effective, the agent must have some degree of clinical activity, yielding objective responses or affecting progression-free survival. Under these circumstances, the randomized phase II design is useful in selecting a maximally efficacious dose with the least amount of toxicity that is applicable to subsequent phase III trials.[47–49]

Efficacy Evaluation

Because of the expanding number of anticancer agents under development with novel mechanisms of action, there is an increased need to develop novel paradigms for demonstrating efficacy. A primary endpoint of objective response rate, considered standard for most phase II trials of traditional cytotoxic agents, is not adequate for targeted agents that produce growth inhibition without tumor regression.

Standard cytotoxic agents result in cell kill and eventual tumor shrinkage, whereas cytostatic agents inhibit tumor growth without direct cytotoxicity. MTAs tend to be more cytostatic than cytotoxic. As a result of their specificity and growth-inhibitory properties, the efficacy evaluation of these agents should apply different approaches than those commonly used for nontargeted cytotoxic chemotherapy (see Table 31-4).[34,50,51]

Phase II trials of nontargeted cytotoxics commonly use objective response rate as a measure of activity warranting further clinical evaluation. Furthermore, evidence of a therapeutic response to cytotoxic drugs is expected to occur relatively early in the course of treatment (e.g., after one to two cycles). MTAs have a wider therapeutic window, may require dosing for longer periods at low doses to be efficacious, may have maximum clinical effects in combination rather than as single agents, and may be cytostatic instead of cytotoxic. Because cytostatic drugs may not necessarily cause tumor shrinkage, the traditional criteria of objective tumor response may not be optimal in assessing efficacy.[50] This is exemplified by the clinical development of sorafenib. The single-agent rate of objective response, using RECIST criteria, with this multitargeted tyrosine kinase inhibitor is minimal (2% to 3%) in patients with advanced renal cell carcinoma. Yet a phase III trial of the agent in renal cell carcinoma resulted in a marked improvement in progression-free survival, forming the basis for FDA approval.[21] Similarly, sorafenib has minimal objective response activity (response rate < 3%) in hepatocellular carcinoma, but a phase III trial resulted in marked improvement in time to tumor progression and a 44% increase in overall survival.[22] If the main decision factor for further development had been objective tumor response, the true effectiveness of sorafenib may not have been established. For this reason, exploratory efficacy trials of molecularly targeted cytostatic agents increasingly include progression-free survival as a primary endpoint.

However, molecular heterogeneity and differences in patient and tumor characteristics make evaluation of progression-free survival difficult to interpret, particularly in relatively small exploratory studies without concomitant comparator controls. One trial design proposed to overcome some of these concerns is the randomized discontinuation design, which is considered a type of enrichment trial.[51,52] With one such design, all eligible patients receive a study agent for a defined period followed by restaging; patients with a predefined degree of tumor shrinkage remain on drug and those with progressive disease are taken off study; only those patients who show evidence of stable disease undergo randomization to receive either the study drug or placebo. Thus, the randomized population is enriched with sensitive patients, because only those patients without early drug failure continue on therapy. That all patients have the opportunity to receive the investigational drug is considered a major attraction of this study design.[52]

The application of the randomized discontinuation design or other types of novel screening designs in exploratory phase II trials may be particularly useful in the early development of a molecularly targeted cytostatic agent for which a dependable assay to select patients based on target expression is not available.[49,53] Furthermore, randomized phase II designs, in general, are applicable to exploratory trials evaluating two or more doses or schedules.[47,48,54,55]

Sometimes the approach taken to evaluate the efficacy (e.g., progression-free survival) of an MTA is to conduct a trial comparing the results of treatment with the targeted agent in combination with a standard agent or regimen to that with the standard regimen alone. The intent of such studies is to show superior efficacy with the combination. The "add-on" approach is useful for the evaluation of agents expected to have little efficacy when used alone, and is particularly attractive because all patients receive an active agent or regimen. For example, these designs were critical to the successful development of trastuzumab in breast cancer and bevacizumab in colorectal cancer.

The approach, however, is not without significant risk of failure, as was the case with the randomized trials of gefitinib and erlotinib combined with chemotherapy in non-small-cell lung cancer.[56,57] Reasons for failure include suboptimal dose of the MTA, antagonism between the MTA and the chemotherapy, lack of synergistic or additive antitumor effects, or dilution of the study population with patients having insensitive tumors.[58] Such designs should only be considered if there is a reasonable estimate of the single-agent activity of the MTA in the specific patient population to be studied, the agent is administered at an optimally efficacious dose, and the combination is supported by a strong scientific rationale. Furthermore, for those agents with targets expressed in only a small proportion of patients, the study should be enriched with patients who have tumors that express the target or have another marker predictive of activity.

Use of Pharmacodynamic Markers

Trial designs for exploratory studies of MTAs may need to rely more on PD endpoints as markers or surrogates for antitumor effect than on toxicity or objective tumor response. This requires the development of PD assays that reliably measure drug-target effect. To do so, the assay must be accurate, precise, reproducible, sensitive, and robust, as well as having a dynamic range tight enough to detect differences between baseline and post-treatment values (Table 31-6).[39] Furthermore, the assay methodology assessing drug effect on the target should be developed and authenticated first in in vivo animal models and then in prephase I or phase 0 clinical trials.

The development of mechanism-based biomarker assays would significantly expedite drug development, because such assays aid in determining early on if a drug modulates the target. This approach could also help select the lead agent from a group of compounds, help determine dose, guide patient selection and assessment of response, and provide the basis for combination trials.[33,59–61] However, this requires having a validated target, understanding the biology of

Table 31-6 Pharmacodynamic Assay Glossary

Accuracy: The ratio of the observed assay readout to the actual quantity of bona fide analyte present at any point within the dynamic range of the assay. Traditional methods of establishing accuracy include recovered fraction of a known mass of the analyte added to a clinical specimen (spike recovery), and measurement of interferences from materials likely to be found in a typical specimen.

Dynamic range: The range of concentrations in which the assay is capable of accurately measuring analyte; ideally concentrations present in both treated and untreated specimens without additional specimen dilutions or processing steps.

Precision: A measure of variability of results for a specimen around the determined value, performed in the range in which measured values approximate the true value; usually accomplished by repeated assays of a set of specimens by multiple technicians on multiple days.

Reproducibility: The closeness of agreement between independent results obtained with the same method on identical test material but under different conditions (different operators, different apparatus, different laboratories, and/or after different intervals of time). It is measured as the total imprecision of the assay from all sources, measured at several points within the dynamic range of the assay. This imprecision must be much less than the clinical endpoint selected: that is, if an undeveloped assay had a total imprecision of about 40%, this would make measurement of a 50% effect impossible.

Robustness: The assay must be transferable to other laboratories. The results obtained from the assay must be stable over time.

Sensitivity: Analytically, this is the slope of the standard curve. The assay should be sensitive enough to allow repeat determinations of the same specimen.

target inhibition, and defining optimal target inhibition. The evaluation of target expression is demanding, because it requires the development of a reliable assay to measure the target, as exemplified by the comparative value of the measurement of Her2/neu by immunohistochemistry versus fluorescence in situ hybridization before selection for trastuzumab therapy.[62,63]

Adequate clinical evaluation of PD endpoints as markers of drug-target effect in tumor tissue in exploratory trials of MTAs requires pre- and post-treatment biopsies. To do this effectively, such trials require careful attention to the use of standardized and validated procedures for tissue acquisition, handling, processing, and assay methodology. This is critical, because these factors could significantly influence biologic processes and significantly increase inter- and intrapatient variability, making the interpretation of the results problematic. In addition, different tissue handling procedures may change the expression or level of activity of targets, such as enzymes or protein substrates. If care is not taken to stabilize the analyte immediately, it may degrade completely and produce a false positive effect. The standard operating procedures from tissue acquisition to target assay methodology should be developed and qualified before initiating clinical trials.

As discussed previously, to minimize the need for invasive tumor biopsies in subsequent trials, early exploratory studies should evaluate effects in other tissues such as skin or PBMCs as potential surrogates. Exploratory efficacy trials should also utilize newer techniques like molecular profiling of the tumor and normal tissue, and there should be a better understanding of the effects of inhibiting the target both in tumor and host tissue. As such, these approaches depend heavily on the availability of clinical and laboratory based investigators and their willingness to collaborate.

RATIONAL USE OF FUNCTIONAL AND MOLECULAR IMAGING

There is an increasing interest in utilizing novel imaging technologies in the development of MTAs.[64,65] Molecular imaging has the potential to monitor both normal and abnormal biochemical and physiologic parameters in individual patients. Unlike anatomic imaging, molecular imaging displays biochemical and physiologic abnormalities underlying disease, rather than the structural consequences of these abnormalities. Functional and molecular imaging can be helpful in phase I studies for dose determination, as discussed previously, and may be applicable as noninvasive tools to detect drug-target effect, as well as to provide early evidence of efficacy. It may also prove useful in patient selection.

Detecting and monitoring responsiveness to a cytostatic agent is more difficult than doing so with a cytotoxic. Clinical efficacy of cytotoxic agents is usually associated with relatively early evidence of tumor shrinkage that is easily discernable by anatomic imaging with computed tomography (CT) or MRI. Conversely, a molecularly targeted agent could halt tumor growth without demonstrable changes visible by CT or MRI; but evidence of response may be detectable with the use of functional imaging, such as [^{18}F]fluorodeoxyglucose (FDG) positron emission tomography (PET). Uptake of the glucose analogue FDG by tumor cells is a marker of glucose metabolism, number of viable cells, and the level of cell proliferation in a tumor mass. Thus, treatment that causes metabolic changes associated with inhibition of tumor cell proliferation or that causes cell death should have a relatively rapid affect on the degree of FDG uptake. Decrease in the maximum standardized uptake value (SUV_{max}) on FDG-PET was found to be an early predictor of response of advanced GIST to imatinib therapy.[66,67] These changes can occur as early as 24 to 48 hours after initiating imatinib and predict for objective response or stabilization of disease as determined subsequently by CT scanning. Conversely, failure to achieve a decrease in FDG-PET uptake following treatment with imatinib is predictive of a poor clinical response for patients with GIST.

DCE-MRI is another noninvasive modality for evaluating pharmacologic response to MTAs; it is particularly useful in the development of angiogenesis inhibitors. Measurement of DCE-MRI parameters pre- and post-treatment has proven helpful in evaluating changes in tumor blood flow and vascular permeability in early-phase trials of a variety of antiangiogenesis inhibitors including the anti-VEGF antibody bevacizumab[68] and small molecule VEGFR inhibitors.[42,69] DCE-MRI provides the potential to evaluate not only treatment-related changes in tumor vasculature and determination of PK-PD relationships but may also be a relevant marker for predicting clinical outcome.[42,70]

Another promising area of mounting interest is the use of PET and novel imaging probes to visualize cancer targets and processes in vivo.[60] These include a wide variety from small molecules, peptides, and antibodies (Table 31-7). The processes that can be imaged include cell proliferation, angiogenesis, apoptosis, hypoxia, PK, and multidrug resistance. In addition, probes exist or are in development to image tumor cell receptors such as EGFR, HER2, and bombesin, to name a few. Future progress in the clinical application of molecular imaging depends on developing probes that have better sensitivity and specificity as well as probes that increase the signal-to-noise or spatial resolution of molecular imaging devices.

3′-[^{18}F]Fluoro-3′-deoxythymidine PET is particularly useful as an in vivo marker of tumor cell proliferation and for monitoring response to antiproliferative therapy.[71] Finally, there is increasing interest in the use of optical imaging by spectral fluorescence enhancement because of its sensitivity and ability to detect very small clusters of cancer cells.[72] However, optical imaging has the disadvantage of being limited to settings where direct imaging is possible (e.g., intraoperative or endoscopic), because whole-body imaging is not yet feasible. Unquestionably, noninvasive imaging will have increasing

Table 31-7 Imaging Probes Used to Visualize Molecular Targets and Processes in Cancer

Molecular Target/Process	Imaging Probes
SMALL MOLECULE PROBES	
Proliferation	2-[^{11}C]Thymidine, FLT, 1-(2′-deoxy-2′-fluoro-β-D-arabinofuranosyl) thymine, 2′-deoxy-2′-fluoro-5-fluoro-1-β-D-arabinofuranosyluracil, [^{124}I]iododeoxyuridine
Apoptosis	[^{99m}Tc]Annexin V, [^{18}F]Annexin V
Hypoxia	[^{18}F]misonidazole, 2-(2-nitro-1H-imidazol-1-yl)-*N*-(2,2,3,3,3-pentafluoropropyl) acetamide, fluoroerythronitroimidazole, fluoroetanidazole, diacetyl-bis(*N*^{4}-methylthiosemicarbazone) copper (II), [^{124}I]iodo-azomycin-galactoside, fluoroazomycinarabinofuranoside
Pharmacokinetics	5-Fluorouracil, *N*-[2-(dimethylamino)ethyl]acridine-4-carboxamide,1,3-bis(chloroethyl)-1-nitrosourea, [^{11}C]temozolomide, [^{13}N]cisplatin
Multidrug resistance	[^{99m}Tc]sestamibi, [^{11}C]verapamil, [^{11}C]daunorubicin, [^{11}C]colchicine, [^{99m}Tc]methoxyisobutylisonitrile
Breast cancer (ER)	FES
Prostate cancer (androgen receptor)	FDHT
PEPTIDE PROBES	
Somatostatin/somatostatin receptor	[^{90}Y]1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid-Tyr^3-octreotide, [^{111}In]diethylenetriamine pentaacetic acid-D-Phe(1)-octreotide, [^{90}Y]1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid-lanreotide/vapreotide
Vasoactive intestinal peptide/vasoactive intestinal peptide receptor-1	^{123}I-labeled vasoactive intestinal peptide, [^{99m}Tc]TP3654
Bombesin, gastrin-releasing peptide/ gastrin-releasing peptide receptor	^{99m}Tc-labeled bombesin
Cholecystokinin, gastrin/cholecystokinin receptor	^{111}In-labeled diethylenetriamine pentaacetic acid-minigastrin
Angiogenesis	^{18}F-labeled Arg-Gly-Asp peptide targeted to $\alpha_v\beta_3$ integrin
Cathepsin proteases	Prosense (VM102)
ANTIBODY PROBES	
Angiogenesis	Paramagnetic nanoparticles using antibodies to integrin $\alpha_v\beta_3$, the integrin $\alpha_v\beta_3$ ligand, vascular cell adhesion molecule 1, E-selectin
CEA	Arcitumomab (CEAscan), satumomab
Prostate-specific membrane antigen	Capromab pendetide (ProstaScint)
CD20	^{131}I-labeled tositumomab (Bexxar), ^{90}Y-labeled ibritumomab tiuxetan (Zevalin) (FDA approved)
CD22	Bectumomab

CEA, carcinoembryonic antigen; FDHT, 16-fluoro-5-dihydrotestosterone; FES, 16α-fluoroestnadiol-17β; FLT, 3′-[18F]fluoro-3′-deoxythymidine.

importance in the development and application of molecularly targeted therapy.

PATIENT SELECTION

An important consideration in the enrollment of patients on exploratory efficacy trials of MTAs is the use of patient selection that optimizes the chance for a positive effect. This is not feasible unless patients enrolled have tumors that express or have a high probability of expressing the target. Until recently, essentially all phase II trials have evaluated a drug in tumors based on organ of origin with further categorization by histologic type (e.g., breast cancer, non-small-cell lung cancer). The presumption is that a given histologic type within an organ site represents a relatively uniform disease entity. However, there is increasing evidence that tumors are very heterogeneous at the molecular level within any given histologic type in a particular organ and that genetic variations in the tumor may significantly affect drug sensitivity. Clearly, patient selection beyond organ site and histologic type is becoming increasingly important in drug development.

Good examples of patient selection based on molecular phenotype include the use of the estrogen and progesterone receptor expression and HER2/neu expression to select breast cancer patients for treatment with selective estrogen receptor modulators (such as tamoxifen) and trastuzumab, respectively. Another example is the use of EGFR expression to identify patients with colorectal cancer amenable to treatment with cetuximab, an anti-EGFR monoclonal antibody FDA approved in this indication.

Further support for selection based on molecular phenotype is the exceptional responsiveness of non-small-cell lung cancer patients who have exon 19–21 *EGFR* gene mutations to the small molecule EGFR tyrosine kinase inhibitor gefitinib.[73] Because these mutations occur in only about 8% of non-small-cell lung cancer patients, the potential benefit of gefitinib in this small proportion of patients can be missed in a group of unselected patients, unless an extraordinary number of patients are studied (Table 31-8).[58] Similarly, exon 11 mutations of c-kit in GIST[4] and T315I bcr/abl mutations in CML,[74] confer sensitivity and resistance to imatinib, respectively.

Thus, it is increasingly important when designing phase II clinical trials of MTAs to consider the effect of molecular heterogeneity on drug efficacy.[75] For example, to maximize the chance of success in non-small-cell lung cancer trials of EGFR tyrosine kinase inhibitors, enrollment should be restricted to patients with a reasonable proba-

Table 31-8 Number of Patients Required for Randomization in Trial of a Target-Directed Agent*

Percent of Patients with Target in Study	Hazard Ratio for Benefit in Patients with Target		
	1:3	1:5	2:0
10	32,000	11,000	3,900
30	3,600	1,800	600
50	1,700	780	280
70	900	400	150

*The model makes several assumptions: all patients are eligible regardless of target expression, only patients with the target benefit from treatment, target expression does not affect prognosis, lack of target does not result in a negative effect with treatment, median survival is about 10 months, about 100 patients are entered per month over 1–6 years and are followed up for 1.5–2 years, and the study has a power of 0.8 (a one-sided α of 0.05).

Data from Dancey JE, Freidlin B: Targeting epidermal growth factor receptor—are we missing the mark? Lancet 2003;362:62–64.

bility of responding, for example those with tumors that are EGFR positive by immunohistochemistry, have increased numbers of copies of the *EGFR* gene, or where the presence of EGFR activating mutations can be demonstrated.[76] Another example is evaluating poly(ADP-ribose) polymerase inhibitors in breast and ovarian cancer patients with *BRCA1–BRCA2* mutations, who may be a uniquely sensitive patient population.[77]

RATIONAL APPROACHES TO COMBINATION THERAPY

An increasing number of MTAs in development have some clinical activity against selected types of cancer. However, with few exceptions, such as imatinib in the treatment of CML and GIST, MTAs have limited effectiveness as single agents and any clinical benefit is restricted to a relatively small proportion of patients. Consequently, there is a clear need to improve the effectiveness and utility of MTAs in the treatment of the vast majority of malignancies. One approach to improve the therapeutic potential of MTAs is to use them in combination with other agents or modalities (Table 31-9).

As noted previously, the use of MTAs in combination with standard chemotherapy has met with mixed success. Among the successes are trials demonstrating improved survival with the addition of trastuzumab in breast cancer[63] and bevacizumab in colorectal[19,78] and non-small-cell lung cancer.[79] Among the failures are randomized trials of gefitinib and erlotinib combined with chemotherapy in non-small-cell lung cancer.[56,57] The reasons why these latter trials failed to show superiority of the combination over chemotherapy alone are not clear, but they include the possibility of suboptimal dosing (as may have been the case for gefitinib), antagonism with the chemotherapy agents, or dilution of the study population with patients having insensitive tumors.[58] Consequently, there is a need to better elucidate these variables in the future using reliable predictive preclinical models and appropriately designed early-phase clinical trials in advance of large phase II–III clinical trials.

There is increasing interest in developing MTAs in combination with radiotherapy based on the premise that some may function as effective radiation sensitizers or modulators without increasing normal tissue toxicity. Radiation can activate multiple cellular processes and signaling pathways, which in turn can regulate radiation-induced cell death.[80] For example, radiation-induced signaling through growth factor receptors such as EGFR may activate multiple downstream compensatory signals that provide radioprotection.[81] In addition, radiation increases the expression of EGFR in cancer cells, overexpression of EGFR correlates with radiation resistance, and blocking EGFR signaling sensitizes cells to radiation effects.[82,83] Furthermore, clinical data support the radiation-sensitizing effects of EGFR inhibition. For example, the administration of radiotherapy in combination with the anti-EGFR monoclonal antibody cetuximab in patients with head and neck cancer results in a significant improvement in local tumor control and reduced mortality without increased toxicity as compared with radiation alone.[84]

Table 31-9 Strategies Combining Molecularly Targeted Anticancer Agents with Other Modalities

Combination Strategies	Potential Mechanism
MTAs plus cytotoxic therapy	Modulate targets involved in tumor sensitivity/resistance or repair mechanisms.
Combination with chemotherapy	
Combination with radiotherapy	
Two or more MTAs	
Antibody directed at ligand or receptor plus a small molecule TKI directed at the same receptor (e.g., anti-VEGF antibody plus VEGFR TKI)	Maximizes target inhibition.
Agents that inhibit two or more signal transduction molecules in the same pathway (e.g., EGFR TKI plus RAF inhibitor)	Maximizes pathway inhibition.
Agents that inhibit parallel pathways (EGFR inhibitor plus HER2 inhibitor)	Maximize tumor inhibition by affecting multiple cellular mechanisms.
Agents that inhibit a target and a compensatory feedback loop (e.g., mTOR inhibitor plus an Akt inhibitor)	Maximize tumor response by inhibiting compensatory resistance mechanisms.
Agents that target the tumor microenvironment/vasculature plus an agent directed against tumor cell proliferation	Maximize clinical benefit by inhibiting tumor cell proliferation, invasion and metastasis.
Epigenetic remodeling agents (e.g., DNA methylation inhibitors; histone deacetylase inhibitors) used in combination or in concert with agents directed against a re-expressed target	Enhance restoration of expression of tumor suppressor genes, apoptotic mechanisms, or tumor antigens.
MTA plus surgery	
Administer MTA following complete anatomic resection	Maximize benefit by targeting minimal residual disease.

MTA, Molecularly targeted anticancer agents; mTOR, mammalian target of rapamycin; TKI, tyrosine kinase inhibitor.

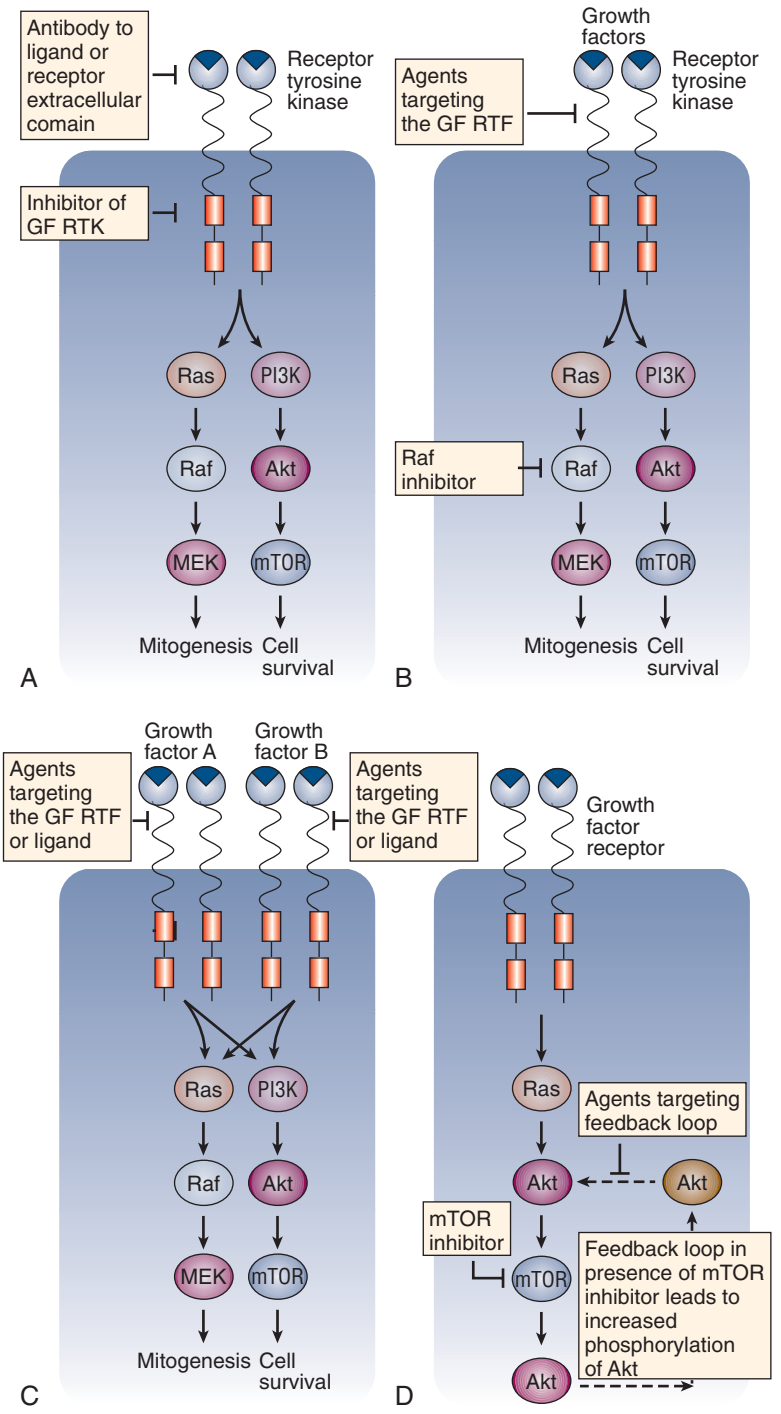

Figure 31-4 • **A,** Maximize inhibition of a target such as a growth factor (GF) receptor by inhibiting both receptor-ligand binding and tyrosine kinase activity. **B,** Maximize inhibition of a pathway by inhibiting a series of signaling components within the pathway. **C,** Inhibit parallel pathways by inhibiting two growth factor receptors or inhibiting downstream components in parallel pathways. **D,** Inhibit a target and the feedback loop that results in resistance. MEK, mitogen-activated protein kinase; mTOR, mammalian target of rapamycin; PI3K, phosphatidylinositol 3-kinase; RTK, receptor tyrosine kinase. (From Dancey JE, Chen HX: Strategies for optimizing combinations of molecularly targeted anticancer agents. Nat Rev Drug Discov 2006;5:649–659.)

Although the results with cetuximab plus radiation in head and neck cancer are very encouraging, the use of an MTA directed at a single target may not be sufficient for optimal radiation sensitizer/modulator effects, because many pathways and processes can regulate radiation-induced cell death. A potentially more effective approach is to target many radiation response–regulatory molecules. One recent line of research focuses on the role of the molecular chaperone heat shock protein 90 (Hsp90), because Hsp90 has several client proteins, many of which are involved in signal transduction and critical to the regulation of radiosensitization. Hsp90 inhibition destabilizes client proteins, leading to their ubiquitination and proteasomal degradation. Preclinical in vitro and in vivo experiments demonstrate that the Hsp90 inhibitor 17-(dimethylaminoethylamino)-17-demethoxygeldanamycin (17-DMAG) sensitizes tumor cells to the effects of radiation therapy, possibly by abrogating radiation-induced G_2 - and S-phase arrest.[85] The potential effectiveness of 17-DMAG and other agents that modulate multiple signal transduction pathways and processes is under clinical investigation.

Because molecular abnormalities in cancer are usually complex and involve multiple processes and pathways responsible for tumor cell proliferation and survival, the likelihood that hitting any one specific target will have a major antitumor impact is relatively low. Consequently, there is considerable interest in developing combinations of MTAs that strategically hit two or more critical targets with

the expectation that such regimens will have more pronounced antitumor effects.[9] However, given the large number of targets and MTAs in development, the number of potential combinations is almost limitless. Thus, the design of clinical trials evaluating MTAs in combination should not be empiric but based on a sound scientific rationale. Examples of rational combinations are those that maximize inhibition of a single target or pathway, those that inhibit two or more parallel cellular processes or pathways, those that inhibit tumor cellular processes and the microenvironment in concert, and those that use epigenetic remodeling agents to increase the expression of a target (Fig. 31-4 and see Table 31-9). In regard to the last example, inhibitors of DNA methyltransferase and histone deacetylase are being studied alone and in combination to restore the expression of tumor suppressor genes and other genes silenced by DNA methylation, including for example hormone receptors and tumor antigens, with the intent to make tumor cells more sensitive to targeted hormonal and vaccine therapy, respectively.[86]

An increasing number of clinical trials are evaluating combinations of two or more MTAs; these trials have recently demonstrated greater than expected level of responsiveness than treatment with either agent alone. Such is the case with the combination of the anti-VEGF antibody bevacizumab plus the VEGFR/RAF kinase inhibitor sorafenib in patients with advanced ovarian cancer.[87] Another promising combination is bevacizumab plus erlotinib in non-small-cell lung cancer.[88] Because this is a very promising area of research, many additional studies exploring rational combinations of MTAs are underway.

The potential advantages of using two or more MTAs in combination are clear. However, another approach to disrupting multiple molecular targets is to design a single agent with specificity against multiple targets of interest. One successful example is the small molecule HER2/EGFR inhibitor lapatinib, an agent that recently received FDA approval for the treatment of advanced breast cancer.[89] Incentives for pharmaceutical companies to take this latter approach are to avoid complex trial designs that may be necessary to isolate the effects of each agent, as well as complicated intellectual property negotiations with another company. Regardless of whether developing single agents with multiple targets or combinations of agents that focus on a limited number of targets, it is important to minimize the risk of toxicity if possible by avoiding overlapping or off-target toxicity.

CONCLUSIONS AND FUTURE DIRECTIONS

Recent advances in cancer genetics, biology, and drug discovery, as well as an enhanced capacity to characterize tumors at the molecular level have created many opportunities for improved treatment of malignancy and accelerated development of new molecularly targeted therapeutics. The expansion of MTAs with more selectivity and less toxicity than conventional chemotherapy over the past decade has been remarkable. However, this paradigm shift has presented new challenges.

The development of MTAs requires different strategies than those traditionally applied to nontargeted conventional chemotherapy. Empirical methods used in the past for the development of standard agents are mostly inadequate for the development of MTAs. Rather, optimal development of MTAs from drug discovery to clinical testing requires the integration of innovative methods that are mainly target based. Furthermore, novel clinical trial designs have evolved with the introduction of MTAs. Most phase I trials of MTAs should have as a primary objective the determination of a recommended phase II dose based on optimal target modulation, because escalation to MTD may not be needed or feasible; however, accomplishing this successfully requires the development of reliable procedures for tissue acquisition and handling and reproducible authenticated assay methodologies to measure target modulation. These target assay procedures are best performed in preclinical in vitro and in vivo models and, if feasible, in phase 0 clinical studies in a limited number of patients in advance of large, more definitive trials.

Another challenge is designing clinical trials that sufficiently evaluate the efficacy of MTAs administered alone or in combination. Because many MTAs are more cytostatic than cytotoxic, objective tumor response defined by RECIST criteria may not be adequate. In addition, it is increasingly apparent that it may be better to base patient selection on target expression rather than on histology and organ site. There is also an increasing appreciation of the value of integrating innovative molecular and functional imaging technologies into early-phase clinical trials as noninvasive means for assessing target modulation, dose determination, patient selection, and early evidence of clinical response.

The development of MTAs has taken cancer therapeutics further on the road of personalized medicine. The major challenge in further advancing and refining these agents lies in understanding them within the context of networks in the cancer cell as well as in association with similar intracellular networks within the tumor microenvironment at both the primary and metastatic sites. The evaluation of the efficacy of MTAs must be based on this complex analysis of the target within the patient. Progressive advancements in molecularly targeted therapy required to meet this challenge are expected in the near future with the development of preclinical models more predictive of human outcome, applications of rationally designed MTA combination therapy, and the more effective integration of molecular imaging and profiling into clinical trials.

32 Hematopoietic Stem Cell Transplantation

Michael R. Bishop and Steven Z. Pavletic

SUMMARY OF KEY POINTS

- Allogeneic or autologous hematopoietic stem cell transplantation (HSCT) is established and curative therapy for many patients with high-risk hematologic malignancies and a critical part of their treatment algorithms.
- Hematopoiesis and immune function can be restored after marrow ablative therapy with hematopoietic stem cells obtained from the bone marrow, peripheral blood, or fetal cord blood.
- The major complication and contribution to mortality and morbidity of allogeneic transplants is acute and chronic graft-versus-host disease (GVHD), which occurs in about 50% of patients; however, most patients ultimately are able to discontinue systemic immunosuppression. GVHD also contributes to the immune-mediated graft-versus-tumor effects. Adequately assessing risk and benefits is a critical part of therapeutic decision-making when deciding whether to recommend transplantation.
- The use of allogeneic transplantation to treat malignancy is limited by lack of a donor—only one fourth to one third of Americans have a human leukocyte antigen (HLA)-matched sibling. However, the unrelated marrow donor volunteer registry continues to grow, and chances of finding a matched unrelated donor today are about 50%; with improving techniques, results of matched unrelated donor transplants today are similar to outcomes when using sibling donors.
- Reduced-intensity (i.e., mini- or nonmyeloablative allogeneic) transplants use less-intensive preparative regimens aimed at the host T cells in an attempt to allow engraftment (and the subsequent immune attack on the cancer) while reducing the early toxicity and mortality. Such procedures permit allogeneic transplantation in older patients (up to age 70 years), in whom cancer is more common, who would not have been eligible for conventional high-dose transplant treatments.
- Autologous transplantation has become standard therapy for recurrent Hodgkin's disease and chemotherapy-sensitive aggressive non-Hodgkin's lymphoma, consolidation of initial response in multiple myeloma, some pediatric malignancies, and refractory testicular cancer. Although autologous transplant is much safer than allogeneic HSCT, the limiting problem is tumor recurrence.
- Adequate supportive care, and prevention and treatment of infections by a well-coordinated multidisciplinary team of subspecialists are critical for a successful transplant procedure. Due to increasing number of long-term survivors after transplantation, oncologists should be aware of late effects of transplantation therapy such as chronic GVHD, second cancers, endocrine, bone metabolism, or other organ system effects.

INTRODUCTION

Hematopoietic stem cell transplantation (HSCT) is the process and intravenous infusion of hematopoietic stem and progenitor cells to restore normal hematopoiesis and/or treat malignancy.[1,2] The term *HSCT* has replaced the archaic term *bone marrow transplantation* (*BMT*), because hematopoietic stem cells can be derived from a variety of sources other than the bone marrow, including the peripheral blood and umbilical cord blood.[3,4] Stem cells used for HSCT are of hematopoietic origin; the distinction is made due to the growing interest in using more primitive stem cells for regenerative therapy due to their plasticity and unique biologic characteristics.[5] Hematopoietic stem cells are further characterized according to their source, that is, from whom they are obtained (Table 32-1). Hematopoietic stem cells obtained from the patient him- or herself are referred to as *autologous*.[1,3] Hematopoietic stem cells obtained from an identical twin are referred to as *syngeneic HSCT*, and hematopoietic stem cells obtained from someone other than the patient or an identical twin are referred to as *allogeneic*. HSCT is most commonly used to restore normal hematopoiesis following the treatment of cancer with chemotherapy and/or radiation at doses that result in severe, often irreversible, damage to bone marrow. The healthy new cells transplanted from a syngeneic or allogeneic source also may allow the restoration of an intact immune system, provide an antitumor effect or, in the case of HSCT for congenital diseases, provide cells that are no longer deficient in certain vital components.

The clinical application of HSCT originated in the identification of the severe myelosuppressive effects of radiation that were observed among nuclear bomb survivors at Hiroshima and Nagasaki.[6] Intensive research efforts were made at that time to develop methods to reverse the myelosuppressive effects of radiation, including the infusion of bone marrow.[7–11] In 1949, Jacobson and colleagues[7] at the University of Chicago reported on the effects of shielding the spleen of mice from lethal does of irradiation. Shielding of the spleen protected nearly all mice at a total body irradiation dose of 700 cGy, whereas unshielded mice all died from marrow aplasia. As the dose of radiation was raised to 1050 cGy, approximately one third of the shielded mice survived, and a dose of 1200 cGy was lethal to all mice. At autopsy, these latter radiation groups were found to have died from fibrosis of the lungs, liver, and kidneys. The authors

Table 32-1 Comparison of Allogeneic and Autologous Hematopoietic Stem Cell Transplantation

	Allogeneic	Autologous
Oldest age to which applicable		
Myeloablative	40–60 y	60–70 y
Nonmyeloablative	65–75 y	N/A
Major problem in finding a donor	Finding a closely HLA-matched sibling or unrelated donor	Ability to collect sufficient numbers of hematopoietic progenitor cells uncontaminated by tumor cells
Most important complication	Graft-versus-host disease	Relapse of original disease
Anti-cancer effect of infused cells	Proved or suspected in a number of malignancies	Probably no
Most commonly treated cancers	Acute leuekemias	Multiple myeloma
		Non-Hodgkin's lymphoma
		Hodgkin's disease

unfortunately concluded that shielding the spleen was protecting a humoral factor that affected hematopoiesis; however, it subsequently was determined that early hematopoietic progenitors actually were protected from the effects of radiation. From these early studies, theories evolved into the concept that radiation and chemotherapy could be administered at controlled yet highly myelosuppressive doses, which were capable of eliminating malignant hematopoietic clones, and normal hematopoiesis could be re-established by the infusion of normal bone marrow. Early animal studies of HSCT were thwarted by incompatibility between bone marrow recipients and donors, which led to a high degree of graft rejection.[11] Among animals that did not reject their marrow grafts, a syndrome of weight loss, alopecia, diarrhea, and eventually death was commonly observed. This syndrome, originally referred to as "runting" disease, now is referred to clinically as *graft-versus-host disease* (GVHD) and is discussed in more detail later in this chapter.[12] Understanding of the major histocompatibility complex (MHC) and human leukocyte antigens (HLA) as the major determinants of graft rejection, which was developed subsequently, significantly advanced laboratory studies and clinical application of allogeneic HSCT.[13]

The first successful clinical bone marrow transplantation trials among patients with severe combined immunodeficiency disorders and advanced acute leukemias were reported in the late 1960s and early 1970s (Fig. 32-1), after clinical methods to determine HLA were developed, permitting the "matching" of bone marrow donors and recipients.[1,11] Subsequently, in the late 1970s, reports were published on the successful use of high-dose chemotherapy and autologous BMT to treat patients with advanced lymphomas.[14] Today allogeneic HSCT is a standard treatment for many immunodeficiency states, metabolic disorders (e.g., Hurler's syndrome), and defective hematopoietic states (e.g., severe aplastic anemia, thalassemia). Autologous HSCT currently is being investigated in nonmalignant diseases, including autoimmune diseases (e.g., multiple sclerosis), and the emerging field of regenerative medicine, which takes advantage of the plasticity of stem cells to repair defective or damaged tissues (e.g., cardiac muscle after a myocardial infarction).[15,16] Both autologous and allogeneic HSCT are standard treatment options for a variety of hematologic malignancies and selected solid tumors. This chapter focuses primarily on the rationale for the application of HSCT in the treatment of malignancy.

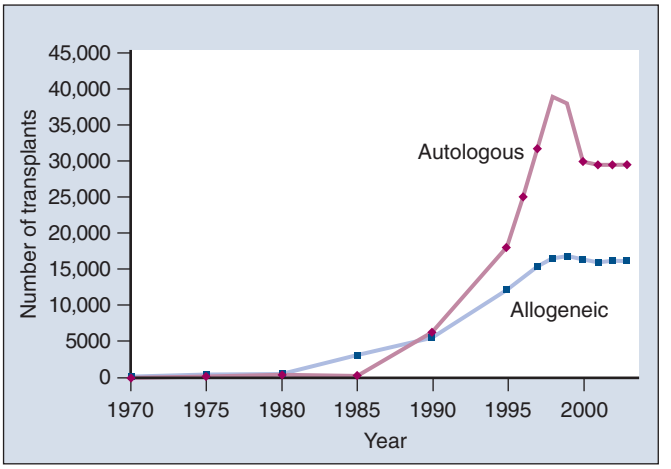

Figure 32-1 • Annual numbers of blood and marrow transplants worldwide, 1970–2003. (Data from the Center for International Blood and Marrow Transplant Research, Milwaukee, WI.)

TYPES OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

The type of HSCT that a patient receives—allogeneic versus syngeneic versus autologous—usually is predetermined, because very few patients have an identical twin (i.e., syngeneic), and the availability of an allogeneic donor is limited even with potential use of unrelated donors and stored cord blood units. Autologous hematopoietic stem cells are available to most patients provided that the autologous hematopoietic stem cells product, bone marrow or peripheral blood, is relatively free of contamination by malignant cells and that prior therapy has not limited the number of cells that can be collected.

Allogeneic Hematopoietic Stem Cell Transplantation

In allogeneic HSCT, stem cells are obtained from a donor other than the recipient. Donor and recipient usually are identical or "matched" for HLA, which is derived from the MHC located on chromosome 6.[17] A single set of MHC alleles, described as a *haplotype*, is inherited from each parent, resulting in HLA pairs. The most important HLAs include HLA-A, HLA-B, HLA-C, DR, and DQ loci. Among siblings, the genes which encode for HLA-B and HLA-C are located so close to each other in the MHC that one is rarely inherited without the other. As a result, an HLA match among siblings is referred to a "6 of 6," as they are matched for HLA-A, B, and DR; however, in actuality they are matched for all of the HLA antigens.[3] The other antigens, such as HLA-C, become more important in alternative sources of hematopoietic stem cells, such as unrelated donors and cord blood, which are described in more detail later in this chapter.[18,19]

The distinctive characteristics of allogeneic HSCT are that the stem cell graft (1) is free of contamination by malignant cells and (2) contains T cells that are capable of mediating an immunologic reaction against foreign antigens. This latter characteristic can be a major advantage if the immunologic response is directed against malignant cells—the *graft-versus-leukemia* or *graft-versus-tumor effect*—thus potentially eradicating disease and reducing the chance of disease relapse. However, if the immunologic response is directed against antigens present on normal tissues, it can lead to the destruction of normal organs, described clinically as GVHD. The risk of both graft rejection (host-versus-graft reaction) and GVHD rises with HLA disparity.

The graft-versus-leukemia effect first was recognized in animal models and subsequently was noted among patients undergoing allogeneic HSCT for acute and chronic leukemias.[20–23] The clinical importance of the interactions between immunocompetent donor T cells and tumor cells in mediating a graft-versus-leukemia effect is supported by an increased rate of relapse in allogeneic stem cell grafts from which T cells have been removed (T-cell depletion), an inverse correlation between relapse and severity of GVHD, and increased rate of relapse after syngeneic or autologous HSCT using the same myeloablative conditioning regimen.[23,24] These data suggested that T cells within the allograft were involved directly in eradicating leukemia. Finally, the most compelling evidence for a T-cell-mediated graft-versus-leukemia effect originates from the observation that infusion of allogeneic lymphocytes, a donor lymphocyte infusion, at a time remote from the transplant conditioning regimen, can treat leukemia relapse successfully after allogeneic HSCT.[25–28] In an early report, donor lymphocyte infusion therapy was given to three patients with chronic myelogenous leukemia whose disease had recurred after an allogeneic HSCT.[25] The donor lymphocyte infusion, without any additional cytotoxic therapy, resulted in sustained cytogenetic and molecular remissions. Over time it became increasingly apparent that a significant part of the curative potential of allogeneic HSCT could be directly attributed to the graft-versus-leukemia effect. However, there is tremendous variability relative to the clinical effectiveness of the graft-versus-leukemia effect against different malignancies after allogeneic HSCT.

The choice of donor for an allogeneic HSCT takes into account several factors, including the patient's disease, disease state, and urgency in obtaining a donor. When allogeneic HSCT is being considered for a patient, a fully HLA-matched sibling is the preferred donor source, because the risk of graft rejection and GVHD is lowest with this source of allogeneic stem cells. As described earlier, a haplotype is inherited from each parent, and by simple Mendelian genetics it would be expected that the probability that two siblings would share the same haplotypes would be 1 : 4. The probability of having an HLA-matched sibling increases with the number of siblings within a specific family. The probability can be estimated using the following formula: The chance of having an HLA-matched sibling = $1 - (.75)^n$, where n is the number of potential sibling donors.[3] There is an approximately 1% chance of crossing over (i.e., genetic material switched between chromosomes during meiosis), primarily between the HLA-A and the HLA-B loci. The clinical outcomes for allogeneic HSCT using a sibling with a single HLA mismatch are similar to those with a fully HLA-matched sibling.[29]

For patients who lack a fully HLA-matched sibling donor, the preferred alternative sources for allogeneic stem cells include an unrelated fully HLA-matched donor, a partially HLA-matched cord blood unit, or a partially HLA-matched family member.[30–32] A closely HLA-matched volunteer hematopoietic stem cell donor may be identified through a bone marrow donor registry, such as the National Marrow Donor Program in the United States, which includes about 6 million potential donors. Many HLA phenotypes are possible, which sometimes makes the identification of a matched unrelated donor difficult and time consuming.[33,34] Depending on the ethnic descent of both patient and donor, the probability of identifying an HLA-matched unrelated donor is between 50% and 80%.[8,9] Due to advances in HLA-typing through the use of molecular typing techniques and improved supportive care over the last decade, current results of matched unrelated donor transplants for malignancy are not significantly different when compared to HSCT from matched sibling donor transplant.[19,35]

One major disadvantage of using an unrelated donor is that the average time required to identify and procure an HLA-matched unrelated donor is approximately 2 to 3 months, which may be too long for patients with rapidly progressive malignancies.[36] The alternative stem cell source to an unrelated bone marrow donor for allogeneic HSCT is stored umbilical cord blood.[31,36,37] The major advantages of umbilical cord stem cells are that they can be obtained in less than 4 weeks and that even cord blood units mismatched in up to 2 of 6 HLA may be used for allogeneic HSCT. This degree of HLA mismatching is acceptable, because the overwhelming percentage of T cells within the cord blood unit are naïve, and the incidence of acute GVHD is comparable to or less than that associated with an HLA-matched unrelated bone marrow donor. The major disadvantage of umbilical cord blood units is they are associated with a relatively high degree of graft rejection, especially in adults.[31,37] Engraftment and treatment-related mortality appear to be directly related to umbilical cord cell dose. It may be that the limitation of cell dose can be overcome by the use of more than one cord blood unit; this approach currently is under clinical investigation.[38] The other significant disadvantage is that once the cord blood unit is used, there is no way to go back and get additional cells for a donor lymphocyte infusion or in the event of graft failure.

The other alternative source of allogeneic hematopoietic stem cells is to identify among the patient's first-degree relatives individuals who share at least one haplotype (haplo-identical) with the potential recipient.[32] The major advantage with the use of a partially HLA-matched family member is that the donor is readily available for almost all patients. The major disadvantages are an increased risk of graft rejection, GVHD, and severe immune dysregulation, which rises with higher degrees of HLA-mismatching. Haplo-identical allogeneic HSCT has been limited primarily to use in children.[32,39]

Once an allogeneic stem cell source has been identified, patients are put on regimens with the intent of "conditioning" or "preparing" them for the infusion of hematopoietic stem cells. Most conditioning or preparative regimens use a combination of radiation and chemotherapy.[1,3] They also may contain radioimmunoconjugates and/or monoclonal antibodies that target T cells (e.g., alemtuzumab).[40] The choice of a specific conditioning regimen depends on the disease that is being treated. The earliest conditioning regimens were designed to permit the administration of maximum doses of chemotherapy and/or radiation (i.e. "high-dose" regimens) for the eradication of disease and to be adequately immunosuppressive to prevent graft rejection. The most commonly used chemotherapy agents in these regimens are alkylating agents (e.g., cyclophosphamide and/or etoposide) with or without total lymphoid or total body irradiation at doses varying between 800 to 1440 cGy. The doses of chemotherapy and radiation used in these regimens are referred to as *myeloablative*, because they result in a degree of myelosuppression and immunosuppression that is nearly universally fatal without the infusion of hematopoietic stem cells as a rescue product.[41]

Allogeneic HSCT with myeloablative conditioning regimens has been performed successfully in patients older than 60 years of age; however, survival after these transplants declines with increasing age, limiting the application of allogeneic transplantation to a minority of patients who potentially could benefit from this procedure. However, the demonstration that an immune-mediated graft-versus-leukemia effect plays a central role in the therapeutic efficacy of allogeneic HSCT led to the hypothesis that myeloablative conditioning regimens were not essential for tumor eradication.[42] This idea subsequently led investigators to develop less intense conditioning regimens, which were adequately immunosuppressive to permit the

engraftment of donor hematopoietic stem cells, decrease toxicities associated with myeloablative conditioning regimens, and serve as a platform for the administration of donor T cells as adoptive cellular therapy. A variety of nonmyeloablative and reduced-intensity conditioning regimens has been reported.[43–46] These regimens are associated with decreased early post-transplant morbidity and mortality; however, the important clinical question is whether this reduction in toxicity comes at the cost of a loss of antitumor activity within the conditioning regimen.

Syngeneic Hematopoietic Stem Cell Transplantation

Syngeneic HSCT utilizes stem cells from an identical twin.[47,48] Because the hematopoietic stem cells are genetically identical with the recipient, the major advantage of a syngeneic HSCT is that it is not associated with GVHD or graft rejection, resulting in a relatively low risk of treatment-related morbidity and mortality. Another significant advantage of syngeneic HSCT, which is shared with allogeneic HSCT, is there is no risk of contamination by malignant cells. The major disadvantage is that syngeneic HSCT does not provide the graft-versus-leukemia effect that is associated with allogeneic HSCT. The greatest disadvantage is that far fewer than 1% of patients have an identical twin, and consequently, this is not an option for most patients. However, when an identical twin is available, syngeneic HSCT is considered the preferred type of HSCT in almost all clinical situations.

Autologous Hematopoietic Stem Cell Transplantation

Autologous HSCT employs stem cells from the patient him- or herself. The principle behind autologous HSCT, as well syngeneic HSCT, is that certain malignancies, such as leukemias, have a steep dose-response curve to chemotherapy and, to a relative degree, radiation.[49–51] The major limitation to the administration of higher doses of chemotherapy or radiation is the myelosuppressive effects of these therapies. Autologous, allogeneic, and syngeneic hematopoietic stem cells permit the administration of high-dose chemotherapy and/or radiation by restoring hematopoiesis. The major advantages of autologous HSCT compared with allogeneic HSCT are that (1) the patient can serve as his or her own donor and (2) it may be performed in older patients with significantly decreased mortality, due to the absence of GVHD as a major complication. However, autologous HSCT can be associated with more morbidity than conventional doses of radiation and chemotherapy. A potential disadvantage of autologous HSCT is the possible reinfusion of viable tumor cells.[52] Numerous methods, including in vitro treatment with chemotherapeutic agents or monoclonal antibodies plus complement, have been developed to remove contaminating tumor cells from the graft, a process often referred to as *purging*, or to concentrate hematopoietic stem cells, a process referred to as *positive selection*.[53–56] Retrospective analyses have suggested that purging leads to a reduced relapse rate in patients with acute myelogenous leukemia and B-cell non-Hodgkin's lymphomas.[57,58]

Hematopoietic Stem Cell Acquisition and Processing

Hematopoietic stem cells may be obtained from the bone marrow, the peripheral blood, and umbilical cord blood. Hematopoietic stem cells from bone marrow are used in both autologous and allogeneic HSCT, although less frequently than in the past. Peripheral blood hematopoietic stem cells are used in approximately 90% of autologous HSCT and in approximately 70% of allogeneic HSCT.[59] The greater use of peripheral blood hematopoietic stem cells is related to their relative ease of attainment and moderate improvement in the rate of hematopoietic recovery after infusion as compared to hematopoietic stem cells derived from bone marrow. In steady-state, the concentration of hematopoietic stem cells and myeloid progenitor cells is quite low, and prior to collection of peripheral blood hematopoietic stem cells by apheresis, attempts are made to increase or "mobilize" the number of circulating hematopoietic stem cells by various techniques.[60] Hematopoietic stem cells may be mobilized into the peripheral blood following administration of myeloid hematopoietic growth factors (e.g., granulocyte colony-stimulating factor), during the recovery phase from exposure to chemotherapy, or by using both chemotherapy and growth factors.[61–64] Collection of peripheral blood hematopoietic stem cells from a normal donor for allogeneic HSCT is performed following mobilization with myeloid hematopoietic growth factors only. In general, at least 1×10^6 CD34+ cells/kg of recipient weight are collected from the peripheral blood by apheresis. The cells are then processed with dimethylsulfoxide (DMSO) with or without hydroxyethylstarch and then stored in liquid nitrogen until needed for transplantation.[65]

Methods for collecting or "harvesting" hematopoietic stem cells from bone marrow are modifications of the technique initially reported by Thomas and Storb.[66] The bone marrow harvest usually is performed under general anesthesia and generally is well tolerated.[67,68] Bone marrow hematopoietic stem cells usually are harvested by repeated aspirations from the posterior iliac crest until an adequate number of cells have been removed. If sufficient cells cannot be obtained from the posterior iliac crest, marrow also can be harvested from the anterior iliac crest and sternum. The minimal number of nucleated marrow cells required for long-term repopulation in humans is not precisely known. In practice, the number of nucleated marrow cells harvested is usually $1 - 3 \times 10^8$/kg of recipient weight, depending on the diagnosis (i.e., higher for aplastic anemia), the type and intensity of pretransplant conditioning, and whether the marrow graft will be modified in vitro. Marrow sometimes is treated in vitro to remove unwanted cells before it is returned to the patient. In allogeneic HSCT with major ABO incompatibility between donor and recipient, it is necessary to remove the mature erythrocytes from the graft to avoid a hemolytic transfusion reaction.[69] After collection and processing, hematopoietic stem cells from bone marrow may be directly infused or cryopreserved in an identical manner as hematopoietic stem cells from the peripheral blood.

Hematopoietic stem cells from cord blood are collected immediately after delivery. A minimally acceptable cord blood unit dose is 1.7×10^5 CD34+ cells per the patient's weight in kilograms to ensure engraftment in the allogeneic HSCT setting.[70] This criterion is a significant problem for adult patients, where the application of cord blood transplantation has been associated with delayed hematopoietic recovery, especially platelets, graft failure, and a relatively high treatment-related mortality in comparison to other sources of allogeneic hematopoietic stem cells.

MALIGNANT DISEASES TREATED WITH HEMATOPOIETIC STEM CELL TRANSPLANTATION

Clinical evidence exists that syngeneic, autologous, and allogeneic HSCT all provide benefit—defined as response, freedom of progression, or overall survival—for most hematologic malignancies and for a minority of solid malignancies (Fig. 32-2).[3] However, the beneficial effects of these various forms of HSCT vary greatly with each type of malignancy. Data indicate that due to their relative responsiveness to cytotoxic therapy, myeloablative conditioning regimens with syngeneic, autologous, or allogeneic HSCT result in higher response rates than cytotoxic or conventional agents for almost all hematologic malignancies. However, the durability of these responses and their effect on survival varies from disease to disease. Similarly, there is evidence of a clinical graft-versus-leukemia effect in almost every hematologic disease; however, the potency and clinical relevance are highly variable. Interpretation of the results of trials of HSCT always is complicated by issues of patient selection. This can lead to either

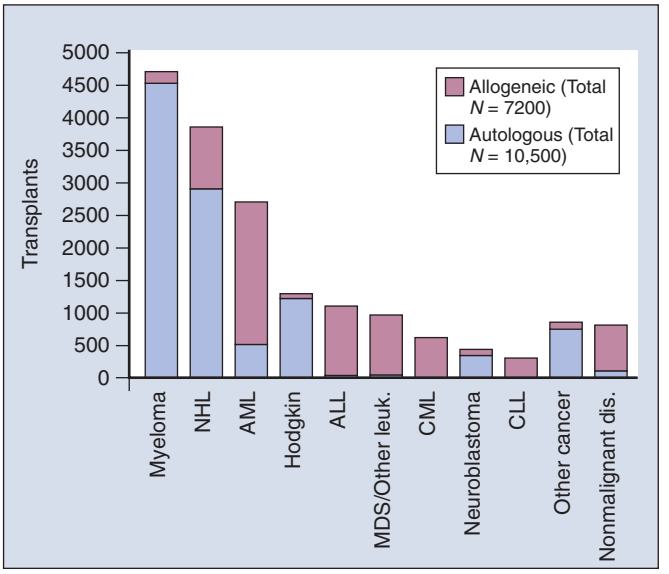

Figure 32-2 • Indications for blood and marrow transplantation in North America in 2003. ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; NHL, non-Hodgkin's lymphoma; MDS, myelodysplastic syndrome. (Data from the Center for International Blood and Marrow Transplant Research, Milwaukee, WI.)

underestimating the efficacy of HSCT if it is used after exhausting all other available therapies or overestimating its efficacy if only the patients with favorable prognostic characteristics are selected. The specific indications for HSCT are covered in the chapters for each respective disease. This section briefly addresses the outcomes for malignancies with different forms of HSCT.

Acute Myelogenous Leukemia

Acute myelogenous leukemia (AML) and acute lymphocytic leukemia (ALL) were the first malignancies in which all forms of HSCT were demonstrated to be effective.[22,24,71] Initial studies of myeloablative allogeneic HSCT demonstrated that this treatment was capable of resulting in long-term survival for a minority of patients with refractory and relapsed AML.[71] Unfortunately, the cure rate in these latter cases is only about 10%. Long-term survival and an apparent cure rate of 20% to 40% have been achieved in patients treated in second or subsequent complete remission, and cure rates of 40% to 70% have been reported in patients given transplants in their first complete remission.[72–75] Randomized controlled trials comparing autologous and allogeneic HSCT to conventional chemotherapy in patients with AML in first complete remission have demonstrated improved leukemia-free survival with both forms of HSCT; however, there has been no significant improvement in overall survival.[76–79] The one exception has been in pediatric AML, where allogeneic HSCT has been demonstrated to improve both leukemia-free and overall survival for patients transplanted in first complete remission.[80] The lack of improvement in overall survival in adults is attributed to high rates of treatment-related mortality with allogeneic HSCT, high relapse rates with autologous HSCT, and the fact that patients could successfully undergo HSCT at first sign of relapse.[81] Because a significant proportion of patients can be cured with standard chemotherapy regimens without HSCT and because cure rates of 20% to 30% have been reported for HSCT in early first relapse, withholding HSCT until the first sign of treatment failure is an alternative treatment strategy.[82] Reduced-intensity and nonmyeloablative conditioning regimens may increase the applicability of allogeneic HSCT for older patients. The Acute Leukemia Working Party and European Group of Blood and Marrow Transplant compared the results of reduced-intensity conditioning with myeloablative regimens in patients with AML over 50 years of age undergoing allogeneic HSCT from HLA-matched siblings.[83] Transplant-related mortality was significantly decreased, but the relapse incidence was significantly higher after reduced-intensity conditioning. Leukemia-free survival was not statistically different between the two groups.

Myelodysplastic Syndrome

The only known curative treatment for myelodysplastic syndrome (MDS) is allogeneic HSCT. In this setting, long-term disease-free survival of greater than 40% has been obtained.[84] The best results have been obtained in relatively younger patients, who are earlier in their disease course and have not received any prior therapy. To identify factors influencing transplantation outcome for MDS, the International Bone Marrow Transplantation Registry (IBMTR) studied 452 recipients of HLA-identical sibling transplants for MDS.[85] Sixty percent of patients had refractory anemia with excess blasts ($N = 136$) or with excess blasts in transformation ($N = 136$). Three-year transplantation-related mortality, relapse, disease-free survival, and overall survival rates were 37%, 23%, 40%, and 42%, respectively. Multivariate analyses showed that young age and platelet counts higher than 100 at transplantation were associated with lower transplant-related mortality and higher disease-free and overall survival rates. Because the optimal timing for bone marrow transplantation for MDS is unknown, the IBMTR constructed a Markov model to examine three transplantation strategies for newly diagnosed MDS: transplantation at diagnosis; transplantation at leukemic progression; and transplantation at an interval from diagnosis but prior to leukemic progression.[86] Analyses using individual patient risk-assessment data from transplantation and nontransplantation registries were performed for all four IPSS risk groups with adjustments for quality of life. For low and intermediate-1 IPSS groups, delayed transplantation maximized overall survival. Transplantation prior to leukemic transformation was associated with a greater number of life years than transplantation at the time of leukemic progression. In a cohort of patients under the age of 40 years, an even more marked survival advantage for delayed transplantation was noted. For intermediate-2 and high IPSS groups, transplantation at diagnosis maximized overall survival. There is evidence that reduced-intensity allogeneic HSCT may benefit older patients with MDS.[87,88] The use of autologous HSCT for MDS remains investigational.[89]

Acute Lymphocytic Leukemia

The results of standard therapy in childhood acute lymphocytic leukemia (ALL) are sufficiently good with intensive chemotherapy regimens that HSCT probably should be performed as part of primary therapy only in special situations, such as in patients with childhood ALL who are Philadelphia (Ph) chromosome-positive, in whom the cure rate with standard therapy is very low.[90] However, the overall prognosis for both pediatric and adult patients with relapsed ALL is relatively poor, and the general treatment strategy is to obtain a second complete remission and then proceed to an allogeneic HSCT.[91,92]

In light of this significantly higher relapse rate with conventional therapy, there has been strong interest in the use of both allogeneic and autologous stem cell transplantation as consolidation of adult patients with ALL who are in first complete remission.[93–95] The French protocol LALA 87 was designed to compare chemotherapy alone versus autologous or allogeneic HSCT as postinduction (i.e., consolidation) strategies in adult ALL.[93] This trial demonstrated a significant superiority of allogeneic bone marrow transplantation in high-risk patients with ALL. A trend also was detected in favor of autologous BMT over chemotherapy in those same patients. The BGMT Group performed a prospective, randomized trial in adults to compare disease-free survival after allogeneic or autologous bone

marrow transplantation in a total of 135 previously untreated adult patients with ALL.[94] The 3-year post–complete remission probability of disease-free survival was significantly higher in the allogeneic stem cell group. The authors concluded that early allogeneic transplantation was an effective consolidation treatment for adult patients with ALL in first complete remission. The French LALA-94 trial determined the benefits of a risk-adapted postremission strategy hematopoietic stem-cell transplantation in 922 adult patients with ALL.[95] The study demonstrated that allogeneic HSCT improved disease-free survival in high-risk ALL in the first complete remission, whereas autologous HSCT did not confer a significant benefit over chemotherapy for high-risk ALL.

