LMM occurs on chronically sun-exposed skin, especially the face and neck, in older persons. More than 75% of such patients are older than 60 years of age, and they typically have a history of a slowly growing mole that has been present for a decade or more. Histologically, LMM lesions have a predominant radial growth phase, and there is associated solar elastosis of the surrounding skin as a result of chronic sun damage. These lesions probably are less aggressive in their metastatic behavior compared with other growth patterns, although this is controversial.

ALM is relatively uncommon. In contrast to SSM, NM, and LMM, which occur almost exclusively in fair-skinned persons, ALM can occur in any ethnic group or in persons with any degree of skin pigmentation. Lesions occur on the palms, soles of the feet, and nail beds. They tend to present as more locally advanced lesions. Even when accounting for their greater tumor thickness at presentation, they tend to be more aggressive in their behavior.

DM is uncommon. Lesions often are nondescript papules, plaques, or nodules, and may be nonpigmented; the appearance of DM may be more suggestive of basal cell carcinoma or a verruca. DM often occurs in the head and neck area and can be associated with neurotropism. The biologic behavior of DM is similar to that of a soft tissue sarcoma, in that lesions can invade across fascia and along peripheral nerves. DM has a higher rate of local recurrence than the other common forms of melanoma.

Biopsy Technique

Proper biopsy of a suspicious lesion is critical for accurate staging.[13] When melanoma is in the differential diagnosis, a full-thickness biopsy is done to interpret the maximum tumor thickness and the presence or absence of ulceration accurately. Excisional biopsy with a narrow margin of normal-appearing skin is preferred for small lesions and can be performed on most small lesions. The biopsy scar should be oriented to be compatible with a subsequent wide local excision should the lesion prove to be melanoma. On the extremities a longitudinal or oblique incision is preferred. On the trunk or the head and neck the biopsy should be oriented parallel to the skin lines. Punch biopsy is appropriate for large lesions or those at a vital anatomic site where one would want to know the diagnosis before removing the entire lesion. Punch biopsy should be performed at the most raised area. Final determination of the tumor thickness cannot be made until the entire lesion has been excised and examined. A thin shave biopsy of suspicious lesions should be avoided, because it may compromise histologic interpretation and proper measurement of thickness.

PATHOLOGY

Melanoma Histopathology

The histopathologic diagnosis of melanoma often is straightforward and relies heavily on the presence of specific alterations in growth pattern relative to that of benign nevi. Melanocytes are identified easily and differentiated from keratinocytes by their propensity for "retraction artifact" on well-prepared, routine hematoxylin and eosin (H & E)-stained sections. In normal skin they usually are located in the basal layer of the epidermis, where the ratio of melanocytes to keratinocytes is approximately 1 : 9. Benign nevi are characterized by the presence of nevus cells that are arranged in clusters or nests. Their nuclei are small, without hyperchromasia or mitoses. Nevic melanocytes are arranged uniformly and predominantly as nests and occasional single units at the rete tips of the dermo-epidermal junction and within the dermis. Nevic cells "mature" or diminish in size as they descend into the dermis. Significant alterations in these basic growth patterns are cause for concern, and when they occur, a diagnosis of melanoma must be considered.

In contrast to nevi, and with few exceptions, melanomas are asymmetric and poorly circumscribed. Melanocytes, as nests and single units, may be present at all levels of the epidermis, a pattern known as *Pagetoid spread.* Dermal melanocytes do not mature evenly, and are characterized by enlarged, hyperchromatic nuclei. *In situ melanoma* is defined as an irregular proliferation of atypical melanocytes confined to the epidermis. *Invasive melanoma* is defined as the presence of melanoma cells, at a minimum, within the papillary dermis. The concept of radial and vertical growth phases of melanoma initially was introduced by Wallace Clark and colleagues.[14] *Radial growth phase* refers to the progressive intraepidermal proliferation of melanocytes that occurs in superficially invasive melanoma in the papillary dermis. It precedes the vertical growth phase of melanoma in all subtypes except nodular melanoma, which lacks prominent radial growth. Approximately one third of melanomas arise in association with a pre-existing nevus. Distinguishing between melanoma and a benign process can be challenging, particularly when attempting to distinguish a Spitz nevus from a Spitzoid melanoma or a nevus from a nevoid melanoma.[15] In these instances, the histologic differences may be subtle, and interpretation by an experienced dermatopathologist is necessary.

PROGNOSIS AND MICROSTAGING OF MELANOMA

Multivariate statistical analysis has revealed several features of primary melanoma that have prognostic significance and should be incorporated into pathology reports of invasive melanomas.[16] At a minimum, melanoma pathology reports should include site, Breslow thickness, presence or absence of histologic ulceration, Clark's level, mitotic rate, presence or absence of vascular or neural invasion, presence and degree of regression, degree of lymphocytic infiltrate, presence or absence of a pre-existing nevus, and subtype classification. Greater Breslow thickness, presence of histologic ulceration, elevated mitotic rate, microscopic satellite deposits, and angiolymphatic invasion are associated with a poorer prognosis.[17] Clark level, histologic subtype, and the presence of a coexisting nevus are of limited value in determining prognosis.[16] *Histologic regression* is defined as the absence of melanoma in a focal area that, instead, consists of dermal fibroplasia mixed with blood vessels, lymphocytes, and melanophages; melanoma is present in the immediate adjacent areas. Regression of the radial growth phase of melanoma is associated with poorer prognosis.[18] Regression of the vertical growth phase, which is less rigorously defined as the presence of tumor-infiltrating lymphocytes (TILs), in contrast, is associated with a better prognosis.[19]

Breslow Thickness

Alexander Breslow determined that melanoma thickness correlates with prognosis. A micrometer is used to measure the distance from the top of the granular layer to the deepest level of invasion, excluding adnexal extension. A Breslow thickness of 0.75 mm or less is associated with excellent prognosis. Breslow thickness is the strongest and most reproducible prognostic feature of the primary tumor.[20]

Ulceration

Histologic ulceration is defined as the loss of continuity of the epithelium over the tumor surface and has prognostic significance. Increasing breadth of the ulceration, specifically of 3 mm or greater or defined as involving the majority of the epithelium, has a greater chance of correlating with true ulceration. Ulceration is included in the AJCC staging system.[21]

Histologic Subtypes of Melanoma

Lentigo maligna melanoma (LMM) arises predominantly on sun-exposed areas of the head, neck, and extremities. These lesions may arise de novo or in association with a pre-existing nevus. These melanomas are characterized histologically by the confluence of enlarged hyperchromatic or atypical melanocytes arranged as single units at the dermo-epidermal junction. Prominent adnexal extension of confluent melanocytes often is present. Pagetoid spread is not always evident. Adjacent atypical keratinocytes and prominent dermal elastosis often are present, attesting to the long-standing nature of sun exposure at these sites. Complete excision of LMM sometimes is difficult, because the extent of the pathologic abnormality is not always clinically apparent. The invasive component of LMM may consist of spindled or epithelioid melanocytes.

Superficial Spreading Melanoma

Superficial spreading melanoma (SSM) is characterized by a marked intraepidermal proliferation of atypical melanocytes which are present at all levels of the epidermis. If the tumor is invasive, atypical melanocytes are found in the dermis and are arranged as irregular nests, fascicles or lobules that fail to mature. The melanocytes may appear spindled, epithelioid, or even nevus-like. Melanin pigmentation may be irregular. The dermal component may have an associated lymphohistiocytic infiltrate, with or without prominent melanophages.

Nodular Melanoma

Nodular melanoma, by definition, lacks a radial growth phase and shows extensive dermal invasion. The presence of a pre-existing nevus or an epidermal connection allows for distinction from metastatic melanoma in most cases.

Acral Lentiginous Melanoma

Acral lentiginous melanoma occurs on the hands and feet, including subungual locations. The most common location of this subtype is the sole of the foot. This subtype of melanoma can occur in all races, and is the most common subtype found in darkly pigmented races. The poorer prognosis of this subtype has been attributed to the likelihood of higher stage at diagnosis.

Desmoplastic or Spindle-cell Melanoma

Desmoplastic or spindle-cell melanoma is characterized by a fibroblastic or scar-like proliferation of spindled melanocytes. Desmoplastic melanoma tends to have a surrounding sclerotic stromal response associated with blood vessels and characteristic lymphoid aggregates scattered throughout the dermis. They may occur alone or in association with an overlying lentigo maligna melanoma. This subtype of melanoma ranges from a paucicellular, fibrosing variant, with a prominent stromal response, to a high-grade cellular and spindled or sarcomatous subtype exhibiting only focal desmoplasia. Most desmoplastic melanomas stain strongly and diffusely with S100, but are negative or only focally positive for other melanoma markers such as HMB45. They must be differentiated from other malignant spindle cell tumors of muscle, epithelial, neural, or fibroblastic origin, typically by the use of a panel of immunohistochemical markers, as discussed earlier. In some series, the paucicellular variant of desmoplastic melanoma has been shown to have improved survival relative to other, more common types of melanoma.[22]

PATHOGENESIS

Melanoma arises from transformation of melanocytes, which are of neural crest origin. Most melanocytes reside in the basal layer of the epidermis or within benign common nevi. Melanocytes synthesize melanin using the enzyme tyrosinase, and thus, under normal conditions, help to protect against UV damage. Melanoma induction by UV radiation is a multistep process, involving both UVB and UVA. Melanoma has been conceptualized as growing first in a radial growth phase with little risk of metastatic behavior. This phase is followed by the vertical growth phase with the capacity for metastasis. Different clinical and histologic features are associated with the different phases. Tumor progression likely is the consequence of multiple genetic events.

Melanoma can arise in a pre-existing nevus or de novo. Most melanomas probably do not arise from pre-existing benign nevi. Only about 20% to 30% of melanomas are pathologically associated with melanocytic nevi, and epidemiologic studies strongly suggest that the risk of an individual nevus undergoing malignant transformation is low.[23] Thus, although the presence of large numbers of nevi is associated with increased risk of melanoma, the actual precursor lesion is still in question. It is likely that both the stepwise evolution of melanocytic nevi to melanoma and the de novo onset of melanoma from malignant conversion of epidermal melanocytes are mechanisms of tumorigenesis.

BIOLOGY

Over the last decade, much progress has been made in defining the genetic events that influence melanoma development. Most recently, systematic approaches to identifying cancer-associated genetic defects have been undertaken, abetted, in large part, by the sequencing of the human genome. Such studies have brought new molecular pathways to light in the area of melanoma investigation. Greater knowledge of the molecular events that govern melanoma development is expected to result in the design of targeted therapeutic strategies that may improve patient outcomes.

RAS and RAF and the MAP Kinase Pathway

Although mutations of RAS genes are uncommon in human melanomas, mouse models of melanoma suggest that activation of this pathway in conjunction with inactivation of the p16/INK4a tumor suppressor pathway is important for tumor development.[24] Recent studies have supported the importance of this pathway in melanoma development, because a genome-wide screen of alterations in RAS or its downstream effectors identified activating mutations of the serine/threonine kinase BRAF in 59% of melanoma cell lines and six of nine primary melanomas.[25] Most BRAF mutations identified (80%) were accounted for by a single amino acid substitution (V600E, formerly identified as V599E) that rendered the kinase constitutively active. Subsequent studies showed a similarly high incidence of activating BRAF mutations in benign nevi,[26] suggesting that activation of BRAF kinase may be an initiating event for melanocyte proliferation, but is unlikely to be an important mediator of malignant conversion to melanoma. Additional studies have not identified BRAF kinase germline mutations in large-scale evaluations of patients with familial melanomas,[27–29] but it has been suggested that *BRAF* mutations in nevi may serve as markers of melanoma susceptibility in an individual.[26]

Interestingly, studies of mucosal, uveal, and other noncutaneous melanomas identified considerably fewer activating mutations of BRAF versus intermittently sun-exposed cutaneous melanomas, suggesting that the high-frequency BRAF mutation is targeted specifically to cutaneous melanocytic lesions that are intermittently sun exposed, rather than those that are chronically exposed or unexposed.[30–32]

Although evaluation of primary melanocytic lesions confirmed the high rate of activating BRAF kinase mutations in both benign and malignant lesions,[33,34] it was specifically noted that early, radial-growth-phase melanomas showed the lowest incidence of BRAF mutation (10%),[34] suggesting that BRAF kinase activation may not be necessary for malignant conversion of melanocytes. Because most large radial growth phase melanomas would be of the "lentigo maligna" type, such chronic sun-exposed melanomas could, alternatively, be initiated through non-BRAF-associated genetic events. Indeed, a recent study of genome-wide alterations in DNA copy number and *BRAF* and *N-RAS* mutational status in primary human melanomas demonstrated correlation between genomic changes and unique melanoma subtypes, stratified according to site and UV exposure.[35] Array-based comparative genomic hybridization, DNA sequencing, and immunohistochemical analyses were used to determine DNA copy number and *BRAF*/*N-RAS* mutational status, where primary melanomas were classified into four groups: mucosal, acral, and cutaneous melanomas with and without chronic sun-damaged (CSD) skin (defined by presence of solar elastosis). Most cutaneous melanomas on non-CSD skin (intermittent sun-exposed) possessed mutations in *BRAF* or *N-RAS* (59% and 22%, respectively). Other common findings included alterations in DNA copy numbers of *CDK4, CCND1* (cyclin D1 gene), *CDKN2A (p16INK4a),* and chromosome 10 (site of *PTEN*).[35]

Current data on BRAF kinase mutations in benign and malignant melanocytic lesions suggest that these mutations are not sufficient to induce malignant conversion of melanocytes to melanoma. However, it may be necessary for the mutations of BRAF or other genes within the MAP kinase pathway to be activated for melanoma to develop. Thus, inhibition of BRAF kinase may be a useful therapeutic intervention when used in conjunction with other therapeutic modalities. Because therapeutic targeting of tyrosine kinases has resulted in effective treatment for a variety of malignancies, there has been much excitement over the development of BRAF kinase inhibitors as treatments for melanoma. Sorafenib, originally thought to be a raf kinase inhibitor, but clearly a multitargeted tyrosine kinase inhibitor (TKI), has been investigated in a variety of solid tumors, including melanoma.

Cell-Cycle Regulatory Proteins in the Development of Melanoma

p16/INK4A and the Retinoblastoma Pathway

Cell-cycle regulatory proteins are required for the precise regulation of cell growth and division and, therefore, are critical targets in the malignant conversion of all cells. Frequent deletions in the 9p21 locus were found in familial primary melanomas and melanoma cell lines, and linkage studies eventually led to the identification of the p16/INK4a gene as a candidate tumor-suppressor gene for familial melanoma.[36,37] It later was discovered that this same genetic locus (referred to as CDNK2A) also encodes a second tumor suppressor gene, *p14/p19ARF*. The p16/INK4a gene encodes an inhibitor of the cyclin-dependent kinases, CDK4 and CDK6, and leads to cell-cycle arrest at the G1 phase of the cell cycle. Because CDK4/CDK6 phosphorylates the retinoblastoma protein pRb and inactivates its tumor suppressor function, this was considered a major mechanism of p16/INK4a tumor suppression in melanomas. Inherited mutations of the gene encoding the cell-cycle regulatory protein p16/INK4a or its associated cyclin-dependent kinase, CDK4,[38] predispose patients to melanoma. Defects in the p16/INK4a gene or CDK4 play a role in the development of a relatively small percentage of sporadic melanomas, and only about 20% of familial melanoma cases harbor p16/INK4a mutations, suggesting that most familial melanoma cases are associated with other genetic defects. Expression of p16/INK4a is silenced in sporadic melanomas via epigenetic inactivation through promoter methylation[39]; however, this form of gene silencing seems to be activated in a limited number of primary tumors. Of note, in thin sporadic melanomas, loss of p16 expression is associated with disease progression, despite the low incidence of loss of heterozygosity at the p16/INK4a locus, p16/INK4a intragenic mutations, and p16/INK4a promoter methylation (<10% in lesions thinner than 4 mm).[40,41] This finding suggests that alternative mechanisms exist to allow for decreased expression of p16/INK4a in these early lesions. Other mechanisms of p16/INK4a inactivation in melanoma are under investigation, including transcriptional repression of the p16/INK4a promoter itself.

An area of interest is the potential role of Id helix-loop-helix transcription factors in melanoma initiation. In general, high Id expression levels are found in proliferative, undifferentiated cells, a feature that is characteristic of tumor cells. Id genes have been identified as potential proto-oncogenes because overexpression of Id proteins in primary cells promotes cellular immortalization.[42,43] Id gene expression also is elevated in various tumor cell lines as well as a broad spectrum of primary human tumors.[44] In situ evaluations have shown a correlation between tumor invasiveness, aggressiveness, and progression and Id expression. Recently, Id1 was shown to be a repressor of the familial melanoma gene p16/INK4a,[45,46] and early studies of primary melanocytic lesions showed that Id1 expression correlated with decreased p16/INK4a expression in early melanomas that were confined to a radial growth phase. In addition, later stages of melanoma that did not express Id1 had sustained genetic mutations that inactivated the p16/INK4a gene. The data suggest that Id1 transcriptional repression of p16/Ink4a may represent one of the earliest mechanisms of dysregulation of p16/INK4a expression, resulting in melanoma initiation, and that Id1 expression may be a useful marker for malignant disease in melanocytic lesions of questionable malignant potential.[47] Large-scale studies are underway to determine the utility of Id1 expression in melanocytic lesions as both a marker of malignant disease and an independent predictor of clinical outcome.

p53 and Melanoma

As with the retinoblastoma pathway, the p53 tumor suppressor pathway often is inactivated in cancers; however, alterations of p53 itself rarely are seen in melanomas (0–25%).[48] p53 is a transcription factor that functions to maintain the genome during cellular stress, including the DNA damage induced by UV radiation. Downstream functions of p53 include repair of DNA damage, growth arrest through inhibition of the cell cycle, senescence, and apoptosis.[49]

Given the importance of such functions to the prevention of cancer, it is not surprising that the regulation of p53 functions in the cell is complex. HDM2, a negative regulator of p53, promotes p53 loss through ubiquitin-mediated proteasomal degradation and is overexpressed in early melanomas.[50] As mentioned earlier, the p16/INK4a gene has been shown to reside at a genetic locus that encodes a second tumor suppressor gene, p14/ARF. This gene functions through the p53 tumor suppressor pathway by binding to MDM-2 and decreasing its ubiquitin ligase functions. Melanoma-associated CDKN2A mutations have been documented to occur within p16/INK4a alone, p14/ARF alone, or both genes simultaneously, confirming the independent tumor suppressor functions of each.[51] PAF-1, a downstream effector of p53 involved in induction of apoptosis, has been shown to be inactivated in metastatic melanomas,[52] suggesting that p53 dysfunction in melanoma is related to targeting of p53-associated molecules.

Apoptotic Pathways and the Development of Melanomas

The process of apoptosis, or programmed cell death, is critical to cellular responses to stress and is a major pathway of cell death induced by radiation therapy and traditional chemotherapy. Melanoma cells can be resistant to therapies that have shown efficacy in other tumor types; this is related, in part, to their ability to evade normal apoptotic signals.[53] Over the last decade, the particular signaling cascades regulating apoptotic pathways have been delineated. The

two major apoptotic pathways have been designated the *extrinsic pathway,* which is induced on activation of cell-membrane-associated death receptors by their associated ligands, and the *intrinsic pathway,* which is dependent on mitochondrial membrane permeability in response to cellular stress signals. Both pathways result in activation of caspases that are critical effectors of apoptosis. Melanomas evade both intrinsic and extrinsic apoptotic pathways, critical determinants of tumor response to traditional cytotoxic therapies. The cytochrome c-associated factor Apaf-1 is downregulated in advanced melanomas and influences the death response of melanoma cells to cytotoxic agents.[52] In addition, Fas and TNF-related apoptosis-inducing ligand (TRAIL) death receptors are downregulated by a variety of mechanisms, leading to impaired activation of the extrinsic apoptotic pathway.[53] Therapeutic strategies aimed at circumventing impaired apoptotic pathways in melanoma are likely to require multiple interventions to ensure the continued activation of effective death pathways, given the variety of resistance mechanisms present in melanoma cells.

CLINICAL EVALUATION AND IMAGING

On initial presentation, patients with newly diagnosed thin or intermediate-thickness melanoma rarely show evidence of metastatic disease. Most melanoma metastases cause symptoms or can be discovered on physical examination. Appropriate evaluation of patients with newly diagnosed primary cutaneous melanoma includes a thorough history, a skin examination to search for other primary skin cancers, and examination of the regional node basins. For patients with a primary melanoma 1 mm or thicker, chest x-ray and liver enzymes, including lactate dehydrogenase (LDH) are reasonable screening tools. In patients with findings on history and physical examination that raise concern or abnormal findings on chest x-ray or liver function tests, further imaging studies are warranted.

Liver function tests, including LDH, are commonly used screening tools for patients with newly diagnosed invasive melanoma, although there is no universal agreement about the utility of these tests for screening. Extensive routine radiographic evaluation of asymptomatic patients with American Joint Committee on Cancer (AJCC) stage I, II, or IIIA melanomas with routine computed tomography (CT) or positron emission tomography (PET) rarely shows distant metastases. For most asymptomatic patients, a standard chest x-ray provides adequate basic radiologic screening. Patients who have findings that raise concern on screening history and physical examination or on chest x-ray or liver enzyme tests should undergo further evaluation.

For patients with suspected intra-abdominal or hepatic metastases based on abnormal findings on physical examination or abnormal liver chemistry findings, contrast-enhanced spiral CT scan of the abdomen should be obtained. Magnetic resonance imaging (MRI) also can be used to detect melanoma deposits by a high signal on T1-weighted images. Other than MRI, a bone scan is probably the most sensitive test to detect skeletal metastatic disease, but a careful history and directed radiographs are necessary to ensure that areas of uptake do not represent old trauma or inflammation.

PET and CT scans obtained with 2-[^{18}fluorine]-fluoro-2-deoxy-D-glucose(^{18}FDG) have gained acceptance as a tool for detecting metastatic melanoma and for following the results of systemic or surgical therapy in stage IIIB, IIIC, or IV melanoma.[54–56] PET scanning is based on metabolic changes that could detect early metastatic disease in high-risk patients and has a reported sensitivity of 78% to 100% in detecting metastatic melanoma.[57,58] False-positive findings have been observed in association with inflammatory responses and second primary or metastatic tumors. Wagner and associates[59] reported that the sensitivity of PET with FDG (FDG-PET) for detection of metastatic melanoma in lymph nodes depends on sufficient tumor volume. FDG-PET begins to detect metastatic tumor in lymph nodes reliably at volumes greater than approximately 80 mm^3, but sensitivity decreases rapidly below this point. Fused PET-CT scans also allow correlation of metabolic findings with morphologic findings and have come into frequent use in the evaluation and treatment planning of patients with stage III and IV melanoma.

Prognostic Features

In a multifactorial analysis of 13,581 patients with localized melanoma (either clinically or pathologically), the two most powerful and independent characteristics of the primary melanoma, among all of the prognostic variables analyzed, were tumor thickness and ulceration.[16] No other feature of the melanoma or the patient with localized melanoma had the predictive capability of these two factors. Other factors that were statistically significant prognostic factors were patient age, site of the primary melanoma, level of invasion, and sex. Subsequent studies have demonstrated that mitotic rate is an independent predictor of melanoma survival outcome and risk of sentinel node metastasis.[60–64]

Thickness

In virtually all studies analyzing the prognosis of patients with stages I and II melanoma using a Cox regression analysis, melanoma thickness is the strongest predictor of outcome. Increasing melanoma thickness correlates with increasing risk of local recurrence, regional metastasis, and distant metastasis, and with poorer melanoma-specific survival.[16,64,65] Melanoma thickness is a continuous variable for which there are no naturally occurring breakpoints that delineate different biologic risks for melanoma-specific mortality.

Ulceration

Melanomas with histologic ulceration are more biologically aggressive, and are associated with a substantially increased risk of metastasis. In virtually every Cox regression analysis of prognostic factors that includes ulceration, melanoma ulceration portends a significantly worse prognosis and a higher risk of metastatic disease compared with nonulcerated melanomas of equivalent thickness.[16,66] Melanoma ulceration correlates with increased tumor thickness, mitotic rate and increasing age, further suggesting that this factor is associated with increased risk of metastatic behavior.

Mitotic Rate

Tumor mitotic rate is a reflection of the proliferation rate of the primary melanoma. Although the pathologic definition has not yet been standardized, mitotic rate is an independent factor in predicting both incidence of sentinel node metastases and survival.[60–64,67] Mitotic rate also has been associated with ulceration, further supporting its recognition as an indicator of poor prognosis.[62,63,68]

Site of Primary Melanoma

The anatomic site of the primary melanoma correlates significantly with survival, with trunk and head and neck sites having a poorer prognosis than extremity sites. The biological reasons for this are unclear; nevertheless, several large studies have shown this to be an independent prognostic indicator of survival.[69,70]

Age

Although older patients have thicker melanomas and a higher incidence of ulcerated melanomas, age is an independent adverse prognostic factor, even after multivariate adjustment for other factors.[71] There is a consistent and incremental decline in both 5- and 10-year survival rates with each decade increase in age. Many studies have shown that older patients have a lower survival rate, especially those older than 60 years of age.[66,72]

Anatomic Site

The anatomic site of primary melanoma is directly associated with prognosis, with extremity lesions having a better prognosis than truncal or head and neck lesions.[69,70]

Level of Invasion

The level of dermal invasion has been viewed as a valuable prognostic factor for decades.[73,74] There is less reproducibility in this determination than for thickness, and when all of the prognostic factors are analyzed in a multifactorial fashion, the level becomes much less important than thickness and ulceration for melanomas thicker than 1 mm. However, among patients with thin (≤1 mm) melanoma, the level of invasion was more predictive of survival outcome than was tumor ulceration.[16]

Sex

Men in general have a worse prognosis than do women of similar melanoma presentation and stage, a finding that has been consistent across many studies [69,75]

STAGING CLASSIFICATION

The current staging system went into effect in January 2003.[76] The AJCC Melanoma Database consisted of a total of 30,450 patients with melanoma. Of this group, 17,600 patients (58%) had information available for all of the factors required for the proposed TNM classification and stage grouping. Of the 17,600 patients included in this analysis, 12,837 (73%) had at least 5 years of follow-up information, 8633 (49%) had at least 10 years of follow-up, and 2485 (14%) had at least 20 years of follow-up. The data were merged from prospective databases of patients who did not receive any adjuvant systemic therapy and all of whom had quality control measures in place for data entry, pathology, and surgery. The current melanoma TNM categories are listed in Table 73-1, and the stage groupings are shown in Table 73-2. The 15-year survival curves for patients with stage I to IV melanoma are shown in Figure 73-1.[21] The distinction between clinical and pathologic staging is worth noting.

Clinical Staging

Patients with clinical stage I and II disease have invasive melanoma with no evidence of metastases at either regional or distant sites, based on clinical, radiologic, or laboratory evaluation. Patients with clinical stage III melanoma have clinical or radiologic evidence of regional metastases in the regional lymph nodes or evidence of intralymphatic satellite or in-transit metastases. The clinical or radiologic assessment of the regional lymph nodes is inherently difficult, especially with respect to assessing the presence and number of metastatic nodes. There are, therefore, no subgroup definitions of clinically staged patients with nodal or intralymphatic regional metastases. Patients with clinical stage IV melanoma have metastases at a distant site and are not subgrouped.

Pathologic Staging

In contrast to clinical staging, greater accuracy is possible in defining distinctive prognostic subgroups for appropriate patients for whom pathologic information is available about the regional lymph nodes (after sentinel or complete lymphadenectomy). Pathologic stage I and II melanoma has no evidence of regional or distant metastases, based on absence of nodal metastases after pathologic examination of the regional lymph nodes and absence of distant metastases based on routine clinical and radiologic examination.

Pathologic stage III melanoma has pathologic evidence of regional metastases, either in the regional lymph nodes or in intralymphatic sites. Quantitative classification of pathologic nodal status requires that pathologists perform a careful examination of the surgically resected nodal basin and report on the number of lymph nodes examined and the number of nodes involved with metastases, and that they determine whether the nodes are microscopically or macroscopically involved. Pathologic stage IV melanoma has histologic documentation of metastases at one or more distant sites.

Table 73-1 American Joint Committee on Cancer TNM Definitions

PRIMARY TUMOR (T)

Tx: unable to assess (e.g., shave biopsy or regressed melanoma)

T0: no evidence of primary tumor

Tis: melanoma in situ

T1: 0.1–1.0 mm thick

- T1a: without ulceration and level II/III
- T1b: with ulceration or level IV/V

T2: 1.01–2.0 mm thick

- T2a: without ulceration
- T2b: with ulceration

T3: 2.01–4.0 mm thick

- T3a: without ulceration
- T3b: with ulceration

T4: >4.0 mm thick

- T4a: without ulceration
- T4b: with ulceration

REGIONAL LYMPH NODES (N)

Nx: Cannot be assessed

N0: No regional lymph node metastasis

N1: metastasis in one node

- N1a: micrometastasis (clinically occult)
- N1b: macrometastasis (clinically apparent)

N2: metastasis in two to three nodes or in-transit metastases without nodal metastases

- N2a: micrometastases
- N2b: macrometastases
- N2c: in-transit met(s)/satellite(s) without metastasis in nodes

N3: metastasis in four or more regional nodes, matted notes, or in-transit metastasis or satellite(s) with metastasis in node(s)

DISTANT METASTASES (M)

Mx: cannot be assessed

M0: no distant metastasis

M1: Distant metastasis

- M1a: skin, subcutaneous, distant lymph node metastases
- M1b: lung metastases
- M1c: all other visceral metastases, or distant metastases at any site with elevated serum LDH

From Greene FL, Page DL, Fleming ID, et al (eds): AJCC Cancer Staging Manual, 6th ed. New York: Springer-Verlag, 2002.

Clinical versus Pathologic Staging

The ability to stage patients more accurately with sentinel node evaluation has had a profound effect on staging, treatment planning, and the conduct of clinical trials of patients with melanoma.[77,78] The widespread use of sentinel lymphadenectomy has led to considerable stage migration of patients previously staged as "node-negative" when their nodal metastases were undetected.[79] These patients have shown the extraordinary heterogeneity of metastatic risk for stage III melanoma.[16,66] Survival differences between patients with clinically and pathologically staged disease were statistically significant among all T substages, except T4b.

Table 73-2 American Joint Committee on Cancer Pathologic Stage Grouping

Stage 0:	TisN0M0
Stage IA:	T1aN0M0
Stage IB:	T1bN0M0
	T2aN0M0
Stage IIA:	T2bN0M0
	T3aN0M0
Stage IIB:	T3bN0M0
	T4aN0M0
Stage IIC:	T4bN0M0
Stage IIIA:	T1–4aN1aM0
	T1–4aN2aM0
Stage IIIB:	T1–4bN1aM0
	T1–4bN2aM0
	T1–4aN1bM0
	T1–4aN2bM0
	T1–4a/bN2cM0
Stage IIIC:	T1–4bN1bM0
	T1–4bN2bM0
	Any T N3M0
Stage IV:	any T, any N, M1

TNM Criteria

The primary criteria for the T classification are tumor thickness (measured in millimeters) and the presence of histologic ulceration. The T category thresholds of melanoma thickness are defined in even integers (i.e., 1.0, 2.0, and 4.0 mm), because they represent a statistical "best fit" and are most compatible with current thresholds in clinical decision-making.[80,81] A clinically convenient and widely used threshold of 1.0 mm or less is used for T1 melanomas. T2 melanomas are 1.01 to 2.0 mm thick, T3 melanomas are 2.01 to 4.0 mm thick, and T4 melanomas are more than 4.0 mm thick. Melanoma ulceration heralds a high risk for metastases; survival rates for patients with an ulcerated melanoma are remarkably similar to those for patients with nonulcerated melanomas of the next highest T category.[21,73] The level of invasion is an independent prognostic feature of "thin" (T1) melanomas, but not of thicker lesions.[16,73] Therefore, the level of invasion is incorporated into the stage grouping definitions of T1 melanomas only. In the cohort of T1 melanomas, the assignment of T1a is restricted to patients whose lesions meet three criteria: (1) lesion thickness of 1.0 mm or less; (2) absence of ulceration; and (3) depth of invasion limited to level II or III. T1b melanomas are defined as those with a thickness of 1.0 mm or less and with the more aggressive features of level IV or V, or with ulceration. All T2, T3, and T4 melanomas are defined according to the thickness and ulceration criteria as described previously, but not according to the level of invasion.

The definitions used for clinical and pathologic staging of stage III disease are more complicated than those used for the other stages because of the need to accommodate the marked diversity in the natural history of pathologic stage III melanoma. This is demonstrated by fivefold differences in 5-year survival rates for defined substages, ranging from 69% for patients with a nonulcerated melanoma (regardless of thickness) and a single clinically occult nodal metastasis to a low of 13% for patients with an ulcerated melanoma of any thickness and four or more clinically apparent nodal metastases documented by therapeutic lymphadenectomy (Table 73-3).[16]

The stage groupings for pathologic stage III melanoma use four criteria to assign patients with regional metastases to one of three groups, designated as stages IIIA, IIIB, and IIIC (Fig. 73-2). Patients with pathologic stage IIIA disease have three or fewer microscopic (clinically occult) nodal metastases arising from a nonulcerated melanoma (T1–4aN1aM0 and T1–4aN2aM0). Three subgroups of patients with pathologic stage IIIB disease have equivalent survival rates: (1) those with three or fewer microscopic (clinically occult) nodes arising from an ulcerated primary melanoma (T1–4bN1aM0 and T1–4bN2aM0); (2) those with three or fewer gross metastatic nodes and a nonulcerated primary (T1–4aN1bM0 and T1–4aN2bM0); and (3) those with satellite or in-transit metastases, but no evidence of nodal or distant metastases (T1–4 a/bN2cM0). Patients with stage IIIC disease include (1) those with four or more microscopic metastatic nodes and an ulcerated primary melanoma (T1–4bN2aM0); (2) those with three or more grossly involved nodes and a nonulcerated primary lesion (T1–4aN2bM0 and T1–4aN3M0); and (3) those with any combination of satellite or in-transit metastases and nodal metastases[16,21] (see Fig. 73-2).

In patients with distant metastases, the site (or sites) of metastasis and elevated serum levels of LDH are used to classify the M categories into three groups: M1a, M1b, and M1c. The 1-year survival rates range from 40% to 60%.[16,21] The factors that are most predictive of poor survival are the site and number of metastases and elevated serum LDH levels.[82–84] Patients with distant metastases to the skin, subcutaneous tissue, or distant lymph nodes are categorized as M1a. Patients with metastasis to the lung are categorized as M1b, and have

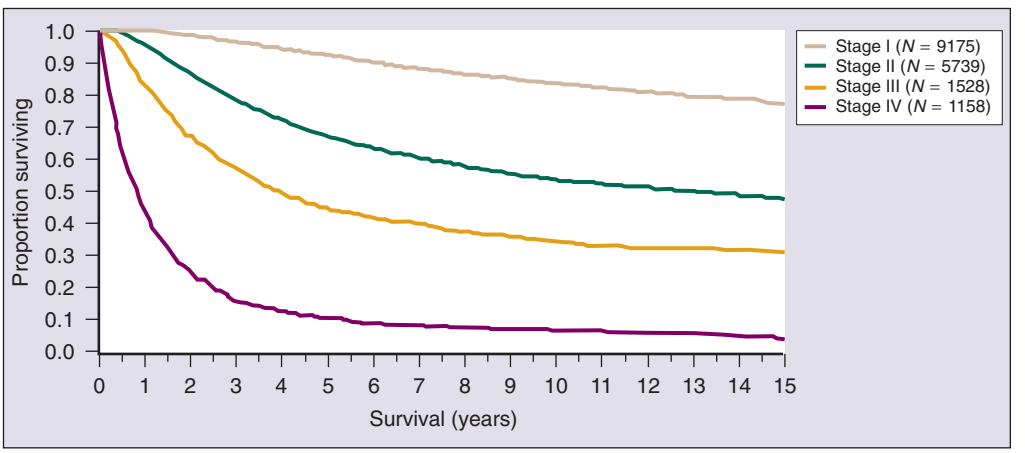

Figure 73-1 • Fifteen-year survival curves for stages I, II, III, and IV melanoma. For each curve, *N* = the number of patients in the AJCC melanoma database used to calculate rates. Curve differences are all highly significant ($P < 0.0001$). (From Balch CM, Buzaid AC, Soong SJ, et al: Final version of the American Joint Committee on Cancer staging system for cutaneous melanoma. an "intermediate" prognosis when comparing 1-year survival rates.[85] Patients with metastases to all other visceral sites have a relatively worse prognosis, and are designated as M1c. When the serum LDH level is elevated above the upper limits of normal at the time of staging, patients are classified as M1c, regardless of the site of distant metastasis.

PROGNOSIS

Patients with Primary Melanoma

In a multifactorial analysis of 13,581 patients with localized melanoma (either clinically or pathologically), the two most powerful and independent characteristics of the primary melanoma were tumor thickness and ulceration. Other statistically significant prognostic factors were patient age, patient sex, site of the primary melanoma, and level of invasion.[16]

Patients with Regional Metastases

There are four major determinants of outcome for patients with pathologic stage III melanoma: (1) the number of metastatic lymph nodes; (2) the tumor burden, either microscopic (clinically occult and detected pathologically by sentinel node biopsy or elective lymphadenectomy) or macroscopic (clinically apparent by physical or radiologic examination and verified pathologically); (3) ulceration of the primary melanoma; and (4) satellite or in-transit metastases.[86,87] Table 73-2 shows the stage groupings for stage III melanoma. Figure 73-2 shows the survival rates for these patients.

Patients with Advanced Disease

The site of metastasis, the number of metastatic sites, and elevated serum LDH levels were the factors that were most predictive of poor survival in all studies analyzing prognosis in patients with distant metastases using a Cox regression analysis.[88,89] Patients with distant metastasis to the skin, subcutaneous tissue, or distant lymph nodes have a relatively better prognosis compared with patients with metastasis to another anatomic site.[88,90] Lung metastases are associated with better prognosis compared with other visceral sites.[16] The number of metastases at distant sites is as an important prognostic factor.[82,83] There is significant variability in the use of diagnostic tests to comprehensively search for distant metastases. Until the indications for testing and the types of tests used are better standardized, the number of metastases cannot be used reliably for staging purposes. Elevated serum LDH is among the independent factors most predictive of decreased survival, even when the site of metastasis and the number of metastases are considered.[88,89]

TREATMENT OF THE PRIMARY

Locoregional Disease

Margins

Every primary melanoma requires wide local excision of the surrounding skin to decrease the risk of local and satellite recurrences. In most cases, wide local excision can be done as an elliptical excision with primary closure. Excision is carried down to a plane between the superficial and the deep (muscular) fascia. Primary closure often can be facilitated by a length-to-width ratio of the ellipse of approximately 3 : 1 and by undermining the flaps to close the defect with an advancement flap, if needed. In areas where the skin edges cannot be approximated primarily, a split-thickness skin graft or a rotational flap can be used to cover the defect. The skin graft donor site preferentially should be chosen outside the area of potential in-transit metastasis. Today, surgical excision margins are less radical than in most of the 20th century; the previously routine margin of 5 cm is no longer used. Primary invasive melanoma should be excised with a 1- to 2-cm minimum radial margin of normal-appearing skin around the biopsy site, with the margin determined by the anatomic site and the thickness of the melanoma.