Multiple Myeloma

Both allogeneic and autologous HSCT have been performed for multiple myeloma, because standard chemotherapy regimens rarely, if ever, cure the disease. The efficacy of high-dose chemotherapy in multiple myeloma has led to inclusion of autologous HSCT as part of its initial therapy.[96,97] Its unique biologic characteristics have led to clinical data demonstrating that the inclusion of more than one cycle of high-dose chemotherapy with autologous HSCT may improve upon the results of a single transplant.[98] Although clear evidence exists of a graft-versus-leukemia effect against multiple myeloma, a tumor-specific antigen has not been identified. The use of myeloablative allogeneic HSCT is controversial, because it has been associated with a high mortality rate.[99] Results of allogeneic HSCT in multiple myeloma have improved with the use of nonmyeloablative conditioning regimens, and there is evidence to suggest that this approach can result in an improvement in progression-free and overall survival.[100]

Chronic Myelogenous Leukemia and Other Myeloproliferative Disorders

Chronic myelogenous leukemia (CML) is highly susceptible to the graft-versus-leukemia effect, as evidenced by the long-term, leukemia-free survival rates exceeding 70% for patients who were transplanted in early chronic phase and the response of CML to donor lymphocyte infusion.[101–104] Allogeneic HSCT from an HLA-matched sibling or unrelated donor previously was the treatment of choice for patients of an appropriate age with chronic-phase CML.[101–103] However, due to the tremendous clinical success of imatinib (STI-571, Gleevec), the emerging predominant strategy is to use allogeneic HSCT in patients with more advanced CML, and it is reserved for patients who have failed or progressed on imatinib.[105] Autologous HSCT has limited efficacy in CML due to the relative lack of sensitivity of CML to cytotoxic therapy and the difficulty of obtaining a relatively tumor-free autograft.[106]

Myeloproliferative disorders usually are chronic in nature but can progress to a "spent" phase and develop myeloid metaplasia, which is characterized by bone marrow fibrosis and a generally poor prognosis with transformation into acute leukemia and a median survival of less than 3 years.[107,108] Conventional treatment options at this state of the disease are limited, and the accepted standard of care for myeloid metaplasia/myelofibrosis is allogeneic stem cell transplantation with a myeloablative conditioning regimen.[109,110] There have been anecdotal reports of the use of nonmyeloablative allogeneic HSCT for myelofibrosis and other myeloproliferative disorders.[111]

Chronic Lymphocytic Leukemia

Both allogeneic and autologous HSCT have been used for the treatment of chronic lymphocytic leukemia (CLL).[112–114] However, the application of allogeneic and autologous HSCT for CLL has been limited by treatment-related mortality and relapse for each type of HSCT. Considerable interest and research has been devoted to the use of nonmyeloablative and reduced-intensity conditioning regimens prior to allogeneic HSCT for CLL in hopes of reducing the treatment-related mortality.[115–117] The Chronic Leukemia Working Party of the European Blood and Marrow Transplant Group reported on 77 patients with CLL who underwent a nonmyeloablative allogeneic HSCT.[115] Treatment-related mortality after 12 months was 18%. At a median follow-up of 18 months, the 2-year probability of relapse was 31%. Event-free and overall survival rates at 24 months were 56% and 72%, respectively. The Cooperative German Transplant Study Group reported on 30 patients with advanced B-cell CLL who underwent reduced-intensity allogeneic stem cell transplantation from either related (N = 15) or unrelated (N = 15) donors.[116] The probabilities of overall survival, progression-free survival, and treatment-related mortality at 2 years were 72%, 67%, and 15%, respectively. These data indicate that allogeneic HSCT after reduced-intensity conditioning can result in relatively high, durable, complete response rates (>50%) with acceptable treatment-related mortality rates.

Non-Hodgkin's Lymphoma

Allogeneic, syngeneic, and autologous HSCT have been reported to yield long-term disease-free survival and an apparent cure for patients with intermediate and high-grade non-Hodgkin's lymphomas (NHL).[118–120] Due to its relative sensitivity to chemotherapy, there is substantial evidence that autologous HSCT is efficacious for patients with primary refractory or chemotherapy-sensitive recurrent NHL of specific histologies including "intermediate-grade" (e.g., disease-diffuse, large B-cell) NHL.[121] It is now apparent that patients who fail to achieve an initial complete remission, but who do not have other adverse prognostic factors such as poor performance status or bulky disease, also can achieve long-term disease-free survival.[122] Because of the superior results achieved in patients treated earlier in the course of the disease, a number of investigators have incorporated high-dose therapy and autologous HSCT into the primary treatment of patients with intermediate and high-grade non-Hodgkin's lymphoma.[123,124]

Autologous HSCT also has been used to treat patients with indolent ("low-grade") NHL (e.g., follicular center cell) with either purged bone marrow or peripheral blood stem cells, resulting in disease-free survival rates as high as 60%.[125,126] However, the late relapses seen in this illness and long overall survival observed with conventional therapy make very long follow-up necessary to document the efficacy of this approach.

The demonstration of a potent graft-versus-leukemia effect against NHL is less clear, and the efficacy of donor lymphocyte infusion in lymphoma is anecdotal at best.[126–128] Consequently, the specific role of allogeneic HSCT has not been defined. However, there are data that myeloablative allogeneic HSCT can result in long-term survival for patients with recurrent or refractory NHL,[120,129] and evidence exists that nonmyeloablative allogeneic HSCT may provide benefit for patients with recurrent follicular non-Hodgkin's lymphoma. Some evidence, however, indicates that this approach requires that the disease remains chemotherapy-sesitive.[130]

Hodgkin's Disease

High-dose therapy with autologous or allogeneic HSCT has been widely used in patients with recurrent Hodgkin's disease (HD; also known as Hodgkin's lymphoma).[131–133] As in NHL, patients with HD whose disease fails to respond to front-line therapy can derive benefit from high-dose therapy and autologous HSCT.[134] Allogeneic HSCT has had a limited role in the treatment of HD due to the efficacy of autologous HSCT, the treatment-related toxicities associated with myeloablative allogeneic HSCT, and lack of evidence of a graft-versus-leukemia effect against HD. However, recent data indicate that reduced-intensity allogeneic HSCT may benefit patients with recurrent HD, and a graft-versus-leukemia effect against HD may exist.[135]

Soft Tissue Sarcomas and Neuroblastoma

High-dose therapy and autologous HSCT have been used as either consolidation of primary therapy or treatment of metastatic or recurrent soft tissue sarcomas, such as Ewing's sarcoma, rhabdomyosarcoma, and osteosarcoma in children.[136,137] Burdach and colleagues reported a 45% relapse-free survival for patients with poor-risk and recurrent Ewing's sarcoma who received high-dose therapy and autologous HSCT, as compared with 2% for a historical control group.[136] The European BMT Solid Tumor Registry reported the results from 21 European transplant centers on 50 patients with Ewing's sarcoma in first or second complete remission consolidated with high-dose chemotherapy and autologous HSCT.[137] Thirty-two patients with high-risk or metastatic disease in first complete remission achieved an actuarial event-free survival of 21% at 5 years. Results of prospective studies of high-dose therapy and autologous HSCT in soft tissue sarcomas, primarily in children, suggest a possible improvement in remission duration and possibly on overall survival.[138,139] Autologous HSCT remains investigational in adults with sarcomas.

Autologous HSCT has been found to be beneficial for both newly diagnosed and recurrent neuroblastoma.[140–143] The Children's Cancer Group assessed whether high-dose therapy and autologous bone marrow transplantation improved event-free survival as compared with chemotherapy alone.[140] All patients were treated with the same initial regimen of chemotherapy, and those without disease progression were then randomly assigned to receive continued treatment with high-dose therapy and purged autologous bone marrow transplantation or to receive three cycles of intensive chemotherapy alone. The mean event-free survival rate was significantly better among the patients who were assigned to undergo transplantation.

Germ Cell Tumors

In patients with germ cell tumors for whom platinum-based chemotherapy regimens fail to effect a cure, the use of high-dose chemotherapy and autologous BMT has resulted in prolonged disease-free survival, including patients with refractory disease.[144,145] Evidence exists suggesting that tandem transplant may result in improved results; however, no direct comparison of single versus tandem transplants has been performed.[146]

Other Solid Tumors

Several nonrandomized trials and retrospective analyses had suggested that high-dose chemotherapy and autologous stem cell transplantation were beneficial in regard to prolongation of survival in stage II/III breast cancer.[147,148] Subsequently, several randomized trials addressed the role of high-dose therapy and autologous stem cell transplantation in patients with stage II/III breast cancer.[149–153] Most of these trials found no evidence of a survival advantage for patients randomized to receive high-dose therapy, although some of the trials suggested an improvement in event-free survival in the high-dose arm. Evidence also is lacking that high-dose chemotherapy and autologous HSCT improve survival in metastatic breast cancer.[154]

There has been considerable interest in investigating the presence of a "graft-versus-tumor" effect in a variety of solid tumors, including renal cell carcinoma and breast cancer.[155–157] Childs and colleagues[155] reported on a series of 19 patients with metastatic renal cell carcinoma who underwent nonmyeloablative allogeneic stem cell transplantation. Nine patients had responsive disease (47%), of which three were complete responses.

COMPLICATIONS AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION

In addition to the acute toxicities associated with prolonged cytopenia, other organ toxicities can be associated with transplantation. A simple index, based on pretransplant comorbidities, has been developed that reliably predicts nonrelapse mortality and survival.[158] This comorbidity index is useful for patient counseling prior to HSCT. The late toxicities always must be kept in mind when choosing therapies for patients.[159]

Graft Rejection

Graft rejection occurs when immunologically competent cells of host origin destroy the transplanted cells of donor origin.[160] This complication occurs more commonly in patients who receive transplants from alternative or HLA-mismatched donors, in T cell-depleted transplants, and in patients with aplastic anemia who receive a non–total body irradiation (TBI)-containing regimen. Graft rejection is less likely to occur in nontransfused patients with aplastic anemia.

Cardiac Toxicity

Most transplant centers screen potential patients for underlying cardiac abnormalities that would place them at potential increased risk during the procedure.[161] Despite this screening, however, a small number of patients experience cardiotoxicity, either acutely during the transplant or at a later time, manifested as a cardiac arrhythmia, congestive heart failure, or cardiac ischemia due to the large volumes of fluids administered during the procedure or from the added physiologic stress.[162] Complications associated with a pericardial effusion can be seen in some patients during or after transplant and are more common in patients with disease near that area and those receiving radiation therapy in that field. An idiosyncratic cardiomyopathy associated with the administration of high doses of cyclophosphamide can be demonstrated in a small number of patients. Viral cardiomyopathies also can be seen as a late transplant complication.

Engraftment Syndrome

Engraftment syndrome occurs during neutrophil recovery following both autologous and allogeneic HSCT.[163] It consists of a constellation of symptoms and signs that may include fever, erythrodermatous skin rash, and noncardiogenic pulmonary edema, and, in its most extreme forms, acute renal failure and diffuse alveolar hemorrhage. These clinical findings reflect the manifestations of increased capillary permeability. Making a distinction from hyper-acute GVHD in the allogeneic setting has been difficult, however. Corticosteroid therapy often is dramatically effective for engraftment syndrome, particularly for the treatment of the pulmonary manifestations.

Pulmonary Toxicities

Pulmonary toxicities are common during and after transplantation. Patients who receive certain chemotherapeutic agents, such as 1,3-bis (2- chloroethyl)-1-nitrosourea (BCNU; carmustine) have an increased incidence of chemotherapy-induced lung tissue damage after transplant, which usually can be treated successfully with the prompt initiation of corticosteroid therapy.[164] In addition to these complications, patients who are undergoing allogeneic transplant are at increased risk for pneumonitis caused by cytomegalovirus, fungal infections due to the patient's increased immunosuppression, and adult respiratory distress syndrome or interstitial pneumonia of unknown etiology. Chronic GVHD also can manifest as bronchiolitis obliterans in the lung.[165]

Liver Toxicity

The most common liver complication associated with transplantation is veno-occlusive disease (VOD [sinusoidal obstruction syndrome of the liver]).[166,167] Symptoms associated with VOD include jaundice, tender hepatomegaly, ascites, and weight gain. Progressive hepatic failure and multiorgan system failure can develop in the most severe cases. Predisposing factors appear to be previous hepatic injury, use of estrogens, and high-dose intensity conditioning.[167]

Table 32-2 Graft-versus-Host Disease Categories

Category	Time of Manifestation after HSCT or DLI	Presence of GVHD Features	
		Acute	Chronic
ACUTE GVHD			
Classic acute GVHD	≤100 d	Yes	No
Persistent, recurrent, or late-onset acute GVHD	>100 d	Yes	No
CHRONIC GVHD			
Classic chronic	No time limit	No	Yes
Overlap syndrome	No time limit	Yes	Yes

DLI, donor lymphocyte infusion; GVHD, graft-versus-host disease; HSCT, hematopoietic stem cell transplantation.

Renal Toxicity

Acute renal failure requiring dialysis during the transplant occurs infrequently.[168] However, patients with underlying renal dysfunction are at risk for this complication. The judicious use of nephrotoxic agents can decrease its incidence. The need for dialysis typically is a short-term complication, because the patient's underlying problem (e.g., a septic event) either improves with time or becomes life-threatening, sometimes leading to death. An idiopathic or cyclosporine-induced hemolytic-uremic syndrome can be a serious complication after allogeneic stem cell transplantation, posing a high mortality risk or resulting in end-stage renal disease. Recently, nephrotic syndrome and membranous nephropathy have been described in long-term survivors; these complications seem to be associated more commonly with chronic GVHD and nonmyeloablative conditioning.[169]

Graft-versus-Host Disease

In the setting of allogeneic HSCT, complications associated with acute and chronic GVHD also are of concern. Previously, acute and chronic GVHD were distinguished chronologically by whether GVHD occurred before or after the fist 100 days after transplant, respectively. However, acute or chronic GVHD is a clinical diagnosis, based on the characteristic clinical manifestations and context, and neither is specifically defined by the "day 100" dichotomy any longer (Table 32-2). In the evaluation of both acute and chronic GVHD, which usually includes a tissue biopsy, it is important to exclude other potential diagnoses such as infection, drug reaction, or second malignancies, which can mimic GVHD. Acute GVHD is manifested by symptoms in several organ systems, including the skin, gastrointestinal tract, and liver (Table 32-3).[170] This complication typically occurs within the first 100 days after transplantation. The skin manifestations range from a maculopapular rash up to generalized erythroderma or desquamation. The severity of liver GVHD is scored on the basis of the bilirubin and the gastrointestinal severity on the quantity of diarrhea per day.

Patients who receive transplants from unrelated donors are at much higher risk for GVHD, the incidence and severity of which rise with the age of the patient. Other risk factors for the development of GVHD include a female donor (particularly a multiparous donor), more advanced age, and cytomegalovirus seropositivity of the donor or patient. Patients receive prophylaxis for GVHD prevention most commonly with cyclosporine, with or without methotrexate and corticosteroids.[171] Treatment for acute GVHD includes high-dose corticosteroids, antithymocyte globulin, or various monoclonal antibodies.[172–174]

Chronic GVHD occurs most commonly between 100 days and 2 years from the transplant and has polymorphic features similar to a number of autoimmune diseases. It is most likely to develop in older patients who also had acute GVHD or received peripheral blood rather than bone marrow grafts.[175] Symptoms associated with chronic GVHD include sicca syndrome, rashes or skin thickening, diarrhea, wasting syndrome, bronchiolitis obliterans, or liver function abnormalities.[176–178] Patients also are at greatly increased risk for infectious complications, due to either the GVHD itself or the treatment administered. Adverse prognostic factors include thrombocytopenia, a progressive clinical presentation, extensive skin involvement, and an elevated bilirubin. Treatment for the chronic form of the disease includes corticosteroids, cyclosporine, thalidomide, ultraviolet light treatments, or other immunosuppressive agents.[179,180]

Infertility

Many of the preparative regimens used for transplant are associated with a high incidence of permanent sterility. The use of TBI almost

Table 32-3 Classification of Patients with Acute Graft-versus-Host Disease

CLINICAL STAGING

Stage	Skin	Liver	Gut
+	Rash <25% BSA	Total bilirubin 2–3 mg/dL	Diarrhea 500–1000 mL/day
++	Rash 25%–50% BSA	Total bilirubin 3–6 mg/dL	Diarrhea 1000–1500 mL/day
+++	Generalized erythroderma	Total bilirubin 6–15 mg/dL	Diarrhea >1500 mL/day
++++	Desquamation and bullae	Total bilirubin >15 mg/dL	Pain, with or without ileus

CLINICAL GRADING

	Stage			
Grade	Skin	Liver	Gut	PS
0 (none)	0	0	0	0
I	+ to ++	0	0	0
II	+ to +++	+	+	+
III	++ to +++	++ to +++	++ to +++	++
IV	++ to ++++	++ to ++++	++ to ++++	+++

BSA, body surface area.

always is associated with sterility. However, successful pregnancies have occurred after the use of non–TBI-containing regimens.[181] This is most likely to be the case in patients who were less heavily retreated before the transplant and were under the age of 25 years at the time of transplant.

Secondary Malignancies

With the increasing number of long-term survivors following HSCT, complications that develop years later are beginning to be recognized. One complication of the chemo- plus radiotherapy that is used to treat a malignancy is the development of a secondary malignancy.[182,183] Several reports have now been published of the development of secondary AML or MDS after autologous transplantation. Some studies have suggested that the use of TBI may increase the risk of these complications.[183] It is unclear to what degree the transplant itself contributed to the development of the AML/MDS, because all patients received chemotherapy or radiotherapy, or both, before the transplant and, in some cases, after the transplant.

CONCLUSION

There has been tremendous success since the 1980s in the increased safety of hematopoietic stem cell transplantation and in the expanding application of this treatment to more patient populations. Areas currently under development that may further improve the use and efficacy of transplantation include continuous improvements in supportive care for transplant patients, broadened use of alternative donors, more refined graft manipulations, and further improvements in the nonmyeloablative transplantation techniques and GVHD prevention. Future progress depends on our ability to identify safer and better-targeted antitumor therapies that can be incorporated in the transplantation regimens without attenuating the graft-versus-tumor responses. This remains a challenge for future clinical research.

33 Gene Therapy in Oncology

James E. Talmadge and Kenneth H. Cowan

SUMMARY OF KEY POINTS

Recent Major Improvements in Gene Therapy

- Vector development
- Vector targeting
- Regulated transgene expression
- Clinical development strategies

Ideal Vector Attributes

- Can be targeted either physically or via promoter expression, and is nontoxic, noninflammatory, and nonimmunogenic
- Should have the potential to incorporate a large transgene and result in high levels of both transduction and transgene expression
- Duration of transgene expression and/or genomic integration ought to be regulatable

Current Concerns Regarding Gene Therapy

- Gene therapy has been implicated in the death of at least one patient, resulting in the temporary suspension of clinical trials (2000) with adenovirus (Adv) vectors in the United States. The first gene therapeutic to be approved (China, 2003) was an Adv vector with a p53 transgene used in combination with chemotherapy for the treatment of head and neck squamous cell carcinoma (HNSCC). A second, conditionally replicative Adv vector, H101 (ONYX-015), was approved in China in December of 2005.
- Leukemic transformation by insertional mutagenesis occurred in several patients treated with retroviral vectors. However, because retroviral vectors have been successful in the treatment of patients with severe combined immune deficiency (SCID-X1) for whom no other therapy is available, their use continues to be approved on a case by case basis.

Future Directions of Gene Therapy

- The choice of disease, clinical implementation, and vector are critically important to the future development of successful gene therapy.
- Because of deficiencies in gene delivery and targeting, as well as expression levels, it is critical to pair protocols with specific vector attributes.

INTRODUCTION

The development of nucleic acid technologies has provided insight into the molecular basis of neoplasia. The resultant detection of phenotypic and genotypic alterations in neoplastic diseases has increased optimism that molecular intervention might lead to improved clinical care for patients with cancer. One such approach is gene therapy, which is the introduction of a nucleic acid sequence into a target cell. The objectives are the delivery of a transgene to an adequate number of cells and at an effective level of expression sufficient to result in therapeutic outcomes. Both criteria require the use of a vector and potentially, a formulation such that these objectives can be met. Although this approach is both simple and attractive, thus far gene therapy has promised much and delivered little because of the technical hurdles. Several preclinical studies and clinical trials have been undertaken to improve gene transfer systems. In 2003 the first gene therapeutic was approved in China. This was an adenovirus (Adv) serotype 5 vector engineered to express TP53 (Gendicine) for treatment of patients with head and neck squamous cell carcinoma (HNSCC).[1] A second gene therapy product, H101 (ONYX-015), an Adv vector modified to replicate in and kill cancer cells with TP53 mutations, was approved in December 2005.[2] Regardless of these approvals, the primary challenges in gene therapy remain improvements in the targeting of our existing vectors and increasing gene transduction efficiency. Overcoming these obstacles will facilitate the development of targetable vectors and, given the systemic nature of most malignancies, help in the development of vectors that can be administered intravenously (IV). This chapter focuses on strategies to improve efficacy, as well as ongoing gene therapeutic strategies. We also will examine and discuss recent advances and indicate areas that require further development for clinical gene therapy to become a widely used treatment modality.

VECTORS

Viral Gene Transfer Vectors

Viral gene delivery has developed from a virus' innate ability to infect cells, which offers many intrinsic advantages:[3,4]

- Specific cell-binding and cell-entry properties
- Efficient targeting of the transgene to the nucleus of the cell
- Ability to avoid intracellular degradation

Most viral vectors are based on the principle that an intact wild-type (wt) virus can be modified for safe and effective gene transfer. In general, the more severely attenuated the viral vector is from the wt, the safer the virus is for use in gene therapy protocols, yet the poorer the yield obtained after propagation. Typically, two (or preferably, three) noncontiguous partial or complete gene sequences are deleted to reduce the potential for homologous recombination. Specific genes critical to viral replication are then modified or deleted, resulting in a recombinant viral vector that is "replication defective."

The transgene to be delivered by the virus is then inserted into the viral genome at the site created by the removal of the viral replication genes. The transgene must be a smaller size to fit within the available space, which is a critical characteristic because the transgene cannot be packaged into an infectious particle if the new viral genome is too large. Many of the viruses that are used as vectors lack genes for replication in normal cells; therefore, the recombinant virus and its transgene must be grown in a packaging cell line that provides the complementary genes required for viral replication. The recombinant viral particles are purified as live infectious viruses and are replication incompetent in the absence of the packaging cell line. Alternatively, the packaging cell line can be used to infect (transduce) cells or tissues in vitro.

Retroviridae—Retrovirus

The Retroviridae is a large family of ribonucleic acid (RNA) viruses including Moloney-murine-lentivirus-related viruses (e.g., Moloney murine leukemia virus [MMLV]) and lentiviruses (e.g., human immunodeficiency viruses 1 and 2 [HIV-1 and HIV-2]).[5] Their genomes consist of two identical positive-sense, single-stranded RNA molecules (~3.5 kb), and are encased in a capsid along with integrase and reverse transcriptase enzymes. Initially, retroviral vectors were the most widely used viral vectors, a distinction that has been replaced by Adv vectors in recent years. Retroviruses can transduce only those cells that are actively undergoing mitosis, limiting their utility with certain cell populations, especially hematopoietic stem cells. Retroviral vectors provide good gene expression and are technically easy to produce, although the titers obtained are suboptimal. In addition, the production of retroviral vectors requires careful monitoring because of the potential for helper virus contamination.

RECOMBINANT MOLONEY MURINE LEUKEMIA VIRUS. Most of the retroviral vectors that are used for gene therapy are based on MMLV. Vector replication is prevented by the deletion of the *gag, pol,* and *env* gene regions. The *gag* region encodes the capsid proteins, the *pol* region encodes reverse transcriptase and integrase, and the *env* region encodes proteins required for receptor recognition and envelope anchoring (Fig. 33-1). The genome includes long terminal repeats at either end that play a vital role in initiating deoxynucleic acid (DNA) synthesis and regulating transcription of the viral genes. The *gag, pol,* and *env* gene products are supplied by a complementary packaging cell line. When a retroviral vector plasmid is introduced into a packaging cell line, viral RNA is produced, packaged into virions, and secreted into the medium. Each resultant viral particle is able to integrate itself into the genome of the host cell, but is unable to produce additional viral particles because it lacks the *gag, pol,* and *env* genes. The transduced DNA sequences are stably integrated into the chromosomal DNA of the target cells and in this way are transferred to cellular progeny of transduced cells. Highlights of results obtained to date with retroviral vectors include the therapeutic studies in children with severe combined immune deficiency (SCID-X1), which will be discussed later in this review, as well as the gene-marking studies of Malcolm Brenner and others.[6,7] In the latter studies, it was shown that tumor cells within autologous stem cell transplant products could be responsible for tumor relapse, at least in leukemia patients.

RECOMBINANT LENTIVIRUS. The most recently discovered members of the retrovirus family are the human and simian immunodeficiency viruses (HIVs and SIVs, respectively), which belong to a subclass of retroviruses known as lentiviruses.[8,9] The development of HIV gene therapy vectors has several potential advantages based on the following characteristics:

- Transduce actively dividing and nondividing cells.
- Long-term, stable transgene expression occurs due to genetic integration.
- Inherent tropism for CD4 T cells, macrophages, and hematopoietic stem cells.

Genetic modifications, such as the introduction of vesicular stomatitis virus G protein into the lentiviral envelope, can widen the tropism of this vector. Until it has been demonstrated that HIV-based vectors are safe, however, the use of these vectors for therapies targeting diseases other than HIV could be difficult to initiate clinically.[10] The in vitro efficiency of lentiviral vectors is at an acceptable level; however, in vivo expression has not been demonstrated at an acceptable level for clinical utility. In addition, there is a need to find protocols and/or procedures that can elevate the expression levels of the HIV virus in nondividing cells.[11]

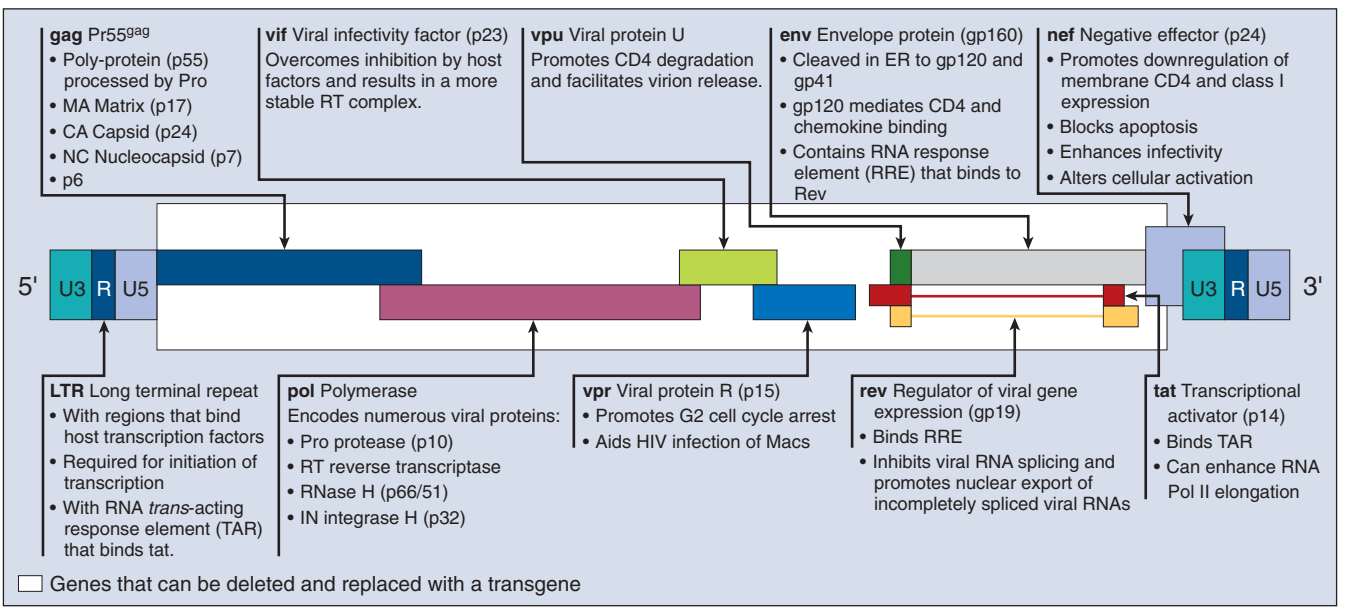

Figure 33-1 • Retrovirus proviral genome and gene product functions. Overview of the 9-kb genome of the HIV provirus and a brief summary of the functions for the 9 genes encoding 15 proteins.

The first clinical study using a lentivirus vector was undertaken in HIV-infected patients.[12] This study investigated the safety of infusing autologous T cells modified with an HIV type 1 (HIV-1)–based lentiviral vector expressing an antisense gene against the HIV envelope. Five patients with HIV infections that were resistant to antiviral therapy and had viral loads of more than 5000 copies/mL and $CD4^+$ T cells counts between 200 and 500 cells/mm^3 were treated. The primary endpoints included adverse events, viral load, $CD4^+$ counts, and the emergence of replication-competent lentivirus derived from the vector. In this phase I study, one subject was reported to have a sustained decrease in viral load. The CD4 counts remained steady or increased in the other four subjects, and sustained gene expression was observed. These preliminary studies support the safety of lentivirus vectors.

Recombinant Adenovirus

Recombinant Adv is a nonenveloped, icosahedral, double-stranded DNA virus with a capsid containing 252 capsomeres (240 hexons and 12 pentons).[13] The large genome of Adv (36 kilobases, kb) allows large genes to be inserted into an Adv-based vector. Transgenes in Adv vectors are not incorporated into the genome of transduced cells but instead remain as an extrachromosomal entity in the nucleus. First isolated from U.S. army recruits who had acute respiratory symptoms, Adv vectors have been found to be common human pathogens. To date, 49 serotypes have been characterized and associated with a variety of symptoms, ranging from a mild cold to acute febrile pharyngitis.[14] Replication-defective recombinant Adv vectors are currently the most commonly used viral vectors in clinical trials. Ad2 and Ad5 are used primarily for gene therapy applications. Recently, however, the Ad11 and Ad35 serotypes were shown to exhibit a unique tropism that includes hematopoietic stem cells, a finding that potentially widens their utility.[15–17]

The Adv vector's genome (Fig. 33-2) can be divided into two main regions: early (E) and late (L) according to the time at which their genes are expressed during virus replication. There are four regions of early genes that are termed *E1, E2, E3,* and *E4,* and one region of late genes comprising the five coding units termed *L1, L2, L3, L4,* and *L5.* The *E1* region is essential for viral replication; therefore, recombinant Advs without the *E1* region are considered replication defective. In a replication-defective Adv vector, the *E1* region can be replaced with a transgene for expression. Moreover, removal of genetic material from the vector, such as the *E3* and/or the *E4* region(s), allows for larger genes to be inserted and reduces the viral immunogenicity.[18] Viruses without the *E3* and *E4* regions are referred to as "gutless" and have decreased antigenicity.[19]

The *E1* region of Adv vectors is subdivided into *E1A* and *E1B.* The *E1A* gene product is a viral transcription unit that activates the expression of other Adv transcription units by binding to viral promoters. The *E1B* region codes for a 55-kd protein that interacts with the cellular p53 tumor suppressor protein and regulates the host cells' cycle progression supporting viral replication. *E1B* also binds to viral *E4* proteins and to p53, which together act to depress host protein synthesis. The *E2* region codes for viral DNA polymerase and the Adv single-stranded DNA-binding protein. The *E3* region is not required for in vitro replication; however, it does offer the virus some protection against host defense mechanisms. The *E4* region codes for proteins involved in

- Regulation of viral and cellular protein expression
- Replication of viral DNA
- Switching off of host protein synthesis

The late genes (*L1–L5*) are expressed at the onset of viral DNA replication and encode structural polypeptides that are needed for virion assembly. This understanding of viral replication has allowed the development of extremely elaborate, conditionally replicative Adv vectors capable of replication only in cancer cells.[20]

The transduction efficiency of Adv vectors is high as compared with that of most other viral vectors. Because of the structural stability of the capsid polypeptides of Adv, viral particles can be purified and concentrated to a very high titer of ~1×10^{12} plaque-forming units (pfu)/mL. This is in contrast to retroviral titers that achieve much lower titers (~1×10^7 pfu/mL) because of their envelopes' instability. Another distinguishing characteristic of Adv vectors is their lack of integration into the human genome. The Adv genome remains in the nucleus of the target cells as a nonreplicating extrachromosomal entity, thereby avoiding any potential for mutagenic effects caused by random integration into the host.

However, Adv vectors have potential shortcomings, including

- Transient expression because the viral DNA does not integrate into the host
- Viral protein expression by the Adv vector after administration into a host
- A common pathogen and in vivo delivery could be hampered by the prior induction of host immunity.[3]

The period of Adv transgene expression is relatively short; therefore, this is a suboptimal vector if expression is desired for longer than 10 to 14 days. This short expression time is due primarily to the induction of a cytotoxic T lymphocyte (CTL) response to viral polypeptides, as well as potentially to the transgene itself, especially if it is not expressed normally. Because the Adv genome does not integrate into the target cell, only one of the daughter cells (if the target cells are dividing) will contain the transgene. Manipulation of the immune response can result in longer expression; however, Adv gene delivery is ideally suited to those situations that require only a single period of transgene expression in which transient expression is desired, for

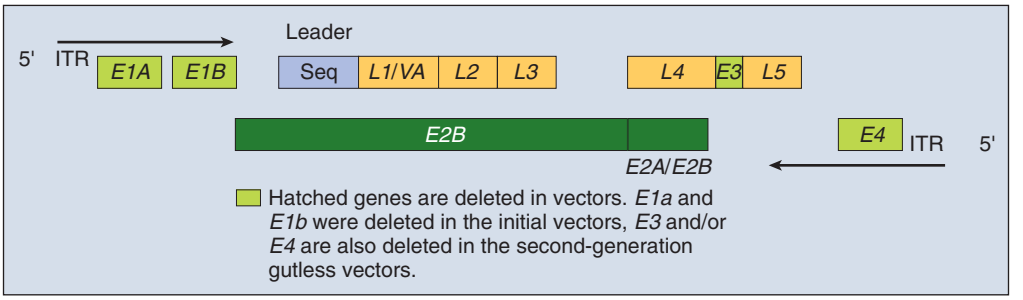

Figure 33-2 • Adenovirus genome. The Adv genome is composed of early and late genes. The *E1A* gene encodes the initial viral transcription unit and must be deleted to prevent the recombinant virus from replicating. In most of the original Adv vectors, *E1A* and *E1B* are deleted. The second-generation vectors (known as gutless vectors) typically also have the *E3* and/or *E4* genes deleted. This deletion allows larger transgenes to be inserted into the Adv vector, and the deletion of *E4* significantly reduces vector immunogenicity with the potential for a more prolonged transgene expression.

Box 33-1. ADENOVIRAL VECTORS

Adenoviral (Adv) vectors have a number of positive and negative attributes. The positive attributes include the transduction of a wide profile of cellular phenotypes such as epithelial, carcinoma, and hematopoietic cells. Further, the use of Adv vectors results in a high frequency of transduction and high levels of transgene expression. A negative attribute of Adv vectors is transient expression, although for appropriate targets such transitory infection is a positive attribute. The transient expression is due, in part, to the high level of innate vector immunogenicity, which can limit multiple cycles of transduction and chronic transgene expression. The resulting Adv profile of activity is ideal for the transduction of dendritic cells (DCs) as vaccines, the purging of tumor cells from stem cell products, and intralesional injection of carcinomas. Further, the ability to develop Adv vectors that are conditionally replicative has great potential for the treatment of neoplastic disease. It is noted that two Adv vectors have received regulatory approval in China. These controversial studies have resulted in the treatment of several thousand patients, supporting the safety of these vectors.

example, growth factor therapy. A second major disadvantage of Adv vectors used in vivo is the immune response (CTL and antibody [Ab]), both endogenous and induced, which can preclude infection and cause the destruction of transduced cells, resulting in local tissue damage and inflammation. This shortcoming was demonstrated in the initial studies with intrabronchial delivery of Adv for the treatment of cystic fibrosis.[21] Host cells presenting peptides from Adv-encoded transgene products target the host cell for CTL-mediated destruction. A third major disadvantage of Adv vectors is that most humans are primed against at least one serotype, because Adv is a naturally occurring virus. Using the same serotype in a gene therapy context will probably result in a rapid and vigorous immune response such that high levels of Adv-specific Abs occur in the sera within days of Adv vector administration. Another similar problem is the potential secondary immune response induced by the readministration of a vector. It must be stressed that transgene expression can occur during a boost, although a shortened duration is observed. The augmentation of a CTL response by an Adv vector suggests the utility of Adv vectors as vaccine adjuvants (Box 33-1).

Recombinant Adeno-associated Virus

Adeno-associated virus (AAV) vectors offer many of the same advantages as Adv vectors, including a wide host-cell range and a relatively high transduction efficiency.[22,23] AAV vectors stably integrate at specific sites in the host genome, resulting in a longer lasting transgene expression. In addition, these stable vectors can infect a variety of dividing and nondividing cells without inducing an immune response. AAV vectors cause little damage to target cells—unlike Adv vectors that can cause a high degree of cytopathogenicity. There is evidence, however, to suggest that AAV vectors are significantly less efficient than retroviral vectors at transducing primary cells, because most of their DNA remains extrachromosomal and does not integrate into the host genome. Furthermore, they cannot incorporate genes larger than 5 kb and must be screened closely for Adv contamination.

Recombinant Herpes Simplex Virus

Herpes simplex virus (HSV) vectors are developed primarily for protocols that target neuronal tissue.[24] Similar to Adv vectors, HSV vectors are maintained as an extrachromosomal DNA element in the nucleus of host cells, but can establish long-lived asymptomatic infections in the sensory neurons of the peripheral and central nervous tissue.[25] HSV vectors also have a wide host range and are similar to Adv vectors in that they allow large gene inserts of up to 20 kb. These vectors are infective even with multiple deletions of immediate-early (*IE*) genes that are essential for replication, resulting in less cytotoxic vectors, thereby reducing safety concerns.[26] HSV vectors can be produced at high titers and express transgenes for a long period of time in the central nervous system.[27] The major concern associated with HSV is the potential for wt virus to replicate lytically in the human brain, resulting in encephalitis. Other significant disadvantages with HSV vectors include

- Requirement for additional engineering to increase efficiency[26]
- Transient expression associated with lytic infection and viral protein expression
- Relatively low transduction efficiency

Recombinant Pox Vectors

The origin of vaccinia virus (VV), the virus used for vaccination against smallpox, is not known, but it was probably derived from cowpox virus, variola virus, or a hybrid of the two.[28,29] Percutaneous VV vaccine administration results in protective cellular and humoral immune responses in greater than 95% of primary vaccinees. Recombinant VV vectors are highly attenuated, host-restricted, and non- or poorly replicating poxvirus strains (including the modified vaccinia Ankra [MVA] and canarypox or avipox vector [Alvac]) and thus do not create productive infections.[30,31] MVA is avirulent in normal and immunosuppressed animals, and safe in humans.[32] Recent studies using transgenic mice provided a comparison of VV immunogenicity, including MVA and Western Reserve (WR). These studies demonstrated that MVA vaccines elicited $CD8^+$ T-cell responses that are comparable to those induced by the replication-competent WR strain. Furthermore, MVA vaccination was shown to be protective against a lethal respiratory challenge with the virulent WR strain.[33] The most frequent adverse complication of VV vaccination is inadvertent inoculation (usually autoinoculation) at other sites. Serious complications, which are more common among primary vaccinees and infants than among revaccinees and adults, include the following:

- Generalized vaccinia in otherwise healthy individuals, which is generally self-limiting
- Eczema vaccinatum, which consists of disseminated cutaneous lesions in highly susceptible patients with eczema or other chronic skin diseases, which can be severe or even fatal
- Progressive vaccinia (vaccinia necrosum), which is a severe, potentially fatal illness seen in patients with immunodeficiency, whether congenital, acquired (e.g., via leukemia or lymphoma), iatrogenic (e.g., via chemotherapy or glucocorticoid treatment), or HIV induced
- Postinfectious encephalitis, which is rare (three cases per million primary vaccinees), but can be fatal in 15% to 25% of cases and can leave 25% of patients with permanent neurologic sequelae

Similar to Adv vectors, VV vectors are used for immune manipulation and as a vector for vaccines.[34] VV vectors have been used worldwide to eradicate smallpox and as discussed earlier, provide a relatively safe live vaccine. Vaccinia vectors do not integrate into the genome of the host cell; however, they can accommodate large transgenes and are extremely immunogenic. VV vectors are used to immunize patients against tumor antigens (Ags) by cloning Ags and/or genes encoding proteins with adjuvant activity (e.g., cytokine or costimulating factor genes) into the viral genome. Most transgenes are expressed at high levels in vivo, eliciting an Ag-specific response. Vector-induced immunity, however, can limit the ability of the vaccinia transgenes to boost an immune response, which is an observation similar to that seen with Adv vectors. The current emphasis is on VV infection of dendritic cells (DCs) using a vector with an antigenic transgene.[34,35]

In association with the immunogenicity of VV vectors and their ability to deliver an antigenic transgene, they have been used clinically

as a melanoma vaccine. In clinical studies by Wallack and colleagues,[36] a phase III trial of a vaccinia melanoma oncolysate, delivered as an active specific immunotherapy, was found to increase the disease-free or overall survival of patients with stage III melanoma in a surgical adjuvant setting. Other studies have used VV mutants that are conditionally replicative and can lyse cancer cells after viral replication. These vectors have been used in a strategy whereby insertional inactivation of the VV thymidine kinase (tk) gene was used to limit viral replication in cells with large intracellular nucleotide pools, such as tumor cells. In a similar approach, Mastrangelo and coworkers[37] inserted the gene for granulocyte-macrophage colony-stimulating factor into the VV tk gene locus as a strategy to generate an oncolytic virus that induced antitumor immunity after infection of malignant melanoma. This vector is currently in a clinical trial of intralesional administration to patients with refractory recurrent melanoma. In the first seven patients studied, two patients had a complete response and three other patients had partial responses. Other oncolytic VV vectors have been engineered with complementary DNAs for cytokines such as interleukin 2 or with prodrug-activating enzymes such as cytosine deaminase to augment antineoplastic efficacy.[38,39]

The role of VV vectors as vaccines has focused predominantly on carcinoembryonic Ag (CEA) as the vaccine Ag. CEA is a glycoprotein self-Ag found on breast, lung, gastric, colon, and ovarian tumors. One such vector is a recombinant VV containing the CEA gene (rV-CEA).[40,41] In a phase I clinical trial, the safety of rV-CEA was demonstrated; however, no significant antineoplastic effects were observed.[42] Possible reasons for the lack of clinical efficacy in these trials include

- Prior exposure to the VV, leading to the development of anti-vaccinia immune responses after repeated vaccinations
- Advanced state of the patients' tumors
- Potentially compromised immune status of the patients

Another phase I rV-CEA vaccine study demonstrated that CEA-specific T-cell responses could be generated in humans after vaccination.[42] A second recombinant anti-CEA vaccine, Alvac-CEA, has been developed.[43,44] Similar to rV-CEA, Alvac-CEA contains the CEA gene; however, unlike rV-CEA, it cannot replicate in mammalian cells. The safety of Alvac-CEA has been documented in phase I trials in patients with advanced carcinomas.[45] A moderate but statistically significant increase in the number of CEA-specific CTL precursors was observed in seven of nine HLA-A2$^+$ patients treated with Alvac-CEA, although objective anticancer effects were not observed. Preclinical studies have suggested that the combination of rV-CEA and Alvac-CEA in a prime and boost protocol can induce a more vigorous T-cell response than either vaccine alone.[44] In a clinical prime-and-boost study, 18 patients with advanced tumors expressing CEA were randomized to receive either rV-CEA followed by three Alvac-CEA vaccinations, or Alvac-CEA (three times) followed by one rV-CEA vaccination. In this study, vaccination with rV-CEA followed by Alvac-CEA resulted in an increased frequency of Ag-specific interferon γ cells by enzyme-linked immunospot assay (ELISPOT) relative to the reverse order of vaccination.[46]

Another method to enhance the responses to a vaccine is to incorporate a costimulatory signal. In the absence of a costimulatory signal, presentation of an Ag to T cells can result in anergy.[47] B7.1, which binds to CD28 on T cells, is one such costimulatory signal that results in the production of interleukin 2 and interferon γ by T cells. In a vaccine study using VV vectors, 39 patients were treated with Alvac-CEA B7.1.[48] In one study using the Alvac-CEA-B7.1 vaccine, patients with metastatic CEA-expressing adenocarcinomas received vaccine intradermally every 2 weeks for a total of four injections. In this phase I trial, 27% of the patients had disease stabilization after four vaccinations. Six of 31 patients with elevated serum CEA levels had a temporary decline in CEA. In addition, HLA-A2$^+$ patients demonstrated increased CEA-specific T-cell frequencies after three vaccinations. Based on these studies and additional phase II data, a phase III trial was initiated in 255 patients with advanced pancreatic cancer at approximately 60 medical centers.[49] The protocol was powered to detect a 2-month improvement over control chemotherapy based on a median overall survival of 6 months. Unfortunately, this study did not meet its primary endpoint of improving overall survival compared with palliative chemotherapy or best supportive care. However, this outcome is not unexpected, because patients with advanced pancreatic cancer have a rapid disease progression and are poorly responsive to intervention in general (Box 33-2).

Box 33-2. VACCINIA VIRAL VECTORS

Vaccinia viral (VV) vectors have a profile of activity analogous to that of adenoviral (Adv) vectors. That is, they can easily transduce a wide range of cells, resulting in transient expression, and have as a negative attribute a brief transgene expression due to the innate antigenicity of the vector. In contrast to Adv vectors, VV vectors almost inevitably lyse the transduced cell, rendering it potentially less attractive as a vector (especially for dendritic cell [DC] transduction) due to the shorter half-life of the transduced cell. Significant experience with the administration of both VV and Adv vectors as vaccines has provided a strong safety profile for both. In theory, the concomitant use of VV and Adv vectors makes possible cycles of vaccine delivery via transduced DCs, allowing a prime and boost immunization with DCs, which have a high frequency of transduction and levels of transgene expression, while reducing the concerns associated with the innate antigenicity of the viral vectors.

Recombinant Alphavirus Vectors (Sindbis)

High-titer alphavirus vectors can provide efficient gene delivery both in vitro and in vivo. In addition, efficient central nervous system infections via intranasal and vascular injections with virulent and avirulent replication-competent Semliki Forest virus (SFV) strains have been shown in animal models.[50–52] Replication-deficient alphavirus particles have a high local and transient transgene expression in rodent brains. Furthermore, repeated SFV injections are possible in the absence of an immunogenic response against SFV, which is in contrast to Adv and VV vectors. Modifications to the envelope structure of Sindbis virus are possible with resultant changes in host range and targeting. The favorable characteristics of alphavirus vectors include

- Rapid production of high-titer virus
- Broad host range
- High RNA replication rate in the cytoplasm
- High transgene expression levels

Negative attributes include

- Short-term expression
- Strong cytotoxic effects on host cells

Nonetheless, both these properties are advantageous for certain indicators, particularly vaccine production.

Nonviral Gene Transfer Vectors

Nonessential genes can be removed from viral vectors to allow room for transgene(s) to reduce inflammatory responses and to increase safety.[53,54] This process involves simplifying the virus, sometimes to an extreme. After undergoing such a process, a virus vector can be an artificial "vector shell" allowing the gene of interest to be expressed at high levels, in a highly regulated manner, and for a controlled period of time. Another approach to achieve the same result is to produce a vector that can introduce genetic material to the nucleus of cells.[53,55,56] This strategy has resulted in the development of several

nonviral vector systems; however, the efficiency of "naked DNA" as a therapeutic is suboptimal without some form of carrier or formulation.

Direct DNA Injection and Transduction

One form of nonviral gene delivery is the use of purified DNA plasmids.[55] The transgene expression is low following intramuscular or intratumoral injection; however, high levels are observed if hydrodynamic injection is used.[57,58] The approach of naked DNA injection is typically done as an intramuscular or intratumoral injection. Despite the simplicity of this approach, transfection efficiency is low and results in limited expression. Various formulations, including lipid or pluronic formulations, and incorporation into nanoparticles or liposomes, have been used to improve transduction efficacy and gene expression (Box 33-3).[59–61]

Nonviral liposomal delivery systems can be IV injected with limited vector-associated toxicity, but with transgene expression, especially in the lungs.[62] Tumor targeting using tumor-specific promoters, ligandation of receptors to the liposome surface, and pegylation of liposomes have all been studied.[63–69] Although some degree of tumor targeting has been observed using these delivery systems, the level of transgene expression is generally low. Studies have revealed that liposome-DNA complexes can also elicit an inflammatory response when injected systemically, resulting in suppression of transgene expression.[70–72] Furthermore, failure to achieve increased or sustained gene expression after repeated injections has been a major obstacle in the development of liposomes.[70,73] Recently, it was shown that cationic liposome (DOTAP : cholesterol or DOTAP : Chol)–DNA complexes can achieve effective levels of transgene expression in tumor-bearing lungs and when injected IV can achieve levels sufficient to cure immunocompetent mice with disseminated experimental metastases.[74] Furthermore, repeated daily injections can result in a dose-dependent increase in transgene expression in tumor-bearing lungs.[75]

Hydrodynamic Gene Delivery

Hydrodynamic tail-vein plasmid delivery results in high levels of transgene expression in the livers of rodents.[76] Lower levels of transgene expression (100- to 1000-fold) are found in the spleen, heart, kidneys, and lungs. This simple nonviral gene transfer procedure entails the rapid delivery of naked plasmid DNA in a relatively large volume of physiologic saline.[57] In a typical mouse, weighing 20 g, the plasmid is delivered in a total volume of 2.0 mL over a period of 5 to 7 sec. Although there are toxicity issues, clinical studies are under discussion for the delivery of dystrophin into the arms of Duchenne muscular dystrophy patients.[77]

Liposomes and Virosomes

In their most basic form, liposomes consist of two lipid species: a cationic amphiphile and a neutral phospholipid.[75,78] Liposomes spontaneously bind to and condense DNA to form complexes that have a high affinity for the plasma membranes of cells, resulting in the uptake of liposomes to the cytoplasm by endocytosis. Many variations of this approach are used, resulting in varying levels of gene expression. Unfortunately, liposome-facilitated gene delivery is relatively ineffectual in vivo. More recently, some of the advantages of viral delivery vectors have been combined with the safety and "simplicity" of the liposome to produce fusigenic virosomes.[78] Virosomes are engineered by forming complexes of the membrane fusion proteins with liposomes that have already-encapsulated plasmid DNA. The inherent ability of the viral proteins in virosomes to fuse with cell membranes results in the efficient introduction of DNA to the target cell, providing improved gene expression. Viral vectors have limitations based on the size of transgene that can be incorporated; in contrast, no such limit exists for virosome or liposome technology (at least in theory).

Ballistic Delivery (Gene Gun)

This physical method of gene delivery involves microcarriers (usually gold particles) coated with DNA and "fired" at high velocity using an explosive or gas-powered ballistic device called a "gene gun."[79–81] Once the particles are inside the target cell, the DNA is slowly released from the microcarriers, resulting in gene transcription and translation. This application has been used extensively in vivo, but its clinical use is restricted to exposable surfaces or ex vivo transduction because the fired particles do not penetrate tissues deeply.[82]

Nanoparticles

Novel polymeric delivery systems (e.g., nanospheres) that can be administered in novel ways are being developed.[83–85] These particles are potentially useful because the smaller the condensed DNA particles are, the better will be their in vivo diffusion toward target cells and the trafficking within the cell. Individual plasmid molecules can be collapsed into a nanoparticle using detergents. For example, nanoparticle-based gene delivery was targeted to the neovasculature of mice using an integrin-targeting ligand, resulting in tumor regression.[86] Nonetheless, the size of the transgene that can be delivered by nanoparticles is limiting, and the primary focus has been on small interfering RNA (siRNA) delivery, which will be discussed in the following section.

Box 33-3. PLASMID AND RETROVIRAL VECTORS

The transduction efficiency of plasmid vectors is low, even with the use of formulations to improve transfection efficiency and increase transgene expression. Further, this approach appears to work better in vitro than in vivo. In contrast to viral vectors, plasmid vectors offer little innate antigenicity, although there have been reports of immune responses to bacterial genes. Positive attributes of plasmid vectors include the low level of innate immunogenicity and the potential for genomic integration. The use of hydrodynamic delivery in rodents has provided a powerful preclinical tool. However, clinical translation is problematic with the potential for utilization in an isolated limb. In contrast, retroviral and lentiviral vectors provide the same characteristics with higher levels of transgene expression and improved transduction efficiency relative to plasmids. However, the improved transgene expression and transduction levels of retroviral and lentiviral vectors remain significantly lower than those of adenoviral and vaccinia vectors.

Nucleic Acid-Based Therapeutics

DNA Transduction

High-molecular-weight, double-stranded DNA constructs containing transgenes, which encode specific proteins, are classically used in gene therapy to introduce transgenes into cells that inherently lack the ability to produce a protein of interest. In addition to being used to treat congenital diseases, DNA vectors can be used as vaccines for genetic immunization.[87] Suicide gene therapy is another rapidly emerging strategy for the induction of transgenes.[88,89] In this approach, chemosensitization genes are delivered to tumor cells, which upon gene expression convert a separately administered, nontoxic prodrug into a chemotoxic drug. Because only the transfected tumor cells can convert the prodrug, the susceptibility to the chemotoxic entity is limited to the tumor cells—hence the term suicide gene therapy.

RNA Transduction

Thus far the primary transgene source for DC transduction is DNA, although other Ag sources are also used with DCs, including peptides, recombinant or purified proteins, cellular extracts from tumor

cells, apoptotic bodies, and RNA or DNA plasmid vectors. Nevertheless, the carrier of choice for loading DCs with tumor Ags is DNA or RNA.[90] Nucleic acid transfection leads to the display of multiple antigenic epitopes by both class I and II major histocompatibility complex via the Ag-processing machinery of the patients' DCs, resulting in the display of the "most appropriate" peptides. This is in contrast to vaccine strategies based on synthetic peptides, which require the knowledge of the patient's unique peptide epitopes. Thus, nucleic acid transfection of DCs offers several advantages for both immunologic and practical considerations.

The bias for the use of DNA vectors includes an increased stability as compared with RNA, the ability to produce plasmids in large quantities, and the ease with which the sequence can be modified to regulate expression.[91] In several respects, however, RNA vectors are also advantageous when compared with DNA transfection. RNA vector advantages include the ability to use total messenger RNA (mRNA) isolated from tumors to transfect DCs with no intervening cloning steps and the ability to express several or potentially all tumor-derived genes within DCs. Transfected RNA need only reach the cytoplasm of DCs, whereas DNA requires entry into the nucleus and subsequent transcription. Furthermore, it has been suggested that the low level of antigenic epitope expression that occurs with RNA-transfected DCs could be advantageous, provided that expression levels are sufficient to generate a T-cell response.[90,91] When low levels of antigenic peptides are presented by DCs, only those T cells with high-affinity recognition are activated, thus skewing the response toward T cells that can better recognize the tumor cells. Conversely, when DCs present high levels of antigenic peptides, T cells of low affinity may be activated, thus masking or even preventing the activation of high-affinity T cells. This could result in T cells that kill cells with high Ag expression but cannot kill tumor cells, which typically express low Ag levels. Thus, RNA-transfected DCs might have greater efficacy for the activation of high-affinity T cells.[91]

Oligonucleotides

Oligonucleotides are short single-stranded segments of DNA or RNA that upon cellular internalization can selectively inhibit the expression of a single protein.[92] Multiple forms of oligonucleotides are used in gene therapy including antisense, siRNA, and ribozymes. Most of these constructs form a duplex with the mRNA or the pre-mRNA and inhibit their translation or processing, consequently inhibiting protein biosynthesis. This occurs by multiple mechanisms, as discussed in the following section.

Small Interfering RNA

RNA interference is a recently discovered mechanism for silencing the transcription of mRNA. siRNA is generated by dicer, an endonuclease that cleaves long double-stranded RNA molecules into fragments of 21 to 23 base pairs (bp) and is highly specific for the nucleotide sequence of its target mRNA siRNAs.[93–96] These siRNAs associate with helicase and nuclease molecules and form a large complex, which is termed RNA-induced silencing complex that unwinds siRNA and directs precise, sequence-specific degradation of mRNA. Although RNA interference was discovered only recently, the field has exploded.[97] It is now apparent that RNA interference is a highly conserved molecular mechanism that is used by eukaryotic organisms to control gene expression during development and to defend their genomes against invaders, such as transposons and RNA viruses. Recently, it was shown that siRNA is active in vivo with resultant therapeutic activity.[98] In one study, siRNA knockdown of the mutant K-*ras* oncogene had pronounced antitumor activity.[99] In this study, siRNA was delivered as a nonreplicative retroviral transgene and was shown to inhibit the relevant mutant K-*ras* and prevent anchor-independent growth and tumorigenicity.

Antitumor activities can also be induced in vivo through siRNA knockdown of other critical components of tumor growth, metastasis, angiogenesis, and chemoresistance.[100] Stable transfection and expression of siRNA is obtained with nonreplicating viruses[101,102]; however, oncolytic virus vectors provide a potential method to extend bioactivity. The tumor-selective infectivity has the potential to restrict transgene expression to the cancer microenvironment, potentially reducing toxicity and extending transgene expression via viral replication and multiple cycles of the infection of permissive cancer cells.[103,104] Furthermore, viral oncolysis has the potential to augment antitumor outcomes by siRNA-mediated therapeutic activity. In a recent study,[105] the replication-competent, oncolytic adenovirus, ONYX-411, was used to deliver a mutant K-*ras* siRNA transgene. In this study, additive tumor growth-inhibitory responses via siRNA-mediated K-*ras* knockdown and ONYX-411–mediated oncolysis were observed. Therapy with ONYX alone or ONXY-411 with green fluorescent protein siRNA as controls had significantly lower therapeutic activity.

Antisense

The principles of antisense technology are conceptually simple. Oligonucleotides are designed to hybridize to a defined target mRNA and to inhibit its translation into protein.[106,107] This approach was first employed in 1978 by Stephenson and Zamecnik[108] to inhibit the Rous sarcoma virus expression in chicken fibroblasts. Several antisense oligonucleotides are in clinical trials, and one has received Food and Drug Administration (FDA) approval for the treatment of cytomegalovirus retinitis. Currently, an antisense to Bcl2 has been submitted for licensing by the Food and Drug Administration for the treatment of leukemia.[109] Although it is relatively easy to synthesize phosphodiester oligonucleotides, they cannot be used as drugs because of their sensitivity to nuclease degradation. To improve their resistance to nuclease digestion, different chemical modifications are used, including phosphorothioates, methylphosphonates, and phosphoramidates.[110] These modifications increase the stability of oligonucleotides, but they also alter the capacity to hybridize with RNA and reduce cellular internalization.

Ribozymes

Ribozymes are RNA molecules capable of sequence-specific cleaving of mRNA molecules.[111] They selectively bind to target mRNAs and form a duplex that is easily hydrolyzed, suppressing specific genes.[54] Two types of ribozymes, the hammerhead and hairpin, have been extensively studied.[112] However, the RNA backbone in ribozymes is an easy target for RNases, so they are biologically unstable in vivo.[54] Ribozymes have been used primarily for gene suppression, the induction of apoptosis, and antiproliferative effects. Phase I clinical trials using ribozyme gene therapy to treat AIDS patients are ongoing.[113]

GENE TARGETING

Targeted gene therapy of cancer can be achieved through

- Targeted gene expression
- Vector targeting[13,114,115]

Although it is less important during ex vivo or intratumoral gene delivery, targeted gene therapy becomes crucial with systemic gene transfer. Impediments to gene therapy include the poor selectivity of existing vectors and the low efficiency of gene transfer. Overcoming these hurdles is critical to achieving vectors that can be targeted and injected IV—an important goal given the systemic nature of cancer.

Conditional Gene Targeting

Vector targeting is a goal for both viral and nonviral vectors[13,114]; however, the current emphasis is on tissue- or target-specific promoters. Transcriptional regulatory sequences are used because they are responsible for protein production in carcinoma cells such as oncogene products. One example is the use of tissue-specific promoters to

facilitate tumor-specific killing via expression of a suicide gene (such as the HSV-tk) followed by exposure to ganciclovir, or the expression of the cytosine deaminase gene and exposure to 5-fluorocytosine. In addition, transcriptional targeting is used to achieve conditionally targeted transgene expression.

Tissue-Specific Promoters

The production of proteins within a cell requires that the appropriate gene be transcribed into mRNA and then translated to protein.[116] This process is under multiple levels of control, with the regulation of transcription mediated by interactions between the enhancer/promoter region of the appropriate piece of DNA and the specific proteins or transcription factors that bind to this region. Activation or repression of promoters is achieved through interactions with specific transcription factors. Thus, some tissues might express specific proteins because the promoter for that gene is activated in that tissue alone. The success of transcriptional targeting is dependent on achieving a differential gene expression in cancer cells as compared with normal cells. Transcriptional control of gene therapy is an important goal for two reasons:

1. Current gene transfer vectors can be inefficient in gaining entry into the types of cells needing treatment.
2. Many therapeutic genes can be toxic if delivered to an unintended cellular target.

Criteria for selecting a promoter for use in a gene therapy protocol include consideration of the promoter's strength, tissue specificity, and size. Promoter candidates include regulatory elements that are already expressed by the malignant cell, tissue-specific promoters, or externally inducible sequences. Unfortunately, any of these candidate promoters can lack sufficient activity, specificity, or both. To address promoter potency, promoters and enhancers that retain cell-specific function are often linked to transactivators. Additional strategies to enhance promoter activity in malignant tissues include the use of cell-cycle elements, normal or abnormal tissue differentiation factors, hormones, cytokines, chemicals, or physical stimuli.

A convenient classification of candidate promoters for cancer gene therapy (Table 33-1) includes tumor-associated, tissue-specific, and inducible promoters. These are further discussed in the ensuing sections, as is the role of transcriptional regulation of replication-competent viruses. Specific examples are provided that are the most mature developmentally but should be viewed as representative. The most focused reviews and articles are referenced.

Tumor-Associated Promoters

Selective delivery of a transgene to a tumor is not currently an achievable clinical goal. Consequently, tissue and tumor promoters are used to regulate transgene expression in a given tumor tissue with the goal of reducing nonspecific transgene expression. However, this approach retains challenges, including the infection of only a small fraction of tumor cells within the target tissue. As such, tumor-specific and associated promoters are also extensively utilized to target transgene expression, especially ones associated with the tumor vasculature.[117–119]

TELOMERASE. Telomerase, an RNA-dependent DNA polymerase that synthesizes new telomeric repeats at the end of chromosomes, is expressed in high levels in malignant tumors, stem cells, and germ cells, but not in normal tissues. It is thought to be essential for the maintenance of the proliferative capacity of tumor cells and, for this reason it represents an attractive target for gene therapy. The human telomerase reverse transcriptase is regulated primarily at the transcriptional level, and its promoter has the potential for targeted cancer gene therapy.[120,121]

TUMOR VASCULATURE. Another target for gene therapy is provided by the tumor's vasculature. The tumor vasculature has excellent accessibility to systemic delivery across all solid tumor types.[122] Indeed, high levels of vascular endothelial growth factor (VEGF), a growth stimulus for endothelial cells, have been correlated with a poor prognosis for specific tumor histotypes. VEGF activity is mediated by two high-affinity receptors: the tyrosine kinases VEGFR-1/fms-like tyrosine kinase (Flt-) 1 and VEGFR-2/flk-1. These ligand-stimulated tyrosine kinases are induced in a tumor stage-dependent manner during cancer progression and are expressed exclusively in tumor vascular endothelial cells.[123] This suggests that VEGF receptors are promising targets for tumor endothelial cell-specific therapy.[122,124] Thus, the 939-bp Flk-1 promoter fragment and an enhancer element located in a 2.3-kb fragment upstream have been used to induce tumor endothelium-specific reporter gene expression in transgenic mice.[125] Targeting of the VEGF receptor/ligand system has been shown to be a useful approach with which to inhibit tumor growth and prolong survival in colon cancer.[124] The human preproendothelin-1 promoter has also been shown to have specificity for breast microvascular endothelial cells using a recombinant retroviral vector.[126]

Tumor-Specific Promoters

PROSTATE-SPECIFIC ANTIGEN. Prostate-specific Ag (PSA) is expressed at a high level in the luminal epithelial cells of the prostate and is absent or expressed at low levels in other tissues. The PSA promoter is usually regulated by androgens, but it might retain its activity in an androgen-free environment. The minimal PSA promoter, however, is weak in both PSA^+ and PSA^- cells and does not respond to androgenic stimuli. Nonetheless, the PSA promoter has been used to target the delivery of therapeutic genes to prostate tumors.[127,128]

TYROSINASE. Specificity for malignant melanoma may be conferred by the human tyrosinase promoter.[129,130] Driven by this promoter, in vitro and in vivo melanoma transduction by constructs results in selective transgene with the potential to induce tumor regression. Similarly, a construct consisting of the human tyrosinase promoter linked to two enhancer elements causes high-level, melanoma-specific expression of a reporter gene in transient transfection assays. The murine tyrosinase promoter-enhancer expression cassette expressed by an Adv vector maintains transcriptional specificity for pigment cell lineages, especially human melanoma cell lines.

Conditional Replication and Inducible Promoters

During evolution, various stress response genes developed, and their promoters are now considered as gene therapy transcriptional regulators. Heat, hypoxia, glucose deprivation, irradiation, and chemotherapeutic agents upregulate stress response genes. Because of the relative weakness of tissue- and tumor-specific promoters, these inducible promoters are attractive as mediators of transient transgene activation. Promoters of these genes are also attractive for cancer gene therapy because they depend to a large extent on the biology of the tumor or are already induced by various therapeutic modalities.[131,132]

STRESS-ASSOCIATED GENES. Genes that are upregulated during stress include *ABCB1*, human heat-shock protein (*HSP*), *VEGF,* irradiation-inducible *EGR1* (early growth response gene), and the tissue plasminogen activator (tpa) promoters. Irradiation-responsive promoter sequences have been identified for the tpa and *EGR1* genes.[133] The first irradiation-inducible promoter system used in combination with gene therapy involved the *EGR1* promoter driving either the radiosensitizing cytokine tumor necrosis factor α (TNF-α) or tk. The HSP family is induced by a variety of environmental conditions, including heat, irradiation, photobeam irradiation, hypoxia, acidosis, hypoglycemia, and osmotic changes. These conditions can exist in poorly vascularized tumors and can trigger anticancer gene expression linked to the *HSP70* promoter.[134] It is significant that HSP70 expression is upregulated in p53-deficient tumor cells, thereby providing transcriptional targeting.

Table 33-1 Transcriptional Regulation for Cancer Gene Therapy

Transcriptional Mechanism	Promoter	Target Tumor
TISSUE SPECIFICITY	PSA, Kallikrein	Prostate
	Tyrosinase	Melanoma
	CEA	Hepatocellular carcinomas (HCC): breast, lung, and pancreas cancers
	α-fetal protein (AFP)	HCC
	c-erb B2	Pancreas
	Amylase	Pancreas
	SP-B	Lung cancer
	Grp	Small cell lung carcinoma
	AVP	Small cell lung cancer
	Immunogloblin heavy chain	B lymphomas
	AP-2	Breast cancer
	α-lactalbumin	Breast cancer
	Osteocalcin	Osteosarcoma
	Prolactin	Prolactinoma
	Insulin	β-islet cells
	Whey acidic protein	Breast cancer
	Cirulatory leukoprotease inhibitor (CLPI)	Lung, colon, breast, bladder, oropharyngeal, ovarian, and endometrial carcinomas
	Glial fibrillary acidic protein	Brain astrocytes, glioma cells
	Albumin	Liver
	T-cell receptor	T lymphocytes
	Her 2/*neu*	Breast, pancreatic, and gastric carcinomas
	Myc-Max responsive element	Lung cancer
	MUC-1	Adenocarcinomas
ABERRANT TUMOR BIOLOGY	Telomerase	Urinary bladder and HCC
	FLK-1	Melanoma, fibrosarcoma and breast tumor vessels
	E-selectin	Tumor vasculature
	VEGF	Lung cancer
	Hexokinase II	Lung cancer
	c-erb B2	Breast and pancreas tumors
	c-Myc	Small cell lung cancer
	L-plastin	Ovarian carcinoma
	SLPI	Lung and ovary tumors
INDUCIBLE PROMOTER	EGR-1	Glioma
	Hsp70	Prostate, breast, and melanomas
	Grp78	Fibrosarcoma
	ABCB1	Breast

MULTIDRUG RESISTANCE GENES. ABCB1 encodes a membrane effluxing glycoprotein, whose expression is induced by vincristine, actinomycin D, and doxorubicin. Its promoter is indirectly transactivated by these compounds and induces transcription and expression of therapeutic genes, such as TNF-α in tumors exposed to chemotherapy.[135] Chemotherapy can also induce another mechanism of drug resistance, namely, activation of the glutathione detoxification system and apoptosis-controlling gene alterations (especially p53 and bcl-2). Because the ABCB1 promoter contains heat-responsive elements, it is also activated by HSP. In addition to its promoter activity, ABCB1 can be transduced into hematopoietic stem cells to reduce the myelosuppressive effects of chemotherapy and radiotherapy.[136]

DEXAMETHASONE. Several drug-related gene expression systems are available to control target gene transcription through the use of small-molecule-inducing compounds.[137,138] Although the utility of such systems has been demonstrated in vitro and in transgenic mice, they are also targeting use in a therapeutic context.[139,140] Dexamethasone, a synthetic glucocorticoid, can selectively activate the p21 promoter in rat hepatoma cells via a glucocorticoid-responsive region between nucleotides 21481 and 21184.[141] This region

does not contain a canonical glucocorticoid response element, but it confers specific dexamethasone responsiveness to heterologous prostate promoters.

TETRACYCLINE RESPONSE ELEMENTS. The Tet-controlled transcription system is made up of Tet-off and Tet-on transcriptional regulation, derived from the *Escherichia coli* Tet-resistance operon.[142] The Tet-R system can be used to suppress or induce cytotoxic and reporter gene expression.[143,144] The latter selects gene expression to p53-deficient tumor cells. Similar to Tet-R, mifepristone is an orally bioavailable antiprogestin that can switch on gene expression in allosteric systems, whereby a chimeric transactivator activates a target gene.[145] This system can circumvent constitutive expression of transgenes in normal tissues by drug-specific and temporal regulation of the target gene. In addition, the replacement of the activation domain of the chimeric transactivator with a transcriptional repressor domain results in inducible repression of the transgene.[146]

Conditionally Replicative Viruses

Toxic or tumor suppressor gene expression from nonreplicative vectors, as a single therapeutic, is inadequate to control solid-tumor growth in humans.[147,148] Thus, replication-competent viruses have been developed and tested as therapeutic agents in cancer. Adv vectors are the most commonly used agents in this context, although retrovirus, reovirus, HSV, and vesicular stomatitis virus are all used for the treatment of malignancies.

The criteria governing the utility of replication-competent viruses include infection efficacy, replication selectivity, viral dispersion from the injection site, and evasion of the host immune response. Augmented gene transfer efficiency has been reported for Adv vectors based on the coxsackievirus Adv receptor (CAR)-independent cellular entry pathways.[149] Propagation of these vectors within tumor tissue remains a challenge, however. Recent improvements in our understanding of cancer biology have made possible the development of viral vectors with improved tumor-selective replication and the restriction of lytic effects to cancer cells. Dysregulation of the normal control over cell cycle and circumvention of physiologic apoptotic signals might allow tumor-selective replication of an engineered virus and, subsequently, direct oncolysis by viral cell killing.[150]

Conditionally Replicative Adenoviruses

Conditionally replicative Ads (CRAds) are designed by the deletion of Adv natural genes encoding cell-cycle regulatory proteins and/or by placing a tissue-specific promoter to control a viral gene essential for viral replication. An example of a vector with a deleted Adv gene is the deletion of CRAd *E1A* (Table 33-2). This results in a loss of its conserved region 2, which precludes binding to the retinoblastoma gene (*Rb*) and eliminates the inhibitory effect of *Rb* on *E2F*. Consequently, the engineered Adv replicates selectively within cells in which the G1-S phase checkpoint is impaired (i.e., tumor cells).[151,152] Deletion of the Adv *E1B* 55-kd protein was initially suggested to be selective for replication in p53-mutant cells, but this hypothesis has since been questioned.[153,154] Despite the mechanistic uncertainty, the *E1B*-deleted ONYX-015 virus selectively infects head and neck tumor cells and could show a clinical benefit in patients with recurrent carcinomas.[155] Although ONYX-015 does not have a therapeutic transgene and relies on its lytic effect, this is the first clinical utility of a CRAd for cancer therapy. It should be remarked that development of ONYX-015 by the American biotechnology company, ONYX Pharmaceuticals, was halted primarily because of financial concerns. Shanghai Sunway Biotech Co. licensed world rights to ONYX-015 and obtained regulatory approval in China in December 2005.[2] This gene therapy product, H101 (ONYX-015), is a recombinant Adv modified to selectively replicate in and kill tumor cells with TP53 mutations. This involves a loss-of-function mutation at the *E1B* locus. The *E1B* locus product is a 55-kd protein that binds to and inactivates the p53 tumor suppressor protein. Thus, the vector is crippled in its ability to grow in cells with wt TP53, and replicates and causes the death of cells with mutant TP53.[156] Phase I, II, and III clinical trials undertaken in China have been reported to show the safety of H101 with efficacy demonstrated in patients with HNSCC. Approval was based on a study that combined H101 and chemotherapy, which was reported to be effective in 78.8% of patients with this disease.[157]

Recently, mutants of human Adv 5 (Ad5) with enhanced oncolytic activity have been isolated using a procedure termed bioselection. In this process, Ad5 is mutagenized and repeatedly passaged in a human colorectal cancer cell line. From such a cell line, mutants can be found that replicate more rapidly than wt Ad5 and that lyse cells up to a thousand-fold more efficiently.[158] Another strategy for designing CRAds uses tissue-specific promoters to drive expression of *E1A,* thereby restricting viral replication to specific tissues or tumors.[159] The application of heterologous promoters in Adv vectors is difficult because their activity and specificity are often affected by viral enhancers and promoters. The *E1A* gene expressed from the alpha fetoprotein (*AFP*) gene promoter induces relatively selective replication in hepatocellular carcinoma cells.[159] Control of Adv *E1A* expression under the minimal PSA enhancer/promoter has also been shown to confer prostate-specific oncolytic viral replication.[160] Recently, a reengineered Adv vector with enhanced oncolytic efficacy was developed. This vector contained a novel regulatory circuit in which p53-dependent expression of an antagonist of the *E2F* transcription factor inhibits viral replication in normal cells. In tumor cells, however, the combination of the p53 pathway defects and deregulated *E2F* allows replication at near-wt levels. This Adv vector also has significantly enhanced efficacy for the treatment of human xenograft tumor models compared with the extensively studied *E1B*-deleted Adv vectors.[20]

CRAds for breast tumors have been created using the DF3/MUC1 promoter (which is abnormally activated in breast tumors) and are

Table 33-2 Transcriptional Regulation of Adv Replication

Genetic Modification	Biologic Result
Deletion of E1A (AA 121–127)	Transformation deficiency
Deletion of E1B 55 K protein	Susceptibility to apoptosis
E1A control by the αFP promoter	E1A transcription limited to αFP^+ cells
E1A control of the PSA promoter	E1A transcription limited to PSA^+ cells
E1A control by the DF3/MUC1 promoter	E1A transcription limited to $DF3/MUC1^+$ cells
E1A control by the pS2 promoter	E1A transcription limited to estrogen $receptor^+$ cells
E1A control by the Sp-B promoter	E1A transcription limited to surfactant producing cells
E1 deletion	Selective DNA replication of Adv vectors in trans-complementing tumor cells

used to drive the expression of *E1A.* This CRAd selectively replicates in MUC1$^+$ cells and can inhibit the growth of human breast cancer xenografts.[161] Another approach is to target CRAd replication within estrogen receptor (ER)-positive tumors based on replacing the *E1A* and *E4* promoters with a portion of the pS2 promoter containing two estrogen-responsive elements.[162] This promoter induces transcriptional activation of the *E1A* and *E4* in response to estrogen in cells that express an ER. This CRAd is able to lyse ER$^+$ human breast cancer cell lines as efficiently as Adv, with decreased capacity to affect ER$^-$ cells.

Another strategy that has been reported recently makes use of the generation of a functional promoter/gene constellation only on Adv DNA replication, thereby providing selective transcriptional activation.[163] These strategies to discriminate between tumor and normal tissue are based on selective DNA replication of Adv vectors with the entire *E1* gene in tumor cells deleted. An *E1* deletion is considered to abolish Adv replication; however, human tumor cell lines apparently can support DNA replication of Ad with an *E1* deletion. Inverted repeats insert into the *E1* region of AdE1 vectors can mediate genomic rearrangements, and bring a transgene into control of a promoter. Thus, formation of a functional expression cassette depends on viral DNA replication, which is expected to occur specifically in tumor cells.

Vector Targeting

Targeted in vivo gene transfer is becoming a reality as a result of an improved understanding of influences that govern gene delivery.[13,14,114] Viral-based vectors are designed to avoid gene transfer through their native receptors and are redirected to tissue- and tumor-specific receptors. In most therapeutic applications, the vector is introduced into a mixed population of cells with the goal of delivering the therapeutic transgene to specific cells. Transduced stem cells can also be targeted to treat certain genetic diseases, improve tolerance to chemotherapy, or assist in tissue repair and remodeling. DCs can also be targeted for the development of improved vaccines. Finally, a systemically administered, targeted vector can potentially reach systemic disease. Nevertheless, these vectors require additional development, including clinical testing, reduced liabilities (including innate and acquired immune augmentation), and an improved understanding of the mechanisms that govern biodistribution and pharmacokinetics.

Ligand-directed targeting of gene vectors allows control of the site at which genes are expressed by imparting the capacity to distinguish between target and nontarget tissue(s). These ligand-directed targeting vectors achieve this capability through the addition of ligands to the vector that recognize receptors specific for a tissue or disease. This approach has met two goals:

1. Improved efficiency for the current gene transfer vectors in transducing the targeted cells that need treatment
2. Reduction in the toxicity due to delivery of therapeutic genes to unintended target cells

Thus, ligand-directed targeting can potentially improve both the safety and the efficacy of gene transfer and make possible therapies that could not be envisioned with standard gene transfer vehicles.

Although targeting gene transfer to specific cells and tissues holds promise, it is a challenge for vector design. Regardless of the vector, three variables are critical to ligand-directed targeting. These include cellular specificity, physical barriers, and the host innate or acquired response, which could eliminate the vector from the circulation. Cellular specificity can be achieved by the use of ligands that recognize cell-specific receptors. For viral-based vectors, specificity requires a targeting element plus modification of the vector so that it no longer binds to its native cellular receptors. In the case of nonviral vectors, targeting requires modification of the vector to avoid nonspecific uptake. Apart from cellular specificity, physical barriers (e.g., the cellular matrix) can limit access of the vector to the target cell. Finally, avoiding elimination and neutralization of vectors by innate and acquired immunity is critical to gene transfer. This is critical, because Abs and serum proteins can directly inactivate the vector or direct it to the liver for rapid clearance, if the vector is given systemically.

Adenoviral Vectors

Our improved understanding of the attachment and entry processes of Adv vectors has facilitated the development of Adv-targeting vectors.[13,34,114] The nonenveloped subgroup C Adv vectors use at least two coat proteins to gain entry into cells. The knob portion of the fiber coat protein binds to the cellular receptor, CAR, and mediates virus attachment.[164,165] At the base of the fiber protein, the penton base coat protein contains an Arg-Gly-Asp (RGD) motif that binds to integrins and facilitates vector uptake into the cell.[166] Compared with a vector with native receptor binding interactions intact, gene expression in the liver and other organs is substantially reduced after systemic administration of a vector containing mutations that ablate CAR and integrin binding.[167] This observation suggests that these receptor interactions are important for in vivo gene transfer. The loss of CAR and integrin binding also reduces gene transfer after direct injection. Furthermore, it allows Adv vectors to be retargeted genetically.[17,168] Ablation of CAR binding alone does not significantly reduce liver gene transfer, which suggests that the standard two-step model of attachment via the CAR and entry by means of integrins does not apply to in vivo gene transfer to the liver, which instead probably involves Kupffer cells.

Adv vectors have been retargeted by both genetic and nongenetic means. Peptides (including the fiber, penton base, and hexon) have been functionally incorporated into coat proteins, although few functional peptide ligands have been identified thus far.[166,169–173] In addition to genetic modifications for retargeting viral vectors, ligation approaches have also been used with Adv vectors. Such approaches involve a bifunctional adaptor or bridging molecule that binds to the vector and to a target receptor. Such systems have demonstrated the feasibility of targeting conventional Adv vectors to more than 20 different receptors, including α_v integrins, endoglin, E-selectin, EpCAM, and folate receptors.[114] Specific targeting to the lung vasculature has also been demonstrated through a combination of receptor-based targeting via lung endothelial-specific receptor, angiotensin-converting enzyme, and promoter-based targeting through the endothelial-specific promoter, Flt-1.

Structural Modification of the Fiber Protein

One approach to Adv retargeting involves engineering of the knob domain of the fiber protein. In this domain, the introduction of heterologous cell targeting peptides requires consideration of the structural limitations of the fiber three-dimensional configuration. The fiber is synthesized as a monomer, which undergoes trimerization before its attachment to the penton base. Thus, any modification of the knob domain of the fiber must not impair trimer formation. In addition, the final quaternary configuration of the new fiber must make the incorporated ligand accessible to target cell receptor recognition and binding.

Recombinant Adv vectors have been constructed with a heparin/heparan sulfate-binding domain, consisting of polylysine residues added to the C terminus of the fiber. Gene transfer to different mammalian cells has been obtained with a level of efficiency 10- to 300-fold higher as compared with unmodified vector.[174] The main drawback with this approach is the lack of specificity, because most mammalian cells express heparin-containing cellular receptors. Genetic modification of the Adv fiber C terminus is limited, because the addition of more than 25 to 30 amino acid residues renders the fiber trimer unstable and limits function.[175] The modification of Adv vectors by placing an RGD peptide in the HI loop rather than in the C terminus of the fiber knob domain was reported recently.[176] This

modification resulted in an increase in gene transfer to ovarian cancer cell lines (30- to 600-fold) and ovarian cancer cells (twofold to threefold).

Modification of the Penton Base

Retargeting of Adv vectors has also focused on the modification of the penton base, which mediates the second step of Adv infection (i.e., internalization). Recombinant Adv vectors have been generated in which the RGD motif in the penton base has been replaced by the FLAG peptide. A complex of this vector with a bispecific Ab—consisting of a monoclonal Ab to the FLAG epitope and a monoclonal Ab to integrins—was shown to target cells lacking the Adv fiber receptor, such as endothelial cells or human intestinal smooth muscle cells. Thus, the first two steps of Adv infection binding and internalization are both mediated by α integrins.[177] In addition, recombinant Adv vectors can be constructed of chimeric penton base proteins that recognize tissue-specific integrin receptors.[178]

Retroviral Vectors

Retroviral vectors were the first viral vectors to be targeted and the first to demonstrate the promise of vector targeting.[34,114] Since that time, the challenge has been to incorporate targeting ligands without compromising vector entry into target cells. There are now several approaches used to address this problem. One approach exploits pseudotyping, classically with the G-glycoprotein from the vesicular stomatitis virus, in which entry events are mediated through common membrane phospholipids.[179] Pseudotyped lentiviral and retroviral vectors have also been generated with glycoproteins from a variety of enveloped viruses, including Ebola virus, Marburg virus, rabies virus, lymphocytic choriomeningitis virus (LCMV), Mokola virus, human foamy virus, gibbon ape leukemia virus, murine leukemia virus, influenza virus, avian leukosis-sarcoma virus, and respiratory syncytial virus.[180–184] Although these pseudotyped vectors vary in terms of degree of envelope shedding, efficiency of packaging, titer, and stability, they can be concentrated to high titers for in vivo comparisons of cellular tropisms.

Another vector modification involves the ligation of polypeptides at the N terminal of env to extend the host range of ecotropic murine leukemia virus (MLV). Examples include erythropoietin, heregulin, and CD4.[185–187] It should be stressed that coexpression of the wt env protein is necessary for infection to occur, possibly because incorporation of the engineered env protein in the virons can be facilitated by the oligomerization of both wt and chimeric env proteins. Another approach for engineering of the ecotropic MLV env protein involves the display of different polypeptide binding domains to the N terminus of the ecotropic MMLV surface protein. Examples include the N-terminal moiety of the amphotropic MLV env, single-chain Abs recognizing different cell surface receptors, heregulin, and epidermal growth factor.[188–191] In some of these studies, infection specificity was redefined, though with lower efficiencies than those obtained with viruses expressing wt amphotropic envelopes.[192,193]

Bifunctional bridging agents that recognize both the retrovirus and the targeted cell surface molecule provide evidence that retroviruses can enter cells via cell surface molecules that are not viral receptors. Such bridging agents have been used to infect human cells that are naturally resistant to ecotropic MLV-based vectors. The agents used usually consisted of an Ab to the MLV envelope protein connected to either another Ab or a growth factor that would bind to the appropriate receptor such as the epidermal growth factor receptor, the insulin receptor, or major histocompatibility complex class I and class II molecules. Unfortunately, infection efficiencies for these agents are extremely low, emphasizing that binding of a retrovirus to a target other than the natural receptor cannot guarantee success.[194,195]

Nonviral Vectors

Nonviral vectors have no native receptor binding, yet do have a high incidence of nonspecific gene transfer from the high positive charge on many nonviral vectors.[54–56] Many nonviral vectors transduce lung vasculature, potentially as a result of vector-mediated red blood cell aggregation and arrest in the lung subsequent to IV administration. The solution to the problem of nonspecific delivery is to shield the vectors, either with hydrophilic polymers such as polyethylene glycol (PEG) or with a ligand to reduce the surface charge. This type of shielding is applied successfully to lipid-based systems and to cationic polymer-based systems (polyplex).

Ligand-directed liposomes have shown some success in targeting tumors. Coupling of a synthetic $\alpha_v\beta_3$-integrin ligand to cationic liposomes permits the selective delivery of a mutant *Raf* gene that causes apoptosis in angiogenic blood vessels within tumors. Systemic injection of the $\alpha_v\beta_3$-targeted liposome results in apoptosis of tumor-associated endothelium and the regression of primary and metastatic tumor(s). This accomplishment highlights the extension of this approach from in vitro to in vivo efficacy.[86]

Another promising advance is to coat polyethylenimine (PEI)-DNA polyplexes with a ligand, such as transferrin or transferrin plus PEG. Shielding by PEG or transferrin prevents nonspecific interactions with plasma proteins and erythrocytes but does not interfere with target cell interactions. When systemically administered in a subcutaneous tumor mouse model, the shielded complexes were shown to selectively transduce a well-vascularized, rapidly growing tumor. Although the specificity of this approach is high, the overall level of transduction is low.[196]

In all the studies to date that use nonviral approaches, the need for relatively high dosing levels (~100 mg/mouse) suggest that innate clearance mechanisms might have to be saturated before substantial gene transduction can occur. Other potential issues that remain include determining whether the high doses used in the animal studies can be manufactured and delivered successfully for human studies. Attaining further improvements in the efficiency of gene transfer and better defining the toxicity profiles associated with these vectors are also critical steps.

CLINICAL TRIAL STRATEGIES

The development of gene therapy over the last decade has been on a roller-coaster ride that has yet to fulfill the promise of this exciting new research and therapeutic tool. Retroviral gene therapy has inarguably been shown to reverse congenic diseases. This was the first success for gene therapy, whereby a retroviral-based treatment was undertaken for infants suffering from X chromosome-linked SCID-X1. These studies provided the first demonstration of the potential for long-term treatment of hereditary diseases.[197] The success of this approach is due not only to gene therapy but also to improvements in our understanding of hematology and the availability of clinical-grade cytokines to support the transduction of adequate numbers of stem cells. These studies have resulted, however, in the concept of retroviral insertional carcinogenesis moving from a theoretic to a real concern in recent months. Two of the initial 11 children who received retroviral gene therapy for the treatment of SCID developed a leukemia-like condition.[198] Both of these cases, as well as a third in which leukemia has not yet developed, seem to be due to the insertion of the corrective gene near another gene called *Lmo2,* which helps to control cell growth and can contribute to cancer if turned on at the wrong time.[198] Nonetheless, the unique nature of this therapeutic strategy for patients who have no other viable therapeutic modality, and the responsiveness of the resultant leukemias to chemotherapy, suggest that it remains a justifiable therapeutic strategy for those patients who have no matching allotransplant donor.

Therapeutic activity has also been demonstrated[199] for retroviral vector transduced stem cells in infants with a defective gene for adenosine deaminase (ADA-SCID). In contrast to children with SCID-X1, enzyme replacement therapy has been available for children with ADA-SCID using pegylated ADA (PEG-ADA). Initially,

ethical concerns required that gene therapy studies in ADA-SCID patients be undertaken concomitant with PEG-ADA therapy. A generalized schema for these gene therapy protocols is shown in Figure 33-3. However, the SCID-X1 studies by Cavazzana-Calvo revealed that a strong selective pressure was needed to expand the transduced cells following infusion.[197] This revelation provided the impetus for studies in ADA-SCID whereby PEG-ADA was discontinued, allowing the selection of transfected stem cells and more importantly differentiated T cells. In addition, nonmyeloablative conditioning with busulfan was used to provide space in the marrow for the infused stem cells. Although insertional mutagenesis remains a concern, no clonal expansion has been reported to date. A recent follow-up at a median of 3 years was presented at the 2006 American Society of Hematology (ASH) annual conference and reported that seven of eight children responded to gene therapy, with approximately 95% of T cells expressing ADA. The one patient who did not show improvement was treated at an older age, suggesting a higher level of disease damage.

The second vector type that has shown significant clinical potential is Adv vectors. In contrast to retroviral vectors, Adv vectors induce a transient gene expression and demonstrate both high transduction efficiency and high transgene expression; in addition, these vectors can be grown to high titer for virus stocks. Furthermore, the activity profile of these vectors (particularly transient gene expression) provides an attractive characteristic for many current clinical development strategies. Most notably, these protocols involve the induction of tumor apoptosis via systemic or intralesional injection of vectors with transgenes that induce apoptosis or result in the activation of cytotoxic drug precursors, such as TK or cytosine deaminase. In addition, Adv vectors are being used to deliver Ags to Ag-presenting cells (e.g., DCs), resulting in the induction of an Ag-specific immune response and (theoretically at least) therapeutic activity.

In a recent phase I/II trial of extensive stage, small cell lung cancer,[200] 29 patients received standard first-line chemotherapy and three vaccinations with Adv-transfected DCs as a vaccine. Patients with stable disease to first-line chemotherapy had DCs prepared from enriched monocytes, which were then transfected with Adv-p53 and the resultant p53-DC injected three times. Following disease progression, patients received second-line chemotherapy. The objective response rate to vaccine alone was low, although it was reported that following p53-DC vaccination one patient had lymph node metastasis regress with the remainder of patients rapidly progressing. In contrast, 60% of patients with progressive disease following vaccination had objective clinical responses to second-line chemotherapy, resulting in an overall survival of greater than 11 months after immunotherapy. Indeed, the major response rate to second-line chemotherapy (complete and partial responses) was 90% in those patients who developed an immune response to p53 as compared with 40% for those patients who did not develop an immune response. In this disease, aggressive combination chemotherapy regimens can extend the median survival time to 9 to 10 months from diagnosis, as compared with 2 to 3 months if untreated.

Similar to retroviral vectors, Adv vectors have experienced "growing pains." Although the majority of the vectors used in current

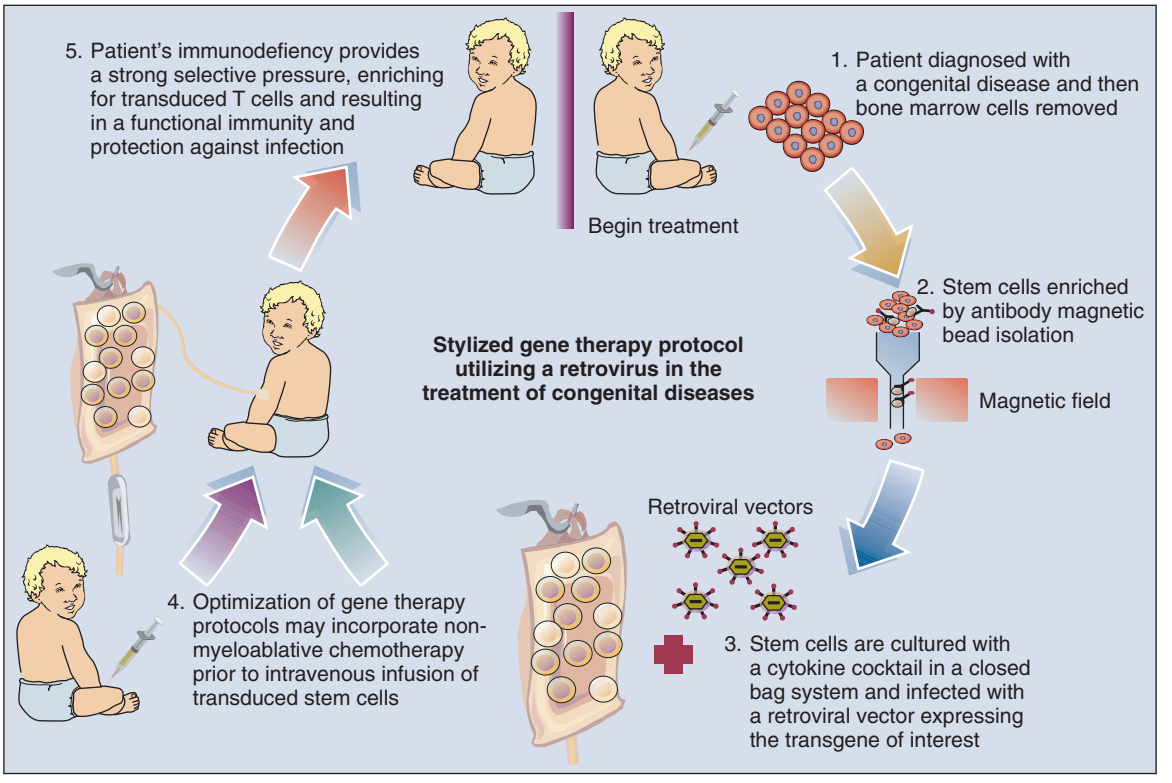

Figure 33-3 • Characteristic protocol for retroviral treatment of congenital diseases. An improved understanding of stem cell culture has facilitated therapeutic efficacy for the treatment of children with common γ-chain, severe combined deficiency; SCID-X1; and ADA-SCID. Protocols for other congenital diseases are similar. In general, children have a bone marrow harvest either in utero or more commonly in the first few years of life. The harvested cells are briefly cultured, typically with a mixture of cytokines active on primitive hematopoietic stem cells; transfected with a retroviral vector; and then cultured again to allow transgene insertion into the chromosome. The patient may also undergo nonmyeloablative conditioning, typically with busulfan, before receiving the transfected cells. Several studies have shown that supportive therapy must be withdrawn to allow selection of the transfected cells. Typically within a few weeks post-transplant, a high percentage of the circulating T cells are transduced with retroviral vector, resulting in normalization of T-cell numbers and a significant decrease in infections.

practice have been replication incompetent, the routes of administration and therapeutic targets have been variable and—in part because of this—various toxicity issues have developed. Studies using Adv-p53 vectors have shown clearly that these can be injected at doses up to approximately 7.5×10^{13} for intraperitoneal administration, and 2.5×10^{13} viral particles has been identified as the maximum total dosage.[201] This same particle number, administered via the hepatic artery for the treatment of hepatic metastasis, has also been identified as the maximum total dosage.[202] Initially, Adv vectors were delivered based on plaque-forming units, a strategy found to be less rigorous quantitatively when compared with a particle number strategy.[203] Yet, despite the known biodistribution and toxicity profile of Adv vectors—including Adv vectors delivered by vascular injection—one child with a non-life-threatening disease, ornithine transcarbamylase deficiency, was dosed with a high number of viral particles, resulting in his untimely demise.[204] The incident resulted in a regulatory hold on Adv for a period of time, which limited the use of Adv vectors. This toxicity problem has largely been overcome with increased clinical conservatism. Similarly, the immunologic reaction to the Adv vectors can be reduced as shown with some second- or third-generation vectors (gutless), providing a significant impact on safety, transgene expression, and duration of expression.[205] Indeed, Adv vectors have been used to deliver receptors for retroviral vectors to improve their transduction frequency.[206] Thus, in addition to "naked DNA" vectors, retroviral and Adv vectors have been used predominantly in the clinic thus far. Clearly, other agents are used, including AAV, α viruses, and herpes vectors, but to a lesser extent.

Several factors directly related to vectors have hampered the clinical progression of gene therapy. These include

- Inefficient gene delivery, which is associated predominantly with nonviral and retroviral vectors that have reasonable gene delivery efficacy in vitro but disappointing efficacy in vivo
- Poor ability to target transgene expression to either cells or tissues of interest to avoid expression of toxic gene products in healthy or unintended target tissue
- Short duration of expression due to poor replication and/or stability of episomal vectors and to inefficient or inappropriate integration of vectors into the host genome
- Poor production of vectors at high titer, which is developmentally limiting in the cases of retroviral and gutless Adv vectors
- Safety, which is a prerequisite for clinical gene therapy trials. Safety includes not only issues of direct toxicity but also the potential for homologous recombination, which has to be maintained at theoretically acceptable levels. Furthermore, targeted genomic integration has also recently been shown to be potentially critical.

Because of the challenges associated with targeting and transfection efficiency, the therapeutic strategies currently in use take advantage of the positive aspects of the vectors and limit their deficiencies. There are four overall approaches that reduce the challenges associated with the targeting and delivery of the transgene:

1. Hepatic arterial delivery of Adv-p53 for the treatment of hepatic metastasis[202,207,208]
2. Intratumoral administration of Adv vectors for head and neck tumors[155,209,210]
3. Intralesional injection for the treatment of bladder cancer with Adv vectors[211]
4. Intralesional injection for the treatment of lung cancer

The use of Adv vectors to purge hematopoietic stem cell products is also an exciting strategy that initially targeted breast cancer.[212–216] It has become a historical approach, however, with the reduction in transplantation for the treatment of metastatic breast cancer. These are the types of approaches that are needed for the successful development of gene therapeutics. The future of gutless vectors or vectors with improved targeting is bright, but at present such vectors introduce additional deficiencies such as low manufacturing titers.

In 2004, Adv-p53 vectors were approved in China for the treatment of patients with HNSCC.[1] This approval was based on a single clinical study using an Adv serotype 5 vector engineered to express p53 (Gendicine). In this multicenter, randomized clinical trial, 135 patients were randomized and entered to receive Gendicine in combination with radiotherapy (GTRT) or radiotherapy alone (RT). It was reported that the response rate in the GTRT group was 93%, with 64% showing complete regressions and 29% partial regressions. This contrasts with a phase I study in the United States by Introgen that entered 106 patients, which were reported to have only a 10% tumor response rate, defined as a 30% reduction in tumor size, in patients who received gene therapy alone.[217] This response increased to 26.5% for the clinical biomarker defined population, resulting in a progression-free interval of greater than 12 months from initial treatment of patients who had prior chemotherapy. In the overall treatment population, tumor response was associated with a significant increase in survival. The median survival of responders was 16.9 months, a significant increase as compared with 5.4 months for nonresponders. Thus, there is some controversy regarding the Chinese studies; however, the resulting population of patients that have received Gendicine (≥3,000) has provided valuable information. One such observation is that Gendicine has a better response if injected directly into the tumor. This potentially minimizes any immune reaction against the Adv vector and improves the efficiency of p53 delivery.

The majority of gene therapy trials are focused on cancer, and to date, approximately 66% of the over 1000 gene therapy trials in the United States have been initiated for this indication. This represents approximately 63% of all clinical trials. The predominance of clinical vectors used is retroviral vectors, although Adv vectors are also being used extensively. The majority of therapeutic strategies are focused on immunotherapy, with the predominance of transgenes used being either cytokine or Ag. When one considers the timeline for most drug development, gene therapy is on target. Although there was considerable initial optimism, the reality is that a period of time and appropriate attention to toxicities, adverse events, and pharmacologic issues (including biodistribution and cell targeting) are required before success can be achieved. Great strides have been made as vector biology begins to catch up with improvements in vectors. It is our expectation that future successes (such as those found with SCID and retroviral vectors) can be expected, although future frustrations are also to be expected and appropriate conservatism must be maintained. One area that has a high potential for success is the utility of vectors such as VV and Adv to deliver Ags to DCs as a vaccine for the treatment of infectious diseases or tumors. Clearly, Adv and VV vectors have innate vector antigenicity, which is limiting these approaches and providing opportunities for "naked DNA" and formulated "naked DNA" for either vaccine priming or boosts. A successful clinical protocol will be achieved only if these liabilities are considered carefully, with appropriate attention to well-designed protocols that take advantage of the positive attributes of vectors and minimize their negative attributes. Within this review, we have attempted to stress the great strides have been made recently with targeting and to illustrate that the future is clearly bright.

ACKNOWLEDGMENTS

34 Therapeutic Antibodies and Immunologic Conjugates

Nai-Kong V. Cheung

SUMMARY OF KEY POINTS

- Because of their tumor selectivity, monoclonal antibodies offer exceptional opportunities for targeted therapy.
- As naked antibodies, they kill tumors by receptor blockade and by actively inducing apoptosis.
- Tumor cytotoxicity is mediated in the presence of white cells by activating antibody-dependent cell-mediated cytotoxicity; and in the presence of serum, it is mediated by complement.
- The effector functions of antibodies can be greatly enhanced as immunoconjugates, which include radioimmunoconjugates, immunocytokines, immunotoxins, immunoenzymes, immunoliposomes, and cellular immunoconjugates.
- Naked antibodies can, on occasion, have overlapping toxicity profiles with chemotherapy and radiation therapies.
- Dose-limiting toxicities of immunoconjugates depend on the cytotoxic moiety (e.g., myelosuppression in radioimmunoconjugates) being used.
- Antibodies are likely to be most beneficial at the time of minimal residual disease, especially when used in conjunction with standard therapy.
- The following antibodies have been licensed by the FDA for specific cancers:
  - Alemtuzumab (Campath): B-chronic lymphocytic leukemia (CD52)
  - Bevacizumab (Avastin): colorectal cancer (VEGF)
  - Cetuximab (Erbitux): colorectal cancer, head and neck cancer (EGFR)
  - Gemtuzumab ozogamicin (Mylotarg): acute myelogenous leukemia (calicheamicin, CD33)
  - Ibritumomab (Zevalin): non-Hodgkin's lymphoma (^{90}Y, CD20)
  - Rituximab (Rituxan): non-Hodgkin's lymphoma (CD20)
  - Tositumomab (Bexxar): non-Hodgkin's lymphoma (^{131}I, CD20)
  - Trastuzumab (Herceptin): breast cancer (HER2)
- In the coming decade, other monoclonal antibodies that are currently in various phases of clinical trial as well as those approved for nononcologic indications could be added to the list. The prospects for further innovation in this maturing modality are highly favorable.

INTRODUCTION

The clinical development of antibody therapy was accelerated by the introduction of the hybridoma technique in 1975 and the emergence of recombinant technology.[1] Through these innovations, individual plasma cells can be immortalized, and cloning of heavy and light chain repertoires from animals and humans is now possible. In the last three decades, monoclonal antibodies (MAb) have evolved from research tools to inclusion in a rapidly increasing list of licensed pharmaceuticals. They have generated excitement on many fronts and will likely play a pivotal role in the history of cancer medicine (Box 34-1). The clinical utility of MAb for in vitro diagnosis and ex vivo manipulation of blood or stem cells is well recognized. Their role in the treatment and prophylaxis of graft versus host disease is detailed in Chapter 32. The use of B-cell idiotype and anti-idiotypic antibodies as tumor vaccines is described in Chapter 6. This chapter summarizes the application of therapeutic antitumor MAb and immunologic conjugates in cancer therapy.

EFFECTOR MECHANISMS OF MONOCLONAL ANTIBODIES

Antitumor MAb can mediate highly effective tumoricidal functions both in vitro and in vivo (Fig. 34-1). These include signaling through receptor binding, antibody-dependent cell-mediated cytotoxicity (ADCC), and complement-dependent cytotoxicity (CDC).

Signaling by Receptor Cross-Linking and Receptor Blockade

When the antigen is a cell surface receptor, its clustering by multivalent MAb can induce apoptosis.[2] Apoptosis increases with hyper-cross-linking (e.g., CD20 target on lymphoma cells).[3–5] Both caspase dependent and independent programmed cell death pathways appear to be involved.[6] In AIDS-related lymphoma, anti-CD20 MAb diminishes p38MAPK signaling and Bcl-2 expression, while in non-AIDS-related lymphoma, signaling through CD20 inhibits AP-1 in addition to NF-κB, leading to downregulation of Bcl-$_{XL}$, sensitizing lymphoma cells to chemotherapy.[7] Direct receptor blockade by MAb has also been reported for EGF-R1[8] and HER-2 (EFG-R2),[9] leading to upregulation of the BH3-only protein Bnip3L, thereby sensitizing tumor cells to chemotherapy.[10] MAb inhibition of VEGF-R1[11] or VEGF-R2[12] can also enhance the efficacy of chemotherapy.

Cytophilic MAb and ADCC

The Fc region of IgG MAb interacts with both activating and inhibitory Fc receptors (FcγR).[13] In humans, there are four activating FcγRs: FcγRI (CD64) is a high-affinity FcγR, whereas FcγRIIA

Box 34-1. ANTIBODY THERAPY OF CANCER: HISTORICAL PERSPECTIVE

1901: Nobel prize awarded to Emil von Behring for work on serum therapy in collaboration with Shibasaburo Kitasato
1908: Nobel prize awarded to Paul Ehrlich for his work on passive immunization
1927: Serotherapy of chronic myelogenous leukemia
1975: Hybridoma technique of Hans Kohler and Caesar Milstein (winners of 1986 Nobel prize)
1980: MAb therapy of lymphoma
1986: FDA approval of MAb as standard pharmaceuticals
1992: Murine ^{111}In-anti-B72.3 for imaging colon and ovarian cancer
1997: Chimeric anti-CD20 (rituximab) for B-cell lymphoma
1998: Humanized anti-HER2 (trastuzumab) for breast cancer
1999: Humanized anti-CD33 immunotoxin for acute myelogenous leukemia
2001: Humanized anti-CD52 (alemtuzumab) for B-chronic lymphocytic leukemia
2002: ^{90}Y-anti-CD20 (Ibritumomab) for B-cell lymphoma
2003: Murine ^{131}I-anti-CD20 (tositumomab) for B-cell lymphoma
2004: Chimeric anti-EGFR (cetuximab) for colorectal cancer and head and neck cancer
2004: Humanized anti-VEGF (Bevacizumab) for colorectal cancer

(CD32A), FcγRIIIA (CD16A), and FcγRIIIB (CD16B) are low-affinity FcγRs. FcγRIIB (CD32B) is the only known inhibitory FcγR (Table 34-1). All FcγRs (except FcγRIIIB) are transmembrane glycoproteins that are anchored on neutrophils by glycosylphosphatidylinositol. Activating FcγRs (with the exception of FcγRIIA) require the accessory γ chain, which carries a cytoplasmic immunoreceptor tyrosine-based activation motif for activation. Immunoreceptor tyrosine-based activation motif becomes tyrosine phosphorylated by members of the Src-kinase family with subsequent recruitment of SH2-containing kinases. These events lead to the activation of phosphatidylinositol 3-kinase and phospholipase-Cγ, followed by protein kinase C activation and sustained calcium elevation.[13] These biochemical cascades trigger phagocytosis, degranulation, cytokine release, and antibody-dependent cell-mediated cytotoxicity. In sharp contrast to activating FcγRs, FcγRIIB is a single-chain receptor that carries the immunoreceptor tyrosine-based inhibitory motif in its cytoplasmic domain. Engagement of this inhibitory receptor downregulates both biochemical and cellular functions. The ratio of activating to inhibitory FcγRs on immune cells, such as dendritic cells, macrophages, and neutrophils, can greatly influence the antitumor properties of MAb.

Inflammatory mediators (interferon-γ or C5a) increase activating FcγRs and downregulate inhibitory FcγRIIB, while IL-4, IL-10, and TGF-β upregulate FcγRIIB, thereby raising the thresholds for cell activation. Removing the inhibitory signals by FcγRIIB-blocking antibodies have shown efficacy in preclinical models.[13] This is particularly relevant for cross-presentation of antigens that are acquired

Table 34-1 Properties of IgG Fc Receptors[13]

Fc Receptor	Function	Affinity for hIgG	Distribution on WBC
CD64			
FcγR1	A	High	PMN, MONO, MΦ, DC
CD32			
FcγRIIA	A	Low*	PMN, MONO, MΦ, DC, NK
FcγRIIB	I	Low*	PMN, MONO, MΦ, B-cell
FcγRIIC	A	Low*	PMN, MONO, MΦ
CD16			
FcγRIIIA	A	Intermediate	MONO, MΦ, NK, DC
FcγRIIIB†	A	Low*	PMN

A, activating; DC, dendritic cells; hIgG, human IgG; I, inhibiting; MONO, monocytes; MΦ, macrophages; PMN, neutrophils; WBC, white blood cells.
*Prefers antibody-antigen complex.

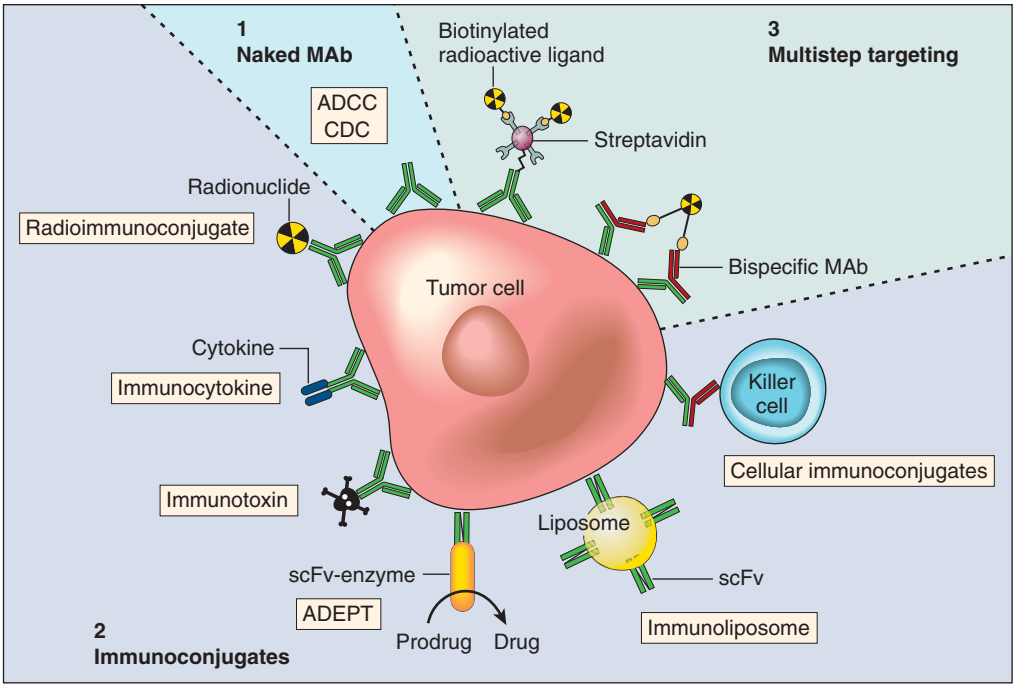

Figure 34-1 • Effector mechanisms of monoclonal antibodies. ADEPT, antibody-directed enzyme prodrug therapy; ADCC, antibody dependent cell-mediated cytotoxicity; CDC, complement-dependent cytotoxicity; MAb, monoclonal antibody; scFv, single-chain variable fragment. (Modified from Carter P, Improving the efficacy of antibody-based cancer therapies. Nat Rev Cancer 2001;1:118–129.)

endocytically through Fc receptors on dendritic cells during the induction of tumor-specific T-cell responses.[14] In addition to these FcγRs, a unique class of Fc receptor called FcRB (Brambell)/FcRn (neonatal) is found on endothelial cells and regulates antibody catabolism.[15] Although most therapeutic antibodies have been primarily IgGs, both IgA1 and IgA2 can also mediate efficient ADCC by binding to FcαRI (CD89) on human neutrophils and monocytes/macrophages.[16]

Certain cancer cells, such as colon carcinoma, lymphoma, leukemia, neuroblastoma, and melanoma, are effectively killed by natural killer (NK) lymphocytes, granulocytes, and activated monocytes in vitro in the presence of specific MAb. Depending on the affinity of the MAb for the individual FcγR, both NK cells (carrying FcγRII and FcγRIII) and neutrophils (bearing all three FcγRs) can mediate efficient ADCC. Because of the high affinity, FcγRI is generally occupied by monomeric IgG in human plasma. Human IgG subclasses (IgG1, IgG2, IgG3, and IgG4) have differential affinity for FcγRII and FcγRIII. Chimeric or humanized IgG1 antibodies (e.g., Lym-1 specific for HLA-DR and ch14.18 for GD2) exploit FcγRIII for lymphocyte ADCC while using FcγRII for myeloid ADCC.[17,18] Among the four IgG subclasses, IgG2 has the lowest affinity for the inhibitory receptor FcγRIIB.[13] Mouse IgG3 (e.g., 3F8 specific for GD2) can engage both FcγRII and FcγRIII in ADCC,[19] despite its low affinity for human FcγRs. The correlation of patient FCGR2A[20,21] and FCGR3A polymorphism[21,22] with clinical responses to MAb suggests that affinity for Fc receptor can influence antitumor responses in patients. In addition to FcγRs, adhesion molecules are critical for MAb-mediated ADCC. These molecules include CR3 (CD11b/Cd18),[17–19] plus CD66b[17] for neutrophil ADCC and LFA-1 (CD11a/CD18) for lymphocyte ADCC.[23] Because cytokines can increase the expression of adhesion molecules, GM-CSF or interferon-γ has been used to activate granulocyte ADCC,[18,24–26] and IL-2 has been used similarly for lymphocyte ADCC.[27,28] Furthermore, because both GM-CSF and IL-2 expand the effector cell pools, they can have additional benefits in tumor therapy. Optimal combinations of MAb and cytokines in the appropriate clinical setting are being explored.[29–31]

Complement Activation

IgG initiates the classical complement cascade by binding C1q to its CH2 domain. C1q is more avid for human IgG1 and IgG3 than for IgG2 and has no affinity for IgG4.[32] CDC potency of individual MAbs is also correlated with its slow off-rate.[33] Although some tumor cell lines (e.g., lymphoma and neuroblastoma) are sensitive to CDC, many are resistant to complement because of anticomplement surface proteins such as decay-accelerating factor (DAF, CD55),[34–36] homologous restriction factor (CD59),[34,37,38] and membrane cofactor protein (CD46).[35–37,39] The effect of complement activation extends beyond direct tumor lysis. Following complement activation, tumor-bound C3b is cleaved rapidly by plasma protease factor I to iC3b. Through CR3 (Mac-1 or $\alpha_M\beta_2$-integrin) and CR4 (CD11c/CD18, $\alpha_X\beta_2$-integrin) receptors on leukocytes, tumor cells are opsonized.[40] C3a and C5a, by-products of complement activation, are also potent mediators of inflammation[41] and are chemotactic for phagocytic leukocytes, drawing them to the tumor sites. C5a can also downregulate the inhibitory receptor FcγRIIB[13] or induce secondary cytokines to increase vascular permeability for both MAb and effector cells.

CLINICAL APPLICATION OF NAKED MAb DIRECTED AT CANCER CELLS

Lymphoma and Leukemia

In 1997, the anti-CD20 chimeric antibody rituximab became the first MAb to be approved by the U.S. Food and Drug Administration (FDA) for the treatment of cancer (Table 34-2). In a single-arm multicenter study of 166 patients with relapsed or refractory, low-grade, or follicular non-Hodgkin's lymphoma (NHL), rituximab at a dose of 375 mg/m^2 four times weekly produced an overall response (OR) rate of 48%, a complete response (CR) rate of 6%, and a partial response (PR) rate of 42%. Median time to progression in responders was 13.1 months.[42] In this study, rituximab demonstrated activity in chemoresistant disease (29%) and in patients relapsing after anthracycline therapy (51%). FDA approval was later expanded to include patients with bulky disease, retreatment of responders, and an extended treatment schedule of eight infusions. For most patients, rituximab was well tolerated.[43] Severe adverse events that were thought to be secondary to complement activation often occurred with the first infusion,[44] especially if there were high numbers of circulating tumor cells. These infusion-related reactions usually appeared 30 to 120 minutes after MAb injection and typically were associated with severe cardiopulmonary events, with deaths (<0.1%) occurring within 24 hours. B-cell depletion occurred in most patients, although serum IgG level remained normal for 12 months or longer without increased incidence of infection.[42] Severe mucocutaneous reactions occurred rarely (0.07%), resulting in some fatalities.

Because of its chemosensitization, rituximab was tested in diffuse large B-cell NHL. Chemotherapy (cyclophosphamide, doxorubicin, vincristine, and prednisone [CHOP]) plus rituximab was superior (76% CR, 69% progression-free survival [PFS], 83% overall survival [OS]) to CHOP alone (60%, 49%, and 68%, respectively).[45] In a randomized trial of 399 elderly subjects with previously untreated

Table 34-2 Naked MAb for Cancer Therapy

Antibody	Antigen	Antibody Form	Cancer	Effector Function/Molecule	Drug Status
Alemtuzumab[191]	CD52	huIgG1	CLL, PLL	ADCC, CDC	Campath: Licensed
Bevacizumab[222]	VEGF	huIgG1	CRC	Neutralizing VEGF	Avastin: Licensed
Centuximab[74]	EGFR	chIgG1	H&N CRC	ADCC, CDC; interrupts signaling pathways	Erbitux: Licensed
Rituximab[108]	CD20	chIgG1	CLL	ADCC, CDC; interrupts signaling pathways	Rituxan: Licensed
Trastuzumab[58]	HER2	huIgG1	Breast cancer	ADCC, CDC, receptor blockade	Herceptin: Licensed
3F8[29]	GD2	mIgG3	NB	ADCC, CDC	Phase II
ch14.18[62]	GD2	chIgG1	NB	ADCC, CDC	Phase II/III
Epratuzumab[46]	CD22	huIgG1	NHL	ADCC, CDC; interrupts signaling pathways	Phase III

ADCC, antibody-dependent cell-mediated cytotoxicity; ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; APL, acute promyelocytic leukemia; CDC, complement-dependent cytotoxicity; CRC, colorectal cancer; ch, chimeric; CLL, chronic lymphocytic leukemia; EGFR, epidermal growth factor receptor; H & N, head and neck cancer; hu, humanized; Ig, immunoglobulin; Licensed, licensed by the FDA; MAb, monoclonal antibody; MDS, myelodysplastic syndrome; NB, neuroblastoma; NHL, non-Hodgkin's lymphoma; PLL, prolymphocytic leukemia; VEGF, vascular endothelial growth factor.

diffuse large B-cell lymphoma, CHOP plus rituximab compared to CHOP produced an OR of 76% compared to 63% and a 2-year OS of 70% compared to 57%, respectively.[46] Other antibodies in active clinical trials included epratuzumab (huIgG1 anti-CD22) for NHL, as single agents[47,48] or in combination with rituximab,[49] and SGN-30 (chIgG1 anti-CD30) for Hodgkin's disease.[50]

Campath-1H (Alemtuzumab), a humanized rat IgG1 anti-CD52 MAb, has activity against recurrent chronic lymphocytic leukemia and T-cell prolymphocytic leukemia.[51,52] In an international phase II study involving 21 centers ($n = 93$ patients), Campath-1H was administered at 30 mg three times weekly for a maximum of 12 weeks to patients with relapsed or refractory B-cell chronic lymphocytic leukemia who had previously failed fludarabine therapy. OR was 33% (CR: 2%, PR: 31%). The median times to response and progression were 1.5 and 4.7 months, respectively, and median survival was 16 months. Grade 3 or 4 infections were reported in 26.9% of patients.[53] On the basis of this study, the FDA approved Campath-1H. Other clinical trials have also reported opportunistic infections, including bacterial sepsis and viral infections, as well as marrow aplasia following Campath-1H treatment.[52,54]

In myeloid leukemia, the addition of lintuzumab (huM195, IgG1, anti-CD33) to salvage induction chemotherapy was safe but did not result in a statistically significant improvement in response rate or survival in patients with refractory/relapsed AML.[55]

Solid Tumors

Trastuzumab (Herceptin) is a humanized MAb against the receptor tyrosine kinase ERBB2 (also known as HER-2/NEU) on breast cancer cells. It can mediate a diverse spectrum of antitumor effector mechanisms. Besides CDC and ADCC, it can induce HER-2 protein downregulation, prevent HER-2-containing heterodimer formation, initiate G1 arrest, induce p27, prevent HER-2 cleavage, and inhibit angiogenesis.[56] The application of trastuzumab in metastatic breast cancer achieved OR of 15% (3.6% CR, 11.7% PR, $n = 222$) with median response duration of 9.2 months and OS at 13 months.[57] Its efficacy in patients with recurrent or refractory ovarian cancer was limited by the low expression of HER-2 among these patients.[58] On the basis of its synergy with chemotherapy in vitro,[59,60] trastuzumab was tested in a large phase III trial of 469 patients with breast cancer, in which its combination with chemotherapy produced a longer median response duration (9.1 versus 6.1 months), higher OR (50% versus 32%), and lower death rate at 1 year (22% versus 33%)[61] than chemotherapy alone. However, there was a significant increase in cardiotoxicity. On the basis of this trial, the FDA approved the use of trastuzumab and paclitaxel as a first-line treatment of HER-2-overexpressing metastatic breast cancer. Subsequent studies showed that one year of treatment with trastuzumab after adjuvant chemotherapy significantly improved disease-free survival among women with HER-2-positive breast cancer (either node-negative or node-positive) after locoregional therapy and at least four cycles of neoadjuvant or adjuvant chemotherapy.[62] When combined with paclitaxel after doxorubicin and cyclophosphamide, trastuzumab also improved outcomes among women with surgically removed HER-2-positive breast cancer.[63]

Cetuximab (chIgG1 anti-EGFR) is another FDA-approved antibody designed to induce receptor blockade. It showed activity when given alone or when combined with irinotecan in patients with colorectal cancer (CRC).[64] In 346 patients with metastatic CRC that was refractory to irinotecan, oxaliplatin, and fluoropyrimidines, the overall response was approximately 12%.[65] An acneiform rash occurred in 82.9% of patients; a grade 3 rash was observed in 4.9%. Response and survival correlated strongly with the severity of the rash. In contrast, clinical benefit did not relate to EGFR immunostaining. Neither EGFR kinase domain mutations nor EGFR gene amplification appeared to be essential for response to cetuximab in this setting. When combined with radiotherapy for squamous cell carcinoma of head and neck (H&N), cetuximab improved the duration of locoregional control from 14.9 to 24.4 months, increased OS from 29.3 to 49 months, and improved PFS.[66] Except for the known acneiform rash and infusion reactions due to cetuximab, the incidence of grade 3 or greater toxic effects, including mucositis, did not differ significantly between the two groups. In phase I/II combinations with chemotherapy, cetuximab had activity for both H&N[67] and CRC.[65] In a phase III randomized study, cetuximab plus cisplatin significantly improved response but not PFS or OS among patients with metastatic/recurrent H&N cancer.[68] The addition of cetuximab to chemotherapy for non-small-cell lung cancer showed only slight benefit.[69] Panitumumab, a fully human antibody that is specific for EGFR generated by using human IgG-transgenic mouse technology, also showed promise in phase II/III clinical trials.[70]

Despite initial enthusiasm,[71] adjuvant therapy with edrecolomab (17–1A, Panorex), a mouse IgG_{2a} antibody specific for EpCAM on malignant and normal epithelial cells, did not improve DFS or OS in subsequent phase III studies in CRC.[72,73] Even with the lack of clinical efficacy, anti-idiotype network and T-cell responses against antibody-modified tumors were found.[74,75] Oregovomab (MAb B43.13, anti-CA125), a murine IgG_1 antibody for ovarian cancer, did not improve time to relapse in a phase III randomized trial of 145 patients.[76] A correlation of improved survival and human anti-mouse antibody (HAMA)/idiotype network response was of biologic interest.[77]

Among the ganglioside antigens on neuroectodermal tumors, GD3 (MAb R24 for melanoma)[78] and GD2 (MAb 3F8 and ch14.18 for neuroblastoma)[79,80] have been tested clinically. GD2 is present on a variety of solid tumors in addition to neuroblastoma, including osteosarcoma, retinoblastoma, some soft-tissue sarcomas, and brain tumors. Although the clinical effectiveness of anti-GD2 MAb for soft-tissue disease was modest, response of microscopic marrow disease was consistent.[31,81] Clinical development of anti-GD2 MAb was limited by its pain side effects, precluding dose escalation. At current doses, optimal application of anti-GD2 antibody is at the time of minimal residual disease.[82,83] An association of HAMA response and favorable patient outcome plus the induction of Ab2 and Ab3 through the idiotype network has also implicated a potential role of the host immune response in maintaining clinical remission.[84,85]

Complications and Contraindications

Toxicities of MAb are in general manageable and self-limited. Common acute reactions include fever, chills, headache, nausea, fatigue, angioedema, urticaria, pruritus, blood pressure fluctuations, and bronchospasm. Lethal or irreversible side effects include cytokine release (antilymphocyte MAb) and complement activation (anti-CD20) syndromes,[44] immune suppression (anti-CD52),[52,54] and cardiotoxicity (anti-HER-2).[61] A severe self-limited side effect is the pain syndrome from cross-reactivity of anti-GD2 MAb with peripheral pain fibers.[79,80] Murine MAb induces HAMA responses that can alter the pharmacokinetic and pharmacodynamic properties of repeat MAb injections. HAMA is directed primarily to the murine Fc portion of the antibody, although anti-idiotypic responses have also been reported.[86] With chimeric, humanized, primatized, and human antibodies, immunogenicity is drastically reduced.[87,88]

IMMUNOCONJUGATES

The clinical utility of naked MAb can be limited by both host (number and activity of effector cells, FcR polymorphism, and interference by inhibitory FcR) and tumor factors (antigen heterogeneity and complement regulatory proteins). Although the CDC and ADCC functions of naked MAb (see Fig. 35-1) can be improved by altering the Fc protein structure[87] or by modifying Fc-glycosylation,[89–91] substantial gains in clinical potentials of MAb can derive from immunoconjugates. These include (1) radioimmunoconjugates to deliver β- and α-emitters,[92] (2) immunocytokines to deliver cyto-

kines to tumor sites while minimizing systemic toxicities,[93] (3) immunotoxins,[94] (4) antibody-directed enzyme prodrug therapy (ADEPT) to pretarget enzymes to tumor sites for prodrug activation so that high local concentrations of active drugs are released without triggering systemic toxicities,[95] (5) immunoliposomes to deliver drugs or toxins,[96] and (6) bispecific MAb (pretargeted to tumor or by ex vivo arming) to direct cells or ligands selectively to tumor.[97] More recently, a multistep targeting strategy has been developed to enhance tumor to normal tissue ratios (see Fig. 35-1).[98,99] The tumor is pretargeted using an antibody construct which has affinity for the tumor on one arm and for a radiolabeled hapten on the other arm (e.g., bispecific antibody or single-chain Fv-streptavidin systems). The radiolabeled hapten is administered after the antibody construct is cleared from circulation. Substantial improvements in the therapeutic index can be achieved.[92,100,101]

Radioimmunoconjugates[92]

MAb have the potential to target and ablate tumors in radioimmunotherapy (RIT). Radioimaging can map the biodistribution of MAb and quantify the relative amounts of MAb deposited in various tissues and organs, thus allowing more precise radiation dose estimates in therapeutic studies. With the advent of single photon emission computed tomography and positron emission tomography, accurate dosimetry is readily achievable. In preclinical models, ablation of established xenografts is possible, although radiation damage to the marrow remains dose-limiting. For patients with lymphoma and leukemia, antitumor activity of RIT is highly reproducible, but major responses in solid tumors are rare. Unlike naked antibodies, the bystander effect of RIT from cross-firing of the radioisotopes accounts for most of the toxicities of radioimmunoconjugates, hence limiting their efficacy.