Five randomized clinical trials have been conducted that address surgical margins around a primary melanoma.[91–95] Three trials involved patients with "early melanomas," those less than 2.0 mm in thickness and with a low risk for local recurrences. The WHO Melanoma Program, the first to conduct a prospective clinical trial of patients treated in Europe and the United States, randomized patients with melanomas smaller than 2 mm to either a 1- or 3-cm margin of excision.[92,96] This seminal clinical trial showed that melanomas less than 2 mm in thickness could be safely excised with a 1-cm margin. The Swedish and European (French) randomized trials were initiated at the same time but were published later.[91,93] These two trials were more conservative; both studies randomized melanomas smaller than 2 mm to either a 5- or a 2-cm radial margin of skin excision. Both studies concluded that the narrower 2-cm margin was safe.

Two clinical trials were conducted for thicker melanomas: the Intergroup Melanoma Trial conducted in the United States on melanomas 1.0 to 4.0 mm in thickness, comparing 2- vs. 4-cm radial margins, and the British study of melanomas larger than 2.0 mm in thickness, comparing 1- vs. 3-cm margins of excision. The Intergroup Melanoma Trial showed that the narrower 2-cm surgical margin was safe with regard to local and regional recurrences, and overall survival.[94] The British study concluded that the 1-cm margin might not be as safe in this cohort of higher-risk patients, since the disease-free survival rates were lower in the narrower excision margin cohort, although there was no difference in overall survival.[95] This study, therefore, leads to some circumspection about adopting a 1-cm surgical margin in all patients, because a narrower margin appeared to be associated with some increased risk for the subsequent development of local and regional metastases.

Difficult Sites

EAR. Primary melanoma of the ear usually can be treated with wedge excision. Primary closure usually is possible, with acceptable cosmetic results. Complete amputation is used only for extensive involvement of the ear or for a local recurrence that is not amenable to wedge excision.

FINGERS AND TOES. Digital melanoma often requires amputation at the midphalanx proximal to the melanoma and follows the same margin recommendations as other sites. The great toe is the most common site of melanoma of the digits and generally requires amputation at the midproximal phalanx. Sufficient skin and soft tissue often can be saved on the plantar surface to allow soft tissue coverage of the stump. As long as the metatarsophalangeal joint is preserved, this amputation causes essentially no functional impairment. Primary melanoma of the distal second through fifth toes usually requires amputation at the midproximal phalanx. Melanoma of the distal finger or nail bed typically requires amputation one phalanx proximal to the melanoma. Melanoma of the proximal finger or web space may be managed with soft tissue excision, with preservation of underlying tendon and bone and coverage with a full-thickness skin graft. For optimal preservation of function, patients with melanoma of the hand should be treated by a hand surgeon.

SOLE OF THE FOOT. Primary melanoma on the sole of the foot requires wide local excision down to the plantar fascia, with either skin graft or soft tissue coverage. When primary melanoma occurs on the instep, a split-thickness skin graft may be sufficient. On weight-bearing surfaces, the tendons should be preserved, and a myocutaneous free flap can be used to provide optimal coverage.

Management of the Clinically Negative Regional Node Basin

Most melanoma experts recommend lymphatic mapping and sentinel lymphadenectomy as a staging procedure for patients with clinical stage I or II melanoma if their primary tumor is at least 1 mm thick, or, if thinner, when the melanoma is ulcerated or is level IV or V (T1bN0M0). The morbidity of the procedure is low and the staging information gained is valuable. Patients found to be node positive are then classified as having pathological stage III melanoma and usually should undergo a therapeutic lymphadenectomy of that nodal basin and should be considered for systemic adjuvant therapy.

Accurate detection of the sentinel node depends on mapping the lymphatic drainage from the skin directly next to the melanoma in a coordinated effort by the surgeon and the nuclear medicine specialist. Preoperative lymphoscintigraphy is vital to the success of sentinel node biopsy. With truncal or head and neck primary lesions, drainage to more than one node basin often occurs, and it is important to retrieve the sentinel node(s) from each node basin in which a sentinel node is identified.[78,97] Preoperative lymphoscintigraphy facilitates the identification of sentinel nodes that lie outside traditional node basins or at unexpected sites. Sentinel nodes occasionally have been identified at popliteal and epitrochlear sites and in the triangular intramuscular space in the back, at the supraclavicular fossa, and at internal mammary and paravertebral sites.

The sentinel node should be placed in formalin for permanent fixation. Frozen section analysis is discouraged; it is preferable to save the lymph node intact for permanent processing only, so that multiple sections can be taken with immunohistochemical stains (e.g., HMB-45, S-100, Melan-A) to look for microscopic evidence of disease. Immunohistochemical staining increases the node-positive rate by 10% to 12% over staining with H & E alone.[98,99] The risk of histologic node positivity is related to the thickness of the primary melanoma[78,100]: In patients with lesions less than 0.76 mm thick, the chance of finding a positive sentinel node is minimal; for melanomas 0.76 to 1 mm thick, the chance of finding a metastatic sentinel node is 5% to 6%; for melanomas 1.1 to 1.5 mm thick, the chance is 7% to 8%; for melanomas 1.5 to 4.0 mm thick, the chance is 18% to 19%; and for melanomas 4 mm or thicker the chance is 29% to 34%.

Sentinel lymphadenectomy, initially described by Morton and colleagues, is a highly accurate, minimally invasive method of identifying those primary melanoma patients who have clinically occult nodal metastases. In a recent report of the results of a randomized prospective study of 1269 patients with intermediate-thickness melanomas (1.2–3.5 mm), Morton and colleagues[101,102] confirmed the prognostic significance of the sentinel node and documented improved disease-free survival among the patients having a sentinel node biopsy. This report conclusively showed that nodal metastases could be detected 16 months earlier (median) than with the nodal observation approach in the 20% of patients who had nodal metastases. In the SLN biopsy arm, SLN status was the most significant predictor of survival in a multifactorial analysis; these results con-

firm other analyses examining the prognostic significance of SLN biopsy.[78,103]

With regard to regional disease control, the nodal observation group had multiple follow-up examinations before nodal metastases became clinically detectable; most of those who suffered a regional recurrence did require a radical lymphadenectomy, as it was usually a solitary site of metastasis. In the group with regional recurrence, there were a larger number of metastatic lymph nodes (3.3 metastatic lymph nodes vs. 1.4 in the SLN group). The implications for this higher number of nodal metastases are important. First, the subsequent regional recurrence rates increase significantly as the number of metastatic nodes in a nodal basin increases, and reaches about a 20% regional failure rate after standard lymphadenectomy in patients with four or more metastatic nodes (compared with <5% in patients with a single metastatic node). In many melanoma centers, patients with multiple, grossly detectable nodal metastases would be considered for adjuvant radiation therapy to the nodal basin, and would be more likely to receive adjuvant high-dose interferon. In contrast, patients with one or two nodal micrometastases would not be considered for adjuvant radiation therapy and would be candidates for other systemic treatments, especially on clinical trials, such as melanoma vaccine trials, in lieu of high-dose interferon.

With regard to survival rates, the two randomized groups overall were comparable; however, among the 16% of patients in each randomized cohort who had nodal metastases, survival rates were higher in the arm with early surgical intervention as directed by the SLN biopsy. The dilutional effect on overall survival rates by the 84% of patients who, in retrospect, never had nodal metastases, will make it difficult ever to demonstrate a survival advantage of the group. It would also be difficult—perhaps even impossible—to design a randomized trial differently to address this issue, because the presence or absence of nodal metastases is known only retroactively, after either the SLN procedure or close clinical examination of the regional nodal basin by palpation or ultrasound.

The use of SLN biopsy has changed the current management of melanoma dramatically, and it offers many significant benefits. First, it provides accurate prognostic information. Second, patients with a positive sentinel node biopsy can undergo a completion lymphadenectomy when the nodal metastatic burden is low. Third, patients with nodal micrometastases can be considered for adjuvant therapy or clinical trials if deemed appropriate. And finally, future trials of systemic therapy can use the results of sentinel node biopsy to assure more homogeneous groups of patients entering trials. The concept of the sentinel node is now well-established and should be used in all melanoma patients where the staging information will be useful for staging and treatment planning.

Management of Regional Nodal Metastases

Complete lymphadenectomy currently is standard treatment for patients with identified regional nodal metastases (Fig. 73-3). The goals of surgery include staging, regional control of disease, and, possibly, improved survival. Most patients who require lymphadenectomy are those who have histologically positive sentinel nodes. In an era when most node-positive patients have micrometastases found by sentinel node biopsy, the value of routine dissection for patients

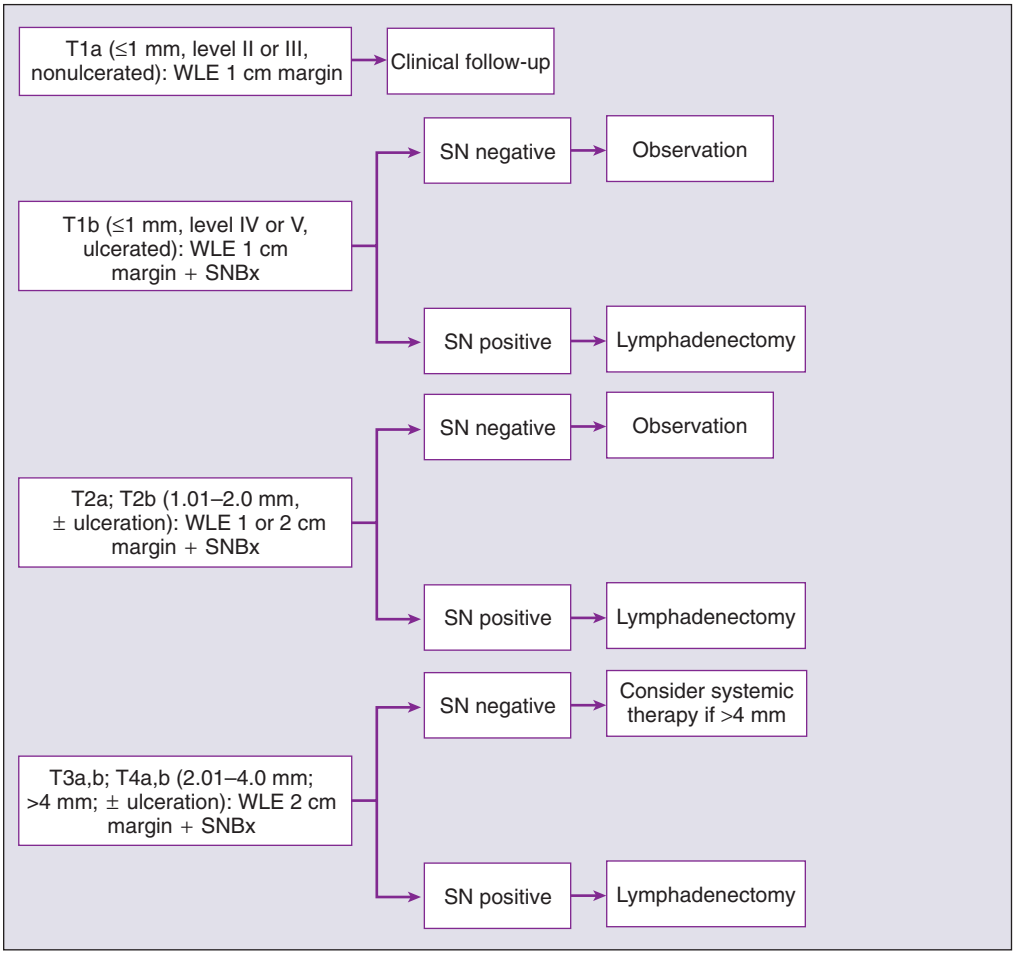

Figure 73-3 • Surgical management of clinical stage I and II melanoma. Sentinel nodes should be evaluated with multiple levels of immunohistochemical staining. All patients with positive nodes or melanoma >4 mm should be strongly considered for interferon or a clinical trial of systemic adjuvant therapy. Some patients with negative nodes and melanoma >1.5 mm may qualify for clinical trials and should be considered for them if interested. SN, sentinel node; SNBx, lymphatic mapping and sentinel node biopsy; WLE, wide local excision.

with microscopically positive nodes has been questioned, and clinical trials are ongoing to determine the magnitude of any benefit in this population.

Patients presenting with clinically suspicious nodes should be evaluated with fine-needle aspiration, if possible, with excisional biopsy done only if the results of fine-needle aspiration are indeterminate. Patients with biopsy-proven bulky nodal disease should be evaluated with baseline spiral CT scans, a complete blood count, and measurement of liver enzymes, including LDH, to rule out identifiable distant disease before proceeding with nodal surgery. As a general principle, lymphadenectomy should be anatomic. The nodal contents are excised in a single block of tissue within their surrounding fatty tissue, preserving motor nerves and muscle whenever possible.

Axillary Dissection

Therapeutic axillary dissection for melanoma should include complete dissection of levels I, II, and III. The long thoracic nerve and the thoracodorsal neurovascular bundle are left intact unless they are directly invaded by tumor. A closed-suction drain is placed. Patients should have no appreciable loss of range of motion or motor function. Complete dissection carries approximately a 10% risk of lymphedema in the upper extremity.

Inguinal and Iliac Dissection

For patients with positive inguinal or femoral nodes, anatomically complete inguinofemoral dissection is performed. The boundaries of the dissection extend superiorly to approximately 6 cm above the inguinal ligament, medially to the pubic tubercle and the midbelly of the adductor longus, laterally to the anterior superior iliac spine and the lateral border of the sartorius, and inferiorly to the apex of the femoral triangle. In patients not known to have iliac nodal metastases in preoperative imaging, the femoral canal is opened and Cloquet's node (the lowest node in the iliac chain) is removed. If Cloquet's node is negative, iliac and obturator dissection usually is not done, and the femoral canal is closed. The sartorius muscle is taken down from its insertion to the anterior superior iliac spine, rotated over the femoral vessels, and tacked in place to the edge of the inguinal ligament and the fascia of the adductor longus. A closed-suction drain is placed in the inguinofemoral area. Inguinal dissection wounds have an infection rate of at least 10% to 15%. The risk of symptomatic lymphedema of the lower extremity is approximately 20%. Routine measures to reduce the risk of lymphedema include a program of wearing a fitted compression garment at 20 to 30 mm Hg during the day for the first 6 months postoperatively and leg elevation when possible.

Absolute indications for iliac and obturator dissection include the finding of a positive Cloquet's node intraoperatively and the finding of enlarged, suspicious iliac or obturator nodes on preoperative imaging. Iliac and obturator dissection may also be considered if four or more lymph nodes positive for disease are found at the inguinofemoral level or if the patient has bulky disease at the inguinofemoral level. The boundaries of the dissection are from the inguinal ligament inferiorly to the bifurcation of the common iliac vessels superiorly and to the obturator vessels medially.

Cervical Dissection

The extent of cervical lymphadenectomy depends on the location of the positive node and the presence of direct invasion into the structures of the neck. When a positive sentinel node is found, a functional neck dissection preserving the internal jugular vein, spinal accessory nerve, and sternocleidomastoid is appropriate. These structures should be sacrificed only if they are directly invaded by tumor.

Radiation Therapy

The risk of regional recurrence sometimes can be lowered by judicious use of radiation therapy after lymphadenectomy in selected patients at particularly high risk, such as those with four or more positive nodes or bulky nodal disease with extracapsular extension. Although there are no prospective randomized studies showing superior outcome with the addition of postoperative radiation, a few retrospective studies strongly suggest that radiation may improve regional control in patients at particularly high risk for treatment failure.[104–107]

Management of Locoregional Recurrence

Local Recurrence

Local recurrence rates after appropriate wide local excision are low. With long-term follow-up of intermediate-thickness lesions in the Intergroup Melanoma Trial, 2.1% to 2.6% of patients overall had a local recurrence.[66] Patients at particularly high risk for local recurrence include those with thick primary lesions (≥4 mm) and those with histologic ulceration, desmoplastic features, or a high mitotic rate. Local recurrence can be a sign that the patient either has or soon will have systemic disease. When local recurrence is detected, the minimal systemic workup that should be done includes careful physical examination, chest x-ray, and measurement of liver enzyme levels, including LDH. If any abnormalities are found by this examination, CT scans, PET scan, or other investigations may be indicated. Local recurrences are treated with wide local excision with 1-cm margins whenever possible (Fig. 73-4). Radiation therapy or systemic IL-2 therapy for unresectable or confluent lesions also is a consideration in selected patients.

In-Transit Disease

In-transit metastases of melanoma appear as identifiable tumor nodules in the subcutaneous or cutaneous tissues between a primary site and its nearest draining node basin. Approximately 2% to 4% of

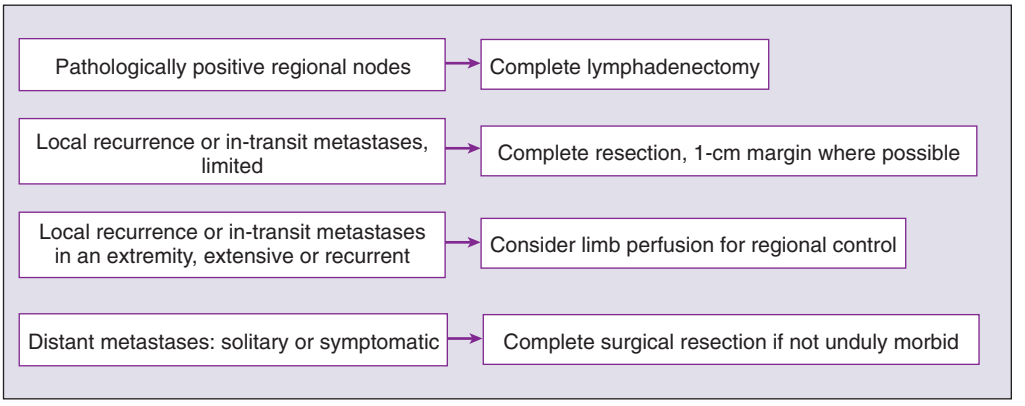

Figure 73-4 • Surgical management of stage III and IV melanoma. All stage III and IV patients should be strongly considered for systemic therapy. Radiation therapy may be considered after lymphadenectomy for patients with ≥4 positive nodes or extranodal extension.

patients with melanoma eventually have in-transit disease after excision is performed for localized primary melanoma.[108] As with local recurrence, in-transit disease can be a harbinger of impending systemic disease; therefore, patients with in-transit disease should undergo a staging evaluation. If limited in-transit lesions are present and they are amenable to excision, wide local excision with negative margins is the treatment of choice.

Nodal Recurrence

Patients with recurrence in a previously undissected node basin should undergo evaluation and complete node dissection, as described previously. Recurrence in a previously dissected basin should be evaluated with a staging workup, including CT scans and measurement of liver enzymes, including LDH, and should undergo surgical excision of the area of recurrence. Adjuvant radiation therapy can be considered as well.

Isolated Limb Perfusion or Infusion

The indications for isolated limb perfusion or infusion are confined to extensive in-transit lesions or local recurrences involving an extremity.[109,110] Limb perfusion with hyperthermia and melphalan has never been shown to be associated with improved survival, but it has a role in securing local and regional control for patients with unresectable local recurrence or a large volume of in-transit disease.[110,111] Still under study is the addition of tumor necrosis factor, which in some studies shows a suggestion of improved disease response, but in others appears to offer no benefit.[112,113] However, the risk of regional toxicity is significant; isolated limb perfusion should be performed only in centers with experience with the technique, preferably in the setting of a clinical trial. A technique of isolated limb infusion using a low-flow infusion of melphalan and actinomycin without oxygenation via percutaneous catheters has been reported that is technically simpler and has reported responses similar to those of melphalan limb perfusion with hyperthermia.[109,114] Overall response rates were reported at 85% (41% complete response) with median response duration of 16 months.[114]

SYSTEMIC THERAPY AND SPECIAL TOPICS

Systemic Adjuvant Therapy

The recently revised AJCC staging system for melanoma allows us to predict an individual's chance of survival more accurately and to identify the patients most likely to benefit from adjuvant therapy, e.g., those with relapse rates of 50% or greater.[76] Trials of adjuvant therapies for high-risk patients have been largely unsuccessful. In 1996, based on a randomized trial showing a survival benefit of 1 year, high-dose interferon alfa-2b was approved by the U.S. Food and Drug Administration (FDA) as adjuvant therapy for patients with resected stage IIB (≥4 mm primary) or stage III (regional lymph node involvement) disease.[115] Subsequent randomized trials of high-dose interferon alfa-2b have shown a consistent disease-free survival benefit, but no significant overall survival benefit.[116] The use of high-dose interferon alfa-2b remains controversial. A variety of therapies, including vaccines, biochemotherapy, and biologic agents, continue to be evaluated in clinical trials for high-risk patients in the adjuvant setting, but to date none have improved overall survival rates.

Early Adjuvant Therapy Trials

A variety of chemotherapeutic agents, including dacarbazine (DTIC)[117] and carmustine (BCNU),[118] showed no benefit in the adjuvant setting. The biologic agents bacillus Calmette-Guérin[119] and interferon-gamma[120] did not improve survival in high-risk postoperative patients. A small, prospective, randomized study showed a survival benefit for patients who took megestrol acetate compared with control subjects.[121] One of four randomized studies of levamisole hydrochloride showed a survival benefit for patients in the treatment arm.[122]

High-Dose Interferon Alfa-2b

Three large published randomized trials conducted under the auspices of the Eastern Cooperative Oncology Group (ECOG) evaluated 1 year of treatment with high-dose interferon alfa-2b in high-risk patients. All defined high-risk patients as those with primary melanomas at least 4 mm thick or with regional lymph node involvement. The high-dose interferon alfa-2b dose schedule was the same in all three studies: 20 million units/m^2 intravenously (IV), Monday through Friday for 4 weeks, followed by 10 million units/m^2 subcutaneously (SC), three times a week for the remaining 11 months. In ECOG protocol 1684, the first trial, 287 patients were randomized to receive high-dose interferon alfa-2b or no treatment postoperatively. In 1996, a statistically significant disease-free survival (DFS) benefit (1.72 years vs. 0.98 years) and an overall survival (OS) benefit (3.82 years vs. 2.78 years) were seen in the interferon alfa-2b arm, at a median follow-up of 6.9 years.[115] The FDA then approved high-dose interferon alfa-2b for high-risk patients, as defined in this study. While at a median follow-up of 12.6 years, the DFS benefit persisted, the OS benefit did not, with both arms now having an equal number of deaths.[123]

The follow-up study, ECOG protocol 1690, involved a three-way randomization with patients receiving high-dose interferon alfa-2b, low-dose interferon alfa-2b (3 million units/day SC three times a week for 2 years), or no therapy. The study enrolled 642 patients; statistical analysis in this study focused on hazard ratios. At a median follow-up of 4.3 years, high-dose interferon alfa-2b led to a reduction in the risk of recurrence compared with no treatment (hazard ratio = 1.28). However, there was no difference in OS at 5 years.[116] The relapse-free survival (RFS) benefit, with no OS benefit, was confirmed at median follow-up of 6.6 years as well.[124] Of note, two confounding issues were that the patients in the observation arm had a surprisingly good survival rate, median survival of 6 years, even after relapse and that some of these patients eventually received high-dose interferon alfa-2b therapy.

In ECOG protocol 1694, high-dose interferon alfa-2b was compared with a GM2-ganglioside vaccine in 880 high-risk patients (high risk as defined previously). The Data Safety Monitoring Committee stopped this study early, at a median follow-up of 16 months, because a statistically significant DFS benefit (hazard ratio = 1.47) and an OS benefit (hazard ratio = 1.52) were noted for the high-dose interferon alfa-2b arm. The estimated DFS rate at 2 years for the patients receiving high-dose interferon alfa-2b was superior (62% vs. 49%), as was OS (78% vs. 73%).[125] Because there was no observation arm, it is impossible to know whether the vaccine was inferior or equivalent to no therapy.

A pooled analysis of ECOG trials upheld the finding of prolonged RFS, but not OS, in patients treated with high-dose interferon alfa-2b vs. observation on two-sided univariate log-rank analysis of E1684 and E1690 pooled data. Multivariate models adjusted for negative prognostic factors also confirmed a significant RFS benefit in pooled populations.[124] A meta-analysis of adjuvant interferon randomized trials also attempted to clarify the varied results.[126] RFS and OS were evaluated, and a subgroup analysis was performed according to interferon alfa-2b dose. Again, a significant RFS improvement was seen in those treated with high-dose interferon alfa-2b (three studies) compared with control (hazard ratio = 0.83, CI: 0.77–0.90). However, the benefit in OS was less clear as the confidence interval crossed 1.0 (hazard ratio = 0.93, CI: 0.85–1.02). Odds reduction in RFS appeared to correlate directly with increasing dose of interferon alfa-2b; namely, the greatest reduction in odds for recurrence was in the high dose groups (hazard ratio = 0.74). Yet again, no consistent benefit in OS was seen.[126]

High-dose interferon alfa-2b is associated with a number of potential toxicities, which necessitate dose reduction in approximately 75% of patients. Side effects include fatigue, anorexia, flu-like

symptoms, depression, liver abnormalities, and cytopenia. Patients require frequent blood draws: weekly for 4 weeks, and then monthly.[115] The treatment is expensive, and some insurers do not reimburse for home SC administration. Many patients are not candidates for high-dose interferon alfa-2b because of age or comorbid conditions.

The results of studies of high-dose interferon alfa-2b continue to inspire much controversy.[123,127] Since the FDA approved high-dose interferon alfa-2b in 1996, the treatment regimen has not been widely embraced by U.S. medical oncologists and has not been accepted at all by European practitioners.[123] There is a consistent DFS benefit in multiple studies that cannot be denied. However, the OS benefit faded in ECOG protocol 1684 and was never seen in ECOG protocol 1690. In ECOG protocol 1694, at a median follow-up of 2 years there was a survival benefit, but no subsequent data have been published. If there is a survival benefit to high-dose interferon alfa-2b therapy, it is likely small.

Other Interferon Alfa-2b Schedules

A number of other interferon alfa-2b schedules have been evaluated in the adjuvant setting. High-dose interferon alfa-2b given for 3 months was ineffective.[128] Low-dose interferon alfa-2b schedules of 3 million units/day SC three times a week for 3 years for patients with stage III disease,[129] or for 18 months for patients with primary melanomas more than1.5 mm thick,[130] did not show an OS benefit compared with observation. The European Organization for Research and Treatment of Cancer (EORTC) studied intermediate-dose schedules of interferon alfa-2b, 10 million units SC five times a week for 4 weeks, then three times a week for 12 or 24 months in a randomized controlled trial of 1388 patients with stage IIB or III melanoma (protocol 18952).[131] The measured endpoints were distant-metastasis-free interval (DMFI), distant metastasis-free survival (DMFS), and OS. After a median follow-up of 4.5 years, neither group evidenced a statistically significant improvement in DMFI or OS. There was a trend toward significance in DMFI and OS in patients treated with 2 years of interferon alfa-2b vs. observation; among those patients, those with stage IIb melanoma showed the greatest effect. These findings were thought to underscore the impact of tumor burden and duration of treatment on treatment effect. Another EORTC protocol (18991) that involves an extended course of pegylated interferon alfa-2b for 5 years versus observation in 1256 stage III melanoma patients reported that subjects with micrometastasis in regional nodes had improved relapse-free survival, but not improved overall survival, when treated with 5 years of pegylated interferon alfa-2b.[131]

Vaccines

Currently, increasing numbers of melanoma vaccines are in preclinical development and in phase I, II, and III clinical trials in the adjuvant setting. Despite the scientific promise of melanoma vaccines, to date none has proven beneficial in the adjuvant setting when tested in a randomized clinical trial. A notable disappointment in the field of melanoma research came in 2005 when the phase III study of CancerVax (CancerVax Corporation) in resected stage III melanoma, as well as the phase III study in resected stage IV melanoma, were stopped early by the respective external data safety monitoring committees. After interim analyses, the likelihood of a survival benefit in the Canvaxin-treated patients was sufficiently low to warrant trial closure. CancerVax was an allogeneic whole-cell vaccine composed of three highly antigenic, irradiated melanoma cell lines. In a phase II trial, CancerVax appeared to improve survival compared with historical controls.[132] M-Vax (AVAX Technologies, Philadelphia, PA), an autologous whole-cell melanoma vaccine modified by the hapten dinitrophenol and then irradiated, also improved survival in patients with stage III disease compared with historical control subjects and demonstrated that development of a delayed type-hypersensitivity response (DTH) correlated with improved DFS and OS.[133,134] A phase III study of M-vax in metastatic melanoma is ongoing.

In addition to the Canvaxin trial just mentioned, a limited number of other phase III adjuvant vaccine trials have been completed. A vaccinia melanoma oncolysate vaccine did not improve outcome in patients with stage III melanoma.[135] In a large randomized trial, a vaccinia viral lysate of melanoma showed no benefit in patients with melanomas more than 4 mm thick or with regional lymph node involvement.[136] Melacine (Corixa Corp., Seattle, WA), a cell-lysate vaccine, was compared with observation by the Southwest Oncology Group (SWOG) in patients with melanomas 1.5 to 4 mm thick without lymph node involvement. No DFS benefit was seen.[137] However, in a retrospective analysis, vaccinated patients who were positive for HLA-A2 or C3 had a DFS rate of 77%, compared with 64% for those who received observation only.[138] Unfortunately, no further studies are planned. In a study by Bystryn and colleagues,[139] polyvalent shed-antigen vaccine showed a survival benefit in a very small phase III trial that involved 38 patients with stage III disease. In ECOG protocol 1694, discussed earlier, the GM2-ganglioside vaccine was inferior to high-dose interferon alfa-2b at a relatively short median follow-up.[125]

Granulocyte-Macrophage Colony-Stimulating Factor

Granulocyte-macrophage colony-stimulating factor (GM-CSF) is a colony-stimulating factor approved by the FDA for treatment of bone marrow transplant graft delay or failure and for speeding neutrophil recovery after induction chemotherapy in elderly patients with acute myelogenous leukemia. It also promotes melanoma antigen presentation through activation of macrophages, monocytes, and dendritic cells. GM-CSF was studied in 48 high-risk patients with melanoma (stage III with >4 involved lymph nodes or stage IV) after surgical resection with no evidence of disease. The outcome was much better in the treated patients compared with historical controls, with a median survival of 37.5 months vs. 12.2 months.[140] Based on these results, ECOG designed a double-blinded, randomized, six-arm phase III study of various combinations of a peptide vaccine, GM-CSF, and placebos of both (protocol 4697) in resected high-risk stage III and stage IV patients, which recently closed to accrual.

Adjuvant Biochemotherapy

With the initial success of biochemotherapy in advanced disease,[141] it seemed logical to design a trial for the high-risk adjuvant setting. Intergroup trial S0008 is comparing three cycles of biochemotherapy with 1 year of high-dose interferon alfa-2b administration in very-high-risk patients with stage III disease (i.e., ulcerated primary lesion with regional lymph node involvement, grossly involved or clinically palpable nodes, matted nodes, two or more involved nodes, or satellite lesions). The study continues to accrue patients, although the disappointing recently released data on biochemotherapy in patients with stage IV disease casts doubt on the utility of this intensive, toxic approach in stage III disease.[142]

Neoadjuvant Therapy

A newer strategy involves neoadjuvant therapy for regionally advanced melanoma. A dramatic response recently was reported in patients with stage IIIB-C melanoma who were treated with standard high-dose interferon alfa-2b: IV infusion daily for 4 weeks prior to curative surgical resection, followed by SC injections three times a week for 11 months.[143] Of the 20 enrolled patients, 11 demonstrated an objective clinical response and 3 evidenced a complete pathologic response. Fifty percent of patients were free of recurrent disease at median follow-up of 18.5 months.[143] Biochemotherapy in the neoadjuvant setting also has been evaluated in two phase II studies.[144,145] Both studies showed promising results that urge further evaluation in randomized phase III setting.

MANAGEMENT OF ADVANCED DISEASE

Diagnosis and Evaluation

When metastatic disease is suspected, the diagnosis should be pathologically confirmed whenever possible. Often this can be accomplished with a minimally invasive procedure, such as excisional biopsy, fine-needle aspiration, or core biopsy. Routine staining of the pathology slides plus immunohistochemical staining with S100, HMB-45, and anti-MART-1/Melan-A, should confirm the diagnosis of melanoma and differentiate it from other malignancies. In the rare circumstance in which it is necessary to differentiate clear cell sarcoma from melanoma, the presence of the t(12;22)(13;q13) translocation can be used to exclude the diagnosis of melanoma. Patients should be fully staged with appropriate imaging studies before therapy is initiated. All patients should undergo an MRI scan of the brain, and whole-body imaging with either spiral CT scans of the chest, abdomen, and pelvis or combined PET/CT. Patients with bony symptoms should have a bone scan, plain x-rays, or MRI, depending on the clinical assessment.

Role of Surgery in Advanced Melanoma

Because highly effective chemotherapy is not available, surgery can be an appropriate treatment for isolated metastases. Surgical excision of isolated metastatic melanoma can provide quick and effective palliation and, in some cases, long-term survival.[146,147] Surgical candidates should be selected carefully. Surgery should be used only in cases of accessible lesions and when the risk of perioperative morbidity is acceptable. Isolated visceral metastases, especially to the brain and lung, are amenable to surgical therapy. The same is true for both symptomatic and asymptomatic gastrointestinal metastases, as well as for lesions in the skin, subcutaneous tissues, or distant lymph nodes.

Chemotherapy

DTIC is an alkylating agent that is converted to its active metabolite, 5-(3-methyl-1-triazeno) imidazole-4-carboxamide (MTIC), in the liver. As a single agent, it has been studied extensively in metastatic melanoma. In early studies by the Central Oncology Group, DTIC had an overall response rate of 20%, with 5% of patients achieving complete responses.[148] Most of the patients responding to this treatment had nodal or cutaneous metastases. Subsequent randomized studies showed objective response rates of 5% to 20%.[148,149] With modern antiemetic agents, DTIC is very well tolerated. Although multiple dosage schedules have been studied, 800 to 1000 mg/m^2 IV over 1 hour every 3 to 4 weeks is more convenient and at least as effective as any other schedule.[149] Unfortunately, DTIC has not been proven to provide a survival benefit compared with supportive care or other treatments. Temozolomide, also an alkylating agent, is a pro-drug of MTIC. In contrast to DTIC, temozolomide is orally available and penetrates the blood–brain barrier. It currently is FDA-approved for the treatment of primary brain tumors, but not for melanoma. In a phase II trial, temozolomide at a dose of 150 to 200 mg/m^2 orally on days 1 to 5 in a 28-day cycle had similar activity to DTIC, with a complete response rate of 5% and an overall response rate of 21%, with some responses in the central nervous system (CNS).[150] In a head-to-head comparison, the survival rates were similar—6.4 months for DTIC and 7.7 months for temozolomide.[151] Both agents are well tolerated. The oral administration route for temozolomide is attractive to patients, but without FDA approval, it is not always adequately reimbursed by insurance. Temozolomide also is used on an extended schedule, 75 mg/m^2 orally every day for 6 weeks followed by a 2-week break. This is the preferred dosing when concurrent external beam radiation to the CNS, or elsewhere, is indicated, since temozolomide is radiosensitizing.[152,153] Studies currently are in progress to determine whether one dosing regimen is better than the other. A phase I study showed greater drug exposure with an extended dosing regimen,[154] whereas selective CD4+ lymphopenia is more common with the extended regimen.[155] Consideration should be given to prophylaxis against *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) pneumonia in these patients, especially those who are receiving concomitant radiation.

A long list of chemotherapeutic agents has shown low levels of activity in metastatic melanoma, including the platinum compounds cisplatin[156] and carboplatin,[157] BCNU,[158] vindesine,[159] paclitaxel,[160] docetaxel,[161] and vinorelbine.[162] None has been shown to be superior to DTIC as a single agent, in either efficacy or toxicity profile. Two-drug combinations have not yet yielded superior results to single-agent DTIC. A small, randomized trial comparing DTIC with DTIC plus tamoxifen showed almost a doubling of the response rate with the addition of tamoxifen.[163] This result, however, was not confirmed in a follow-up study.[164] A three-drug combination of cisplatin, vinblastine, and DTIC showed encouraging early results in a phase III trial comparing the combination with single-agent DTIC, but unpublished follow-up data showed no advantage to the combination.

Two combination chemotherapy regimens—bleomycin, vincristine, lomustine, and DTIC (BOLD) and a combination of three alkylating agents (DTIC, BCNU, and cisplatin) with tamoxifen, known as the Dartmouth regimen—showed great promise in the treatment of metastatic disease and became quite popular among clinicians during the 1980s and early 1990s. The BOLD regimen demonstrated an objective response rate of greater than 40% in a phase II trial.[165] However, in a phase III study, the response rate dropped to the single digits and the regimen fell out of favor.[166] In several single-institution studies of the Dartmouth regimen, very high response rates of greater than 50% were consistently reported.[167] In one single-institution study, when tamoxifen was removed from the regimen to minimize the risk of deep vein thrombosis, the response rate dropped precipitously.[168] In a randomized trial performed by the National Cancer Institute of Canada in which the Dartmouth regimen was compared with the Dartmouth regimen minus tamoxifen, no survival advantage was shown to occur with the addition of tamoxifen.[169] However, there were more objective responses in the tamoxifen group, particularly in patients who would now be categorized as stage M1a. In an Intergroup study led by investigators at Memorial Sloan-Kettering Cancer Center, the Dartmouth regimen was compared with single-agent DTIC. In this large randomized study, no survival benefit was seen with the Dartmouth regimen. Of note, again there were more objective responses seen in the combination chemotherapy arm.[149] Further, in a randomized trial comparing the Dartmouth regimen with Melacine (Corixa Corp.), a melanoma cell-lysate vaccine, alone, survival rates were equally poor in both arms, but toxicity was significantly less with the vaccine.[170]

Immunotherapy

Since the early 1980s, two biologic therapy agents, interferon-alfa (2a and 2b) and interleukin-2 (IL-2) have been studied extensively in metastatic melanoma. In multiple studies of single-agent interferon alfa in metastatic disease, the objective response rate was approximately 15%. With single-agent interferon alfa, there are very few complete responses, and a survival benefit has never been demonstrated. Most responses are in patients with soft tissue or lymph node involvement (stage M1a).[171,172] Higher, more toxic doses appear more active, but low, nontoxic doses (1 to 3 million units/m^2 SC) appear inactive in the metastatic setting.[172] There is no randomized clinical study showing a survival benefit when interferon-alfa is added to any single agent, such as DTIC[164] or IL-2,[173] or to any combination therapy regimen, including the BOLD[174] and Dartmouth regimens.[175]

IL-2, originally known as T-cell-derived growth factor, was first reported by Rosenberg and associates[176] to have significant response

rates in metastatic melanoma when given at high doses. While it does activate several types of immune effector cells, including lymphokine-activated killer cells, natural killer cells, B and T lymphocytes, and macrophages, its mechanism of action remains unclear. Its principal anti-melanoma activity is believed to be mediated by the activation of melanoma-specific cytotoxic T cells. High-dose IL-2 has been extensively studied in metastatic melanoma. Two large series have been published using the high-dose schedule of 600,000 to 720,000 units/kg IV every 8 hours for 14 doses originally described by Rosenberg and associates.[176] The National Cancer Institute reported an overall response rate of 18% and a complete response rate of 5%, with some of the responses being quite durable.[177] Similar results were reported by Atkins and associates.[178] The striking finding in both studies was that of a few, very durable responses, some maintained for longer than 120 months.