Choice of Radioiosotopes for Radioimmunoconjugates

Most clinical applications of RIT utilize β-emitting radioimmunoconjugates (Table 34-3). β-Particles have a relatively long range (0.8 to 5 mm) and low linear energy transfer (approximately 0.2 keV/μm). This long range results in the delivery of radiation not only to the antigen-positive tumor cells, but also to antigen-negative tumor cells, as well as to the surrounding normal tissues. Thus, β-emitters can treat bulky diseases effectively but are not optimal for killing single cells or micrometastasis. Most early human studies of RIT have used iodine-131 (^{131}I), a long-lived β-particle emitter. Because of its γ-particles emission, it is also suitable for dosimetry studies. However, this γ-particle emission poses a radio hazard at high treatment doses, necessitating patient isolation. In vivo dehalogenation can compromise tumor dose with subsequent thyroid damage from the released iodide. Yttrium-90 (^{90}Y) is a pure β-emitter; its lack of γ-radiation allows outpatient treatment. However, ^{90}Y has its limitations, including deposition in bone when dissociated from the MAb complex. Unlike ^{131}I, which binds directly to tyrosine residues on the MAb, ^{90}Y requires the coupling of a chemical chelator to the MAb. Furthermore, the lack of γ-emissions means that biodistribution and dosimetry studies of ^{90}Y necessitate trace-labeling with indium-111 (^{111}In), the biodistribution of which is not identical to that of ^{90}Y. Besides ^{90}Y, other β-emitters that have recently been explored include rhenium-186 (^{186}Re), rhenium-188 (^{188}Re), copper-67 (^{67}Cu), and lutetium-177 (^{177}Lu), but all have limitations.

Alpha-particles are helium nuclei; when compared with β-particles, they have a shorter range (50 to 80 μm) and a higher linear energy transfer (approximately 100 keV/μm).[102] As few as one or two α-particles can destroy a target cell. Radioimmunotherapy using α-emitters should result in less nonspecific toxicity to normal bystanders as well as more efficient single-cell killing. This is ideal for controlling minimal residual disease. α-Particle-emitting isotopes such as astatine-211 and bismuth-213 have been tested in clinical trials. ^{213}Bi-HuM195 (anti-CD33) administered intravenously for AML[103] and ^{211}At-8C16 administered intraventricularly or intrathecally for gliomas[104] have been well tolerated and produced clinical responses. The relative lack of extramedullary toxicities should encourage further development of this targeting technique for micrometastases or neoplasms on the surface of body compartments, such as ovarian cancer and leptomeningeal metastasis.[105–107]

Radiolabeled MAb for Lymphoma

In patient studies of RIT, sequestration of MAb in liver or spleen can compromise tumor delivery. To overcome uptake by the reticuloendothelial system, a large dose of naked anti-CD20 antibody is needed to reduce liver uptake before RIT (Table 34-4).[108] In a three-component regimen (Zevalin), rituximab at 250 mg/m^2 at the rate of 100 mg/h was first administered to clear peripheral blood B cells, followed within 4 hours by ^{111}In-ibritumomab tiuxetan and ^{90}Y-ibritumomab tiuxetan infusion. At 0.2 to 0.4 mCi/kg (7.4 to 15 MBq/kg) of ^{90}Y-ibritumomab, dosimetry data derived from four large trials showed median radiation absorbed doses of 7.4 Gy to spleen, 4.5 Gy to liver, 2.1 Gy to lung, 0.23 Gy to kidney, 0.62 Gy (blood-derived method) and 0.97 Gy (sacral image–derived method) to red marrow, and 0.57 Gy to total body, with a median effective blood half-life of 27 h.[109] Grade 4 neutropenia, thrombocytopenia, and anemia occurred in 30% to 35%, 10% to 14%, and 3% to 8% of patients, respectively. Myelodysplasia and acute myelogenous leukemia (AML) were reported in 1% of patients 8 to 34 months after treatment.[110] Serious grade 3 and 4 toxicities occurred in 3% of patients, and life-threatening events occurred in 1% to 5%. Four weeks after therapy, no circulating B cells could be detected, and recovery began about 12 weeks after therapy, usually to normal limits by 9 months. Serum IgG and IgA remained unchanged throughout, while IgM dropped below normal and recovered by 6 months; 3.8% of patients developed HAMA or human

Table 34-3 Choice of Radioisotopes for Radioimmunotherapy

Isotope	Particle(s) Emitted	Half-Life Hours	Maximum Energy (keV)	Mean Range of α- or β-Particle Emission (mm)
Iodine-131 (^{131}I)	β, γ	193	610	0.8
Yttrium-90 (^{90}Y)	β	64	2280	2.7
Copper-67 (^{67}Cu)	β	62	577	1.8
Lutetium-177 (^{177}Lu)	β	161	496	1.5
Rhenium-188 (^{188}Re)	β, γ	17	2120	2.4
Actinium-225 (^{225}Ac)	α	240	5935	0.05–0.08
Astatine-211 (^{211}At)	α	7.2	7450	0.05–0.08
Bismuth-213 (^{213}Bi)	α	0.77	5982	0.05–0.08

Table 34-4 Radiolabeled MAb for Radioimmunotherapy

Antibody Status	Antigen	Antibody Form	Cancer	Isotope	Drug	Status
Tositumomab[114–118]	CD20	muIgG2a	NHL	^{131}I	Bexxar	Licensed
Ibritumomab[109–111]	CD20	muIgG1	NHL	^{90}Y	Zevalin	Licensed
hMN14[92] (Labetuzumab)	CEA	huIgG	CRC	^{90}Y	CEA-Cide	Phase I/II

CRC, colorectal cancer; hu, humanized; Ig, immunoglobulin; Licensed, licensed by the FDA; mu, murine; NHL, non-Hodgkin's lymphoma.

antichimeric antibody. Among patients with relapsed or refractory NHL,[111] OR rate was 83% (37% CR and 40% PR). Median time to progression was 9.4 months. In a phase III randomized study, a single dose of 0.4 mCi/kg ^{90}Y-ibritumomab ($n = 73$) was more effective than rituximab, 375 mg/m^2/week for 4 weeks in patients ($n = 70$) with relapsed or refractory low-grade, follicular, or transformed NHL.[112,113] This difference was statistically significant for OR (80% versus 56%), CR (30% versus 16%), and the probability of ≥6-month durable responses (64% versus 47%), respectively. In other studies, increasing the dose or dose intensity of rituximab has not produced a meaningful improvement in outcome.

^{131}I-tositumomab (Bexxar, anti-CD20) achieved 71% OR (34% CR) in a phase II trial ($n = 59$) of chemotherapy-refractory/relapsed patients with NHL. In 17% of patients, HAMA was induced.[114] Using myeloablative doses of 280 to 785 mCi (calculated to deliver 25 to 72 Gy to critical organs), 30 of 36 patients (83%) achieved durable CR, with OS of 68% and PFS of 42% (median follow-up, 42 months).[115,116] Hypothyroidism developed in 60% of patients 6 to 12 months after therapy, and secondary myelodysplastic syndrome/AML was reported in 2% to 5%.[116,117] Similarly, myeloablative doses (10 to 31 Gy) of ^{131}I-anti-CD37 MAb produced 84% CR and 11% PR in patients with NHL, with eight patients in continual remission 46 to 95 months after therapy. Extramedullary toxicities were mild at doses of less than 23 Gy, beyond which cardiopulmonary toxicity became dose-limiting.[118]

Because the B-cell antigen CD22 is internalized, anti-CD22 antibody may be more effective when used in RIT than in its naked form. ^{131}I-epratuzumab (LL2, humanized anti-CD22),[119] ^{90}Y-epratuzumab,[120] and ^{186}Re-epratuzumab[121] have all shown antitumor activity against B-cell lymphoma. In addition, unlike anti-CD20, good biodistribution was achieved with a humanized antibody (hLL2) without the need for preinjection of unlabeled antibody. Other promising antigen systems for RIT include internalizing antigens such as CD19[122] and HLA-DR,[123] CR2,[124] CD37,[125], CD30,[126] and B-cell idiotypes.[127] In one study, HAMA response to the MAb Lym-1 appeared to correlate with improved survival.[128]

As part of autologous hematopoietic cell transplant conditioning for patients with NHL, cyclophosphamide and etoposide were combined with ^{131}I-tositumomab[129] or ^{90}Y-ibritumomab tiuxetan in one study.[130] In another study, carmustine, etoposide, cytarabine, and melphalan were combined with ^{131}I-tositumomab.[131] There were no significant added toxicities from RIT, and the EFS and OS were highly favorable when compared to historical controls. In stem cell transplant for relapsed mantle cell lymphoma, ^{131}I-tositumomab when added to high-dose etoposide plus cyclophosphamide also produced encouraging results.[132] The addition of RIT therapy to conventional conditioning regimens deserves to be explored further, especially among patients with high-risk aggressive lymphomas, mantle cell lymphoma, and relapsed follicular NHL.[133] Rituximab is an accepted treatment strategy for most patients with NHL.[134] However, most if not all patients eventually relapse and require further therapy. Although it can achieve a second response in follicular or low-grade NHL, resistance usually develops requiring switching to radioimmunotherapy with ^{131}I-tositumomab or ^{90}Y-ibritumomab.[135] The outcome for patients who are treated first with a radiolabeled antibody and then with an unconjugated antibody has not been evaluated. However, because of myelosuppression, patients might not tolerate other therapy after failing RIT. A general approach in NHL is to use rituximab after chemotherapy failure, followed by RIT if rituximab fails.

Radiolabeled MAb for Leukemia

Radiolabeled MAb targeted to lineage specific antigens have been safely administered to patients with leukemia.[136] ^{90}Y-anti-CD25 was active in acute T-cell leukemia (2 CR, 7 PR among 16 evaluable patients),[137] and myelosuppression was the primary toxicity. ^{131}I-anti-CD33 (AML, myelodysplastic syndrome [MDS], myeloblastic CML),[138,139] ^{90}Y-anti-CD33,[136] ^{131}I-anti-CD45 (AML, acute lymphoblastic leukemia, MDS),[140] and ^{188}Re-anti-CD66c (AML, ALL, CML)[141] all delivered significant radiation doses to the bone marrow and are particularly effective as part of a conditioning regimen for hematopoietic stem cell transplantation. Radioconjugates that emit α-particles (^{213}Bi-anti-CD33 and ^{225}Ac-anti-CD33) might be better suited for the treatment of small-volume disease.[142,143]

Radioimmunotherapy of Solid Tumors

The antitumor activity of RIT in solid tumors is less impressive (see Table 34-4).[144] A number of radiolabeled MAb have been tested in phase I/II setting in CRC with modest clinical benefit: ^{131}I-17-1A (specific for Ep-CAM), ^{131}I-B72.3 (pancarcinoma), ^{131}I-anti-CEA (carcinoembryonic antigen), ^{90}Y-CC49 (a second-generation murine antibody of B72.3), and ^{131}I-CC49 or ^{131}I-A33, some at myeloablative doses (50 to 300 mCi/m^2).[144] ^{131}I-hMN-14 (humanized anti-CEA IgG at 60 mCi/m^2) has been administered to patients in remission or with small-volume colorectal metastasis; the potential for long-term benefit will have to await formal randomized trials.[92] For breast cancer and ovarian cancer, RIT targets have included MUC1, B72.3, L6, CEA, and gp38, whereas in renal cell cancer, G250 has been the main antigen of interest.[144]

Intravenous anti-GD2 ^{131}I-3F8 was tested in children with metastatic neuroblastoma at high doses (6 to 28 mCi/kg).[145] Responses were seen in both soft-tissue masses and bone marrow. The use of myeloablative ^{131}I-3F8 (20 mCi/kg) to consolidate remission was tested in 35 patients (>1 year of age) with newly diagnosed stage 4 neuroblastoma.[31] Extramedullary toxicities were limited to hypothyroidism, which occurred despite aggressive thyroid protection using potassium iodide, liothyronine (T3), and potassium perchlorate. Intrathecal and intraventricular administration for leptomeningeal carcinomatosis and intratumoral therapy of malignant brain tumors using ^{131}I-81C6 (anti-tenascin MAb) have produced objective responses and prolonged patient survival.[146,147] ^{211}At-81C6 is an example of α-particle therapy for minimal residual disease in malignant glioma.[148] Intraventricular ^{131}I-3F8[149] and ^{131}I-8H9[150] are also being tested in RIT for leptomeningeal cancers in both children and

adults, with highly favorable CSF to blood radiation dose ratios; among children with recurrent neuroblastoma metastasized to the CNS, long-term remissions have been achieved.[151]

Multistep Targeting or Pretargeting

To improve tumor uptake and reduce systemic toxicity, a multistep procedure that pretargets the antibody before the binding of the cytotoxic ligand to the tumor has been employed successfully.[152] Generally, a tumor-specific antibody is conjugated to a ligand binder, such as streptavidin or avidin (with high affinity for biotin), or a ligand-specific antibody (binding to metal chelators such as diethylenetriamine pentaacetic acid [DTPA] or 1,4,7,10-tetraacetic acid [DOTA]).[98,153] In the first step, these antibody-streptavidin or F(ab′)2-streptavidin conjugates (172 to 200 kd) are allowed to localize to tumors in vivo, and any excess is cleared from the blood. A small radiolabeled ligand (or its biotinylated form) is then injected intravenously. The ligand penetrates tissues rapidly and, by virtue of the high affinity interaction, binds tightly to the antibody-conjugate at the tumor site. Unbound ligand is quickly excreted through the kidneys. Because of the short transit time of the toxic ligand (radionuclides or toxins), a substantial improvement in the therapeutic ratio is achievable without sacrificing the percent injected dose per gram in tumor.

Antibody pretargeting has improved tumor imaging for colorectal, lung, and medullary thyroid cancers, especially when positron emission tomography radioisotopes are used. Multistep targeting of 110 mCi/m^2 of ^{90}Y-DOTA was well tolerated except for dose-limiting gastrointestinal toxicity that was thought to be related to MAb NT-LU-10 cross-reactivity with the gut.[154] Delayed renal toxicity was also observed. A similar approach that was applied to MAb CC49 in GI cancer[155] and anti-CD20 MAb in NHL[156,157] achieved tumor doses of 0.289 Gy/mCi and 0.26 Gy/mCi, respectively, although the tumor-to-kidney dose ratio was less than 2.5. A three-step approach, which used biotinylated MAb, followed by avidin/streptavidin and then by biotinylated radiometal-chelate, was also applied to glioma with encouraging results.[100,158] The bispecific antibody pretargeting system takes advantage of a bivalent hapten that binds to the two arms of a tumor-localizing bispecific antibody.[92] When anti-CEA bispecific antibody was tested in patients with SCLC[159] and in patients with medullary thyroid carcinoma,[160,161] an average tumor dose of 0.192 Gy/mCi was achieved, accompanied by tumor stabilization in 45% of patients. Building on these early results, clinical studies combining with chemotherapy are under way.[162] Furthermore, pretargeting concepts may be potentially useful in targeting small ligands in addition to radioisotopes.

Immunocytokines

Cell-mediated cytotoxicity has been highly effective against tumors in vitro and in animal models. Immunocytokines[93,163] have shown remarkable success in activating and redirecting effectors to human tumors. Most of these studies have focused on NK, natural killer T, or T cells[93] and granulocytes.[18] Antibody-IL-2 immunocytokine can eradicate metastatic murine neuroblastoma while inducing long-term antitumor immunity.[93,163] Following initial successes with IL-2 immunocytokine, constructs containing other cytokines also have been tested with encouraging results.[93] These include IL-12, tumor necrosis factor, and lymphotoxin. This emerging technology has been successfully applied to a number of antigens and tumor models, including GD2, human epithelial cell adhesion molecule (hEpCAM), CEA, EGF-R, HER2, folate receptor, and B-cell idiotype. More recently, the combination of a plasmid DNA vaccine and IL-2 immunocytokine in the mouse model was shown to be more effective than when either one was administered alone.[164] KS-IL-2 (anticolorectal CA) and 14.18-IL-2 (anti-GD2) are both in clinical trials; their toxicity profiles are generally acceptable, but clinical efficacy has yet to be established.

Immunotoxins

Ribosome-inactivating toxins can be potent cancer drugs. One major limitation is the lack of tumor selectivity.[165] Two-chain toxins (e.g., ricin and diphtheria toxin [DT]) utilize their B chain for cell-binding and their A chain for inhibition of protein synthesis; other toxins (e.g., Pseudomonas exotoxin [PE], Pokeweed antiviral protein, and gelonin) have a built-in receptor for cell attachment. When conjugated to MAb, they become immunotoxins. These toxins can be genetically modified for MAb conjugation and for improved safety profile.[94] In recombinant toxins (e.g., PE40, PE38, or diphtheria toxin DAB_{486}), the cell-binding domains are replaced by single-chain variable fragments (scFv).[94,165]

Various monoclonal MAb have been conjugated to different toxins for clinical trials:[165] ricin toxin A chain (RTA conjugated to anti-CD7, anti-CD22, and anti-CD25), DT (anti-IL-2R), and PE (anti-CD25, anti-CD22,[166] anti-Lewis Y,[167] and anti-HER-2). A common toxicity is the vascular leak syndrome, characterized by marked fluid overload, dyspnea, and sensorimotor neuropathies.[168] Deglycosylated RTA devoid of mannose and fucose has reduced hepatic sequestration, allowing longer serum half-life. An OR of 31% (2.6% CR, 29% PR) was achieved in patients with NHL following anti-CD22-deglycosylated RTA treatment.[169] Among 16 patients with cladribine-resistant hairy cell leukemia, anti-CD22-dsFv-PE (RFB4[dsFv]-PE38, BL22) induced 11 CR and 2 PR.[170] In addition to transient hypoalbuminemia and elevated aminotransferase levels, 2 patients had serious but reversible hemolytic-uremic syndrome. Other highly toxic natural compounds have also been explored recently, such as calicheamicins[171] and maytansinoids.[172] Gemtuzumab ozogamicin (Mylotarg) is an anti-CD33 antibody that is conjugated to calicheamicin. Acting like a prodrug, calicheamicin is released from the antibody following internalization, forming a diradical that induces double-strand DNA breaks. Gemtuzumab was active in childhood refractory AML[173] and achieved a 30% response rate among refractory AML patients 60 years of age or older.[174] In contrast, antimucin MAb-calicheamicin conjugate has not been successful to date in solid tumors.[175] With most immunotoxins, immunogenicity has been a major constraint, although pegylation may reduce immunogenicity.[176]

Immunoenzymes for ADEPT and Drug-Antibody Conjugates

To enhance the effector functions of MAbs, drugs have been conjugated to MAb for selective tumor delivery. Doxorubicin, melphalan, methotrexate, and vinca alkaloids conjugated to MAb have limited clinical success. BR96-doxorubicin directed at Lewis Y antigen has shown no clinical benefit in phase II trials in breast cancer[177] or gastric cancer.[178] Another novel approach (ADEPT) uses MAb to deliver a covalently conjugated enzyme to the tumor, which can then activate a nontoxic prodrug.[95,179] Despite preclinical successes, ADEPT has been difficult to translate into clinical benefit. Significant impediments to broaden their clinical implementation include immunogenicity of antibody-enzyme conjugate, as well as the presence of endogenous enzymes or endogenous substrates and endogenous inhibitors of these enzymes within the tumors.

Immunoliposomes

With advances in liposome technology, several liposomal agents have been licensed for use in cancer patients.[180,181] When coated with polyethylene-glycol, uptake by the reticuloendothelial system is inhibited, thereby prolonging residence time in the blood. Concurrent developments in drug-loading technology have improved the efficiency and stability of drug entrapment in liposomes. Although there is passive accumulation of liposomes in tumors through enhanced permeability and retention, their uptake can be greatly enhanced when engrafted with surface antibodies or their derivatives.

For example, scFv or Fab can target liposomes for uptake into tumors bearing CD19,[182] HER-2,[183] EGFR,[184] and GD2.[185] When liposomes fuse with the tumor targets, their contents can be efficiently delivered intracellularly. While their potential is high, the clinical benefit of MAb-targeted liposomes remains to be proven.

Cellular Immunoconjugates with Bisepecific Antibodies

Tumor-selective MAb can be rendered cytophilic by conjugation with MAb that are specific for trigger molecules on T-lymphocytes, NK cells, and granulocytes.[186–188] These molecules include CD3, CD28, Fc receptors (CD64, CD16), and FcαRI (CD89).[97] One binding site of the bispecific antibody engages CD3 on T-cells; the other binding site determines tumor specificity, for example, B-NHL (CD19),[189] breast cancer (HER-2),[190] and Hodgkin's lymphoma (CD30).[191] Similar successes have been reported for the trigger molecule CD28 for acute lymphoblastic leukemia (CD19 and CD20)[192,193] and Hodgkin's disease.[194] A phase I trial of the bispecific (HER-2, CD3) and trifunctional (metastatic breast cancer, T cells and FcγRI/III) antibody at low doses (100 μg per injection) was tolerable, tumor responses being noted in 5 of 15 patients.[195] Bispecific MAb targeted at FcγRI can redirect ADCC to specific tumors, including epithelial cancer (EGF-R)[196] and breast cancer (HER-2),[197] while those directed at FcγRIII have been successful against Hodgkin's disease (CD30)[198] and breast cancer (HER-2).[197] Because serum IgG competes for FcγR, bispecific MAb that is made to recognize the FcγR outside its Fc-binding domain is also being tested. Although bispecific MAb can induce generalized cytokine release from leukocytes and trafficking of effector cells into tumors is limited,[186] this treatment modality is being actively explored in clinic trials.

IMPROVING THE EFFICACY OF ANTIBODY-BASED CANCER THERAPIES

Measures have been taken to improve the efficacy of antibody-based cancer therapies.[199] To reduce immunogenicity, MAb have been chimerized and humanized, cloned from phage display libraries,[200] or produced in human IgG-transgenic or human transchromosomal mice (Fig. 34-2). Chimeric MAb are made by joining the antigen-combining variable domains of a mouse MAb to human constant domains: mouse VL to human CL and mouse VH to human CH1-CH2-CH3.[87] In humanized MAb, the antigen-binding loops, known as complementarity-determining regions from a mouse MAb are grafted into a human IgG.[201] Human antibodies can also be derived from scFv or Fab phage display libraries,[202] which are particularly useful for self-antigens.[203] Alternatively, human MAb can be made from hIgG-transgenic mice.[204]

Because Fc is necessary for antitumor effect, chimerizing mouse MAb with the human IgG1 or IgG3 Fc regions can improve ADCC and CDC functions. Similarly, removing FcγRIIB inhibitory receptor recognition also can enhance antitumor activity.[205] Point mutations in the Fc region have increased its affinity for activation receptors or decrease its affinity for the inhibitory receptor.[206] Glycosylation of IgG at Asn297 stabilizes the tertiary structure of the C_H2 domain, which is critical for effector function.[207] Glycosylation depends on the producer line, and increasing the bisected complex oligosaccharides in the Fc region[89] or defucosylation has greatly improved ADCC properties of MAbs.[90] Complement-dependent cytotoxicity can also be improved by Fc region mutations to increase C1q binding.[208]

The antigen-binding affinity, molecular architecture, and oligomerization states of MAb can be reengineered to enhance tumor delivery and therapy.[209] For example, affinity can be increased by using phage display libraries,[210] ribosome display,[211] DNA shuffling,[212] or yeast display combined with DNA shuffling.[213] However, because the binding-site barrier can impede tumor penetration if the MAb has high affinity,[214] the optimal MAb may indeed be a low-affinity IgG binding to a surface antigen that is expressed at high density. In addition, the size of the MAb is critical. ScFv are small (25 kd) and rapidly cleared by the kidney. On the other hand, oligomers with molecular weights in the range of 100 to 200 kd should be ideal for tumor targeting. Besides increasing avidity, oligomerization can increase antitumor activity through a multitude of mechanisms, including CDC/ADCC, induction of apoptosis, growth arrest, and synergy with chemotherapy or immunotoxins.[4] While scFv are a powerful building block for polymeric forms or novel fusion proteins,[215,216] single-domain antibodies may further expand the possibilities of antibody-based cancer therapies.[217]

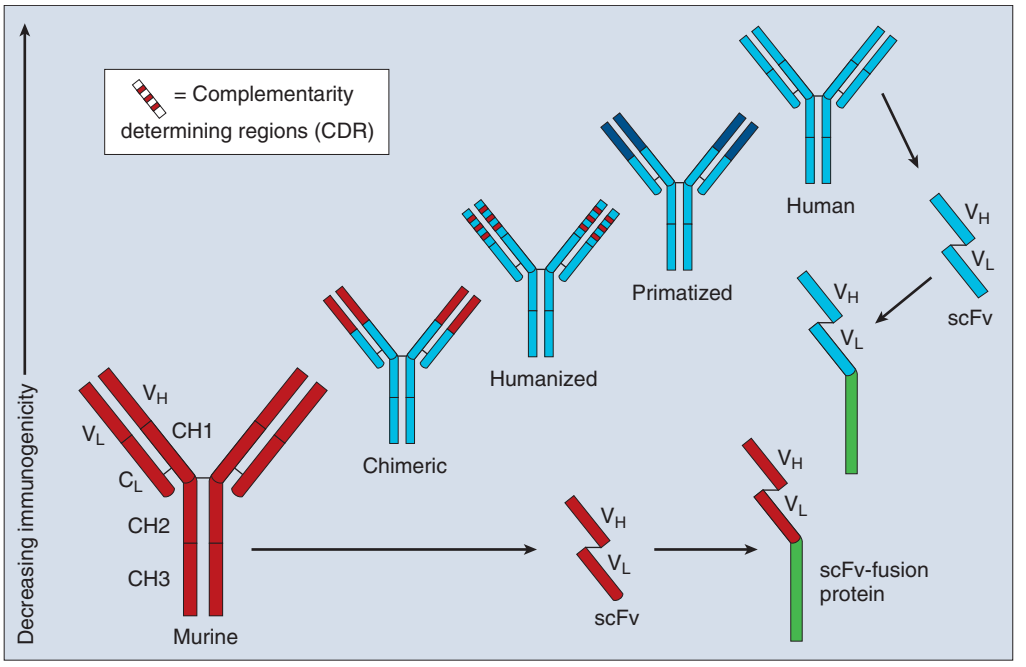

Figure 34-2 • Immunogenicity of MAb. CH1, CH2, and CH3, constant region domains of an IgG heavy chain; scFv, single chain variable fragment; V_H, variable region of the heavy chain; V_L, variable region of the light chain. *Red,* mouse; *blue,* human; *green,* recombinant protein to which scFv is genetically fused.

ALTERNATIVE TARGETS FOR ANTICANCER ANTIBODIES

Besides the ability to block receptors from interaction with their natural ligand, MAb can inhibit receptor dimerization or receptor interaction with coreceptors.[218] HER-2 is a ligand-less member of the ErbB receptor family that functions as a coreceptor with HER-1/EGFR, HER-3, and HER-4. MAb 2C4 sterically hinders the recruitment of HER-2 into HER ligand complexes and inhibits in vitro and in vivo growth of breast and prostate tumors. The humanized antibody Omnitarg is currently in clinical trial. Most of the MAb targeting effort has been focused on individual tumor cells, but alternative strategies directed at tumor neovasculature,[219] tumor stroma,[220] or tumor infiltrating T cells[221] are promising approaches. Bevacizumab (Avastin), a humanized IgG1 that is specific for vascular endothelial growth factor (VEGF) was effective for metastatic renal cancer[222,223] and, when combined with chemotherapy, for non-small-cell lung cancer,[224] metastatic CRC,[225] and metastatic breast cancer.[226] Furthermore, MAb can be made to inhibit homing of angiogenic progenitors (e.g., anti-VLA4 [Natalizumab][227] and anti-VEGF-R1[228]) or to block the VEGF-R2/KDR (e.g., IMC-1C11, chimeric anti-KDR).[229,230] Targeting tumor vasculature may have significant advantages over direct tumor targeting,[231] in that endothelial cells, unlike tumor cells, are less likely to acquire resistance. Another angiogenesis target is $\alpha V\beta 3$ integrin, which initiates endothelial proliferation, migration, and matrix remodeling.[232] In a phase I trial, chimeric IgG1 (MEDI-522) that is specific for $\alpha V\beta 3$[233] was well tolerated, and tumor perfusion was possibly modified. Ipilimumab (also known as MDX-010) is a fully human antibody against human CTLA-4, a molecule on T cells that attenuates their immunocompetence. Ipilimumab is currently being tested in metastatic melanoma as monotherapy or in combination with melanoma-peptide vaccine.[221]

WHAT IS THE FUTURE ROLE OF MAb AS A TREATMENT MODALITY?

Can One Size Fit All?

Human tumors and their response to MAb-based therapies are heterogeneous. Although MAb share common structures and properties, the successful translation of their antitumor activity into survival benefit in patients requires a much better appreciation of the clinical biology of each individual tumor type as well as an understanding of the fundamental biology of the antigens being targeted.

Is There an Optimal Time to Use MAb Therapy?

It is likely that MAb therapy is most beneficial at the time of minimal residual disease (MRD). Accurate and sensitive measures of MRD will provide objective indicators of tumor response to help guide clinicians to apply this modality more effectively.

What It the Future Role of Antibody Therapy in Treating Cancer?

As a rapidly expanding class of pharmaceuticals, MAb are now an important modality for cancer treatment. They have demonstrated antitumor activity in a broad spectrum of malignancies in the last two decades. The successful integration of MAb and immunoconjugates with other treatment modalities has the potential for achieving further improvements in symptom control and patient survival.

35 Complementary and Alternative Medicine

James M. Metz and Heather Jones

SUMMARY OF KEY POINTS

- Complementary and alternative medicine (CAM) therapies are used by a significant number of cancer patients worldwide.
- Providing a nonthreatening environment for discussion of CAM will facilitate communication on this topic between physicians and patients.
- Many types of CAM may interact with conventional medications or cancer treatments to increase the toxicity or decrease the efficacy of the drug or therapy.
- Some CAM therapies have been shown to have side effects that mimic those of conventional cancer treatments.
- Physicians must warn patients about potential problems with CAM. They also should support those patients using those types of CAM that do not adversely affect conventional cancer treatment.
- A number of complementary therapies may be effective for stress reduction and combating pain or nausea.
- Health care providers must familiarize themselves with the most common CAM treatments used by patients with cancer so that informed discussions can occur.

INTRODUCTION

Complementary and alternative medicine (CAM) has infiltrated mainstream medical practices in recent years, driven mainly by patient desires to obtain these treatments. These therapies have gained increased exposure through television, radio, magazines, books, and the Internet. Most health care professionals have limited formal education on the subject and are unable to provide informed responses to questions about complementary and alternative methods. Patients' expectations of their health care team have expanded to include open discussions of CAM. They no longer accept labeling all of these CAM treatments by health care providers as ludicrous and unfounded. Numerous interactions with conventional medical therapies have been described in the scientific literature, so there are important medical reasons for physicians to understand the utilization of CAM. Medical professionals must be able to converse intelligently with the patient about CAM practices and to provide information about relevant dangers and hoaxes when appropriate. Health care providers also must learn to accept patients' use of alternative and complementary techniques so long as such modalities are safe.

Physicians must ask all patients under their care specifically about alternative and complementary medical practices that may be in use. Patients are more likely to discuss their adoption of these techniques openly when the physician provides a nonthreatening environment for discussion. Patients who have cancer are prime consumers and targets for alternative medical therapies. Many feel that they are in a desperate and hopeless situation. Many simply want to regain control over their lives, and use of CAM is an expression of this desire.

This chapter provides a general introduction to the topic of CAM and considers some of the more commonly used CAM therapies. Not every CAM modality in use is covered, because this would be beyond the scope of the discussion; rather, relevant information on commonly used therapies is presented to promote optimal physician-patient interactions whenever CAM treatments are discussed.

DEFINITION OF COMPLEMENTARY AND ALTERNATIVE MEDICINE

The terms *alternative medicine* and *alternative therapy* have become popular in recent years but do not accurately reflect or encompass the practices for which they are used. *Alternative* is the generally accepted term that refers to a diverse assortment of philosophies, theories, diagnostic, preventive, and therapeutic practices not generally viewed as arising from or belonging to the modern Western medical paradigm.[1] Other popular terms are *complementary, unconventional*, and *integrative medicine*. Each of these terms attempts to encompass the practice modalities not common to Western medicine. The terms *complementary medicine* and *integrative medicine* often are used to acknowledge the combination of these nontraditional treatment modalities with more conventional views and therapeutic approaches. Although some authors prefer to define alternative medicine as treatment approaches not amenable to combination with conventional therapy,[2,3] several other terms have been used to define this subject: *unconventional, unorthodox*, *nontraditional*, *holistic*, and *non-Western*.[1]

The National Institutes of Health (NIH) Office of Alternative Medicine established a Panel on Definition and Description, charging it "to establish a definition of the field of complementary and alternative medicine for purposes of identification and research; and to identify factors critical to thorough and unbiased description of CAM systems and practices that would be applicable to both quantitative and qualitative research."[4] The panel defined complementary and alternative medicine as follows: Complementary and alternative medicine is a broad domain of healing resources that encompasses all health systems, modalities, and practices and their accompanying theories and beliefs, other than those intrinsic to the politically dominant health system of a particular society or culture in a given historical period. CAM includes all such practices and ideas self-defined by their users as preventing or treating illness or promoting health and well-being. Boundaries within CAM and between the CAM domain and the domain of the dominant system are not always sharp

Box 35-1. COMPLEMENTARY AND ALTERNATIVE MEDICINE AS DEFINED BY THE NATIONAL INSTITUTES OF HEALTH

In 1992, the National Institutes of Health (NIH) convened a meeting to discuss the major areas of alternative medicine and to direct future research activities.[1] As part of this meeting, the group defined the following seven fields of alternative therapy:

1. **Alternative systems of medical practice.** This field includes "folk" medicine and organized health care systems based on alternative practice. Examples include acupuncture, homeopathy, and naturopathy.
2. **Bioelectromagnetics.** Researchers in this field study how living organisms interact with electromagnetic fields. Magnetic field therapy is one example of bioelectromagnetics practice. It most often is used to treat osteoarthritis and nonunion of bone fractures.
3. **Diet and nutrition.** This field includes the use of special diets to improve health. Examples include the macrobiotic diet and orthomolecular medicine.
4. **Herbal remedies.** This field includes the use of herbs and plants to promote and improve health. Herbal therapy is considered to be the most popular alternative therapy used in the United States. It is used for many conditions.
5. **Manual healing methods.** Practitioners use touch and manipulation to promote and improve health. Examples include chiropractic therapy, massage therapy, and therapeutic touch.
6. **Mind-body interventions.** This form of therapy uses the interconnectedness of mind and body to improve health. Examples include psychotherapy, meditation, guided imagery, hypnosis, biofeedback, and prayer. Such interventions most commonly are used to treat nausea and vomiting (particularly for anesthesia- or chemotherapy-induced hyperemesis gravidarum) and postoperative dental pain.
7. **Pharmacologic and biologic treatments.** This field includes treatment with drugs and vaccines not accepted by mainstream medicine. Examples include the use of shark cartilage, EDTA for chelation therapy (for coronary artery disease), and apiotherapy.

EDTA, ethylenediaminetetra-acetic acid.

or fixed. Box 35-1 presents a list of CAM modalities defined by the NIH.

UTILIZATION OF COMPLEMENTARY AND ALTERNATIVE MEDICINE

Many studies have been performed to identify the utilization patterns of CAM throughout the world. This section addresses the worldwide use of CAM, which can be influenced by demographic factures such as culture, religion, race, geographic location, and gender of the patient. A number of questionnaire studies have suggested that a significant percentage of cancer patients are using CAM. Estimates range from 9% to 64%, depending on the definition of CAM and the cancer patient population studied.[5–10] Some evidence indicates that the use of these treatments within the general U.S. population increased during the past decade.[11] Also, studies suggest that many patients do not discuss their use of these treatments with their physicians.[8]

Risberg and colleagues evaluated 252 cancer patients in Norway and found a 45% likelihood (i.e., cumulative risk) of using CAM among patients under observation or cancer treatment.[5] Females were much more likely to use these therapies than males. Liu and associates evaluated 100 patients with advanced cancer receiving conventional cancer treatment in China; 64% were found to be using some form of CAM, mainly herbal therapies.[6] Begbie and colleagues evaluated 319 cancer patients in Australia and found that 22% used CAM treatments; 40% of the users did not discuss them with their physicians.[7] Downer and coworkers found that the 16% of 415 patients with cancer surveyed in England used CAM. The typical user of CAM tended to be younger, of higher socioeconomic status, and female.[8]

In the United States, the use of CAM also is prevalent. In a telephone survey of patients with cancer, 452 of 5047 (9%) admitted to using CAM techniques.[9] Mind-body interventions and diet therapies were the most common. A study from the University of Pennsylvania showed that 40% of patients with cancer undergoing radiation therapy were using CAM. However, only 7% admitted to using these therapies during the standard history and physical examination.[11] Only after the addition of a few directed questions regarding use of CAM did a majority of these patients reveal that they were using these therapies. Exercise and prayer were specifically excluded as CAM practices in this study. A recent study of patients with stage I and II breast cancer found that a complementary or alternative medical system was used by 57.3% of the patient population.[10] When exercise therapy was excluded from the analysis, 40% were using CAM. Younger age and increasing income and educational level were predictors of such use. The definition of CAM can vary significantly between studies, which affects the percentage utilization reported, as noted. Clearly, it is important to understand the precise definitions used in each study when comparisons are made.

Very limited information is available concerning the use of CAM therapies in the pediatric oncology population. An interview of the parents of 84 pediatric patients with cancer in The Netherlands found that 26 of 84 children (31%) had used or were using CAM.[12] Among these children, 19 of 26 (73%) had suffered a relapse before using these techniques. Fernandez and associates performed a study of pediatric oncology patients in British Columbia and found that 42% of the 366 respondents used some form of CAM treatment.[13]

CANCER PREVENTION AND COMPLEMENTARY AND ALTERNATIVE MEDICINE

A growing body of literature relating cancer prevention and CAM is available to the public. More than 50% of U.S. adults use some type of vitamin, mineral, or other micronutrient supplement.[14] Several studies indicate that users of dietary supplements believe that supplements can prevent or treat chronic diseases, such as cancer and cardiovascular disease, despite limited scientific support for the efficacy of such use.[15–18] Information about micronutrient supplements is becoming more common in the popular medical literature and is creating increased curiosity and a broader awareness. The explosion of the micronutrient supplement market is compelling physicians to become aware of dietary supplements. Whether or not they are used in clinical practice is a decision for the individual physician. In view of the increasing number of patients who are using micronutrient supplements, however, it is imperative that physicians have a good understanding of this topic (Box 35-2).

Antioxidants

Fruits and vegetables appear to be protective against the major cancers.[19] People who eat more fruits and vegetables that are rich in carotenoids or who have higher serum beta-carotene levels have a lower risk of cancer, according to randomized trials in human populations.[20] The antioxidant vitamins—vitamin A and related compounds such as beta-carotene, as well as vitamins C and E—are prominent components of many fruits and vegetables. Conjecture regarding the micronutrients responsible for this beneficial effect has been extensive because the antioxidant vitamins function as scavengers for DNA-damaging, mutagenic oxygen free radicals.

Box 35-2. WHY PATIENTS USE COMPLEMENTARY AND ALTERNATIVE MEDICINE

The complex trend of public awareness of and use of complementary and alternative medicine (CAM) has grown extraordinarily in the past decade. This seemingly insatiable desire for ancient philosophies and approaches to medical care by the general public seems particularly odd because it comes at a time of extraordinary technological and therapeutic advances. The physician should strive to understand what motivates a particular patient to seek CAM therapies before entering into a discussion with a patient—reaching this understanding can be quite challenging. The clinical literature for the most part has done an excellent job in documenting the incidence and patterns of CAM use but often has overlooked the more important question of why patients choose alternative modes of care. This motivation stems from a complex combination of social, cultural, philosophical, and personal factors that often differ among ethnic groups and disease types.

One reason for this phenomenon, no doubt, is the enormous increase in public access to worldwide information available on the Internet and from extensive media coverage. Commercial advertising and continuous exposure through the lay press, ranging from tabloid publications to magazines, medical journals, and books, have vigorously promoted the concepts of disease prevention and healing by unconventional means, striking a responsive (and highly lucrative) chord in a truly global population.

Another reason for the popularity of CAM is the escalating cost of modern allopathic medical care. New technologies have been developed at a record pace, producing many medical, surgical, and diagnostic innovations, most of which are unquestionably improvements but which also are very costly. The expense and the resulting rationing of these new modalities by managed care programs in an attempt to reduce the costs of medical care have placed them out of reach for a considerable segment of the population. The outcome appears to be the creation of a strong public desire for a wide range of CAM modalities to prevent and treat the full scope of human illness.

Other reasons sited for CAM use have included an affinity for a holistic or natural approach to healing, the need to manage side effects, dissatisfaction with the mindset of physicians, and an overall failure of conventional therapies to meet patient needs. Additional insight can be gained by reviewing patient assessments of CAM providers. Patients often praise CAM providers for the ability to define an illness, the amount of time provided for patient visits, continued involvement of the same provider over the course of treatment, and the attention to personality and personal experience. The satisfaction with treatments received often is not contingent on clinical improvement with regard to the presenting complaint.

Many patients are more informed about complementary and alternative therapies than their physicians are, a situation that, in itself, should encourage physicians to learn more about CAM. CAM therapies offer patients "a participatory experience of empowerment, and authenticity, when illness threatens their sense of intactness and relationship to their world."* Understanding what motivates patients may better enable physicians to enter into a dialogue with them and encourage a positive physician-patient relationship.

*Pappus S, Perlman A: Complementary and alternative medicine: the importance of doctor-patient communication. Med Clin North Am 2002;86:1–10.

Accumulating epidemiologic evidence suggests that a number of micronutrients may decrease the incidence of cancers of epithelial cell origin. These include vitamin A, vitamin C, vitamin E, and beta-carotene. Dietary deficiency of vitamins A, C, and E has been implicated in the development of cancers of the lung, breast, oropharynx, stomach, bladder, prostate, and colon.[21–26] Squamous tissues deficient in vitamin A exhibit metaplastic differentiation that can be reversed by administration of vitamin A and related compounds.[27] Additional evidence suggests that diets rich in vitamin A and related compounds not only diminish the risk but also are protective against the development of certain cancers. Whereas vitamin C appears to inhibit the formation of carcinogenic nitrosamines that have been associated with the development of gastric cancer, vitamin E inhibits mutagenesis and cell transformation mainly through its antioxidant function.[28] Nonetheless, the role of vitamins C and E in neoplastic development remains particularly unclear. Although vitamins C and E function as antioxidants, little evidence is available to support any direct role for these vitamins in the inhibition or reversal of neoplastic growth and development.

Several recent studies of dietary supplementation highlight the importance of clinical trials in defining benefit.[29] Both the CARET (beta-carotene and retinol) and the alpha-tocopherol–beta-carotene trials suggest that pharmacologic doses of beta-carotene *increase* the risk of lung cancer among smokers or those with asbestos exposure.[30,31] A large, four-arm clinical trial of multiple dietary supplements in 30,000 subjects in Linxian, China, demonstrated no significant effect on cancer incidence. However, those subjects who received a combination of selenium, beta-carotene, and alpha-tocopherol enjoyed statistically significant lower total and gastric cancer–specific mortality rates.[32]

Vitamin D, Calcium, and Selenium

Among the many minerals required for normal tissue development, calcium and selenium have received the most attention with regard to carcinogenesis. Laboratory data, as well as preliminary clinical data, suggest a role for calcium deficiency in the development of colon cancer. In epidemiologic studies, an inverse relationship also has been reported between vitamin E, vitamin D, and calcium supplementation and prostate cancer.[33] In addition, laboratory studies have shown that the active metabolite of vitamin D, 1,25-dihydroxyvitamin D (calcitriol), inhibits growth of both primary cultures of human prostate cancer cells and cancer cell lines; however, the mechanism by which cellular growth is inhibited has not been clearly defined.[34]

Recently, a large randomized trial of more than 1000 patients with a history of polyps showed that daily supplementation with 1.5 g of calcium reduced new adenomatous polyp formation by 20%.[35]

The Nutritional Prevention of Cancer Study by Clark and associates randomized 1312 patients to receive placebo or 200 μg of selenium per day and was designed to evaluate the effect of this supplement on risk of developing new basal cell and squamous cell skin cancers. In the analysis of the primary outcomes, selenium supplementation had no effect on reducing the incidence of these skin cancers. After preliminary analyses showed a reduction in total carcinoma, however, the protocol was modified in 1990 to add total and cancer mortality, as well as the incidence of lung, colon, rectal, and prostate cancers, as secondary endpoints. Analysis of these endpoints revealed a preventive effect for cancers of the lung, prostate, colon, and rectum, but no reduction in risk of breast or bladder cancer.[36]

Soybeans

Soy products are the primary food source for the isoflavone glycosides genistin and daidzin, which are metabolized by colonic microflora to the biologically active aglycones genistein and daidzein. These compounds, along with lignans, are generically named phytoestrogens and have structural similarities to estradiol. Evidence suggests that the consumption of diets rich in soybean products is associated with lower cancer mortality rates, particularly for cancers of the colon, breast, and prostate.[37–40]

The soy protein Bowman-Birk trypsin inhibitor (BBI), also found in other beans and peas, now in clinical trials, has been shown to suppress carcinogenesis in laboratory animals and in in vitro transformation systems.[40]

It is difficult to study the effects of micronutrient supplementation on the formation of cancers, in view of the inherent complexity of carcinogenesis. Information about the mechanisms of chemopreventive agents that inhibit carcinogenesis is still imperfect. Elucidation of how various dietary components inhibit carcinogenesis will be instrumental in the development of novel dietary chemopreventive agents in the future. Results from large trials such as the Women's Health Initiative Trial and the Selenium and Vitamin E Cancer Prevention Trial (SELECT) will provide a great deal of information regarding the effects of dietary modification and calcium, selenium, vitamin D, and vitamin E supplementation on breast, prostate, and colon cancer.

COMPLEMENTARY AND ALTERNATIVE MEDICINE MODALITIES AND THEIR LEGISLATION AND REGULATION

National Center for Complementary and Alternative Medicine

In 1990, Congress became aware of the rapidly developing interest in CAM in the United States. In 1991, the Office of Alternative Medicine (OAM) was established at the NIH but did not have formal status as a section or subsection. Initially, it was given an annual budget of approximately $2 million. The budget was increased to $20 million by 1997, and the OAM has since been given increased status by being renamed the National Center for Complementary and Alternative Medicine (NCCAM), with an annual budget of $50 million.[41] The charge of the NCCAM is to begin to appraise various CAM products as scientifically as possible through controlled studies. The NCCAM has thus far been slow in reporting results, no doubt at least in part because of the complex nature of conducting meaningful double-blind, clinical trials with CAM products. Numerous studies, however, are now in various stages of completion through the NCCAM and many other facilities throughout the world. At present, 13 institution-affiliated centers of research on CAM exist in the United States, and 75 medical schools in the United States are now teaching integrative medicine courses to their medical students.[41]

Herbal Medicine

Herbs have been used for medicinal purposes for thousands of years. Ancient Egyptians used herbs for the treatment of disease as early as 3000 BC. Almost one fourth of the current pharmacopoeia is derived from botanicals. Digoxin is derived from foxglove, aspirin is derived from willow bark, narcotics are derived from opium poppy, and birth control pills were developed from the Mexican yam. With the advent of modern medical science, people came to believe that synthetic ingredients were more effective than those found in nature, and the use of herbal remedies quickly diminished, especially in the United States. Currently available herbal preparations are sold mainly as nutritional products.[42]

Today, herbs are widely used in Europe and are again gaining popularity in the United States.[43] The most informative longitudinal data on use of herbal medicine derive from two Harvard surveys.[43,44] The results indicated that between 1990 and 1997, the use of self-prescribed herbal medicines within the U.S. general population increased from 2.5% in 1990 to 12.1% in 1997. During the same period, the proportion of persons consulting practitioners of herbal medicine rose from 10.2% to 15.1%. These survey studies estimated that in 1997, the entire U.S. population spent approximately $5 billion on herbal medicines. Most of this was out-of-pocket expenditure.[43–45]

Regulation of Herbals

The over-the-counter availability of herbal medicines fosters the notion that these medications are safe, and many casual users have inadequate knowledge about the use of these medications. Users often avoid discussing the use of these medications with their conventional care providers unless specifically asked.[46] These factors may set the stage for potential adverse drug reactions and interactions. Consumers in the United States are accustomed to products that have been tested and approved before sale. The U.S. Food and Drug Administration (FDA) functions to oversee the safety of foods, drugs, and medical devices sold in this country.

Most herbal products in the United States are considered dietary supplements and thus are not regulated as medicines and are not required to meet the standards for drugs specified in the Federal Food, Drug, and Cosmetic Act. In 1994 the Dietary Supplement and Health Education Act (DSHEA) was passed. This legislation had profound effects on the regulation and marketing of herbal products in the United States. Herbs or other botanicals could be sold as dietary supplements and were not subjected to the rigorous regulations that applied to medicines.[47] Herbal products may be produced without the assurance of compliance standards for good manufacturing practice (although such standards are being developed), and they are marketed without previous approval of their efficacy and safety by the FDA. According to the DSHEA, the manufacturer of a herbal preparation is responsible for the truthfulness of claims made on the label and must have evidence that the claims are supported, yet the DSHEA neither provides a standard for the evidence needed nor requires submission of the evidence to the FDA. Under the DSHEA, the manufacturer is permitted to claim that the product affects the structure or function of the body, so long as no claim is made of efficacy for the prevention or treatment of a specific disease, and provided that a disclaimer is supplied informing the user that the FDA has not evaluated the agent. Some of the claims on the labels of herbal products suggest that they can be used to treat disease, and supplementary materials, produced by persons other than the manufacturer, that overtly promote such use may be available where the herbal remedies are sold. According to the DSHEA, the manufacturer is responsible for controlling quality and safety, but if a concern about safety arises, the burden of proof lies not with the manufacturer but with the FDA, which has to prove that the product is unsafe.[48,49]

Several European countries have implemented guidelines for licensing herbal remedies. In Germany, such products can be registered as medicines on the basis of information in approximately 300 monographs on herbs ("positive" monographs with concise information about terminology, composition, uses, contraindications, side effects, drug interactions, dosage, mode of administration, and actions, and "negative" monographs explaining insufficient benefits or unacceptable risks).[50]

The European Commission (which governs the European Union) has recently publicized a draft directive on the licensing of traditional herbal preparations. If accepted, this proposal will require all members of the European Union to introduce a simplified procedure for these preparations so that they can receive a "traditional use" registration without the need to present data on efficacy from randomized trials.[49,51] The simplified licensing approach allows a premarketing assessment of the quality and safety of a product and facilitates postmarketing surveillance and product recalls.[49]

Generally, herbal products are not evaluated by the strict preclinical toxicology and pharmacology guidelines that are in place for conventional drugs. Instead, the focus of the clinical trials is on the efficacy of the products. A number of herbal formulations currently are undergoing clinical trials. The FDA has established a hotline for information about herbal products and one for reporting adverse effects.[47]

Acupuncture

Acupuncture has been practiced in China for more than 5000 years. Around the same time, acupressure, which uses similar points without needles, was developed in Japan. Acupuncture may be recommended by some practitioners for a variety of conditions, but abatement of pain or of nausea and vomiting is of greatest interest for cancer patients.

Acupuncturists use fine needles that range in length from 0.5 cm to several centimeters. The needles, usually made of stainless steel or copper, are placed approximately 5 mm deep and are gently manipulated by hand. The needles may be stimulated with a weak electrical current or by heat. Many patients describe a tingling sensation and feel a sense of heaviness in the area where the needles are placed.

The classic acupuncture teaching states that a life force called *qi* (pronounced "chi," to rhyme with "eye") dominates every organism and flows along interconnected meridians through the body and crosses at specific points. The meridians surface at various locations denoting the acupuncture points (these points are very similar for both acupuncture and acupressure). The opposing forces of *yin* and *yang* must be in balance before *qi* can get the body's vital functions to work normally; imbalance causes an accumulation of lactic acid in the muscles. Stimulating the acupoints dissipates the lactic acid and restores the *yin-yang* balance and the flow of *qi*.

To date, scientists in the Western world have found no evidence to support the existence of *qi*, *yin*, or *yang*. Bing and colleagues observed that stimulation of acupoints with needles activates the subnucleus reticularis dorsalis neurons that send projections to the dorsal horn of the spinal cord at all levels.[52] These investigators suggest that this anatomic structure may be involved in the modulation of pain. Grossman and Clement-Jones postulated that the release of endorphins within the nervous system may reduce the perception of pain.[53] Of interest, it also has been shown that the acupoints have a similarity in location to some of the anatomic sites used for local and regional anesthesia.[54]

Cancer Pain and Acupuncture

Owing to the widespread use of acupuncture and evolving scientific studies, in 1997, an NIH panel of experts issued a consensus statement for the use of acupuncture. According to this statement, clear evidence supports the effectiveness of acupuncture for the treatment of postoperative and chemotherapy-induced nausea and vomiting, nausea associated with pregnancy, and postoperative dental pain.[55]

In the palliative care setting, acupuncture is increasingly being used alongside conventional medical treatment for pain and symptom management.[56] Select evidence indicates that acupuncture effectively reduces acute perioperative and postoperative pain.[57–60] Despite numerous observational studies showing the effectiveness of the technique for chronic cancer pain relief, randomized controlled trials (RCTs) of acupuncture remain scarce. A recent review of the published data revealed only a single high-quality RCT for pain control in cancer,[61] by Alimi and colleagues.[62] This study showed statistically significant pain relief with auriculoacupuncture in patients with cancer compared with those in two control groups: a "nonpoint" needling control group and a noninvasive control group. Numerous observational and case series suggest that acupuncture may help relieve a variety of pain symptoms, including postsurgical and treatment-induced breast pain, often resulting in reduction in analgesic requirements and an improvement in mobility and circulation.[63–70]

Non-Pain Syndromes and Acupuncture

Nausea and vomiting are harrowing symptoms that commonly accompany cancer treatments. Numerous RCTs and reviews have been performed using the traditional point and have shown efficacy for postoperative nausea and vomiting and chemotherapy-related nausea and vomiting.[71,72] Fatigue is a commonly encountered debilitating symptom in cancer and may persist after successful cancer treatment.[73,74] A recent study concluded that acupuncture was worthy of further study in the treatment of fatigue following chemotherapy.[75] Studies indicate that pilocarpine-resistant xerostomia can be ameliorated by acupuncture.[76] Vasomotor symptoms and hot flashes secondary to cancer treatment and hormone manipulation also have been ameliorated by acupuncture.[5,77,78]

Regulation of Acupuncture

Acupuncturists can be certified in either of two ways: They can complete a formal, full-time educational program that includes both classroom and clinical hours, or they can participate in an apprenticeship program. Acupuncturists also must complete a "clean needle technique" approved course. Medical doctors with training in acupuncture also can obtain board certification. Certification for formally trained acupuncturists is through the National Certification Commission for Acupuncture and Oriental Medicine (NCCAOM). Medical doctors are certified through the American Academy of Medical Acupuncture and must possess a valid medical license. Currently, 37 of the 40 states that regulate acupuncturists require NCCAOM certification.

In response to petitions submitted by the acupuncture community, the FDA has reclassified acupuncture needles for general use from class III, the category in which clinical studies are required to establish safety and efficacy, to class II, a category that involves less stringent control by the FDA but does require good manufacturing and proper labeling. Manufacturers are required to label FDA needles for single use only. Use of acupuncture needles for clinical practice would be restricted to qualified practitioners as determined by state practice laws.[47]

Homeopathy

From the Greek words *homoios* ("like") and *pathos* ("suffering"), homeopathy is a system of medicine whose first tenet is the "principle of similars": A substance that can cause symptoms in a healthy person possibly can encourage self-healing in a person with an illness presenting with similar symptoms. This principle was developed into a practice of medicine in the nineteenth century by the renowned German physician Hahnemann. The theory of homeopathy is rooted in three of Hahnemann's principles: (1) the "law of similars," which states that a substance that can cause disease in a well person can cure similar symptoms in the diseased; (2) the "principle of the minimum dose," which states that by diluting a substance, its curative properties are enhanced and its side effects minimized; and (3) prescribing for the individual, which advocates basing treatment not only on the medical diagnosis but also the patient's temperament, personality, and emotional and physical responses.[58]

The principles of homeopathy are not well understood by the public or the medical profession, yet medical consumers are using homeopathic treatments in increasing numbers. In the United States and Europe, the sale of homeopathic medicines increased by 20% to 30% per year in the 1980s and 1990s.[80] A recent survey study revealed that many women who have breast cancer turn to alternative treatments in the hope of minimizing adverse reactions to treatment, rather than in the hope of a cure,[81] and use homeopathy for the reduction of treatment-related side effects. Two reviews identified 11 additional RCTs of homeopathy between 1997 and 2001.[82,83] These trials did not show any strong evidence that homeopathy was effective for any specific condition, and some of the better-designed trials had the least positive results. Even more recently, a comparative study of 100 placebo-controlled trials of homeopathy and conventional medicine found no specific effect for homeopathy when sources of bias were removed.[84]

Two meta-analyses have been published suggesting that homeopathic remedies are more effective than is placebo alone. However, both studies conclude that the current research and literature in the field do not meet the rigorous, scientific proof needed to establish

efficacy of homeopathy for specific clinical conditions.[85,86] More research is needed before homeopathy can be declared clinically useful for any one condition.

Regulation of Homeopathy

Although in other countries, homeopathic training and certification have been available for decades, the United States has not had full-time homeopathic schools or accredited professional education for more than 40 years.

Only three states—Arizona, Connecticut, and Nevada—license homeopaths. The scope of practice varies but includes the use of substances of animal, vegetable, or mineral origin given in microdoses and prepared according to homeopathic pharmacology. All three states use licensure as a means to authorize practice. These states require a DO or MD degree, as well as certification in the study of homeopathy. Arizona and Nevada have independent examining boards. In Delaware and New Hampshire, the practice of homeopathy is regulated by the state, although under no specific board. The Council of Homeopathic Education has implemented a voluntary certification process that includes a written multiple-choice examination, an oral examination, a videotaped interview, and 10 case reports. A person can be admitted to examination only after completion of a required curriculum and clinical supervision. Thus far, this certification process has not been recognized by the U.S. (or other) medical boards.

The FDA currently is attempting to establish guidelines for the regulation of homeopathic products. The FDA takes the position that homeopathic remedies, which are used in the treatment of disease, are by definition drugs and should be regulated. In recent years, the FDA has exempted homeopathic products from the regular drug-reviewing process if such drugs have been reviewed and approved by the Homeopathic Pharmacopeia of the United States.[47]

Massage

Massage therapy has had a long and well-known history, having been known to the ancient Chinese and Japanese and the Greeks, Romans, and Egyptians. The "laying on of hands" was the primary form of healing throughout history in places such as ancient Greece, where Hippocrates wrote that the "physician must be experienced in many things, most especially in rubbing."[87] Massage therapy is considered a form of medical treatment in several countries where it is covered by national health insurance, including China, Japan, Russia, and West Germany. In the United States, massage therapy still is considered a CAM modality. The popularity of massage therapy is growing. National and international massage therapy associations increased their membership by thousands of therapists during the 1990s.[88]

Regulation and Training for Massage

To become certified, massage therapists must complete a formal therapeutic massage bodywork program. They also may be considered for certification if they have training in anatomy, physiology, and kinesiology, as well as formal education and professional experience in bodywork or massage, or both. Massage provider practice acts for the regulation of massage exist in 22 states. Most statutes include directives for the treatment of soft-tissue or muscle, or both. Techniques may include, but are not limited to, friction, beating, and percussion. Types of health conditions treated, depending on the practice act, include maintaining good health, improving muscle tone, and reducing stress. Board certification is through the National Certification Board for Therapeutic Massage and Bodywork and is required in 20 of the 29 states that regulate massage therapists.[47,88]

Naturopathic Medicine

Benedict Lust, a German physician, introduced naturopathy to the United States. He used the term *naturopathy* (from *natur*, to indicate nature, and *pathy*, from homeopathy) to encompass all natural approaches to healing. Several healing modalities have been added to the healing module to arrive at modern naturopathy. Naturopathic medicine is far from being a single scientific discipline. The basic principle is that healing comes from within more than from without, and that medicine depends on the healing power of nature to cure (Table 35-1). Naturopathy employs various natural means to empower the patient to reach the ability to self-heal. The tools include lifestyle modifications, nutrition, dietetics, herbs, breathing, education, and hydrotherapy. In addition, naturopaths may elect to use a variety of healing modalities, including acupuncture, botanicals, homeopathy, massage, and Oriental medicine. Naturopaths are the "generalists" of the alternative medicine world. The emphasis of their practice is on prevention, education, and health maintenance.[89]

Table 35-1 Six Basic Principles of Naturopathic Medicine

Belief	Resultant Principle
The belief that the body has the inherent nature to heal itself	The healing power of nature underlies the ability to recover from illness or injury.
The belief that health and disease result from the interaction of a person's physical, mental, emotional, genetic, environmental, and social components	Treat the whole person.
The belief that the cause of disease, not merely the symptoms, should be treated	First, do no harm.
The belief that a physician's major role is to educate, empower, and motivate patients to take responsibility for their own health	Identify and treat the cause.
	Prevention is the best cure.
	The physician is a teacher.

Shealy CN, Thomas R (eds): The Complete Family Guide to Alternative Medicine. Rockport, Mass., Element Books, 1996.

Regulation and Training for Naturopathy

Naturopathic practitioners undergo a 4-year training program that includes therapies such as homeopathy, clinical nutrition, manipulation, herbal medicine, and hydrotherapy. Naturopaths often may have additional training in Chinese medicine (acupuncture and herbs). Naturopaths are licensed in 12 states. The naturopathic certification examination is administered by the North American Board of Naturopathic Examiners. Each state defines the scope of practice differently, using several adjunctive therapies including acupuncture, biofeedback, and nonprescription medications.[47,89]

Chiropractic

The term *chiropractic* is derived from two Greek words meaning "done by hand" and is defined as "the diagnosis, treatment and rehabilitation of conditions that affect the neuromuscular system."[89] Chiropractic care origins are in the manipulative health care modalities. It became an organized discipline approximately 100 years ago when Canadian Daniel David Palmer introduced it in the United States. The chiropractic system of health is based on two principles: a testable principle, that the structure and condition of the body influence how it functions and heals, and the untestable principle that the mind-body relationship is instrumental in maintaining health and affects the healing processes. Hence, the focus is on the body's ability to self-heal, on the nervous system's role in overall health, and on the interaction between body structure and the functioning of the nervous system. In the past decade, chiropractic care

gained measured acceptance and has developed into a treatment and wellness modality that is practiced by 55,000 licensed practitioners and used by roughly 10% of the U.S. population. A majority of visits to chiropractors in the United States are for back pain. According to some studies, chiropractic treatment is as beneficial for low back pain as treatment given by primary care providers, orthopedists, and physical therapists.[90,91] The evidence for the use of chiropractic for other conditions is less compelling.

Regulation and Training for Chiropractic Care

Chiropractic care is licensed in all 50 states, with 45 requiring insurers to include it in their plans. A large variation exists in the scope of practice; certain states restrict the practice to spinal manipulation, whereas others permit different procedures to be performed, such as acupuncture, electromyography, and laboratory diagnosis. The Council on Chiropractic Education (CCE) (www.cce-usa.org) has accredited 17 colleges of chiropractic medicine in the United States. Since 1974, chiropractic education has been established with a 4-year curriculum monitored by the CCE. Admission requirements differ from school to school, although a minimum of 2 years of college education and specific science courses are required by all.[47,92] Chiropractors must pass either a state licensing examination or an examination given by the National Board of Chiropractic Examiners.

Ayurveda

The word *Ayurveda* is derived from the Sanskrit *ayur*, meaning "long life," and *veda*, "knowledge." One of the world's oldest traditional healing systems, Ayurveda has been documented and practiced in India for thousands of years. Ayurveda is a holistic system that deals with all aspects of life: mind, body, and spirit. The ayurvedic practice is founded on the pooled wisdom of ancient Hindu saints and healers. Ancient Ayurveda was meant essentially to promote health, rather than fight disease.