Adoptive immunotherapy with lymphokine-activated killer cells does not appear to improve the response rate seen with high-dose IL-2 alone.[179] The response rate with tumor-infiltrating lymphocytes and IL-2 was reported to be 40%, but this has not been confirmed in a phase III trial.[180]

High-dose IL-2 can cause substantial toxicity. The patient must be hospitalized for administration of the drug and subsequent close monitoring. Major side effects include fluid retention, renal failure, myocardial ischemia, and neurologic changes. Patients with underlying cardiac, renal, or pulmonary disease are not candidates for high-dose IL-2 therapy.[181] Patients with any risk factors for cardiac disease should have a normal cardiac stress thallium study before receiving high-dose IL-2. Many low-dose, alternative IL-2 regimens have been evaluated, including low-dose bolus administration, continuous infusion, and SC administration. Although these regimens are associated with less toxicity, none has shown a significant objective response rate and none has provided long-term remission. Polyethylene glycol modified-IL-2[182] and liposomal IL-2[183] have not shown any substantial clinical benefit.

Based on the in vitro synergy between IL-2 and interferon alfa-2b in metastatic melanoma, several clinical trials have been conducted combining the two agents. Activity was seen only with doses of IL-2 that required inpatient administration.[173] The hope that combined therapy with relatively nontoxic, low-dose, outpatient IL-2 and interferon would yield significant clinical activity in metastatic melanoma has not been realized.

Biochemotherapy

In the early 1990s, several investigators began to study intensive regimens that included combination chemotherapy and the biologic agents interferon alfa-2b and IL-2. Single-institution studies showed significant objective response rates. Richards and colleagues[184] combined BCNU, cisplatin, and DTIC with high-dose IL-2 and interferon in a sequential fashion and obtained an overall response rate of 55% and a complete response rate of 14%. Legha and colleagues[141] combined the cisplatin, vinblastine, and DTIC (CVD) chemotherapy regimen with continuous-infusion IL-2 and SC interferon alfa-2b, first sequentially and then in a combined regimen, with all of the drugs given over a 5-day period and the cycle repeated every 3 weeks. The combined regimen consisted of cisplatin, 20 mg/m^2 IV on days 1 through 4; vinblastine, 1.5 mg/m^2 IV on days 1 through 4; DTIC, 800 mg/m^2 IV on day 1 only; IL-2, 9 million units/m^2 daily by continuous infusion on days 1 through 4; and interferon alfa-2b, 5 million units/m^2 SC on days 1 through 5, and on days 7, 9, 11, and 13; and was repeated every 21 days. The authors reported an overall response rate of 64% and a complete response rate of 21%. The combined regimen seemed as active as the more protracted sequential regimen.

Two large single-institution randomized phase III studies have been reported comparing combination chemotherapy with biochemotherapy. The National Cancer Institute Surgery Branch compared a regimen of cisplatin, DTIC, and tamoxifen with the same regimen followed immediately by high-dose IL-2 and interferon alfa-2b. The overall response rate was higher in the biochemotherapy arm, but median survival was superior in the chemotherapy arm (15.8 vs. 10.7 months).[185] At M.D. Anderson Cancer Center, CVD was compared with CVD plus IL-2 and interferon alfa-2b given sequentially. The overall response rate and median survival rate were superior in the biochemotherapy arm (48% vs. 25% and 11.8 months vs. 9.5 months, respectively).[186]

The encouraging results reported in these studies led to a large randomized Intergroup study led by ECOG (protocol 3695).[142] This study compared CVD with the combined CVD, IL-2, and interferon alfa-2b regimen of Legha,[141] with several modifications, including reducing the dose of vinblastine by 25%, using prophylactic G-CSF, and limiting the number of chemotherapy cycles to four. This modified Legha biochemotherapy regimen previously was studied in a phase II trial and yielded an objective response rate of 48% and a complete response rate of 20% in 40 patients.[187] In ECOG 3695, 416 patients were enrolled between 1998 and 2002 and no previous chemotherapy or IL-2 was permitted. Sixty percent of the patients had received high-dose interferon alfa-2b prior to the development of metastatic disease. The overall response rate was 17.1% in the biochemotherapy arm vs. 11.4% in the chemotherapy arm, and complete response rates were 3% vs. 1.4%, respectively. OS was equally poor in both arms of the study, 8.7 months for biochemotherapy vs. 8.4 months for chemotherapy.[142] The results of this large, well-done, randomized trial were very disappointing. It may be that the reduced vinblastine dose and the lack of familiarity by physicians and nurses with the complex biochemotherapy regimen contributed to the low response rates in the cooperative group setting. However, the results show that biochemotherapy, as given in this trial, leads to very few durable responses and should not be considered a standard therapy. It is possible that when this study is published with a more detailed analysis, subsets of patients may be identified who are more likely to benefit from biochemotherapy, such as those who have an excellent performance status, low-volume disease, or no previous treatment with interferon alfa-2b. It seems unlikely that any variation of biochemotherapy currently being evaluated will prove superior to the regimen studied in ECOG 3695.

O'Day and colleagues[188] explored the use of maintenance biotherapy (IL-2 and GM-CSF) for patients who achieved stable disease or partial remission with biochemotherapy. One hundred thirty-three patients were enrolled and treated on a 1-year program consisting of IL-2, 1 million units/m^2 SC Monday through Friday; GM-CSF, 125 μg/m^2 SC, 2 weeks on and 2 weeks off; and seven 2-day IV infusions of decrescendo IL-2. The reported 12- and 24-month survival was 57% and 23%, respectively, and 12% of patients were disease-free at a median follow-up of 30 months. Although the results are intriguing, in light of the low response rates to biochemotherapy reported in the ECOG 3695 trial, it seems that only a very small number of patients would benefit from this approach.

New Therapies

New treatment options are under development for patients who have advanced locoregional or widely disseminated melanoma. From a clinical and basic research perspective, melanoma occupies the crossroads of molecular biology and immunology. As an externally visible tumor, it offers a unique opportunity to investigate lesions at the earliest stages of carcinogenesis for molecular events or signatures portending progression, invasion, and dissemination. Knowledge of the genetic basis for aggressive melanoma behavior has led to the design of molecularly targeted therapies. In addition, melanoma is among the most immunogenic of all human cancers, and as such has been the prototype for defining cancer-specific antigens and developing anti-cancer immunotherapies.

IMMUNOTHERAPY

Cancer vaccines are a form of active immunotherapy, the effects of which depend on target-specific activation of the patient's immune system. Vaccines directed against melanoma-associated or melanoma-specific proteins (antigens) have proved capable of enhancing anti-tumor immune responses in patients that can be detected in vitro, and yet have had limited clinical success in the setting of advanced metastatic disease. Most melanoma vaccine trials for advanced melanoma have been nonrandomized phase I/II studies. These have included inoculation with whole melanoma cells or gene-modified cells, heat shock proteins, naked DNA, recombinant viral vectors, recombinant proteins, synthetic peptides, and dendritic cells pulsed with peptides or cell lysates.[189] Peptide vaccines have been studied most intensively, due to ease of manufacturing at relatively low cost, low potential for toxicity, and well-developed laboratory techniques for immunomonitoring. The targeted antigens have included commonly expressed cancer-testis antigens (e.g., MAGE, NY-ESO-1) and melanoma differentiation antigens (e.g., tyrosinase, gp100, MART-1/Melan-A). Clinical trials have explored the best way to administer peptide vaccines, whether as a single peptide, with multiple peptides binding to HLA class I alone or to both class I and class II (eliciting both cytotoxic and helper T cell responses); with amino acid substitutions that augment their immunogenicity; or in combination with other biologic agents. However, the results of melanoma vaccine trials to date, and cancer vaccine trials overall, have been generally disappointing in the setting of advanced disease, with objective response rates of less than 5%.[190] It is possible that melanoma vaccines will be more efficacious in the adjuvant setting, against microscopic disease burdens.

The immunosuppressive in vivo milieu of the tumor microenvironment is now thought to play a critical role in determining the outcome of interactions between the immune system and cancer. Recent studies indicate that immune responses are tightly regulated by positive and negative signals, through receptor-ligand interactions on the cell surface. Specific interactions between costimulatory or coinhibitory receptors on resting and activated T lymphocytes (CD28 family of molecules), and their ligands on tumor cells or professional antigen presenting cells (B7 family), trigger biochemical signals leading to cascades of transcription and expression of downstream genes in the cell nucleus. These are among the earliest events regulating the initiation, differentiation, functional maturation and termination of innate and adaptive immune responses. CTLA-4, an inhibitory member of the CD28 family of molecules which binds to B7.1 and B7.2 on antigen presenting cells, has been recently targeted in phase I and II clinical trials via infusions of blocking antibodies to treat patients with advanced stage III/IV melanoma.[191,192] Objective response rates (complete + partial responses) of 13%, including durable complete responses, have been observed, but a significant rate of serious autoimmune complications (approximately double the response rate) has limited the use of this agent.[193] Current investigations aim to identify molecular markers that might make it possible to select patients most likely to benefit from this therapy and least likely to develop autoimmune responses. However, available clinical data indicate a significant correlation between autoimmunity and tumor regression,[192,193] consistent with the mechanism of action of anti-CTLA-4. Blocking antibodies directed against other CD28 and B7 family members are under clinical development, and based on information from preclinical models they may provide a more favorable therapeutic ratio than anti-CTLA-4. These include antibodies blocking PD-1, a co-inhibitory receptor on T cells, and B7-H1, a ligand for PD-1 that is expressed on most melanomas.[194] Because preliminary data have revealed PD-1 expression on highly activated melanoma-specific T cells stimulated by cancer vaccines and other means, the combination of PD-1:B7-H1 blockade with immunization is envisioned for future clinical trials.

Adoptive immunotherapy, a form of passive immunotherapy involving the transfer of ex vivo-expanded tumor-specific T lymphocytes into immune-replete or depleted patients, has been under study for the past two decades as a treatment for advanced metastatic melanoma.[195] Preclinical models have indicated the potential advantages of removing tumor-specific lymphocytes from the immunosuppressive in vivo milieu, and manipulating them in vitro to express a "favorable" phenotype of rapid proliferation and anti-tumor reactivity (cytokine secretion, cytolysis, highly avid T cell receptors) prior to transfer back into the autologous cancer-bearing host. For patients with at least one surgically resectable metastatic lesion, tumor infiltrating lymphocyte (TIL) therapy seems to offer the highest probability of objective clinical response. Adoptive TIL transfer in the context of lymphodepleting chemotherapy and high-dose IL-2 has yielded an objective response rate of 51%, including heavily pretreated patients who have not responded previously to high-dose IL-2 therapy.[196] As expected, serious toxicities related to chemotherapy-induced cytopenias and IL-2 administration, as well as some significant autoimmune events, were encountered. For patients without resectable tumors, or whose tumors fail to yield reactive TIL, alternative T cell transfer options have been explored in the clinic. These include melanoma peptide-specific T cell clones and cell lines derived from peripheral blood,[197,198] or peripheral blood lymphocytes genetically engineered to express melanoma peptide-specific T cell receptors.[199] These approaches have yielded relatively low objective response rates (0 to 15%), possibly due to the lack of T cell help, failure of transferred T cells to traffic to tumor sites, expression of PD-1 or other coinhibitory receptors on T cells, or emergence of antigen-negative tumor variants. Currently, clinical development of adoptive T cell transfer still is restricted to a limited number of medical centers due to the complex and intensive nature of this treatment.

Anti-Angiogenic Agents

Melanoma is a highly vascular tumor, and because new blood vessel formation is thought to play an important role in its pathobiology, the clinical use of anti-angiogenic agents is being actively investigated in advanced metastatic disease. Thalidomide, which has anti-angiogenic as well as immunomodulatory properties, is ineffective as a single agent against metastatic melanoma.[200] However, recent clinical trials have investigated the activity of thalidomide in combination with extended dosing of temozolomide. In a phase II trial which excluded patients with brain metastases or prior chemotherapy, an objective response rate of 32% was observed among 38 patients with advanced stage IIIC or IV disease.[201] A markedly lower response rate of 12% was observed in a phase II study using the same dosing regimen, which included patients with brain metastases and prior chemotherapy.[202] Of note, a phase II trial of the same combination regimen in patients with brain metastases, with or without extracranial metastases, was discontinued prematurely because of a high rate of serious or lethal adverse events (31%), particularly thromboembolic events, in the absence of objective tumor regressions.[203] Newer anti-angiogenic agents evaluated in early-phase melanoma clinical trials include the thalidomide analog lenalidomide (CC-5013, Revimid)[204]; the anti-avβ3 integrin antibody MEDI-522[205]; and anti-vascular endothelial growth factor (anti-VEGF, bevacizumab, Avastin).[206] Owing to the mechanism of action of this class of antineoplastic agents, it is possible that disease stabilization, rather than objective tumor regression, will prove to be the most appropriate indicator of efficacy.[207]

Targeted Therapies

Recent scientific advances have increased our understanding of the molecular events promoting melanoma carcinogenesis and maintaining the cancer cell phenotype. Most commonly, these involve

aberrations in the mitogen-activated protein kinase (MAPK) pathway supporting cell proliferation, the phosphatidylinositol 3′ kinase (PI3K) pro-survival pathway, and/or the melanocyte-stimulating hormone (MSH)/microphthalmia-associated transcription factor (MITF) melanocyte lineage-specific survival pathway.[35,208] Knowledge of these genetic events has permitted the rational targeting of critical molecules supporting melanoma growth and survival.[209] In the largest randomized trial conducted to date in patients with advanced stage III/IV melanoma, Bcl-2 antisense oligonucleotide (oblimersen, Genasense [Genta Incorporated]) was combined with DTIC in an attempt to enhance the chemosensitivity of melanoma cells by blocking pro-survival mechanisms. Studies have shown variable overexpression of Bcl-2, which inhibits the intrinsic apoptosis pathway, in melanomas. Compared to patients treated with DTIC alone, patients receiving the combination regimen showed small but statistically significant increases in objective response rate, durable response, and progression-free survival. Increased benefits were observed in a subset of patients with normal serum LDH, suggesting that such patients should be selected for future trials with oblimersen.[210]

BRAF is a member of the MAPK signaling pathway, which transduces extracellular signals via cell surface receptor tyrosine kinases to promote cell activation and proliferation. A somatic Val600Glu missense mutation in the kinase domain of BRAF is associated with more than 50% of melanomas, as well as with smaller percentages of some other cancers, and causes constitutive activation of the MAPK pathway contributing to melanoma progression.[25] The multikinase inhibitor sorafenib (Nexavar [Onyx Pharmaceuticals]), which targets mutant and wild-type BRAF as well as c-Kit, VEGFR-2, VEGFR-3, and some other proliferation and angiogenesis receptors, recently was shown to be ineffective against advanced melanoma as a single agent.[211] In addition, in 2006 the corporate drug sponsor announced failure to demonstrate improvement in PFS, the primary endpoint, in its international randomized phase III trial comparing sorafenib to placebo in combination with carboplatin and paclitaxel in chemotherapy-refractory patients with advanced melanoma.[212] An ECOG trial that is of similar design but targets chemotherapy-naïve patients and has OS as its endpoint, is currently in progress.

Several clinical trials exploring the efficacy of imatinib (Gleevec) in advanced melanoma have been conducted, despite varied data regarding the expression of c-Kit tyrosine kinase receptor in melanoma.[213,214] The results of two phase II trials using high-dose imatinib as a single agent have shown no evidence of clinical efficacy.[215,216] However, a recent report has demonstrated the association of genetic abnormalities in c-Kit (mutations, amplifications) with distinct clinical subtypes of melanoma, specifically acral melanoma, mucosal melanoma, and melanomas arising from chronically sun-exposed skin.[32] Kit abnormalities were not observed in melanomas arising from skin without chronic sun damage. Of note, this pattern of genetic abnormality is distinct from that observed in melanomas with mutated NRAS/BRAF, underscoring the fact that clear genetic subtypes of melanoma exist. Thus, rational selection of patients for treatment with imatinib as well as other molecularly targeted agents in future clinical trials will depend on the identification of subsets of melanoma patients harboring the relevant genetic alterations.

Ending Treatment

Patients with a poor performance status, comorbid conditions, multiple brain metastases, or advanced age are unlikely to benefit from intensive systemic therapy. These patients also may experience more side effects than healthier patients from the currently available therapies. Providing comfort measures only may be a reasonable option in some patients with metastatic melanoma. Likewise, if first-line therapy for metastatic melanoma has been unsuccessful, the patient should undergo a thoughtful assessment of his or her overall status before additional anti-tumor therapy is given. In any case, supportive care and comfort measures are essential aspects of oncologic practice.

Special Clinical Situations in Stage IV Disease

Solitary Metastasis

Occasionally, patients have a solitary metastatic lesion. There have been several reports of prolonged survival after surgical resection of solitary brain, lung, and liver metastases, regardless of whether patients also received postoperative adjuvant therapy.[146] A number of clinical trials are underway for patients with stage IV melanoma and no evidence of disease, and patient enrollment should be strongly considered. There is no established role for adjuvant therapy in this setting, including interferon alfa-2b, outside of a clinical trial.

Brain Metastasis

Patients with brain metastases generally do poorly. Standard therapy is whole-brain irradiation, which offers some palliation. Patients with a solitary brain lesion and no disease elsewhere, or responding or slowly growing systemic disease, should be considered strongly for neurosurgical resection, stereotactic radiosurgery, or gamma-knife therapy.[217] For patients with multiple brain metastases and a good performance status, consideration should be given to stereotactic radiosurgery or gamma-knife surgery, after whole-brain radiation. Those patients with measurable brain metastases also should be considered for temozolomide therapy, in addition to local measures, because this is the only systemic treatment that penetrates the blood–brain barrier. In the appropriate setting, these approaches can provide significant local control and palliation.

Unusual Problems

Unknown Primary Site

Patients can present with stage III or IV disease without a history of previously diagnosed melanoma. All of these patients should have a thorough skin examination, including the anal region. An eye examination is appropriate if the metastatic pattern is consistent with ocular melanoma. Unless there are specific intestinal or gynecologic signs or symptoms to suggest a mucosal primary, invasive tests, such as colonoscopy or upper endoscopy, are not recommended. Often a primary site is not found. Sometimes patients provide a history of an unusual skin lesion arising and disappearing without biopsy or treatment, or a history of a skin lesion that was cauterized or frozen. Patients who appear to have only regional lymph node involvement should undergo a potentially curative regional lymph node dissection, like any other patient with regional metastases. These patients should then be considered for systemic adjuvant therapy. Patients with isolated or disseminated metastatic disease should be treated according to the same paradigms as those with known primaries. Periodic follow-up with a dermatologist still is recommended.

Uveal Melanoma

Uveal, or ocular, melanoma is rare. Although it can be morphologically similar to cutaneous melanoma, clinically it behaves differently. Primary ocular melanoma most often is treated with iodine 125 plaque brachytherapy or enucleation.[218] Ocular melanoma metastasizes via a hematogenous route, often spreading primarily to the liver. Sometimes the metastatic process moves relatively slowly, with several years passing before recurrence with metastatic disease. It appears to respond less often to chemotherapy and biologic therapy, although this was not confirmed in a review of the SWOG experience.[219] Some biologic correlates may explain these differences: human leukocyte antigen expression appears downregulated on ocular melanoma cells,[220] the BRAF mutation is not present,[221] and distinct chromosomal abnormalities, such as monosomy 3, are present.[222] Although initial results using the BOLD plus interferon alfa-2b regimen in metastatic ocular melanoma were promising, these results were not

confirmed in a large trial.[223] Some patients with primarily liver metastases appear to benefit from chemoembolization[224] or liver perfusion.[225] Many clinical trials for metastatic melanoma exclude patients with ocular melanoma.

Mucosal Melanoma

Primary mucosal melanoma also is rare. Patients often have advanced disease at the time of initial diagnosis because primary sites in locations such as the gastrointestinal tract or sinuses make early detection difficult. This, too, appears to be a distinct disease, although morphologically similar to cutaneous melanoma.[32,35] Interestingly, a retrospective analysis showed a surprisingly good response rate of 44% for biochemotherapy in 18 patients with metastatic anorectal melanoma.[226] Currently, treatment options for metastatic disease are the same as those for cutaneous metastatic melanoma.[227]

TREATMENT COMPLICATIONS

Serious postsurgical complications are uncommon. The risks of bleeding and infection after most surgeries for melanoma are small. After sentinel node biopsy, some patients have a transient lymphocele at the site of node excision. The risk of lymphocele can be minimized by tying off the lymphatics during the sentinel node resection. If a lymphocele is large or painful, a simple office aspiration should provide adequate management. Small, asymptomatic lymphoceles can be observed and usually resolve on their own. Lymphedema has been reported in patients after sentinel node biopsy of the axilla and the inguinal area, but the incidence is low.[228]

Complete lymphadenectomy for regionally metastatic melanoma carries a risk of seroma, sensory loss, and lymphedema. A few patients have a seroma or prolonged drain output. Lymphedema is the most feared common complication of lymph node dissection and can occur after axillary or inguinal lymphadenectomy. The risk of lymphedema in this population in general is low, and most cases are mild to moderate and controllable with diligent care.

FOLLOW-UP AND SURVEILLANCE PLANS

Most melanoma recurrences are recognized first by the patient him- or herself or on a routine physical examination. A study from the Sydney Melanoma Unit reported that 73% of all first melanoma recurrences were detected by the patients themselves.[229] Mooney and colleagues[230] reported the results of a surveillance program using physical examination, blood tests, and chest x-rays for 1004 patients with stage I or II cutaneous melanoma. Physical examination detected 72% of recurrences, constitutional symptoms indicated 17% of recurrences, and chest x-ray showed 11% of recurrences. Among the 373 patients followed in a surveillance program at the Yale Melanoma Unit, of the 78 patients who had recurrences, 76% were diagnosed by a complete history and physical examination alone.[231] Routine laboratory or radiologic studies have never been shown to be beneficial for follow-up of patients with early stage melanoma.

For patients with stage III or IV disease there is no consensus about utility of, or the optimal frequency of, routine surveillance imaging. Occasionally, false-positive lesion findings on CT scan can lead to anxiety, further diagnostic tests, or even biopsy of lesions that may be unrelated to the melanoma. CT scans are useful for evaluating suspected pulmonary, mediastinal or intra-abdominal metastases, and often are of greatest use in the evaluation of patients with symptoms that raise concern or new findings on physical examination.

In patients with known distant metastases, scans are most useful when the presence of additional metastases would alter the treatment plan or when better definition of lesions is required for treatment planning or patient entry into a research protocol. FDG-PET has a sensitivity of 78% to 100% in detecting metastatic melanoma. False-positive findings may be seen in patients with inflammatory processes, such as sarcoid, and in those with second primary tumors.[57,58,232] PET also can be used to determine the need for further diagnostic procedures, such as radiologically guided needle biopsy of suspicious, accessible lesions.

In a patient with symptoms, an abnormal finding on physical examination or laboratory tests, or an abnormal x-ray, the definitive diagnosis of metastatic melanoma can be made only by a biopsy. Excisional or needle biopsy is relatively easy to perform when the suspected metastasis is easily accessible. However, in the right clinical setting, radiologic studies are sufficient for a clinical diagnosis, especially if the metastases involve more than one site and the abnormality was not present on previous studies.

ISSUES FOR THE FUTURE

Today, most melanomas are found at an early stage and thus are very treatable. In fact, surgery often is the only necessary treatment. However, some melanomas are at an advanced stage when they are detected, and even some early melanomas eventually will recur. There is no routinely reliable and successful way to treat patients with advanced disease. Today the most important ways to improve melanoma-related survival are prevention and early detection.

Although much progress has been made in identifying the molecular defects that are common to malignant melanocytic lesions, few of these discoveries have thus far been translated to effective therapies. It is expected that further research in the molecular genetics and the immunology of melanoma will result in an explosion of information about the events governing melanoma onset and progression. Given the limited pathologic materials available for study, multi-institutional collaboration will be required to substantially improve our understanding of the pathogenesis of melanoma. Ultimately, these discoveries will provide the framework for the design of targeted therapies for future melanoma patients.

74 Nonmelanoma Skin Cancers: Basal Cell and Squamous Cell Carcinomas

Gary S. Wood, Juliet Gunkel, Daniel Stewart, Ellen Gordon, Mamad M. Bagheri, Manish Gharia, and Stephen N. Snow

SUMMARY OF KEY POINTS

Incidence
- 1 million new cases occur annually including 80% basal cell carcinomas (BCCs) and 20% squamous cell carcinomas (SCCs).
- Incidence is increasing 2% to 3% per year.
- SCC incidence is increased 18- to 36-fold in organ transplant recipients.

Etiology and Epidemiology
- Ultraviolet radiation from sun exposure is a major risk factor and causes mutations in key genes.
- Hedgehog signaling pathway mutations are involved in BCC pathogenesis.
- p53 mutations are involved in both SCC and BCC pathogenesis, as well as in the development of actinic keratoses, which are the precursors of SCCs.

Pathology and Biology
- Several histopathologic subtypes exist.
- The more infiltrative or poorly differentiated variants are more clinically aggressive (e.g., morpheaform BCC and spindle cell SCC).

Clinical Findings
- BCC and SCC are found mainly on sun-exposed skin.
- Classic BCC is a pearly, telangiectatic, variably ulcerated nodule or a pale, sclerotic plaque.
- Classic SCC is a flesh-tone or red, variably keratotic, variably ulcerated nodule.

Differential Diagnosis and Staging
- Amelanotic melanoma, keratoacanthoma, cutaneous metastasis, cutaneous lymphoma, cutaneous lymphoid hyperplasia, adnexal tumor, Merkel cell carcinoma, and sebaceous gland carcinoma are included in the differential diagnosis.
- BCCs that are large, deep, or infiltrative may be locally aggressive and recurrent but metastasize only rarely (<0.05%).
- SCCs have a greater metaststic rate, especially those that are large, deep, have perineural invasion, or are located on the dorsal hands, lips, ears, penis, or sites of chronic infection, ulceration, or radiation.

Primary Therapy and Salvage Therapy
- Primary treatment for both BCCs and SCCs is surgical. Mohs' surgery is preferred for ill-defined or aggressive lesions because it allows microscopic control of tumor margins.
- Alternative therapies include various forms of physical destruction and radiation therapy. Interferons and inducers of interferons (e.g., imiquimod) are proving useful in selected cases.
- Retinoids, COX-2 inhibitors, and difluoromethylornithine are promising chemopreventive agents.
- Combinations of surgery, radiation therapy, and chemotherapy can be used for metastatic disease.

Complications
- Complications are principally related to local factors and include local recurrence, destruction of adjacent structures, scarring, and loss of function.

Prognosis
- Relative to most other forms of cancer, the overall prognosis for BCCs and SCCs is very good. There are only about 2000 deaths annually in the United States as compared with about 1 million new cases diagnosed.
- Local recurrence is a problem for large, deep, or histologically infiltrative variants. SCCs with these features may also metastasize. The 5-year survival for patients with metastatic SCC is <50%.
- The rarer forms of nonmelanoma skin cancer have a significantly more aggressive clinical course as compared with BCC and SCC. These include sebaceous carcinoma, Merkel cell carcinoma, dermatofibrosarcoma protuberans (DFSP), and cutaneous angiosarcoma.

INTRODUCTION

Most nonmelanoma skin cancers (NMSCs) are basal cell carcinomas (BCCs) or squamous cell carcinomas (SCCs). However, several rarer forms of NMSC exist, including four malignant neoplasms discussed in this chapter: sebaceous gland carcinoma, Merkel cell carcinoma, angiosarcoma, and dermatofibrosarcoma protuberans (DFSP). Each of these neoplasms is discussed separately after a summary of genetic alterations in BCC, SCC, and selected genodermatoses. Understanding the genetic basis of skin cancer is an important step in improving prognosis among patients with these neoplasms. Analysis of germline mutations in familial cancer syndromes and somatic mutations in sporadic skin cancers is providing new information that will facilitate the diagnosis of cutaneous malignant diseases and revolutionize their management.

GENETICS OF NONMELANOMA SKIN CANCER

Advances in molecular genetics have allowed for key advances in our understanding of NMSC, the most common cancer in the United

States. Like visceral malignant neoplasms, cancer of the integument is caused by defects in the normal genetic code. These genomic defects are either germline mutations (those caused by inherited mutations) or somatic mutations (those caused by acquired mutations). Actual tumor formation, however, is a complicated process, usually requiring more than a single mutation and sometimes a combination of germline and somatic mutations. In addition, these cancerous cells are frequently altered in ways that help them escape detection by the host's immune system.

Tumor suppressor genes and oncogenes are two basic classes of genes that undergo mutations leading to skin cancer. Examples of tumor suppressor genes include the patched gene involved in development of BCC, p53 involved in development of SCC, and the xeroderma pigmentosum genes involved in development of BCC, SCC, and melanoma.[1–3] These genes can be further divided into tumor suppressor genes that directly participate in growth regulation, such as the patched and p53 genes, and those that participate indirectly and are called caretaker genes, such as the xeroderma pigmentosum genes encoding DNA repair enzymes.

Oncogenes are the other class of genes contributing to skin cancer formation. These are generally growth-signaling molecules that once mutated can perpetually lead normal cells to become malignant cells by altering cellular growth. One example is the *ras* oncogene implicated in several skin cancers, including BCC, SCC, and melanoma.[4,5]

Sonic Hedgehog Pathway

The sonic hedgehog (Shh) pathway has been implicated in both hereditary and sporadic cases of BCC. These tumors are the most common of all skin cancers, with an estimated 1 million new cases per year.[6] In the Shh pathway, the transmembrane protein receptor for Shh, known as patched1 (Ptch1), binds and inhibits another transmembrane protein called smoothened (Smoh).[7] Smoh is responsible for growth promotion, and binding by Ptch1 keeps this growth in check. However, when the soluble lipoprotein Shh binds Ptch1, this regulation is disrupted. Smoh is thus activated, and unregulated growth is promoted through downstream zinc-finger family transcription factors, such as gli1, gli2, and gli3.

The hedgehog pathway was originally elucidated in the fruit fly (*Drosophila melanogaster*), in which mutations in the gene cause segmental patterning defects, hence the name patched.[8] Involvement in human disease was found through analysis of nevoid BCC kindreds (Gorlin's syndrome, basal cell nevus syndrome).[9] Persons with this autosomal dominant disease have odontogenic cysts, skeletal defects, palmar pits, various associated visceral tumors (medulloblastoma, meningioma, fibrosarcoma, cardiac fibroma, and ovarian fibroma), and multiple BCCs by a median age of 20 years. Early analyses mapped the defect to a tumor suppressor gene on chromosome 9q22–q31.[10] This site proved to be the location of the *Ptch1* gene. It was later elucidated that patients with nevoid BCC syndrome inherit one defective chromosome 9q region with loss of heterozygosity in the *Ptch1* locus. Many BCCs from these patients show inactivation of the remaining *Ptch1* gene through acquired somatic mutations, consistent with the view that the BCC phenotype develops once both alleles are nonfunctional. Thus, *Ptch1* acts as a classic tumor suppressor gene in the skin. Mutations in *Ptch1* also are present in many sporadic BCCs, as are mutations in other Shh pathway genes, including *Smoh*, *Ptch2*, and *Shh*.[11]

p53 Mutations

The protein p53 is encoded by the *TP53* gene on chromosome 17p and is an important regulator of cell proliferation, DNA repair, and apoptosis.[12] *TP53* can act classically as a tumor suppressor gene or act in a dominant-negative role whereby abnormal, mutant p53 protein can bind normal p53 molecules and disrupt their function.

Inactivation of the p53 gene seems to play a principal role in the development of both premalignant actinic keratosis and SCC.[13] SCC is the second most common skin cancer, accounting for approximately 200,000 cases per year and 2000 deaths per year.[6] p53 mutations causing SCC are ultraviolet (UV) induced, and many are pyrimidine alterations with CC to TT changes.[14,15] It seems that it is both the loss of the tumor suppressor ability of p53 and the ability of UV irradiation to affect induction of apoptosis by p53 that leads to tumor formation.[13]

Mutations of *TP53* have been implicated in development of sporadic BCC.[15] It seems that UV-induced alterations similar to those in SCC are involved in BCC induction. Many of the mutations are CC to TT or C to T alterations, consistent with UV damage.

Mutations of Caretaker Genes

Tumor suppressor genes involved in maintaining genomic integrity are called caretaker genes.[16] Examples of diseases associated with cutaneous malignant tumors and known defects in caretaker genes include xeroderma pigmentosum, Bloom syndrome, Rothmund-Thomson syndrome, Werner's syndrome, and Muir-Torre syndrome.

The tumor suppressor genes involved in all of these familial syndromes have the common feature of being involved in an enzymatic DNA reparative process following a mutagenic insult. Defects in these genes inhibit the ability to repair genetic damage from naturally occurring events or environmental carcinogens such as UV radiation.

Xeroderma pigmentosum is a collection of autosomal recessive disorders characterized by severe photosensitivity with onset of cutaneous malignant lesions at a very early age. BCC, actinic keratosis, SCC, and melanoma develop during the first decade of life in persons without adequate photoprotection. Mutations in eight genes have been implicated in different xeroderma pigmentosum phenotypes, which vary in severity of cutaneous neoplasia and frequency of neurologic delay.[17] All xeroderma pigmentosum-associated genes encode proteins that are part of a DNA repair process known as nucleotide excision repair, which responds to UV-induced DNA damage.[3] These proteins recognize the damaged DNA, unwind the coiled DNA structure, and repair the damaged strand. Germline mutations in these genes result in defects in the repair process and their genomic caretaker role; however, actual tumor production is still caused by mutagenic inactivation of tumor suppressor genes such as *TP53* and activation of oncogenes such as *ras*.[18,19]

Rothmund-Thomson syndrome, Bloom syndrome, and Werner's syndrome all are rare autosomal recessive disorders that have known defects in helicase genes and affect nucleotide excision repair. Like xeroderma pigmentosum, these defects allow development of malignant skin lesions in affected patients. Rothmund-Thomson and Bloom syndromes both are marked by early onset of SCC; however, patients with Werner's syndrome seem to have only increased risk of melanoma. Other syndromes with helicase gene defects, such as Cockayne's syndrome and photosensitive trichothiodystrophy, have no associated increase in cutaneous malignant tumors. It is becoming clear that development of cutaneous malignant tumors is a complex process in which ability to repair DNA is but one part of an intricate pathway. It seems that other mutations in tumor suppressor genes and oncogenes, whether germline or somatic, are necessary to invoke a tumor phenotype, as seen in xeroderma pigmentosum.

Muir-Torre syndrome (MTS) is an autosomal dominant syndrome characterized by various sebaceous gland tumors and internal malignant lesions. The sebaceous gland tumors range from benign sebaceous adenoma to malignant sebaceous gland carcinoma predominantly on the face. Keratoacanthoma is another cutaneous neoplasm of variable malignant potential that has been reported in as many as 20% of MTS patients.[20]

In initial studies of MTS families, investigators identified germline mutations in the human *MSH2* gene.[21,22] Subsequently, mutations in human *MLH1* have also been identified in patients with MTS.[23] It seems that, like other caretaker genes, human *MSH2* and *MLH1* encode a type of DNA-mismatch repair enzyme involved in repairing errors in DNA replication that occur naturally at a low rate.

In cells that have this defect, the result is varying lengths of repetitive DNA sequences known as microsatellite instability.[23] This microsatellite instability can result in functional gene mutations and has been observed in keratoacanthoma and sebaceous tumors from MTS patients.[24]

ras Oncogene

Mutations in *ras* have been implicated in development of sporadic BCC, premalignant actinic keratosis, and sporadic SCC. They are among the most common mutations in human malignant disease.[25] ras proteins are small G-proteins responsible for transducing intracellular signaling. Activation of *ras* occurs only when guanosine triphosphate (GTP) is bound. The signal is attenuated by hydrolysis of GTP to guanosine diphosphate (GDP). Mutations in *ras* alter the rate of this hydrolysis, resulting in activated protein and promotion of cell growth and hence tumor growth. There is a class of proteins that deactivates ras by increasing GTP hydrolysis to GDP (GTPase-activating proteins).[26] There is evidence that alterations in GTPase-activating proteins are implicated in the development of sporadic BCC.

BASAL CELL CARCINOMA

Epidemiology and Pathogenesis

BCC is the most common malignant tumor in the United States and in other areas with predominantly white populations. Approximately 900,000 cases per year are identified in the United States.[6] Australia has the highest incidence of skin cancer, the incidence of BCC being more than 2% among men and that of SCC being approximately 1% among men.[27] The incidence of BCC has increased over the past decades in a manner similar to the increase in melanoma. It is estimated that the incidence of NMSC is increasing 2% to 3% yearly.[28] One study, conducted in New Hampshire, showed an annual increase in incidence of SCC of approximately 10% and of BCC of approximately 5%.[29] Cumulative UV exposure and, more important, severe sunburn during childhood and adolescence are risk factors for BCC.[30] Other associated risk factors are Fitzpatrick skin types 1 and 2, red hair, freckling in childhood, family history of skin cancer, male sex, and Celtic ancestry.[31] BCC is more common in lighter skinned African Americans than in darker persons.[32] Immunodeficiency secondary to acquired immunodeficiency syndrome or transplantation also is associated with increased risk of BCC. Other uncommon risk factors include exposure to arsenic and ionizing radiation, especially among patients who have received radiation for acne.

Keratin pattern and immunohistochemical results suggest the origin of BCC is the outer root sheath of the hair follicle below the isthmus.[33] The locally invasive characteristic of BCC could be related to the presence of abnormal hemidesmosome-anchoring fibril complex.[34] Genetic abnormalities and mutations are thought to play a major role in development of BCC, especially in inherited syndromes of BCC. Patients with xeroderma pigmentosum cannot repair the UV-induced DNA mutations; therefore, they are at increased risk of cutaneous carcinogenesis. Mutations in the hedgehog signaling pathway genes and *TP53* are important in the pathogenesis of sporadic BCC and those arising in patients with the nevoid BCC syndrome and xeroderma pigmentosum.[11,13, 35–37]

Clinical Manifestations

The most common location for BCC is the head and neck, especially the nose. BCC occurs on hair-bearing skin; mucosal surfaces are not involved. The major types of BCC include nodular, pigmented, superficial, and morpheaform. The typical nodular BCC is a dome-shaped, pearly papule with a telangiectatic surface and translucent rolled borders (Fig. 74-1). The surface might become ulcerated (Fig. 74-2). In darker skinned individuals, especially African Americans, the more darkly pigmented BCCs may be misdiagnosed as seborrheic keratosis or nodular melanoma. Superficial BCC is a well-demarcated erythematous scaly plaque with elevated borders that often occurs on the trunk or extremities. It might be confused with Bowen's disease or nummular eczema. The most difficult BCC to diagnose and manage is the morpheaform or sclerosing variant. This ill-defined, white, indurated plaque can be mistaken for a scar or localized patch of scleroderma and therefore is ignored by patient and physician, with resulting wide subclinical extension.

Figure 74-1 • Typical presentation of basal cell carcinoma on the nose.

Histopathology

In common nodular BCC, nodular masses of basaloid cells extend from the epidermis or outer root sheath into the dermis with surrounding connective tissue stroma (Fig. 74-3). A palisade arrangement of cells is present in the periphery. Sometimes as a result of tumor necrosis and disintegration, cystic spaces form. The

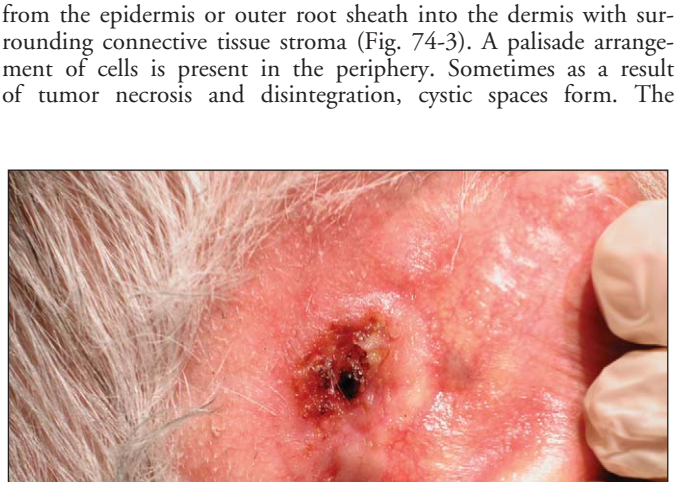

Figure 74-2 • Ulcerated basal cell carcinoma with rolled borders on posterior ear.

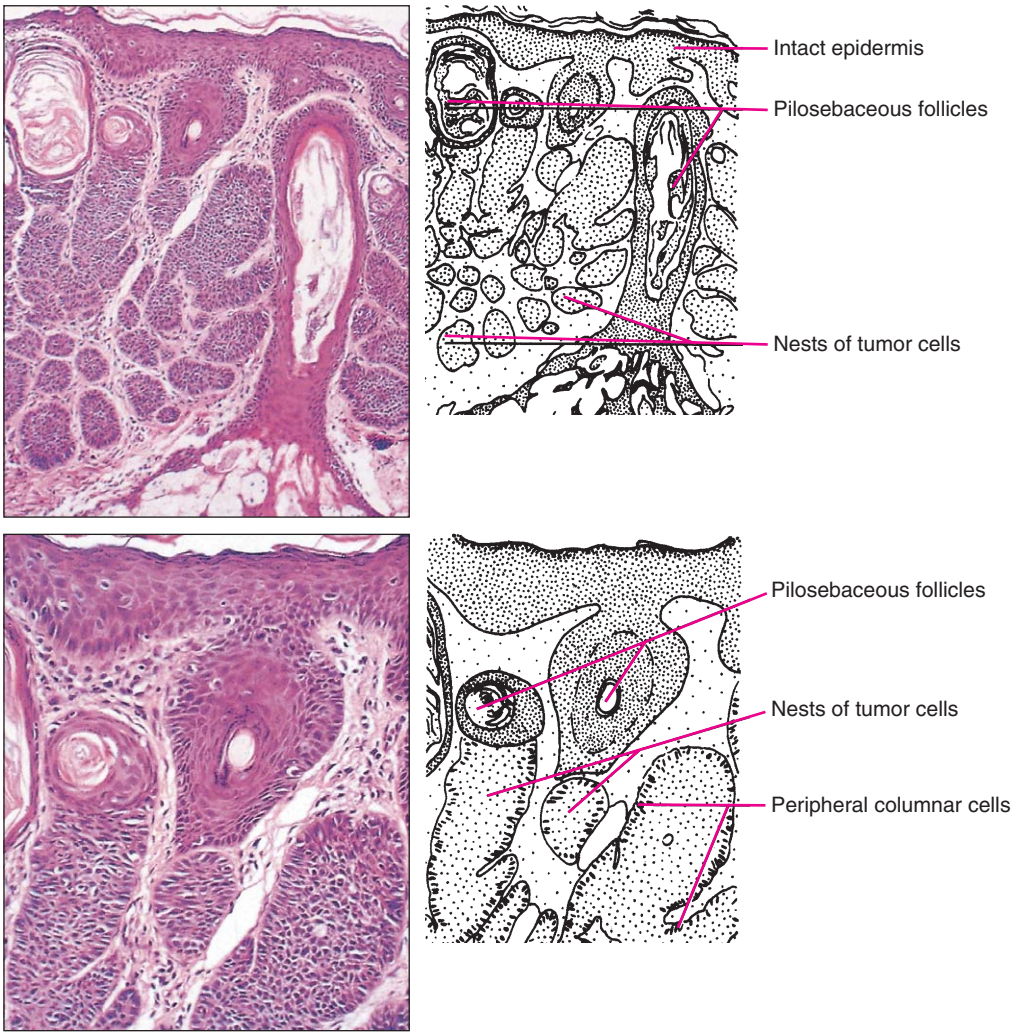

Figure 74-3 • Histopathology of basal cell carcinoma. (From Skarin AK [ed]: Atlas of Diagnostic Oncology, 3rd ed. St. Louis, Mosby, 2003, p 374.)

surrounding stroma may retract from the tumor mass forming the typical lacunae, a sign that aids in diagnosis. In the pigmented type of BCC, large amounts of melanin are produced in the melanocytes that colonize the tumor. The many melanophages in the surrounding stroma also contribute to pigmentation. The superficial type of BCC shows multifocal small nests of basaloid tumor cells budding off the epidermis and adnexa. Morpheaform BCC is different in that strands of tumor cells are embedded in a dense fibrous tissue stroma. These strands often extend in the deeper dermis. Micronodular BCCs contain small nodules of tumor cells that invade surrounding stroma. The morpheaform and micronodular types are generally the most locally invasive variants of BCC. It is common for BCCs to show mixed histologic patterns of these various types. Even the less invasive variants may invade deeply when located in regions of embryonic fusion planes, such as around the nose and ears.

Treatment

BCC is rarely metastatic but can be locally invasive (Fig. 74-4). Therefore, eradicating the primary tumor is the goal of therapy. Several treatment options are available, both surgical and nonsurgical. Selection depends on the tumor type, patient profile, size and location of tumor, recurrence, physician's experience, and patient preference. Surgical modalities include Mohs' micrographic surgery,

Figure 74-4 • Basal cell carcinoma of 10 years' duration invading the scapula.

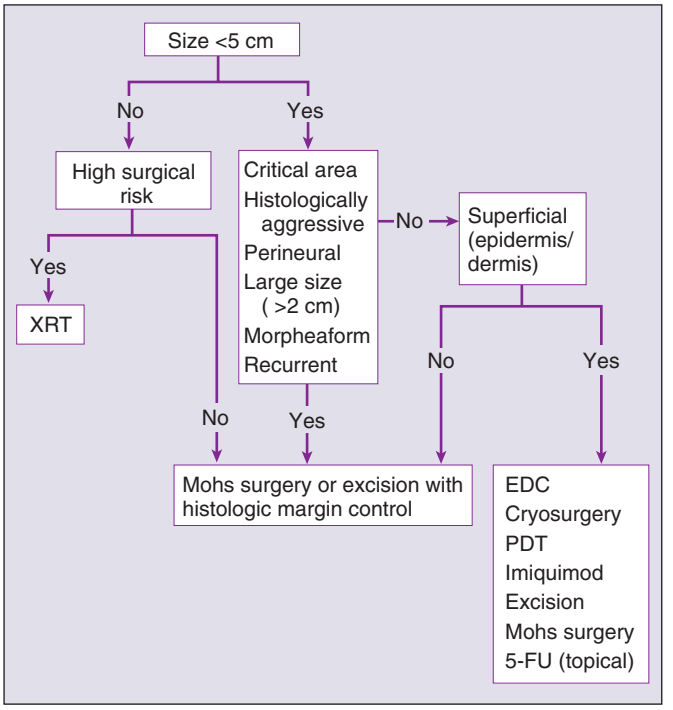

Figure 74-5 • Treatment for basal cell carcinoma. EDC, electrodesiccation and curettage; 5-FU, 5-fluorouracil; PDT, photodynamic therapy; XRT, radiation therapy.

surgical excision, cryosurgery, and electrodessication and curettage (EDC).[32] Nonsurgical options include radiation therapy and photodynamic therapy.[38] Other treatment modalities, such as immunotherapy with intralesional interferon[39] and topical 5% imiquimod (Aldara),[40] chemotherapy with 5-fluorouracil,[41] and retinoids,[42] have been reported with variable success (Fig. 74-5).

A systematic review of studies in which investigators reported recurrence rates of BCC after different treatment modalities showed that the mean 5-year recurrence rates after Mohs' surgery and surgical excision were approximately 1% and 5.3%, respectively.[43] Risk factors for BCC recurrence include greatest dimension larger than 2 cm, location in the midface (H zone) or ear, morpheaform or other aggressive histologic pattern, and long duration.[44] These tumors should be completely resected, preferably by Mohs' technique or excision with margin control. Mohs' surgery should be used in areas where preserving maximum tissue is important, such as eyelids, nose, and lips. It is also indicated for recurrent BCC and tumors with ill-defined clinical margins. If simple excision is used, the margin for excision should be at least 4 mm around tumors of 1 cm or less and 5 to 10 mm for tumors larger than 1 cm.[45] If there are contraindications to surgery, or the tumor is small and located on less critical sites such as the trunk, cryotherapy or EDC can be used with good outcome. Because of the less favorable long-term cosmetic results and possibility of secondary radiation-induced skin cancer, radiation therapy is best avoided in the care of relatively young patients. Very large or poorly controlled BCC may necessitate a coordinated approach of standard surgical excision, Mohs' surgery, radiation therapy, and immunotherapy or chemotherapy.[46]

Prognosis and Follow-up Evaluation

The prognosis of BCC is generally good. Metastasis is rare, and tumor growth is slow. Two thirds of recurrences occur during the fist 3 years after treatment.[47] The risk of development of another BCC is approximately 45% within 5 years.[48] The risk of development of another NMSC is associated with the number of previous NMSCs. In an Australian study of patients with three to nine previous NMSCs, the risk of development of a new cancer was 93%.[49] Patients treated for BCC need to be examined at least once a year for the first few years, preferably for 5 years after the last cancer was diagnosed. For patients with a history of multiple skin cancers, more frequent follow-up examinations are recommended. Photoprotection starting at a young age is advised to reduce the cumulative damage induced by the sun.

SQUAMOUS CELL CARCINOMA AND BOWEN'S DISEASE

Epidemiology and Pathogenesis

SCC is a malignant tumor of keratinocytes of the skin or mucosal surfaces. SCC has greater metastatic potential than BCC and causes the majority of NMSC deaths. SCC can arise de novo or from a precursor like actinic keratosis. Bowen's disease is a SCC in situ arising de novo. If Bowen's disease occurs on the glans penis or rarely vulva it is referred as erythroplasia of Queyrat. Bowen's disease can slowly progress into invasive SCC.

SCC is the second most common skin cancer in the United States, representing about 20% of NMSCs. Interestingly, SCC occurs more than BCC in blacks and Asians.[50] It is more common in men than women.[6] There are many risk factors for SCC, the most important being solar radiation. The incidence of SCC is increasing especially on the head and neck area as a result of exposure to sunlight.[51] SCC is thought to be correlated with recent (in the 10 years preceding diagnosis) chronic sunlight exposure[52] and cumulative sun exposure.[53] Phototherapy with PUVA (psoralen + ultraviolet A) increases the risk of SCC. Other risk factors for SCC include fair skin, red hair, albinism, and Celtic origin. Nonsolar risk factors include exposure to chemicals (insecticides and herbicides),[54] arsenic, organic hydrocarbons, chronic thermal injury and scars, ionizing radiation, and chronic immunosuppresion.[55] SCC is increased 18 to 36 times in organ transplant patients.[56] This increase of risk is correlated with the type of organ transplantation and elapsed time after transplantation. Heart transplant recipients have a higher risk of NMSC than kidney transplant recipients, possibly because of more intense immunosuppression.[57] Tobacco is a risk factor for oral SCC. Viruses, especially human papillomavirus (HPV), have been linked to epithelial malignancies including SCC. This is especially true among patients with epidermodysplasia verruciformis, who have an underlying immunodeficiency and can develop SCCs within HPV-infected warts.[55]

Carcinogens such as ultraviolet radiation (UVR), certain chemicals and viruses play a role in the pathogenesis of SCC by damaging keratinocyte DNA and other cellular contents. It is known that UVR, especially UVB, causes mutations in DNA of keratinocytes.[58] Early repair of these mutations is important for the prevention of SCC. Patients with NMSC are thought to have decreased ability for DNA repair compared with controls, thus making them more susceptible to the effects of UVR.[59] One example is the effect of UVR on DNA alterations in patients with xeroderma pigmentosum who are genetically unable to repair these defects. UVR also causes cutaneous immunosuppression, weakening the host's immune response against tumor cells and promoting tumor growth.[60,61] Studies of SCCs have shown that mutations in the *TP53* tumor suppressor gene are an early event.[2,62] Most of the mutations occur at dipyrimidine sequences, in the form of UV-induced cyclobutane pyrimidine dimers.[63] The development of SCC does not occur by a simple single step, but rather through a multistage process. Conversion of susceptible keratinocytes to premalignant cells and then progression to carcinoma occurs as a result of successive genetic hits.[64] In the initiation stage of carcinogenesis there is clonal expansion of premalignant cells. The next stage is increased proliferation of premalignant cells and

subsequent chromosomal aberrations. The final stage is conversion to SCC. DNA aneuploidy with a single peak was detected by flow cytometry in lesions of Bowen's disease, suggesting a monoclonal proliferation of abnormal keratinocytes and a clonal basis for skin cancer.[65] Aberrant expression of P-cadherin, and changes in expressions of cytokeratins and transforming growth factors all play a role in tumor progression.[66]

Clinical Manifestations

SCC occurs more on the head and neck area in whites, but in blacks there is no predilection for sun-exposed areas of the body.[67] SCC in situ may develop from premalignant lesions such as actinic keratosis or arsenical keratosis. In fact, in whites the majority of SCCs arise from actinic keratoses. These can eventually spread beyond the epidermis and become invasive. Invasive SCC can also arise from normal skin. It starts as a small, firm, dull red nodule, which can undergo central ulceration. Sometimes if SCC arises from solar keratosis an adherent keratotic scale can be seen. If ignored, the lesion grows horizontally and vertically and may become fixed to the underlying tissue. The surface might become ulcerated with bleeding, malodorous exudate or crust. The borders are usually elevated and firm. Occasionally a fungoid lesion without ulceration can be seen. SCC of the lower lip often arises from previously solar-damaged areas (actinic cheilitis). Initially local thickening of the vermilion border occurs that then progresses into a noduloulcerative lesion (Fig. 74-6). Persistent subungual erythema with pain and swelling should alert the physician for SCC of the nail region. This form of SCC may be confused with warts (Fig. 74-7). As mentioned earlier, SCCs can arise from chronic sinuses, scars, and chronic thermal damage.

Verrucous carcinoma is a distinct slow-growing low-grade type of SCC. The most common location is the plantar foot (epithelioma cuniculatum) but it can occur on the buttocks, genitals (giant condyloma of Buschke and Löwenstein), face, oral cavity (oral florid papillomatosis), trunk, nails, and extremities. It grows as an exophytic verrucous mass. Clinically, on the foot it can be mistaken for a plantar wart. It is locally aggressive and may penetrate into deep soft tissue or bone.

Bowen's disease often appears as a well-defined single red plaque with dry surface scaling. Lesions are slow growing and asymptomatic, thus ignored by many patients. The physician might initially treat it as psoriasis or nummular eczema with no response. There is a 3% to 5% chance that Bowen's disease can progress into invasive SCC.[68] Clinically erythroplasia of Queyrat resembles Bowen's disease but lacks the dry superficial scale. Instead the surface is moist and smooth.

Figure 74-6 • Squamous cell carcinoma of the lip of 5 years' duration.

Figure 74-7 • Squamous cell carcinoma of the nail bed. Patient was being treated for a wart.

The risk of metastasis of SCC is variable, depending on the site and tumor characteristics. The deeper and larger the tumor, the higher is the chance of metastasis. Recurrent tumors are at high risk for metastasis. Lesions with perineural involvement have a 35% metastatic rate.[69] Among the different histologic types, desmoplastic SCCs are more likely to metastasize.[70] The risk of metastasis of SCC derived from actinic keratosis is low (0.5% to 3.7%) compared with SCC arising in radiation-induced SCC and chronic osteomyelitis (20% and 31%, respectively).[71,72] High-risk areas for metastasis include tumors arising from the dorsal hands, lips, ears, and penis. For example, SCC of the lower lip has a 15% risk of metastasis.[73] Bowen's disease and erythroplasia of Queyrat also have a low chance of metastasis, but once they become invasive the risk of metastasis increases significantly.

Histopathology

A deep shave or punch biopsy that includes the base of the tumor is needed to distinguish SCC in situ from invasive SCC. Bowen's disease is carcinoma in situ. The stratum corneum is thickened, and epidermis is hyperplastic with disordered maturation of keratinocytes. Mitotic figures, mutinucleated keratinocytes, and dyskeratotic cells with hyperchromatic nuclei and eosinophilic cytoplasm are seen in the epidermis. The histology of SCC shows masses of epidermal cells proliferating into the dermis. Atypical squamous cells and mitotic figures are seen (Fig. 74-8). The cells have abundant eosinophilic cytoplasm and large nuclei. Horn pearls, which are a result of keratinization of squamous cells, are seen. The dermis may show a marked inflammatory reaction. Spindle cell SCC is a rare variant composed of mainly spindle cells, but some squamous differentiation may be seen. Spindle cells have large vesicular nuclei and scant cytoplasm and intermingle with the collagenous stroma. Spindle cell SCC is poorly differentiated with numerous mitoses and deep invasion and requires immunohistochemistry to differentiate it from other spindle cell tumors. Another uncommon histologic variant of SCC is the acantholytic or adenoid SCC, seen more on the face and neck. There are nests of tumor cells with dyskeratotic cells and central acantholysis forming pseudoglandular structures.

Treatment

The treatment options for SCC are similar to BCC treatment, with some differences (Fig. 74-9). The first step is to estimate the peripheral and vertical extension of tumor cells. Tumors at high risk for local or distant spread are those larger than 2 cm or deeper than

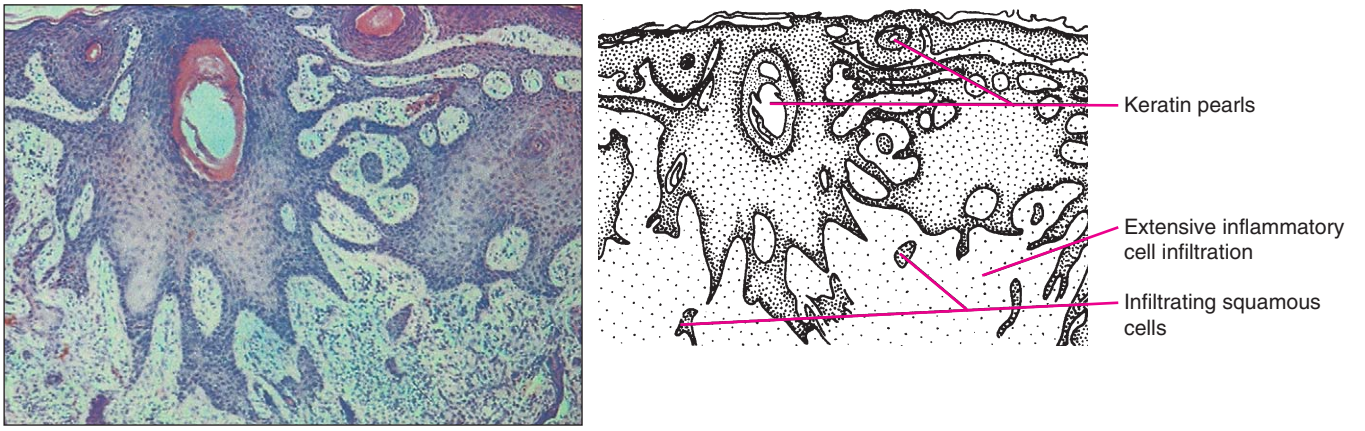

Figure 74-8 • Histopathology of squamous cell carcinoma. (From Skarin AK [ed]: Atlas of Diagnostic Oncology, 3rd ed. St. Louis, Mosby, 2003, p 376.)

6 mm, recurrent tumors, poorly differentiated tumors, and those with perineural invasion or arising in immunocompromised hosts.[74] Second, the patient should be evaluated for metastasis to the lymph nodes and other organs.

Destructive methods or surgical excision can treat Bowen's disease effectively. Small uncomplicated SCCs (<1 cm) in low-risk locations are frequently treated with EDC. Cryotherapy is an alternative treatment. Simple surgical excision with margin control is commonly used for smaller tumors and those on the trunk and extremities. The recommended margin for low-risk SCC is 4 mm and for high-risk tumor is 6 mm.[75] The excision should include the subcutaneous fat. Mohs' micrographic surgery is the treatment of choice for high-risk SCCs or for tissue preservation where tissue sparing is cosmetically or functionally vital.[76] Aggressive or deeply invasive SCCs are treated with deep surgical excision with margin control when practical. Mohs' surgery may be helpful in delineating critical areas in massive tumors or tumors with ill-defined borders. SCC invading surrounding structures such as bone and cartilage must also be excised. Tumors with neural or perineural involvement that are at high risk of recurrence should be completely excised preferably with the Mohs' technique. High-risk tumors may require adjuvant therapy with radiation therapy[77] or chemotherapy.[78,79]

Radiation can also be used as a primary choice of treatment. Usually 4000 cGy of radiation is given in 5 to 16 fractions. This form of treatment might be appropriate in the elderly at high risk for surgical complications or other patients with contraindications to

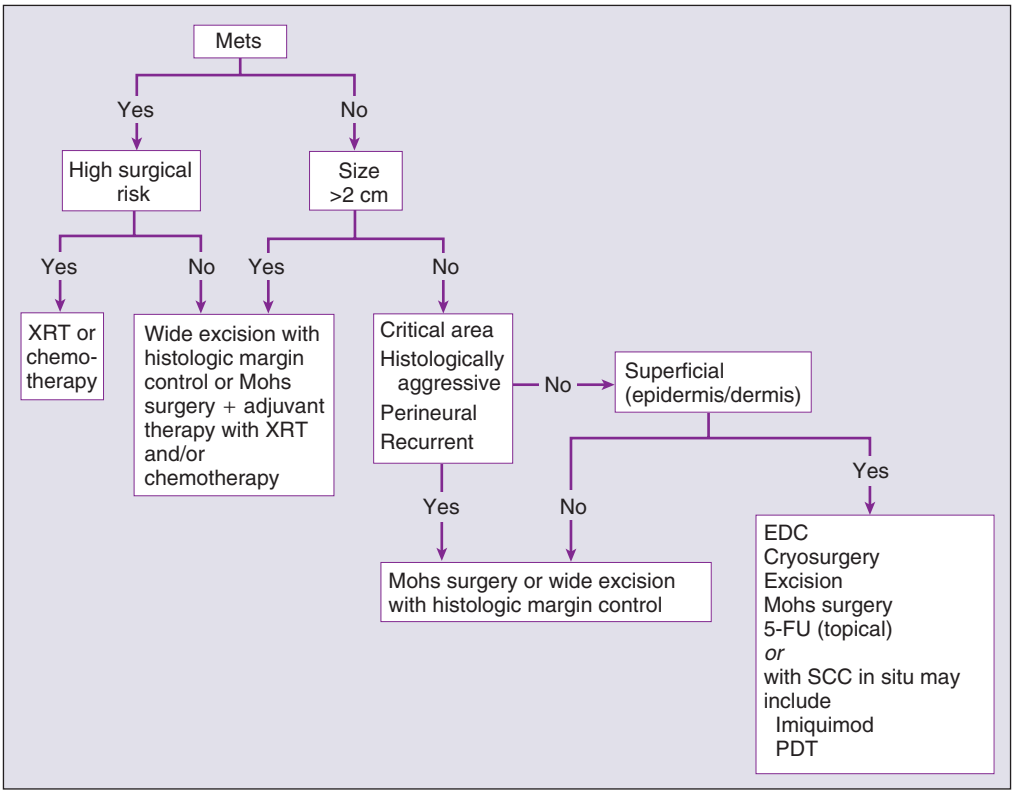

Figure 74-9 • Treatment for squamous cell carcinoma (SCC). EDC, electrodesiccation and curettage; 5-FU, 5-fluorouracil; PDT, photodynamic therapy; XRT, radiation therapy.

anesthesia or surgery. Radiation can be useful to treat tumors on the eyelids, nose, ears, and lips when surgery is not practical. The disadvantages are the cost, blind margin control, and prolonged treatment duration. The cure rate for tumors larger than 2 cm is about 85% to 95%.[80] Radiation therapy is best avoided in treating verrucous carcinomas and younger patients because of poor long-term cosmetic results. SCCs that have arisen from ulcers, scars, and irradiated sites are better removed by margin-controlled surgery than by radiation therapy.

If lymph node metastasis has occurred, treatment is wide surgical resection of tumor with regional lymph node dissection with or without adjunctive radiation. However, elective lymph node dissection is not commonly performed in the absence of evidence for regional spread. Sentinel lymph node biopsy may be considered.[81]

For patients with Bowen's disease or advanced SCC, chemotherapy with isotretinoin alone or in combination with α interferon has been used with success.[82,83] Promising chemopreventive agents for lesions in the actinic keratosis–SCC spectrum include retinoids, COX-2 inhibitors, and difluoromethylornithine.

Prognosis and Follow-Up

SCCs in general have a greater potential for recurrence and metastasis than BCCs; therefore, the follow-up must be more aggressive. The patient should be followed at close intervals (every 3–6 months) for the first several years, depending on the location, size, aggressiveness, and node status of the primary tumor. The exception would be small SCCs arising from actinic keratoses on sun-exposed surfaces, where the rate of metastasis is very small (0.5%). In these patients, routine follow-up every 6 to 12 months is all that is required.

KERATOACANTHOMA

Keratoacanthomas are common cutaneous neoplasms that are thought to derive from the infundibular portion of hair follicles. They most often present as solitary rapidly growing, pink or flesh-colored, dome-shaped, or cratiform nodules. They occur most commonly on sun-exposed areas in fair-skinned elderly individuals. Keratoacanthomas are historically characterized by their spontaneous involution over several months with residual atrophic scarring and local tissue destruction. Histologically, a mature keratoacanthoma has a distinctive architecture characterized by a keratin-filled crater lined by a proliferating squamous epithelium with abundant pale eosinophilic "glassy" cytoplasm, epithelial lipping, and multiple keratin horn pearls with central orthokeratosis. Cytology is often indistinguishable from that of a well-differentiated cystic SCC. At the base of the tumor, islands and strands of atypical cells may invade the dermis. Frequently there is a heavy inflammatory infiltrate at the base of the lesion comprising lymphocytes, plasma cells, neutrophils, and eosinophils. Atypical mitoses as well as perineural and perivascular invasion may also be present, particularly in tumors involving the head and neck. Several cases of highly aggressive and metastatic keratoacanthomas have also been reported; however, some have questioned whether these were truly keratoacanthomas or rather keratoacanthoma-like SCCs.[84]

Although most cases of keratoacanthoma are solitary, subsets of individuals with multiple keratoacanthomas have been described. These include the familial Ferguson Smith type comprising multiple keratoacanthomas at an early age, and the generalized eruption of thousands of small keratoacanthomas as described by Grzybowski (see ref. 84). Keratoacanthomas frequently occur in individuals with the Muir-Torre syndrome, xeroderma pigmentosum, and solid-organ transplantation.[85] They also occur in areas of scarring from prior trauma, thermal burns, and surgical treatment, and in association with many benign conditions such as stasis dermatitis, lichen planus, lichen simplex chronicus, psoriasis, and discoid lupus erythematosus.

Debate exists as to whether keratoacanthomas are a distinct clinical entity or a subtype of well-differentiated SCC. Significant efforts have been made to find practical, reliable criteria to distinguish keratoacanthoma from SCC, but none have yielded reliable criteria for routinely distinguishing these entities. Recent studies with the apoptotic marker $P2X_7$ and with comparative genomic hybridization suggest that keratoacanthoma and SCC possess distinct genetic aberrations that result in separate developmental pathways.[86,87] These findings may provide an avenue in the future for reliable separation of keratoacanthoma and SCC. However, given the potential for local destruction and metastatic disease, it is recommended that keratoacanthomas be treated in the same manner as SCCs. Complete conservative excision is the most common treatment technique for keratoacanthomas. Radiotherapy, EDC, systemic medications, and topical and intralesional modalities have been reported with varying success.

NONMELANOMA SKIN CANCER IN IMMUNOCOMPROMISED HOSTS

The incidence of NMSC is significantly increased in patients who are immunocompromised secondary to human immunodeficiency virus/acquired immunodeficiency syndrome, heritable immunodeficiencies, the effective immunosuppression of chronic lymphocytic leukemia, and immunosuppressive medications. Patients with human immunodeficiency virus infection, congenital immunodeficiency, and lymphoma manifest decreased immunosurveillance due to defects in cell-mediated immunity. An increased susceptibility to infection with oncogenic HPV types may be important in the pathogenesis of Bowen's disease (SCC in situ), SCC, keratoacanthomas, and genital dysplasias in these patients.[88] Epidermodysplasia verruciformis is a rare inherited disorder of unknown etiology that predisposes those affected to widespread infection with HPV types 5 and 8, which is associated with the development of SCC. A history of UV exposure further compounds the risk in these populations.[89]

Iatrogenic immunosuppression, an important treatment modality for autoimmune diseases and for prevention of transplant rejection, is associated with both direct carcinogenic effects and decreased immunosurveillance. Solid-organ transplant recipients (OTRs) require long-term immunosuppression and, therefore, are at increased risk for BCC, melanoma, Kaposi's sarcoma, and especially SCC over their lifetime. The highest incidence is seen in heart transplantation followed by renal and then liver transplantation. The impact on public health is significant, in that more than 25,000 solid-organ transplants are performed in the United States annually, the majority being renal, and survival rates for OTRs are increasing. In OTRs, SCC can be more aggressive and the SCC/BCC ratio is increased.[90]

Factors associated with SCC in OTRs include sun exposure, epidermodysplasia verruciformis-associated HPV types 5 and 8, fair skin, heart transplant, older age at transplant, male sex, and intense immunosuppression. Indeed, intensity and duration of immunosuppression have been associated with development of aggressive SCC.[89] Studies suggest that antirejection therapies using tacrolimus, mycophenolate mofetil, or rapamycin versus cyclosporine, glucocorticoids, or azathioprine may decrease incidence of NMSC in OTRs.[89,91]

The burden of skin cancer, especially SCC, is markedly elevated in OTRs. The magnitude and severity of disease can be devastating.[90] Many are diagnosed with numerous lesions annually, each lesion with an increased potential for aggressive behavior and metastasis relative to occurrences in the general population.[92] Metastatic disease usually involves noncontiguous spread along lymphatic vessels and nerves, and represents a poor prognosis and therapeutic challenge.[93]

Management of NMSC in OTRs consists of the same treatment modalities described for NMSC in the general population. Increased vigilance including frequent follow-up, a high level of suspicion for new or changing skin lesions, and a low threshold for biopsy is

essential to ensure early detection and timely treatment. By stratifying lesions as lower versus higher risk (rapid growth, large size, recurrence, aggressive histology, or location on lip, ear, or scalp), those lesions more likely to recur or metastasize can be prioritized in a treatment regimen in OTRs with an overwhelming burden of disease.[90,93] Whereas topical agents, curettage, and cryotherapy may be appropriate for treatment of lower risk lesions, higher risk lesions usually require a surgical approach (excision or Mohs' micrographic surgery) to ensure clear margins. Radiation therapy can be an important adjunct for metastatic and perineural disease. Although the diagnostic and therapeutic role of sentinel lymph node biopsy in such cases is not established, it may be considered in selected high-risk cases.[89,90]

Data suggest that acitretin may be beneficial as a chemopreventive agent in this population. Moreover, reducing immunosuppressive therapy has been shown to decrease the development of NMSC and metastatic disease, although coordination with the primary transplant physician is essential to avoid allograft rejection.[89,90]

SEBACEOUS CARCINOMA

Epidemiology and Pathogenesis

Sebaceous carcinoma is a rare, potentially devastating tumor derived from the adnexal epithelium of sebaceous glands. Principally, the tumor occurs in two different clinical scenarios: ocular sebaceous carcinoma (OSC) and extraocular sebaceous carcinoma.[94,95] OSC accounts for 0.2% to 0.8% of all eyelid tumors and 1% to 1.5% of all malignant tumors of the eyelid. Approximately 400 cases have been described in the English literature.[96] OSC affects women 1.5 times more frequently than men; however, a slight male preponderance occurs in cases of extraocular sebaceous carcinoma.[97–101] The mean age at diagnosis is 65 years (range, 40–60 years), but OSC has been reported in young children (12 years of age, after radiation therapy for retinoblastoma) and in persons as old as 90 years.[102,103] Sebaceous carcinoma seems to have a higher incidence in the Asian population.[102,104–106] This tumor has been associated with MTS, an autosomal dominant disorder of mismatch repair genes characterized by sebaceous tumors (benign and malignant) as well as other visceral malignant tumors.[20,107] Sebaceous carcinoma with microsatellite instability has been found in several renal organ transplant recipients.[107]

Clinical Manifestations

OSC typically manifests as a painless, slowly growing, yellowish papule (Fig. 74-10). The upper lid is affected two to three times more frequently than the lower lid. The tumor usually originates from the meibomian gland (sebaceous gland in the tarsus) or from a sebaceous gland of the eyelash (glands of Zeis).[101,103] Clinically, the signs can be subtle with only moderate lid thickening, eyelash alopecia, pale corneal changes, conjunctival injection, or thickening along the temporal or inferior temporal limbus.[97,108–110] There have been case reports of ipsilateral upper and lower eyelid involvement and bilateral upper and lower lid involvement.[96,109,111] The diagnosis is often elusive, because OSC is notorious for masquerading as more common ocular disorders, such as chalazion (most common), keratoconjunctivitis, blepharoconjunctivitis, SCC, BCC, granulomatous disorders, and benign neoplasms.[97,109–112] Initial recognition is 50% among ophthalmologists and only 18.6% among general practitioners.[113–115] Often there is a delay in diagnosis of 6 months to a year and in some series up to 2.9 years, contributing to increased morbidity and mortality.[97,113] With regard to the rarer extraocular sebaceous gland carcinoma, initial diagnosis can be elusive because the clinical appearance often is pleomorphic and nonspecific and varies from a banal-appearing nodule to large ulcerating masses.[116–119] This variant of sebaceous gland carcinoma most often occurs on the head and neck region, reflecting the abundance of sebaceous glands there.

Figure 74-10 • Ocular sebaceous carcinoma involving the lower eyelid.

Histopathology

Full-thickness biopsy is required to ensure adequate tissue sampling. Microscopic examination shows that OSC invades surrounding tissue by direct extension into the dermis or the overlying epithelium.[113,120,121] The tumor demonstrates epitheliotropic spread in 37% to 80% of cases. Atypical sebaceous cells have a pagetoid distribution within the conjunctival epithelium.[103,113] As many as 18% of cases of OSC may have multifocal regions of tumor involvement.[96]

There are basically two broad classification schemes with regard to light microscopic findings. Font[122] described three classes of tumor based on degree of differentiation: well differentiated, moderately well differentiated, and poorly differentiated. Others prefer to classify the tumor on the basis of growth pattern: lobular, comedocarcinoma, papillary, and mixed.[100] The intraepithelial neoplasia growth pattern and pagetoid spread are not addressed in this classification scheme. The histologic features are anaplastic cells with varying degrees of differentiation. Squamoid or basaloid features may be present.[97] Lobulated aggregates of basaloid cells usually contain irregular, hyperchromatic nuclei and vacuolated cytoplasm.[96,109,123,124] In cases of intraepithelial neoplasia, the epithelial pagetoid cells lack intercellular bridges and contain large hyperchromatic nuclei, prominent nucleoli, and abundant, pale-staining cytoplasm. Special stains, such as oil red O or Sudan black, often are helpful in delineating the atypical sebocytes; however, poorly differentiated tumors may not stain positively for lipids.[110,113] In addition, undifferentiated sebocytes often lack the foamy cytoplasm of their more differentiated counterparts and may resemble atypical SCC at standard hematoxylin and eosin staining.[97,109,123] Recognition of this particular biphasic nature of OSC is critical to appreciating the biologic behavior of this recalcitrant tumor. Ophthalmologists have known for years about the difficulty of assessing the tumor margins of this epitheliotropic neoplasm. It has been recommended that as many as nine mucosal biopsy specimens be obtained and mapped from the medial and lateral portions of the bulbar and palpebral conjunctiva of the upper and lower lids.[125,126]

Treatment

Evaluation of patients with known or suspected sebaceous gland carcinoma includes complete history with review of systems, family history and consideration of MTS, complete skin examination, and palpation of nodal basins and structures adjacent to the lesion. A chest radiograph, complete blood cell count, liver function tests, and electrolytes are recommended. If MTS is a consideration, colonoscopy is warranted.

Management of sebaceous gland carcinoma is primarily surgical, although there are a few reports of tumors managed primarily with radiation.[127] Given the paucity of cases, no randomized, controlled studies have been conducted to evaluate therapy. Traditionally, wide local excision with a margin of 4 to 6 mm of clinically normal tissue has been used.[97] Exenteration is recommended for extensive bulbar conjunctival involvement or evidence of orbital invasion.[101] In his personal series of 60 consecutive patients with a mean follow-up of 41 months, Shields and colleagues reported a local recurrence rate of 18%, exenteration of 13%, and metastasis of 8%.[113] Some experts consider Mohs' micrographic surgical technique the treatment of choice, because it preserves the maximum amount of healthy tissue. This quality is especially crucial in the treatment of ocular tissue.[109,113,128–131] In addition, it allows for microscopic examination of all margins of the obtained tissue to ensure complete tumor eradication. In 2002, we reported our results of nine cases treated by Mohs' micrographic surgery achieving a 90% success rate with 3-year follow-up.[118] Four of these patients have now gone 5 years without evidence of local recurrence in all patients (unpublished data).

Local recurrence usually is the result of inadequate management of the primary tumor.[97] If the recurrent lesion is small enough, treatment can be repeated with Mohs' micrographic surgery or local excision.[113] More extensive OSC tumor involvement usually necessitates exenteration.[115,124] Ophthalmologists have considered cryotherapy a useful modality in the management of epibulbar disease in a small subset of patients, and this therapy may be an alternative to exenteration.[105,132,133] Regional lymph node metastasis is managed by surgical resection and adjuvant radiation.

Prognosis and Follow-up Evaluation

Both OSC and extraocular sebaceous gland carcinoma are aggressive tumors that recur locally if inadequately managed and readily metastasize. Metastasis may occur through lymphatic vessels, and in the case of OSC, it is postulated to occur through the lacrimal and excretory systems.[97] Risk factors associated with poor prognosis include duration longer than 6 months; vascular or lymphatic involvement; orbital extension; poorly differentiated tumor morphology; multicentricity; pagetoid spread into the conjunctival epithelium, cornea, or skin; upper and lower lid involvement; and history of radiation exposure.[102,103,109,113] In the past, 14% to 25% of patients reportedly had metastasis, most frequently involving regional nodal basins, followed by spread to the liver, lung, brain, and bones.[97,99–102] Because of increased index of suspicion, physician education, and earlier recognition with biopsy, the metastatic rate has decreased to 10% in some series.[113] Among industrialized countries, periocular mortality is reportedly 9% to 15%. Systemic disease is associated with a grave prognosis.

Follow-up care includes examining the individual on a regular basis, probably for the rest of his or her life. Given the complex issues in dealing with this aggressive tumor, individuals are best served by being cared for in a tertiary care setting with a multidisciplinary approach. Physical examination, evaluation of the surgical site, and a low threshold for biopsy of suspicious lesions is a reasonable approach.