A basic theory of Ayurveda states that everything in the material world is a sign of the unseen universe of energy or life force. The world was created from the unseen universe when the primordial sound created the five fundamental elements responsible for the material world: space, air, fire, water, and earth. These five elements manifest in the human physiology as three life energies called *doshas*. The three doshas are *vata* (space and air), *pitta* (fire and water), and *kapha* (water and earth). Each dosha, its subdivision, and underlying structures confer a particular characteristic and quality to each person. Health is a state of balance among the mind, body, and consciousness. Several factors can disturb this balance, including congenital and genetic factors, natural tendencies, habits, seasonal factors, and internal and external traumas. The imbalance produced in the doshas disturbs the life force, producing the disease state.

Diagnosis is based on identifying the exact quality and nature of the imbalance and correcting it. This is accomplished through a detailed history, inspection, and examination. Radial pulses (three superficial and three deep pulses, bilaterally) and tongue, nail, and eye examinations, among others, are important parts of the ayurvedic diagnostic examination. Treatment consists of amplifying or reestablishing the body's balance through a combination of interventions, including lifestyle changes, diet modifications, meditation, yoga, breathing exercises, massage, aromatherapy, herbs, and detoxification.[93] Studies have documented the favorable effects of regular meditation on reducing cardiovascular risk factors and stress. Further studies investigating the effects of the ayurvedic herbal products on a wide variety of conditions including cancer, aging, and health promotion are ongoing.[94]

Regulation and Training for Ayurveda

Ayurvedic medicine is the progenitor of several CAM disciplines. These include aromatherapy, homeopathy, and massage. There is no national standardization of training and credentialing of ayurvedic providers. A wide variance of training and experience exists among providers.

THE CANCER PATIENT AND POPULAR COMPLEMENTARY AND ALTERNATIVE MEDICINE THERAPIES

The tendency of CAM modalities to change and shift in popularity does not arise in response to new developments or randomized clinical trials; rather, particular therapies simply go in and out of vogue. Typically, a CAM therapy remains popular for a limited period of time, after which it is replaced by a new and usually nonvalidated CAM therapy. Popular CAM modalities that currently are used by cancer patients are discussed in this section under the categories developed by the NIH (see Box 35-1).

Mind-Body Techniques

The effectiveness of meditation, biofeedback, and yoga in stress reduction and in the control of particular physiologic reactions is well supported by accepted research. The belief that patients can use mental attributes and mind-body work to prevent or cure cancer has not been demonstrated in clinical studies.

Biofeedback

Biofeedback manipulates the body's physiologic responses that are normally controlled by the autonomic nervous system. A biofeedback therapist, of which there are over 10,000 in the United States, can teach a patient how to control many involuntary functions. Some patients learn to control their heart rate, blood pressure, muscle tension, and emotions.

Monitoring electrodes are placed on the body or scalp by the biofeedback therapist. The electrodes then are connected to a computer or polygraph, which will emit a noise or signal indicating the intensity or level of the process to be controlled. The patient is instructed to concentrate on influencing the signal. Specific mental exercises are carried out under the direction of the therapist. The patient is asked to visualize certain images that affect mood and in time may become able to identify which mental exercises change the signals. After a number of sessions (usually 8 to 10), the patient may be able to affect certain of the autonomic processes.

Researchers at Vanderbilt University performed a randomized study to evaluate the effectiveness of a combination of biofeedback and relaxation training for the reduction of side effects of chemotherapy.[95] Biofeedback reduced some indices of physiologic arousal but did not modify the side effects of chemotherapy. However, relaxation training was found to produce a decrease in nausea and anxiety during chemotherapy and a decrease in physiologic arousal after chemotherapy. The researchers concluded that the major benefit of biofeedback was the relaxation training that accompanies the instruction and not the biofeedback alone.

The potential benefit from biofeedback therapy for the cancer patient is relaxation and reduction of stress. This can undoubtedly improve quality of life and allows the cancer patient to take an active role in overall management. Biofeedback is a noninvasive procedure. A group of 10 sessions with a biofeedback therapist costs approximately $500. No specific reports in the medical literature have described side effects attributed to the use of biofeedback.

Guided Imagery

Guided imagery is a technique that relies heavily on the power of suggestion to create relaxing mental images. It is particularly useful for relieving stress and promoting serenity. Some patients find that it helps them cope more effectively with the impact of the diagnosis and the side effects of treatments.

In this technique, the therapist instructs participants to visualize a specific image. Sometimes the participant is asked to visualize a mass of cancerous cells being attacked by the immune system, chemotherapy, or radiation therapy. Many patients use guided imagery audiotapes that provide instruction on meditation exercises, guided relaxation, and visualization techniques. Some patients use these tapes while they are undergoing chemotherapy or radiation therapy, or en route to receive treatment.

Syrjala and colleagues evaluated relaxation and imagery training along with cognitive-behavioral coping skills for control of oral mucositis pain in patients undergoing bone marrow transplantation.[96] These investigators found that patients who received relaxation and imagery training reported less pain than the control groups. No benefit was obtained with the addition of cognitive-behavioral skills, however.

The goal of guided imagery is total relaxation. Patients learn breathing exercises to help them attain an "inner calm," or they try to modify their experience of anxiety or pain by imagining a pleasurable scene or situation. Some patients with cancer find the method effective in promoting relaxation and relieving anxiety. It must be emphasized, however, that no reliable evidence indicates any effect of this technique on disease progression or survival.

Guided imagery is a noninvasive therapy. Relaxation and guided imagery audiotapes cost approximately $10 to $20 and are available in local bookstores. Some patients prefer to visit a therapist for individualized training, which may be more expensive. No reports in the medical literature describe any side effects related to guided imagery.

Herbal Medicine and Biological Supplements

PC-SPES

PC-SPES (PC stands for "prostate cancer," and SPES is the Latin word for "hope") is a patented preparation of eight herbs[97] (Box 35-3). PC-SPES is the only herbal medicine for prostate cancer that has been subjected to clinical trials.

Four clinical trials of PC-SPES have been carried out in the United States and Germany.[98–101] These trials have been single-arm, phase I and II studies in patients with prostate cancer and have demonstrated prolonged decreases in prostate-specific antigen (PSA) levels in most of the men in the study. The side effect profile of PC-SPES has been suggestive of an estrogenic effect (i.e., breast tenderness, decreased libido, impotence, venous thromboses), and components of PC-SPES contain known phytoestrogens.[99]

The largest and most recently reported study was a phase II trial in 70 patients with prostate cancer.[101] Each patient received 320 mg of dried PC-SPES extract orally, three times a day. All androgen-dependent patients experienced PSA declines of 80% or more, and 26 patients (81%) experienced PSA decreases to undetectable levels. At 15 months, only one patient exhibited biochemical or objective progression. More than half of the patients with androgen-independent disease had a PSA response, with a median duration of response of 18 weeks. In the two androgen-dependent patients with positive findings on bone scans at study entry, one patient's follow-up scan revealed complete resolution of the osseous lesions, and the second patient's follow-up scan showed improvement but did not yield normal results. One patient had measurable disease and experienced complete resolution of a bladder mass seen on pelvic CT scan, accompanied by a decline in PSA from 8.9 ng/mL to an undetectable level. PC-SPES generally was well tolerated but was associated with a number of endocrine side effects, including decreased libido, erectile dysfunction, gynecomastia or mastodynia, and hot flashes.

Despite these encouraging results, a survival benefit for PC-SPES thus far has not been demonstrated. A worrisome possibility is that PC-SPES may decrease PSA levels while masking increases in tumor growth. PC-SPES also is associated with an increased risk of thromboembolic events.[102–104] Of enormous concern, PC-SPES was found to contain warfarin (and SPES, a more generic version for all cancers, to contain alprazolam), prompting the U.S. Food and Drug Administration (FDA) to issue a recall of both products in February 2002.[105]

Box 35-3. COMPONENTS OF THE HERBAL PREPARATION PC-SPES

Dendranthema morifolium Tzvel. (chrysanthemum)
Isatis indigotica
Glycyrrhiza glabra L.
Ganoderma lucidum
Panax pseudo-ginseng
Rabdosia rubescens
Saw palmetto
Scutellaria baicalensis Georgi (skullcap)

Hydrazine Sulfate

Cachexia remains a major problem in patients with advanced disease undergoing cancer treatment. There has been interest for a number of years in hydrazine sulfate for combating cachexia seen in cancer patients. Gold evaluated 84 patients with disseminated cancer and found that 59 of the 84 patients (70%) improved subjectively and 14 of the 84 (17%) improved objectively when receiving hydrazine sulfate. It was concluded that the compound may favorably influence nutritional status and clinical outcome in patients with disseminated cancer.[106]

Enthusiasm has been dampened by three prospective trials that showed no benefit when hydrazine sulfate was added to standard treatment regimens. Loprinzi and coworkers randomized 243 patients with non-small-cell lung cancer and 127 patients with advanced colorectal cancer to receive hydrazine sulfate or a placebo in addition to conventional anticancer regimems and showed no benefit with use of hydrazine sulfate.[107,108] Kosty and colleagues randomized 291 patients with advanced non-small-cell lung cancer to receive chemotherapy with or without hydrazine sulfate.[109] No benefit was found for pain control, cachexia, or survival in any of these studies. Hydrazine sulfate is not recommended for the treatment of any cancer-related symptoms, although it remains widely promoted on the Internet.

Shark Cartilage

Shark cartilage has gained increased popularity as the basis for an unconventional medical therapy (UMT) for the treatment and prevention of cancer. Shark cartilage was initially promoted by William Lane, PhD, in his book *Sharks Don't Get Cancer* and the follow-up book, *Sharks Still Don't Get Cancer*. In fact, however, tumors, including malignant tumors, do develop in sharks, in which thyroid and central nervous system neoplasms,[110,111] papillomas,[110–112] oral cavity cancers, adenomas of the liver, chondromas, and odontomas[110] have been observed.

Shark cartilage is purported to contain angiogenesis inhibitors. In fact, a modest antiangiogenic effect has been seen in vitro.[113] Shark cartilage is supplied in powder and capsule forms. It usually is taken orally but sometimes as an enema.

The television news program *60 Minutes* gave shark cartilage a huge boost a few years ago. The program reported a Cuban study of 29 patients with "terminal" cancer who were placed on shark cartilage; most "felt better" several weeks thereafter. "Feeling better" is not a reliable endpoint in a scientific study. The National Cancer Institute (NCI) performed a review of the study and found the data to be "incomplete and unimpressive."[114] The *60 Minutes* program allegedly refused to broadcast the findings of the NCI.

A small study on shark cartilage was reported at the American Society of Clinical Oncology in 1997.[115] Of the 58 patients with advanced cancer who were given shark cartilage for 12 weeks, not one objective complete response or partial response to shark cartilage was obtained. Only two patients reported significant improvement in the quality of life. Rigorous studies of shark cartilage are ongoing at a number of institutions, but no positive results have yet been published. It has been reported that shark cartilage can cause an elevation of values on liver function tests (LFTs) and frank hepatitis.[116] Patients on chemotherapy should be urged not to use shark cartilage enemas because of the risk of infection associated with chemotherapy-associated neutropenia.

Shark cartilage is relatively expensive. If it is taken as described by William Lane, the cost of the 16-week program is approximately $3000.

Mistletoe

Mistletoe (*Viscum album* L.) is one of the most commonly used CAM herbal medicines in Europe.[5,117–118] The active compounds identified in mistletoe are lectins (glycoproteins) and viscotoxins (proteins). The lectin component has in vitro immunostimulant activity and has been shown to increase the number of peripheral blood lymphocytes, as well as lymphocyte activity, in patients with gliomas.[119–121] The viscotoxins have been shown to have direct cytotoxic activity against certain cancer cell lines.[122]

Mistletoe has been used primarily as an adjuvant to conventional cancer therapies to manage micrometastatic disease. Various mistletoe products have been evaluated in several randomized, controlled clinical trials. An analysis of 11 of the randomized trials of mistletoe published in 1994 found that although 10 of these studies reported improved survival in the mistletoe treatment group, many of these trials had deficiencies in 5 or more of the 10 criteria of good methodology. These methodologic issues have led reviewers to question the validity of these studies and promoted demands for further well-defined studies.[123]

Recently, two well-designed prospective randomized trials have reported negative results. The effect of adjuvant treatment with mistletoe lectin-1, a standardized mistletoe preparation (Eurixor), was tested in a prospective, randomized clinical trial involving 477 patients with head and neck squamous cell carcinoma.[124] The European Organization for Research and Treatment of Cancer (EORTC) has completed a phase III randomized trial of adjuvant treatment with low-dose interferon-α versus interferon-γ versus mistletoe extract (Iscador M) versus no further treatment after curative resection of high-risk stage I or IIB malignant melanoma. No benefit was seen in disease-free survival or overall survival for patients receiving either Eurixor or Iscador.[124,125]

Ginseng (Panax Ginseng)

Ginseng has been touted as enhancing mental and physical strength. It may affect nitric oxide synthesis in the endothelial tissue of the lung, heart, and kidney.[126] In addition, effects on serotonin and dopamine may be responsible for its actions. Survey data indicate that breast cancer survivors seeking treatment for fatigue often turn to this drug for amelioration of fatigue.[127] A recent randomized, double-blind, placebo-controlled pilot trial was carried out by Kim and colleagues. Fifty-three patients were randomly assigned to receive sung ginseng 3000 mg a day or placebo. Quality of life was assessed using the World Health Organization Quality of Life Assessment and the General Health Questionnaire-12. The investigators concluded that ginseng did improve the quality of life scores of patients and that this intervention warranted further investigation.[128]

Adverse effects may include irritability, insomnia, and gastrointestinal disturbance. Ginseng may interact with oral anticoagulants, antiplatelet agents, corticosteroids, and hypoglycemic agents.[129]

Ginger

Several studies have demonstrated the efficacy of ginger for the treatment of nausea and vomiting. Most of the investigations involved pregnant women.[130–134] A randomized study of ginger for the amelioration of nausea caused by platinum-based chemotherapy showed that ginger is at least equivalent to the commonly used medication metoclopiramide and has less toxicity.[135]

Hoxsey Regimen and Essiac

The Hoxsey regimen, a herbal compound comprising pokeroot, burdock root, barberry root, buckthorn bark, and stillingia root, was used first in 1924 by Harry Hoxsey. The recipe was passed down to him by his grandfather, a farmer who observed a horse cure itself of cancer by eating certain plants. Despite decades during which no supporting data have been forthcoming, the Hoxsey formula remains popular and in use among patients with cancer.[80]

Essiac is one of the most popular herbal medicines in North America and is a mixture of four herbs given by a Native American healer to nurse Renee Caisse. ("Essiac" is Caisse spelled backward.) Despite a lack of systematic research or documentation of its value, Essiac is promoted and purchased for all forms of cancer.[135]

Diet and Nutrition

Macrobiotic Diet

Various dietary regimens have been promoted for both prevention and treatment of cancer. The macrobiotic diet was first described by George Ohsawa (1893–1966). He developed a diet consisting of 10 stages, with each stage more restrictive than the previous one. The final stage consisted of only rice and water. The American Medical Association and various governmental agencies have opposed the macrobiotic diet owing to its restrictive nature. In fact, a number of health problems and even deaths have been reported among persons who have followed the diet.[137]

The macrobiotic diet subsequently has been modified and is regaining popularity in the United States and generally consists of 50% to 60% whole grains, 20% to 25% vegetables, 5% to 10% beans and sea vegetables, and 5% soups. Some variations of the diet allow small amounts of fish. There may be alterations of the diet depending on the disease process.

The Kushi Institute in Massachusetts is a strong proponent of the macrobiotic diet. This institute teaches the macrobiotic diet and lifestyle. Specific foods for the individual cancer patient are recommended. Numerous testimonials supporting the effectiveness of the macrobiotic diet are provided, but no controlled studies have been performed to evaluate the Kushi Institute methods.

A number of nutritional deficiencies have been reported in association with the macrobiotic diet. Breast milk from mothers who follow the macrobiotic diet contains less vitamin B_{12}, calcium, magnesium, and saturated fatty acids than in the milk of mothers following "regular" diets.[138] Infants of mothers on the macrobiotic diet were found to have retarded growth, fat and muscle wasting, and slowed psychomotor development. Bone mineral content was evaluated in a study of adolescents who had followed a macrobiotic diet and compared with that in control patients without dietary restrictions.[139] The bone mineral content was found to be significantly lower in both boys and girls who had followed the macrobiotic diet. The study investigators suggest that this decreased bone density may hold important implications for fracture risk in later life. Machiels and associates reported a rare case of nutritional rickets in a young child due to the macrobiotic diet.[140]

Megadose Vitamin C: A Closer Look

The use of vitamin C for the treatment of cancer has been publicized for many years. Many continue to claim efficacy without strong scientific data to back these claims. Linus Pauling, PhD, and Ewan

Cameron, MD, claimed that high doses of vitamin C could significantly improve survival in cancer patients. The claim was based on the known antioxidant properties of vitamin C and some epidemiologic evidence that populations with high dietary intake of the vitamin have a decreased risk for development of some types of cancer. These scientists believed that much higher doses than the recommended daily intake of 60 mg/day of vitamin C were needed to prevent free radical damage within the body. Pauling and Cameron reported a study of 100 patients in the terminal stages of cancer treated with megadose vitamin C who had significantly improved survival when compared with historical controls.[141] It was recommended that patients with cancer take 10,000 mg of vitamin C daily on the basis of their research.

The study was plagued by significant design issues. The "terminal" patients in the vitamin C treatment group all came from Dr. Cameron's practice, whereas the historical controls were "terminal" patients who came from other sources in the geograhic region. It is conceivable that significant selection bias occurred between Dr. Cameron's patients given vitamin C and the patients of other physicians who were not offered any additional treatments.

Owing to the exceptional reputation of Nobel Laureate Dr. Pauling, investigators at the Mayo Clinic performed a prospective randomized study to evaluate vitamin C. Creagan and colleagues randomized 150 patients with advanced cancer to receive 10 g of vitamin C or a placebo.[142] No difference in symptoms, performance status, appetite or survival was found between the two groups. These investigators concluded that high-dose vitamin C had no therapeutic benefit.

Dr. Pauling criticized the design of the Mayo Clinic study, claiming the patients had poor performance status and too much prior treatment with chemotherapy. Based on his criticisms, a new trial was launched. Moertel and coworkers randomized 100 patients with advanced colorectal cancer in a double-blind study to receive high-dose vitamin C (10 g daily) or a placebo.[143] No patient received previous cytotoxic therapy, and all had good performance status. Again, vitamin C showed no advantage over placebo therapy with regard to disease progression, objective improvement in measurable disease, or survival. The researchers concluded that high-dose vitamin C therapy is not effective against malignant disease regardless of whether the patient has had any prior chemotherapy.

In a recent trial of oral supplementation with ascorbic acid (vitamin C, 6100 mg/d), DL-alpha-tocopherol (a form of vitamin E, 1050 mg/d), and beta-carotene (vitamin A precursor, 60 mg/d), patients who had stage IIIB or IV non-small-cell lung cancer were randomly assigned to chemotherapy with paclitaxel and carboplatin (72 patients) or to this chemotherapy regimen plus the supplements (64 patients). No significant survival differences were reported, with 1-year survival rates of 33% and 39% and 2-year survival rates of 11% and 16% in the chemotherapy and the combination treatment groups, respectively.[144]

The argument has been made that the inability to confirm Pauling's results may reflect the use of oral rather than intravenous vitamin C.[9,145] A 1.25-g dose of vitamin C given orally results in a mean plasma level of 135 µmol/L, whereas the same dose given intravenously results in a level of 885 µmol/L. The same study showed that the maximum tolerated oral dose of 3 g every 4 hours increased the plasma level to only 220 µmol/L, whereas the maximum tolerated intravenous dose of 50 g resulted in a plasma level of 13,000 µmol/L. The form of oral vitamin C also affects its bioavailability. A solution of vitamin C has an approximately 40% lower bioavailability than that of a slow-release formula.[146] Vitamin C intake also has been examined for the amelioration of toxicity associated with chemotherapy administration.

Weijl and colleagues[147] investigated the use of oral vitamin C, vitamin E, and selenium for the prevention of cisplatin-induced renal toxicity and ototoxicity. No significant overall effect was demonstrated, but a correlation with plasma levels of the vitamins and lower toxicity was observed. These investigators, however, concluded that poor compliance or inadequate supplementation may have confounded the results. Song and coworkers[148] investigated the use of an intravenous administration of 10 g vitamin C twice with a 3-day interval and an oral intake of 4 g vitamin C daily for a week. They then evaluated demographic data and assessed changes in patients' reported quality of life after the administration of vitamin C. Quality of life was assessed with the EORTC QLQ-C30 questionnaire. These researchers concluded that high-dose vitamin C therapy did indeed significantly improve quality of life scores.

Side effects of megadose vitamin C include diarrhea, formation of renal stones, iron overload, and gastrointestinal discomfort. Ardent supporters of megadose vitamin C remain, however, despite the strong scientific evidence refuting its use in the treatment of cancer. Based on the current scientific literature, megadose vitamin C is not recommended for the prevention or treatment of cancer.

COMPLEMENTARY AND ALTERNATIVE MEDICINE AND TOXICITIES

A multitude of potential interactions are possible between conventional cancer treatments and UMTs. Many such interactions are just beginning to be recognized by the medical establishment and reported in reputable scientific journals.[149,150] Both renal and hepatic function can be impaired by various UMTs.[151–156] Multiple biochemical pathways can be affected, including the lipoxygenase, cyclooxygenase, and cytochrome P-450 pathways.[112] Such effects may have an impact on drug concentrations in the body, resulting in increased toxicity or changes in effectiveness of chemotherapy and radiation therapy. Antioxidants may decrease the effectiveness of radiation therapy as a result of the scavenging of free radicals, which can damage DNA, leading to cell death.[157] Moreover, many of these therapies have their own side effects that can mimic those of conventional cancer treatments[158–177] (Tables 35-2 and 35-3). If the oncologist is not aware

Table 35-2 Potential Adverse Effects of Some Common Herbal and Other Alternative Medicines

Preparation/ Medication	Adverse Effect(s)
Ephedra species	Hypertension, tachycardia, stroke, seizures
St. John's wort	Depression, nausea, hypersensitivity reactions
Amygdalin (Laetrile)	Emesis, headache, dizziness, obtundation, dermatitis
Antineoplastons	Somnolence, confusion
Ginseng	Sedative, diarrhea, headache, hypertension, insomnia, nausea
Echinacea	Hypersensitivity reactions
Kelp	Hyperthyroidism
Saw palmetto	Urinary retention, headache, diarrhea, constipation, hypertension, nausea
Mistletoe	Local irritation, allergic reactions
Shark cartilage	Hepatitis, emesis, constipation
Ginkgo	Emesis, headache
Green tea	Insomnia, emesis, diarrhea, confusion
Hydrazine sulfate	Hepatorenal failure
Goldenseal (*Hydrastis canadensis*)	Uterine contractions

Data from references 163 to 179.

Table 35-3 Potential Interactions between Herbal Medicines and Conventional Drugs

Herb(s)	Drug(s)	Potential Interaction/Effect(s)
St. John's wort	Irinotecan, protease inhibitors, other drugs metabolized by cytochrome P-450	Reduced drug levels
	Cyclosporine	
	Oral contraceptives	
	Digoxin	
Hawthorn flower, devil's claw, licorice	Digoxin	Alters pharmacodynamics; drug levelmonitoring is prudent
Licorice	Potassium-sparing diuretics	Affects potassium levels
Kelp	Thyroxine	Iodine content of herb may interfere with thyroid replacement
Kava	Alprazolam	Additive sedative effects, coma
	Terazosin	
Evening primrose oil	Anticonvulsants	Lowered seizure threshold
Feverfew, garlic, ginseng, gingko, ginger, dong quai	Warfarin	Altered bleeding time
Yohimbe bark	Centrally active antihypertensive agents	Yohimbine may antagonize guanabenz and methyldopa through its α_2-adrenoceptor–antagonistic properties
Ginseng	Phenelzine sulfate	Headache, tremulousness, manic episodes
	Estrogens, corticosteroids	Additive effects

Data from references 163 to 176.

that a patient is using a particular UMT, signs or symptoms developing as a result of that UMT may be erroneously attributed to a conventional cancer treatment with established efficacy, which may then may be unnecessarily altered or discontinued.

Many forms of CAM are associated with no or minimal risk to a cancer patient; however, this is not true for all such therapies. It is well established that a variety of herbal medications may produce serious side effects. Quality control of these preparations can be a major concern. Issues include variability in biologic potency in different crops, the very realistic possibility of contamination (e.g., by fungal or bacterial organisms), and use of wrong plant species.[158] Herbal remedies may contain lead, arsenic, mercury, tin, or zinc, each of which can itself be toxic.[159]

Immunoaugmentative therapy (IAT) of Burton is based on balancing four protein components in the blood while strengthening the patient's immune system. The use of various organ extracts from cows and pigs is claimed to selectively suppress tumors and stimulate the immune defense cells.[160,161] No studies have shown clinical effectiveness of immunoaugmentative therapy; however, samples of infected material from patients who received IAT revealed evidence of hepatitis virus.[161]

New toxic effects of a variety of herbal preparations continue to be reported. Kava, for example, a widely publicized natural sleep medication, has been associated with severe liver dysfunction, leading to at least one case of hepatic failure and the requirement for a liver transplant.[167] Other herbal medications also have been shown to be associated with hepatotoxicity.[168]

Laetrile (amygdalin), derived from apricot and other fruit pits, one of the oldest CAM medications, continues to be marketed to the public.[178] Amygdalin had been used for centuries, but, in the 1950s it was elevated to new heights under the trade name Laetrile. Proponents of Laetrile claim that proper use of this substance can eradicate cancer entirely (www.worldwithoutcancer.com and www.sumeria.net/health/laetrile.html). Moertel and colleagues carried out a phase II clinical trial of Laetrile, along with vitamins A, C, E, and B complex and various minerals and pancreatic enzymes, in 178 patients with cancer not previously subjected to conventional cancer treatment and with good performance status. Only one patient, who had gastric carcinoma with cervical lymph node metastases, had a possible short-lived partial 10-week response. All others showed no signs of response. No evidence of disease stabilization was noted. Evaluation of toxicity revealed blood cyanide levels in the ranges known to kill animals and humans in several patients.[171] Studies have demonstrated that this drug can produce signs and symptoms of nausea, vomiting, headache, dizziness, and obtundation.[170,171]

To date, one of the gravest examples of the potential for harm associated with herbal medications is that of the development of renal failure and urothelial carcinoma in persons who used the Chinese herb *Aristolochia fangchi*.[179,180] As a result of a manufacturing error, this herb replaced another preparation (*Stephania tetrandra*) used in a weight-reducing pill. More than 40 people who took this pill experienced progressive renal failure, and almost 50% subsequently were found to have a urothelial cancer.[179]

Vitamin toxicities are uncommon but well defined. Megadoses of vitamin A can cause increased intracranial pressure and vomiting in children, and its chronic use in adults can lead to hypercalcemia.[181] Vitamin B complex overdose can lead to cardiovascular toxicity including arrhythmias, edema, vasodilation, and allergic reactions. Megadoses of niacin can cause cardiac toxicity with arrhythmia, as well as liver toxicity and peptic ulceration. Long-term high-dose toxicities include gouty arthritis, hyperglycemia, dry skin, and rashes. Vitamin B_6 in megadoses can cause peripheral neuropathies, with resulting numbness lasting for weeks. Vitamin C toxicities include the formation of renal stones.[182] High-dose vitamin E therapy can interfere with blood coagulation by antagonizing vitamin K and inhibiting prothrombin production. A recent study of vitamin E demonstrated an increased number of strokes in the vitamin E treatment group as compared with the control group.[183]

Both acupuncture and chiropractic medicine generally are quite safe; however, they too can be associated with irritating and more serious side effects.[184,185] Reported toxic effects of acupuncture include transmission of infectious agents through needle insertion; broken, forgotten, or misapplied needles; pneumothorax; transient hypotension; minor bleeding; contact dermatitis; and pain.[184] A small but finite risk of a cerebrovascular accident is always associated with cervical spinal manipulations.[185]

THE INTERNET AND COMPLEMENTARY AND ALTERNATIVE MEDICINE

The Internet has become a hotbed of CAM offerings and information over the past decade. However, patients must be advised to be extremely careful about where the information is being derived and what is being marketed over the Internet. Since the public introduction of the Internet in 1994, this computer resource has experienced exponential growth. In August 2002 it was estimated 64% of the U.S. population (177.6 million people) had access to the Internet.[186] This was increased from 56.5% of the population in October 2000.

Studies have been performed to specifically evaluate the use of the Internet by patients with cancer to obtain information about CAM. In a study of 921 patients presenting to radiation oncology centers in the United States, it was found 42% of those presenting to an academic medical center and 25% of those presenting to a community medical center were using the Internet to find cancer-specific information.[156] A questionnaire study from England showed that 24% of prostate cancer patients were using the Internet to obtain further health information.[187] A Canadian questionnaire study of patients with prostate cancer revealed that 35% of patients had used the Internet to obtain cancer-related information.[188] Another recent Canadian questionnaire study evaluated 191 cancer patients on the reliance on the news media and the Internet as sources of medical information.[189] This study showed that 50% used the Internet to obtain information and 7% used the Internet as their primary source of information. A study reporting on use of the Internet by 295 patients with prostate cancer in the United States showed that 32% were using the Internet to gather information.[190] Of interest, 58% of these patients used the Internet to search for information on CAM.

Many more patients probably are obtaining Internet-derived information from other people. As indicated by questionnaires placed on OncoLink (http://www.oncolink.upenn.edu), the cancer information resource from the University of Pennsylvania, many patients' friends and family members are using the Internet to obtain cancer-related information. Vordermark and colleagues used a questionnaire study to identify where patients were obtaining information.[191] Of 139 German radiation oncology patients, 12% had used the Internet to obtain information about their cancer, but an additional 15% received Internet-derived information about their cancer from friends or family members. Of note, only 24% discussed the information obtained from the Internet with their physicians.

Yakren and coworkers used a patient survey to analyze the use of media information, including that from the Internet, among cancer patients and their companions at Memorial Sloan-Kettering Cancer Center.[192] As indicated by the responses of the 443 patients who returned the completed surveys, 44% of the patients and 60% of the companions reported use of the Internet to obtain cancer-related information. This is very similar to the utilization rate of 41% for patients at the University of Pennsylvania Cancer Center.[11]

The identification of good Internet sites can be difficult for the nonmedical person searching for information on complementary and alternative medicine. The general public requested 30% of all PubMed searches performed in 1999. A study by Bernstam and associates evaluated the ability of a computer-literate lay user to perform multiple searches for various question types related to cancer on MEDLINE.[193] A blinded investigator then rated each search's relevancy. The computer user was then given a custom interface to help with the searches through MEDLINE. Overall, significantly higher precision was observed with use of the MEDLINE interface than with unaided novice searching. This finding emphasizes the need for the medical community to help guide patients' search for medically relevant information on the Internet. Although this study does not specifically evaluate Web searches, these results may be generalizable to patients looking for information on the Internet regarding CAM.

It can be a daunting task for the nonmedical person to objectively evaluate the quality of Internet sites, particularly those offering CAM. A recent study by RAND Health reported on the quality of health information on the Internet.[194] A variety of health Web sites were evaluated, including 20 major Web sites for breast cancer information. It was found that on average, two to four websites needed to be visited to find more than minimal coverage for at least 75% of the indicators for a topic. Although experts may be able to quickly evaluate the quality and appropriate coverage of a topic, as in the RAND study, this can be very difficult for the patient. Meric and colleagues found that popularity and traffic of breast cancer Websites do not always correlate with quality.[195] This finding again emphasizes the need for professionals to help guide the lay public to appropriate medical material on the Internet.

Most health care providers have experienced a visit from a patient entering the office with pages of CAM information printed from the Internet. Only a limited number of studies, however, have documented the use of the Internet to find information on CAM. A study from the University of Pennsylvania showed that 53% of cancer patients using the Internet were interested in finding information about CAM.[196] Most of these patients were doing so without their health care providers' knowledge. CAM therapies were purchased over the Internet by 12% of Internet users in this study. However, this study did not specifically evaluate the type of therapy purchased. Health care providers need to familiarize themselves with the therapies offered over the Internet in order to have an informed discussion with their patients regarding these treatments. Particular discussions should emphasize the potential side effects and interactions with conventional cancer treatments.[11] A typical search on Yahoo, one of the Internet search engines (http://www.yahoo.com), for "alternative and complementary medicine" reveals greater than 6.14 million different Web site matches. This is increased from 432,000 in 2004. Some of these Web sites provide credible information. Unfortunately, many are designed only to sell a specific product and give false or misleading information. It can be overwhelming for the average person without medical knowledge to sift through and understand the claims presented on many of these sites.

Some patients will ask their health care providers for recommendations on evaluating Web sites offering CAM information. It generally is recommended to start with sites managed by major academic centers and the government. These institutions maintain a level of quality outside of the Internet that typically is upheld on these Web sites in keeping with the general philosophies of these organizations. Patients also should be warned to be wary of sites designed to sell a specific product or treatment. Many of these sites do not give unbiased information and are designed strictly to generate revenue. Box 35-4 provides some suggestions to guide patients in evaluating Internet sites. Table 35-4 recommends selected Web sites with reliable information on CAM for the cancer patient and health care provider.

ALTERNATIVE MEDICINE CANCER CLINICS

Numerous cancer clinics promoting alternative medicine techniques have formed throughout the world. Many centers are transient, but

Box 35-4. EVALUATING MEDICAL WEBSITES

- **Accuracy of information:** Websites that post information that is not referenced, or articles that do not state authors and dates for content, should be avoided.
- **Availability of editorial staff:** An online resource should list the names of its editorial staff, the credentials of the people behind the resource. An address and email contact information also should be provided.
- **Qualifications of editorial staff:** Many online resources are run by people who are not qualified to provide medical advice. Fundamentally, there is nothing wrong with this, provided that it is clearly stated. In general, however, the best information is provided by health care professionals who are health care providers themselves. Much of what physicians, nurses, and other professionals are trained to do involves interacting with patients and providing information in the clearest, most appropriate manner.
- **Freshness of content:** Sites with content that is updated regularly are likely to be ones that are best managed and most up to date.
- **Disclosure of conflicts of interest:** Conflicts of interest should either be obvious or clearly disclosed to the users.
- **Price of information:** So far, very few online medical resources are charging for information. Although this may change in the future, open access to information with fees that are minimal should be the rule. If you are being charged for the information, make sure it is not information others are providing for free.
- **Confidentiality:** Most online medical resources will not respond to direct medical inquiries by users. This is due in part to concerns about patient confidentiality, and about accuracy of information either sent to or received by the patient. It is important to ensure that sites that require registration are not releasing contact data without permission.
- **Reputation:** Resources known to be run by reputable institutions are more likely to be providing more timely, accurate, and unbiased information.
- **Look and "feel":** Resources must balance between having an attractive resource and being able to provide the best possible information to users. Certainly, content rich in graphics is attractive, but if it is poorly organized, or if downloading it takes an inordinate amount of time, it may not be serving its primary purpose.
- **Navigation and searching:** Make sure a site is well organized and easy to navigate and has a good search engine.

Reproduced, with slight modifications, with permission from the editors at http://www.oncolink.org.

some have been established for quite some time and have a large following and have marketed their facilities to the general public. A complete enumeration is beyond the scope of this chapter, but none of the treatments offered by these facilities are known to have shown verifiable beneficial results when compared with conventional medical treatments. Nevertheless, case reports and testimonials abound. It is important that health care providers recognize that these treatments are being promoted to their patients through the Internet and print publications, and by word of mouth.

For example, Tijuana, Mexico, has long been a destination for patients seeking alternative medical therapies. The government has acted to close down a number of these centers at various times, but many continue to thrive. At any one time, some 50 to 70 alternative medicine clinics are in operation. It has been estimated that roughly 40,000 people travel to Tijuana in search of alternative treatments each year. Of these patients, 95% are from the United States. Many of these clinics operate in a hospital-type atmosphere, and patients stay for a number of days or weeks for their therapy. A few such clinics are strictly outpatient or day treatment centers.

The therapies offered in these centers range from simple dietary management to complex operative treatments. Some of these treatments are innocuous, whereas others may be quite dangerous. For instance, some patients are offered insulin-induced hypoglycemia therapy (IHT). Patients are given insulin to drop the blood glucose level to less than 40 mg/dL and then are infused with a glucose solution incorporating a diluted chemotherapy preparation. The rationale for this treatment is that "starving" cancer cells need more glucose and thus more readily take up the chemotherapy drugs, so no side effects develop.

Claims of benefit by these alternative medicine centers have not been substantiated by the outside medical establishment. As confirmed by our own observations in such centers, however, some patients with hormone-responsive tumors such as breast cancer and prostate cancer are receiving hormonal therapies. Also, as mentioned earlier, chemotherapy sometimes is offered along with the alternative treatments. This may account for some for the claims of response to these treatments.

These treatments generally constitute out-of-pocket medical expenditures, because these are not covered by medical insurance programs. Table 35-5 shows the estimated cost at some of the more popular centers offering alternative cancer treatments. Some of the prices do not include room and board. Many have added charges that may not become specified until the patient is seen and evaluated at the clinic. All require cash payment before treatment. Travel expenses are not included in the estimates.

Table 35-5 Popular Unconventional Cancer Therapy Clinics

Clinic	Location	Type of Treatment	Duration of Therapy	Estimated Cost
Kushi Institute	Brookline, Massachusetts	Macrobiotic diet	1 week	$1,500*
Burzynski Clinic	Houston, Texas	Antineoplastins	6 months	$50,000†
Immuno-Augmentive Centre	Bahamas	Immuno-Augmentive	3 months	$13,100‡
Hosp de Baja California del Sol	Tijuana	Gerson Method	1 month	$20,000§
Bio Medical Center	Tijuana	Hoxsey Herbal	Variable	$3,800‖
Center for Cell Specific Therapy	Santo Domingo	Magnet Therapy	Variable	$20,000¶

*Based on published advertising on the Internet of $1,495 for 1 week. Private counseling sessions are an additional $225 each.

†Based on telephone quotation of intravenous therapy of $14,000 for the first month and $7,200 for each additional month, which averages 6 months in duration. Cost of the oral formula is $6,000 for the first month and $2,000 for each additional month.

‡Published advertising fee schedule from the Immuno-Augmentive Centre of $7,500 for the first 4 weeks and $700 per week thereafter, up to 8 additional weeks. Cost of supplies for home maintenance is $50 per week indefinitely.

§Based on published advertising on the Internet of $3,990 per week for basic charges, with a recommended stay of 1 month; ". . . actual costs for any individual will become evident only during the course of treatment."

‖Based on telephone quotation of $3,500 lifetime supply of Hoxsey Tonic, $300 to $400 for blood work, and $25 consultation fee.

¶Based on brochure from the Center for Cell Specific Therapy. All patients are charged $20,000 regardless of the length of treatment.

CONCLUSIONS

Many patients with cancer, as well as their friends and and family members, are searching for information regarding CAM. Health care providers must become educated on this topic so that they can appropriately guide these patients. CAM is here to stay, and patients need to be supported in their decision to use complementary therapies that are safe. Health care providers must warn patients of potential or known interactions with conventional medications and treatments when appropriate. Clinical trials evaluating CAM should be developed and encouraged. CAM needs to be held to the same stringent criteria as those in place for conventional treatment modalities.

A. SYMPTOM MANAGEMENT AND PALLIATIVE CARE

36 Cancer Pain

Stuart A. Grossman and Suzanne Nesbit

SUMMARY OF KEY POINTS

Incidence

Major Presenting Symptom of Malignancies

- Affects more than 30% of patients undergoing antineoplastic therapy
- Moderate to severe pain occurs in over 70% of patients during the later phases of their illness
- Significantly affects quality of life
- Frequently managed poorly

Etiology of Complication

- Can be of nociceptive, neuropathic, or sympathetically maintained origin
- Due to direct tumor involvement (70%), evaluation or therapy (20%), or illness unrelated to the malignancy (<10%)

Evaluation of the Patient

- Determining the etiology of pain is key to appropriate therapy
- Treat pain aggressively during evaluation
- Fully evaluate the pain using a careful history and physical examination, validated pain assessment scales, and selected laboratory tests

Grading of the Complication

- Measurements of pain intensity using validated pain assessment scales
- Results should be recorded serially as an integral part of the medical record

Treatment

- 85% of patients can be well palliated using simple, inexpensive, "low-technology," oral analgesics
- Addition of appropriate adjuvant pain medications, alternate routes of opioid administration, antineoplastic therapy, nonpharmacologic approaches, neurostimulatory techniques, regional analgesia, and neuroablative procedures provides excellent palliation for nearly all patients with cancer pain

INCIDENCE

Facts

Pain is one of the most common and dreaded symptoms associated with cancer. It occurs in one-quarter to one-half of patients with newly diagnosed malignancies, in one-third of those undergoing treatment, and in more than three-quarters with advanced disease. Overall, 75% of patients with cancer experience pain severe enough to require treatment with opioids during their illness.[1] Unrelieved pain directly affects patients' daily activities, quality of life, and psychologic status. The importance of this symptom and the availability of excellent analgesic therapies make it imperative that health care providers be adept at the evaluation and treatment of cancer pain (Table 36-1).

Etiology

Pain in patients with malignancies is a complex and often recurring process that occurs from many causes. Ninety percent of pain in patients with cancer results from the tumor or its evaluation or therapy, whereas less than 10% is due to unrelated illnesses. In 70% of patients, pain develops from tumor invading or compressing soft tissue, bone, or neural structures. The common pain syndromes that result are listed in Table 36-2. The remaining 20% of cancer pain occurs from diagnostic and therapeutic procedures that these patients undergo in the process of evaluation and treatment.[2] Examples of these procedures include venipuncture, bone marrow aspiration and biopsy, endoscopy, lumbar puncture, invasive radiologic procedures, surgery, chemotherapy, and radiation therapy.

Surgery is a frequent cause of pain in patients with cancer and can consist of biopsy, removal, or debulking of a tumor or management of a complication of the tumor or its treatment, such as a small-bowel obstruction. These procedures are associated with postoperative pain and injury to local nerves, which can produce neuromas and chronic pain syndromes that are severe and difficult to manage. Surgically induced nerve injuries are most commonly seen after breast cancer surgery, thoracotomy, radical neck dissection, and limb amputation.[3] Postmastectomy syndrome occurs in 4% to 10% of all women undergoing this type of breast cancer surgery. It is most frequent in patients with postoperative complications or keloid formation and is characterized by a constricting, burning sensation in the posterior arm, axilla, and anterior chest. It can develop immediately after the procedure or months later and can be complicated by the secondary development of a frozen shoulder. Post-thoracotomy syndrome occurs after nerve injury secondary to rib retraction and typically presents as an aching, burning sensation in the incisional area with local tenderness, sensory loss, and occasional autonomic changes. Injury to local nerves after a radical neck dissection can produce tightness and burning dysthesias in the area of sensory loss and acute, lancinating pain. The loss of neck musculature from this surgery can also result in a "droopy shoulder," thoracic outlet syndrome, and suprascapular nerve entrapment.

Chemotherapy and radiation also produce significant pain in patients with cancer. Phlebitis, mucositis, hemorrhagic cystitis, and peripheral neuropathy are common complications of antineoplastic agents. Glucocorticoids, administered as a component of therapy, can cause aseptic necrosis of the hip, and severe perineal pain when given rapidly in high doses. Examples of radiation-induced pain include mucositis, local skin reactions, enteritis, proctitis, fibrosis with nerve

Table 36-2 Etiology of Pain in Cancer Patients

A. Direct tumor involvement (70%)
   1. Invasion of bone
   2. Invasion or compression of neural structures
   3. Obstruction of hollow viscus or ductal system of solid viscus
   4. Vascular obstruction or invasion
   5. Mucous membrane ulceration or involvement

B. Cancer-induced syndromes (<10%)
   1. Paraneoplastic syndromes
   2. Pain associated with debility (i.e., bedsores, constipation, rectal or bladder spasm)
   3. Other (i.e., postherpetic neuralgia)

C. Diagnostic or therapeutic procedures (20%)
   1. Procedure-related pain (i.e., bone marrow aspiration or biopsy, lumbar puncture)
   2. Acute postoperative pain or postsurgical syndromes (i.e., postmastectomy, postthoracotomy, postamputation syndromes)
   3. After radiation (i.e., injury to plexus or spinal cord, mucositis, enteritis)
   4. After chemotherapy (i.e., mucositis, peripheral neuropathy, aseptic necrosis)

D. Pain unrelated to the malignancy or its treatment (<10%)

From Grossman SA, Baumohl L: Evaluation and management of cancer pain. In Bone RC (ed): Current Practice of Medicine. Philadelphia, Current Practice, 1993, p 18.1.

entrapment syndromes, and radiation myelopathy. Electric shock-like sensations that accompany flexion of the neck (Lhermittes syndrome) can last for months after radiation to the spinal cord. Painful peripheral nerve tumors can also follow radiation therapy, especially in patients with neurofibromatosis.

Patients with malignancies are also predisposed to painful infections. Common examples include pneumonia, urinary tract infection, wound infections, candida esophagitis, oral or genital herpes, and herpes zoster.

Current Status of Cancer Pain Management

Studies from hospices and from World Health Organization demonstration sites suggest that 85% of patients with cancer pain can be well palliated using oral opioids. A wide array of effective options exist for the remaining 15% of patients. These include parenteral, transdermal, transmucosal, or intraspinal opioids, glucocorticoids, anti-inflammatory and adjuvant medications, antineoplastic therapies, and anesthetic and neurosurgical procedures.

Although proper use of available therapeutic approaches should result in excellent pain control in nearly 95% of patients with cancer pain, cancer pain remains grossly undertreated throughout the world.[4] In most countries, the unavailability of oral opioids is a major contributing factor.[5,6]

Even in countries such as the United States and the United Kingdom, where a wide range of opioid analgesics and routes of administration are available, studies suggest that cancer pain is undertreated. A survey of oncologists highlights their reluctance to assess pain routinely and prescribe appropriate analgesics. These findings prompted the creation of cancer pain initiatives in most states and the development of cancer pain guidelines and algorithms by the American Society of Clinical Oncology, the American Pain Society, and the U.S. Public Health Service's Agency for Health Care Policy and Research.[7–11] In addition, to improve the overall management of pain in the United States, the Joint Commission on Accreditation of Healthcare Organizations has recently set new standards for pain management that are required for continued accreditation.[12]

Barriers to the Provision of Adequate Analgesia

Many reasons have been cited for the inadequate treatment of patients with cancer pain in developed nations. Some of them relate directly to health care providers, including

- Failure to appreciate the intensity of the pain their patients are experiencing
- Reluctance to evaluate the etiology of the pain
- Lack of training in pain management
- Excessive concern regarding the regulatory oversight of opioid prescribing

One major barrier to the provision of adequate analgesia in patients with cancer is the failure of health care providers to appreciate the intensity of patients' pain. This occurs because pain is entirely subjective and can only be experienced and quantified by the patient. There are no pathognomonic findings on physical examination, and laboratory studies can be normal. Assessment of pain is further complicated by the complexities surrounding death and dying and the possibility that patients with chronic, severe pain might not appear or act uncomfortable. In one study examining health care provider perceptions of patient pain, pain intensity was quantitatively assessed using a visual analog scale in 103 consecutive patients admitted to the solid-tumor service of a large cancer center.[13] Each patient's primary care nurse, house officer, and oncology fellow rated his or her perceptions of their patient's pain intensity using the same pain rating instrument as the patient. The results (Fig. 36-1) demonstrate a lack of correlation between the patient's and the health care provider's perception of patient pain. Furthermore, the concordance between patient and health care provider pain intensity scores was

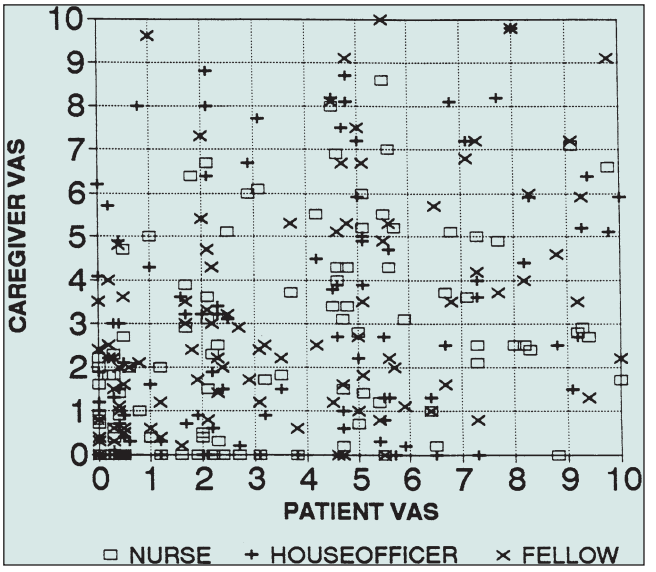

Figure 36-1 • Correlation of health care provider and patient perceptions of patient pain. (Data from Grossman SA, Sheidler VR, Swedeen K, et al: Correlation of patient and caregiver ratings of cancer pain. J Pain Symptom Manage 1991;6:53. Copyright U.S. Cancer Pain Relief Committee.)

highest when patients had no pain and lowest when the patients were experiencing severe discomfort. Similar results have been obtained in studies of patients with cancer and their next of kin and in burn patients.

There are many reasons why health care providers might be unaware of the pain their patients are experiencing. Because pain is entirely subjective, its presence and intensity must be communicated to health care providers by patients. Patients, however, might not discuss their pain if they expect cancer to be painful or if they are concerned about opioid addiction, tolerance, or side effects or about diverting their physician's attention from treating the tumor. In addition, they might be reluctant to admit to themselves or others that their pain has worsened, knowing that this could signify progression of the cancer. Health care providers also contribute to the lack of communication by neglecting to emphasize their interest or abilities in controlling pain and by failing to use validated pain assessment tools. Serial numeric pain ratings in the medical record will foster the necessary dialogue between patients and health care providers about pain management issues.

These issues are greatly magnified in children, the elderly, or individuals with a history of drug abuse. Children have special difficulty in communicating pain intensity, and their unique pain management needs have been relatively neglected. Special pain assessment tools are required, and the child's age and developmental level must be considered when planning assessment or interventions. Many elderly patients also find it difficult to communicate their discomfort to health care professionals, have multisystem disease, and are especially sensitive to the adverse effects of analgesics.[14] Those with cancer and a current or prior history of drug abuse often have difficulty finding health care providers who believe their reports of pain and who will provide the high doses of analgesics required in these opioid-tolerant individuals.[15]

Another barrier to the provision of adequate analgesia relates to the training of medical professionals. The principles of cancer pain management receive little attention in academic centers and relevant scientific societies. Medical school courses and textbooks typically focus on diseases rather than symptoms, and pain management issues are infrequently highlighted at rounds, educational conferences, or in the formal curriculum of those training to care for patients with cancer. These circumstances leave many health care professionals eager to concentrate on medical problems they feel competent to handle. In addition, the scarcity of research abstracts on cancer pain at the scientific meetings of physician oncologic societies reinforces the notion that pain control is a topic of limited importance.

The lack of training and emphasis on cancer pain management manifests in many ways, including physicians' lack of opioid-prescribing skills, failure to evaluate the etiology of cancer pain, and excessive concerns regarding the regulatory oversight of opioid prescribing. In one study, 81 physician trainees, given a hypothetical patient case that included performing opioid conversions, 75% calculated a dose that was only one-third the correct dose, and only 5% calculated the dose correctly.[16] Another study of experienced oncology nurses indicated that they lack the capacity to recognize physician orders that could result in serious over- or underdosing of opioids. These difficulties in calculating equi-analgesic doses have prompted the development of software to facilitate opioid conversions.[17]

Many physicians and nurses consider "cancer pain" a diagnostic entity that requires opioids, without a formal evaluation of the etiology of the pain. Although this approach can provide relief, it is often ineffective and can lead to indefensible medical practices. For example, progressive back pain in a patient with metastatic lung cancer can occur from a postobstructive pneumonia or tumor invasion of the esophagus, liver, spleen, pleura, pericardium, rib, vertebrae, intercostal nerves, brachial plexus, leptomeninges, or epidural space. Each of these diagnostic possibilities can be associated with a different therapeutic approach or sense of urgency. To provide opioids without evaluation would be an error in such a patient with an impending epidural cord compression. Furthermore, many common cancer pain syndromes might be better treated with therapies tailored to a patient's individual pain problem. These may include local radiation, nerve blocks, glucocorticoids, anticonvulsants, or surgery to maximize analgesia, minimize side effects, and improve quality of life.

Physicians, pharmacists, and nurses caring for patients with cancer must be willing to prescribe, dispense, and administer the opioids in doses required to alleviate their pain. Drug enforcement agencies often discourage opioid prescribing, however, in an attempt to reduce the illegal diversion of these drugs. Unfortunately, many health care professionals with limited knowledge and experience in the treatment of cancer pain react to the perceived threat of investigation by law enforcement agencies with dramatic decreases in opioid prescribing.[18] This perception further contributes to the undertreatment of patients with cancer pain.

EVALUATION OF THE PATIENT WITH PAIN

A comprehensive assessment of cancer pain is the first important step toward optimal pain relief.[2] This evaluation should provide the clinician with sufficient information to carry out the following tasks:

- Estimate the severity of pain.
- Form a clinical impression regarding the etiology of the pain.
- Determine the need for further diagnostic studies.
- Formulate therapeutic recommendations that take into account the patient's overall medical and psychosocial status (Table 36-3).

As with any serious medical condition, the assessment of cancer pain requires a detailed history, physical examination, and review of available records, laboratory data, and imaging studies. The special challenges associated with the assessment of cancer pain include the entirely subjective nature of pain, the complex multisystem involvement in patients with advanced malignancies, and the ever-changing clinical situation in this patient population.

A detailed pain history is the cornerstone of the assessment. This can be complex, because 75% of patients with advanced cancer have several concurrent painful sites, and nearly one-third have four or more separate pain problems.[19,20] Each distinct pain must be

Table 36-3 Components of a Comprehensive Assessment of Cancer Pain

I. Detailed history of current pain problem
  A. Catalogue of pain (number and locations)
  B. Information for each pain
    1. Intensity (0–10)
    2. Locations and radiation
    3. Onset and changes over time
    4. Temporal pattern (constant, intermittent, etc.) and quality (burning, etc.)
    5. Exacerbating and relieving factors
    6. Associated neurologic or vasomotor abnormalities
    7. Other associated factors
    8. How the pain interferes with the patient's life
    9. Current therapeutic modalities (schedule, efficacy, side effects)
    10. Prior therapeutic modalities (schedule, efficacy, side effects)
II. Oncologic history
  A. Histologic
  B. Presentation: date, stage, sites of involvement
  C. Antineoplastic therapies: dates, types, doses, toxicities, and response to each therapy
  D. Current sites of disease: stable, responding, or progressive
  E. Patient expectations and goals
III. Medical history—may be affected by pain therapies
  A. Coexisting diseases
  B. Medications and allergies
  C. Substance abuse history
  D. Other constitutional symptoms (i.e., anorexia, fatigue, sedation and other changes in mental status, nausea, vomiting, dysphagia, dyspnea, constipation, urinary and sexual function, depression, dry mouth, ability to take medications by mouth, presence of a central venous catheter)
IV. Personal and social history
  A. Background: age, educational, employment, marital, residential, religious, cultural, ethnic
  B. Current status: functional status, caregivers and their health and availability, support system
V. Physical examination
VI. Review of additional information
  A. Medical records, radiologic/laboratory studies
  B. Family members and physicians and/or nurses who know the patient and his or her illness
VII. Differential diagnosis
VIII. Recommendations regarding workup and therapy
IX. Reassessment

From Grossman SA: Cancer pain assessment: a continual challenge. Support Care Cancer 1994;2:105.

identified and characterized. Pertinent information should include its intensity, location, radiation, how and when it began, how it has changed over time, and what makes it better or worse. The quality of each pain, its temporal pattern, whether it is associated with neurologic or vasomotor abnormalities, how it interferes with the patient's life, and an account of the successes and failures of current and prior therapeutic modalities also provide valuable insight.

Many instruments have been developed to aid in pain assessment.[21] These attempt to characterize and quantify the quality and/or intensity of a patient's pain and represent the best available means to document the discomfort and to follow the results of therapy serially. Each instrument has its shortcomings, but several have been validated in patients with cancer pain and incorporated into clinical practice. Most contain a variant of the unidimensional visual analog scale and a schematic representation of the body for the patient to indicate where their pain is located. The McGill Pain Questionnaire is comprehensive, but too awkward and time-consuming for most oncology patients in a clinical setting.[22–24] The Wisconsin Brief Pain Inventory, which can be completed in 15 minutes, provides information on the characteristics, severity, and location of the pain, its interference with normal life functions, and the efficacy of prior therapy. The Memorial Pain Assessment Card can be completed in less than a minute and features scales for the measurement of pain intensity and pain relief.[25] It is also designed to provide insight into global suffering or psychologic distress. The Hopkins Pain Rating Instrument is a validated plastic version of the visual analog scale that obviates the need for the paper, pencil, ruler, and measurements associated with the standard visual analog scale.[26] This simplifies repeated pain intensity measurements, making it easier to reassess the efficacy of therapeutic endeavors on a continuing basis.[27]

A complete oncologic history is also essential, because 90% of cancer pain is related to the malignancy or cancer treatment. The histology, presentation, stage, sites of involvement, and natural history and the history of surgery, radiation, chemotherapy, and hormonal treatments will help shape a therapeutic approach. In addition, it is important to note whether the malignancy is responding to therapy, stable, or progressing. A general medical history is also helpful, because pain treatments can affect coexisting medical problems, exacerbate constitutional symptoms, interact with other medications, or be contraindicated because of allergies. For example, a patient with painful bone metastases and severe peptic ulcer disease would not be an ideal candidate for potent anti-inflammatory agents. Opioids can be problematic in patients with severe benign prostatic hypertrophy or severe obstructive pulmonary disease and carbon dioxide retention. Likewise, knowledge that a patient tolerates food or fluids poorly by mouth, has an indwelling venous access device, or admits to substance abuse might influence decisions about the best way to control that patient's pain. The patient's age, functional status, social support, education, residence, health insurance, finances, and religious and cultural background might also figure prominently in planning therapy. A careful neurologic and physical examination also provides important clues as to the etiology of the pain. Added insight can come from a review of available laboratory and imaging data, from medical records, and from discussions with family members and physicians who are familiar with the patient and his or her illness.

The history, physical examination, and review of other available data should provide the clinician with sufficient information to formulate a differential diagnosis for each of the patient's distinct pains and to make recommendations regarding the workup and therapy for each. Based on this initial impression, analgesic therapy should be initiated. The nature of the treatment prescribed might depend on the clinician's judgment regarding the origin of the pain. Somatic, visceral, neuropathic, and sympathetically maintained pain are each approached somewhat differently (Table 36-4). Prompt institution of therapy reassures patients that their pain will receive immediate attention, ensures patient comfort for diagnostic studies, and can provide information on the accuracy of the clinician's assessment. Excellent pain relief suggests an accurate initial diagnosis and appropriate therapy, whereas suboptimal control might prompt a new treatment approach or a search for a different etiology of the pain.

One of the most difficult aspects of cancer pain management is that the patient's clinical situation is rarely static. The patient's

Table 36-4 Classification of Cancer Pain

Type	Characteristics	Examples	Primary Therapies
Somatic	Constant, aching, gnawing, often well localized	Bone metastases	Treatment of tumor, anti-inflammatory agents, analgesics
Visceral	Constant, aching, often associated with nausea	Pancreatic cancer	Treatment of tumor, analgesics, nerve blocks
Neuropathic	Paroxysmal shocklike pain on top of a burning, constricting sensation	Plexopathy or postherpetic neuralgia	Treatment of tumor, analgesics, TENS, nerve blocks
Sympathetically maintained	Severe burning, squeezing, or constricting with local edema	Reflex sympathetic dystrophy	Sympathetic blockade, physiotherapy, adjuvant analgesics

TENS, transcutaneous electrical nerve stimulation.
From Grossman SA, Staats PS: The current management of pain in patients with cancer. Oncology 1994;8:93.

underlying malignancy, antineoplastic therapy, and psychosocial status change continually during the course of the illness. As a result, the etiology and intensity of each new or worsening pain must be reassessed. The toxicities of the analgesics should also be evaluated periodically, because they can affect quality of life substantially. If significant toxicities are recognized, alternate approaches with a lower toxicity profile can be attempted.

MANAGEMENT OF CANCER PAIN

Nearly 85% of patients with cancer pain can achieve good control of their pain with conventional oral medications. More aggressive or invasive therapies should provide pain relief to an additional 10% of patients, leaving only a small fraction of patients with cancer with inadequate relief. [28]

Pharmacologic Therapy

Pharmacologic approaches are the most commonly used treatments for cancer pain, because they are effective, safe, and usually inexpensive. These are classified as nonopioids, opioids, and adjuvant analgesics. Twenty years after the World Health Organization's analgesic ladder was introduced, it still provides a framework for analgesic prescribing.[29–31] Aspirin, acetaminophen, or nonsteroidal anti-inflammatory drugs (NSAIDs) are preferred for mild to moderate pain.[32] If these do not provide adequate analgesia, codeine, oxycodone, or hydrocodone will frequently provide excellent relief (Table 36-5). For persistent or severe pain, codeine (or its congener) is replaced by a potent opioid, such as morphine (Table 36-6). Drug substitution should be considered before an entire class of agents is abandoned, because patients frequently tolerate one NSAID or opioid better than another. In addition, patients with severe pain might need a strong opioid as initial therapy to ensure rapid pain relief.[33]

The site of action of the nonopioids is primarily the peripheral nervous system. These agents are not associated with physical dependence, tolerance, or addiction, and they have a maximum dose associated with analgesia. Many are available in combination with a weak opioid. The anti-inflammatory component of aspirin and of the NSAIDs and COX-2 inhibitors is often useful for patients with somatic pain from bone metastasis, inflammation, or mechanical compression of tendons, muscles, pleura, and peritoneum, and for nonobstructive visceral pain. Because some of these agents can affect platelet and renal function or act as antipyretics, they should be administered thoughtfully to patients receiving chemotherapy. COX-2 inhibitors allow NSAIDs to be used with less risk of gastrointestinal bleeding and platelet dysfunction. However, the mounting evidence of increased cardiovascular risk calls into question the overall safety of all NSAIDs. Caution must be exercised in using these agents in patients with a history risk of cardiovascular disease.[34–36] In addition, it is important to recognize that sustained high doses of acetaminophen can cause renal and hepatic damage, especially when combined with more than 2 ounces of alcohol per day or with other agents that cause liver damage or induce hepatic microsomes.

Most patients with moderate-to-severe pain rely primarily on opioid analgesics for the management of their cancer pain. The vast majority of patients can be managed with oral opioids. These are best given "around the clock" to keep pain under control. Although tolerance to these agents occurs, tumor progression is the most common reason for increasing opioid requirements. Tolerance can easily be overcome by raising opioid doses. Addiction is extremely rare in patients with cancer who are taking opioids for pain relief (Table 36-7). Most opioid side effects can be managed without excessive

Table 36-5 Opioids for Mild to Moderate Pain

Drug	Route	Equi-Analgesic Dose (mg)*	Peak Effect (hr)	Duration of Effect (hr)	Comments
Codeine	PO	200	0.5	3–6	Ceiling for analgesia reached at doses >240 mg/day orally.
	IV/IM	130	0.5	3–6	
Oxycodone	PO	30	0.5	3–6	No ceiling dose if given without fixed combinations; parenteral formulation not available.
Hydrocodone	PO	NA	0.5	4–6	Only available as fixed combination with acetaminophen or aspirin.
Propoxyphene	PO	NA	1.0	4–6	100 mg napsylate = 65 mg hydrochloride salt. Not recommended for treatment of cancer pain.