MERKEL CELL CARCINOMA

Epidemiology and Pathogenesis

Merkel cell carcinoma (MCC) is a rare aggressive tumor of unknown incidence. Fewer than 700 cases have been reported since the tumor was first described by Toker in 1972.[134–135] Many names have been ascribed to this neoplasm, including primary small cell carcinoma of the skin, trabecular carcinoma, APUDoma, neuroendocrine carcinoma, endocrine carcinoma, and primary undifferentiated tumor of the skin.[135–138] New SEER data indicates that the incidence of MCC is rising with about 470 new cases reported annually.[139]

MCC is a tumor that primarily affects elderly persons. Ninety percent of cases reported occur in patients older than 50 years, and the mean age at diagnosis is 69 years.[135,138,139] There does not appear to be a sex predilection.[140] White persons are more frequently affected than those of other races; however, MCC has been reported among Asian and black persons.[141–145] MCC has been reported in association with BCC, SCC, a history of radiation exposure, certain familial cancer syndromes, and immunosuppressed states[121,142,146–148] such as OTRs.[149]

Clinical Manifestations

MCC often manifests as a painless, indurated, erythematous to violaceous nodule on sun-damaged skin, 50% of tumors arising on the head and neck.[134–139,142,150] Ten percent of these tumors are in the periocular areas (Fig. 74-11).[151] The extremities are the second most affected site, followed by the trunk.[136,141,152,153] MCC also has been reported in areas not normally exposed to sunlight, such as the vulva, endocervix, penis, esophagus, bladder, and calvarium.[154–158] The overlying epidermis usually is unremarkable; however, ulceration may be found.[138,142,159] In addition, there may be overlying or surrounding telangiectasis.[135] The clinical differential diagnosis includes BCC, SCC, amelanotic melanoma, lymphoma, and metastatic disease. The ultimate diagnosis is made on the basis of clinical appearance, histologic findings, and supporting immunohistochemical studies of the tissue subjected to biopsy.

Histopathology

MCC has a histologic appearance similar to that of other small cell neoplasms and must be differentiated from cutaneous metastatic lesions from carcinoid or small cell undifferentiated carcinoma of the lung.[135,137,142,159] The tumor cells are characteristically uniform in size, monomorphic, basophilic, and ovoid, and measure up to 15 mm in diameter. The nuclei have finely dispersed chromatin with minimal surrounding cytoplasm.[137,152,159–161] Pathognomonic features include numerous mitotic figures, vesicular nuclei with essentially inconspicuous nucleoli, and apoptosis, especially when appreciated with certain architectural features.[135,137,162] The tumor involves the dermis, may extend into the subcutaneous fat or deeper, and usually spares the epidermis.[142] There may be a pagetoid pattern of epidermal spreading, which can mimic Bowen's disease, Paget's disease, extramammary Paget's disease, melanoma, and mycosis

Figure 74-11 • Merkel cell carcinoma involving the upper eyelid.

fungoides.[150,162] MCC also may have both squamous and adnexal differentiation.[138,161]

The architectural patterns of MCC have been classified into three separate groups: trabecular, intermediate cell, and small cell.[137] The trabecular pattern is the least common.[134,163,164] The cells are arranged in cords admixed among a fibrovascular background.[134,136,160] This pattern may be associated with pseudoglandular structures.[164,165] The tumor often involves tissue surrounding adnexal structures, such as hair follicles. More often, in the intermediate cell type, MCC displays large sheets or clusters of uniform cells with foci of necrosis.[136] The tumor also can arise near adnexal structures and connect with the epidermis.[164,165] The cells in this pattern are less compact than those in the trabecular type. There often is a surrounding lymphocytic infiltrate.[135,162–166]

Finally, the small cell type of MCC arises in the dermis and appears as sheets of cells interrupted by strands of connective tissue.[164] Glandular or pseudoglandular structures are absent. The cells are round and small and may demonstrate "crush" artifact. It has been proposed that the intermediate cell type and the small cell type behave in a clinically more aggressive manner than the trabecular type.[164,165] Lymphatic invasion is frequently encountered and has negative prognostic implications.[137,142,163,164,166,167]

Immunohistochemical studies aid in the diagnosis of MCC and help to differentiate it from other tumors. A characteristic paranuclear dotlike pattern against cytokeratin 20 is probably the most useful immunohistochemical stain.[135,164,168,169] In addition, MCC stains positively for neuron-specific enolase.[136,160,164,168] However, neuron-specific enolase is not specific for MCC and cannot be relied on for differentiation of MCC from small cell carcinoma of the lung.[135,169] Chromogranin A and synaptophysin are specific for MCC but less sensitive than neuron-specific enolase. MCC also stains positively for epithelial membrane antigen and Ber-EP4.[135,160,169]

Treatment

When MCC is diagnosed, a detailed history should be obtained and a physical examination performed with emphasis on the skin and lymph nodes. Complete blood cell count and hepatic and renal function tests are reasonable. Evaluation of the chest, abdomen, and pelvis with computed tomography may be useful in differentiating MCC from metastatic small cell carcinoma and for initial staging.[150] Individuals with MCC of the head and neck region need imaging for evaluation of draining nodal basins, especially if there is clinically evident lymphadenopathy.[135,150] Tumor staging is performed at clinical presentation.[170] Stage I disease is a primary tumor with no evidence of nodal involvement. Stage II disease equates to regional lymph node involvement. Stage III disease is defined by the presence of systemic metastasis.

Local disease is best managed by surgical excision to lower the tumor burden, and excision is followed by radiation.[139,141,150,166,170] Wide local excision of 2.5- to 3.0-cm margins is especially suitable for MCC of the trunk or extremity, being the historical standard.[135,139,141,150,166,170] The use of Mohs' micrographic surgery for areas in which this goal would not be achievable, such as the face or neck, has been a logical extension of surgical therapy.[150,171] In addition to tissue conservation, the technique allows microscopic examination of all margins.[150,171]

Prophylactic or elective lymph node dissection in all patients has been advocated by some surgeons.[135,136,170,172] Others suggest that sentinel lymph node biopsy for evaluation of draining lymph node basins would be a reasonable approach and avoid the morbidity of elective lymph node dissection.[137–139] Sentinel lymph node biopsy is best performed when the primary surgical site has been subjected to the least amount of manipulation. Thus far no studies have been conducted to compare the two methods. Elective lymph node dissection currently is recommended for large primary tumors, head and neck lesions, small cell subtype, and evidence of vascular or lymphatic invasion.[136,139,141,153]

MCC is considered a radiosensitive tumor. Thus, radiation therapy has been used as adjuvant primary treatment when surgery is not an option and for palliation.[139–142,150,170,172] Use of adjuvant external beam radiation therapy has been advocated by many authorities.[139,141] Current recommendations call for surgical management of the primary MCC followed by radiation to the primary site as well as the regional lymph node draining system.[141,142,150,172–177] Adjuvant chemotherapy has not been studied in a controlled manner. Many cytotoxic regimens have been used, including cyclophosphamide, methotrexate, 5-fluorouracil, cisplatin, etoposide, doxorubicin, procarbazine, dacarbazine, streptozocin, and nitrogen mustard.[138,139,178–180] Review of the literature on adjuvant chemotherapy has not demonstrated clear clinical benefit regarding relapse or survival.[143,146,170,176,177] Chemotherapy has been used for salvage therapy in patients with systemic disease.[147,170,178–180] Most regimens involve two or three drugs, and results are modest at best. No large, randomized studies have been conducted because of the rarity of MCC.

Prognosis and Follow-up Evaluation

MCC has been compared to malignant melanoma because of its similar aggressive behavior.[138,139,174] The local recurrence rate is 26% to 44% after primary treatment. As many as 30% of patients have regional lymph node involvement at the time of diagnosis with a 55% rate of regional lymph node relapse after treatment and a 34% to 49% rate of distant metastasis.[139,142,150,176,177,180] Survival rates reportedly are 68% for women and 36% for men at 3 years.[152,179] Given the relative rarity of the tumor, no large multicenter randomized trials have been conducted to assess stage, treatment modality, recurrence rate, and overall survival. There have been reports of individuals with spontaneous resolution of MCC.[181–183]

Patients should be monitored closely for recurrence of locoregional or distant disease. Lymph node or distant metastatic disease has a uniformly grave prognosis; however, there may be a role for chemotherapy in prolonging survival. Almost all individuals with metastatic disease eventually die of the disease.

DERMATOFIBROSARCOMA PROTUBERANS

Epidemiology and Pathogenesis

DFSP is an uncommon tumor of intermediate malignancy that arises in the dermis. It is a locally aggressive neoplasm with notoriously high recurrence rates even after wide local excision. In 1924, Darier and Ferrand[184] first described DFSP as a distinct clinicopathologic entity; however, it was Hoffman in 1925 who introduced the term dermatofibrosarcoma protuberans.[185]

DFSP constitutes less than 1% of all malignant tumors. The estimated incidence is 0.8 to 5 cases per 1 million persons per year.[186–190] The tumor commonly occurs between 20 and 50 years of age, rare cases occurring in young children.[191] In addition, there have been a few reported cases of congenital DFSP.[191–194] The sexes are affected equally; however, in some series there is a slight male preponderance.[186–188,191,195] Most reported cases of DFSP occur in white persons, but historically race rarely is mentioned.[186–188,196] DFSP also occurs in African Americans and Asians.[191,196,197]

DFSP is not known to have a genetic or familial predisposition.[198,199] The cause of DFSP is unknown. Chromosomal abnormalities consistent with a monoclonal origin have been found in several studies.[200,201] Most frequently, these abnormalities include ring 22 chromosomes, ring chromosomes containing chromosome 17 sequences, abnormal clones, and t(2;7) translocations.[201–204] Approximately 10% to 20% of patients report a history of antecedent trauma.[186,191,199,205,206] There have been reports of DFSP arising in multiple immunization sites, burn scars, and surgical

scars.[196,207,208] DFSP has been associated with pregnancy as well as long-term arsenic exposure, acanthosis nigricans, and acrodermatitis enteropathica.[186,209–211]

Clinical Manifestations

DFSP usually manifests as a flesh-colored, firm, asymptomatic nodule or plaque (Fig. 74-12). The tumor is firm to palpation, and a subcutaneous component often is appreciated. There may be fixation to overlying skin but rarely to deeper structures. Lesions associated with pigment are known as Bednar's tumors.[212] In addition to pigment, there may be red to violaceous erythema. Characteristically, DFSP initially manifests as a solitary nodule; however, there may be multiple primary lesions. The size typically ranges from 1 to 5 cm, but neglected lesions can be as large as 20 cm in diameter.[186,188,196] The lesion slowly enlarges in a relentless manner. Accelerated growth phases can result in nodularity or multiple outcroppings or protuberances. Ulceration occurs when the tumor erupts through the epidermis. Atypical clinical manifestations include sclerotic plaques with a morpheaform appearance.[213]

Approximately 50% to 60% of DFSP lesions occur on the trunk, 25% of those occurring on the chest and shoulders.[187,188,191,196] Twenty percent to 30% arise on the proximal aspects of the extremities.[188–191] Ten percent to 15% occur on the head and neck, the scalp being affected less than 5% of the time.[187,188,191,196] In rare instances acral sites have been reported, mostly in young children and adolescents.[187,191,192,214] Often there is a delay in diagnosis given the indolent and nonspecific features of the tumor. DFSP often is mistaken for lipoma, deep-seated epidermal cyst, scar, hypertrophic scar, keloid, dermatofibroma, nodular fasciitis, and insect bite. The diagnosis is confirmed with biopsy and microscopic examination of the tissue.

Histopathology

The histological features of DFSP often are easily recognized on low-power view. There is densely packed proliferation of monomorphic, bluish, spindle-shaped cells seated in and expanding the dermis. The overlying epidermis usually is normal appearing unless there has been invasion by the tumor. The central or nodular areas of the tumor demonstrate numerous spindle cells arranged in a characteristic "whirling, storiform or herringbone" configuration.[160] The lateral tumor margins have sharply pointed tumor cells and irregular strands dissecting between the native collagen bundles. Inferiorly, the DFSP cells invade downward within the fibrous septa that separate the adipose cells of the panniculus. The peripheral margins may have a deceptively bland appearance resembling normal collagen and making interpretation of tumor margins difficult.[188] Fascia, muscle, and underlying bone may be involved in long-standing lesions.[188,191,196,200] Histological variants include DFSP with entirely myxomatous features (myxoid DFSP) and pigmented DFSP, also known as Bednar's tumor.[212,214–216] This variant tends to occur more often in dark-skinned persons and accounts for approximately 1% to 5% of all cases of DFSP.[212] Bednar's tumor has the characteristic storiform pattern of spindle cells admixed with a variable amount of melanin-laden dendritic cells. Immunohistochemical studies that may be helpful include positive staining for CD34, a human hematopoietic progenitor cell antigen. Unlike dermatofibroma, DFSP stains negatively for factor XIIIa.[160]

Figure 74-12 • Dermatofibrosarcoma protuberans involving the back. Central linear scar from previous partial excision is encircled by ink to highlight clinical margins of the lesion.

Treatment

After the diagnosis of DFSP has been confirmed, a complete history, review of systems, and physical examination with focus on the skin and structures contiguous with the tumor and palpation of lymph node basins are performed. Unless the physician suspects metastatic disease, extensive laboratory studies and radiological investigation are not indicated.

The traditional mainstay of therapy for DFSP has been surgical resection, specifically wide local excision with a margin of 2 to 4 cm of normal-appearing skin.[196,217,218] Unfortunately, the biological and histological features of the tumor coupled with the inability to clinically determine tumor margins account for exceptionally high recurrence rates with standard surgical therapy. Reported local recurrence rates are as high as 60% after standard surgical excision and 23% after wide local excision with margins greater than 4 cm.[217] Approximately 80% of local recurrences occur within 3 years.[186,196,201] Local recurrence after 10 years is rare but has been reported.[188,191] Mohs' micrographic surgery has been receiving greater recognition as a useful method of management of DFSP.[217–226] The capability of microscopic examination of the entire specimen margins allows the surgeon to localize and excise the tumor in a precise manner. This method also allows for maximum conservation of tissue, a crucial factor in certain anatomic areas, such as the face, scalp, distal extremities, and genitalia. Results of several studies have suggested that Mohs' micrographic surgery may be beneficial in the management of DFSP; however, few series have provided complete 5-year follow-up data.[217–226] At the University of Wisconsin, Madison, 36 patients with DSFP were treated with Mohs' micrographic surgery. Of these, 29 participated in follow-up study for 5 or more years (range, 5–20 years). As of this writing, there have been no local recurrences or cases of regional metastasis.[227] Recently, imatinib mesylate (Gleevec), an inhibitor of platelet-derived growth factor receptors, has shown promise for unresectable DFSP.[228]

Prognosis and Follow-up Evaluation

Although it is locally aggressive, DFSP rarely metastasizes. The overall rate of distant metastasis is approximately 5% and of regional metastasis is 1%.[195] In the past the causes of the higher rate of metastasis were probably inclusion of malignant fibrohistiocytoma (MFH) in the database and degeneration of DFSP to a more sarcomatous subtype with its subsequent increased risk of metastasis.[227–229] MFH is now understood to be a totally different entity from DFSP. Its cellular morphological characteristics and architecture have been clarified, and pathologists and dermatopathologists have reached consensus on the diagnostic criteria for MFH. The regional rate of metastasis of MFH is estimated to be greater than 50%.[160,226–228]

Recommendations for patient follow-up care include physical examination every 3 to 6 months postoperatively for 3 years and then annually for life. Particular attention to evaluation of surgical site,

regional lymph node palpation, and a complete review of systems is appropriate.

CUTANEOUS ANGIOSARCOMA

Epidemiology and Pathogenesis

Cutaneous angiosarcoma (CAS) is a rare, highly malignant, potentially lethal tumor originating from the dermal vasculature endothelium. Elderly persons are most commonly affected, and there is a 2 : 1 male predominance.[230–233] White persons are affected most often, but CAS has been reported among other persons as well.[234,235] With the exception of CAS associated with lymphedema, the cause of CAS is uncertain. Cases have been associated with history of trauma, radiation, herpes zoster, fistula of chronic osteomyelitis, vinyl chloride and arsenic oxide exposure, and arteriovenous fistula sites in renal transplant recipients.[230,231,236–245] UV light exposure does not seem to be an inciting factor. Only a minority of patients with CAS have temporally associated skin cancer.[232,233,246]

Clinical Manifestations

Principal clinical patterns include (1) CAS of the scalp and face, (2) CAS associated with chronic lymphedema most commonly following mastectomy (Stewart-Treves syndrome), and (3) radiation-associated angiosarcoma, which is the least common variant.[230,236] CAS of the scalp and face usually manifests as a painless, rapidly proliferating growth of the subcutaneous tissue plane (Fig. 74-13). CAS of this pattern occurs 50% of the time on the scalp and 30% of the time on the face or neck.[230–233,237,240,246] The tumor may be firm or spongy to palpation, the overlying skin surface smoothened because of tumor distention of the underlying structures.[247] An ill-defined area of dusky to violaceous erythema resembling a bruise or healing contusion often is present. The tumor infiltrates the surrounding tissues in a centrifugal and multifocal manner. As a result tumor involvement extends much farther than the clinical appearance of the margins. Multiple lesions may be separated by an isthmus of normal-appearing skin found at initial presentation if the primary tumor is more than 6 cm in diameter. Long-standing CAS may develop superimposed tumors and nodules. Ulceration and bleeding are not characteristic unless the CAS is larger than 10 cm in diameter. Misdiagnosis is common given the subtlety and nonspecific nature of the clinical findings. Initial differential diagnoses include cellulitis, nonspecific inflammatory changes, fungal infection, trauma, and hemangioma.[230,231,247] Reported atypical clinical scenarios include rosacea-like signs and symptoms, chronic edema of the eyelids, xanthelasma-like lesions, and even recurrent angioedema.[235,247,248]

Figure 74-13 • Cutaneous angiosarcoma involving the scalp. Ink highlights clinical margins of the lesion.

Because the prognosis of advanced CAS is poor, every effort should be made for early diagnosis and treatment. Favorable outcomes are more likely when the tumor (1) has been present for less than 6 months, (2) is less than 5 cm in size, and (3) is amenable to combined surgery and radiation therapy (e.g., CAS of the nose).[246]

In 1948, Stewart and Treves described six patients with postmastectomy chronic lymphedema in whom CAS developed in the affected extremity.[249] The estimated risk among postmastectomy patients who survive more than 5 years is approximately 0.5%.[250] The time interval between mastectomy and recognition of angiosarcoma ranges from 1 to 30 years with a mean duration of 10 years.[251] Clinically, the ipsilateral, upper inner aspect of the arm is a frequent site of early involvement. Less frequent are lesions distal to the elbow or on the chest wall that most often resemble a bruise or blotchy erythema. These color changes initially are attributed to trauma; however, rapid growth and induration often lead to ulceration and hemorrhage. Other causes of chronic lymphedema have been associated with development of angiosarcoma, including congenital lymphedema and postsurgical, post-traumatic, and infectious etiological factors.[251–257]

Histopathology

Histologically, CAS has essentially three different cell growth patterns: (1) angiomatous or well differentiated with obvious vasoformative activity, (2) spindle cell with a range of differentiation, and (3) undifferentiated or highly anaplastic.[246,258] A single tumor may have all three growth patterns.[237,246,247,258] The well-differentiated variant (angiomatous) is characterized by recapitulation of atypical endothelial cells lining irregular vascular channels. These atypical vessels are located throughout the dermis, dissect through the collagen, and surround but do not invade the adnexal structures. With time there is infiltration into the subcutaneous fat, muscle, and fascia. This particular variant is often poorly recognized initially with frozen sections. The vessels do not contain red blood cells, because hemolysis of the red blood cells during processing makes microscopic examination difficult. The spindle cell tumor variant forms dense cellular bundles that penetrate the dermis and underlying tissue.[246] Vascular channels are not easily recognized. The more anaplastic or undifferentiated CAS characteristically contains large, basophilic, pleomorphic polyhedral cells arranged in solid sheets or cords.[246,258] The dermis and subcutaneous structures often are occupied by tumor. Immunohistochemical stains for endothelium-related markers such as CD34 antigen, factor VIII–related antigen, or *Ulex europaeus* agglutinin I lectin binding may be helpful. Negative cytokeratin staining is helpful for differentiating CAS from carcinoma. Negative staining results for S-100 help to differentiate the tumor from melanoma.[247,258]

Treatment

Computed tomography and magnetic resonance imaging have not been extremely helpful unless there has been marked bony invasion.[259,260] Soft-tissue invasion of the tumor may be partially visualized, but the exact extent of the margins is poorly delineated because of the diffuse infiltrating nature of the tumor. Radiographic imaging is even more unreliable if the tumor is poorly appreciated microscopically. The peripheral margin of CAS may be partially assessed with random biopsies performed in a gridlike pattern circumferentially around the tumor.[246] Ideally, the biopsies should be full thickness of the skin and include the muscle and fascia if possible for complete assessment of the depth of the margin.

Traditional management of CAS has been wide local excision with a margin of 3 to 6 cm of normal-appearing skin. More recently,

Mohs' micrographic surgery with adjuvant radiation has been shown to produce favorable outcome.[246,261–263] The Mohs' technique combines the benefits of both fresh-tissue and fixed-tissue technique. Well-localized lesions are good candidates for the fresh-tissue technique, because a microscope can be used for identification of the tumor and excision of the entire lesion. After excision, zinc chloride fixative paste may be applied circumferentially around the surgical skin edges to stimulate an immune response around the operative site.[262] The final defect is repaired with a flap or skin graft.

For scalp lesions, orthovoltage or electron beam radiation with a curvilinear delivery system is administered over the entire scalp in a swimming cap distribution.[264] The region from the eyebrows to the occipital nuchal line is included, and both auricular-temporal sulci are encompassed. The curvilinear delivery system distributes the radiation equally to all parts of the scalp simultaneously. Thus are avoided overlapping and undertreatment of radiation sites that would otherwise accompany conventional flat-plate radiation when applied to curved surfaces, such as the scalp and forehead. Attention to these details of radiation treatment is essential, because CAS is resistant to most forms of surgical therapy, and chemotherapy has not been reported effective.

Recurrence of CAS of the scalp usually is the result of inadequate treatment of the primary tumor.[232,246] Localized recurrence can be managed with radiation with a good response.[246,261] Management of regional lymph node metastasis is surgical resection and adjuvant radiation.[232,246] Systemic disease has a grave prognosis. Given the rarity of angiosarcoma, no single institution has enough experience to establish definitive treatment guidelines. Practical strategies include use of Mohs' micrographic surgery combined with radiation, in the manner described earlier, for tumors less than 5 cm in diameter. For tumors larger than 5 cm, peripheral margin assessment (because of the multicentricity of the tumor spread), followed by orthovoltage or electron beam radiation should be considered.[246]

Prognosis and Follow-up Evaluation

The prognosis among patients with any form of angiosarcoma is uniformly poor. CAS of the scalp has an expected 5-year survival rate of less than 12%.[232] Histologic degree of differentiation, mitotic index, age, sex, location of primary lesion, and clinical appearance have no statistical bearing on survival. Tumor size has been found the only statistically significant indicator of prognosis. Lesions smaller than 5 cm correlate with improved survival at 5 years.[230] Another favorable indicator has been the presence of prominent lymphocytic infiltrate associated with the tumor. Local recurrence is common, and metastasis occurs hematogenously and through lymphatic vessels to the cervical lymph nodes, lungs, liver, and soft tissues.[232,234] There have been rare reports of spontaneous regression of CAS of the scalp and face.[265,266] Complete regression in one unreported case at the University of Wisconsin, Madison, was associated with frequent application of hot compresses.

Follow-up recommendations include frequent physical examinations with particular attention to the surgical site, contiguous structures, and palpation of lymph nodes. A complete review of systems, laboratory data, and radiologic studies should be performed as indicated. These individuals are best treated in a tertiary care center with a multidisciplinary approach.

BEST PRACTICES FOR PATIENT SCREENING AND TUMOR PREVENTION

A full-body skin examination is advised as part of an annual physical, especially for older adults or those with a family history of skin cancer. For those with a personal history of skin cancer, examination every 4 to 6 months is advised. For NMSC, special attention is paid to sites of previous skin cancer, changing or new skin lesions, and sun-exposed areas in general. Peripheral lymph nodes are palpated if there is a history of skin cancer with above average metastatic potential, such as SCC of the lip.

Prevention of NMSC mainly involves protection from the sun. Suntans should be avoided because they are a sign of, and response to, UV damage. The skin should be protected with a combination of clothing and SPF 30 sunblock effective against both UV-A and UV-B wavelengths. Hats should have a 360-degree brim to protect the neck and ears as well as the face. Sunglasses that block UV light should be worn to protect the eyes, eyelids, and periorbital skin. Outdoor daylight activities are best restricted to the early morning, late afternoon, and early evening. The peak sunlight hours of 10 AM to 3 PM are best avoided by planning indoor activities during this period. The UV index is a daily rating of local UV intensity on a scale of 1 through 10. Although the scale can be useful in assessment of relative sun exposure risk, the best practice is always to follow the sun protection measures just outlined. Protect children, because sun-induced genetic damage begins in childhood, and most persons receive most of their lifelong sun exposure before adulthood. Retinoids, antioxidants, and COX-2 inhibitors may be beneficial for chemoprevention of NMSC.

WHEN AND HOW TO PERFORM BIOPSY

Unless logistical reasons preclude it, biopsy should be performed on all lesions suspected of being NMSC to establish the correct diagnosis, plan definitive therapy, and obtain prognostic information. The most important subjective symptoms can be summarized under the heading "change". The changes may be appearance of a new growth or a change in the size, shape, color, sensation (itch or pain), crusting, or bleeding of a pre-existing lesion.

For most cases of NMSC, standard shave biopsy performed with a scalpel or razor blade is adequate. Well-differentiated SCC and keratoacanthoma can be difficult to diagnose unless the deepest portions are included in the biopsy specimen, because these often are the areas most likely to yield enough information for a diagnosis. Deep shave, punch, incisional, or excisional biopsy often is preferable to standard shave biopsy in these cases. For large or ill-defined tumors it is frequently helpful to perform multiple mapping biopsies to identify the most biologically aggressive features, define margins, and plan treatment.

75 Cancer of the Endocrine System

Geeta Lal, Thomas O'Dorisio, Ross McDougall, and Ronald J. Weigel

SUMMARY OF KEY POINTS

Thyroid Cancer

Incidence
- 33,500 cases per year

Types
- Follicular cell
- Differentiated (papillary follicular variants)
- Undifferentiated (anaplastic)
- Parafollicular cell (medullary)
- Connective tissue (lymphoma, sarcoma)
- Miscellaneous metastases (breast, lung, kidney, melanoma)

Presentation and Diagnosis
- Mass in the neck
- Mass noted on ultrasound, computed tomography (CT), magnetic resonance imaging (MRI) by chance
- Abnormal cervical lymph nodes
- Differentiate primary thyroid cancer, lymphoma, benign nodule, other causes of enlarged lymph nodes
- Tissue diagnosis required, usually by fine-needle aspiration
- Ultrasound identifies cysts likely to be benign.
- Scintiscan distinguishes functioning nodules with a low likelihood of cancer.

Treatment
- Thyroid resection (lobectomy or total thyroidectomy)
- ^{131}I for differentiated tumors
- External beam irradiation—palliative
- Chemotherapy—palliative

Adrenocortical Cancer

Incidence
- Rare (2 cases per 1 million)

Clinical Features
- Abdominal mass, metastases
- Virilization in females
- Cushing's syndrome
- Feminization in males (rare)
- Hyperaldosteronism (rare)

Diagnosis
- Imaging techniques: CT scan and MRI of upper abdomen
- Biochemical: increased urinary steroid excretion (functional tumors)

Treatment
- Radical adrenalectomy for localized tumor
- Antihormonal therapy—palliative
- Chemotherapy—palliative

Malignant Pheochromocytoma

Incidence
- Rare

Diagnosis
- Episodic hypertension
- May be familial
- May be part of MEN-2a or MEN-2b

Biochemical
- Vanillylmandelic acid, metanephrine, and catecholamine in urine
- Serum catecholamine measurements

Imaging
- CT and MRI scans
- Metaiodobenzylguanidine (MIBG) radionuclide scanning

Treatment
- Surgical resection of localized disease with preoperative α-blockade
- Palliative α- and β-adrenergic blockade

Parathyroid Carcinoma

Incidence
- Rare

Diagnosis
- Refractory hypercalcemia
- Mass in neck

Imaging
- Sestamibi
- Imaging may be unnecessary

Treatment
- En bloc resection of cancer and involved structures and ipsilateral lobe of thyroid
- Radiation—palliative only
- Chemotherapy—dacarbazine
- Therapy for hypercalcemia (etidronate, gallium nitrate)—palliative

Carcinoid Tumors

Incidence
- Clinical disease: 7 to 13 cases per 1 million
- Autopsy: 6500 per 1 million

Diagnosis
- Nonfunctional bowel obstruction
- Abdominal pain
- Carcinoid syndrome (diarrhea, flushing, hypotension)

Imaging Techniques
- CT scan of the abdomen
- Contrast radiography study with small bowel follow-through
- Enteroscopy—investigational

Special Diagnostic Techniques
- Urinary 5-hydroxyindoleacetic acid (5-HIAA) measurement
- Radiolabeled sandostatin imaging

Treatment
- Complete surgical resection—curative
- Partial surgical resection—palliative
- Tumor embolization—palliative
- Somatostatin analog
- Antiserotonin agents
- Antihistamines
- Anticholinergics
- Streptozotocin + 5-FU chemotherapy; 30% partial response

Pancreatic Islet Cell Tumors

Incidence
- 1 case per 100,000

Diagnosis
- Pancreatic mass
- Metastatic disease
- Varies with hormone produced

Imaging Techniques
- CT scan of the abdomen
- Ultrasound of abdomen
- Endoscopic ultrasound
- Celiac angiography
- Intraoperative ultrasound

Special Diagnostic Techniques
- Plasma hormone assays
- Selective venous catheterization for hormonal levels

Treatment
- Complete surgical resection—curative
- Partial surgical resection—palliative
- Tumor embolization—palliative
- Antihormonal therapy
- Somatostatin analog (for most hormonal excess syndromes)
- H_2-blockers, Na/K pump inhibitors (for gastrinoma)
- Insulin antagonists (for insulinoma)
- Chemotherapy: doxorubicin/streptozotocin 60% response rate

INTRODUCTION

Cancers of the endocrine glands are uncommon. Endocrine tumors—both benign and malignant—although infrequent, present challenges in diagnosis and treatment. Cancers of the thyroid usually do not alter thyroid function, but abnormal hormone secretion can cause the earliest symptoms or signs in cancers of these others endocrine glands. Abnormal plasma levels of these hormones can be useful in monitoring the effects of therapy, and specific inhibitors of hormone biosynthesis or activity can palliate symptoms significantly without having any effect on tumor growth. Diagnosing and treating endocrine cancers requires oncologists, endocrinologists, surgeons, and other subspecialists to work together. This chapter provides a practical guide to the diagnosis and management of endocrine tumors.

THYROID CANCER

Thyroid cancer is the most common tumor of the endocrine system. The biologic behavior of the different histologic types of thyroid neoplasms varies greatly. Approximately 33,550 new cases of thyroid cancer will be diagnosed in 2007, and about 1530 patients will die from thyroid cancer.[1] Recently published studies indicate that the incidence of this malignancy is increasing, from 3.6 per 100,000 to 8.7 per 100,000 in 2002. However, the mortality rate remains unchanged at 0.5 per 100,000 population. This increase in incidence has been attributed largely to the increased detection of small cancers.[2] In general, thyroid tumors do not exhibit aggressive growth characteristics. Papillary cancer, the most common type in the United States, has an excellent prognosis.

Etiology

External radiation to the cervical region has been found to be a cause of thyroid cancer. This association has been recognized in patients who had thymic irradiation in childhood, in patients who had irradiation for acne in teenage years, and in patients with cancer such as Hodgkin's disease who received neck irradiation.[3–6] The incidence of thyroid cancer is increased in children who received irradiation to the scalp.[7] Reports from Israel of children who received scalp irradiation to treat ringworm have shown an increase in thyroid cancer compared with siblings and age-matched nonirradiated control subjects.[8] Retrospective phantom studies demonstrate that radiation doses as low as 0.09 Gy could be incriminated as the cause of cancer in these children. In addition, children exposed to radioactive fallout from Chernobyl have shown an increase in thyroid cancer.[9,10] The radiation doses that originally were blamed were in the range of 1 to 10 Gy, but based on the evidence in patients with Hodgkin's disease, doses as high as 40 Gy are potentially carcinogenic.[11] In laboratory animals, combining radiation with increased thyroid-stimulating hormone (TSH) increases the potential risk.[12,13] The lag time from radiation exposure to diagnosis of cancer usually is 10 to 20 years; however, periods from 5 to 50 years have been reported. Epidemiologic studies show that between 7% and 9% of patients who received 5 to 10 Gy external radiation develop thyroid cancer.[14] About 20% have a palpable abnormality; therefore, about one third of these nodules are cancers. Patients now are rarely given external radiation to the neck for benign disease, so this association should become uncommon. Patients treated for cancer usually are followed closely, and careful palpation of the neck and measurement of TSH annually is advisable. Radiation to the thyroid from internal sources and diagnostic or therapeutic doses of iodine 131 (^{131}I) have not been associated with an increased incidence of thyroid cancer. However, the recent epidemics of childhood thyroid cancers in Belarus and the Ukraine have a clear connection with the massive release of radionuclides, including radioisotopes of iodine, from the Chernobyl reactor.[15] Almost all of these patients were children at the time of exposure, and there was internal radiation to the thyroid from ^{131}I and other shorter-lived radionuclides of iodine,[16] as well as exposure to external radiation and probably internal radiation from ^{137}Cs. The etiology of these cancers probably is multifactorial, but the data must cause us to reconsider the risks from internal radiation.

There is increasing evidence of genetic alterations in some thyroid cancers, especially in Chernobyl survivors.[17,18] Approximately 70% of cancers in children following radiation from this nuclear disaster carried RET and papillary thyroid cancer (RET/PTC) rearrangements, the most common of which were RET/PTC1 and RET/PTC3. The latter was associated with a distinct solid growth type and appeared to be more aggressive.[19] A family history of thyroid cancer also is a risk factor for development of this tumor, particularly medullary thyroid cancer. This tumor occurs commonly within the spectrum of multiple endocrine neoplasia (MEN) syndromes 2A and 2B, and familial medullary thyroid cancer syndrome, all characterized by inherited mutations in the RET proto-oncogene.[20] Familial nonmedullary thyroid cancer (FNMTC) is now recognized as a true phenomenon, with several families reported in the literature. Several candidate gene loci for FNMTC have been explored. Bignell and colleagues[21] studied a large Canadian family with 18 cases of nontoxic multinodular goiter and 2 cases of papillary thyroid cancer and noted linkage to *MNG1* on 14 q. However, detailed analysis of 37 FNMTC families showed that *MNG1* does not account for most cases of this disorder. Linkage analysis in a French family with multinodular goiter and papillary thyroid cancer with oxiphilia revealed *TCO* on 19p13[22] to be a potential candidate gene in a small number of families. Another group noted linkage to *FPTC/PRN* on 1q21[23] in a large three-generation pedigree with papillary renal neoplasia, thyroid nodules, and papillary thyroid cancer. There is an association of nonmedullary thyroid cancer and Gardner's syndrome, Cowden's syndrome, and Werner's (adult progeroid) syndrome.[24,25] Some studies also indicate that individuals with familial nonmedullary thyroid cancer have a worse overall prognosis.[26,27]

Because of varied incidences of thyroid cancer in different ethnic groups, the role of an environmental factor or factors must be considered. A higher incidence of papillary cancer is found in regions with high dietary iodine intake such as the Pacific rim and Iceland.[28] In contrast, follicular cancer is more prevalent in iodine-deficient countries.

Classification and Prognosis

The most common thyroid cancers are papillary carcinoma and mixed papillary and follicular carcinomas (Table 75-1; Fig. 75-1A and B), the latter of which are also classified as papillary carcinomas.

Table 75-1 Histologic Classification of Thyroid Cancers and Their Incidence

Tumor Histology	Incidence (%)
Differentiated carcinomas	81–87
Papillary	
Follicular variant of papillary	
Follicular and Hürthle cell	
Medullary	6–8
Anaplastic	5
Lymphoma	1–5
Metastatic	<1

Occult cancers, now classified as papillary microcarcinoma, are less than 1 cm in size and have been reported in 10% to 30% of autopsy series. These tumors usually were identified at surgery for benign thyroid disease but are being identified more frequently due to the widespread use of ultrasound. They generally are believed to have a better prognosis than larger tumors; however, other studies indicate that these tumors may be more aggressive than previously appreciated.[29,30]

Death from papillary cancer is rare, and in most reports nodal metastasis does not adversely influence prognosis.[31] Recent series, however, have demonstrated a slightly lower survival rate with locoregional nodal metastases.[32,33] The prognosis in intrathyroidal papillary carcinoma depends on the age of the patient and size of the tumor; when the cancer is less than 5 cm in diameter, the prognosis is excellent.[34,35] Lymph node metastases can occur, but even in patients with nodal metastases only a small percentage of patients die of thyroid cancer.[36] The situation in older patients with larger, more aggressive papillary cancers is different. In patients with local invasion and cancers that cannot be totally resected, the recurrence rate and mortality rate are higher.[34] Death can result from local invasion and extensive metastases; nevertheless, the overall death rate from papillary cancer is low (<10%).[37]

In summary, the prognosis for papillary cancer is better in younger patients and in those with cancers smaller than 2 cm that are intrathyroidal and have no evidence of distant spread. The presence of metastases to lymph nodes has not been a negative prognostic factor in most series, although some series have reported increased recurrence and mortality rates for node-positive patients. Based on simple criteria such as the age of the patient, the size of the primary cancer, and whether local invasion or distant metastases are found, it is possible to determine the prognosis at presentation. Scoring systems such as AGES (age, grade of cancer, extrathyroidal spread, and size) and MACIS (metastases, age, complete excision, invasion, and size) are examples of these approaches.[38] The TNM system also stresses the importance of age at time of presentation. In patients under 45 years of age, those without distant metastases are all stage I, and those with distant metastases are stage II.

Pure follicular carcinoma carries a poorer prognosis.[39,40] Even when the disease appears confined to the thyroid gland, 5% to 15% of patients ultimately die of cancer, although survival is measured in decades. Lymph node metastases are seen less frequently than with papillary cancers of similar size. Approximately 50% of follicular cancers demonstrate intrathyroidal spread.[41] Follicular cancers cannot be distinguished from follicular adenomas based on fine-needle aspiration biopsies, because the diagnosis is based on the identification of vascular or capsular invasion. Prognosis in follicular carcinoma

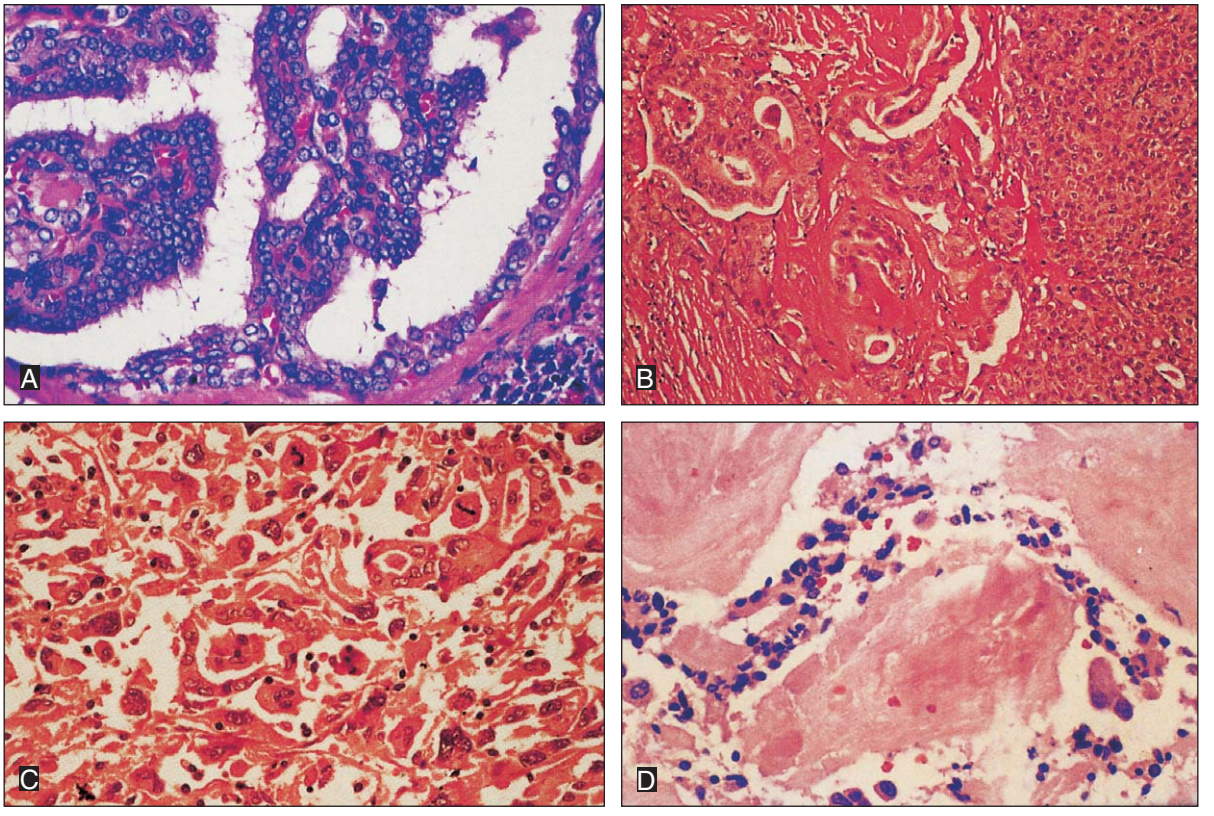

Figure 75-1 • Histologic patterns of thyroid cancer. **A,** Papillary carcinoma. **B,** Pure follicular carcinoma. **C,** Anaplastic carcinoma. **D,** Medullary carcinoma.

depends on the patient's age, the size of the cancer, and the amount of capsular and vascular invasion.[42] Minimally invasive tumors are grossly encapsulated but have evidence of microscopic invasion of the tumor capsule and/or invasion into small or medium-sized vessels in or immediately outside the tumor capsule. In contrast, widely invasive tumors are characterized by large vessel invasion and/or broad capsular invasion. Even though exact definitions are variable among pathologists, widely invasive tumors have a worse prognosis.[43]

The incidence of anaplastic carcinoma appears to be decreasing. and this type now represents less than 3% of thyroid malignancies in the United States[44] (Fig. 75-1C). This apparent decrease may be secondary to improvement in the techniques available to differentiate thyroid lymphoma and medullary carcinoma (Fig. 75-1D) from true anaplastic thyroid cancer. A proportion of patients with anaplastic cancers are immigrants from countries where goiter is common, and the anaplastic cancer probably has arisen from a more differentiated cancer that went undiagnosed for many years. In some cases there is a spectrum from papillary to anaplastic cancer, indicating that anaplastic cancers arise from more differentiated lesions,[45] and earlier diagnosis of the latter also plays a role in the reduced incidence. Anaplastic carcinomas usually occur in persons older than 60 years. These carcinomas are highly malignant and typically cause death within 6 months, either by local invasion or by distant metastases. Cure of anaplastic carcinoma is rare.[46]

Hürthle cell tumors of the thyroid are derived from the follicular cell.[47] Both carcinomas and adenomas of Hürthle cell origin have been described. Hürthle cell cancers often are classified with follicular cancer. As with follicular cancer, the differentiation of Hürthle cell adenoma from carcinoma is based on vascular features, or capsular invasion in the latter. However, Hürthle cell cancers seldom concentrate iodine, and their prognosis is worse, so a separate category is justified. Adenomas have an excellent prognosis with resection, and less than 2.5% are subsequently found to demonstrate malignant behavior.[48,49] Large (>2 cm) malignant tumors have a recurrence rate of 21% to 59% after surgical resection.[50]

Because of differences in the biology and behavior of thyroid cancers, determinging the prognosis of an individual patient may be difficult. Byar and associates[51] examined the impact of several variables on survival. Age, gender, cell type, clinical extent of cancer, lymph node status, and number of metastatic sites had prognostic significance, but not all were independent variables. However, a prognostic index that mirrored actual data was developed. Thus, in the "best" group (i.e., young patients with small localized differentiated tumors), the 5-year survival rate was approximately 95%, whereas in the "worst" group, which contained many patients with anaplastic carcinoma, the 5-year survival rate was less than 5%. These data agree with those from many other large series. To achieve uniformity in assessing the results of therapy, it is important that a single tumor, node, metastasis (TNM)[52] and clinical staging system be used. Tables 75-2 and 75-3 outline the most recent iteration of the TNM staging system for thyroid cancer. This system takes into account not only the effect of histologic type (papillary/follicular, medullary, anaplastic) on staging but also the negative prognostic effect of advancing age on stage and prognosis in differentiated thyroid neoplasms.

Primary lymphoma of the thyroid is not common. It usually occurs in an older woman with untreated Hashimoto's thyroiditis.[53] The condition characteristically presents as a rapidly growing thyroid mass with compressive symptoms and signs and sometimes causes pain. Diagnosis often can be made by fine-needle aspiration and immunophenotyping of the lymphocytic aspirate. Treatment usually consists of chemotherapy in addition to radiation therapy.

Diagnosis

Despite extensive experience with thyroid neoplasms, diagnostic recommendations continue to evolve.[54] In a patient presenting with a thyroid nodule, history and physical examination are important, because a history of radiation exposure to the head and neck or a family history of thyroid cancer should increase the clinician's suspicion of thyroid cancer. In younger patients, a solitary nodule is more likely to be cancerous. The solitary nodule is more likely than a multinodular goiter to be malignant, and a history of recent painless growth is suggestive of cancer. Malignant nodules tend to be harder, and fixation to the underlying structure is suggestive not only of cancer but also of a poorer prognosis. The presence of enlarged cervical nodes also increases the likelihood that a thyroid nodule is malignant. Table 75-4 categorizes the risk factors for a variety of clinical characteristics of thyroid nodules. Patients with nodules demonstrating high-risk characteristics should be referred for surgical resection.

Table 75-2 TNM Classification of Malignant Tumors of the Thyroid Gland

PRIMARY TUMOR (T STAGE)	
Tx	Tumor cannot be assessed
T0	No clinical evidence of tumor
T1	Tumor ≤2 cm limited to the thyroid
T2	Tumor >2 cm and <4 cm limited to the thyroid
T3	Tumor ≥4 cm limited to the thyroid or any tumor with minimal extrathyroid extension
T4a	Tumor of any size extending beyong the thyroid capsule to invade the subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve
T4b	Tumor that invades prevertebral fascia or encases carotid artery or mediastinal vessels
Anaplastic carcinomas*	
T4a	Intrathyroidal—surgically resectable
T4b	Extrathyroidal—surgically unresectable
REGIONAL LYMPH NODES (N STAGE)	
Nx	Regional nodes cannot be assessed
N0	No palpable nodes
N1	Regional nodal metastases
N1a	Level VI nodes (pretracheal, paratracheal, prelaryngeal)
N1b	Metastasis to unilateral, bilateral, or contralateral cervical or superior mediastinal nodes
DISTANT METASTASES (M STAGE)	
Mx	Metastases cannot be assessed
M0	No evidence of distant metastases
M1	Distant metastases present

*All anaplastic carcinomas are considered T4 tumors.

Laboratory Tests

Except for measurement of calcitonin in the diagnosis of medullary carcinoma, assessment of plasma levels of thyroid hormones has limited value in the diagnosis of thyroid cancer except in the rare patient who has a suppressed TSH and has a functioning nodule. Serum thyroglobulin (Tg) levels can be elevated in patients with cancer, but this test is not specific, and similar increases are seen in benign thyroid disorders. The American Thyroid Association guidelines do not recommend measurement of Tg preoperatively.[55] However, serum thyroglobulin is an important test in the follow-up of patients who have undergone thyroid resection for differentiated

thyroid cancer. A level greater than 2 ng/mL with a suppressed TSH or 10 ng/mL while off thyroid hormone is a reliable indicator of locally recurrent or metastatic disease[56,57] and could predict the need for ablative doses of ^{131}I; undetectable values (<0.5 ng/mL), especially after TSH stimulation, greatly reduce the need for further imaging studies to detect presumptive metastases.[58]

In patients who are hyperthyroid with a nodule, scanning with ^{123}I is advised; hyperfunctional or "hot" nodules rarely are malignant.[59] There is one exception to this rule: a functioning nodule in a child has a higher risk of being cancerous.[60] In contrast, patients with Graves' disease can have a nonfunctioning nodule, which can be malignant and should be investigated by fine-needle aspiration.[61] In euthyroid patients, fine-needle aspiration is the best first test.[62] Although "hot" nodules rarely are malignant, approximately 10% to 20% of "cold" nodules are malignant. Thyroid radionuclide imaging, therefore, has limited efficacy in distinguishing reliably between benign and malignant abnormalities. Differentiated thyroid cancers will trap iodine but are less efficient at concentrating iodine than the normal thyroid gland. Therefore, iodine uptake in a thyroid cancer typically can be demonstrated only after all normal thyroid tissue has been ablated and the TSH level is allowed to rise. There can be biochemical, quantitative, and intracellular positional alterations in the sodium-iodide symporter (NIS) in thyroid cancer cells.[63] Ultrasonography may be useful in distinguishing among cysts, cystic tumors, and solid tumors of the thyroid.[62] Small cysts are unlikely to be cancerous, but all cysts should be aspirated and the aspirate examined cytologically. Aspiration of a benign cyst often will suffice for both diagnosis and therapy, whereas fluid tends to reaccumulate in a cystic cancer. Because a malignant tumor of the thyroid may present as a solid, cystic, or mixed lesion, ultrasonography alone is not diagnostic.[64]

Needle biopsy, particularly fine-needle aspiration, is the diagnostic procedure of choice for thyroid nodules in euthyroid patients.[62] When the result of fine needle aspiration biopsy is clearly positive or clearly negative, the decision regarding surgery, or no surgery, can be made confidently.[65,66] However, a negative fine-needle biopsy or cutting needle biopsy does not ensure that a thyroid mass is not malignant (false-negative rate, 1% to 5%), and clinical concern and careful follow-up will dictate the decision to proceed to resection. Fine-needle aspiration biopsy appears to be less reliable in patients with a history of radiation exposure to the head and neck or a family history of thyroid cancer, primarily due to the multifocal nature of the tumors present in these scenarios.[67] High-resolution ultrasound guidance to perform fine-needle aspiration accurately is being used routinely. Ultrasound alone can identify features of nodules that increase the a priori risk of malignancy such as fine stippled calcification and enlarged regional nodes, but a tissue diagnosis is strongly recommended prior to thyroidectomy. The common indications for ultrasound-guided fine-needle aspiration are for biopsy of nodules that are nonpalpable or difficult to palpate, for previously failed fine-needle aspiration, and for nodules incidentally identified during neck

Table 75-3 Staging of Thyroid Cancer

Stage	TNM
Patients < age 45 years	
I	Any T, any N, M0
II	Any T, any N, M1
Patients ≥ age 45 years

imaging for other reasons. Ultrasound-guided fine-needle aspiration has been shown to result in improved cancer diagnosis on significantly smaller nodules compared with fine-needle aspiration performed by palpation.[68]

Treatment

Treatment of thyroid cancer includes surgery, ^{131}I radiation, and suppression with thyroid hormone.[39,69] External-beam therapy also (rarely) has been employed.

Surgery of the Thyroid

Debate continues concerning the optimal surgical treatment of well-differentiated thyroid carcinoma. Preoperatively, the surgeon often cannot be certain whether a thyroid nodule is cancer, and must make a decision concerning the extent of operation based on clinical judgment. Young patients with small, well-encapsulated tumors that appear benign on frozen section, with a normal contralateral lobe, can be treated with lobectomy. A history of neck irradiation, the presence of contralateral disease, and cytologic or histologic findings suggestive of malignancy influence the decision to perform a total or near-total thyroidectomy. The location of the parathyroid glands and recurrent nerve also can influence the extent of lobectomy on the contralateral lobe. When a diagnosis of thyroid carcinoma is clear, a total or near-total thyroidectomy is preferred.[70–72] The rationale for this decision is based on several facts related to the biology of thyroid carcinoma. First, thyroid cancer often can be multicentric, and resection of the contralateral lobe often identifies malignancy. Second, a total thyroidectomy can be performed safely with a low morbidity rate. Patients with thyroid carcinoma will be treated with thyroid replacement postoperatively, regardless of whether an adequate, normal-functioning thyroid is left intact. Resection of the entire gland facilitates both the use of radioiodine postoperatively and the use of thyroglobulin levels as a tumor marker. Because papillary cancer often metastasizes to regional lymph nodes, if enlarged nodes are identified at thyroidectomy, a midneck dissection on the ipsilateral side is performed at resection. Follicular cancer rarely demonstrates lymph node metastases, and a midneck dissection is not routinely justified during thyroidectomy. Modified neck dissection is advocated only in instances of obvious nodal metastases involving the lateral cervical nodes.

Debate continues as to whether recurrence and fatality are influenced by the extent of surgery.[73,74] A study by Van Nguyen and associates[75] showed that for low-risk patients total thyroidectomy gave results identical to those with lobectomy. Shaha and associates[76] reported 1038 patients with thyroid carcinoma, 465 of whom were in the low-risk group. The mean follow-up period was 20 years. Their study did demonstrate significant improvement in local recurrence with lobectomy compared with less extensive operations. However, results for lobectomy compared with those of total thyroidectomy failed to achieve significance, with local recurrence of 4% versus 1% ($P = 0.1$) and overall failure of 13% versus 8% ($P = 0.06$). However, these studies did demonstrate a trend for total thyroidectomy giving superior results when compared to lobectomy. Sanders and Cady[35] did not demonstrate a difference in survival comparing total thyroidectomy and lobectomy in low-risk patients. Of particular interest is the study by Wanebo and associates,[77] who examined extent of operation for low-, intermediate-, and high-risk groups. Their work failed to demonstrate any difference in survival with extent of operation in all risk groups.

Other studies have demonstrated improved outcome with total thyroidectomy. Samaan and associates[78] examined 1599 patients with well-differentiated thyroid carcinoma and reported improvement in recurrence for total thyroidectomy compared to lesser operations. DeGroot and associates[34] demonstrated a decreased recurrence rate for total thyroidectomy compared with lobectomy and a significant improvement in mortality rate. Mazzaferri and Jhiang[33] reported their study of 1355 patients with a mean follow-up of 15.7 years. They reported significant improvements in recurrence rate (26% vs. 40%; $P < 0.002$) and mortality rate (6% vs. 9%; $P = 0.02$) comparing total thyroidectomy with lesser procedures. Loh and associates[79] reported their results in 700 patients with a mean follow-up period of 11.3 years. They demonstrated significant improvement in recurrence and mortality rates with total thyroidectomy or near-total thyroidectomy compared with lesser operations, particularly for advanced tumors. Given these reports, and the fact that accurate risk-stratification of patients preoperatively is not possible, it is recommended that all patients with differentiated thyroid cancers identified preoperatively undergo a near-total or total thyroidectomy, provided the procedure can be accomplished with minimal morbidity.

A thyroidectomy begins with the patient anesthetized in the supine position with the neck in extension (Fig. 75-2). A Kocher collar incision is made, and dissection is carried out through the platysma. Superior and inferior flaps are raised by dissection in the avascular plane deep to the platysma muscle, superiorly to the level of the thyroid cartilage and inferiorly to the suprasternal notch. Strap muscles can be divided in the midline. It rarely is necessary to transect either the strap muscles or the sternocleidomastoid muscle. The thyroid lobe is exposed using blunt dissection. Occasionally, it is necessary to resect en bloc regions of muscle invaded by tumor. The thyroid lobe is reflected medially and the middle thyroid vessels are ligated. The isthmus can be divided between clamps and ligated early in the procedure; this often facilitates dissection, particularly for large goiters. Branches of the superior pole vessels are identified close to the superior pole and ligated individually to avoid injury to the external branch of the superior laryngeal nerve. Once the superior pole is mobilized, the recurrent nerve is identified by careful dissection in the region of the inferior thyroid artery. The parathyroid glands should be sought and left with their blood supply intact. The parathyroid glands usually can be identified within 1 cm of the crossing of the recurrent laryngeal nerve and the inferior thyroid artery. Occasionally, a parathyroid gland is devascularized; after confirmation of identity by frozen section, this gland can be reimplanted into the sternocleidomastoid muscle. The inferior thyroid pole also is mobilized by a combination of blunt dissection and ligation of the inferior thyroid vessels. The thyroid then is dissected off the trachea until the ligament of Berry is reached. This structure often contains small vessels, and the nerve is most vulnerable in this location. Once the ligament is carefully divided, the thyroid can easily be separated off the trachea. The contralateral lobe always should be exposed to examine for gross pathologic processes. A total thyroidectomy is completed by performing the contralateral lobectomy in a fashion identical to that used for the ipsilateral lobe. Occasionally, to preserve the blood supply to the parathyroid glands, it is reasonable to perform a subcapsular dissection of the contralateral lobe, leaving a small area of thyroid in the region of the parathyroid gland. This procedure is referred to as a near-total thyroidectomy.

Radiation Therapy

Metastatic cancer shown to accumulate ^{131}I warrants treatment with 100 to 200 mCi of ^{131}I. Radioiodine treatment is accomplished by discontinuing thyroid hormone replacement and allowing the patient to become hypothyroid, with resultant TSH stimulation of metastases to achieve increased uptake of ^{131}I. A low-iodine diet is advised for 2 weeks prior to testing and treatment. Figure 75-3 shows an example of a radionuclide scan in a patient with pulmonary metastases from papillary thyroid carcinoma. Most authorities obtain a whole-body scan with a diagnostic dose of ^{131}I, or ^{123}I before treatment with ^{131}I. That scan provides information about the quantity of residual thyroid tissue and the presence of local or distant metastases. The information helps in the selection of the appropriate therapeutic dose of ^{131}I. Knowledge of normal and variants of normal distributions of iodine help ensure that interpretation of the scan does

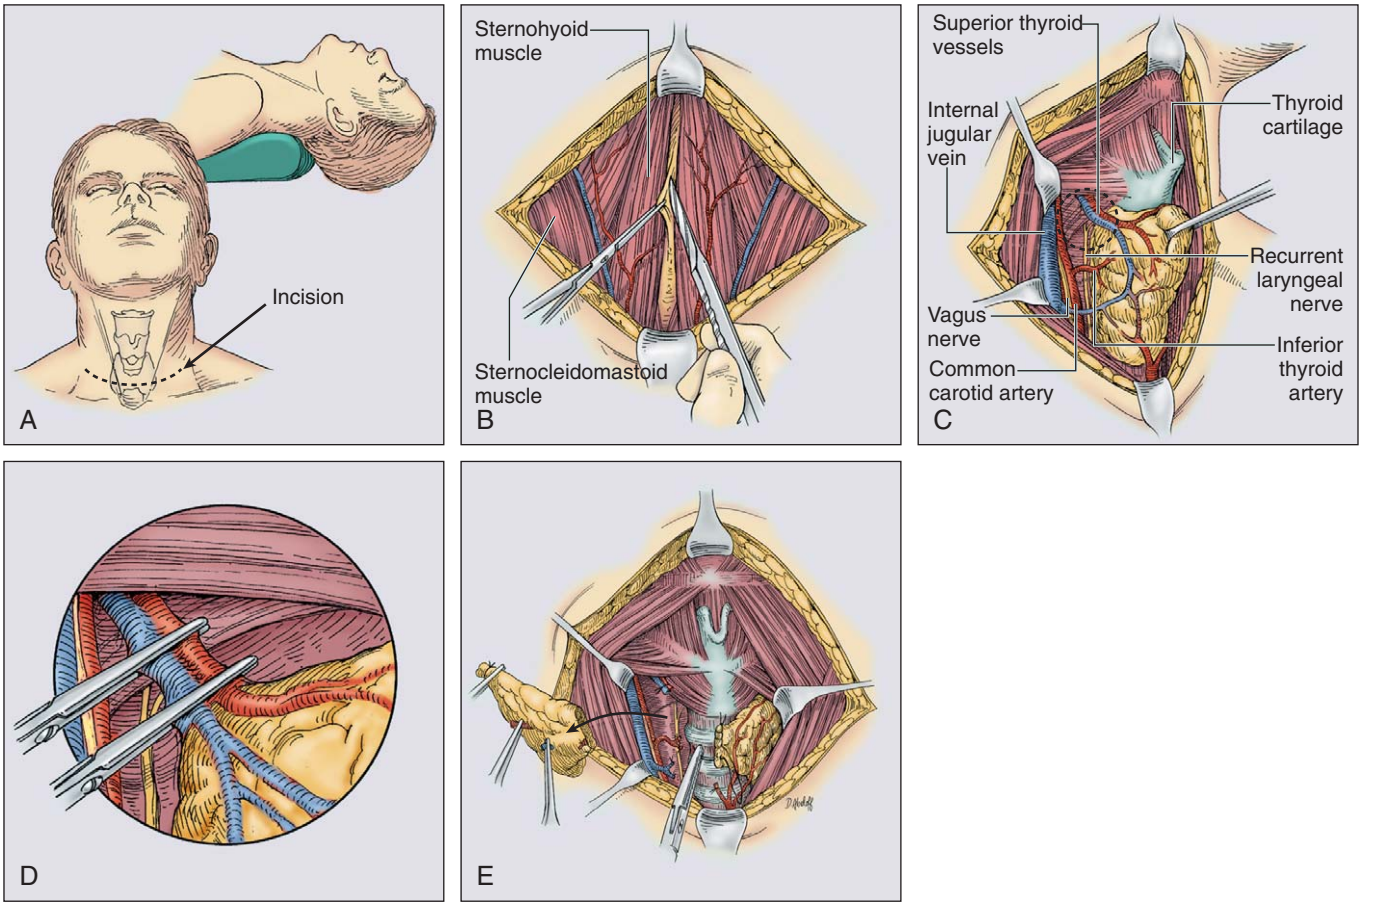

Figure 75-2 • Thyroidectomy. **A,** The patient is placed with the neck in extension. The thyroid is approached through a Kocher collar incision, which is commonly made approximately 2.0 cm superior to the sternal notch. **B,** The strap muscles are divided in the midline to expose the thyroid gland. **C,** The strap muscles are retracted laterally and the thyroid is retracted medially, exposing the structures of the midneck. The recurrent laryngeal nerve can be seen lying within the tracheosophageal groove. **D,** The superior pole vessels are individually clamped and ligated as they enter the thyroid gland. Inferior thyroid vessels, as well as the thyroidea ima vessels, are individually suture-ligated. **E,** The dissection is completed by dissection of the thyroid gland off the trachea. The isthmus is then transected and can be oversewn with a suture for hemostasis.

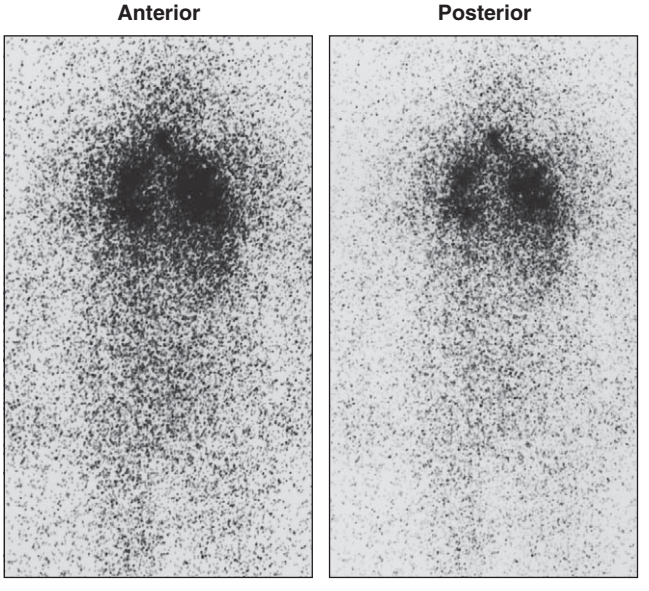

Figure 75-3 • ^{131}I scan in a patient with metastatic papillary thyroid cancer demonstrating diffuse pulmonary metastases from papillary thyroid carcinoma. Anterior and posterior views are shown.

not produce a "false" positive.[69,79] In Figure 75-4 a whole-body scan shows metastases in cervical lymph nodes. In contrast, Figure 75-5 shows uptake in the mediastinum indicating the thymus, not nodal metastasis.[80] Following administration of ^{131}I, thyroid replacement therapy is restarted. This cycle can be repeated at 6- to 12-month intervals. Residual thyroid and locally invasive thyroid cancer can be eliminated, but success is related to extent of thyroidectomy.[81–83] Similarly, functioning metastases in lymph nodes can be eliminated[84–86]; however, when the nodes are palpable it is recommended that they be removed.[87] Small homogeneous pulmonary metastases can be cured, but in bulky distant lesions, especially in the skeleton, cure is uncommon.[88,89] Recent data have failed to demonstrate an improved disease-specific survival or disease-free survival in patients with Stage I thyroid cancer treated with ^{131}I.[36,90]

A number of controversial topics are related to radioiodine therapy:

- Park and associates[91] showed in a small number of patients that large diagnostic doses, especially 5 to 10 mCi, can "stun" the thyroid, and subsequent therapy is not trapped as expected. In a comparison of 300 diagnostic scans made with 2 mCi ^{131}I and subsequent post-therapy whole-body scans, possible stunning was found in only 2%.[92] In two of the four patients, the follow-up scan was negative, so stunning probably had not occurred.
- Is it necessary to conduct a diagnostic whole-body scan? Because of the report of Park and associates, some physicians prescribe ^{131}I

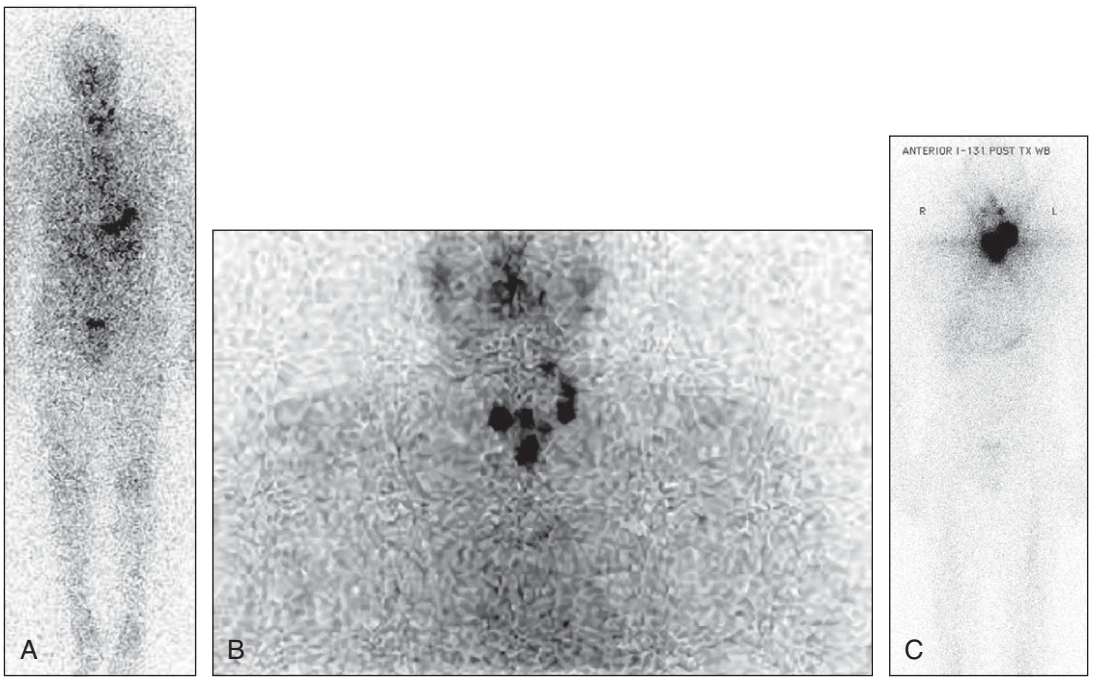

Figure 75-4 • **A,** Whole-body scan acquired 24 hours after administration of 2 mCi ^{123}I. **B,** Spot view of the neck and chest. There are several areas of uptake indicative of residual thyroid and functioning metastases in cervical lymph nodes. **C,** Post-therapy scan made 7 days after administration of 150 mCi ^{131}I. There is intense uptake in the region, but the resolution is not as good as with ^{123}I. There is faint uptake in the liver on the post-treatment scan due to metabolism of radioiodinated thyroid hormones at that site.

therapy without a prior diagnostic scan. This practice could result in treating patients who do not require therapy, and, furthermore, it does not allow tailoring of the dose. For those concerned about stunning, ^{123}I provides superior images and substantially less radiation to the residual thyroid, making stunning extremely unlikely.[93,94]

- How should patients who have a negative diagnostic scan but have elevated thyroglobulin be treated? A small number of patients have been treated with large doses of ^{131}I when the prior diagnostic scan was negative but serum thyroglobulin was elevated.[95] The rationale is that cells producing thyroglobulin can trap enough ^{131}I to expect a therapeutic effect. These patients are then followed by serum Tg measurement and are re-treated when the thyroglobulin remains high. On the other hand, both high-resolution neck ultrasounds and positron emission tomographic (PET) scans, particularly when

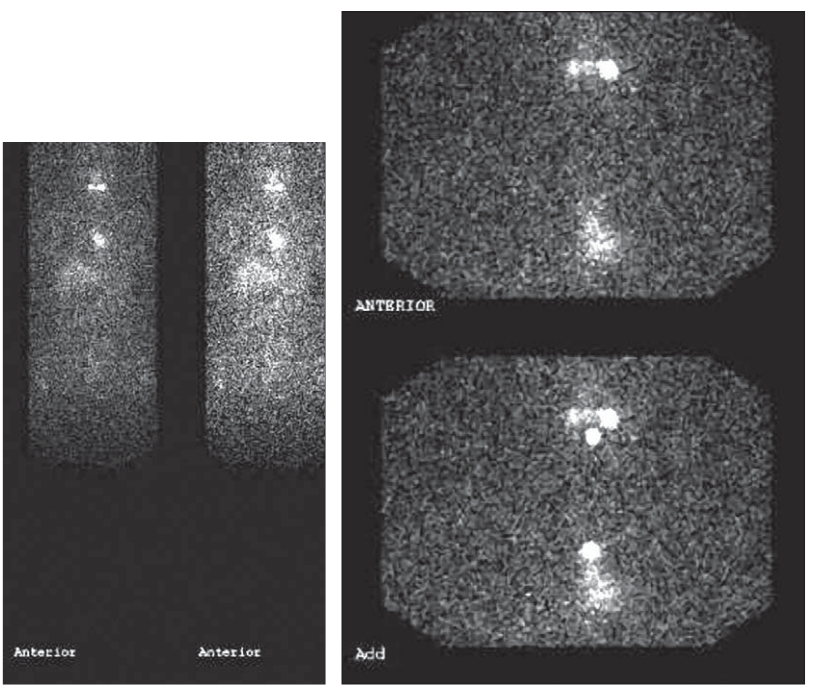

Figure 75-5 • Whole-body scans of a patient who had total thyroidectomy and ^{131}I for thyroid cancer (*left*). Spot views of the neck and chest (*right*). The lower panel has markers at the chin and mid-sternum to help anatomic interpretation. The patient was treated with a second dose of ^{131}I because of an elevated Tg level. This post-treatment scan shows no uptake of ^{131}I in the neck, but there is physiologic uptake in the salivary glands and uptake in the mediastinum. The mediastinal uptake is characteristic of the thymus and is a potential false positive finding.

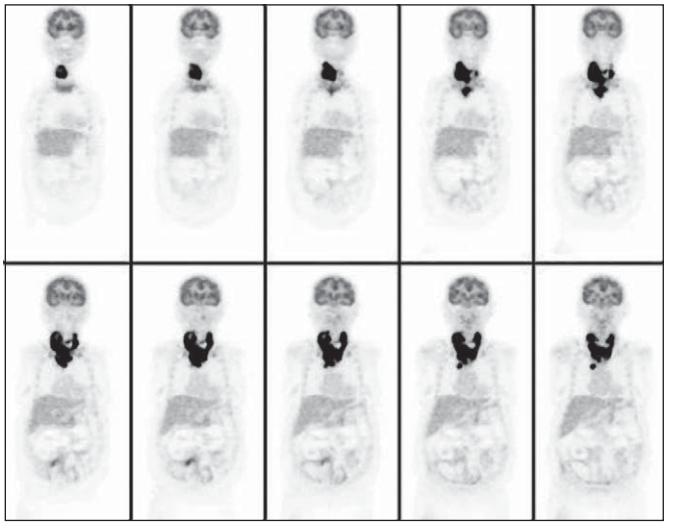

Figure 75-6 • PET scan of a 75-year-old woman with anaplastic cancer of the thyroid. Images were acquired 1 hour after intravenous injection of 15 mCi ^{18}F-fluorodeoxyglucose (FDG). There is intense uptake of FDG in the undifferentiated cancer.

combined with CT scans, have shown utility in identifying sources of increased Tg in patients with biochemical evidence of recurrent or persistent disease but negative ^{131}I scans.[96,97] Figure 75-6 shows a PET scan that was performed to stage the extent of an anaplastic cancer and is presented to demonstrate the superb resolution.

Radioactive iodine treatment generally is well tolerated. Some patients develop swelling of the salivary glands, which can be reduced or prevented by having them suck lemon candy. A dry mouth can be a troubling aftermath. Leukemia has been reported to occur following ^{131}I when given in repeated doses and at shorter intervals than is currently advised.[98] Although there have been reports of pulmonary fibrosis developing when uptake in pulmonary metastases was extensive, the risk of dying from pulmonary metastases is significantly greater. Radiation safety precautions are necessary. The patient should be kept isolated until the body load of ^{131}I is reduced. This approach requires consultation among the patient, the family, and a nuclear medicine physician.

Some studies have examined the use of recombinant human TSH (rhTSH) as an alternative protocol in preparation for ^{131}I treatment. Treatment with rhTSH has been shown to induce increased Tg and improved uptake of iodine in a manner similar to induction of hypothyroidism.[99] However, in a recent study of 127 patients in whom rhTSH and thyroid hormone withdrawal were compared, induction of hypothyroidism was found to be superior to rhTSH.[100] Patients treated under the rhTSH protocol do avoid the symptoms associated with hypothyroidism. We have used rhTSH in more than 160 patients and have found it can replace withdrawal scans provided both the scan and Tg are obtained. The average TSH is well above 100 IU/mL. RhTSH treatment was preferred by the patient over withdrawal of thyroid hormone in all but one patient.[101] In addition, improvement in the treatment protocol with rhTSH may result in improved efficacy.[102] Although ^{131}I is the mainstay of radiation treatment of thyroid carcinoma, external-beam radiation also plays a role in the treatment of this disease.[103,104] Persistent or recurrent thyroid cancer may fail to take up ^{131}I, especially tumors that recur after multiple radioactive iodine treatments. Extremely bulky tumors may fail to be completely controlled with ^{131}I, and the treatment of anaplastic thyroid cancer[105] almost always includes external-beam treatment. Radiation therapy also is useful for bony metastases not amenable to resection.[106] Treatment of the thyroid tumor bed involves both sides of the neck and the upper mediastinum. Minimal residual disease (positive surgical margins or small gross residual in an ^{131}I-negative tumor) can be treated with 60 Gy, whereas larger amounts of disease will require doses of 65 to 70 Gy. Because the target volume wraps around the spinal cord and the tolerance of that structure is only 45 Gy, the dosimetry of thyroid bed irradiation is extraordinarily challenging. Figure 75-7 illustrates the type of complex radiation therapy performed for this disease.

Use of Thyroid Preparations for Suppression of Thyroid-Stimulating Hormone

Differentiated thyroid cancers respond to TSH by growing, producing, and secreting Tg and by trapping more iodine. Conversely, suppression of TSH can slow or reverse growth and lower Tg. Some reports suggest that thyroxine suppression of TSH decreases recurrence after thyroid resection for differentiated carcinomas.[107] When using the strategy of TSH suppression, it is important to follow plasma TSH levels to ensure an adequate thyroxine dose. In patients who have been adequately treated by surgery or radioiodine and who have no clinical evidence of disease, a negative ^{131}I scan, and undetectable Tg, it is debatable whether suppressed TSH adds any benefit,

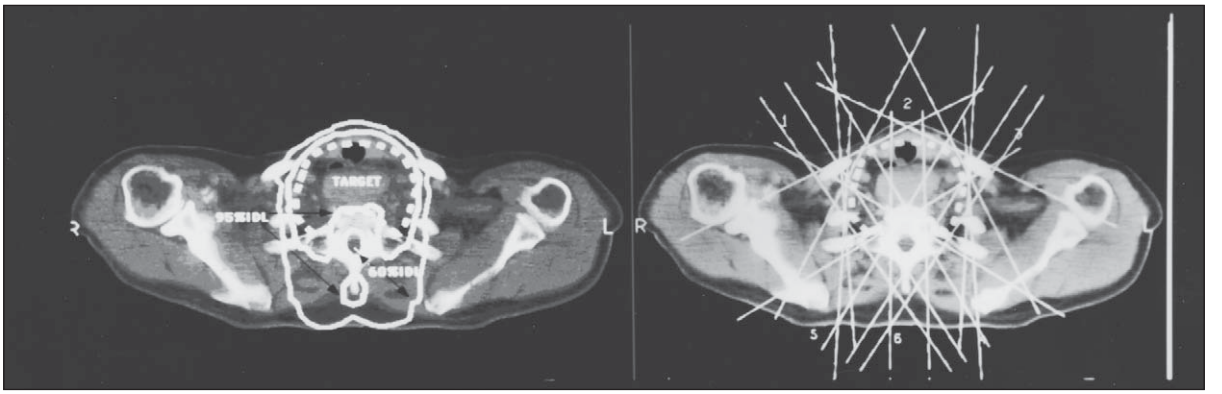

Figure 75-7 • External beam radiation for thyroid carcinoma can be quite complex. On the left, the target for this bulky thyroid carcinoma is marked with a dashed line. The high-dose volume (95% dose line) encompasses this target while avoiding the spinal cord. The radiosensitive spinal cord is in the 60% isodose line, which permits delivery of doses up to 70 Gy with this plan. On the right is a superimposition of the six cross-firing fields that are used to create this dose distribution. The fields either avoid the spinal cord or include a lead block to shadow the spinal cord, protecting it from the high-dose radiation. The treatment planning and dosimetry of thyroid carcinoma treatment is one of the most complex challenges in radiation oncology.

and side effects of long-term TSH suppression such as anxiety, bone loss, and arrhythmias have to be considered, particularly in older patients.