*Approximate potency relative to 10 mg of parenteral morphine.
Modified from Grossman SA, Gregory E: Cancer pain. In Kirkwood MT, Lotze MT, Yasko JM (eds): Current Cancer Therapeutics. Philadelphia, Current Medicine, 1994, p 290.

Table 36-6 Strong Opiates for Moderate to Severe Cancer Pain

Drug	Route	Equi-Analgesic Dose (mg)*	Duration of Effect (hr)	Comments
Oxycodone	PO	20	3–6	No ceiling dose if given without fixed combinations; parenteral formulations not available.
	PO SR		12	
Morphine	PO	30	4–6	Many oral formulations for individual patient needs.
	PO (SR)		8–12	
	IV/IM	10	3–5	
Hydromorphone	PO	7.5	3–4	Good choice for SQ due to potency.
	PR	(?)	Unknown	
	IV/IM	1.5	3–4	
Meperidine	PO	300	3–6	Not preferred due to CNS toxic metabolite that accumulates in renal failure.
	IV/IM	75	2–3	
Levorphanol	PO	4.0	6–8	Long $T_{1/2}$ (11 hr) necessitates slow dose titration. Drug accumulation may occur.
	IV/IM	2.0	6–8	
Fentanyl	TD	(?)	≥12	Short $T_{1/2}$ (<1 hr). TD dose titration difficult with depot in SQ adipose tissue. TD fentanyl 25 μg/hr ≈ 45 mg/day oral morphine.
	IV/IM	0.1	0.5–1.0	
Methadone†	PO	10	6–8	Despite long $T_{1/2}$ (15 to >150 hr), duration of analgesia is not prolonged; however, drug accumulation can result in toxicities. Caution is warranted when converting to methadone in patients with high opioid tolerance.
Oxymorphone	PO	10	7–9	Now available as immediate-release formulations.
	PO SR		12	
	IV	1	7–9	

IV, intravenous; PO, oral; SQ, subcutaneous; TD, transdermal; (?), unknown.

*Approximate potency relative to 10 mg of parenteral morphine. Caution: Cross-tolerance between opioids is incomplete. Use caution when performing equi-analgesic conversions. Titrate to clinical response.

difficulty (Table 36-8). Constipation should be anticipated and treated prophylactically.[37]

The opioids have their primary effect centrally, where they interfere with pain perception. They can be classified into three groups:

1. Morphine-like opioid agonists that bind competitively with μ and κ receptors (e.g., codeine, fentanyl, hydromorphone, morphine, oxycodone, and methadone)
2. Opioid antagonists that have no agonist receptor activity (e.g., naloxone)
3. Mixed agonists-antagonists (e.g., pentazocine and butorphanol) or partial agonists (e.g., buprenorphine).[38]

The mixed agonist-antagonist drugs have limited utility in cancer pain because of their side effect profiles and their propensity to induce opioid withdrawal in patients who have received opioid agonists. Proper opioid prescribing is critical to patients with cancer (Box 36-1), who often require high doses of opioids for long periods of time.[39]

Several classes of drugs that are used primarily for conditions other than pain have been found to be useful adjuvant analgesics in specific circumstances (Table 36-9). Antidepressants and anticonvulsants can be effective in neuropathic pain. Psychostimulants can decrease opioid-induced sedation. Glucocorticoids are effective anti-inflammatory agents and are also used to reduce pain associated with brain edema and epidural metastases. Muscle relaxants, anxiolytic, antispasmodic, and neuroleptic agents also are administered for specific indications.[40] Bisphosphonates reduce the incidence of skeletal complications, particularly in patients with myeloma and breast cancer.[41,42] Caution must be exercised in the use of adjuvant drugs that have sedative properties, in that the dose of opioids should not be compromised by the toxicities of these secondary agents.

Although the vast majority of outpatients can be managed with oral opioids, alternative routes of analgesic administration are sometimes needed. Subcutaneous, intravenous, transdermal, transmucosal, or intraspinal opioids can be delivered by intermittent bolus, continuous infusion, or a combination of both, as is frequently the case with patient-controlled analgesia. These alternative routes of administration should be considered when a patient has one of the following conditions:

- Intractable vomiting or bowel obstruction, making oral therapy impractical

Table 36-7 Important Definitions in the Treatment of Cancer Pain

PHYSICAL DEPENDENCE

- A normal physiologic response to chronic opioid administration characterized by development of the abstinence syndrome on abrupt withdrawal of opioids.
- A potential problem in virtually all patients receiving moderate to high doses of opiates.

TOLERANCE

- A normal pharmacologic response to chronic opioid therapy characterized by the development of a relative resistance to analgesic and other effects of the drug.
- Overcome by increasing the dose administered.

PSYCHOLOGICAL DEPENDENCE (ADDICTION)

- Abnormal behavior pattern characterized by an all-consuming desire to obtain opioids for reasons other than pain relief. This often occurs at the expense of the patient's physical, social, and environmental well-being.
- Extraordinarily rare in patients with cancer pain.
- Not to be confused with "pseudo-addiction," which is behavior commonly seen in patients who are undertreated and in pain attempting to obtain appropriate analgesia.

Definitions Related to the Use of Opioids for the Treatment of Pain 2001. (Available at http://www.ampainsoc.org; www.asam.org). Modified from Grossman SA, Gregory E: Cancer pain. Table 36-8 Management of Common Opioid Side Effects

Side Effect	Management	Specific Agents
Constipation	Begin bowel program when initiating therapy.	Stool softeners
	Combinations of agents may be useful.	Irritants
		Bulk laxatives
		Lubricants
		Enemas
Nausea and vomiting	Treat with antiemetics, especially phenothiazine and anticholinergic agents.	Promethazine
		Prochlorperaxine
	Switch to another opiate.	Olanzapine
		$5HT_3$ antagonists
		Scopolamine
		Hydroxyzine
Sedation	Use of stimulants	
	Dextroamphetamine	
	Methylphenidate	
		Modafinil
Pruritus	Treat with antihistamines.	Hydroxyzine
	Consider another opiate, avoiding morphine.	
	Diphenhydramine	
Myoclonus	Switch to another opiate or lower opiate dose.	
	Benzodiazepines	
	Use of anxiolytics	
	Avoid meperidine, especially in patients with impaired renal function.	
Withdrawal symptoms	Taper dose by one-half every other day when discontinuing.	Clonidine

Box 36-1. MANAGEMENT APPROACH

Tenets of Opioid Prescribing

- Order opioids on a scheduled "around-the-clock" basis to optimize relief.
- Order an as-needed opioid to treat breakthrough or incident pain. For example, if a patient is taking morphine elixir, 100 mg orally every 4 hours, order an additional 25 to 50 mg of oral morphine elixir every 2 hours as needed for pain.
- Initiate a prophylactic bowel regimen at the same time opioids are prescribed. Patients usually require a combination of detergent and stimulant cathartics to treat opioid-induced constipation.
- Treat opioid-induced nausea and vomiting with aggressive antiemetic management. This includes giving patients antiemetics on an around-the-clock basis. Patients often become tolerant to this side effect several days after beginning opioids.
- Once baseline opioid requirements are determined, sustained-release opioid preparations can be used to reduce the number of pills taken each day.
- Teach the patient and family about the purpose and benefits of opioids to allay their fears about side effects and addiction. This instruction will improve patient compliance.
- Frequent assessment of pain relief is paramount during the opioid titration period. Titrate doses based on the patient's report of pain relief and/or the amount of as-needed opioid that has been required for patient comfort.
- Maximize the doses of one opioid before changing to another agent or route. Changes should be made primarily because of toxicities. For example, a patient taking 200 mg of controlled-release morphine every 12 hours and 200 mg of immediate-release morphine daily for breakthrough pain should have the dose of controlled-release morphine increased to 300 mg every 12 hours if he or she is not experiencing significant opioid side effects. This approach is more likely to be beneficial than beginning titration with subcutaneous or intravenous morphine or oral hydromorphone.
- Refer to equi-analgesic tables when initiating or changing a patient's analgesic regimen (see Tables 36-5 and 36–6).
- Avoid chronic administration of intramuscular or rectal opioids.
- Do not use chronic administration of meperidine, which can be associated with the accumulation of normeperidine, a neurotoxic metabolite.

- Ineffective pain relief despite titration to toxicity with several oral opioids
- Unacceptable toxicities to several oral opioids
- Such high opioid requirements that oral administration is impractical

The costs associated with these routes of opioid administration must be considered carefully. In addition, care must be taken not to transform the home unnecessarily into a complex health care setting.

Subcutaneous opioid injections administered through a butterfly or subcutaneous needle on a fixed schedule are used commonly by hospices as an effective, less expensive alternative to continuous intravenous or subcutaneous infusions. A transdermal system for opioid administration can be beneficial for some patients. Although transdermal fentanyl provides patients with continuous drug delivery, it does not eliminate the need for additional analgesics for breakthrough pain. The slow onset of action of fentanyl and the uncertainties associated in conversion from other opioids have led many to reserve transdermal fentanyl for patients with stable opioid requirements who do not have significant incidental pain.[43,44]

Oral transmucosal fentanyl citrate (OTFC) can be effective for patients with incident or breakthrough pain, for whom rapid onset and short duration of action are desired.[45] This opioid is available as a lozenge or a buccal tablet. When placed into the mouth, a portion of the fentanyl is absorbed rapidly through the oral mucosa, while the remainder is swallowed and absorbed through the gastrointestinal tract. The onset of analgesia can be as soon as five minutes. The optimal dose for this delivery system is found through titration and is not predicted by the around-the-clock dose of opioids. The effervescent transmucosal fentanyl tablet has a higher bioavailability than oral transmucosal fentanyl citrate, and the manufacturer recommends converting doses of the two products.[46]

Intraspinal opioids produce analgesia without blocking other sensory, motor, or sympathetic functions. These can be delivered into the epidural space through a tunneled external catheter or to the subarachnoid space or lateral ventricles using a totally implanted pump.[47] Because the total daily dose of intraspinal opioid is one-tenth to one-hundredth of parenteral opioid, it is associated with fewer systemic toxicities. Chronic epidural or intrathecal opioids are invasive, expensive, and frequently ineffective in patients requiring high doses of systemic opioids. Tolerance, pruritus, urinary retention, and nausea and vomiting occur in as many as 20% of patients receiving spinal opioids. Respiratory depression is unusual. The addition of low doses of anesthetic agents or agents such as clonidine to intrathecal and epidural opioids could add considerably to pain relief. Ziconotide, a selective N-type calcium channel blocker, is approved for intrathecal analgesia in patients with pain refractory to other treatments.[48] Intraspinal opioids are generally used after documentation of the failure of maximal doses of opioids through other routes.[49] Consensus guidelines are available to guide the practitioner with proper drug selections for intraspinal analgesia.[50]

Antineoplastic Therapy

Antineoplastic therapy can provide analgesia if it reduces the size of lesions invading or compressing normal tissues. Radiation therapy is the treatment of choice for most patients with local pain from tumor progression. It is frequently administered to patients with symptomatic bone, brain, epidural, and plexus metastases. Systemic radiopharmaceuticals such as strontium-89 and samarium are also used for the treatment of pain from bone metastases.[51] Chemotherapy can provide substantial pain relief in malignancies that respond to this therapeutic modality. Surgery can be effective in relieving pain from intestinal obstruction, pathologic fractures, and obstructive hydrocephalus.

Nonpharmacologic Therapy

Neurostimulatory techniques, such as transcutaneous electrical nerve stimulation, are safe, noninvasive, relatively inexpensive, and easily added to other analgesic approaches.[52] Transcutaneous electrical nerve stimulation could provide short-term benefits in patients with cancer, and a 2- to 4-week trial will often determine its clinical utility. Nonpharmacologic approaches such as progressive muscle relaxation, massage, use of heat or cold, guided imagery, biofeedback, hypnosis, and acupuncture are useful adjuncts to pain management.[53] Although psychotherapy is indicated for an associated depression, unrelieved pain can result in depression that is best treated with analgesic therapies.

Invasive Therapy

Although most cancer pain can be well controlled using the techniques listed in the foregoing discussions, some pain remains refractory, and some patients have persistent adverse effects from opioids despite aggressive therapy with psychostimulants, antiemetics, and laxatives. The side effects can be severe enough that patients might refuse to take sufficient medication to relieve their pain. Adding adjuvant medications, changing to another opioid, or using continuous intravenous or subcutaneous infusions to reduce "peak" levels might be helpful. In selected patients, regional analgesia or neuroab-

Table 36-9 Commonly Used Adjuvant Analgesics for Cancer Pain

Drug Category	Indications	Drugs	Common Toxicities	Comments
Antidepressants	Neuropathic pain	Amitriptyline Nortriptyline Desipramine	Sedation, dry mouth, constipation, postural hypotension, urinary retention	Begin with low doses (10–25 mg); increase dose every few days; expect to see pain relief within several days, mood elevation within several weeks.
Anticonvulsants	Neuropathic pain, myoclonic jerks	Phenytoin Carbamazepine Valproic acid Clonazepam Gabapentin	Drowsiness, dizziness, nausea, rash, bone marrow depression	Use loading dose with phenytoin; monitor platelets wth carbamazepine.
Psychostimulants	Opioid-induced sedation	Dextroamphetamine Methylphenidate Modafinil	Nervousness, irritability, insomnia, dizziness, dry mouth	Give early in the day to avoid insomnia; do not use if patient is already delirious or confused.
Corticosteroids	Spinal cord compression, increased intracranial pressure, visceral distention	Decadron Methylprednisolone Prednisone	Gastritis, insomnia, fluid retention, hyperglyceroximal myopathy, increased appetite	
Muscle relaxants	Muscle spasm	Diazepam Baclofen Methocarbamol Cyclobenzaprine	Sedation, dizziness, nausea, weakness, confusion	
Benzodiazepines	Muscle spasm, myoclonus, anxiety, insomnia	Diazepam Lorazepam Alprozolam Midazalam Temazepam	Sedation, delirium, hypotension, headache, respiratory depression	Not analgesics; synergistic effect with opioids can cause respiratory depression.
Antispasmodics	GI or bladder spasm	Diphenoxylate and atropine Loperamide Scopolamine patch Dicyclomine	Sedation, dry mouth, constipation	
Neuroleptics	Delirium, agitation, nausea and vomiting, hiccoughs	Methotrimeprazine Haloperidol Prochlorperazine Chlorpromazine	Sedation, orthostatic hypotension, confusion, extrapyramidal reactions	Useful for symptoms other than pain; methotrimeprazine has analgesic properties
Bisphosphonates	Bone pain	Pamidronate Zoledronic acid	Hypocalcemia, fever, GI disturbances, anemia	Delays time to painful skeletal events; also used with analgesics for bone pain.

GI, gastrointestinal.

lative procedures might permit the doses of pharmacologic agents to be reduced substantially. In particular, spinal metastases may be treated with minimally invasive therapies such as vertebroplasty, kyphoplasty, or radiofrequency ablation.[54] Neurosurgery has been shown to be the first-line therapy over radiation therapy in the management of a solitary spinal metastasis.[55] These invasive approaches should be considered under the following conditions:

- If significant pain persists at doses of analgesics that are associated with intolerable side effects
- If excessive toxicities result from opioid analgesics
- If a careful assessment suggests that a low-risk procedure is likely to result in excellent analgesia

Regional Analgesia

Regional analgesia can be achieved with long-acting local anesthetics that provide pain relief for 3 to 12 hours, neurolytic agents (alcohol or phenol) that produce analgesia for weeks to months, or opioids injected into the epidural or subarachnoid space (Table 36-10). Diagnostic blocks with local anesthetics are usually performed before neurolysis. This permits the anesthesiologist to determine the response to local therapy and allows the patient to decide whether the "numbness" that replaces the pain is tolerable. If the pain can be relieved temporarily with local anesthetics, alcohol or phenol can be injected into the subarachnoid or epidural space to destroy nociceptive fibers in the dorsal rootlets, thus simulating a surgical rhizotomy. Although

Table 36-10 Regional Anesthetic Techniques

	Types of Blocks	Examples	Indications	Comments
Local anesthetic blocks	Diagnostic	Intercostal nerve block	Determine etiology of pain and the response and side effects following local therapies.	Analgesic effect will last only hours.
	Treatment of sympathetically maintained pain	Stellate ganglion block	Sympathetically maintained pain	Repeated blocks might be needed.
	Trigger point injections	Trigger point injection	Myofascial pain syndrome	Repeated blocks might be needed.
Neurolytic (alcohol or phenol) blocks	Peripheral	Intercostal nerve blocks	Chest wall tumor	Pain relief usually lasts several months.
	Visceral	Celiac plexus block	Pancreatic cancer	Pain relief usually lasts several months.
	Neuraxial	Epidural	Pain localized to two or three dermatomes	Pain relief usually lasts several months
		Intrathecal neurolysis		

From Grossman SA, Staats PS: The current management of pain in patients with cancer. Oncology 1994;8:93, with permission.

injections of these neurolytic agents are commonly called "permanent blocks," pain relief usually lasts several months. Neurolytic blocks can be particularly useful in the thoracic region, where they are associated with few motor complications. In the cervical and lumbar regions, nearly 20% of patients develop motor and/or sphincter dysfunction, which can be permanent. In patients with pre-existing lower extremity paralysis, colostomy, or nephrostomy tubes—cases in which loss of motor or sphincter function might be less critical—lumbar neurolysis might be worthwhile. Other potential side effects of these procedures include hypotension, toxic reactions from accidental intravenous or subarachnoid administration, or pneumothorax after needle placement. Neurolysis is usually restricted to patients with a limited life expectancy, because it can produce a painful neuritis that becomes clinically apparent only months after the procedure.

Neurolytic blocks are used in selected patients who have localized or regional pain. Percutaneous celiac plexus neurolysis is an outpatient procedure associated with few risks; it alleviates pain originating in the pancreas, stomach, gallbladder, or other upper abdominal viscera in most patients. One randomized, prospective, double-blind trial comparing celiac plexus injections of alcohol or saline and systemic analgesic therapy in patients with unresectable pancreatic cancer showed greater pain relief with the block. Opioid consumption and quality of life were not statistically significant, however.[56] In other settings, it has been shown to decrease opioid requirements.[57,58] Although pain can recur months after a celiac block, subsequent blocks are often associated with excellent pain relief. Less commonly used neurolytic procedures include intercostal blocks (chest wall or rib pain), neuroaxial blocks (pain in two to three dermatomes), Gasserian ganglion neurolysis (pain in the anterior two-thirds of the head), brachial plexus blocks (for patients with pre-existing limb paralysis), and ganglion impar and superior hypogastric blocks (for lower abdominal and pelvic pain).

Neuroablative Procedures

Neuroablative procedures are performed infrequently on patients with cancer because of the success of more conservative approaches. The most commonly performed procedures are radiofrequency ablation and the open unilateral anterolateral cordotomy, percutaneous cordotomy, and commissural myelotomy. An open cordotomy is usually performed through a T2 or T3 laminectomy and produces excellent pain relief in the lower part of the body in 80% of patients. A 5% to 10% mortality rate and significant morbidity in an additional 15% of patients are reported for this procedure. Hemiparesis, urinary retention, sexual impotence, unmasking pain on the opposite side of the body, and late sensory abnormalities are not infrequent. Bilateral cordotomies are associated with higher complication rates. Percutaneous cordotomy is safer and provides excellent pain relief; however, pain recurs within 3 months in 50% of patients. A commissural myelotomy can be considered in selected patients who experience bilateral pelvic and perineal pain. This involves a laminectomy and surgical division of the crossing fibers of the spinal cord. Although it can result in pain relief with sphincter sparing, few neurosurgeons have extensive expertise with this procedure.

DIFFICULT-TO-MANAGE PAIN PROBLEMS

Difficult-to-manage pain problems are most common in patients with any of the following conditions:

- Pain of neuropathic origin
- Episodic or incidental pain
- Impaired cognitive or communicative skills
- A history of substance abuse

Referral to an experienced multidisciplinary cancer pain team can be helpful if initial attempts to control pain in patients with these underlying problems are unsuccessful.

Patients with Pain of Neuropathic Origin

Any injury to the peripheral or central nervous system can cause neuropathic pain. This is often characterized by paroxysms of shock-like pain on top of a burning or constricting sensation. Neuropathic pain in patients with cancer commonly arises from tumor invading or compressing peripheral nerve, nerve plexus, or spinal cord. It can occur as a result of surgery, radiation, or chemotherapy as exemplified by postmastectomy and post-thoracotomy syndromes, radiation-induced plexopathies, and chemotherapy-induced neuropathies.[59,60] Neuropathic pain also can accompany disorders that are unrelated to the tumor or its treatment, such as diabetes mellitus, nerve entrapment syndromes, and herpes zoster.

Providing adequate relief from neuropathic pain can be difficult even for the most experienced physicians. Although this pain might improve on opioids, it seems to respond less well to these agents than does nociceptive pain. Optimal therapy for neuropathic pain often depends on opioids used in combination with a variety of nonopioid "adjuvant" analgesics (see Table 36-9).[61] Tricyclic antidepressants have been studied most extensively in this situation. Although the most

convincing efficacy data is with amitriptyline, this agent is associated with significant anticholinergic effects and sedation. Other drugs in this class with a more favorable toxicity profile include desipramine and nortriptyline. Duloxetine, a serotonin and dual serotonin-norepinephrine reuptake inhibitor, has substantial effect in neuropathic pain.[62]

Anticonvulsants are also helpful in the management of neuropathic pain, particularly if the pain has lancinating qualities. The doses of these agents are similar to those used for the control of seizures. Care must be taken to avoid abrupt withdrawal, because this could induce seizures. Randomized controlled trials have demonstrated the efficacy and tolerability of gabapentin for the treatment of postherpetic neuralgia and painful diabetic neuropathy.[63] Other studies suggest that it might help in the management of neuropathic pain secondary to cancer or its treatment.[64] This agent is well tolerated, no drug-drug interactions have been identified, and the average effective dose is 1800 to 3600 mg/day. A newer anticonvulsant, pregabalin, has a mechanism of action and side effects similar to gabapentin. Maximum doses are achieved within 1 to 2 weeks, offering an advantage over gabapentin.[65] Reports support the use of carbamazepine, valproic acid, and diphenylhydantoin, although the myelosuppression associated with carbamazepine might compromise the ability to administer concurrent chemotherapy.

Systemically administered local anesthetics have been used for the treatment of neuropathic pain. Anesthetic creams that produce few systemic side effects are also available. Topical lidocaine patches are an effective means to contol neuropathic pain that is confined to a small area. Capsaicin, a neurotoxin that selectively destroys nociceptors, is also manufactured as a topical preparation and provides relief in some patients. If oral agents and topical creams are ineffective, afferent input can be reduced with transcutaneous electrical nerve stimulation or regional anesthetic techniques such as long-term epidural catheters or intrathecal pumps for the delivery of local anesthetics. Neurolytic blocks, more invasive neurostimulatory techniques, or even neurosurgical procedures might be indicated in extreme situations.

Patients with Episodic or Incidental Pain

It is widely recognized that some patients experience transient, but severe, exacerbations of their pain. These can be difficult to treat and are often very troubling to the patient. These exacerbations can occur as a result of an inadequate analgesic regimen. For example, a patient who receives opioids every 6 hours and has good relief for only 4 hours needs a change in regimen to ensure that opioid levels will not fall below the analgesic threshold after 4 hours. This change is best accomplished by providing the agent more frequently or by administering sufficient doses of a sustained-release preparation. Episodic pain associated with voluntary or involuntary movements poses a more difficult therapeutic problem. Examples of these "incidental pains" are seen in patients with pelvic metastases or pathologic fractures who have severe pain with walking or sitting, patients with rib metastases who experience stabbing chest pain with movement or coughing, or patients with esophageal, rectal, or bladder lesions with pain on swallowing, defecation, or urination, respectively. Involuntary precipitants can include bowel or ureteral distention. In a recent study of incident pain, nearly three-quarters was directly related to neoplastic lesions, 20% resulted from of antineoplastic therapy, and the remainder was unrelated to the tumor or its treatment.[66–68]

Proper management of these patients requires a comprehensive assessment to determine the origin of the pain. Therapy directed at the underlying etiologic factors is most likely to provide pain relief. Relieving a bowel obstruction, repairing or splinting a fracture, treating a local metastatic lesion with radiation therapy, or performing a neurolytic block for a painful rib lesion provides better analgesia than opioids. The frequency and severity of incidental pain might also be reduced significantly by anti-inflammatory agents or corticosteroids in bone or nerve compression pain and by anticonvulsants or tricyclic antidepressants in neuropathic pain. In addition, agents that reduce the frequency of precipitating events should be used. These include antitussives, laxatives, antiperistaltic drugs, or agents that reduce muscle spasms. Physiotherapy can be useful in musculoskeletal complications, and the cognitive and psychologic approaches can be helpful to patients with these pains. Rarely, patients require invasive anesthetic or neurosurgical approaches for relief of these transient but severe pains. Local anesthetic injections might predict whether a patient is likely to respond to chemical neurolysis or a destructive neurosurgical procedure. Continuous epidural anesthetics and opioids might also be helpful in carefully selected patients.

Many of the approaches listed in the foregoing discussion might not be effective, or even possible or advisable, in the context of a patient's illness. In such situations, opioids remain the mainstay of therapy. The baseline dose of opioid can be escalated until pain relief or intolerable side effects occur. Although this approach might produce relief, patients are often excessively sedated during the intervals between the severe pains. Alternatively, patients might elect to take supplemental analgesics (usually short-acting opioids) 30 to 60 minutes before they know a precipitating event is likely to occur. If the pain is unpredictable, the additional medications are taken as soon as the pain begins. The optimal timing of opioids for episodic pain is difficult to achieve. Episodic pain is characterized by a quick onset and short duration. Parenteral opioids, while having a faster onset of action than the oral route, are not practical in the home setting. Alternatively, the transmucosal fentanyl products may provide the best option. The doses of these supplemental opioids must be determined from the patient's baseline opioid requirements. It is common to begin with 5% to 10% of the total daily opioid dose ordered every 2 to 3 hours as needed. The dosing of transmucosal formulations, as previously mentioned, is determined through titration and not based on the baseline opioid requirement.[45,69]

Patients with Impaired Cognitive or Communicative Function

The difficulties that physicians and nurses have determining the intensity of pain in patients with cancer have been described previously in this chapter. Problems in conveying pain intensity are greatly magnified in patients who cannot communicate with their health care providers or who are cognitively impaired. These deficits complicate the assessment of both pain intensity and pain relief. Some patients are unable to speak the language of the health care provider, whereas others have severe neurologic deficits, such as an expressive aphasia. As previously noted, children and the elderly have special difficulty communicating pain intensity.[70] Patients with severe cognitive deficits present obvious problems in assessing an entirely subjective symptom. Delirious patients with cancer are often restless, moaning, and unable to convey the intensity, nature, or even location of their pain. These patients require a review of correctable factors contributing to the delirium. Neurologic events, infections, trauma, bladder distention, fecal impaction, hypoxia, or metabolic abnormalities are common. The patient's drug regimen should be simplified, and all agents with anticholinergic properties should be discontinued. If the patient is on an opioid, reducing the dose, switching agents, or using a continuous infusion or sustained-release preparation to avoid wide fluctuations in drug levels might result in improvement.[71]

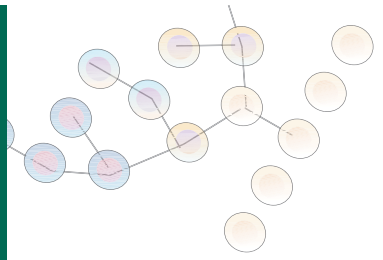
Patients with a History of Substance Abuse

The principles of cancer pain assessment and management in patients with a current or prior history of drug abuse are similar to those for any patient with cancer pain.[15] These individuals should not remain in pain as a result of this complicating medical problem. Patients with a history of drug abuse, however, often have difficulty finding physicians who believe their reports of pain and who will provide the high doses of analgesics required in these opioid-tolerant individuals. As a result, they can become angry, frustrated, and more persistent in their

demands for opioids. This constellation of symptoms is also seen in patients who do not have a history of drug abuse but who have severe, untreated pain. Their preoccupation with obtaining analgesics is referred to as pseudo-addiction and tends to disappear rapidly with appropriate pain therapy.

A frank discussion of major issues relating to the proper use of opioid analgesics for pain management with the patient, the patient's family, and the drug counselor is important. Pain management agreements often help to ensure that all parties understand and agree to the same principles and plans for therapy. Oral agents are preferred, or regional pain management techniques that could limit the need for opioids can be considered. Opioids such as methadone might be prescribed in lieu of morphine or hydromorphone.

CONCLUSION



Pain is common in patients with cancer and remains one of the most feared aspects of this illness, despite the excellent therapies that are available to provide pain relief. Cancer pain commonly results from tumor compressing or invading soft tissue, bone, or nerves or from diagnostic or therapeutic endeavors. The key to optimal pain management rests with a thorough assessment of the patient's pain. This involves a determination of pain intensity, an evaluation of the etiology of the pain, a carefully considered therapeutic plan, and repeated assessments of pain relief after therapeutic interventions. The vast majority of cancer pain can be well controlled with therapies readily available to most physicians. These include nonopioid analgesics, opioid analgesics, adjuvant medications, antineoplastic therapies, nonpharmacologic approaches, and noninvasive neurostimulatory techniques. Regional anesthetic or neurosurgical approaches should be considered for selected patients who continue to experience pain after an adequate trial of the foregoing therapies or who have unrelenting toxicities from these agents. They should also be considered for patients whose pain suggests that an inexpensive, low-risk procedure is likely to result in excellent analgesia. Examples of such cases include pancreatic cancer pain and thoracic pain in a dermatomal distribution. Referral to an experienced multidisciplinary pain team might be required in situations that are known to pose special challenges in pain management. These include patients with neuropathic pain, episodic or incident pain, impaired cognitive or communicative capabilities, or a history of substance abuse.

Cancer pain remains undertreated despite evidence that a careful assessment of cancer pain and the appropriate use of available therapies should result in excellent relief in nearly 95% of patients. Providing optimal cancer pain relief tests the skills and commitment of physicians, nurses, and pharmacists, because the diagnostic, therapeutic, and social issues in these patients are complex and constantly changing. Meeting these challenges can be satisfying, because patients and family are grateful to find that pain can usually be alleviated. Furthermore, as noted in the American Society of Clinical Oncology's policy statement on cancer pain, "patients with cancer have a right to effective treatment of pain" and the "evaluation and treatment of cancer pain are an integral part" of each caregiver's responsibilities.[7]

37 Rehabilitation of Individuals with Cancer

R. Samuel Mayer, Kenneth Silver, and N. Lynn Gerber

SUMMARY OF KEY POINTS

- As cancer treatment improves, more patients are living longer with functional limitations, and quality-of-life (QoL) issues become as important as survival.
- Rehabilitation must be patient centered and goal oriented. It requires an interdisciplinary team with the active participation of the patient.
- Impairments, activity limitations, and participation restrictions from cancer dramatically affect QoL, but these are amenable to rehabilitation efforts.
- The focus of rehabilitation varies with the phase of the disease process.
- Important impairments include pain, fatigue, cognitive dysfunction, mood disorders, paresis, feeding difficulties, bone and soft tissue involvement, and bladder, bowel, and sexual dysfunction.
- Activity limitations can be ameliorated with training in activities of daily living (ADLs), exercise, and adaptive equipment.
- Participation in home, vocational, and recreational activities plays a critical role in QoL. Economic burdens, environmental barriers, and transportation problems often require attention.

INTRODUCTION

The National Cancer Institute Dictionary of Cancer Terms defines rehabilitation as "a process to restore mental and/or physical abilities lost to injury or disease, in order to function in a normal or near-normal way."[1] Rehabilitation is critical to improving quality of life (QoL) for cancer survivors, and maintaining dignity for those with terminal illness. Rehabilitation requires several components to be successful.

First, it must be *patient-centered*—that is, individualized to the patient's needs, desires, and situation. Health care providers always must remember that the patient is the captain of the rehabilitation team. Rehabilitation that fails to respect a patient's wishes will fail altogether. Most problems in rehabilitation occur when there are differences in the team's goals and those of the patient.

Second, it must be *goal-oriented.* Goals should be meaningful to the patient's QoL. They must be measurable and concrete, so that they are transparent to the patient and the caregivers. Goals also must be achievable. Health care providers must balance realism with hope in counseling patients about their goals.

Third, rehabilitation requires an *interdisciplinary team approach.* In traditional multidisciplinary medical teams, different health care professionals each individually set goals appropriate to their area of specialization. In interdisciplinary rehabilitation, the team members work toward common goals by fulfilling the responsibilities of not only their particular discipline, but also the added responsibility as a group toward fulfilling the patient's goals. Team members must demonstrate a high degree of communication skills, humility, and commitment.[2]

Finally, rehabilitation also requires the *active participation of the patient.* Rehabilitation is not something done *to* an individual; it must be done *with* the individual. It is not a passive process, and it requires individuals to take responsibility for *self-management* of their illness. Rehabilitation is largely an educational process for the patient and family members.

The World Health Organization has recently published an International Classification of Functioning, Disability and Health, which is meant to supplement the International Classification of Disease (ICD-10).[3] It lays out a series of definitions that are crucial to understanding the role of rehabilitation in improving QoL. Box 37-1 lists these definitions. In this chapter we will focus on *impairments, activity limitations,* and *participation restrictions* seen in cancer patients, and discuss how rehabilitation can ameliorate these disabilities.

EPIDEMIOLOGY OF CANCER DISABILITY

As a result of the tremendous progress in prevention, early detection, and treatment of cancer in the last quarter century, there has been a decline in mortality rates from cancer. However, the number of cancer survivors continues to grow, as more people are living longer with cancer because of the new advances in surgery, and in medical and radiation oncology.[4] The result is that increasing numbers of patients face more years with cancer-related disability.[5] Data from the National Health Interview Survey 2002 indicate that 11.3% of patients with cancer have difficulty with activities of daily living (ADLs) as compared with 3.8% of people without cancer in the United States.[6] Among prostate cancer patients, 15% have major difficulties with ADLs; among colon cancer patients, 35% have such difficulty, and the proportion rises to 40% among lung cancer patients.[7]

Even among 5-year cancer survivors, elderly women with a history of cancer had statistically significantly more problems with ADLs than age-matched controls.[8] Focus should be directed away from mere survival toward the preservation and improvement of QoL for these survivors. In Japan, for example, the number of breast cancer survivors with lymphedema, as well as chest wall, axilla, and arm pain is expected to double by 2020.[9]

Box 37-1. WORLD HEALTH ORGANIZATION INTERNATIONAL CLASSIFICATION OF FUNCTIONING, DISABILITY, AND HEALTH DEFINITIONS

Impairments: Problems in body function or structure such as a significant deviation or loss of a body part or organ system.
Activity limitations: Difficulties an individual may have in executing activities of daily life.
Participation restriction: Problems an individual may experience in involvement in life situations.

OUTCOME MEASURES FOR CANCER REHABILITATION

Cancer is a complex, chronic illness whose management requires vigilance and a comprehensive and preventive approach to illness and disability. To accomplish this, a systematic approach to patient evaluation throughout all the phases of the disease process is necessary (Table 37-1).

The major concerns of persons with cancer include their overall health, fitness, fatigue, emotional and social function, and pain,[10] which may vary during different phases of the disease. For example, in the initial staging phase, anxiety and disruption of routines may present the greatest challenges. During the treatment phase, the symptoms of fatigue, nausea, and sleep disruption may be the most significant problems.

In general, patient assessments should be tailored to which signs and symptoms are most likely to be associated with the current phase of the disease. Screening tools should include questions relevant to which problems are important to the patient and family, which are likely to be associated with disabilities and which are remediable or need palliation. Once treatments are initiated the care team must assess whether the treatments are effective and at what cost.

Many outcome measures have been developed for cancer patients and have been validated in this population—some for specific cancers, some for toxicity measures, some for specific age groups. In general, it is appropriate to select measures that are easy to use, standardized, and valid for the population and problems being addressed. The following measures are recommended:

- Impairment measures: range of motion, muscle testing (including grip strength), pain indices, fatigue measures, mood/affect
- Functional measures/disability measures: mobility (6- or 9-minute walk time), ADLs
- Health-related QoL/health status measures: SF36, Karnofsky, Eastern Cooperative Oncology Group (ECOG), Eastern Organization for Research and Treatment of Cancer–Quality of Life Questionnaire (EORTC-QLQ).

IMPAIRMENTS

Cancer, even when localized to—or arising from—one organ system, causes the loss of body function across many organ systems in individuals. The physician must obtain a comprehensive review of systems when evaluating a cancer patient, because this will help identify impairments to be addressed by the treatment team.[11] Delineating these impairments in individuals is the first step toward ameliorating them; this lies at the core of cancer rehabilitation.

Pain

Virtually every cancer patient experiences pain during the course of the illness; it can often become debilitating.[12,13] Pain severity correlates closely with function, as demonstrated in one study of 216 Chinese cancer patients with metastatic disease.[14] In that study patients with increasing severity of pain had poorer function, whereas those with mild, well-controlled pain functioned similarly to those without pain. The clinician should distinguish whether the pain is acute in onset or a chronic problem. Often it can be an acute exacerbation heaped upon a chronic underlying pain.

The etiology of pain in cancer patients is myriad and frequently has multifactorial causation. The pain may be visceral (arising from internal organs), somatic (from soft tissue, muscles, and/or bones), or neuropathic (from the central or peripheral nervous system). Visceral pain tends to be poorly localized. It is often described as "deep" and "cramping." Somatic pain, on the other hand, is usually well localized. It is often characterized as "sharp" or "stabbing," and is frequently worsened by weight bearing or movement. There is often point tenderness on examination. Neuropathic pain tends to radiate along dermatomal or peripheral nerve distributions. Patients frequently describe "burning" or "pins and needles." The pain tends to be unrelenting. There may be associated allodynia (pain with light stroking).

Pain often produces psychological distress in patients, which in turn exacerbates the pain.[15] Tishelman and colleagues studied symptoms among 400 patients newly diagnosed with inoperable lung cancer and reported that pain, breathing, and fatigue caused the most distress. They concluded, "Breathing and pain appeared to function as icons representing threats associated with lung carcinoma."[16] Thus, pain may cause the patient to fear disease progression and impending death.

Sadly, pain is often inadequately treated in cancer patients. As many as 50% to 80 % of nonhospice cancer patients receive inadequate analgesia.[17] Yet pain can be well controlled in more than three-quarters of cancer patients using multimodal treatment, according to one study of 2118 patients.[18] Treatments can include opioids,[19] adjuvant medications,[20,21] complementary therapy,[22] physical modalities, exercise,[23] behavior management,[15] injections, implantable opiate pumps,[24] radiation therapy,[25] and surgery.[26]

Table 37-1 Phases of Cancer Rehabilitation

Phase	Patient Needs	Symptoms	Impact
1. Evaluation and treatment planning	Education	Pain, anxiety, insomnia	Disruption of daily routines
2. Primary training	Education, acute care	Pain, fatigue, ROM, ↓ ambulation, ADL support	Daily routines, stamina (psychologic social function)
3. Post-treatment, recovery	Education, support, chronic care, healthy lifestyle	Pain, anxiety, depression, mobility, edema, fatigue, neuropathy, insomnia	Work, family, avocation, cosmesis
4. Recurrence	Education, support	Same as above; metastatic disease effects	Daily routines, work/play
5. End of life	Education, support	Pain, asthenia, depression	Dependence

Fatigue

Cancer-related fatigue (CRF) is a "persistent, subjective sense of tiredness related to cancer or cancer treatment that interferes with usual functioning." (National Comprehensive Cancer Network [NCCN], http://www.nccn.org; American Cancer Society, http://www.cancer.org). This has been expanded to include concepts of "overwhelming and sustained exhaustion and decreased capacity for physical and mental work . . . not relieved by rest."[27] In addition, fatigue has been shown to affect negatively one's economic status,[28] and social and emotional status.[29]

CRF is correlated to treatment intensity[30] and can last well past completion of treatment. As many as 75% of cancer patients[31] have CRF. The likelihood of developing fatigue is increased with any cancer-related treatment (surgical, chemotherapeutic, or radiotherapeutic) and is also more likely to occur with comorbidities (e.g., hepatic, cardiac, renal, pulmonary) and other conditions (e.g., insomnia, inactivity, chronic pain, mood disorders).[32] Fatigue may persist beyond the treatment period.[33]

Treatment is frequently directed at varying the treatment protocol when possible and providing treatment holidays (Practice Guidelines NCCN for Cancer-Related Fatigue. http://www.nccn.org). It has been shown that improving quality of sleep is helpful, but increasing the amount of "rest" is not effective in reducing the symptoms of CRF.[34] Careful attention to comorbidities and their treatment will reduce CRF. Treatment of depression and chronic pain has been shown to improve symptoms.[35] Exercise has been shown to mitigate fatigue.[36]

Delirium and Cognitive Dysfunction

Delirium is a mental state in which a person is confused, disoriented, and not able to think or remember clearly.[1] The incidence in studies of advanced cancer patients ranges from 20% to 86%.[37] Delirium may be reversible in 50% of the cases with proper identification and management.[38] Delirium in cancer usually has multifactorial etiology. Accurate assessment is critical for effective treatment.[39] Direct involvement of the central nervous system by primary or metastatic tumors, especially with resultant cerebral edema, is the most readily apparent cause. However, distant tumor cytokine production may also play a role.[40] Liver metastasis may also elevate serum toxins, causing a metabolic delirium. Risk factors for the development of delirium in bone marrow transplant patients before transplantation include lower cognitive functioning, lower physical functioning, and higher blood urea nitrogen, alkaline phosphatase, and magnesium levels.[41]

Medications certainly play a large role in the development of delirium. In a study of 216 hospitalized cancer patients, corticosteroids, opioids, and benzodiazepines were most frequently associated with delirium.[42] A variety of other medications may also contribute: anticholinergics, anticonvulsants, antihistamines, dopamine agonists, metoclopramide, and selective serotonin reuptake inhibitors. A number of chemotherapy agents have also been implicated: methotrexate, isofamide, fluorouracil, vincristine, bleomycin, carmustine, cisplatin, and procarbazine. It is also important to remember that abrupt withdrawal of certain medications can cause delirium; these include benzodiazepines and muscle relaxants (especially Baclofen).

The clinician must also consider metabolic causes. Fever and sepsis often produce acute delirium. Dehydration and uremia frequently contribute. Electrolyte abnormalities—increased and decreased levels of sodium, calcium, and magnesium—are often associated with cognitive dysfunction. Hypoxia and hypoglycemia are additional possibilities that can be easily assessed.

Delirium may present as either a hypoactive or a hyperactive state. In hypoactive cases, dehydration frequently contributes to delirium. In hyperactive states, medication side effects (especially opioids and corticosteroids) and liver failure are often culprits.[37]

Management of delirium should always start with nonpharmacologic interventions. Family involvement may decrease anxiety and provide familiar surroundings. If family is unavailable to supervise the patient, a sitter may be necessary. Calm, simple communication should be used. Environmental changes should be used to minimize distractions (noise, lights, simultaneous conversations). Physical restraints tend to worsen the situation and should only be applied in extreme situations. The clinician should discontinue the use of unneeded medical devices such as intravenous lines and urinary catheters.

Pharmacologic intervention can be of help when there is agitation or hallucination. Haloperidol is considered to be the major tranquilizer of first choice.[21] Newer antipsychotics such as olanzapine may be helpful as well. Benzodiazepines are effective when there are convulsions or in cases of alcohol or sedative withdrawal, but they often worsen confusion in other causes of delirium. Methylphenidate has been used successfully in a small study (in cancer patients with hypoactive delirium (psychomotor retardation).[43]

Mood Disorders

Receiving a cancer diagnosis is stressful and frightening for most individuals. Initially patients may experience symptoms of shock, disbelief, denial, or despair as they struggle to accept and incorporate the reality of the diagnosis. Patients may also experience a variety of normal fears throughout their treatment course, including fears of disability, loss of societal roles, loss of control, loss of desirability, abandonment, and death. Overall, however, most patients cope successfully with cancer diagnosis and treatment and experience good long-term psychologic adjustment.[44] Many patients even describe positive changes in their lives related to their diagnosis, including positive changes in self-perception, interpersonal relationships, priorities, and goals.[45]

Although most patients cope well, a significant number do experience serious mood disorders. The average estimates of the prevalence of depression among cancer patients are from 15% to 25%.[46] The importance of correctly diagnosing and treating depression is underlined by research showing that depression is associated with poor compliance with medical care, longer hospitalizations, and higher mortality rates in patients with chronic illnesses.[47]

Anxiety is quite common in cancer patients and may be related to poorly controlled pain, abnormal metabolic states, or medication side effects. They may also develop post-traumatic stress disorder in response to cancer diagnosis and treatment. Post-traumatic stress disorder is an anxiety disorder that develops after an extremely stressful event, such as the development of a life-threatening illness. Within 5 years of diagnosis, between 10% and 15% of cancer survivors may meet criteria for post-traumatic stress disorder.[48]

Neurologic Impairments

A wide variety of impairments of nervous system function may result from cancer, either by direct effect at the primary or metastatic tumor site or secondarily as a consequence of surgical or radiation treatments. These impairments, regardless of the tumor's location, extent, or type, may significantly affect the individual's physical, social, vocational, and emotional capabilities. Important differences exist between the management of patients with cancer of the central nervous system and those with other types of acquired neurologic disability. Rehabilitation strategies must consider progressive, sometimes rapid, functional decline, toxic effects of cancer treatments, tumor recurrence, CRF, medical fragility, insurance and workplace discrimination, and psychologic and family issues associated with an often terminal disease. The interdisciplinary rehabilitation team is best equipped to handle the complexities of restorative care in these situations, and meet the patient's and family's goals of maximizing functional recovery and preserving QoL.

Hemiplegia

Tumors affecting brain tissue are either primary or metastatic in origin, with metastatic lesions composing roughly 50% of all

intracranial tumors.[49] Brain metastases occur in 20% to 40% of patients with cancer and their frequency has increased in recent years, probably as a result of improved detection and treatment.[50] Lung, breast, and skin (melanoma) are the commonest sources of brain metastases, and in as many as 15% of patients the primary site remains unknown.[51] In those with metastatic brain tumors, studies demonstrate that the three strongest prognostic factors are physical performance status, response to steroids, and evidence of systemic disease.[52] Brain tumors vary widely in aggressiveness and prognosis. To what extent tumor type or location has an impact on rehabilitation outcomes is not clear. However, one study found a tendency for greater gains for meningiomas and patients with left hemispheric lesions.[53] Brain tumor patients receiving inpatient acute rehabilitation show similar gains between those with metastatic origin and primary brain tumor.[53] However, functional gains were superior on initial presentation to rehabilitation as compared with those with recurrence of the cancer.[54] Brain tumor patients have been found in some studies to have shorter lengths of stay on acute rehabilitation units as compared with other noncancerous brain disorders,[49] possibly as a result of higher initial levels of functional independence on admission, fewer behavioral issues, better social support, and expedited discharge planning due to cancer-related prognostic factors. Despite increases in survival rates of patients with primary brain tumors and advances in treatment, survival is limited for many and must be considered with regard to the timing, duration, and types of rehabilitation interventions.[52] Statistics show the mean survival for glioblastoma multiforme patients with optimal treatment is about 1 year,[55] and that patients with brain metastases assessed as having the best prognosis survive only a mean of 7.1 months.[56]

Most patients with brain cancer have multiple impairments, depending on tumor location and size, and in those who have undergone surgery, the volume of tissue excised. In a study of patients with brain tumor undergoing acute rehabilitation, the most common neurologic deficits included impaired cognition (80%), weakness (78%), and visual-perceptual dysfunction (53%).[53] Rehabilitation efforts for brain cancer patients should focus on the patient's neurologic and functional status, coexisting medical problems, and tolerance of physical activity. As with patients with stroke or traumatic brain injury, goal setting should be appropriate to the individual's physical, cognitive, and behavioral status, and include early planning for post-acute rehabilitation care.

Specific rehabilitation measures for patients with brain cancer-related disability emphasize early attention to mobilization, including bed mobility, transfer training, and ambulation or wheelchair skills. Those patients presenting with unilateral leg weakness will benefit from a physical therapist assisting with progressive gait and balance training, and when necessary using an assistive device appropriate for the degree of stability required (single-point cane, four-pronged cane, or walker). Provision of an ankle-foot orthosis to control weakness and/or spasticity of ankle musculature is often needed. The risk of limb contracture—especially in ankle plantar flexion, wrist and finger flexion, and shoulder adduction and internal rotation—is increased in patients with weakness, particularly spastic hemiplegia. Early and regular stretching programs, along with appropriate limb positioning and supportive devices such as Multi Podus (LEEDER Group Inc., Miami, FL) boots are critical. Glenohumeral support and position in bed and wheelchair, the latter involving a lap table or arm trough, is key to preventing hemiparetic shoulder pain. A flaccid or significantly subluxed glenohumeral joint may require a humeral cuff or sling-type arm support, used judiciously so as to not promote a contracture in internal rotation and adduction. For individuals limited by unilateral arm weakness, an occupational therapist can provide adaptive equipment such as reachers, sock donners, or elastic shoelaces.

Additionally, attention should be given to other potential complications of reduced mobility including deep venous thrombosis and skin breakdown. Awareness among physicians of the risk of thromboembolism in brain tumor surgery patients may be insufficient,[57] highlighting the need to be vigilant in prophylaxis for deep venous thromboses. Seizures represent the most frequent medical problem encountered during rehabilitation for brain tumor patients, occurring in about 20% to 40% of patients with brain metastases.[58] Anticonvulsants are appropriate in patients with documented seizures and probably for short-term use perioperatively, but prophylactic use of these agents in patients with tumor but without seizures is generally not recommended.[59]

Paraplegia and Tetraplegia

Injuries to the spinal cord may be secondary to either traumatic or nontraumatic causes. Cancer-related spinal cord injury (SCI) incidence may actually exceed that from trauma and represents the most frequent type of nontraumatic SCI.[49] Symptoms consistent with SCI occur as a result of metastasis in as many as 5% of all cancer patients.[60] Symptoms such as weakness, sensory loss, and bladder and bowel sphincter dysfunction can be a consequence of either tumor compression on, or invasion of, the spinal cord or its vasculature, spinal instability from bony invasion, or secondary to the cancer therapy itself (radiation or surgery). Spinal metastases occur more commonly in the thoracic spine (70%), followed by the lumbosacral (20%) and cervical (10%) spine, and most often originate from primary tumors of breast (15%), lungs (10%), and prostate (10%). Lymphoma, myeloma, and primaries of unknown origin also metastasize to the spine, each accounting for around 10% of cases. The majority (95%) of metastatic spine involvement is extradural, arising from a vertebral body.[61] Primary tumors of the spinal cord such as meningiomas, neurofibromas, and gliomas are relatively rare. Spinal cord metastases produce a clinical syndrome characterized initially by pain in 90% of cases, followed by weakness, sensory loss, and sphincter dysfunction. Weakness is present in 74% to 76% of patients, autonomic dysfunction in 52% to 57%, and sensory loss in 51% to 53%.[62] Pain alone may persist for a month or more (average 6 weeks) before significant neurologic changes develop. Acute onset of back or neck pain in a patient with cancer should be considered as spinal metastasis until proven otherwise.

Positive results have been demonstrated following rehabilitation for individuals with disability from spinal cord tumors, with significant functional gains measured after inpatient rehabilitation.[54,63] For patients who retained some motor or sensory function, those with the most neurologic deficits were found to benefit most from inpatient rehabilitation. Factors that have been identified as better prognostic indicators for survival after inpatient rehabilitation include lymphoma, myeloma, breast and kidney tumor types, SCI as the presenting symptom, slow progression rate of neurologic symptoms, combined surgery and radiation treatments, partial bowel control, and partial independence with transfers on admission.[64]

As with traumatic injuries, dysfunction resulting from spinal cord tumor may be classified according to the level of motor and sensory impairment as well as the completeness of the involvement. However, nontraumatic SCI, which includes cancer etiology, differs from traumatic involvement. For spine tumor patients, McKinley and associates[65] found less severe neurologic impairment, greater likelihood of presenting with paraplegia than tetraplegia, and greater frequency of motor incomplete lesions than complete lesions.

Medical complications associated with recent SCI are common, potentially life-threatening, and require a vigilant and knowledgeable hospital staff. Comprehensive SCI care includes attention to ventilatory ability in those with high spinal levels of injury, and management of pain, autonomic dysreflexia, pulmonary and urinary tract infections, thromboembolic disease, bowel and bladder dysfunction, decubitus ulcers, limb contractures, and spasticity. Certain measures instituted immediately after onset of spinal cord dysfunction remain standards of acute care in this patient population. Prophylaxis for lower-extremity venous thromboses with low-molecular-weight heparin should be immediately initiated unless otherwise medically

contraindicated, and continued for at least the duration of the rehabilitation phase, and in cases of plegia or severe paresis, for a total of 3 months. Other areas of management that should be instituted early for those with loss of thoracic musculature include incentive spirometry and chest physiotherapy. Initiation of intermittent bladder catheterization every 4 to 6 hours when daily bladder volumes are less than 2 liters should be routine treatment, as well as instituting a bowel program with daily or every other day suppository or digital stimulation. Other key measures in early spinal cord care include prevention of skin breakdown in body areas commonly at risk (occiput, sacrum, greater trochanter, heels, and ischial tuberosities) including turning in bed every 2 hours, specialized pressure relief bed and wheelchair mattresses, and heel protectors. Additionally, at least daily limb range of motion should be initiated immediately after onset of the SCI. Patients with severe spinal cord dysfunction above T6 level are prone to developing autonomic dysreflexia—a significant increase in blood pressure above baseline, as a result of vasoconstriction from splanchnic sympathetic nerve stimulation by noxious stimuli below the level of the spinal lesion. If blood pressure remains significantly elevated, pharmacologic measures and intensive monitoring may be required.

Speech, Swallowing, and Nutrition

Disorders of speech and swallowing may be the result of direct tumor invasion of the oral cavity, larynx, pharynx, esophagus, or adjacent structures; secondary to surgical or radiation treatments; or consequent to cancers of the nervous system that affect pharyngeal or laryngeal control. Head and neck cancers constitute about 3% to 5% of all malignancies. Preservation of swallowing, having a natural airway, and intact speech are critical components that influence QoL in head and neck cancer patients. Among these, swallowing has been shown to have the largest impact on global QoL.[66]

Head and neck cancer and its treatment often results in major effects on nutrition, swallowing, and communication function. Depending on the tumor location, surgical excision and repair often impairs key articulatory, deglutitory, or airway-protective structures causing difficulty in speaking, transporting food, and maintaining a healthy airway. For example, deeply infiltrative cancerous lesions of the tongue requiring more than 50% tissue resection significantly impair speech and swallowing.[67] In one study, some surgical patients, depending on the extent of tissue resection, achieved functional swallowing and eating within 3 months of surgery, whereas for others significant impairment remained for as long as 9 months postoperatively.[68]

Postsurgical nutrition is initially via nonoral means (percutaneous endoscopic gastrostomy or nasogastric feeding tubes). However, prompt and early evaluation of oropharyngeal function is required before oral intake is resumed. The physical examination should include the neck, mouth, oropharynx, and larynx, and related neurologic function. As soon as feasible following surgery, oral-motor exercises are initiated with speech-language pathology focusing on strength, range of motion, and sensory awareness of the involved structures. Dysphagia assessment and treatment typically begin with a radiographic evaluation defining the nature of the patient's swallow dysfunction, with attention to alterations of the local anatomy. A videofluorographic swallowing study is particularly useful for identifying aspiration risk and for empirically testing therapeutic and compensatory techniques to eliminate food entry into the airway and promote successful and timely passage into the esophagus.

Swallowing strategies focus on prevention of aspiration and the efficiency and completeness of moving the food bolus through the oral, pharyngeal, and esophageal segments. Common interventions include modifying food texture, such as thickening liquids or blenderizing solid food, and/or altering head posture and swallowing behaviors. The latter may include techniques such as chin tuck to prevent laryngeal penetration, head rotation to reduce retention in the piriform sinus, enforced double or effortful swallows to reduced pharyngeal residue, or supraglottic swallow to optimize vocal fold closure and airway clearance.[69]

In the majority of head and neck cancer patients, impaired vocal communication occurs at some point during treatment. It is important to keep in mind that multiple conditions other than total laryngectomy can result in deficient phonation in cancer patients. These include copious secretions, localized edema, fibrosis and scarring, presence of a tracheostomy, glossectomy, loss of oral mobility from local tumor or trismus, and neurogenic pharyngeal or laryngeal paralysis. The patient with total laryngectomy lacks a source of voice production and must replace laryngeal function with an artificial larynx (electrolarynx), esophageal speech, or tracheoesophageal puncture voice restoration with a prosthetic surgical device.

Bone Tumors, Amputation, Bony Metastases

In 2007, about 2370 new cases of cancer of the bones and joints will be diagnosed. Skeletal tumors account for less than 0.2% of all cancers.[70] Soft-tissue and bony sarcomas are managed with amputation or limb-sparing procedures. Limb salvage procedures are increasing in frequency and are associated with long-term survival, local recurrence rates, and QoL equivalent to those of amputations, largely made possible by improved surgical techniques that preserve unaffected tissue, advances in endoprosthetic design and durability, soft-tissue reconstructive procedures, and radiation and chemotherapy effectiveness in controlling local and distal spread.[71]

Rehabilitation after limb-sparing procedures depends on the extent of soft-tissue and bony resection, and because of combined tumor resection, skeletal reconstruction, and soft-tissue and muscle transfers, may be more intensive than that following amputation. The planning process begins preoperatively, with the rehabilitation specialists providing evaluation of the individual's functional level before surgery and then projecting what the probable functional needs will be postoperatively. This includes instruction on mobility aids, orthotics for joint stabilization, as well as strengthening and endurance exercises in collaboration with the treating surgeon. The possible need for long-term limb bracing should be discussed if sacrifice of major nerves or muscles is required. Complex limb reconstruction requires an astute team to assess for possible complications during the recovery process. The majority of microsurgical complications occur within the first 24 to 36 hours after surgery, but that period may extend to as long as 1 or more weeks when the patient begins initial mobilization of the extremity after a period of bedrest. Complications may include arterial or venous microvascular thrombosis, hematoma, or flap dehiscence during ambulation. Splinting and wound dressing must be done with care to avoid problems associated with pressure on the flap. Although various strategies are used in mobilizing patients following reconstruction of the lower extremity, they often require a period of strict bedrest (as long as 7–10 days) to allow wound healing, control edema, and maintain limb alignment, followed by several days of dangling the extremity for short intervals. If this has been successfully achieved, physical therapy can begin with toe-touch ambulation with an assistive device such as a crutch or walker. Upright activity progresses to partial and full weight bearing depending on the patient's strength and degree of wound healing. After adequate healing has occurred, a pressure garment should be fitted so as to prevent or lessen the onset of lymphedema.[72]

Other lower limb-sparing procedures undertaken in this population may involve wide excision of portions of muscle, typically involving hip adductors, quadriceps, hamstrings, and gastrocnemius muscles. Leg elevation, active range-of-motion exercises, and compression garments to control edema are instituted as part a rehabilitation program following these procedures. Approximately 15% to 20% of sarcomas arise in the upper extremities, and are generally smaller in size and associated with better survival than those in the lower extremities, with whole muscle groups only rarely removed.[73,74]

However, major resections of tumors of the shoulder region can present significant challenges to the rehabilitation team, depending on the extent of tissue loss and neurologic involvement. Upper-extremity reconstructive procedures often require a sling or shoulder harness for support, with the goal to develop adequate strength and function of the hand and control edema through the use of low-stretch bandages. Early rehabilitation should avoid humeral motion, and range of motion after acute healing should not exceed 90 degrees of abduction, with adduction not permitted. To minimize contracture formation of the digits, the hand should be placed in a functional position with the wrist dorsiflexed at 30 degrees, the metacarpophalangeal joints flexed at 70 to 90 degrees, the interphalangeal joints extended, and the thumb abducted.[75] The salvaged limb becomes for the long term non–weight bearing and nonlifting. A shoulder mold can be fashioned that allows a more cosmetic clothing fit. For soft-tissue sarcomas involving the forearm extensor muscles or radial nerve removal, a cock-up splint to maintain wrist extension or a brace that incorporates a dynamic outrigger to substitute for weak or absent finger extension may be prescribed.

Tumor amputees differ from dysvascular and traumatic amputees in several important ways. Fatigue, anemia, nausea, and toxic effects of chemotherapy may diminish functional capacity. Wound healing may be delayed over irradiated areas and skin less tolerant of prosthetic wear. Cancer amputees typically have shorter residual limbs so as to obtain tumor-free margins. It is more common in this population to have more proximal sites of amputation, in that the primary pathology is often located at proximal sites, such as forequarter or shoulder disarticulation in the upper limbs or hemipelvectomy in the lowers.[61] Weight loss, muscle atrophy, and residual volume shifts, particularly during chemotherapy, may prolong the wait for a definitively fitted prosthesis. In these cases, the use of flexible, adjustable sockets to permit continued prosthetic wear and training has proven beneficial for patients with early postoperative fluctuations in stump size.[76,77]

If amputation is required the most functional level should be selected, allowing for as much residual limb length without sacrificing tumor control. For instance, a very short above-knee amputation can be accommodated with a prosthesis and is more energy efficient and functional than a more proximal hip disarticulation. Similarly, prosthetists are able to effectively fit short below-knee and below-elbow stumps, functionally superior to their above-elbow and above-knee counterparts.[78] Otherwise the rehabilitation of tumor amputees is similar to that for other patients, including the use of a multidisciplinary team, preoperative education for the family and patient about what to expect at different stages of preprosthetic and prosthetic training, and early initiation of exercises to improve strength and stamina. Rehabilitation often commences in the operating room when it is recommended that an immediate postoperative rigid dressing be fitted to the residual limb. Early use of rigid stump dressings have been shown in some studies to reduce time to delivery of the first definitive prosthesis, control stump edema and pain, reduce phantom limb sensation, help shape the residual limb, and speed incision healing.[79] Otherwise stump shrinker socks or elastic wraps are applied to control the shape of the residual limb. Proper positioning both in bed and in the wheelchair is necessary to prevent contracture formation and reduce edema in the residual limb, along with range-of-motion exercises and judicious use of splinting. Management of postoperative pain is critical, often requiring narcotics for the initial period. Desensitization techniques can help prepare the stump for acceptance of the prosthetic socket. Preprosthetic training includes upper-body strengthening and endurance exercises, and should include unipedal walking with appropriate assistive devices until weight bearing through the prosthetic leg is advised. The timing of fabrication of a permanent prosthesis will depend on the type and extent of the surgery as well as the status of other concurrent medical management, including chemotherapy.

The vast majority of skeletal cancer is of metastatic origin, with breast cancer being the most common primary source in women and prostate cancer in men. Other common primaries that metastasize to bone include lung, renal, and thyroid cancers.[80] The vertebrae, pelvis, femur, ribs, and skull are the most frequently involved sites of bone metastases, with the axial skeleton and the lower extremities, particularly the hip region, affected most frequently. One or more of the following problems may occur with bone metastasis: pain, hypercalcemia, pathologic fractures, myelosuppression, and spinal cord and/or nerve root compression with subsequent progressive immobility.

Bone metastases are a frequent source of cancer-related physical impairment that requires the active involvement of the rehabilitation team. Challenges for the treating team arise when metastatic bone lesions produce severe pain that limits function or imposes risks of fracture during therapeutic exercise or mobility. Factors that inform the therapeutic approach will include the degree of associated pain, lesion location, response to radiation therapy, neurologic compromise, and the presence or risk of fracture. The type of metastasis (lytic versus blastic) is also important, with lytic lesions considered more prone to fracture. The incidence of pathologic fracture among all tumor types is about 8%, with breast carcinoma responsible for the majority of these. Sixty percent of all long bone fractures involve the femur, with most of these involving the proximal portion.[81] Patients who are deemed at risk for a pathologic fracture should be made non–weight bearing to the affected structure, pending surgical consultation.