Postirradiation Tumors

The natural history of postirradiation thyroid carcinoma has been reviewed by Roundebush and DeGroot.[108] Patients tend to be younger (mean age, 28 years) and have a higher incidence of multifocal tumors. This study and others[109] have contributed to the development of treatment recommendations for persons known to have been exposed to ionizing radiation. When palpation of the neck is normal, the patient is followed by careful clinical examination at yearly intervals. The value of a thyroid scan has not been proved. When a discrete nodule is noted, fine-needle aspiration is indicated, and if the result is suspicious, the patient is referred to surgery. In the case of small benign nodules, clinical follow-up with or without thyroid hormone is appropriate. Shimaoka[110] noted that exogenous thyroid hormone caused shrinkage of the nodules in about 50% of cases. Some authorities recommend thyroidectomy for patients with a history of radiation exposure and a thyroid nodule, skipping fine-needle biopsy due to the high rate of false-negative biopsy in this setting.[111]

Schneider and associates,[112] reporting on a large surgical experience with postirradiation thyroid carcinoma, found results similar to those noted for spontaneous thyroid cancers. Because many thyroids have multifocal disease, the surgeon usually cannot perform lobectomy for an apparent single nodule, and in general, when there is preoperative suspicion of thyroid cancer, total or near-total thyroidectomy is advised. Schneider and associates[112] found that the likelihood of nodules developing in the remnant following subtotal thyroidectomy was 36%. The risks of total thyroidectomy (i.e., damage to the laryngeal nerve and hypoparathyroidism) must be balanced against the slow growth of papillary carcinoma and the potential for cure.

Chemotherapy

Cytotoxic drug treatment for metastatic thyroid cancer has not been evaluated extensively. The largest experience is with anaplastic carcinomas, which have high growth rates and a very poor prognosis. Doxorubicin is the most active single agent in both medullary and nonmedullary carcinomas of the thyroid.[105,113] In a report from the Southwest Oncology Group, the combination of doxorubicin and cisplatin resulted in an objective response in 27% of 41 patients.[114] A similar trial reported by the Southeastern Cancer Study Group, however, failed to document this level of activity, with only two partial responses out of 22 subjects.[115] Novel therapies currently being investigated for the treatment of thyroid cancers refractory to other treatments include tyrosine kinase inhibitors targeting RET/PTC translocations[116] and angiogenesis inhibitors.[117,118] A small phase II clinical trial has shown that treatment with rosiglitazone, a peroxisome proliferator-activated receptor gamma agonist resulted in increased radioactive iodine uptake in 4 out of 10 patients with persistent thyroid cancer that was radioactive iodine scan negative at study initiation.[119]

MEDULLARY CARCINOMA OF THE THYROID

Medullary thyroid carcinoma (MTC) arises from the parafollicular C cells, which are part of the amine precursor uptake decarboxylation (APUD) system, rather than thyroid epithelial cells (see Fig. 75-1D). Medullary thyroid carcinoma accounts for 6% to 10% of all thyroid cancers. It can occur sporadically or in a familial form, either as part of multiple endocrine neoplasia type 2 (MEN-2) or as a familial MTC without MEN association. The gender distribution is approximately equal. The tumor is unilateral in most sporadic cases and bilateral and multifocal in familial cases.[120–122]

Diagnosis

Any thyroid nodule could be MTC (Fig. 75-8); however, a family history of MTC, pheochromocytoma, hyperparathyroidism, or other manifestations of MEN-2 increases this likelihood. Plain film radiography of the neck may be useful. Keiser and associates[123] reported that tumor calcification was present in 35% of the patients in their series. Lymph nodes often are enlarged clinically and at surgery are involved pathologically in two thirds of patients.[124] Amyloid deposition between the spindle-shaped tumor cells is characteristic of MTC. The presence of calcitonin messenger RNA (mRNA) has been used to diagnose MTC when the histologic type is unclear.[125] The molecular diagnosis of MEN-2 is discussed later in this chapter. The parafollicular C cells secrete calcitonin, a peptide hormone that inhibits bone resorption. Calcitonin secretion is stimulated by calcium infusion. In patients with MTC, the basal calcitonin level is elevated above normal[126] and can be increased further with infusion of calcium and pentagastrin. The few cases of MTC that exhibit normal basal plasma calcitonin levels demonstrate an exaggerated response to calcium and pentagastrin.[126,127] The excessive calcitonin secretion does not appear to exert any metabolic effect. In the familial form, the associated parathyroid hyperplasia is an independent manifestation of the MEN syndrome inasmuch as it may precede MTC. MTC tumors also may contain large quantities of histaminase[128] and dopadecarboxylase,[129] neither of which produces any clinical syndrome. Serum histaminase is increased in many patients with metastatic disease, and its presence suggests metastases.[130] The diarrhea that

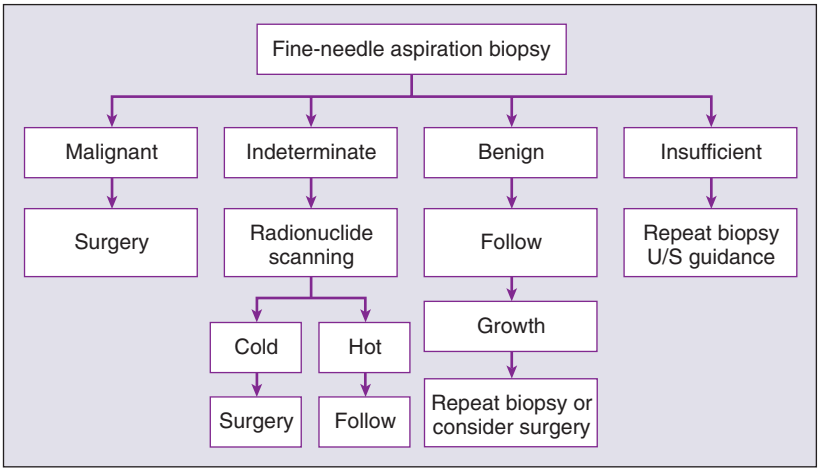

Figure 75-8 • Diagnosis of a thyroid mass.

occasionally accompanies the syndrome has been attributed in some studies to prostaglandin secretion,[131] but other investigators have not found this association.[132] Other compounds secreted by C-cells include carcinoembryonic antigen (CEA), corticotrophin, vasoactive intestinal peptide, and serotonin. MTC is one cancer in which it is possible to recognize the precancerous state. In the familial form, C-cell hyperplasia occurs prior to the development of carcinoma,[133] making it crucial for the physician to measure basal and stimulated calcitonin levels in all family members of a patient with MTC. Stimulation tests performed with calcium or pentagastrin predicted MTC in 12 members of one family, 11 of whom had no clinical evidence of disease.[134,135] Similarly, Jones and Sisson[136] were able to identify eight children, whose disease was diagnosed by appropriate testing, who were members of a family with the MEN-2 syndrome. However, these stimulation tests were associated with unpleasant side effects that could potentially affect compliance with annual provocative testing in members of MTC families. Because mutations in the RET proto-oncogene have now been established in MEN-2, family members can be screened at birth, obviating yearly provocative testing and allowing affected members to be offered early thyroidectomy.[137]

Treatment

Treatment of MTC is surgical excision. Because the cancer often is multifocal, surgery should include total thyroidectomy with complete resection of nodes in the central neck, that is, between the carotid sheaths laterally and from the thyroid cartilage superiorly to the suprasternal notch inferiorly. This includes paratracheal and upper mediastinal lymph nodes as well. If the patient presents with palpable lymph node disease, an ipsilateral modified radical neck dissection is also performed. Since the rate of contralateral lymph node metastases in this setting is high, some authors advise a prophylactic contralateral lymph node dissection, whereas others advise following postoperative calcitonin levels. In the absence of palpable disease, prophylactic modified radical neck dissection is recommended for primary tumors larger than 1.5 cm.[138,139] Deftos and Stein[140] have reported that ^{131}I treatment is occasionally a useful adjunct to surgery when a calcitonin-secreting remnant is identified following total thyroidectomy; however, subsequent studies have failed to show any benefit from ^{131}I.[122] The cancer per se does not trap iodine. Because pheochromocytomas occur in the MEN-2 syndrome, it is necessary to exclude their presence in MTC patients, as thyroid surgery in a case with an undetected pheochromocytoma could be disastrous. An identified pheochromocytoma should be removed first and the patient given time to recover before the MTC is excised.

The clinical course in cases with metastatic MTC is variable. Death due to lung, liver, or bone metastases may occur quite quickly. However, it is not uncommon for patients with MTC to be relatively asymptomatic, even with large tumor burden. Many patients may be debilitated by intractable diarrhea,[132131] which correlates with plasma calcitonin levels of greater than 20 ng/mL and which may be palliated by cytoreductive surgery[141] or the somatostatin analog octreotide.[142] Other therapies that have shown promise in small clinical trials include an anti-CEA antibody (Labetuzumab)[143,144] and tyrosine kinase inhibitors STI571 (Imanitib) and SD6474 (Zactima). STI571 has been used as therapy for gastrointestinal stromal tumors and has shown some efficacy against medullary thyroid cancer cells in vitro, however the doses needed to achieve inhibition indicate that it is less likely to be useful in clinical studies.[145,146] SD6474 is an orally administered tyrosine kinase inhibitor that has shown activity against medullary thyroid cancer in a small phase II study. About 26% of patients had evidence of partial response by CT criteria.[20,147]

ADRENOCORTICAL CANCER

Adrenocortical carcinoma is infrequent, representing less than 0.2% of all cancers,[148] and has an incidence of only 2 per 1 million population.[149] Adrenal cancer may develop at any age but most frequently appears in middle age. Hormonally functional tumors are slightly more common in women, and nonfunctioning tumors are more frequent in men. Although both functioning and nonfunctioning adrenal tumors occur, steroid-producing tumors[148,150] are more common. Secreted hormones include cortisol, androgens, estrogens and aldosterone, with up to 35% of tumors secreting multiple hormones. Nonfunctioning tumors are usually diagnosed after the patient has complained of pain or presents with a large abdominal mass. The combination of retroperitoneal location and inefficient steroid biosynthesis makes it likely that adrenal cancers will attain a large size before symptoms due to the mass or to hormonal secretion are noted. Thus, early detection and cure are unlikely.[148,150]

Clinical Features

Adrenocortical carcinomas may or may not produce steroid hormones. However, the steroid-synthesizing potential of adrenal tumors explains many of their laboratory and clinical features. For example, many women with functional adrenal cancers are virilized. This finding derives from the fact that the biosynthetic pathway to C19 steroids is almost always intact in functioning adrenal cancers, resulting in high urinary 17-ketosteroid (17-KS) excretion. Because adult men cannot be "hypervirilized," excessive androgen synthesis will not be clinically apparent in them unless urinary 17-KS or plasma androgens are measured. However, women are easily virilized, and this detection bias may account to some extent for the apparent predominance of functional tumors in women. Table 75-5 lists the hormonal syndromes produced by adrenal cancer, with estimates of their frequency. Specific diagnostic features of these syndromes are described in the following paragraphs.

Cushing's Syndrome

The characteristic endocrine abnormality of Cushing's syndrome is an increase of plasma 11-deoxycortisol and its urinary metabolite.[150] Cushing's syndrome may be a paraneoplastic syndrome associated with ectopic adrenocorticotropic hormone (ACTH) production by solid tumors. However, in such cases, virilization is rare. Virilization in association with Cushing's syndrome almost always indicates adrenal cancer,[151] because urinary 17-KS secretion ranges from 100 to 1000 mg/day—considerably higher than that produced by ectopic ACTH.

Virilization

Virilization is caused by testosterone, which is synthesized peripherally from adrenal androstenedione and dihydroepiandrosterone. It is the excess urinary 17-KS resulting from metabolism of these steroids that helps distinguish adrenal cancer from other virilizing syndromes. Occasionally, hirsutism is the only presenting feature with virilizing tumors.

Table 75-5 Clinical Syndromes Produced by Adrenocortical Cancer and Their Frequency

Syndrome	Frequency (%)
Virilization and Cushing's syndrome	50
Virilization	25
Cushing's syndrome	20
Feminization	<5
Precocious puberty	<5
Hypokalemia alkalosis	<5
Hypoglycemia	<5

Feminization

Plasma androstenedione may be converted peripherally to estrogen, a phenomenon that results in gynecomastia. Feminization with adrenal cancer is unusual. The relatively few cases in the world literature have been summarized.[152] Rates of aromatization are low; therefore, large quantities of androstenedione are required to produce significant plasma estrone concentrations. The major fraction of androstenedione is metabolized to urinary 17-KS. Thus, measurement of urinary 17-KS will distinguish the feminization caused by adrenal carcinoma from the gynecomastia seen with human chorionic gonadotropin (hCG)-producing tumors of the testis and with hCG-producing cancer. One should also be aware that prepubertal adrenal cancers have been reported to produce hCG in quantities large enough to cause a positive result in pregnancy testing.

Precocious Puberty

In children, precocious puberty or virilization may be an important and presenting clinical finding because androgens are the predominant products of adrenal cancer secretion. Isosexual precocious puberty in boys and virilization in girls are usual. A few cases of feminizing adrenal cancer causing isosexual precocious puberty have been reported in girls.[153]

Sodium Retention and Hypokalemic Alkalosis

Rarely patients with adrenal cancer will present with the picture of primary hyperaldosteronism. Most patients with Conn's syndrome have either idiopathic hyperaldosteronism (IHA) or an aldosterone-producing adenoma (APA). Carcinomas that secrete aldosterone are rare, although a syndrome of mineralocorticoid excess may be caused by secretion of deoxycorticosterone.[151,154,155] In this situation, urinary 17-KS is high, and the tumor is generally much larger than the APA.

Hypoglycemia

As with other large mesenchymal tumors in the abdomen, adrenal cancer may cause hypoglycemia. Measurement of plasma insulin levels will rule out insulin-secreting tumors as a cause of hypoglycemia.

Diagnosis

The diagnosis of adrenal cancer depends on clinical suspicion, urinary and plasma biochemical tests, and diagnostic imaging studies (Fig. 75-9). The size of the adrenal mass is important because in masses larger than 6 cm, the incidence of cancer has been reported to be 35% to 98%.[156] Copeland demonstrated that 92% of 114 examined adrenocortical cancers were >6 cm.[157] The sensitivity, specificity and likelihood ratio of tumor size in predicting malignancy (based on SEER data) was recently reported as 96%, 51% and 2 tumors = 4 cm; and 90%, 78% and 4.1 tumors = 6 cm.[158] The most useful imaging tests are CT scan, ultrasonography, and MRI. The CT scan also defines local extent of cancer, thereby facilitating surgical planning. Evidence of calcification in an abdominal mass on CT scan or plain abdominal film suggests adrenal carcinoma. MRI scanning can define the presence or absence of regional extension and influence the decision in regard to resectability. The characteristics of the adrenal mass on T_2-weighted MRI scanning can be useful in distinguishing adenomas and pheochromocytoma from carcinomas or metastatic cancer to the adrenal gland.[159,160] Iodocholesterol imaging is not useful[161] because steroid synthesis rates are low. More recently, PET scans have been used to identify malignant and metastatic lesions but these results need further validation.

Pathology

Adrenal cancers are frequently large and can weigh more than 100 g. They can be locally invasive into kidney, liver, and large blood vessels, with the inferior vena cava involved in many cases of right adrenal tumors. Grossly, the tumor is yellow to tan, with areas of necrosis and hemorrhage. Cytologically, it may be difficult to distinguish carcinoma from adenoma.[162,163] The tumor cells vary in configuration from spindle-shaped in less differentiated cancers to large polyhedral cells with abundant eosinophilic cytoplasm. Mitoses can be rare; some variation in nuclear morphology may be evident in both adenomas and carcinomas. Capsular invasion or blood vessel invasion is the most reliable sign of cancer. The combination of the following nine criteria was studied by Weiss and associates for usefulness in distinguishing malignant from benign adrenal tumors: nuclear grade III or IV; mitotic rate greater than 5/50 high-power fields; atypical mitoses; clear cells comprising 25% or less of the tumor; a diffuse architecture; microscopic necrosis; and invasion of venous, sinusoidal, and capsular structure. Tumors with four or more of these criteria were likely to metastasize and/or recur.[164,165] The diagnosis of malignancy of a completely resected adrenal tumor, however, may be made only in retrospect by the finding of metastatic disease many years later. Patterns of steroid secretion cannot be predicted by histologic or histochemical characteristics of adrenal neoplasms.

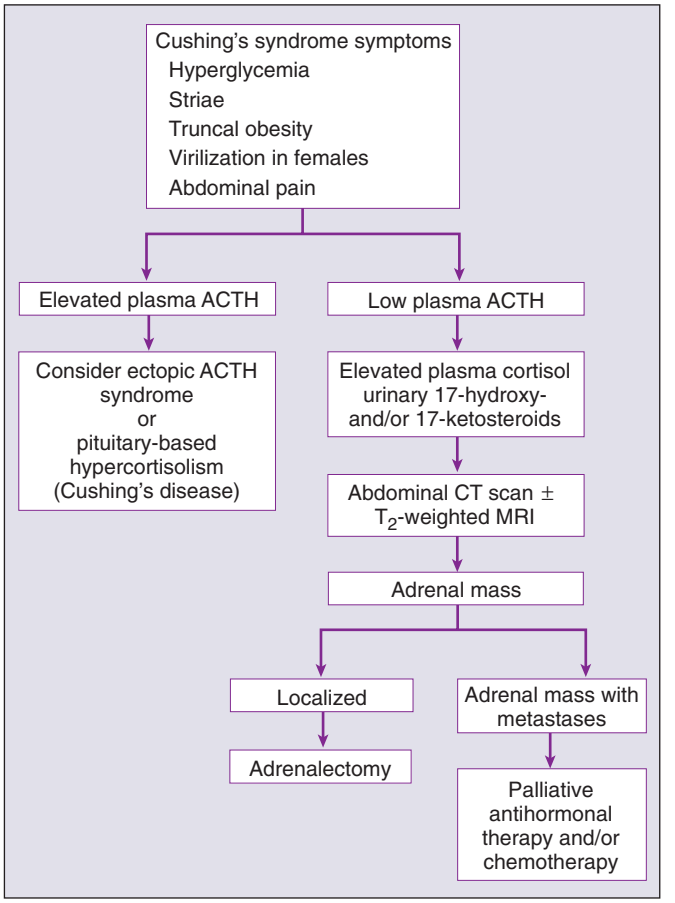

Figure 75-9 • Diagnosis and treatment of adrenal carcinoma. ACTH, adrenocorticotropic hormone.

Primary Treatment and Prognosis

The only curative therapy for adrenal cancer is aggressive en bloc resection of the primary tumor including the ipsilateral kidney.[166] This approach is attempted only in patients who have relatively limited cancers deemed to be potentially resectable.[167] Even with this approach, adrenocortical cancer is highly lethal, with a 5-year survival rate of 20% to 30%.[168] Fifty percent of patients have metastatic

disease at diagnosis. In patients with incurable adrenal carcinoma, suffering from symptoms secondary to tumor bulk or hormone excess, partial resection of tumor may offer significant palliation. In a minority of cases, the course may be indolent, with metastases developing over a period of 5 to 10 years. Metastases occur in lung, liver, and peritoneum, but uncommonly involve brain or bone.

Therapy for Metastatic Disease

Antihormonal Therapy

Some patients suffer more symptoms from hormonal excess than from tumor bulk. In them, antihormonal therapy can be useful. Metyrapone, an inhibitor of the 11β-hydroxylation step in cortisol biosynthesis, has been reported to be useful in the management of individual cases of Cushing's syndrome of adrenal carcinoma. However, it has proved largely ineffective in patients with metastatic disease.[169] Chemical confirmation of its effectiveness requires direct measurement of plasma cortisol. Urinary concentration of 17-OH steroids cannot be used to assess the efficacy of metyrapone, because the drug produces elevation in urinary 11-deoxycortisol, and therefore elevation in 17-hydroxycorticosteroids (17-OHCS), even though it decreases plasma cortisol.

Aminoglutethimide, an anticonvulsant that causes adrenal insufficiency, has been used in the treatment of adrenal carcinoma.[170] It is an effective palliative treatment in Cushing's syndrome secondary to adrenocortical carcinoma, adenoma, and ectopic ACTH production by extra-adrenal carcinoma, with the potential for rapid and sustained suppression of corticosteroid synthesis.[171,172] Because the drug may alter extra-adrenal metabolism of cortisol, measurement of urinary 17-OHCS excretion alone may overestimate the effectiveness of therapy; plasma cortisol concentration is a more reliable index of drug efficacy.[173] The usual clinical dose is within the range of 1 to 2 g/day. Significant adverse effects include anorexia, dermatitis, somnolence, ataxia, and decreased thyroid function.

Ketoconazole is another 11-β-hydroxylase inhibitor and blocks the production of not only cortisol, but also mineralocorticoids and androgens.[174] There are some reports of its efficacy in treating metastatic ACC.

Antineoplastic Therapy

In animals, the drug o,p′-DDD (mitotane) induced adrenocortical necrosis. Studies also demonstrated that mitotane was capable of inhibiting steroidogenesis.[175–177] Mitotane was initially evaluated in the 1960s.[178] In 138 cases of adrenal cancer evaluated, 17-KS and 17-hydroxycorticosteroid excretion was decreased by 50% in 70% of cases. A minimum of 4 weeks of therapy was required to ensure an adequate trial of therapy. Although steroid secretion was frequently improved with mitotane, tumor regression was uncommon, occurring in only 34% of cases with measurable disease. The mean duration of antitumor response was 10 months. Although objective response correlated with increased survival, hormonal response did not. The prognosis in women was better than in men; 52% of women and 38% of men survived for 4 years following diagnosis, with median survival times of 56 and 19 months, respectively.[178] Complete regression of tumors was not achieved.

Other investigators have also reported experience with mitotane. Libitz and associates[179] reported 115 patients with adrenal carcinoma treated with mitotane between 1965 and 1969. The measurable disease response in this series was 61%, with a steroid excretion response of 89%. The improved response rate in this series is attributed to a shorter median time between diagnosis and treatment with mitotane. Nader and associates[180] reported only a 19% remission rate in 77 patients. These results are likely secondary to differences in patient selection. Most patients treated with mitotane have experienced some degree of toxicity when the dosage was increased to the therapeutic range of 8 to 10 g/day. In general, the toxic reactions are mild, consisting of anorexia, nausea, vomiting, or diarrhea. Neuromuscular toxicity develops in 40% to 60% of patients, usually in the form of lethargy and somnolence. Vertigo and dermatologic toxicity are observed in 15%. Leukopenia and liver function abnormalities are rare.[178,179] Plasma mitotane levels may be useful in preventing toxicity.[181] With successful treatment of a functioning tumor, a substantial number of patients will develop signs of adrenal insufficiency. In summary, it is reasonable to expect objective rates of tumor regression following mitotane therapy in approximately 25% of cases.[150,178] The median duration of remission is 1 year, although some remissions have lasted longer than 3 years. Dosage regimens vary. Most clinicians initially administer 10 g/day, reducing the dose gradually to 1 to 2 g/day as regression is obtained. Diminution in size of metastases is rarely apparent before 6 weeks, although laboratory evidence of decreased steroid production may be noted earlier. Prolonged regression has been reported, and an apparent cure was seen with combined use of mitotane and 5-fluorouracil (5-FU).[182] Mitotane treatment is generally not recommended in the adjuvant setting since trials addressing this question have not been able to show a survival benefit.[183]

Very few chemotherapeutic agents other than mitotane have been evaluated in adrenocortical carcinoma in other than anecdotal experiences. Partial responses have been reported with doxorubicin.[184,185] Cisplatin has caused tumor regression in four patients, three of whom had previously received mitotane adjuvant therapy.[186] In two reports of only six patients, the combination of etoposide and cisplatin was reported to produce a response in five or six cases.[187,188] One patient had a complete response lasting 1 year. In general, adrenocortical cancers respond poorly to chemotherapy, likely due to increased expression of the multi-drug resistance (MDR-1) gene product which has been identified as p-glycoprotein. Mitotane has been demonstrated to inhibit p-glycoprotein, leading to increased efficacy of chemotherapeutic agents.[189] There has been recent interest in the use of suramin, a growth factor inhibitor, as therapy for adrenocortical carcinoma. In a Phase I study in 21 heavily pretreated patients, three cases developed partial response to suramin.[190–192] The role of suramin requires further definition, particularly because this drug may be associated with significant neurotoxicity. There was some interest in a new drug, gossypol, a naturally occurring (from the cotton plant *Gossypium* species) insecticide which appeared to inhibit the growth of adrenocortical cancer cell lines and tumors in vivo.[193,194] However, poor response rates combined with high death rates in limited clinical studies have reduced enthusiasm for this agent.

Surgical Approach to the Adrenal Gland

The surgical approach to the adrenal gland is influenced by the type of adrenal tumor. Adrenalectomy may be performed laparoscopically or via the open approach. Both open and laparoscopic adrenalectomy can be performed via the transperitoneal or posterior approach. The choice of approach depends on several factors including size of the lesion, nature of the lesion, and surgeon expertise. Laparoscopic adrenalectomy has been reported by a number of institutions with excellent results and has rapidly become the procedure of choice for benign-appearing lesions smaller than 6 cm in size. Laparoscopic adrenalectomy in the setting of malignancy is a subject of debate.[158] Although the data on the risk of local recurrence and widespread intraperitoneal carcinomatosis following these procedures is conflicting, most authorities agree that open adrenalectomy is indicated for suspected or known adrenocortical cancers and malignant pheochromocytomas.

Adrenocortical Adenomas

Laparoscopic adrenalectomy via the transperitoneal approach can be performed with the patient supine or in the lateral decubitus position. The latter is preferred as it uses gravity to aid retraction of surrounding organs, however, the patient does need to be repositioned for a bilateral procedure. This approach is depicted in Figure 75-10.

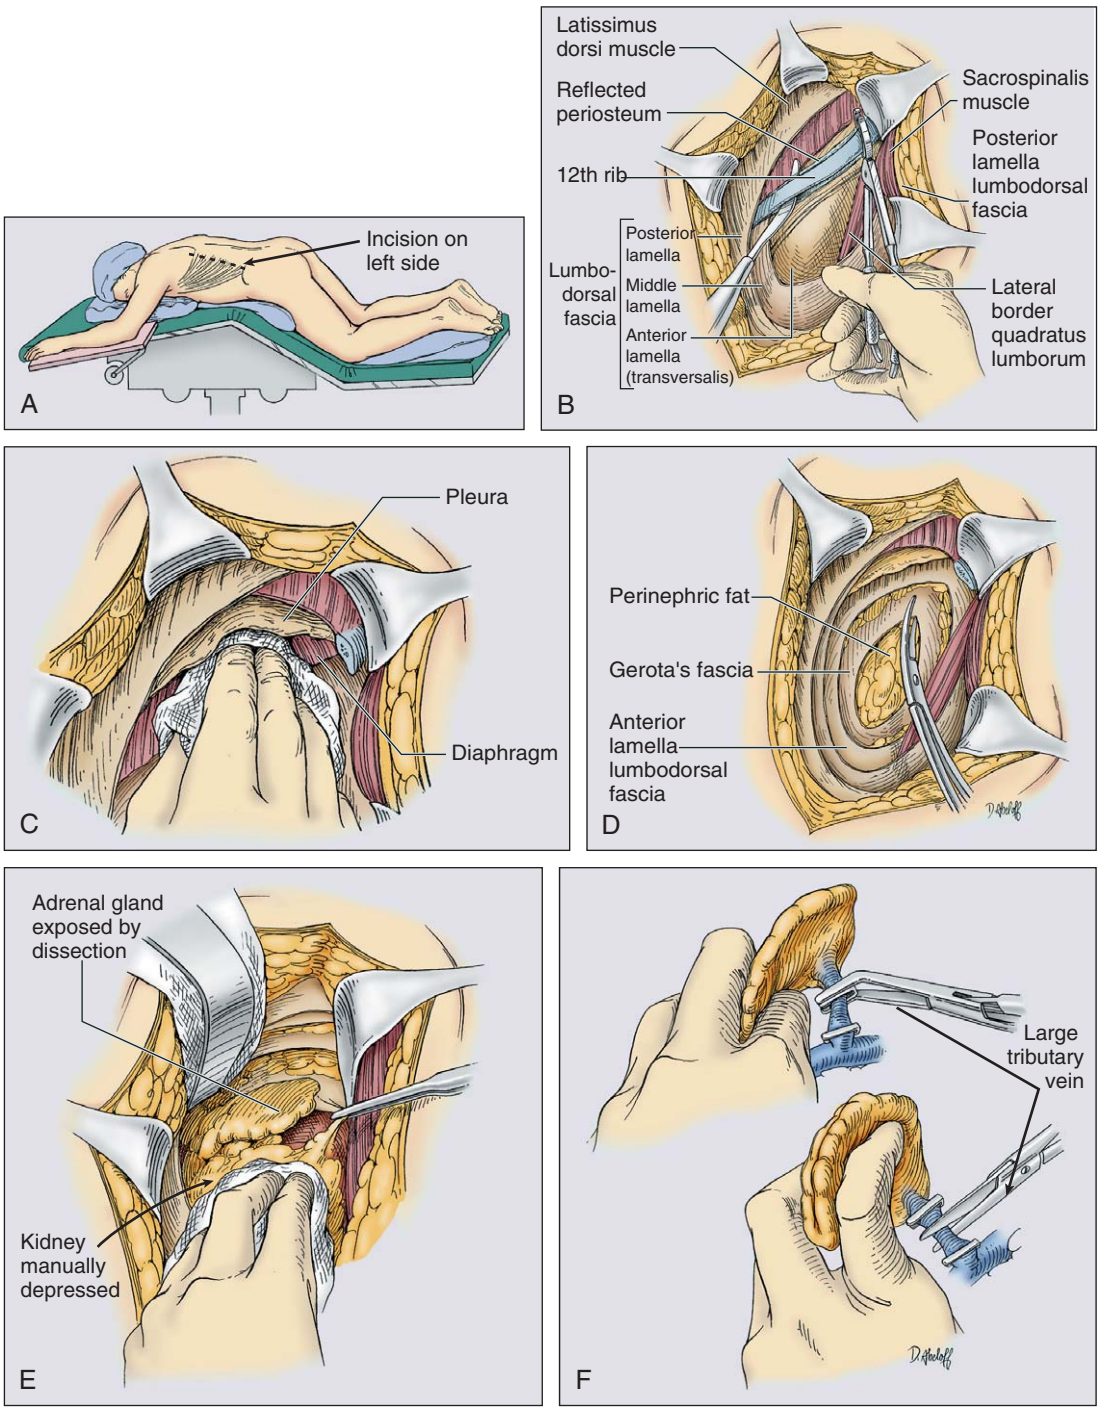

Figure 75-10 • Posterior approach to the adrenal gland: **A,** The patient is placed in a jack-knife, prone position, and a curvilinear incision is made in the flank. **B,** The 12th rib is removed subperiosteally, exposing the lumbodorsal fascia. **C,** The pleura is swept superiorly using a gauze-covered finger. **D,** The diaphragm is transected, exposing Gerota's fascia, which is then opened. **E,** The adrenal gland is exposed. **F,** Vessels of the gland are ligated with hemoclips and then transected. Abdominal approach to the adrenal gland: **G,** The adrenal glands commonly can be approached through a chevron incision. When only unilateral adrenal exploration is required, this incision can be limited to either a right or left subcostal incision. **H,** Basic anatomy of the adrenal glands as shown from an anterior approach. **I,** Positioning and trocar placement for laparoscopic adrenalectomy. The camera is inserted through port # 2, the fan retractor through port # 1; ports 3 and 4 are working ports. **J,** Dissection of the right adrenal. The liver is retracted upward with a fan retractor, and the adrenal is dissected circumferentially with L-hook or harmonic scalpel. **K,** Dissection of the left adrenal. The spleen is retracted upward, and the adrenal is dissected circumferentially. **L,** The right adrenal gland can be exposed by performing a Kocher maneuver and retracting the duodenum to the left. This allows good exposure of the right adrenal gland. **M,** Exposure of the left adrenal gland in the retroperitoneum is accomplished by mobilizing the spleen and retracting the spleen and stomach medially.

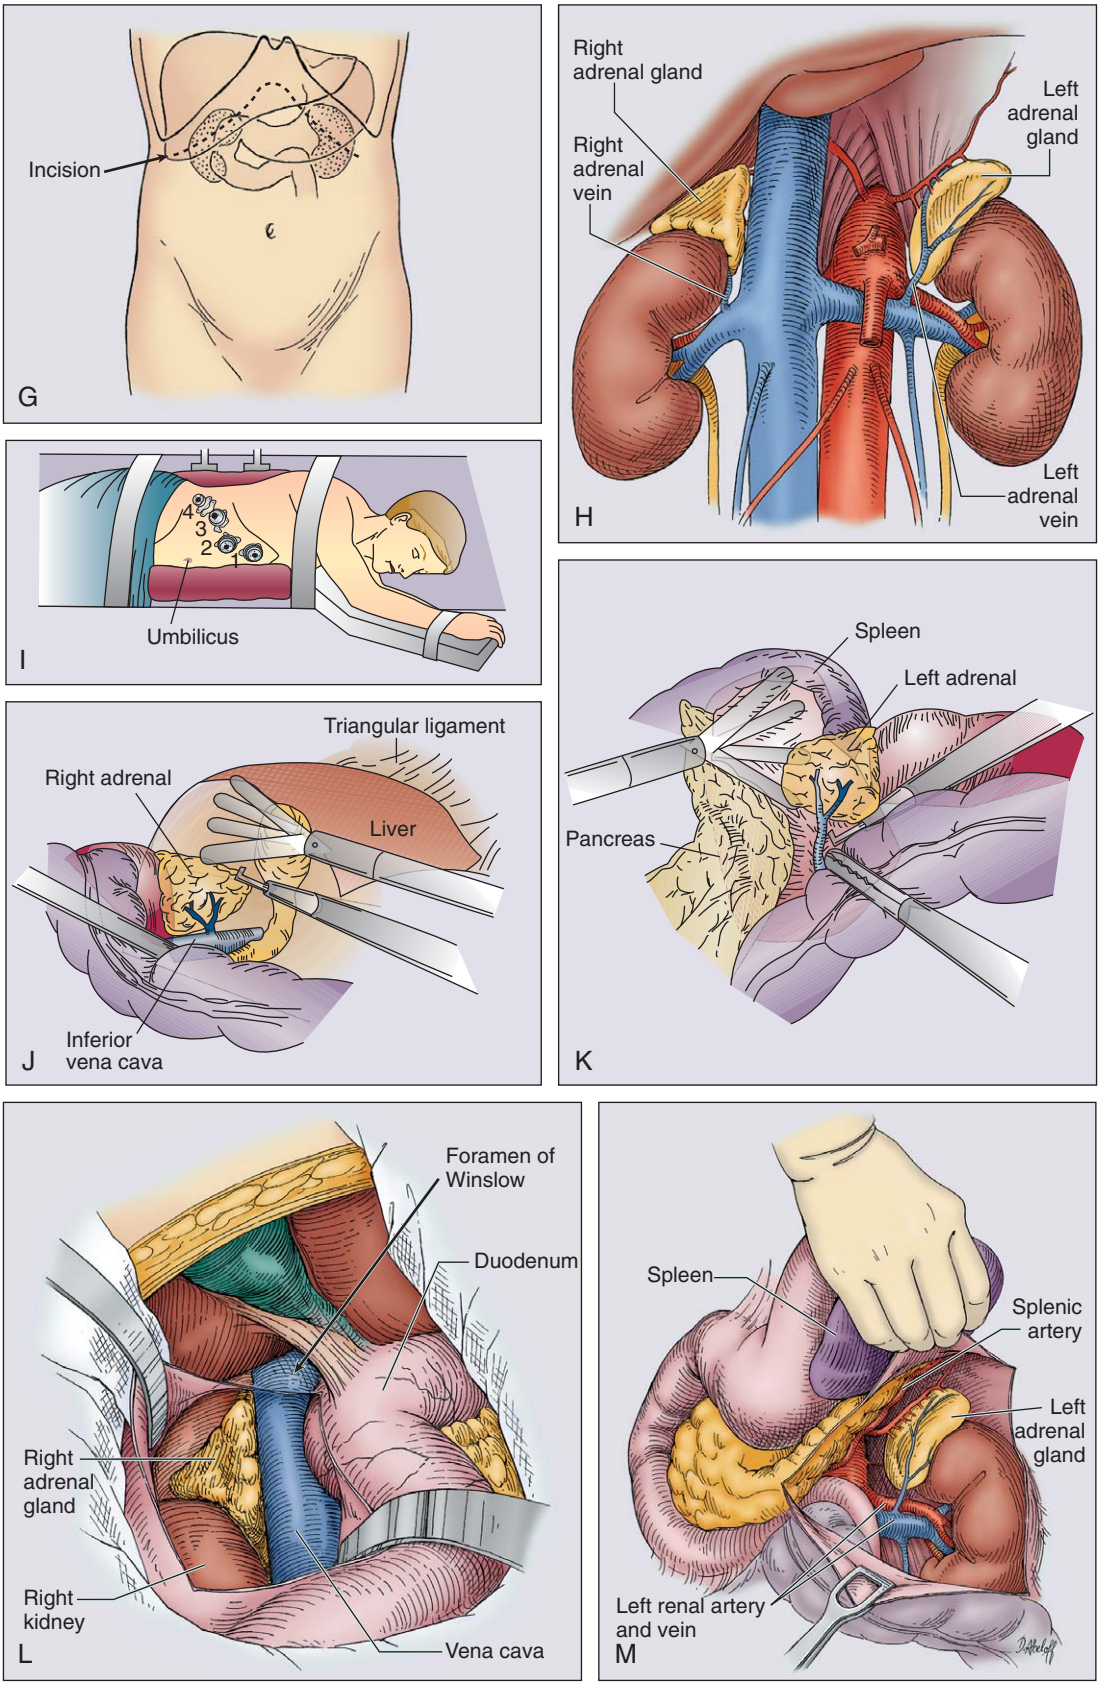

Figure 75-10, cont'd

The patient is placed in the lateral decubitus position with the table flexed at the waist to open the space between the lower rib cage and the iliac crest. After pneumoperitoneum is created, four 10-mm trocars are placed between the mid-clavicular line medially and the anterior axillary line laterally, 1 to 2 fingerbreadths below the costal margin. For a right adrenalectomy, a fan retractor is inserted through the most medial port to retract the liver. The right triangular ligament is divided and the liver is rotated medially. Rarely, the hepatic flexure of the colon may need mobilization during a right adrenalectomy. The right kidney is identified visually and by palpation with an atraumatic grasper. The adrenal gland is identified on the superomedial aspect of the kidney. Gerota's fascia is incised with cautery. Dissection of the adrenal is started superomedially and then proceeds inferiorly, dissecting around the adrenal in a clockwise manner. The periadrenal tissues are grasped or moved with a blunt grasper to facilitate circumferential dissection. The right adrenal vein is identified at its junction with the inferior vena cava, ligated with clips and divided using endoscopic scissors.

For a left adrenalectomy, the fan retractor is used to retract the spleen. The splenic flexure is mobilized early and the lateral attachments to the spleen and the tail of the pancreas are divided using electrocautery. Gravity allows the spleen and the pancreatic tail to fall medially. The remainder of the dissection proceeds similarly to that described for the right adrenal. In addition to the adrenal vein, the inferior phrenic vein, which joins the left adrenal vein medially, also needs to be divided.