Rehabilitation for this patient population focuses on removal of weight bearing or immobilizing compromised bone through the provision of assistive devices and orthoses, strength and balance training, and modification of the patient's environment. Whenever possible, bedrest should be avoided, because it adds to general debility and further functional loss, as well as increasing the risks of hypercalcemia and thromboembolic disease. Depending on the severity and location of the lesion, mobility restrictions can range from non–weight bearing to weight bearing as tolerated. For complete non–weight bearing restrictions, assistive devices in the form of walkers or bilateral crutches are typically necessary. Single-point canes are used for patients with minimal balance deficits and smaller lesion size, but patients with larger, more symptomatic lesions should be advanced to a forearm (Lofstrandt)-type crutch, which permits a greater degree of weight support. It is critical to first rule out the coexistence of upper-extremity lytic lesions before prescribing assistive devices that require weight support through the arms. Bracing may reduce risk or symptoms of a pathologic fracture involving the upper extremities, and can facilitate use of the arms in functional activities. Those individuals with upper-limb lesions should be taught to minimize torsion and weight loading, and may benefit from an arm sling or humeral cuff support. In the spine, Jewett bracing to prevent spinal flexion, or a custom-molded clam-shell design to give stability in all directions can be prescribed. When more rigid bracing is not tolerated secondary to poor skin tolerance or discomfort, a thoracolumbar corset provides limited support and pain relief. Spinal bracing should extend several segments above and below the involved area of the spine.

Cancer patients suffering from pathologic fractures and associated functional deficits have been shown to make significant gains when admitted to an inpatient rehabilitation hospital unit.[82] It should be recognized that rehabilitation of patients with skeletal metastases has many inherent risks, and strategies to exercise these patients remain largely theoretical because of a lack of empiric data. However, the alternative to rehabilitation therapies is often bedrest, which carries its own set of potential complications, including muscle contractures, weakness and atrophy, osteoporosis, orthostatic hypotension, pressure sores, pulmonary infection, and increased risk of thromboembolic disease.

Soft-Tissue Impairments Associated with Cancer Diagnoses

Cancer and or its treatments can cause significant soft-tissue abnormalities. One of the most frequently observed is lymphedema, extremity swelling that results from disruption of the lymphatics following axillary or groin dissection. The prevalence of this in breast cancer patients has been reported to be 200,000 (10%),[83] or generally between 15% and 30%.[84] In the ALMANAC study,[85] the relative risks of any lymphedema and sensory loss for the sentinel lymph node biopsy group compared with the standard axillary treatment group at 12 months were less, as were drain usage, length of hospital stay, and time to resumption of normal day-to-day activities after surgery. Overall patient-recorded QoL and arm functioning scores were statistically significantly better in the sentinel lymph node biopsy group. Although the prevalence of limb edema is high following standard treatment, the treatment options for managing this have improved. The use of manual lymph drainage and compression garments is effective in controlling edema. When applied early in the course of treatment, before the development of significant volume increase (e.g., >250 mL increase in the arm), lymphedema can almost be reversed.[86]

The second, frequently seen soft-tissue complication of cancer treatment is frequently radiation induced. In the brain this causes gliosis, in the lung and gastrointestinal tract, fibrosis. Each is associated with significant inflammatory reaction and subsequent scarring. In the musculoskeletal system, muscle, fascia, and tendon all respond in a similar fashion. Long-term sequelae include fibrosis and contracture, eventually resulting in loss of muscle mass. This process is associated with vascular permeability and inflammation and release of proinflammatory cytokines (interleukins, transforming growth factor-β) and continues well past cessation of the radiation therapy.[87] The use of antifibrotic agents in the treatment of this problem has shown promise.[88]

Allogeneic bone marrow transplantation has prolonged life for many with hematologic malignancies. One of the complications of this procedure has been the rejection by the host of the transplanted, immunocompetent engrafted cells, called graft versus host disease. The immunologic reaction is often quite brisk, resulting in organ damage (fibrosis) to lung, liver, gastrointestinal tract, and notably skin and soft tissue. In the chronic form of graft versus host disease, limb edema, peau d'orange, fasciitis, and enthesitis can occur, resulting in significant loss of joint motion. There may be subsequent muscle atrophy secondary to disuse and associated loss of upper- and lower-extremity mobility.[89]

Bladder and Bowel Management

Loss of bladder or bowel control in cancer patients is often multifactorial and can be secondary to neurogenic causes, such as with brain or spinal cord tumors, can result from nonsurgical or surgical cancer therapies, or can occur as a direct effect of gastrointestinal or genitourinary tumors. Incontinence in this population may also be related to immobilization in bed, side effects of pharmacologic management, or diminished alertness and communication skills. This condition encompasses both medical consequences and QoL issues. Medical sequelae of loss of bladder and bowel function include renal infection and stone formation, skin ulceration, autonomic dysreflexia, fecal impaction, hemorrhoids, diverticulosis, and rectal prolapse. Loss of self-esteem, depression, and social isolation may develop. Incontinence after stroke, for instance, has been shown to be a strong predictor of mortality, dependency, and need for institutional care.[90] It is incumbent on the treating team to properly assess patients with fecal or urine incontinence and institute a management plan.

The formulation of a bowel management program should take into account the limitations of the patient's functional mobility and self-care skills, available family support and resources, and concurrent medical problems. Patient and family need to be educated on the long-term management of bowel dysfunction including the rationale, goals, and techniques of bowel management. This should include instruction in the safe use of assistive devices for bowel emptying, efficient and effective techniques for bowel emptying, and the importance of timing, regularity, and positioning in bowel evacuation.

Any destructive lesion or process above the conus medularis can lead to an upper motor neuron bowel pattern of dysfunction, characterized by fecal distention of the colon, overactive segmental peristalsis, underactive propulsive persistalsis, and a hyperactive holding reflex with spastic external anal sphincter constriction. The latter requires a mechanical (i.e., digital stimulation) or chemical (i.e., bisocodyl suppository) aid to trigger a reflex defecation. A lesion at the level of the conus medullaris, cauda equina, or inferior splanchnic or pudendal nerves affects the parasympathetic and somatic pudendal cell bodies. This condition results in a lower motor neuron lesion characterized by colonic slowing, constipation, fecal incontinence, and difficulty with emptying.[91] In such patients routine manual clearance of stool from the rectum may be necessary. Inactivity and debility associated with hospitalization for cancer management promotes the supine position, which inhibits effective bowel evacuation. Hospitalized cancer patients should also be placed on a consistent timed emptying program based on stimulating regular bowel evacuation, and where appropriate, the use of stool softeners, bulk-forming agents, and/or natural stimulants such as senna. Stimulation of the rectocolic reflex using manual stimulation and/or bisocodyl or glycerine suppository may induce bowel movement on a regimen basis. Taking advantage of the gastrocolic reflex with planning defecation after meals is also useful. Overactive intestinal motility with frequent stooling and/or diarrhea may require judicious use of medications to decrease peristalsis.

Management of bladder incontinence in cancer patients follows many of the same principles outlined previously for managing bowel incontinence. The patient should be taught to take responsibility wherever feasible for understanding and directing his or her bladder program. Patients with cancer involving bladder outlet obstruction such as with prostate cancer are at added risk of incomplete emptying, urinary stasis, hydronephrosis, and urinary tract infection. Certain commonly encountered medications may impair bladder control and function, including sedatives, muscle relaxants, opiates, calcium channel blockers, and antihistamines.

Voiding disorders in cancer patients may be a result of neurologic conditions, such as spinal cord tumor involvement, myelopathic consequences of radiation therapy, brain tumor, or lesions affecting sacral or pelvic nerve structures. Spinal cord lesions at suprasacral levels result in bladder dysfunction characterized by detrusor hyperreflexia and uncoordinated micturition with detrusor-sphincter dyssynergia. Tumors involving more caudal spinal regions including the conus medullaris, cauda equina, and S2 to S4 peripheral nerves will cause variable loss of parasympathetic and somatic nerve function, resulting in areflexia and loss of external sphincter function. Suprapontine lesions due to brain tumors may lead to uninhibited bladder contractions possibly secondary to loss of cerebral cortex inhibition at the sacral micturition center. Voiding dysfunction may also be classified functionally as failure to store urine due to bladder hyperreflexia, or insufficient sphincter outlet control, or due to failure to empty because of bladder hypo- or areflexia, or from inadequate sphincter opening (Table 37-2).

Sexual Function

Sexual function can be very important to cancer patients, yet it is seldom discussed by the patient and physician. In breast cancer, treatment often produces side effects of fatigue, nausea, diminished

Table 37-2 Functional Classification of Voiding Dysfunction and Management Options

FAILURE TO STORE

Reason: bladder hyperreflexia

Management options

1. Behavioral: timed voiding
2. Collection devices: condom catheters, intermittent catheterization, indwelling catheter (Foley or suprapubic)
3. Medications: anticholinergics, calcium channel blockers, botulinum toxin
4. Surgery: augmentation, continent diversion, denervation procedures

Reason: inadequate outlet pressure

Management options

1. Behavioral: timed voiding, pelvic floor exercises
2. Collecting devices: condom catheters, indwelling catheters, diapers
3. Medications: α-agonists, imipramine, estrogen cream
4. Surgery: implantable artificial sphincter, fascial sling, collagen and Teflon injections

FAILURE TO EMPTY

Reason: Detrusor hypo- or areflexia

Management options

1. Behavioral: timed voiding, bladder stimulation such as tapping; Valsalva and Credé's maneuver
2. Collecting device: condom catheter, indwelling catheter, diapers
3. Medications: cholinergic agonists
4. Surgery: Neurostimulation device

Reason: Inadequate outlet relaxation

Management options

1. Behavioral: anal stretch
2. Collecting device: indwelling catheterization
3. Medications: α-blockers, striated muscle relaxants, botulinum toxin
4. Surgery: sphincterotomy, pudendal neurectomy, bladder outlet surgery

vaginal lubrication, not to mention the significant body image changes from mastectomy.[92] A meta-analysis of 36 studies of sexuality in testicular cancer patients showed that problems were largely related to ejaculatory dysfunction, but, fortunately, rates of decreased sexual desire were low and may improve with time.[93] Erectile dysfunction is a common side effect of prostatectomy, and of hormonal and radiation therapy for prostate carcinoma.[94] Colorectal cancer surgeries often lead to sexual dysfunction in men.[95] Not surprisingly, gynecologic cancers often produce changes in vaginal sensation, structure, and lubrication.[96] On a positive note, however, of cancer patients who received brief sexual counseling, 63.5% reported improvement.[97]

ACTIVITY LIMITATIONS

With their multitudes of possible impairments, it is not surprising that many individuals with cancer have significant limitations in their activities. These limitations include reduced mobility and limited ability to perform ADLs. These often result from neurologic or orthopedic impairments but may also be related to fatigue. Communication and socialization skills may be negatively affected by cognitive deficits, by impairment of speech, or by depression and anxiety.

Activities of Daily Living

Basic ADLs include feeding, dressing, hygiene, and toileting. These ADLs are virtually universal to human dignity across world cultures. Impairments of upper-limb function play an obvious role in limiting performance of ADLs, but other impairments also can impede these functions. Cognition is critical to sequencing, awareness, and carryover in the performance of ADLs. Pain and fatigue can also limit the individual's ability to complete these tasks. Lower-limb impairments can limit standing and transferring, making it difficult to carry out dressing, hygiene, and toileting.

When individuals become disabled enough to require assistance with these skills, the burden generally falls on caregivers. In one study of 483 cancer patients at varying stages of their disease course, 18.9% had unmet needs in their ADLs as a result of lack of a suitable caregiver.[98] Among advanced-stage cancer patients the percentage of caregivers with a high level of psychologic distress varies from 41% to 62% directly depending upon the functional status of the patient.[99]

Rehabilitation efforts, particularly with the involvement of occupational therapy, can significantly reduce this burden on caregivers and enhance the QoL for cancer patients with disabling impairments.[100] Addressing functional loss from impairments of the upper limb, such as chemotherapy-related peripheral neuropathy of the hand[101] or radiation-induced brachial plexopathy,[102] can substantially improve performance of ADLs. To improve feeding independence among cancer patients with upper-limb neurologic dysfunction, Chinese researchers used positioning, feeding aid supports, and upper-limb supports, and significantly improved function over a 3-week treatment intervention.[103] Use of simple adaptive aids, such as a swivel fork,[104] can enhance function tremendously. Home-based occupational therapy interventions produce a high level of patient and caregiver satisfaction, reducing burden of care.[105]

Exercise for Cancer Patients

Patients with cancer diagnoses suffer from a variety of symptoms attributable to direct effects of tumor and/or their treatments. Some of the treatments—surgical, chemotherapeutic, radiotherapeutic, or biologic—can cause immediate and remote effects.

Typically the treatment substantially affects the neuromusculoskeletal system, resulting in functional loss and fatigue. The latter is reported to be one of the most distressing symptoms.[29,106]

Exercise is one of the most effective strategies for symptoms associated with cancer fatigue, sleep disruption, and abnormalities of mood, physical function, and QoL.[107] Rigorous meta-analyses, however, caution that these studies are subject to significant methodologic problems, such as small sample sizes, diverse forms of exercise, nonrepresentative samples (e.g., few African Americans and Hispanics; few advanced cancers, many breast cancer studies). Another significant methodologic problem is that the instruments used to measure fatigue, mood, and QoL are subjective, relatively insensitive, and inconsistent in measuring intensity, impact on daily routines, or state of satisfaction or well-being. This makes study comparability difficult. Nonetheless, meta-analyses[108] suggest that for adults with a variety of cancer diagnoses and receiving a variety of exercise interventions, exercise improves physical function, QoL, and cardiorespiratory fitness,[109] and decreases CRF.[110] The great majority of these studies use aerobic exercise, using ergometry and walking programs, and occasionally, aquatic therapies.[111]

Strengthening protocols, though not contraindicated, have not been thoroughly evaluated.[112]

Contraindications for exercise include: thrombocytopenia (<50,000 platelets/μL, no resistive exercise; <20,000 platelets/μL,

only ADLs and light activity); anemia (<8 g ADLs only; 8–10 g, light exercise as tolerated); bony metastatic disease (25% to 50% cortical involvement in long bone, partial weight bearing, avoid lifting; 0 to 25%, full weight bearing, no high-impact sports); pulmonary (50% to 75% forced expiratory volume in 1 second or carbon monoxide diffusing capacity, no aerobic exercise); cardiac (low ejection fraction or arrhythmia, consult cardiology; electrolytes (Na below 130 mEq/L, K below 3 mEq/L [correct the hypokalemia], Ca above 6 mEq/L [correct the hypercalcemia], no exercise). Relative contraindications are for tachycardia greater than 100 beats per minute and temperature of >99.5°F or >37.5°C.

Physical Modalities

Physical modalities may be used to control pain and improve range of motion, thus leading to better mobility. Most physical modalities have not been well studied in cancer patients because of the concern of exacerbating an underlying malignancy. Those that are generally believed to be safe include cryotherapy, biofeedback, iontophoresis (transdermal delivery of medication by electrical current), transcutaneous electrical nerve stimulation (TENS), and massage. Electrical stimulation, regardless of how it is delivered, is generally not done directly over a tumor site. The same is true for massage therapy and superficial heat. Deep heat (e.g., ultrasound and phonophoresis) is usually contraindicated in cancer patients. Spinal traction is contraindicated in those patients with spinal metastases or with significant osteoporosis.

Durable Medical Equipment

Durable medical equipment provides an important tool in improving the activity level of cancer patients. Durable medical equipment includes hospital beds, canes, walkers, wheelchairs, and motorized scooters. These can greatly enhance mobility when properly prescribed and when the patient is properly trained in their use. Wheelchairs should be individually fitted, because the wrong size can lead to skin breakdown[113] or make accessibility difficult, if it is too wide.

Oxygen tanks and supplies are also considered durable medical equipment. Oxygen supplementation can enhance endurance and cognition, and reduce dyspnea in patients with hypoxia due to lung cancers or metastases.[114]

PARTICIPATION RESTRICTIONS

Participation refers to the roles an individual plays in society. These roles can include family and social relationships as well as vocational and avocational pursuits, and they often require modes of transportation to accomplish. Cancer patients are often restricted in many of these functions.

Family and Social Relationships

Cancer can often draw a family together; however, it just as often leads to significant distress for families. Caregiver and patient coping styles significantly influence the level of strain in families.[115] Support groups can also be helpful, yet fewer than half of patients receive information about them, even in a large tertiary oncology center.[116] In one study of 121 cancer patients, caregiver QoL was significantly correlated to the social/family and functional dimensions of the patients' QoL; physical and emotional dimensions did not correlate.[117] Early, though, caregivers undergo significant psychosocial stress. There are also significant economic burdens on families.[118] Indeed cost considerations play a large role in patient decision making regarding cancer treatment, especially among the poor.[119]

Vocational Rehabilitation

Work disability following cancer diagnosis is a common occurrence. Short and coworkers[120] conducted phone interviews of 1433 cancer survivors at 1 to 5 years after diagnosis. More than half had quit work during their first year after cancer diagnosis, but fortunately three-quarters of those returned to work subsequently. A projected 13% had indefinite work disability. Survivors of central nervous system, head and neck, and stage IV blood and lymph malignancies had the highest risk of quitting work.

Fortunately U.S. laws in recent years have provided more protection to the cancer survivor returning to work.[121] These include the Americans with Disabilities Act, Family and Medical Leave Act, and the Health Information and Portability Act.[122] Nevertheless, a great deal of barriers still stand in the way of gainful employment for cancer survivors with disability.[4] These include ignorance of both employers and cancer survivors of their rights, discrimination, and limits on pre-existing conditions in health insurance benefits.[123]

Little is known about which medical impairments have the greatest impact on employability.[123] Undoubtedly, cognitive and communication deficits play a large role, as evidenced by the high work disability rates among survivors of central nervous system and head and neck malignancy.[120] Fatigue and pain are also likely to limit work participation. Spelten and colleagues studied 235 cancer survivors in the Netherlands.[124] Fatigue levels strongly predicted inability to return to work.

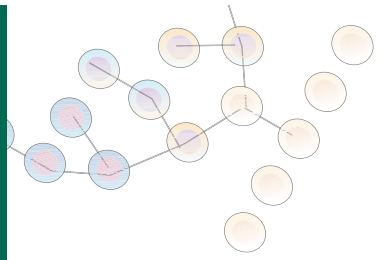
Participation in Recreation

Recreation is much more than fun and games; it is critical to physical and mental well-being. Fatigue, pain, weakness, depression, and other impairments will limit cancer survivors' participation in avocational pursuits. Health care providers and family members should encourage recreational activity for those with cancer. The benefits include improvements in fitness, musculoskeletal problems, immune system function, cognition and sleep. Physical activity reduces the risk of cardiovascular and cerebrovascular disease, as well as diabetes mellitus. It is also reduces the risk for several common cancers, which is relevant to cancer survivors who are already at risk for new primary cancers.[125] One study looked at 97 European youngsters attending a summer camp for adolescents living with cancer and diabetes.[126] Significant improvements were seen in self-esteem, self-efficacy, and anxiety. Adults benefit as well. For example, Tai Chi Chuan, an Asian mind-body practice, has been shown to have beneficial effects on cancer survivors in 11 small studies.[127]

Transportation

Cancer patients may be limited in their ability to drive, fly, or take public transportation. They may not have caregivers available to help with transporting them. This can become a major barrier to cancer treatment, which often involves frequent medical visits. Some patients forgo recommended treatments because of lack of adequate transportation.[128] Thus, it behooves physicians to explore with cancer patients any limits to their ability to get transportation.

Physicians are often leery to allow patients to drive while using opioids. However, Galski and associates showed that patients on chronic, stable, opioid analgesic therapy are safe to drive.[129] Patients with cerebral dysfunction due to tumor, paraneoplastic effects, or treatment side effects should be evaluated for driving safety before allowing them to return to the road. There are well-defined off-road driver evaluation tools available.[130]



Air travel might be problematic for patients with brain tumors. There have been case reports of cerebral edema[131] and hemorrhage,[132] although it is unclear how frequently these events occur.

38 Cachexia

Michael J. Tisdale

SUMMARY OF KEY POINTS

- The cachectic syndrome is defined by body weight loss of ≥10%, reduced food intake (≤1500 kcal/day). and systemic inflammation (C-reactive protein ≥10 mg/L).
- Patients with cachexia have a reduced quality of life, a lower activity level, and a reduced survival time.
- Anorexia is often associated with cachexia, but there might not be a cause-and-effect relationship because of the following:
  - Body composition change in cachexia is different from that in anorexia, with equal loss of muscle and fat.
  - There is selective loss of skeletal muscle in cachexia.
  - It is not possible to reverse the loss of skeletal muscle by nutritional supplementation or drug-induced appetite stimulation.
  - Resting energy expenditure is not uniformly increased in all cancer patients.
  - Levels of uncoupling protein 3 increased in muscle of cachectic patients. This could convert lipid released from adipose into heat.
- Factors involved in the loss of lipid from adipose tissue are the following:
  - Zinc α_2-glycoprotein by the induction of lipolysis and increased expression of uncoupling proteins.
  - Cytokine (TNF-α, IL-6, IFN-γ) inhibition of lipoprotein lipase, although TNF-α can also induce lipolysis and induce uncoupling proteins.
  - Futile energy cycles such as the Cori cycle and the triacylglycerol/fatty acid cycle.
- There is loss of skeletal muscle due to a depression of protein synthesis and an increase in protein degradation.
- Both calpain and the ubiquitin-proteasome proteolytic pathway are involved in the degradation of intact myofibrils.
- Factors involved in the loss of skeletal muscle are proteolysis-inducing factor (PIF), angiotensin II, and tumor necrosis factor-α.
- These factors stimulate increased expression of the ubiquitin-proteasome pathway by activation of the transcription factor NF-κB.
- Although other cytokines such as interleukins-6 and -8 are elevated in cachectic patients, there is less evidence for a direct role in atrophy of skeletal muscle.
- Pharmacologic management of cachexia may involve progestins, corticosteroids, eicosapentaenoic acid, β-hydroxy-β-methylbutyrate, or combination therapy.

INTRODUCTION

The word *cachexia* comes from the Greek *kakos hexis* and literally means "bad condition." In cancer patients, cachexia is a multifactorial syndrome characterized by a progressive loss of body weight with depletion of both adipose tissue and skeletal muscle mass. Cachexia is often, but not invariably, associated with anorexia as well as an elevated acute phase response. While patients are defined as cachectic when their body weight is 5% less than their preillness stable weight, weight loss alone does not identify the full effect of cachexia on physical function, and it is not a prognostic variable. However, by using weight loss (≥10%) together with reduced food intake (≤1500 kcal/day) and systemic inflammation (C-reactive protein ≥10 mg/L), it is possible to identify patients who have both adverse function and poor prognosis.[1]

The incidence of cachexia depends on tumor type, being highest in patients with pancreatic and gastric cancer and lowest in patients with breast cancer and non-Hodgkin's lymphoma. Overall weight loss occurs in 30% to 80% of cancer patients and is severe (>10% of initial body weight) in 15%.[2] Cancer therapies are also associated with the induction of anorexia and further weight loss. Patients with cachexia have a reduced quality of life, a lower activity level, and a reduced survival time.[2] Malnutrition also increases the risk of infections, treatment toxicity, and health care costs and decreases response to treatment.[3] A shorter survival time has been shown[4] to be independently associated with a weight loss of more than 8.1 kg in the previous 6 months and serum albumin levels less than 35 g/L. Weight loss often precedes tumor diagnosis and is often a presenting symptom.

ANOREXIA AND CACHEXIA

The association of anorexia with cachexia has led to the term *cachexia-anorexia syndrome*. Between 15% and 20% of patients are malnourished at the time of diagnosis, and for patients with advanced disease, this is up to 80% to 90%.[5] The tumor may cause reduced food intake, either directly, by interfering mechanically with the digestive tract, or indirectly, by producing inhibitory substances that act on peripheral receptors or in the hypothalamus. The principal biochemical mediators implicated in anorexia are (1) cytokines such as interleukin (IL)-1β, IL-6, IL-8, tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ), and ciliary neurotrophic factor; (2) serotonin; (3) the hypothalamic neuropeptides neuropeptide Y (NPY) and corticotrophin-releasing factor; and (4) peptide hormones such as

insulin, glucagon, and leptin. Although the exact mechanism that triggers cancer anorexia is not known, it has been suggested to result from an imbalance between NPY (orexigenic) and pro-opiomelanocortin (anorexigenic) signals in the hypothalamus.[6] In anorectic tumor-bearing rats, the paraventricular concentration of serotonin was increased.[7] However, in a mouse cachexia model showing mild anorexia, hypothalamic NPY mRNA was significantly raised, suggesting that suppression of hunger might be due to tumor products that inhibit NPY transport or release or that interfere with neuronal targets downstream of NPY.[8]

In humans, cancer anorexia is not due to a dysfunction of leptin production.[9] The levels of leptin are dependent only on the total amount of adipose tissue present in the patient and decrease as adipose mass decreases. Also mean plasma ghrelin levels, a neuropeptide released from the stomach in response to fasting and which stimulates food intake, were found to be higher among cachectic than noncachectic patients,[10] suggesting that this is not involved in the anorexia.

Of the cytokines, most studies show elevations of IL-6, IL-8, and IL-10 but not TNF-α, IL-1β, IFN-γ, or ciliary neurotrophic factor in the serum of cachectic cancer patients.[11–13] IL-6 levels are independently associated with levels of C-reactive protein, which in turn has been linked with survival.[11] Patients with IL-6 levels greater than 5.2 pg/mL or IL-10 levels greater than 9.8 pg/mL had significantly lower survival times than patients with lower levels.[12] Higher IL-6, IL-10, and IL-8 levels were also associated with poor performance status and/or weight loss. Some studies have shown that IL-6 levels increase gradually during the early stages of cachexia and then show a sudden steep rise just before death.[13] The systemic inflammatory response, as evidenced by increased serum C-reactive protein, has been shown to be an important factor in the progressive nutritional decline of patients with non-small-cell lung cancer and is a prognostic factor independent of stage, performance status, and treatment.[4]

Despite the association of anorexia with cachexia, no studies have been able to prove a cause-and-effect relationship. Rather, anorexia might be a separate phenomenon from the chronic wasting syndrome, although it might contribute to the loss of fat mass. Pair feeding experiments in animals have shown that this did not lead to either the same extent of weight loss or the metabolic abnormalities that are found in tumor-bearing animals. Thus, the changes in cachexia resemble those found in infection and injury rather than those found in starvation. Thus, in starvation, adipose tissue is lost preferentially to lean body mass, while in cachexia both are lost to a comparable extent. Also in starvation, when adipose stores are depleted, both skeletal muscle and visceral proteins are lost to an equal extent, while in cachexia, there is a selective loss of skeletal muscle mass. It is not possible to reverse this loss of skeletal muscle mass by nutritional supplementation or by drug-induced appetite stimulation, although such treatments do lead to some repletion of the adipose mass. This suggests that tumor factors or host factors induced by the tumor might lead to loss of adipose tissue and skeletal muscle mass in cachexia.

CHANGES IN HOST TISSUES IN CACHEXIA

Adipose Tissue

Adipose tissue is the main source of energy for the body, and its loss could reflect an increase in resting energy expenditure. However, resting energy expenditure can be unchanged, increased, or decreased in relation to the predicted energy expenditure.[2] In patients with pancreatic cancer, when resting energy expenditure was increased in comparison with the predicted values for healthy individuals, both total energy expenditure and physical activity level were reduced,[14] as might be expected in malnourished subjects. Levels of mRNA for the uncoupling protein 3 (UCP-3) have been shown to be significantly higher in muscle of cancer patients compared with controls and with cancer patients who had not lost weight; this increased level could increase energy expenditure and thus contribute to weight loss.[15] Studies in both animals and humans support a role for UCP-3 in energy balance and lipid metabolism. Transgenic mice that overexpress UCP-3 in skeletal muscle are hyperphagic but weigh less than wild-type littermates, and there is a large reduction in adipose tissue mass.[16] Although UCP-1, found only in brown adipose tissue (BAT), is considered to be the principal UCP involved in decreasing the level of coupling of respiration to ADP phosphorylation, the low level of BAT in adult humans could mean that UCP-3 in muscle is of major importance.

Factors Involved in Loss of Adipose Tissue in Cachexia

Zinc α_2-Gylcoprotein

One of the principal mechanisms by which lipid is lost from adipose tissue in cachexia is through an increased lipolysis, and the UCPs might serve to utilize the excess lipid that is mobilized. Zinc α_2-glycoprotein (ZAG), a 43-kd glycoprotein, is overexpressed in cachexia-inducing tumors and acts as a lipid-mobilizing factor that stimulates lipolysis in adipocytes.[17] ZAG binds to the β_3-adenoreceptor and stimulates lipolysis through a cyclic AMP–dependent mechanism.[18] Administration of ZAG to mice caused a time-dependent decrease of body mass that was attributed entirely to a loss of body fat without an effect on food and water intake.[18] There was an increased expression of UCP-1 in BAT, which probably contributed to the loss of adipose tissue. Both the glucose utilization rate and the rate of lipid oxidation were increased by ZAG lipid-mobilizing factor, suggesting that it increased energy utilization.[19] Although ZAG was originally thought to be produced by the tumor, further studies[17] showed that it was expressed in both white adipose tissue (WAT) and BAT, suggesting that it was produced locally by adipocytes. Tumor-bearing mice with a 19% loss of body weight and a 61% loss of fat mass showed a tenfold increase in ZAG mRNA and protein in WAT and a threefold increase in ZAG mRNA and a 20-fold increase in protein in BAT. In contrast to ZAG, leptin mRNA was suppressed 33-fold, while the adiponectin mRNA level was unchanged. ZAG expression in both WAT and BAT has been shown to be induced by glucocorticoids,[20] suggesting a relationship between the elevated cortisol levels in cachectic cancer patients and induction of ZAG.

Cytokines

Cytokines such as TNF-α, IL-6, and IFN-γ are also capable of reducing adipose tissue mass. The primary mechanism is thought to be suppression of the clearing enzyme lipoprotein lipase (LPL), although there is evidence that TNF-α can directly induce lipolysis.[21] LPL is a rate-limiting enzyme that is responsible for the hydrolysis of circulating triglyceride-rich lipoproteins, such as chylomicrons and very low-density lipoproteins. It is bound to the luminal surface of capillary endothelium in adipose tissue and muscle, and the fatty acids that are generated are utilized by adipose tissue for the synthesis of triglycerides. Thus, inhibition of LPL would deplete adipose tissue of the basic building blocks for lipid synthesis required to maintain levels in the presence of lipolysis. In addition to the cytokines, there are still unidentified factors that can inhibit LPL, since a study of five human cancer cell lines that induced cachexia in nude mice showed that they exhibited LPL-inhibitory activity, which was not due to any of the known cytokines.[22] An unknown lipid mobilizing factor of molecular weight less than 1 kd and stable to heat was also identified. The induction of lipolysis by TNF-α requires prolonged incubation (12 to 24 hours), and although the mechanism involves cyclic AMP, as with ZAG,[18] this is through stimulation of mitogen-activated protein kinase and extracellular signal-regulated kinase rather than through stimulation of adenylate cyclase.[21] As with ZAG, TNF-α induces increased expression of UCPs, which can metabolize released fatty acids.

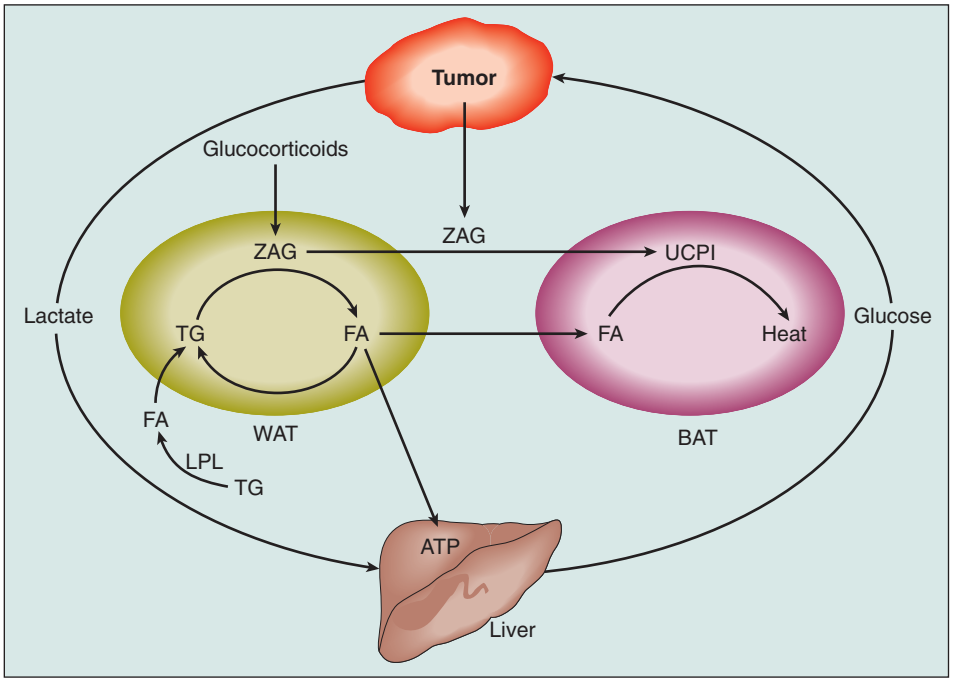

Figure 38-1 • Breakdown of adipose tissue and energy utilization in cachectic cancer patients. BAT, brown adipose tissue; FA, fatty acid; TG, triglyceride; WAT, white adipose tissue.

Futile Energy Cycles

Futile energy cycles also contribute to energy loss in cancer patients. One of the most important of these is the Cori cycle, which might account for an additional loss of energy of 300 kcal/day.[23] The Cori cycle involves utilization of the carbon skeleton of lactate to form glucose in the liver. Tumors consume large amounts of glucose and convert it to lactate, not because of mitochondrial dysfunction but because the oxygen tension is too low for the Krebs cycle and mitochondrial oxidative phosphorylation to operate. Thus, in effect, the liver consumes energy to convert lactate into glucose, which is converted back to lactate again by the tumor. In addition, in mice bearing a cachexia-inducing tumor, the triacylglycerol fatty acid substrate cycle is increased.[24] In this process, a high proportion of nonesterified fatty acids released from adipose tissue are immediately reesterified into triacylglycerol. The reason for the increased operation of this cycle is not known but could be related to a high rate of release of fatty acids combined with a low utilization rate. The interrelationship between tumor and host factors in WAT and BAT and energy-utilizing cycles such as the Cori cycle is shown in Figure 38-1.

Skeletal Muscle

Loss of muscle mass in cachexia leads to muscle weakness (asthenia), reduced respiratory function, and reduced immunity and is probably the most important factor contributing to the shortened survival time. Muscle atrophy is characterized by a decrease in protein content, fiber diameter, force production, and fatigue resistance. About half of the total muscle protein is myofibrillar protein, which is lost at a faster rate than other proteins during atrophy. Not all myofibrillar proteins are lost at the same rate. Thus, of the core myofibrillar proteins, there is selective loss of myosin heavy chain during muscle atrophy, while losses of actin, troponin, and tropomyosin remain constant.[25] Depending on the initiating signal, loss of myosin heavy chain can occur through an RNA-dependent or a proteasome-dependent process. A change in muscle myosin isoform expression has also been reported,[26] with a decrease in type I and an increase in type II (fast) isoform expression.

Muscle atrophy in cachexia is due to a depression in protein synthesis together with an increased rate of protein degradation. The depression of protein synthesis is due to a reduction in both RNA content and RNA activity, that is, the amount of protein synthesized per unit weight of RNA per hour. It has also been suggested that the balance of amino acids might not be correct for muscle protein synthesis because of the synthesis of acute phase proteins, which contain relatively high levels of sulfur amino acids. However, the situation must be more complicated than this, since nutritional supplementation alone is unable to reverse the muscle atrophy. This has been attributed to the high rate of protein degradation through an increased expression and activity of the ubiquitin-proteasome proteolytic pathway.[27,28] Protein substrates are marked for degradation by the attachment of a polyubiquitin chain by a series of enzymes: E1's ubiquitin-activating enzyme, E2's ubiquitin-conjugating enzymes, and E3's ubiquitin-protein ligases. Two muscle-specific E3s, MuRF1 and atrogin-1/MAFbx, have been identified[29,30] and are thought to act as critical components in muscle atrophy in cachexia. Protein degradation occurs in the 26S proteasome, a multisubunit proteolytic complex consisting of a central catalytic core (20S proteasome) and two terminal regulatory complexes (19S and 11S). The 19S regulatory complex plays a central role in the recognition and degradation of proteins by recruiting proteasomal substrates utilizing polyubiquitin chains and chaperone-like binding activities and by opening the access to the core of the 20S proteasome to promote degradation. The expression of mRNA for USP19, a 50-kd deubiquiting enzyme, was shown to be increased in skeletal muscle in a number of catabolic conditions, including cancer cachexia.[31] This suggests that it might play a role in the regeneration of free ubiquitin and might also be involved in post-translational processing of polyubiquitin.

The proteasome does not degrade intact myofibrils. Degradation of Z-band associated proteins, in particular titin and alpha-actinin, and release of myosin and actin from the myofibrils is mediated by the calcium-dependent enzyme calpain, which has been shown to be elevated in both skeletal muscle and heart during cancer cachexia in mice.[32] A diagram illustrating the factors involved in the degradation of myofibrillar proteins is shown in Figure 38-2.

The end-product of the ubiquitin-proteasome proteolytic pathway is oligopeptides, and these are degraded by the extralysomal peptidase tripeptidyl-peptidase II, together with various aminopeptidases, to form tripeptides and amino acids. In mice bearing a cachexia-inducing tumor, both proteasome proteolytic activity and tripeptidyl-

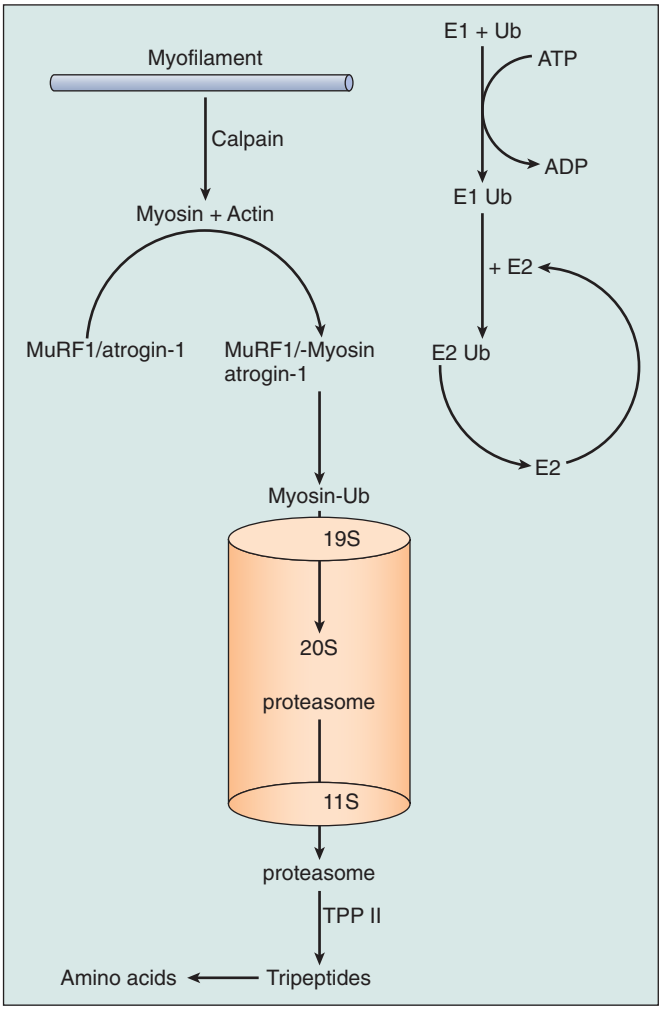

Figure 38-2 • Steps in the breakdown of myofibrillar proteins.

peptidase II activity were found to increase in parallel with increasing weight loss, suggesting that both activities are regulated in a parallel manner.[33]

Factors Involved in Loss of Skeletal Muscle in Cachexia

Proteolysis-Inducing Factor

Proteolysis-inducing factor (PIF) is a 24-kd sulfated glycoprotein produced by both primary and metastatic cachexia-inducing tumors, which induces muscle atrophy through a depression of protein synthesis and an increase in protein degradation. PIF acts both in vitro and in vivo to upregulate expression of both the mRNA and protein of the principal components of the ubiquitin-proteasome pathway including ubiquitin, E2, and proteasome subunits.[34] PIF also induces an increase in activity of tripeptidyl-peptidase II in parallel with the increase in proteasome activity.[33] The mechanism for induction of the ubiquitin-proteasome pathway by PIF involves activation of the transcription factor nuclear factor-κB (NF-κB), and inhibitors of this process, such as resveratrol, attenuated protein degradation induced by PIF in vitro, and muscle protein loss in mice bearing a cachexia-inducing tumor.[35] PIF also induces an increase in apoptosis in muscle cells in vitro,[36] although the importance of this in human cancer has been questioned for patients with a weight loss of less than 10%.[37] However, muscle loss is very small in patients with this degree of weight loss. In rabbits bearing the cachexia-inducing VX-2 tumor, the apoptotic index in skeletal muscle reached 54% to 56% when the loss of lean body mass reached 18%.[38] This suggests that further studies are required in humans at higher levels of weight loss.

Angiotensin II

The vasoconstrictor angiotensin II (Ang II) has also been shown to influence muscle mass by decreasing protein synthesis[39] and increasing protein degradation.[40] The latter effect occurs through the Ang II type 2 (AT_2) receptor by inducing an increased activity and expression of the ubiquitin-proteasome pathway. Like PIF, Ang II is capable of acting directly in vitro as well as in vivo, and as with PIF, induction of the ubiquitin-proteasome pathway occurs through the transcription factor NF-κB.[40]

Cytokines

TNF-α. TNF-α also inhibits protein synthesis and increases protein degradation in muscle, although most studies report that it is inactive when used alone in vitro but that its activity is enhanced when it is used with another cytokine, such as IFN-γ.[25] The induction of protein degradation by TNF-α is due to an increased expression of the ubiquitin-proteasome pathway. In rats bearing the Yoshida AH-130 ascites hepatoma, in which TNF-α plays a pivotal role in the pathogenesis of muscle wasting, treatment with pentoxyfilline, an inhibitor of TNF-α synthesis, prevented the depletion of muscle mass and significantly reduced the activity of both ATP-ubiquitin and the calpain-dependent proteolytic pathways.[41] As with PIF and Ang II, activation of NF-κB is important in the degradation of muscle proteins by TNF-α.[42] Activation of NF-κB by TNF-α in differentiating mouse myocytes has also been shown to inhibit their differentiation, by suppressing production of MyoD mRNA at the post-transcriptional level.[43] MyoD is a transcription factor that is essential for differentiation of skeletal muscle, as well as for repair of damaged tissue, and it may be important for replenishing atrophied muscle. These results suggest that TNF-α has the potential to induce muscle atrophy, although, as was previously discussed, most studies[11–13] have been unable to show elevations in the level of TNF-α in the serum of cachectic cancer patients. While the short half-life of biologically active TNF-α and formation of complexes with its soluble receptor contribute to the lack of detection, this does not explain why it can be detected in other wasting syndromes, such as cardiac cachexia.[44]

IL-6. Of the cytokines, IL-6 is the most closely correlated with the development of cachexia in cancer patients,[11–13] and has been shown to be independently associated with levels of C-reactive protein as a measure of the acute phase response.[11] IL-6 is thought to be the prime regulator of acute phase protein production in human hepatocytes, which has been correlated with a shorter survival time of cancer patients.[45] This possibly explains why IL-6 levels rise sharply before death.[13] In addition to induction by cytokines, IL-6 production in human hepatocytes is induced by PIF, through activation of the transcription factors NF-κB and STAT3.[46] Some human pancreatic tumors also produce IL-6.[47]

Despite the correlation of serum IL-6 levels with the development of cachexia there are doubts about whether it plays a direct regulatory role in muscle protein degradation.[48] Thus, IL-6 did not affect the rate of protein degradation in vitro in rat muscle preparations, and although it induced an acute phase response in mice, it did not induce cachexia and had no effect on the expression of ubiquitin transcripts in muscle. This suggests either that IL-6 is a marker of the cachexia process or that it acts in concert with known or unknown factors to induce muscle atrophy.

IL-8/IL-1β. While serum levels of IL-1β were not significantly elevated in patients with pancreatic carcinoma, levels of IL-8 were

significantly elevated and were correlated with weight loss.[12] Several studies have failed to demonstrate an effect on IL-1β on muscle protein breakdown in vitro, while the IL-1 receptor antagonist had no effect on protein hypercatabolism in rats bearing a cachexia-inducing tumor.[48] There are no reports on the ability of IL-8 to induce protein degradation in muscle. However, IL-8 is a potent angiogenic factor and might play a role in tumor proliferation.

Dystrophin Glycoprotein Complex Dysfunction

Skeletal muscle wasting has been linked to a dysfunctional dystrophin glycoprotein complex, a membrane structure that is associated with muscular dystrophy.[49] Muscles from tumor-bearing mice with cachexia showed reduced levels of dystrophin and increased glycosylation on dystrophin glycoprotein complex proteins. Dystrophin glycoprotein complex dysfunction was shown to mediate the induction of the E3 ubiquitin ligase MuRF1. Carcinoma patients with marked weight loss had large reductions in dystrophin compared to weight-stable healthy controls. These results suggest a similarity between cachexia and muscle dystrophy.

PHARMACOLOGIC TREATMENT OF CACHEXIA

Established Agents

Progestins

Megestrol acetate (MA) and medroxyprogesterone acetate (MPA) are two synthetic progestins derived from 17α-hydroxyprogesterone that have received an extensive evaluation for the treatment of cachexia.[50] These agents are used in the treatment of hormone-dependent tumors, and it was during the evaluation of their antitumor activity that an increase of body weight and appetite was observed, independently of objective response. The mechanism of action of these agents may be related to their glucocorticoid activity. They might stimulate appetite via NPY in the ventromedial hypothalamus,[51] or they might act in part by downregulating the synthesis and release of proinflammatory cytokines.

Maltoni and colleagues[50] reviewed 15 randomized clinical trials of progestin therapy. Dosages ranged from 160 to 1600 mg/day for MA and from 300 to 1000 mg/day for MPA. The pooled odds ratio for weight gain was 2.66, indicating that patients who were treated with progestins had more than twice the probability of gaining weight than did patients who were treated with placebo. However, the pooled odds ratio for appetite was somewhat larger.[4,23] Body composition studies of patients who gain weight with both MA and MPA have shown that the vast majority of the gained weight was adipose tissue and water and that there was no significant effect on fat free mass. This probably explains why the studies showed no improvement in the quality of life.[50] The duration of treatment in the studies was very short, lasting from 1 to 12 weeks, which probably overcame some of the side effects of therapy, which were significantly greater than were observed in the control arm. The side effects of long-term treatment (>12 weeks) are principally hypertension and edema resulting from water retention, as well as thromboembolic events. In a study of elderly men treated with MA (800 mg/day), there was an antianabolic effect on muscle with a significant reduction in thigh muscle cross-sectional area despite a significant increase in body weight.[52] Thus, administration of MA might actually accentuate the loss of lean body mass in cachectic cancer patients. It is surprising, therefore, that MA and MPA are the only agents that are routinely used for the treatment of weight loss in cancer anorexia and cachexia.

Corticosteroids

These include dexamethasone, prednisolone, and methylprednisolone. They induce a temporary effect on symptoms such as appetite, food intake, sensation of well-being, and performance status but show no beneficial effect on body weight. They tend to be used in patients in the end stages of cancer in an attempt to improve the quality of life.

Agents Undergoing Clinical Evaluation

Omega-3 Fatty Acids

Cold water fish such as mackerel, sardines, and salmon contain an oil under their skin containing omega-3 polyunsaturated fatty acids, the major components being eicosapentaenoic acid (EPA:20:5:) and docosahexaenoic acid (DHA; 22:6, ω3). Of the two fatty acids, only EPA has been shown to be effective in attenuating weight loss in a murine cachexia model.[53] Muscle mass is preserved and protein degradation suppressed through inhibition of the ubiquitin-proteasome pathway. EPA has been shown to attenuate the induction of the ubiquitin-proteasome pathway by PIF in murine myotubes by preventing activation of NF-κB.[54]

While most of the clinical studies have been carried out with fish oil, two studies have been carried out with EPA either as free acid[55] or as the propane diol diester.[56] Patients with pancreatic cancer and a median rate of weight loss of 2 kg/month who were administered EPA (6 g/day) showed weight stabilization over the 12-week study period.[55] However, in a placebo-controlled randomized study with EPA ester (2 or 4 g daily), patients with advanced gastrointestinal or lung cancer and with a mean weight loss of 18% showed no statistically significant improvement in survival, weight, or other nutritional variables.[56] A further uncontrolled study of fish oil capsules (supplying 4.7 g EPA/day) in patients with advanced malignancy and weight loss showed weight stabilization over a 1.2-month period.[57] When fish oil was combined with an energy- and protein-dense nutritional supplement, initial studies showed that patients gained 2 kg over a 7-week period and that this represented lean body mass.[58] However, in a randomized double-blind trial, intention to treat group comparisons indicated that omega-3 fatty acids did not provide a therapeutic advantage, mainly because of problems with compliance.[59] Post hoc analysis, however, showed a net gain of weight and lean tissue and improved quality of life in patients with measured increases in plasma EPA. In addition, total energy expenditure and physical activity level increased.[14] The increased physical activity level might reflect an improved quality of life. Interestingly, in a further randomized study, although fewer patients taking the EPA supplement gained 10% or more of baseline weight over a 3-month period than did patients taking MA, the percentage of patients with appetite improvement was similar in the two groups.[60] This suggests that EPA could also be used as an appetite stimulant. Further studies are required to confirm the anticachectic activity of EPA.

Thalidomide

Thalidomide is being evaluated for the treatment of cancer cachexia owing to its ability to promote weight gain in HIV-infected patients. Thalidomide has been shown to block NF-κB regulated genes through suppression of IκB kinase activity.[61] A small study with 10 patients with nonobstructing and inoperable esophageal cancer showed thalidomide (200 mg daily) to increase both body weight (1.29 kg) and lean body mass (1.75 kg), while an isocaloric diet caused a loss of both body weight and lean body mass.[62] A further study in 50 patients with advanced pancreatic cancer who had lost at least 10% of their body weight substantiated these results.[63] Thus, after 4 weeks, patients receiving thalidomide (200 mg daily) had gained an average of 0.37 kg in body weight and 1 cm^3 in arm muscle mass compared with a weight loss of 2.2 kg and arm mass of 4.46 cm^3 in the placebo group. After 8 weeks, patients on thalidomide had lost 0.06 kg in weight and 0.5 cm^3 in arm mass, while the placebo group had lost 3.62 kg and 8.4 cm^3, respectively. These results suggest that thalidomide has the potential to attenuate muscle wasting in cachexia.

β-Hydroxy-β-methylbutyrate

β-Hydroxy-β-methylbutyrate (HMB) is a metabolite of leucine formed by transamination to α-ketoisocaproate in muscle, followed by oxidation of the α-ketoisocaproate in the cytosol of the liver and possibly other tissues. HMB has been shown to attenuate the loss of body weight and skeletal muscle mass in mice bearing a cachexia-inducing tumor by attenuating the increased expression of the ubiquitin-proteasome pathway.[64] HMB acts like EPA to attenuate PIF-induced signaling pathways in muscle, leading to an increased proteasome expression by preventing activation of NF-κB.[65] Only a single clinical study has been reported on the effect of HMB in cancer cachexia.[66] This showed that HMB (3 g/day) in combination with L-arginine (14 g/day) and L-glutamine (14 g/day) produced a 0.95 kg gain in body weight in 4 weeks, whereas control subjects lost 0.26 kg. This gain was the result of a significant increase in fat free mass, and this was maintained over a 24-week study period. Further studies are required to confirm the clinical efficacy of HMB.

Combination Treatment

Evidence has been presented to indicate that oxidative stress plays an important role in age-dependent skeletal muscle atrophy.[67] Since an increase in oxidative stress has been observed in cancer patients, Mantovani and colleagues[68] administered vitamins A, E, and C (antioxidants), polyphenols, omega-3 fatty acids, α-lipoic acid, carboxycysteine, MPA, and a selective COX-2 inhibitor, with or without anti-TNF-α antibodies, to 25 cachectic cancer patients. Over a 4-month period, body weight was significantly increased from 51.3 to 58.1 kg together with lean body mass, appetite, grip strength, and quality of life. It is not certain which components of the treatment were responsible for the beneficial effect, since some have not been tested individually, but combination of agents attacking various components of the cachexia syndrome might be the way forward for improved clinical treatment of cachectic cancer patients.

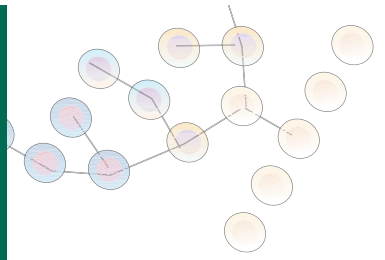
In addition to these treatments there are a number of experimental agents that require clinical investigation:

- Adenosine 5′-triphosphate[69]
- Cyclooxygenase inhibitors (COX-1 and COX-2)[70]
- Interleukin-4[71]
- Interleukin-15[72]
- Ghrelin[73]
- Reseveratrol[35]
- Antibodies to parathyroid hormone–related protein[74]
- Melanocortin-4-receptor antagonists[75]
- Lipoxygenase inhibitors[76]
- Erythropoietin[77]
- β_2-adrenergic receptor agonists (e.g., formoterol)[78]

SUMMARY

Progress in basic science has improved our understanding of the cellular mechanisms underlying tissue wasting in cachexia and has provided new molecular targets for therapeutic drug development. Further studies on tumor and host factors involved in the cachectic process, together with their cellular receptors, will aid in drug design and provide rational drug combinations for therapy. Attention in clinical trials is moving away from appetite and total body weight to measurements of lean body mass and physical functioning, which are important factors in maintaining the quality of life. This is not to say that anorexia is not an important factor that needs attention. Feeding is an important social interaction and something in which the family can help in the treatment of severely malnourished patients. Advances in our understanding of neuropeptides and their relationship to cancer anorexia will lead to new developments in this field, although few have received rigorous clinical evaluation.

Nutritional therapy could prove to be synergistic with other types of agents. Thus, inhibitors of the activation of NF-κB, such as EPA, HMB, and thalidomide, might be expected to attenuate muscle protein degradation but not improve protein synthesis. This is borne out by clinical trials, which show attenuation of the loss of muscle mass but no marked increase in size. Certain amino acids, principally the branched-chain amino acids, are known to stimulate protein synthesis at the translational level and might be expected to be synergistic with agents targeting muscle protein degradation.



Cure of the cancer would of course abolish the need to treat cachexia. However, until this happens, there will be a need for palliative therapy to improve the quality of life of the cancer patient.

39 Nausea and Vomiting

John D. Hainsworth

SUMMARY OF KEY POINTS

Incidence
- Most common chemotherapy-associated toxicities
- More frequent and severe with repetitive doses of chemotherapy
- Significant impact on quality of life and can influence patient compliance with treatment

Etiology of Complication
- Acute nausea and vomiting often mediated by activation of serotonin type 3 receptors in the gastrointestinal tract
- Mechanism of delayed nausea and vomiting (more than 24 hours after chemotherapy) unknown

Evaluation of the Patient
- Risk factors, including type of chemotherapy (drugs, doses, schedule), age, sex, and prior alcohol use, should be assessed before treatment.

Grading of Complication
- Episodes of vomiting should be recorded (number, duration, time to onset); severity of nausea can be graded using visual analog scale.

Treatment
- Optimal treatment provides complete control of acute nausea and vomiting in most patients receiving highly emetogenic chemotherapy regimens; only 15% of patients have severe nausea and vomiting.
- Treatment of delayed nausea and vomiting has recently improved with the introduction of aprepitant and palonosetron; however, as many as one-third of patients still experience this complication.

INTRODUCTION

Nausea and vomiting are common side effects associated with systemic chemotherapy, and are among the adverse effects most feared by patients.[1,2] Although these complications of treatment are usually self-limiting and seldom life-threatening, the deleterious effects on nutritional status and quality of life can be substantial. Many of the recently introduced targeted agents have less potential to produce nausea and vomiting. However, intensive combination chemotherapy continues to be the cornerstone of treatment for many types of cancer, ensuring that antiemetic therapy will continue to be an integral aspect of supportive care.

Antiemetic therapy has improved dramatically during the last 20 years. With optimum treatment, most patients receiving highly emetogenic chemotherapy do not experience any nausea or vomiting during the 24 hours after treatment.[3–11] However, delayed symptoms are more common and are often underestimated by treating physicians and nurses.[12] Accurate assessment of delayed nausea and emesis is essential in providing maximal intervention with recently available agents.

The identification of potent new antiemetics has been made possible by an improved understanding of the physiology of the emetic reflex. Critical assessment of the optimal use of new agents for patients receiving chemotherapy has been facilitated by the development of reproducible methods of assessing nausea and vomiting, and by the conduct of carefully designed, randomized clinical trials.

PHYSIOLOGY OF THE VOMITING REFLEX

The pioneering work of Borison and Wang[13] more than 40 years ago provided the basis for understanding the vomiting reflex. In studies using ablative techniques and electrical stimulation with microelectrodes (primarily in decerebrate cats), these investigators proposed the existence of two distinct sites in the brain stem believed to be critical for the control of emesis. The first of the sites, the so-called vomiting center, was thought to be located in the lateral reticular formation of the medulla. Electrical stimulation of this site triggered the vomiting reflex, whereas ablation prevented the vomiting induced by a variety of stimuli. The vomiting center was thought to be located adjacent to the other structures involved in the coordination of vomiting, including the respiratory, vasomotor, and salivary centers, and cranial nerves VIII and X. More recent studies have suggested that the "vomiting center" is actually not anatomically discrete but that the initiation of the vomiting reflex is controlled by a complex system of networks located in the nucleus tractus solitarius.[14,15] The networks in this area control complex patterns of motor activity such as the vomiting reflex and are more accurately described as "central pattern generators."

The second important center identified by Borison and Wang was the chemoreceptor trigger zone (CTZ), located in the area postrema at the ventral aspect of the fourth ventricle. This center, located outside the blood-brain barrier, is exposed to various noxious agents borne in the blood or cerebrospinal fluid. Although electrical stimulation of the CTZ does not produce vomiting, intimate connections to the vomiting center permit stimulation of this center after exposure to blood-borne toxins. Ablation of the CTZ abolishes vomiting induced by these agents.

Although these concepts have been retained and are integral to the current understanding of the vomiting reflex, several other important components have also been recognized. Input from the gastrointestinal tract, predominantly through afferent vagal fibers, is critical in initiating the vomiting reflex after ingestion of noxious

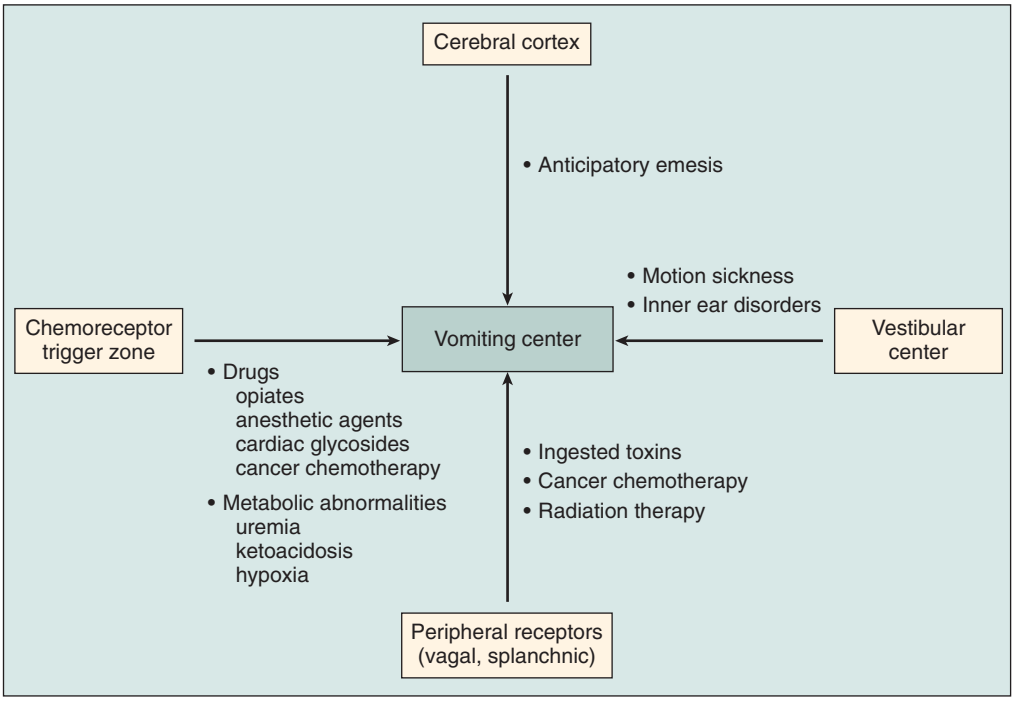

Figure 39-1 • Schematic diagram of the various pathways for initiation of the vomiting reflex. Clinical syndromes mediated by each mechanism are illustrated.

substances.[16] Incoming vagal afferents connect with the vomiting center directly; an intact CTZ is not essential when vomiting is initiated by this mechanism. It is now known that in addition to ingested substances, some blood-borne substances, including chemotherapeutic agents, can trigger the vomiting reflex through activation of the vagal afferent mechanism.

Two additional components of this complex system involve the vestibular apparatus and the higher brain stem and cortical structures. The vestibular system is involved primarily in initiating the vomiting reflex in motion sickness. Input from higher cortical centers seems to be critical in a variety of conditions, including anticipatory emesis seen for patients who have previously experienced chemotherapy-induced emesis. The various components of the vomiting reflex are illustrated diagrammatically in Figure 39-1, along with the clinical situations in which they are operative. Given the complexity of this system, it is not surprising that different pharmacologic approaches are necessary to control vomiting of different etiologies. Improved understanding of the neurochemistry of the emetic reflex has been important in developing antiemetics with new mechanisms of action. The initial focus of such investigation was the area postrema, where receptors for a large number of neuroactive agents have been identified.[17–19] Many of these neurotransmitters (e.g., dopamine, histamine, acetylcholine, norepinephrine, substance P) are in themselves emetogenic agents. The development of pharmacologic agents that block specific sets of receptors (e.g., dopamine, neurokinin-1) has resulted in the identification of valuable antiemetics, and it is likely that continued efforts in this area will be productive of additional valuable agents in the future.

In addition to neurotransmitters located in the CTZ, type 3 serotonin (5-hydroxytryptamine 3 or 5-HT3) receptors are present in large quantities on vagal and splanchnic afferents within the gastrointestinal tract.[20] These peripheral receptors are pivotal in the initiation of the acute nausea and vomiting caused by cisplatin and other strongly emetogenic chemotherapeutic agents; inhibition of this pathway by specific 5-HT3 receptor antagonists results in highly effective antiemetic therapy.[21]

CLINICAL FEATURES OF CHEMOTHERAPY-INDUCED EMESIS

Clinical Syndromes

Chemotherapy-induced nausea and vomiting can be subdivided into three distinct clinical syndromes, each having specific therapeutic implications. These syndromes and their clinical correlates are defined here; treatment approaches are considered later in the chapter. Because nausea and vomiting are common symptoms among patients with cancer, etiologies other than chemotherapy should also be considered. Among the diverse causes of nausea and vomiting among patients with cancer are intestinal obstruction, liver metastases, central nervous system involvement, and other medications (particularly narcotic analgesics). These etiologies should be considered especially when the time course or duration of nausea and vomiting is unusual for the known chemotherapy-induced syndromes.

Acute Nausea and Vomiting

Acute nausea and vomiting after the administration of chemotherapy occur within 24 hours after the chemotherapy dose. The nausea and vomiting during this phase are the most severe, hence the emphasis on therapeutic intervention during this phase. With most chemotherapeutic agents, acute nausea and vomiting begin 1 to 2 hours after intravenous administration. This delay in onset argues against a direct effect at the CTZ, which would be expected to produce emesis within minutes of intravenous drug administration. A peripherally mediated vomiting reflex, probably serotonin release from small intestinal mucosa, offers a better explanation of the delayed onset of emesis.[22] The onset of nausea and vomiting after the intravenous administration of cyclophosphamide is delayed even longer than with other agents, typically occurring 9 to 18 hours after administration of the drug.[23] The mechanism of cyclophosphamide-induced nausea and vomiting is unclear; the difference in the time of onset suggests that the mechanism might differ from that of other agents.

Delayed Nausea and Vomiting

Delayed nausea and vomiting occur 24 or more hours after chemotherapy administration. Although the severity is decreased in comparison with acute nausea and vomiting, the course can be more protracted, resulting in significant difficulties with hydration, nutrition, and performance status. Delayed emesis is most severe and frequent after administration of high-dose cisplatin; most patients treated with this drug experience some degree of delayed emesis, with onset most frequently 24 to 72 hours after chemotherapy.[24] In some patients onset can occur as late as 4 to 5 days after treatment, persisting for several days. Patients who have poor control of acute nausea and vomiting are more likely to experience delayed nausea and vomiting as well; however, delayed emesis can occur among patients who have complete emetic control during the first 24 hours after administration of chemotherapy.

The pathophysiology of delayed emesis remains unclear, but it seems likely that this syndrome is mediated centrally by different neurotransmitters. 5-HT3 receptor antagonists, which are highly effective in the prevention of acute emesis, have less activity in the treatment of delayed emesis. Conversely, the neurokinin-1 (NK-1) receptor antagonists, which block the action of substance P, have consistently shown activity against delayed emesis. Peripheral factors, including residual metabolites of chemotherapeutic agents or gastrointestinal mucosal damage, might also play a role.

Anticipatory Nausea and Vomiting

Anticipatory nausea and vomiting often occur among patients who have experienced poor control of emesis during previous courses of chemotherapy.[25] The onset can occur before or during chemotherapy administration. Because this is a conditioned response, certain associations with chemotherapy administration, such as the hospital environment or the oncologist's office, might trigger the onset of emesis.

Prognostic Factors

Multiple clinical factors that are important in determining the incidence and severity of chemotherapy-induced nausea and vomiting have been identified. These factors include the type of chemotherapy administered, certain patient characteristics, and the antiemetic regimen employed (Table 39-1).

Chemotherapeutic Agents

The commonly used chemotherapeutic drugs are separated into five groups according to emetic potential in Table 39-2. Drugs in category 5 produce emesis in greater than 90% of patients, whereas drugs in category 1 produce emesis in fewer than 10%. The drugs that cause emesis most frequently also cause the most severe emesis. Emesis is most severe during the first 8 hours after onset, but with strongly emetogenic drugs patients are often ill throughout the 24-hour period after administration.

In general, the potential for acute nausea and vomiting increases with the dose of chemotherapy. Schedule of administration is also important with certain agents: Large intravenous bolus doses, or doses administered intravenously over a short period of time, are more likely to cause emesis than are smaller divided doses or continuous infusion.

The use of chemotherapeutic agents in combination increases the emetogenic potential of a treatment regimen. On the basis of the information in Table 39-2, Hesketh and colleagues[26] have proposed a model for predicting the emetogenic potential of a combination regimen (Table 39-3). As new combination regimens are introduced into clinical practice, application of this algorithm can result in optimum, cost-effective antiemetic therapy.

Patient Characteristics

Several patient characteristics are important predictors of the development and severity of acute chemotherapy-induced nausea and vomiting. These are age, gender, history of alcohol intake, and history of previous chemotherapy.

AGE. Data are conflicting regarding the effect of patient age on the severity of chemotherapy-induced nausea and vomiting. However, increasing evidence indicates that chemotherapy-induced emesis occurs more frequently in younger patients.[21,22] Fortunately, the best current antiemetic agents are effective and well tolerated by patients of all ages.

GENDER. Data from large prospective studies indicate that females have more severe and frequent chemotherapy-induced nausea and vomiting than males, even after controlling for chemotherapy regimen. In one study all patients received cisplatin-containing regimens and were treated with ondansetron; more women receiving high-dose cisplatin with either 5-fluorouracil or etoposide for lung cancer or head and neck carcinomas had poor control of emesis than did men receiving these same regimens (49% vs. 29%, respectively).[27]

HISTORY OF ALCOHOL INTAKE. Patients with a history of chronic alcohol intake (four to five mixed drinks per day) have more effective control of chemotherapy-induced nausea and vomiting when optimal antiemetics are used.[28,29] In a prospective study of 52 patients receiving high-dose cisplatin along with combination antiemetic therapy, 93% of those with a high alcohol intake experienced no emesis, as opposed to 61% of patients without this history.[28] It is important to emphasize, however, that the administration of highly emetogenic chemotherapy to these patients, in the absence of appropriate antiemetic therapy, still results in a high incidence of severe acute nausea and vomiting. The mechanism of the alcohol effect is unclear; it is possible, however, that various receptor sites are less sensitive among patients with a history of alcohol intake and that blockade of these receptors is relatively easy with appropriate antiemetics.

PREVIOUS CHEMOTHERAPY. Patients who have experienced poor control of emesis during previous chemotherapy are more likely to have unsatisfactory results with subsequent antiemetics.[27] The development of an anticipatory component to the nausea and

vomiting is certainly one influence; whether additional influences are also involved is unknown.

Conduct and Interpretation of Clinical Antiemetic Trials

Because multiple patient characteristics and chemotherapy variables influence the incidence and severity of chemotherapy-associated nausea and vomiting, optimal design and interpretation of clinical trials with new antiemetics or new combination regimens requires that these factors be taken into account. Definitive demonstration of the superiority of an agent or regimen requires a large, randomized trial in which the comparison groups are matched with respect to the various patient characteristics and chemotherapy received. Patients should be receiving their initial dose of chemotherapy, so as to avoid the confounding effects of anticipatory emesis. Crossover trials are also difficult to interpret for this reason. Optimally, the treatment received should be double-blinded to avoid investigator or patient bias. Because effective regimens now exist for all subgroups of patients, new treatments should be compared with existing treatments; the inclusion of a "no-treatment" or placebo arm in a randomized trial is inappropriate. The completion of this type of large controlled randomized trial has hastened the improvement of antiemetic therapy and the rapid incorporation of new treatments into clinical practice.

Table 39-3 Formula for Estimation of Emetogenic Potential of Combination Chemotherapy Regimens

- Use Table 39-2 to assign emetic level to each agent in the regimen.
- Identify most emetogenic agent.
- When considering the other components of the regimen, use the following rules:

  Level 1 agents do not contribute to emetogenicity.

  Adding level 3 or 4 agents increases emetogenicity by one level per agent.

  Adding level 2 agents (regardless of number) increases emetogenicity by one level greater than the most emetogenic agent.

EXAMPLES OF ALGORITHM USE

Regimen	Emetogenic Level of Agents in Regimen	Emetogenic Level of Regimen
CMF	3 + 2 + 1	4
CAF	3 + 3 + 2	5
Paclitaxel/ carboplatin	2 + 4	5
CVP	3 + 1 + 1	3

A, doxorubicin; C, cyclophosphamide; F, 5-fluorouracil; M, methotrexate; P, prednisone; V, vincristine.

When interpreting the results of antiemetic trials, special attention should also be given to the definitions of therapeutic response and the methods used to assess efficacy. Most trials measure the number of emetic episodes as the primary efficacy parameter, because this is an objective measurement. Some trials also measure various secondary efficacy parameters, including nausea, food intake, and overall patient satisfaction with treatment. Even when emesis is used to measure efficacy, comparisons between trials must be made with caution, as definitions of response have varied also. "Complete response," in various studies, has been defined as "no vomiting," "no vomiting and only mild nausea," or "no vomiting and no nausea" during the 24 hours after chemotherapy. Clearly, response rates can vary substantially, depending on the definition used. Standardization of response assessment would greatly aid in the interpretation of future trials.

TREATMENT OF CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

Acute Nausea and Vomiting

Several families of drugs with antiemetic activities have been identified. Table 39-4 lists the classes of antiemetic agents in current use, in approximate order of antiemetic potency. Only the 5-HT3 receptor antagonists, the substituted benzamides, and the new class of NK-1 receptor antagonists show marked activity against highly emetogenic chemotherapy. Because no single agent is ideal, combination antiemetic regimens have been developed, which have further improved efficacy. Increased understanding of the mechanism of action of the various compounds has led to more rational development of combination regimens; in general, the most effective regimens use agents with different mechanisms of action.

5-HT3 Receptor Antagonists

The selective 5-HT3 receptor antagonists are the most effective family of antiemetics in the treatment of acute emesis. These agents block the serotonin type 3 receptors and are thought to exert their antiemetic activity primarily through peripheral blockade in the small intestine (see the preceding discussion). Before 2003, three agents in this class were available in the United States: ondansetron, granisetron, and dolasetron. All three of these drugs proved superior to high-dose metoclopramide (the previous standard) in the prophylaxis

Table 39-4 Antiemetic Agents: Recommended Dosing

Antiemetic Agent	Recommended Dose: Acute Emesis	Recommended Dose: Delayed Emesis
5-HT3 Antagonists		
Ondansetron	0.15 mg/kg or 8 mg IV; 12–16 mg PO	8 mg PO bid × 2–3 days
Granisetron	1 mg IV or PO	
Dolasetron	1.8 mg/kg or 100 mg IV; 100–200 mg PO	
Palonosetron	0.25 mg IV	
Neurokinin-1 antagonists		
Aprepitant		125 mg PO (or 115 mg IV) day 1, then 80 mg days 2, 3
Corticosteroids		
Dexamethasone	8 mg IV or PO	4–8 mg PO bid days 2–4
Dopamine antagonists		
Metoclopramide	2–3 mg IV prechemotherapy, repeat 2 hr after chemotherapy	20–40 mg PO qid days 2–5
Prochlorperazine	10 mg PO or IV every 3–4 hrs as needed	
Haloperidol	1–3 mg IV or PO every 2–6 hrs as needed	
Benzodiazepines		
Lorazepam	1–2 mg IV every 4 hrs as needed	
Cannabinoids		
Dronabinol	5–10 mg PO every 3–4 hrs as needed	

of cisplatin-induced emesis,[30–35] and all were superior to standard agents when used to prevent emesis associated with cyclophosphamide-based regimens.[36–38] Dose-ranging studies with all drugs demonstrated an efficacy plateau,[39–41] and multiple large randomized trials comparing these agents to one another showed equivalent efficacy.[3–11] For patients receiving high-dose cisplatin therapy, use of appropriate doses of any one of these three agents results in complete control of emesis in 50% to 70% of patients during the first 24 hours after administration of chemotherapy. Complete control of emesis ranges from 70% to 80% among patients receiving moderately emetogenic regimens, usually cyclophosphamide based (Box 39-1).

In July 2003 a new 5-HT3 receptor antagonist, palonosetron, was approved by the U.S. Food and Drug Administration for the prophylaxis of acute and delayed chemotherapy-induced nausea and vomiting. Compared with other 5-HT3 receptor antagonists, palonosetron has a higher receptor binding affinity and a longer half-life (approximately 40 hours). In two phase III randomized clinical trials palonosetron provided superior control of acute and delayed nausea and vomiting when compared with either ondansetron or dolasetron.[42,43] Both trials contained patients receiving moderately emetogenic chemotherapy, and most patients did not receive concurrent dexamethasone.

The adverse events produced by all available 5-HT3 receptor antagonists are essentially identical. Mild to moderate headache is the most frequently observed toxicity and is produced by all three drugs in approximately 20% to 30% of patients. Other adverse events, including constipation and diarrhea, are mild and uncommon.

Recommended intravenous and oral doses of the 5-HT3 receptor antagonist and other antiemetics are outlined in Table 39-4. For prophylaxis of acute nausea and vomiting, a single dose during the first 24 hours is as effective as multiple doses. Therefore, the use of additional doses of these agents for "breakthrough" vomiting during this time is to be discouraged, and the writing of "as needed" orders for these agents should be avoided. Oral preparations are available for all 5-HT3 receptor antagonists except palonosetron and have shown equivalent efficacy.[44–46]

Box 39-1. MANAGEMENT APPROACH

Chemotherapy-Induced Nausea and Vomiting

Antiemetic therapy for acute chemotherapy-induced nausea and vomiting should be based on the emetic potential of the chemotherapy regimen being used and should take into account individual patient risk factors (e.g., sex, age, history of alcohol use, previous emesis with chemotherapy). Excellent algorithms for the prediction of the likelihood of emesis with single chemotherapeutic agents or combination regimens have been developed.

For optimal control of acute nausea and vomiting, patients receiving chemotherapy with moderate or high emetogenic potential should receive prophylaxis with a 5-HT3 receptor antagonist plus dexamethasone. Palonosetron may offer modest advantage over other 5-HT3 receptor antagonists, particularly in patients receiving highly emetogenic regimens.

Patients receiving mildly emetogenic therapy should receive dexamethasone (8 mg intravenously or orally); a 5-HT3 receptor antagonist should be added with subsequent courses only if antiemetic control is inadequate. Patients with breakthrough nausea and vomiting should receive either prochlorperazine (10 mg orally or intravenously) or lorazepam (1 mg intravenously every 4 hours). Additional doses of 5-HT3 receptor antagonists or dexamethasone during the first 24 hours are usually ineffective.

Delayed nausea and vomiting occurs more than 24 hours after chemotherapy is administered and should be anticipated among patients receiving highly emetogenic regimens (particularly cisplatin or cyclophosphamide). These patients should routinely receive prophylaxis: aprepitant should be added to the antiemetic regimen, and palonosetron is the 5-HT3 receptor antagonist of choice.

Neurokinin-1 Receptor Antagonists

The NK-1 receptor is a component of the centrally mediated vomiting reflex that mediates the emetogenic action of substance P, a tachykinin contained in vagal afferents innervating the area postrema and nucleus tractus solitarii in the brain stem.[19] Several selective NK-1 receptor antagonists have shown antiemetic activity,[47,48] and one of these, aprepitant, is currently approved by the Food and Drug Administration for the prevention of acute and delayed chemotherapy-induced nausea and vomiting.[49–52] The most substantial contribution of this drug has been in the management of delayed emesis following moderately or highly emetogenic chemotherapy. In the pivotal randomized phase III study, patients treated with high-dose cisplatin received prophylaxis with either granisetron/dexamethasone or granisetron/dexamethasone plus aprepitant.[49] Patients who received aprepitant more frequently had no vomiting during the first 24 hours (93% vs. 67%; $P < 0.001$) and also during days 2 through 5 (82% vs. 33%; $P < 0.001$). Similar results have subsequently been obtained in patients receiving cyclophosphamide-containing regimens.[52] Side effects with aprepitant are mild and infrequent, and include fatigue, constipation, hiccoughs, and headache.

Substituted Benzamides

High-dose metoclopramide was the first drug to demonstrate substantial antiemetic activity among patients treated with high doses of cisplatin.[53] The mechanism of action was initially attributed to dopamine receptor antagonism. However, high-dose metoclopramide also inhibits the 5-HT3 receptors, probably a more important mechanism.[54] Today, high-dose metoclopramide is rarely used, as a result of the higher efficacy and lower toxicity of the selective 5-HT3 receptor antagonists.

The major side effects associated with high-dose metoclopramide are extrapyramidal reactions caused by dopamine receptor antagonism.[53,55] Acute dystonic reactions are the most dramatic adverse effects but are relatively uncommon in adults, occurring in only 2% to 5% of cases. Akathisia, though less dramatic, is a more common problem and often persists for several hours. Both adverse effects are more common in young patients. In most adults, these side effects are not difficult to control or prevent. Intravenous diphenhydramine quickly ends an acute dystonic reaction, and the addition of lorazepam to metoclopramide-containing regimens greatly reduces the incidence of extrapyramidal reactions.[56]

Corticosteroids

The antiemetic mechanism of action of the corticosteroids is unclear. Unlike most other antiemetics, there is no current evidence that neurotransmitter blockade is involved. The antiemetic activity of the corticosteroids has been confirmed in several trials, predominantly for patients receiving moderately emetogenic chemotherapy.[57,58] Corticosteroids that have been used as antiemetics include dexamethasone, methylprednisolone, and occasionally prednisone. Although no obvious differences in efficacy have been demonstrated among the corticosteroids, dexamethasone is almost universally used currently. A recent randomized dose-finding study identified a single 8-mg dose of dexamethasone before treatment as optimal.[59] Because of their moderate antiemetic efficacy, corticosteroids should be used as single agents only in the prophylaxis of mildly emetogenic chemotherapy. However, they consistently add to the effect of other antiemetics when used in combination (see the discussion later in this chapter), presumably because they have a different mechanism of action.

The adverse effects of short courses of corticosteroid are mild and infrequent. Additional caution must be used in treating patients with

diabetes mellitus or other conditions predisposing to difficulties with steroids. Occasional acute psychotic reactions have been observed.

Phenothiazines

The phenothiazines were the first family of agents to demonstrate substantial antiemetic activity and are thought to act primarily as antidopaminergic agents. Several of these agents, including prochlorperazine, promethazine, and thiethylperazine, are still used frequently. In 1963 a randomized, double-blind, placebo-controlled trial documented the superiority of prochlorperazine and thiopropazate to placebo in the control of nausea and vomiting induced by fluorouracil.[60] Efficacy has also been documented against other moderately emetogenic chemotherapeutic agents.[61] These agents are ineffective against highly emetogenic chemotherapy, however, and should currently be used only in combination with other more effective agents.[53] The side effects of the phenothiazines include sedation, akathisia, and, less commonly, acute dystonic reactions.

Benzodiazepines

Lorazepam is the only benzodiazepine that has found widespread use in antiemetic therapy. Direct antiemetic effects of lorazepam are minor; however, the sedative, anxiolytic, and amnesic effects have made this drug ideal for use in combination regimens.[62] Several trials have documented improved patient acceptance of lorazepam-containing combination regimens, even when the objective antiemetic efficacy increased only slightly.[56] The use of intravenous lorazepam often causes marked sedation lasting several hours, which limits its use in the outpatient setting. In addition, some patients experience confusion, amnesia, and transient enuresis.

Butyrophenones

The butyrophenones, haloperidol and droperidol, have antiemetic activity as a result of specific dopamine receptor blockade.[63,64] Common side effects of the butyrophenones include sedation, dystonic reactions, and akathisia; in addition, hypotension is occasionally encountered. Because the butyrophenones are less efficacious than the 5-HT3 receptor antagonists and high-dose metoclopramide, their use should be reserved for the occasional patient who achieves poor results with standard antiemetic treatment.

Cannabinoids

Anecdotal reports of reduced emesis among patients smoking marijuana during chemotherapy stimulated interest in the cannabinoids during the early 1980s. Several cannabinoids have been evaluated as antiemetics; at present dronabinol is the only commercially available agent in this class. This drug has antiemetic activity for patients receiving moderately emetogenic chemotherapy; in this setting, it has been more effective than prochlorperazine.[65] The mechanism of action of the cannabinoids is incompletely defined; a central nervous system site of action has been postulated because of the marked psychoactive properties of these agents. Clinical use of cannabinoids is limited because of their unfavorable toxicity profile in some patients. Frequent toxicities include dysphoria, hallucinations, vertigo, dry mouth, sedation, and disorientation. These side effects are more common in elderly patients. The cannabinoids should not be considered for first-line antiemetic therapy, because more effective and better tolerated agents exist. They should be considered for the occasional patient with mild to moderate nausea and vomiting who has either poor tolerance or poor response to other antiemetics.[66]

Combination Antiemetic Therapy

Because none of the antiemetic agents is ideal when used alone, a variety of combination regimens has been developed in an attempt to improve efficacy. The most successful combinations use drugs with different mechanisms of action and nonoverlapping toxicities.

The corticosteroids have been most extensively evaluated as "second drugs" in combination regimens because of their ease of administration, minimal toxicity, and different mechanism of action. When combined with the 5-HT3 receptor antagonists, dexamethasone has consistently improved antiemetic efficacy among patients receiving moderately or highly emetogenic regimens.[67–69] In a recent meta-analysis of randomized trials comparing various regimens with or without dexamethasone, complete protection from emesis was increased by 16% when dexamethasone was added to a 5-HT3 receptor antagonist.[70] The addition of dexamethasone to high-dose metoclopramide also improves antiemetic efficacy.[71] A single dexamethasone dose of 8 mg before therapy is as effective as higher doses or multiple dose schedules.[59] Therefore, a corticosteroid should be included in the prophylactic treatment of all patients receiving moderately or highly emetogenic chemotherapy, unless specific contraindications exist.

Aprepitant is also an agent with proven efficacy in combination regimens, usually as a third drug (added to a 5-HT3/dexamethasone combination). The addition of aprepitant reduces acute and delayed emesis in patients receiving moderately or highly emetogenic chemotherapy.[49–52] Aprepitant should be included in the prophylactic antiemetic treatment of all patients receiving highly emetogenic chemotherapy and should be considered in patients receiving moderately emetogenic chemotherapy who are at high risk for emesis (e.g. female, younger patients, emesis with previous chemotherapy). If aprepitant is not initially included in the antiemetic regimen, it should be added during subsequent cycles for patients who have poor control of emesis.

The addition of lorazepam to antiemetic regimens was common when high-dose metoclopramide was the major antiemetic agent, in large part as a result of the reduction of extrapyramidal side effects.[56] However, the contribution of lorazepam to current 5-HT3 receptor antagonist combinations is unclear, and sedation is consistently increased when lorazepam is added. The use of lorazepam should be considered only for patients with a high level of anxiety before treatment.

Anticipatory Nausea and Vomiting

Because anticipatory nausea and vomiting are conditioned responses, effective control of chemotherapy-induced nausea and vomiting prevents the development of this reflex and is therefore the best strategy for preventing this problem.[25,72] The highly effective combination regimens in current use have greatly decreased the prevalence of this problem. For patients in whom anticipatory nausea and vomiting develop, treatment with anxiolytics such as the benzodiazepines is sometimes effective.[62] In addition, various nonpharmacologic approaches, including hypnosis and behavioral modification, have shown some benefit for these patients.[25,73,74]

Delayed Nausea and Vomiting

Until recently, control of delayed nausea and vomiting was poor as compared with the control achieved during the first 24 hours after chemotherapy. The combination of metoclopramide (0.5 mg/kg four times daily for 4 days) and dexamethasone (8 mg twice daily for 2 days, then 4 mg twice daily for 2 days) was superior to dexamethasone alone in patients receiving cisplatin-based chemotherapy (35% vs. 11% control rate).[75] However, most patients did not have adequate control of emesis, and side effects were bothersome for some patients. Similarly, the contribution of the initial 5-HT3 receptor antagonists was modest, when compared with their excellent activity in treating acute nausea and vomiting. Oral ondansetron (8 mg orally twice daily, days 2–6) had modest benefit versus placebo,[76] but in other trials the efficacy of a 5-HT3 antagonist was not any better

than dexamethasone.[77,78] Despite these modestly effective interventions, a recent study showed that the rates of delayed nausea (54%) and vomiting (32%) remained substantial in patients receiving moderately or highly emetogenic chemotherapy.[79] Furthermore, 23% of patients with complete control during the first 24 hours had either nausea or vomiting during the delayed phase.

With the introduction of palonosetron and aprepitant, the treatment of delayed nausea and vomiting has improved substantially. Palonosetron, the newest 5-HT3 receptor antagonist, is more effective than either ondansetron or dolasetron in controlling delayed nausea and vomiting.[42,43] In patients receiving moderately emetogenic chemotherapy, a single dose of palonosetron (0.25 mg) provided complete control of delayed nausea and vomiting in 48%, as compared with 36% for dolasetron 100 mg.[42] Similar results occurred when palonosetron 0.25 mg was compared to ondansetron 32 mg (74% vs. 55% control of delayed emesis; $P < 0.001$).[43] The differences between palonosetron and the other 5-HT3 receptor antagonists are unexplained but may relate to the longer half-life of palonosetron or to the improved control of acute emesis.

The addition of aprepitant, the first NK-1 antagonist, has been even more important in controlling delayed nausea and vomiting.[49–52] When added to granisetron/dexamethasone in patients receiving cisplatin-based chemotherapy, aprepitant reduced the incidence of delayed emesis from 67% to 18% ($P < 0.001$).[49] Improvement also occurred when aprepitant was added to ondansetron/dexamethasone in patients receiving cyclophosphamide/anthracycline chemotherapy (complete control improved from 42.5% to 50.8%; $P = 0.019$).[52]

Currently, optimal management of delayed chemotherapy-induced nausea and vomiting requires prediction of high-risk patients and administration of the most effective antiemetic regimen, beginning with the first cycle of chemotherapy. High-risk patients include all patients receiving highly emetogenic chemotherapy regimens, and certain subgroups (e.g. young patients, females) receiving moderately emetogenic regimens. In these patients, palonosetron should be the 5-HT3 receptor antagonist of choice, and aprepitant should be added to the antiemetic regimen. Similar substitutions or additions should be made in other patients who experience delayed nausea or vomiting regardless of the chemotherapy regimen they are receiving.

Radiation-Induced Nausea and Vomiting

Radiation-induced nausea and vomiting are common with some types of radiation therapy and are related to the size of the radiation portal, the dose delivered, and the site of radiation. Radiation-induced emesis occurs acutely in more than 90% of patients receiving total-body irradiation. Among patients receiving conventional daily doses of radiotherapy (2 Gy/fraction), emesis develops within 2 to 3 weeks in about 50% of patients receiving an upper abdominal portal.[80] The mechanism of radiation-induced emesis remains unclear, but release of serotonin from the gastrointestinal enterochromaffin cells and subsequent involvement of the gastrointestinal 5-HT3 receptors and vagal afferent fibers is most likely.

Most of the antiemetic agents found active against chemotherapy-induced nausea and vomiting also have some activity against radiation-induced emesis; however, few randomized trials have been performed to identify an optimal regimen. Dexamethasone or ondansetron, used as single agents, were superior to placebo in patients receiving upper abdominal irradiation[81,82] or total-body irradiation.[83] With multifractionated courses, the use of daily dexamethasone is problematic; however, the addition of dexamethasone (4 mg orally daily, during the first 5 days only) to ondansetron (8 mg orally twice daily) improved results in patients receiving upper abdominal radiation therapy.[84]

Given the postulated mechanism of radiation-induced emesis and the available clinical data, it seems likely that the 5-HT3 receptor antagonists are the most active antiemetic agents in this setting. Routine prophylaxis for acute and delayed nausea and vomiting should accompany total-body irradiation. For patients receiving upper abdominal irradiation, in which the incidence of nausea and vomiting is lower, initial prophylaxis with phenothiazines or other less expensive agents might be a reasonable option. However, these patients should receive daily oral prophylaxis with a 5-HT3 receptor antagonist if emesis is uncontrolled with other agents; use of concurrent dexamethasone for the first 5 days should also be considered.

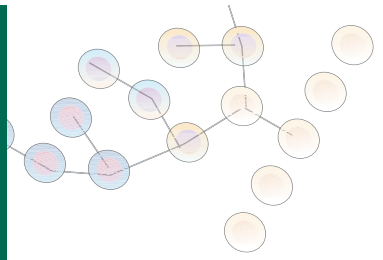
SUMMARY OF RECOMMENDATIONS FOR COMBINATION ANTIEMETIC THERAPY

Optimal selection of antiemetic therapy is based on the emetic potential of the planned chemotherapy regimen. The information presented in Tables 39-2 and 39-3 should be used to assign an emetic level to the chemotherapy agent or regimen being used. Optimal doses of all antiemetic agents are contained in Table 39-4.

All patients receiving regimens with emetic level 4 or 5 should receive routine prophylaxis for acute nausea and vomiting with a 5-HT3 receptor antagonist plus dexamethasone. Because all of these patients also have substantial risk for delayed emesis, aprepitant should be added, and palonosetron should be considered the 5-HT3 antagonist of choice. Patients receiving level 3 regimens are usually well controlled with a 5-HT3 receptor antagonist plus dexamethasone; routine prophylaxis for delayed emesis is not necessary. Patients receiving mildly emetogenic regimens (category 1 or 2) do not require routine use of a 5-HT3 receptor antagonist and are usually managed effectively with either dexamethasone alone (category 2) or no prophylactic antiemetic therapy (category 1).

FUTURE DIRECTIONS

Major improvements in antiemetic therapy during the past 20 years have resulted in complete protection from chemotherapy-induced nausea and vomiting in most patients receiving chemotherapy. A few patients (fewer than 20%) continue to have problems during the first 24 hours after treatment, and in most of these patients breakthrough nausea and/or vomiting occurs more than 16 hours after administration of chemotherapy. Delayed nausea and vomiting remain common, but therapy has improved markedly with the introduction of aprepitant and palonosetron.



The evolution of standard chemotherapy for many types of cancer has had an impact on the antiemetic therapy required. Two highly emetogenic chemotherapeutic agents, mechlorethamine and dacarbazine, are now uncommon in clinical practice. More importantly, the use of cisplatin has declined greatly during the last several years mostly because of its replacement by carboplatin, a drug with a lower emetogenic potential. Many of the more recent cytotoxic agents (e.g., paclitaxel, docetaxel, gemcitabine, topotecan, vinorelbine) are mildly emetogenic agents. Increasing use of these new drugs has also fortuitously allowed the more effective control of chemotherapy-induced emesis. Finally, it is likely that future targeted agents, many of which will be administered orally, will not be associated with nausea or vomiting in most patients. Recent experience with several monoclonal antibodies (e.g., rituximab, trastuzumab, bevacizumab) and oral tyrosine kinase inhibitors (e.g., imatinib, erlotinib) confirms the low frequency of nausea, even in the absence of any prophylaxis.

Future improvement in antiemetic therapy will require continued improvement in understanding of this complex physiologic reflex, and identification of new mediators. Continued well-designed clinical trials are necessary to define the most effective—and the most cost-effective—ways of incorporating new agents into current antiemetic regimens.

40 Oral Complications

Kostandinos Sideras, Charles L. Loprinzi, and Robert L. Foote

SUMMARY OF KEY POINTS

Incidence

- Mucositis is a major dose-limiting toxic effect of chemotherapy for solid tumors developing in 5% to 40% of patients.
- Mucositis develops in 70% to 100% of patients receiving high doses of chemotherapy with bone marrow rescue.
- Radiation therapy to the oral cavity frequently causes a host of oral complications, including mucositis, xerostomia, dental caries, tissue necrosis, and taste alterations.

Etiology of Complications

- Cytotoxic chemotherapy and radiation therapy cause oxidative stress and injury to oral cavity tissues, leading to upregulation of inflammatory cytokines, additional signaling and amplification of inflammatory pathways, and subsequent ulceration and healing.
- Treatment-induced myelosuppression may lead to secondary infections.
- Graft-versus-host disease (GVHD) is a further complication.

Prophylactic Measures

- The importance of instituting oral hygiene protocols in patients receiving chemotherapy is well established.
- Cryotherapy is the most conventional and easy to use preventative method, at least for 5-FU-based bolus therapy and appears to have implications for other chemotherapeutic regimens as well, such as edatrexate and high-dose melphalan therapy.
- The role of antibiotics, either topically or systemically, has not yet been established.
- Glutamine supplementation in the form of AES-15 (Saforis) has recently shown promise as a potentially effective agent.
- Palifermin, a keratinocyte growth factor preparation, has been approved by the FDA for use with high-dose chemotherapeutic regimens associated with high rates of mucositis and has shown promise in other settings as well
- Low-level laser therapy has shown promise, but its use is limited to centers that are able to support its use.
- Pretreatment dental care, good oral hygiene, and sophisticated treatment planning are recommended for patients receiving radiation therapy.

Treatment

- There is an overall lack of evidence regarding the efficacy of various agents in promoting healing of the oral mucosa after mucositis is established.
- Systemic analgesic therapy of mucositis pain with narcotic medications is well established and recommended.
- Antibiotics and/or antifungal medications should be given to patients with evidence of infection.
- In the palliative setting, various mouthwashes are widely used in clinical practice based on provider preference and experience. These mouthwashes most frequently contain combinations of diphenhydramine, viscous lidocaine, magnesium hydroxide/aluminum hydroxide, nystatin, and corticosteroids. The efficacy of these measures has not been adequately evaluated to date.
- Baking soda mouth rinses appear to be the most economical solution, although efficacy has not been clearly established.

INTRODUCTION

The oral cavity is a common site for chemotherapy-induced and radiation-induced toxicity. Manifestations of this toxicity include alimentary tract mucositis; secondary infectious complications induced by bacteria, fungi, and viruses; and graft versus host disease in patients receiving allogeneic bone marrow transplants. Although alimentary tract mucositis can involve the entire gastrointestinal tract,[1] it is most frequently manifested in the oral cavity as ulceration, pain, and bleeding. Mucositis leads to significant patient morbidity and decline in quality of life and limits the use of additional chemotherapeutic treatment. Moreover, the economic burden of this frequent oncologic complication is also considerable.[2,3] This chapter discusses the etiology, incidence, risk factors, prevention, and treatment of oral toxic effects of standard chemotherapy, intensive marrow-ablative chemotherapy, and radiation therapy. The prevention and treatment of graft-versus-host disease is beyond the scope of this chapter (see Chapter 32).

Pathophysiology of Mucosal Injury

It is currently accepted that the processes of mucosal injury and subsequent healing are not limited to the epithelium alone but involve all layers of the mucosa, including the extracellular matrix. A five-stage process has been postulated to explain the complex molecular, cellular, and histologic events that are associated with chemotherapy-induced mucosal injury[4] (Fig. 40-1). Oxidative stress related to chemotherapy is thought to be responsible for the first phase of mucosal injury (initiation phase). The second phase involves the upregulation of transcription factors and the generation of messenger signals (upregulation and message generation phase). In this stage, upregulation of NF-κ beta is thought to play a central role in the

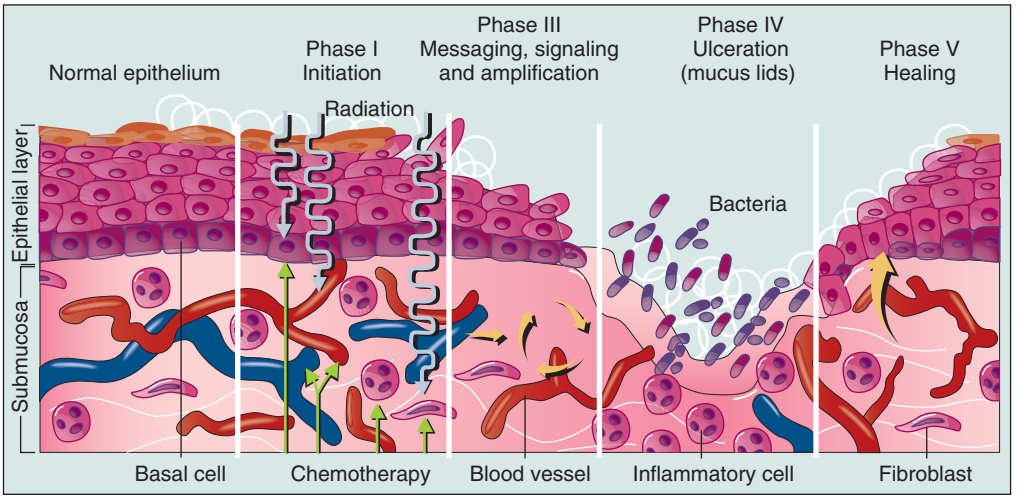

Figure 40-1 • Phases in the development of oral mucositis. (Adapted from Peterson DE: New strategies for management of oral mucositis in cancer patients. J Support Oncol 2006;4:9–13.)

subsequent upregulation of multiple proinflammatory cytokines, such as TNF-α, IL-1b, and IL-6. NF-κ beta is also thought to upregulate cyclooxygenese-2, which in turn is implicated in the upregulation of matrix metalloproteinase.[5] In addition to the sphyringomyelinase and ceramide pathways, fibronectin breakup and macrophage activation are other complex events that take place leading to further mucosal injury and apoptosis. The third phase of mucosal injury involves additional signaling and amplification of the previously discussed pathways, leading to the generation of additional proinflammatory cytokines (signaling and amplification phase). Up to this point, the biologically altered mucosa appears still to be anatomically intact. The fourth phase consists of the symptomatic phase of mucositis, involving mucosal ulceration, pain, and bleeding (ulceration phase). Bacterial superinfection and reduction in salivary gland function can complicate and amplify the mucosal injury at this stage. The fifth and final phase involves the healing of the mucosa, a process that depends on angiogenesis and on increased biological activity in the extracellular matrix (healing phase). In patients who are undergoing myeloablative chemotherapy, the healing phase might not begin until leukocyte recovery. It is important to understand that these phases do not necessarily follow a linear progression but may occur simultaneously at different locations.[4]

Mucositis Assessment

Multiple mucositis scales exist in clinical practice, differing in the level of objective and subjective information used. However, it is known that patient-provided data lead to the same conclusions as do clinician-determined data.[6] The WHO and NCI-CTC scales are the most commonly used ones and combine information from both the patient's signs and symptoms and the patient's functional status and ability to eat.[4]

ORAL COMPLICATIONS FROM CHEMOTHERAPY INCLUDING MYELOABLATIVE CHEMOTHERAPY

Incidence and Risk Factors

The type of chemotherapeutic agents that are used, the specific dose, route, and frequency of administration, and whether the chemotherapy is given as monotherapy or in combination with other agents and modalities of treatment significantly affect the degree of injury (Fig. 40-2).

Antimetabolites such as methotrexate and 5-FU, antitumor antibiotics such as doxorubicin, platinum agents such as cisplatin, purine analogs such as cytarabine, and topoisomerase inhibitors such as etoposide are most specifically associated with mucositis. Methotrexate and etoposide are secreted into the saliva thus enhancing mucosal toxicity. Irinotecan, although notorious for causing gastrointestinal mucositis in the form of diarrhea, has limited oral toxicity.

Regarding the time course of mucosal injury, 5-FU-induced mucositis is usually first noticed anywhere from 3 to 7 days after initiation of therapy. Incidence peaks at 7 to 12 days and diminishes by around 2 to 3 weeks (Fig. 40-3). With myeloablative chemotherapy for hematologic malignancies, mucositis severity can peak up to 18 days following initiation of therapy.[7]

Chemotherapy for the treatment of solid tumors leads to the development of mucositis in 5% to 40% of patients (5% to 15% grade 3 to 4).[8] Many modern treatment approaches have not solved this problem and, owing to their aggressiveness, are frequently more toxic.[9] A vast experience exists with 5-FU, the most commonly used drug to treat gastrointestinal malignancies. Although there has long been the belief that continuous administration of 5-FU carries a higher risk of mucositis than does bolus administration of 5-FU, a meta-analysis of trials failed to support this association.[10]

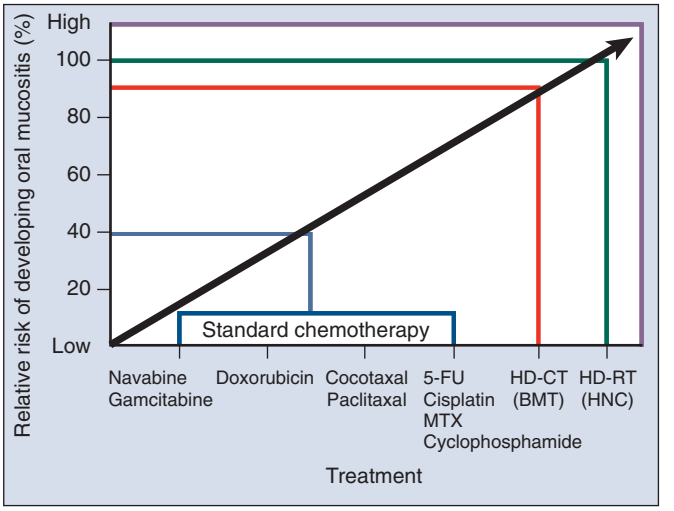

Figure 40-2 • Risk of mucositis according to type of cancer therapy. (Adapted from Peterson DE: New strategies for management of oral mucositis in cancer patients. J Support Oncol 2006;4:9–13.)

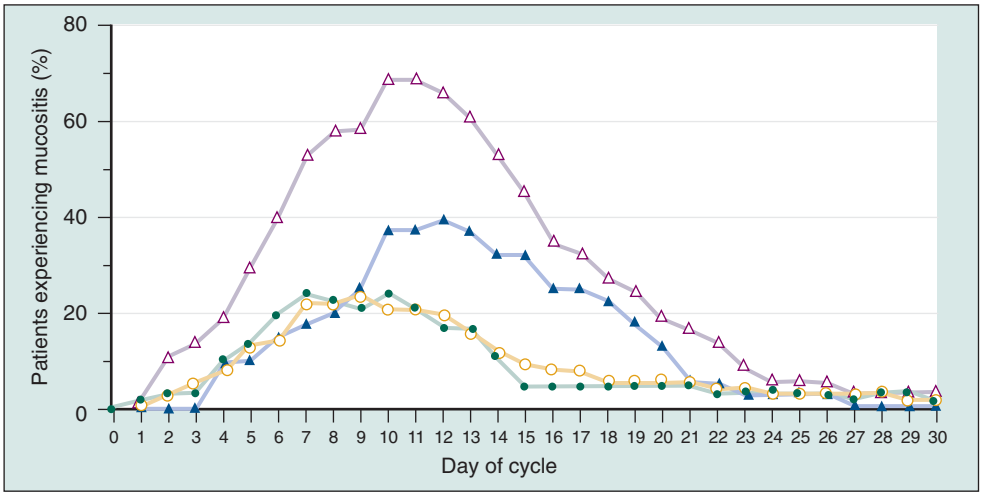

Figure 40-3 • Percentages of patients with mucositis for 30 days after initiation of 5-fluorouracil-based chemotherapy. These data come from two sequential randomized trials:[32,36] one that compared 30 minutes of oral cryotherapy (▲) with a control group (△) and one that compared 30 minutes of cryotherapy (○) with 60 minutes of cryotherapy (●).

When myeloablative chemotherapy is used, the incidence of mucositis increases to 70% to 100% (21% to 67% grade 3 to 4).[7,11] This appears to be especially true for induction regimens that contain high-dose melphalan.[7] When chemotherapy is used in combination with radiation therapy to treat cancer of the head and neck, the rate of mucositis approaches 90% to 100% of patients (43% grade 3 to 4).[12]

The role of age and gender in the development of mucositis has not yet been clearly defined, owing to conflicting reports.[13] There is also conflicting evidence on whether the type of bone marrow transplant (autologous versus allogeneic) or the use of total body irradiation in the conditioning regimen is related to the risk of mucositis.[13] On the other hand, poor oral hygiene, dental caries, periodontal disease, and high titers of herpes simplex virus (HSV) and positive cultures for *Candida tropicalis* are generally accepted to be risk factors.[13]

Finally, interpersonal variability in the development of mucositis been observed for years and could be due to the differences in metabolism of the chemotherapeutic drugs from person to person. A prime example consists of the drug methotrexate, which results in much higher degrees of mucositis[14] in patients with an inability to metabolize this drug.

Prevention of Chemotherapy-Induced Oral Complications

Effective means of preventing chemotherapy-induced oral complications would allow for an improved quality of life for patients receiving chemotherapy as well as a reduction of the rate of life-threatening infections that are thought to be originating from the oral mucosa. Theoretically, it might also improve the effectiveness of antineoplastic therapy by preventing treatment modifications during subsequent cycles and permitting more dose-intensive therapies. Several different methods have been proposed for preventing chemotherapy-induced oral complications (Box 40-1).

Oral Hygiene

Although generally there is insufficient evidence to suggest any one approach, there is enough collective evidence to recommend the institution of a comprehensive oral care protocol for patients receiving chemotherapy for solid tumors.[15] Multiple oral care protocols have demonstrated feasibility and tolerability, and some have shown a reduction in the severity of mucositis and an improvement in the patient's ability to cope with symptoms.[15] Such oral care protocols are usually implemented by nursing staff and involve various degrees of patient education. They can include cavity screening and dental consultations; basic oral care with tooth brushing, flushing, and rinsing; regular inspection of the oral cavity; and avoidance of substances such as smoking, alcohol, and spices.[16,17] The cross-study differences that are seen in two similar treatment arms illustrated in Figure 40-3 could be related to the use of nurse-directed oral care recommendations in the second study that were not used in the first study. Teeth extraction prior to chemotherapy for severe periodontal disease may also be reasonable to consider.[18]

Currently, there is a wide heterogeneity in the approach to mucositis prevention in the United States, and multiple different oral care protocols are available. The need for a more standardized approach is evident, including the institution of multidisciplinary teams.[19,20]

Regarding the oral care of myeloablative chemotherapy candidates, guidelines drafted by the Centers for Disease Control, Infectious Disease Society of America, and American Society of Blood and Marrow Transplantation in 2000 recommend a formal dental evaluation, with appropriate subsequent treatment, prior to initiation of any conditioning regimen. This includes appropriate treatment of caries, proper fitting of any dental prosthesis, and extraction of teeth with significant periodontal disease. These interventions should ideally be performed 10 to 14 days prior to any conditioning therapy. During therapy, oral hygiene should be maintained with rinses four to six times a day using either sterile water, normal saline, or sodium bicarbonate solutions, and patients should brush their teeth at least twice daily with a soft or ultra-soft tooth brush or a toothette (i.e.,

Box 40-1. PREVENTION OF CHEMOTHERAPY-INDUCED ORAL MUCOSITIS

The importance of instituting oral hygiene protocols in patients receiving chemotherapy is well established. Cryotherapy is the most conventional and easy-to-use preventive method, at least for 5-FU-based bolus therapy, and appears to have implications for other chemotherapeutic regimens as well, such as edatrexate and high-dose melphalan therapy. The role of antibiotics, either topically or systemically, has not yet been established. Glutamine supplementation in the form of AES-15 (Saforis) has recently shown promise as a potentially effective agent. The FDA has approved palifermin, a keratinocyte growth factor preparation, for use with high-dose chemotherapeutic regimens associated with high rates of mucositis, and it has shown promise in other settings as well. Low-level laser therapy has shown promise, but it is limited to centers that are able to support its use.

foam swab on a stick). Use of toothpaste is optional, and daily dental flossing should be done only by patients who are experienced in the technique, if it can be done without trauma. Orthodontic appliances and space maintainers can be removed during therapy, although if good tissue integrity and satisfactory daily oral hygiene are maintained, their use can continue during the initial conditioning phase.[21]

Antimicrobial Agents

In the past, microorganisms were hypothesized to play a central role in the pathogenesis of mucositis. This no longer is thought to be true. This is partly because topical and systemic antibiotics, to date, have failed to significantly affect the incidence and severity of mucositis and, as a result, are currently not recommended for routine use.[22] One explanation might be the general failure to significantly eradicate microbes from the oral cavity[23] or the possibility that alterations in the microbial flora by antimicrobial agents might make no difference or cause more harm.[22,24] Another explanation is that microorganisms might play a more complex and possibly a more minor role than was initially thought. It is currently suggested that instead of being involved in the initiation phase, they probably intensify the inflammatory process associated with the later phases of mucosal injury.[4,22] Nevertheless, what appears to be true is the association between the severity of mucositis and the incidence of sepsis and other infections, suggesting that microbes use the already damaged gastrointestinal mucosa as a portal of entry, thus increasing the risk of infectious complications.

Of all the antiseptics, chlorhexidine has been most extensively studied in multiple randomized trials, and the results have been mixed. Therefore, its regular use is not recommended.[15,25,26] Isenagan, a naturally occurring peptide with a broad antimicrobial spectrum, has also failed to show benefit.[27] Although one small placebo-controlled randomized trial has shown benefit for the prophylactic use of topical povidone-iodine, further study is needed before this agent is accepted in clinical use.[25] Regarding systemic antibacterial prophylaxis, data are also not convincing, and systemic antimicrobials therefore are not recommended at this time for the prevention of mucositis.[22,28,29]

Reactivation of HSV can be a significant complication in patients receiving myeloablative chemotherapy and frequently presents with oral ulceration. Although high titers of HSV and positive cultures for *C. tropicalis* have been reported as significant risk factors for the development of mucositis, routine surveillance cultures of oral tissues is not recommended.[30] On the other hand, HSV infection should be suspected if mucositis persists or appears to worsen, 2 or more weeks following transplantation. The guidelines of the Centers for Disease Control, Infectious Disease Society of America (IDSA), and American Society of Blood Marrow Transplantation (ASBMT) recommend testing for serum anti-HSV IgG prior to bone marrow transplant. However, prophylactic treatment with acyclovir is recommended only for seropositive allogeneic stem cell recipients. In this situation, its use is recommended only until engraftment, until mucositis resolves, or up to 30 days after the start of treatment. Prolonged treatment can be considered in patients with frequent recurrent HSV infections. Autologous seropositive recipients can also be potentially treated if significant mucositis is expected from the conditioning regiment. Valacyclovir and Foscarnet are not recommended for this indication.[21] Despite these recommendations, HSV is thought to have a marginal role in causing frank oral mucositis.[15]

Although antifungal medications are currently not recommended for the prophylaxis of oral candidiasis in patients receiving chemotherapy, there is evidence to suggest that prophylactic gastrointestinally absorbable or partially absorbable antifungal medications reduce the rate of oral candidiasis.[31]

Cryotherapy

5-FU-BASED CHEMOTHERAPY. Initially, a North Central Cancer Treatment Group randomized clinical trial demonstrated that oral cryotherapy can inhibit the development of bolus 5-FU-induced mucositis.[32] This has been independently validated by other investigators.[33–35] It is hypothesized that cryotherapy works by causing local vasoconstriction during periods of peak 5-FU blood concentration, thus decreasing the delivery of 5-FU to the oral mucosa. This therapy is administered by having the patient suck on crushed ice, starting 5 minutes prior to 5-FU administration and continuing for a total of 30 minutes. A longer duration of oral cryotherapy (60 minutes) does not appear to provide any additional benefit in this setting.[36]

EDATREXATE. Four small nonrandomized phase I and II trials have used 20 to 30 minutes of oral cryotherapy for prevention of mucositis in patients receiving edatrexate, a methotrexate analog with improved preclinical antitumor activity. Three out of the four trials have shown good tolerability of edatrexate when it is used with oral cryotherapy,[37–39] while one study showed high toxicity despite this preventive strategy.[40] Current guidelines recommend cryotherapy as an attempt to decrease mucositis in patients who are treated with bolus edatrexate.[15]

HIGH-DOSE MELPHALAN. At least five small prospective nonrandomized studies in patients receiving high-dose melphalan therapy have tested the efficacy of oral cryotherapy as compared to historical controls. Grade 3 mucositis developed in only 0% to 11% of patients treated with oral cryotherapy as compared to the incidence of mucositis in historical controls, which is observed in over 70% of patients.[41–45] In the only randomized placebo-controlled study, using room temperature normal saline as placebo, 40 patients were treated with cryotherapy or placebo for 30 minutes before and 6 hours after chemotherapy with high-dose melphalan. Grade 3 mucositis was experienced in 14% of patients receiving cryotherapy and in 74% of patients receiving normal saline.[46] Although the need for such prolonged administration of cryotherapy is questionable, owing to patient noncompliance and the probably equivalent efficacy of shorter administration, cryotherapy appears to be a promising strategy in lowering mucositis in patients receiving high-dose melphalan therapy, and it is currently recommended in this setting.[47] This evidence points to a possible role for cryotherapy in more diverse settings than was previously thought.

Antioxidants, Anticholinergics, and Coating Agents

In general, insufficient evidence exists regarding the effectiveness of antioxidant compounds such as tretinoin and vitamin E in preventing oral mucositis in patients receiving chemotherapy.[13] A small randomized trial of zinc sulfate reported a statistically significant benefit in preventing severe mucositis; more investigation is warranted before accepting this agent as standard practice.[48] There is also insufficient evidence to support the prophylactic use of Propantheline, an anticholinergic drug that is thought to reduce the amount of etoposide secreted in the saliva.[25] Mixed data exist on the role of sucralfate, a coating agent; therefore, sucralfate is not currently recommended for the prevention of oral mucositis.[25,26]

Anti-inflammatory Agents

Since inflammatory mediators appear to play a central role in mucositis development, the use of anti-inflammatory agents has been proposed as a method for preventing mucositis. However, cytokine inhibitors and anti-inflammatory agents have not yet proven to be efficacious.

Pentoxifylline, a TNF-α and IL-2 inhibitor, is currently not recommended in either the standard chemotherapy or bone marrow transplant setting.[15,25] Benzydamine mouthwash has been approved for radiation-induced mucositis in Europe and Canada and is currently being tested in the United States.[15,49] However, evidence regarding its use in prevention of chemotherapy-induced mucositis is weak, and it is currently not recommended in this setting.[25]

Amino Acids

Glutamine is a nitrogen-rich nonessential amino acid with a critical role in nucleotide synthesis, muscle function, and overall metabolic homeostasis. However, during periods of stress, it becomes a conditionally essential amino acid, and its stores can be significantly depleted, as is the case in patients with cancer.[50] Multiple trials to date have attempted to investigate the beneficial potential of different glutamine preparations through both the parenteral and oral routes, with mixed results.[50,51] Glutamine had been administered through the parenteral route, as part of total parenteral nutrition, or in intravenous infusions mixed with normal saline. It has also been administered as oral supplements and as swish and swallow mouthwash preparations. Overall, these trials have been small, and conclusions have been difficult to draw.

However, recent data have emerged regarding Saforis, an oral suspension form of L-glutamine with an enhanced delivery system. Three hundred and twenty-six breast cancer patients who developed grade ≥2 mucositis during the first cycle of treatment with an anthracycline-based regimen were treated with Saforis, 2.5 g/5 mL orally three times per day concurrent with their next chemotherapy dose, swished for 30 seconds and then swallowed, for at least 14 days, versus placebo. The results showed a reduction in the incidence of grade ≥2 mucositis in the subsequent cycle of chemotherapy by 11% (50% to 39%: $P = 0.03$), as well as a reduction in the subsequent severity of mucositis in the patients who were treated with Saforis.[52] In another trial, 197 patients undergoing bone marrow transplant and treated with glutamine via the swish and swallow method for 14 days had a significant reduction in the severity and duration of mucositis. This was true for the autologous transplant patients but not the patients receiving allogeneic transplants.[53] In summary, although glutamine is not yet officially recommended for the prevention of chemotherapy-induced oral mucositis, results of several studies are promising, and if subsequent data are confirmatory, recommendations could change.

Growth Factors

Growth factors, systemically or topically, are hypothesized to help prevent oral mucositis due to their potential to improve healing. Although the use of granulocyte colony stimulating factor and granulocyte macrophage colony stimulating factor (GM-CSF) has been associated with reduced mucositis in certain randomized trials, the data are inconclusive as yet (Cochrane).[25] A recent meta-analysis found a benefit for prophylactic treatment with systemic growth factors but not for topical preparations.[26] However, the results of the meta-analysis were largely dependent on one strongly positive study alone, and further evidence is needed.[54]

Topical keratinocyte growth factor, which is secreted by injured mucosal epithelium, may have a more localized healing effect in the oral cavity. The Food and Drug Administration (FDA) recently approved one such preparation, palifermin, for use in preventing mucositis induced by myeloablative chemotherapy. The recommendation was based on a study of 212 patients who were randomized to receive intravenous palifermin or placebo for three consecutive days immediately before the initiation of conditioning therapy. Grade 3 or 4 mucositis developed in 63 percent of patients in the palifermin group and 98 percent of patients in the placebo group.[55] Palifermin has shown benefit in at least two more trials. In a series of 59 patients undergoing hematopoietic stem cell transplantation 13% of patients receiving palifermin developed severe mucositis compared to 48% of patient who received standard care.[56] Palifermin was also tested in 64 patients with colorectal cancer who received 5-FU-based chemotherapy, and a significant reduction in severe mucositis score was seen, with 29% of patients receiving palifermin developing severe mucositis compared to 61% receiving placebo.[57] Although apparently effective, it constitutes an expensive option for mucositis prevention at this point. In addition, since in these studies, oral cryotherapy was not administered to either the patients who received 5-FU-based chemotherapy or the patients who received high-dose melphalan therapy, it would be interesting to examine how palifermin would fare in comparison to oral cryotherapy.

Low-Level Laser Therapy

Evidence is accumulating that low-level laser therapy might promote healing and reduction of pain in patients who are at risk for oral mucositis.[58,59] However, the expense, the need for specialized training and equipment, and the difficulty in interpreting and comparing the results from the various trials limit the widespread applicability of this approach at this time. Although no guidelines regarding its use exist yet, further investigation with large phase III randomized placebo-controlled clinical trials is encouraged.[15] Moreover, for centers that are able to support the necessary technology and training, this approach is recommended in an attempt to reduce the oral mucositis associated with myeloablative chemotherapy. In fact, low-level laser therapy is considered standard in some centers.[59]

Other Interventions

A variety of protocols include the prophylactic use of oral rinses and mouthwashes, such as normal saline, sodium bicarbonate solutions, and other mixtures. Although there is insufficient evidence to support their use, they constitute parts of various standard oral care protocols. Evidence does exist, however, that rinses that contain alcohol tends to worsen the symptoms of mucositis and therefore should be avoided. In a double-blind controlled trial in patients undergoing bone marrow transplantation, a benefit has been suggested for a neutral supersaturated calcium phosphate rinse (Caphosol) given in conjunction with fluoride when compared to fluoride rinsing alone.[60] Allopurinol mouthwashes, despite constituting standard clinical practice at some institutions the early 1990s, are currently not recommended, since at least two randomized clinical trials have convincingly shown no benefit.[25,61,62] Traumeel S, a homeopathic remedy, was tested as a mouthwash in a randomized placebo-controlled trial of 32 pediatric patients undergoing stem cell transplantation, and a statistically significant reduction in the incidence and severity of mucositis was reported. However, the study is not conclusive, and further investigation is under way. Finally, a double-blind randomized placebo-controlled trial of chamomile mouthwash has also failed to show benefit.[25,26]

Conclusion

The importance of instituting oral hygiene protocols in patients receiving chemotherapy is well established. Cryotherapy is the most conventional and easy-to-use preventive method, at least for 5-FU-based bolus therapy, and appears to have implications for other chemotherapeutic regimens as well, such as edatrexate and high-dose melphalan therapy. The role of antibiotics, either topically or systemically, has not yet been established. Glutamine supplementation in the form of AES-15 (Saforis) has recently shown promise as a potentially effective agent. The FDA has approved palifermin, a keratinocyte growth factor preparation, for use with high-dose chemotherapeutic regimens associated with high rates of mucositis, and it has shown promise in other settings as well. Low-level laser therapy has shown promise, but it is limited to centers that are able to support its use.

Treatment of Chemotherapy-Induced Oral Mucositis

Scant information is available regarding the effective treatment of chemotherapy-induced mucositis, despite a plethora of prescribed remedies (Box 40-2). Hence, initial treatment of established mucositis varies significantly among institutions, and different providers often prescribe remedies based on their individual experience and preference.[19] Among these many proposed treatments are various mouthwashes, coating agents, topical anesthetics or analgesics, anti-

Box 40-2. TREATMENT OF CHEMOTHERAPY-INDUCED ORAL MUCOSITIS

There is overall lack of evidence regarding the efficacy of various agents in promoting healing of the oral mucosa after mucositis is established. Systemic analgesic therapy of mucositis pain with narcotic medications is well established and recommended. Antibiotics and/or antifungal medications should be given to patients who have evidence of infection. In the palliative setting, various mouthwashes are widely used in clinical practice based on provider preference and experience. These mouthwashes most frequently contain combinations of diphenhydramine, viscous lidocaine, magnesium hydroxide/aluminum hydroxide, nystatin, and corticosteroids. The efficacy of these measures has not been adequately evaluated to date. Salt and baking soda mouth rinses appear to be the most economical solution, although efficacy has not been clearly established.

inflammatory agents, systemic narcotics, and topical and systemic growth factors.[15] These treatments are aimed at promoting the healing of the injured oral mucosa and thus limiting the severity and duration of ulcerations, as well as palliating the symptoms of oral mucositis.

General recommendations that are frequently given to the patients with established mucositis include the avoidance of spicy, coarse, hot, cold, or acidic foods or juices or medications or beverages containing alcohol and the encouragement of rather soft, moist foods and non-alcoholic beverages. Moreover, the treating physician should take care not to lose sight of the other important means of support for the cancer patient presenting with mucositis such as proper hydration, nutrition, infectious surveillance, and psychological support, all of which can significantly affect the patient's well-being and quality of life.

Mouthwashes

For patients with established mucositis, one of the first therapeutic measures that is frequently used consists of having the patients rinse their mouths every 2 to 4 hours with a solution of salt and baking soda (1/2 teaspoon salt plus 1/2 teaspoon baking soda in an 8-ounce glass of warm water). This is often soothing and is thought to be cleansing. Some centers use baking soda alone, since the addition of salt is thought to be too drying to the mucosa. In one multicenter study, 200 patients receiving standard chemotherapy, who followed a carefully planed oral hygiene protocol (PRO-SELF), were randomized to one of three different mouthwashes: salt and soda, chlorhexidine, or "magic" mouthwash (lidocaine, Benadryl, and Maalox). No significant differences were observed in time to cessation of the signs and symptoms of mucositis among the three regiments; salt and soda was the least costly.[63]

Mouthwashes, often referred to as "magic" or "miracle mouthwash," are usually topical preparations of analgesic, anesthetic, and coating agents, the composition of which varies across institutions. The most common ingredients are diphenhydramine, viscous lidocaine, magnesium hydroxide/aluminum hydroxide, nystatin, and corticosteroids.[64] Other ingredients include benzocaine, milk of magnesia, chlorhexidine, kaolin, and pectin.[15] Despite their widespread use, the general lack of evidence supporting their efficacy and tolerability does not allow presently any of these preparations to be included into formal guidelines.[15] Further study of these palliative mixtures however is strongly encouraged, given their overall availability, ease of administration, frequent use, and low cost.

Chlorhexidine mouthwashes are not recommended, since studies have failed to support the use of this agent for the treatment of established mucositis.[15] Coating agents, such as sucralfate, have also failed to show any benefit for the treatment of established chemotherapy-induced mucositis when tested in small randomized trials.[65]

Anti-inflammatory Agents

Anti-inflammatory agents in general have failed to find a role in the treatment of chemotherapy-induced mucositis.[66]

Growth Factors

It is hypothesized that GM-CSF, systemically or topically as a mouthwash, might stimulate proliferation of endothelial cells and promote keratinocyte growth, thus enhancing recovery of oral mucositis. However, studies have been limited and are of poor methodological quality.[65,67]

Systemic Analgesics

Oral mucositis pain can be severe and can significantly interfere with the quality of life of patients receiving chemotherapy. Management should follow the same aggressive guidelines that are used to treat pain in patients with cancer in general.[68] The use of patient-controlled anesthesia is effective and well established for treating mucositis pain, especially in the hematopoietic stem cell transplantation setting.[15]

Conclusion

There is overall lack of evidence regarding the efficacy of various agents in promoting healing of the oral mucosa after mucositis is established. Systemic analgesic therapy of mucositis pain with narcotic medications is well established and recommended. Antibiotics and/or antifungal medications should be given to patients who have evidence of infection. In the palliative setting, various mouthwashes are widely used in clinical practice based on provider preference and experience. These mouthwashes most frequently contain combinations of diphenhydramine, viscous lidocaine, magnesium hydroxide/aluminum hydroxide, nystatin, and corticosteroids. The efficacy of these measures has not been adequately evaluated to date. Salt and baking soda mouth rinses appear to be the most economical solution, although efficacy has not been clearly established.