Current techniques of adenoma localization permit a unilateral posterior approach to adrenocortical adenomas. This approach has several advantages over an abdominal approach, including a lower complication rate, avoidance of postoperative ileus, and shorter hospital stay. The adrenal gland is approached through a posterior incision, as shown in Figure 75-10A. The gland is approached through the bed of the 12th rib, and the kidney is retracted inferiorly to expose the adrenal gland. These incisions are well tolerated, and much of the postoperative care is dictated by the metabolic consequences of removing the hormonally active adenoma.

Adrenal tumors may also be resected via an open anterior transperitoneal approach and a chevron incision is often used, as shown in Figure 75-10. On the right, a Kocher maneuver mobilizes the duodenum and exposes the adrenal gland. On the left, the spleen is mobilized; Gerota's fascia is then opened to expose the left adrenal gland.

Pheochromocytoma

Surgical treatment of resectable pheochromocytoma requires careful preoperative preparation. α-Adrenergic blocking agents are administered to inhibit the effects of excess norepinephrine secretion. Phenoxybenzamine is a selective α-adrenergic blocking agent, administered in an oral dose of 20 to 40 mg two to four times daily. Titration of the dose is performed by following physiologic parameters. Prazosin also has been used successfully in the preoperative setting. β-Adrenergic blockers (e.g., propranolol) are added to control tachycardia as a sequela of excess epinephrine secretion. After adequate pharmacologic control and correction of fluid and electrolyte imbalance have been achieved, surgical resection is performed. Intraoperative control of blood pressure can be maintained using short-acting intravenous medications such as nitroprusside. Careful physiologic monitoring during the operation is mandatory. Pheochromocytomas may also be resected via a laparoscopic approach.

MALIGNANT PHEOCHROMOCYTOMA

Ten percent of pheochromocytomas are malignant,[195] and malignancies are reported more commonly in tumors arising in extra-adrenal sites (25% to 40%).

Pheochromocytomas are also a component of MEN-2a and MEN-2b.[196] These syndromes are discussed in detail later in this chapter. Pheochromocytomas are also associated with other inherited disorders such as von Hippel-Lindau (VHL) caused by germline mutations of the VHL gene, neurofibromatosis type I caused by germline NF1 mutations and familial paraganglioma and pheochromocytoma syndromes caused by mutations in the succinyl dehydrogenase family of genes (SDHB, SDHC and SDHD). When pheochromocytomas develop in the MEN syndromes, they are frequently bilateral but rarely malignant. In contrast, patients with familial paraganglioma or pheochromocytoma syndrome caused by germline SDHB mutations appear to have a higher propensity for extra-adrenal and malignant tumors.[197] Some studies also suggest that older patient age and large tumors are associated with a higher risk of malignancy. However, malignancy cannot be determined on clinical features alone. Although risk of malignancy increases with size for all pheochromocytomas, size does not seem to reliably predict malignancy in pheochromocytomas with local disease only.[198] The pathologic diagnosis of malignancy can also be difficult, because pleomorphism, nuclear atypia, and abundant mitotic figures are seen in benign tumors.[199] Even capsular invasion can be seen in benign tumors, although invasion of adjacent tissues indicates malignancy. Recent data suggest that flow cytometry and molecular markers such as expression of Ki-67, tissue inhibitor of metalloproteinase (TIMP-4), and cyclooxygenase (COX)-2 can be useful in determining malignancy.[200–203] Malignant pheochromocytomas can be nonfunctional.

Diagnosis

Functioning malignant pheochromocytomas exhibit the same secretory pattern as benign tumors. The diagnosis is made by finding elevated catecholamines or catecholamine metabolites in the urine or plasma, or both (Fig. 75-11). Urinary metanephrines are useful in diagnosing functional pheochromocytomas,[203] but the results may be falsely negative. The single most useful screening test is analysis of a 24-hour urine for vanillylmandelic acid (VMA), metanephrine, and catecholamines. Alternatively, plasma free metanephrines and normetanephrines may be measured. These tests are highly sensitive (99%) but not specific (89%) for pheochromocytoma.[204] Plasma catecholamines can also be elevated.[205] Oral clonidine will not reduce elevated plasma catecholamines to normal levels in patients with pheochromocytoma.[206] The clonidine suppression test is therefore highly useful in distinguishing pheochromocytoma from other causes of hypertension associated with elevated plasma catecholamine levels. Angiography has been largely superseded by CT and MRI scanning for tumor localization. Van Heerden and associates[207] reported that both techniques are highly accurate in localizing tumor at all sites, obviating other more invasive diagnostic procedures such as angiography and selective venous sampling for catecholamine levels.

Another useful technique for localization is radionuclide scanning with ^{131}I-MIBG, which concentrates in adrenergic tissues. The MIBG scan has proved to have a sensitivity of 87%[208] and a specificity of 96%.[209] An MIBG scan in a patient with metastatic pheochromocytoma is shown in Figure 75-12. Other more recently described techniques for localizing pheochromocytomas include PET with 6-[18F] fluorodopamine ([18F]-DA) and 2-[fluorine 18]fluoro-2-deoxy-D-glucose ([18F]-FDG-PET). Preliminary studies show that PET scanning may be superior to MIBG scanning for localizing pheochromocytomas.[210,211]

Course and Treatment

Complete surgical resection[212] after careful preoperative preparation with α- and β-blocking agents is curative in localized pheochromocytoma. If a malignant pheochromocytoma is suspected preoperatively, open rather than laparoscopic adrenalectomy is indicated. Malignant pheochromocytoma metastasizes to lung, brain, and bone. Metastatic disease generally progresses slowly. However, life-

threatening complications due to secretory products can develop over a period of many years. Survival for up to 20 years has been noted.[212]

Modern therapy for inoperable metastatic disease uses the same strategies employed in preparing a patient with primary pheochromocytoma for surgery. Blockade of α-adrenergic receptors is accomplished with phenoxybenzamine; a gradual increase in dose can be required as disease advances. β-Adrenergic blockade may be of additional benefit but should always follow establishment of α-adrenergic blockade. Otherwise, the absence of the vasodilating effects of the β-adrenergic receptors can precipitate severe hypertension. Surgery and radiation have palliative roles in treating metastatic disease; surgical reduction of metastatic tumors can decrease catecholamine secretion and result in symptomatic improvement. The results of chemotherapy are mainly anecdotal. However, a series of 14 patients treated with a combination of cyclophosphamide, vincristine, and dacarbazine (DTIC) has been reported.[213] The rates of biochemical response and measurable cancer reduction were 79% and 57%, respectively. Median duration of response was greater than 20

months. Other chemotherapy agents including streptozotocin, doxorubicin, and carmustine (BCNU) have not been effective.[214] Thalidomide, alone or in combination with temozolomide, has shown some promise in treating pheochromoctyomas, but their use may be limited due to severe toxicity.[215] Some studies have suggested a therapeutic value of ^{131}I-MIBG, however complete remissions are rare and disease has been reported to progress after therapy.[216–218]

PARATHYROID CARCINOMA

Parathyroid carcinoma is one of the rarest cancers. Schantz and Castleman[219] reported the largest study of such cases. These investigators described 487 cases of hyperparathyroidism, of which only 70 (14%) were documented to be parathyroid carcinoma. In most series, parathyroid carcinoma accounts for about 1% of cases of hypercalcemia and hyperparathyroidism. The prevalence in Japan is higher.

Data concerning the possible origin of parathyroid carcinoma from pre-existing abnormalities are rare. For example, transition to carcinoma from hyperplasia in patients with MEN-1 and MEN-2 syndromes does not appear to occur. However, parathyroid carcinoma has been reported to have developed in patients with familial hyperparathyroidism,[220] suggesting that transition from hyperplasia to cancer can take place. More recent data show an increased incidence of parathyroid carcinoma in families with the hyperparathyroidism and jaw tumor (HPT-JT) syndrome, which is caused by germline *HRPT2* mutations.[221] Interestingly, somatic and germline *HRPT2* mutations have been detected in cases of apparently sporadic parathyroid carcinoma.[222]

Diagnosis

Almost all cases of parathyroid carcinoma are associated with hypercalcemia, and about 70% have values greater than 14 mg/dL, which is rare in benign hyperparathyroidism. The disease usually is diagnosed at surgery for hyperparathyroidism. No unequivocal diagnostic tests distinguish benign parathyroid neoplasms from carcinomas, although plasma calcium concentration and PTH levels tend to be higher (>10 times normal) in carcinoma than in adenoma or hyperplasia.[223] Evidence of a neck mass,[223] cervical lymphadenopathy, hoarseness, or intraoperative finding of invasion of adjacent structures such as the strap muscles, thyroid, esophagus, or recurrent laryngeal nerve also suggests the presence of cancer.

The histologic pattern of parathyroid cancer shows frequent mitosis, and blood vessel and capsular invasion also may be seen. In one study, these features and a trabecular pattern with thick fibrous bands were considered characteristic of malignancy and helped to distinguish cancer from benign hyperplasia or adenoma.[223] However, as with many endocrine tumors, it is difficult to differentiate benign from malignant tumors by histologic features alone.

Natural History

The 5-year survival rate of patients with parathyroid carcinoma varies between 29% and 44%,[223,224] and the 10-year survival rate averages 20%. A smaller, more recent study has been reported, however, with an 89% (eight of nine cases) survival rate at a median follow-up period of 6 years.[225] Although parathyroid cancer metastasizes to lung, bone, and liver in about 20% of patients, metastatic disease is less commonly a cause of morbidity and death than is the severe hypercalcemia associated with this disease.

Management

When parathyroid carcinoma is recognized at surgery, careful en bloc excision of the cancer and involved structures is indicated.[225] In most cases, this is accomplished by an ipsilateral thyroid lobectomy with segmental resection of involved strap muscles and adjacent fibrolymphatic tissue. This tumor usually does not metastasize via the lymphatics; therefore, radical neck dissection is not warranted. Careful dissection without tumor spill is important, because local recurrence has been demonstrated. Local recurrence occurs in about two thirds of patients, in some due to intraoperative seeding. If hypercalcemia persists or recurs after surgery, an attempt should be made to locate the metastasis using selective venous catheterization and measurement of hormone levels in the event other diagnostic modalities fail. Prolonged remission of hypercalcemia has been reported after resection of metastases.[226] In case of unresectable disease, debulking should be attempted for palliation of hypercalcemia.

Nonsurgical treatment of recurrent or metastatic parathyroid cancer is disappointing. Radiation therapy has not been of significant value in treating primary or recurrent neck disease, although it may have some palliative benefit in controlling pain in bone metastases. Cytotoxic chemotherapy has been tested only infrequently, but it appears that dacarbazine has some activity in this disease.[227,228] Essentially, all patients with incurable parathyroid cancer require control of hypercalcemia. Diphosphonates, mithramycin, and calcitonin have been only marginally effective. It appears that the more recently developed pharmacologic therapies for hypercalcemia—etidronate[229] and gallium nitrate[230]—may be more effective in the palliative management of the severe hypercalcemia associated with parathyroid cancer. A new class of drugs known as calcimimetics can reduce PTH by binding directly to the calcium-sensing receptor cells on the parathyroid gland. Cinacalcet hydrochloride, a calcimimetic, has been shown to be useful in controlling hypercalcemia in patients with refractory parathyroid carcinoma.[231]

MULTIPLE ENDOCRINE NEOPLASIA

MEN syndromes are characterized by the familial occurrence of endocrine neoplasms in various sites. MEN syndromes are inherited as autosomal dominant with high penetrance, variable expressivity, and pleiotropic expression. The neoplasms of the MEN syndromes may be either benign or malignant.[133,232] Manifestations of MEN-1, MEN-2a, and MEN-2b are summarized in Table 75-6. Steiner and associates[233] were the first to characterize MEN-1 and MEN-2.

Table 75-6 Syndromes of Multiple Endocrine Neoplasia

MEN-1	MEN-2
Pituitary tumors	MEN-2a and -2b
Eosinophilic adenoma (acromegaly)	Medullary carcinoma of the thyroid
Prolactinoma	Pheochromocytoma
Nonfunctional tumors	MEN-2a
ACTH-secreting tumors	Hyperparathyroidism
Hyperparathyroidism	MEN-2b
Pancreatic tumors	Mucosal neuromas
Most common	Marfanoid habitus
Gastrinoma	Typical facies
Insulinoma	Bowel abnormalities
Pancreatic polypeptide-secreting tumor	
Glucagonoma	
VIPoma	
GRFoma	

ACTH, adrenocorticotropic hormone; MEN-2a, -2b, multiple endocrine neoplasia types 2a, 2b.

Multiple Endocrine Neoplasia Type 1

MEN-1 syndrome is a disorder of three glands: parathyroid, pancreatic islet cells, and pituitary. Recently, the disease gene for MEN-1, *MENIN*, has been localized to the long arm of chromosome 11.[234] *MENIN* has been reported to encode for a nuclear protein[235] of still undefined function, although recent studies suggest roles in physiologic regulation of cell growth, control of the cell cycle, and genome stability.[236]

Clinical Features

Parathyroid hyperplasia is the most frequently noted abnormality.[237] Adenomas of the pituitary gland are noted in 50% to 80%of patients with MEN-1.[237,238] When pituitary adenomas are functioning, prolactin is the most common hormone produced.[239] Acromegaly caused by growth hormone-secreting adenomas occurs in approximately 25% of adenomas.[238] Cushing's syndrome secondary to pituitary adenoma is uncommon. Approximately 80% of patients with MEN-1 will have functional pancreatic islet cell tumors.[239] Islet cell tumors represent the most common cause of death in patients with MEN-1, with 60% of deaths resulting from ulcer disease or problems caused by islet cell tumors.[238]

A wide spectrum of pancreatic islet cell tumors can occur in MEN-1. In a comprehensive review,[238] pancreatic tumors were present in 100 of 122 patients (82%) with MEN-1 with the following frequency: gastrinoma (64%); insulinoma (24%); glucagonoma (3%); and nonfunctioning tumor (9%). Rare cases of secretion of vasoactive intestinal peptide (VIP) and other peptides were observed. Forty-two percent of the gastrinomas were malignant, and 25% of the insulinomas were malignant. This finding is in contradistinction to sporadic insulinomas, in which only 10% are malignant. Pancreatic polypeptide (commonly), α- and β-hCG (less commonly), and other peptides such as ACTH may be elevated in patients with MEN-1 and may serve as tumor markers. The adrenal cortex may be abnormal in about one third of cases, usually with hyperplasia associated with pituitary adenomas producing ACTH. Rarely, a pancreatic tumor may produce ACTH ectopically.[240] Clinical Cushing's syndrome is uncommon. Bronchial carcinoids may occur in approximately 5% of cases.

Surgery

Management of MEN-1 first requires an awareness of the existence of the syndrome. Because almost all of these patients eventually will manifest hyperparathyroidism, continued surveillance of serum calcium is necessary. Parathyroidectomy usually is curative. In cases in which all four glands are enlarged, complete resection with forearm implantation is the preferred treatment. However, parathyroid hyperplasia can be limited to one or a few glands. In this case, it is preferred to resect the abnormal glands and to obtain a biopsy of the normal-appearing parathyroids. The location of these normal glands should be marked with nonabsorbable suture. If possible, all parathyroid tissue on one side of the neck should be removed to avoid the need for repeat bilateral neck exploration. Detectable pituitary tumors may be treated with bromocriptine or are occasionally removed by transsphenoidal resection. The management of pancreatic islet cell tumors is described elsewhere in this chapter.

Multiple Endocrine Neoplasia Type 2

MEN-2 syndrome first was reported by Sipple[241] in 1961. MEN-2 tumors include MTC, pheochromocytoma, and adenoma or hyperplasia of the parathyroid glands. When mucosal neuromas—with or without marfanoid habitus—are present as part of a distinctive syndrome, the designation is MEN-2b. Parathyroid disease is rare in MEN-2b. Specific MEN-2a[242,243] and MEN-2b[244] gene defects map to different regions of the *RET* proto-oncogene in the centromeric region of chromosome 10. More than 70% of pheochromocytomas occurring with MEN-2 are bilateral. These tumors may be derived from a hyperplastic adrenal medulla, yet still be benign, although carcinomas may occur in the same family. This progression from hyperplasia to tumor is similar to the progression noted in MTC.

RET encodes a receptor tyrosine kinase with an extracellular ligand binding domain, a transmembrane domain, and an intracellular domain with tyrosine kinase activity. Genotype–phenotype correlations have been observed in MEN-2a and MEN-2b, with the type of *RET* gene mutation indicating the aggressiveness of the disease.[245]

Clinical Features

The clinical presentation of patients with MEN-2 can be dictated by any of the three neoplasms seen in the syndrome. However, all patients with MEN-2 have medullary carcinoma of the thyroid. In reviews of MEN-2a, pheochromocytoma was seen in 21% to 41% of patients, and parathyroid hyperplasia or adenoma was present in 17% to 60%.[246] All patients had medullary carcinoma of the thyroid.[123,247] In a series of patients with MEN-2b, all had medullary carcinoma, and 60% developed pheochromocytomas.[248] In general, MEN-2b tends to be a more rapidly progressive clinical entity because the medullary carcinoma of the thyroid that develops in this syndrome has a more aggressive course than that seen in MEN-2a. Patients suspected of having MEN-2 syndrome should be screened for medullary carcinoma of the thyroid, pheochromocytoma, and hyperparathyroidism. The most effective way to screen for medullary carcinoma of the thyroid is to measure plasma calcitonin levels initially. All patients with medullary carcinoma of the thyroid will have either elevated basal plasma calcitonin levels or elevation after pentagastrin and calcium infusion stimulation tests.[126] In patients at risk for inherited medullary thyroid cancer, genetic screening for *RET* mutations has replaced yearly calcitonin measurements, because detection by this method allows treatment prior to the development of cancer.[245] The appropriate screening tests for pheochromocytoma include measuring urinary levels of epinephrine, norepinephrine, VMA, and metanephrines as described previously, or serum metanephrines. When these tests are abnormal, tumor localization studies, including MRI and abdominal CT scanning, should be undertaken. When there is biochemical evidence of pheochromocytoma with a negative CT scan, MIBG scan may be useful. MIBG concentrates in pheochromocytoma cells, permitting tumor detection by scintigraphy.[249] Hyperparathyroidism can be assessed by measurement of calcium and PTH levels.

Surgery

Management of patients with MEN-2 syndromes is primarily surgical. The surgical treatment of medullary carcinoma is total thyroidectomy, because the tumor always is bilateral. Central lymph node dissection also should be performed. In patients with MEN-2a and hyperparathyroidism, only abnormal parathyroid glands should be removed at the time of surgery. Patients with pheochromocytoma should undergo preoperative α-adrenergic blockade with phenoxybenzamine.[248,249] After adequate α-blockade has been obtained, β-blockers may be added if the patient has significant tachycardia, although in many instances β-blockade is not needed.

Postoperatively, patients with resected MTC may be followed with serum calcitonin levels, which are a sensitive marker for recurrence of disease. Likewise, appropriate urinary catecholamine studies will demonstrate recurrence of pheochromocytoma. Because MEN-2 syndromes exhibit autosomal dominance, it is important to evaluate family members of patients with documented MEN-2 for presence of the syndrome. Genetic analysis for inheritance of the allele containing the mutant *RET* gene will identify family members likely to develop MEN. Family members who have not inherited the disease allele require no further evaluation. Genetically affected members can be offered early thyroidectomy, usually by age 5 or 6 years in MEN-2a and prior to 6 months of age in MEN-2b.[245]

CARCINOID TUMORS

Carcinoid is an English translation of a term first used by German pathologists in the early 20th century—"karzinoid"—to describe a carcinoma-like tumor that behaves less aggressively than carcinomas.[250] Although their malignant potential was noted, other unique characteristics of the tumors also were described. These tumors arise from enterochromaffin cells in the gastrointestinal tract and lung.[251] Enterochromaffin cells take up and reduce silver. Silver staining documented the argyrophilic nature of carcinoid tumors, ultimately leading to their being described as neoplasms of the diffuse endocrine or APUD system.[252] Other tumors of the APUD system include medullary carcinoma of the thyroid, pheochromocytoma, and pancreatic endocrine tumors. Newer immunohistochemical techniques including neuron-specific enolase (NSE)[253–255] and chromogranin A[256] hormone assays have allowed further characterization of the synthesis and secretion of neuroendocrine peptides by carcinoid tumor cells. It is important to know that these neoplasms have common characteristics as defined by the APUD concept to be able to understand that the production of polypeptides arises from pancreatic islet cell tumors.

Carcinoid tumors typically have been classified as originating in the foregut (lung and upper gastrointestinal tract and, less often, pancreas), the jejunum and midgut (which includes the ileum and appendix), and the hindgut (colon and rectum). The origin of carcinoid tumors may, in part, explain the ectopic hormone secretion and syndromes related to primary tumor site.[257]

About 85% of carcinoid tumors develop in the gastrointestinal tract, usually the appendix. In one report, 44% of carcinoids were appendiceal, accounting for more than three fourths of all tumors in that organ.[258] In the same series, the intestine (19%), rectum (15%), and lung (10%) also were common sites. A recent National Cancer Database (NCDB) study using Godwin's initial experience[258] was recently published,[259] and a revised classification of neuroendocrine tumors of the lung, pancreas, and gut has more recently been released.[260]

Carcinoids account for one third of tumors in the small intestine. Carcinoids of the appendix commonly are discovered incidentally. Most are smaller than 1.0 cm and are cured by surgical resection.[259] In the Mayo Clinic series, no tumor of 1.0 cm or less recurred after resection.[215] Therefore, appendectomy alone is adequate treatment. With the uncommon large appendiceal carcinoid, a true cancer operation (e.g., right hemicolectomy) can be required. Carcinoids of the rectum are similar to appendiceal carcinoids and typically are small and are best treated with conservative local measures. Carcinoids of the small intestine are the most clinically important tumors because of their frequency of presentation, their more advanced stage at diagnosis, and their association with the carcinoid syndrome. The largest and most carefully followed series of patients with small bowel carcinoid has been reported from the Mayo Clinic, where 183 consecutive cases have been followed for a median period of 15 years.[261] Approximately 40% of the tumors occurred within 2 feet of the ileocecal valve, with very few in the proximal small intestine. Thirty-five percent of patients had more than one lesion, and most primary tumors were 2.0 to 4.0 cm in diameter. More than 80% of patients with resectable primary tumors were free of disease at 20 years' follow-up. The overall survival rate in these patients was similar to that of an age- and sex-matched control group. Of the 72 patients who had resected regional node metastases, one half experienced recurrence by 16 years, with continued evidence of relapse after that time. Patients who had unresectable abdominal metastases and hepatic metastases fared least well, with median survival rates of 5 and 3 years, respectively. These data confirm that, even with advanced disease, carcinoid tumors tend to have a relatively indolent course. Goblet cell or adenoid carcinoid tumors may be more aggressive than typical gastrointestinal carcinoids.

Clinical Pathology

Carcinoid tumors usually are readily identified microscopically. Immunohistochemical staining is performed to identify and classify these tumors. In addition to immunohistochemical staining to reveal specific tumor-produced peptides, other semispecific markers including NSE[255] and chromogranin A[256] aid in diagnosis.

Carcinoid Syndrome

Many patients with metastatic carcinoid tumor manifest the signs and symptoms of abnormal hormone production—the malignant carcinoid syndrome.[262] Serotonin (5-hydroxytryptamine, 5-HT), synthesized by the tumor from tryptophan and metabolized to 5-HIAA, which appears in the urine, is particularly important because urinary 5-HIAA levels are used to monitor the course of carcinoid syndrome. However, the relation of serotonin levels to symptoms of the clinical carcinoid syndrome is uncertain.

Carcinoid tumors also release the enzyme kallikrein, which acts on α_2-globulin to produce bradykinin and its precursor, lysyl-bradykinin, both of which can induce flushing.[263,264] Serotonin may be responsible for intestinal hypermotility and hypersecretion, but it probably does not cause the characteristic flushing that occurs with the carcinoid syndrome.[265] Vasodilation, which causes flushing, can be due to one or more substances released by the tumor cells, including bradykinin, substance P (midgut carcinoids), tachykinins, and prostaglandins. The symptoms of the carcinoid syndrome vary in frequency. Flushing is most frequent, followed by diarrhea, heart disease, and bronchoconstriction.

Flushing

Two types of flushing generally are accepted as accompanying the usual metastatic ileal carcinoid. It is thought that any of the activities that drive plasma catecholamines, which instigate the flushing, maybe mediated, in part, by peptides such as the tachykinin substance P or the amine serotonin. Stressors associated with hypercatecholemia include **e**xercise, **e**xcitement, **e**motion, **e**thanol, and decongestants such as **e**phedrin. One type of flushing is red and diffuse, involving the face and upper body; it is of short duration and can be provoked by alcohol, excitement, emotional stress, and catecholamine release.[266] The other is more prolonged, produces venous dilation and a purplish hue about the face, and can give rise to permanent dilation of facial veins and even telangiectasia. This flush is more commonly precipitated by alcohol ingestion. Because infusion of serotonin does not cause either flush, it has been suggested that the kinins cause this symptom.[267] Brief flushes may be due to catecholamine-induced release of vasoactive substances such as kallikreins; these flushes can be blocked effectively by α-adrenergic blocking agents.[268] Carcinoid of the foregut produces a more intense and erythematous flush (such as seen in a serotonin burst), sometimes associated with itching, conjunctival suffusion, and facial edema suggestive of histamine release. Occasionally, gastric carcinoids cause an urticarial reaction, which may be inhibited by the histamine H_1- and H_2-receptor antagonists diphenhydramine and cimetidine.[269,270]

Diarrhea

The diarrhea of carcinoid syndrome does not necessarily correlate with flushing. Diarrhea appears to be related to increased gut motility, rather than to secretion of fluids. Methysergide, a serotonin antagonist, sometimes is effective in treating or preventing diarrhea, hence the presumption that serotonin is directly responsible for this symptom. Infusion of serotonin produces intestinal dysmotility similar to that seen in the carcinoid syndrome.[270] Diarrhea of the carcinoid syndrome rarely is of high volume and, therefore, typically requires only mild palliative antidiarrheal therapy. Although abdominal cramping can be associated with this diarrhea, other possibilities for abdominal pain must be considered, including intermittent partial

small bowel obstruction secondary to mesenteric fibrosis or bowel obstruction secondary to tumor bulk.

Heart Disease

The cardiac disease associated with the carcinoid syndrome is an endomyocardial fibrosis typically involving the right side of the heart, although left-sided lesions have been described. Fibrotic deformation of the tricuspid and pulmonary valves usually leads to pulmonary stenosis and tricuspid insufficiency.[271,272] When left-side lesions are involved (primarily mitral valve), there is usually a patent foramen ovale. In the Mayo Clinic series, carcinoid heart disease was a late complication, with only 5 of 91 deaths identified as having a primary cardiac cause. In that series, most patients with heart disease had high levels of 5-HIAA as well as a lengthy history of carcinoid cardiac disease averaging more than 5 years.

Other, relatively rarer, signs and symptoms may be associated with carcinoid syndrome. Bronchoconstriction may occur in both pulmonary and extrapulmonary carcinoid and usually is associated with flushing. The classic triad of dermatitis, dementia, and diarrhea seen with pellagra occasionally has been identified. This syndrome is secondary to niacin deficiency as a result of shunting of dietary tryptophan from niacin synthesis to indole synthesis. It is very rare, because of better overall nutrition in the population. It is treated simply with nicotinamide from over-the-counter vitamin supplements.

Diagnosis

The diagnosis of carcinoid tumor is made by finding tumor or symptoms related to tumor bulk, biologically active peptides, or urinary tumor markers (Fig. 75-13). While measurement of 5-HIAA is the most common and reproducible test for the presence of carcinoid syndrome, significantly raised levels of 5-HIAA usually occur only after there is a 20% to 25% liver tumor burden. In most laboratories, the upper limit of normal for 24-hour urinary 5-HIAA excretion is 6 to 10 mg. In one study, 5-HIAA measurements were 100% specific and 73% sensitive for the presence of carcinoid syndrome.[273] Not all patients with carcinoid tumor have the associated syndrome, and the sensitivity of assays for detecting the presence of tumor alone is inadequate. Although markedly elevated 5-HIAA in the urine is remarkably specific for carcinoid tumor, a low-level false-positive increase of 5-HIAA may be seen in patients with noncarcinoid tumor and after intake of certain foods (e.g., bananas, walnuts, and pecans) and serotonin reuptake inhibitors (e.g., Zoloft, Prozac) and medications (e.g., acetaminophen, salicylate, guaifenesin).[273–277] 5-HIAA also may be elevated to low abnormal levels (<30 mg) in patients with diarrhea or malabsorption from any cause. In addition to excellent specificity and high sensitivity, 5-HIAA measurement has a high level of consistency, both in individual patients and among groups. In the Mayo Clinic series, the level of 5-HIAA excretion remained constant in a group of 85 patients in whom paired determinations were done during a 10-day period.[261] Moreover, in any given patient, the level of 5-HIAA secretion is a relatively accurate indicator of tumor bulk. Platelet serotonin levels have been reported to be more sensitive than urinary 5-HIAA levels and may be useful in patients with tumors that produce low levels of serotonin.[278] Recently, serum NSE and chromogranin A levels have been shown to correlate with the presence and natural history of gastrointestinal neuroendocrine tumors.[255,256] For midgut carcinoids, which produce high levels of serotonin, the sensitivity of chromogranin A levels is only slightly better than urinary 5-HIAA levels. However, for foregut and hindgut derived tumors, chromogranin A levels are highly sensitive compared with urinary 5-HIAA levels.[279]

The most commonly used modality for imaging carcinoid tumors is CT scanning, although the technique is more sensitive for detecting metastases, rather than primary tumors.[280] Recently, localization of carcinoid and islet cell tumors has been investigated by nuclear medicine techniques, including octreotide scan (Fig. 75-14).[281] The sensitivity of somatostatin receptor or octreotide scanning is reported to be up to 87%, with a positive predictive value of 100%, making it the most useful imaging study for carcinoid tumors.[282] ^{131}I-MIBG scans also have shown usefulness in evaluating carcinoid tumors.[283] PET scans using 11-C-labeled 5-hydroxytryptophan also have shown promising results when compared to CT scan in small series.[284]

Treatment

Patient management depends not only on traditional methods of dealing with bulky disease and its manifestations, but also on management of associated medical problems typically caused by overproduction of hormonally active peptides. In this regard, treatment of carcinoid is similar to that of other neuroendocrine tumors, such as islet cell tumors. For patients on long-term somatostatin therapy, a long-acting somatostatin analog is effective and may be given monthly.[285]

Surgery

Surgery has an important role throughout the course of carcinoid tumor management. Resection of the primary tumor and of associated resectable nodal metastases is primary therapy.[286] Also, complications secondary to recurrent or residual carcinoid may benefit from surgical intervention. Nearly one half of all carcinoids arise in the appendix, and most are small and cured by appendectomy, although right hemicolectomy is recommended for lesions larger than 2 cm.[261,287] The same is true for small lesions of the rectum, but tumors larger than 2 cm in diameter require standard cancer operations such as a low anterior resection or abdominoperineal resection.[286] In small bowel tumors, small bowel resection with removal of mesenteric nodes is recommended. It follows that the surgical approach to bronchial, gastric, or gonadal carcinoid will depend on the location and stage at presentation.

These tumors often elicit a mesenteric fibrosing reaction, in which the bowel becomes shortened and kinked, frequently causing partial small bowel obstruction. Pain or physiologic abnormalities secondary to partial bowel obstruction may be greatly relieved by palliative surgical resection or bypass, or both. The indolent course of carcinoid tumors mandates a high index of suspicion for such complications and an aggressive approach in considering surgical palliation.

Management of hepatic metastases is important given the frequency of such metastases. In many patients, bulky hepatic metastases constitute most of the tumor burden, so that tumor reduction may, at the least, diminish production of peptides that promote the carcinoid syndrome, as well as extend survival.[288] Principles of surgical management of hepatic metastases are similar to those for islet cell tumors. The indications to proceed with hepatic metastases resection are more liberal in carcinoid tumors than in metastases from other solid tumors. For example, partial resection of hepatic metastases is contraindicated in metastatic colon cancer, as neither effective palliation nor prolongation of survival is achieved. However, the much longer survival in carcinoid tumor makes palliative resection of hepatic metastases appropriate to decrease tumor burden and improve patient well-being. A variety of cancer therapies for hepatic metastases may be attempted, including hepatic irradiation, hepatic embolization, and liver-directed chemotherapeutic agents. These therapies are discussed in the following individual treatment sections.

Radiation Therapy

Radiation therapy seldom is used to treat carcinoid tumor or carcinoid syndrome. Patients with carcinoid syndrome often have extensive hepatic metastases, and the dose-limiting toxicity of hepatic radiation limits its usefulness. Palliative treatment of bone metastases

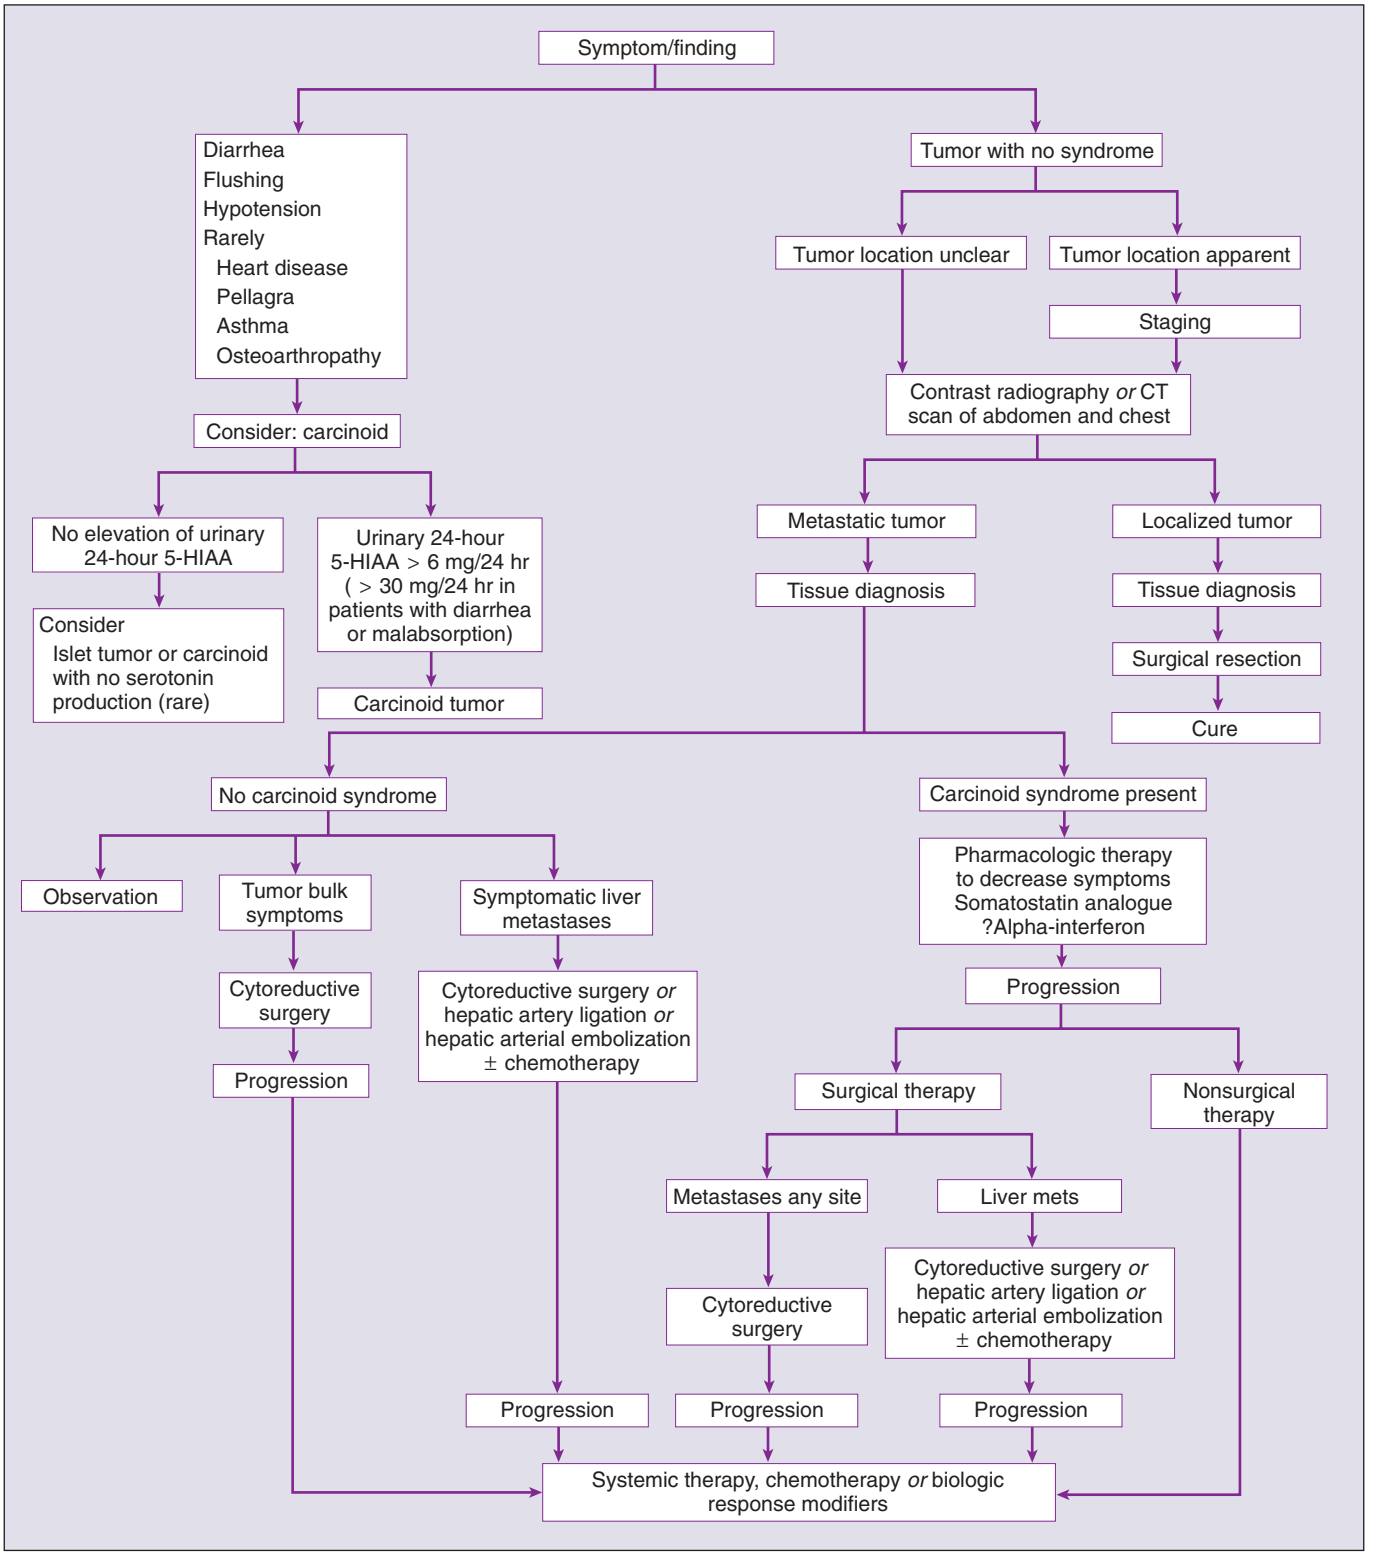

Figure 75-13 • Diagnosis and treatment of carcinoid tumors.

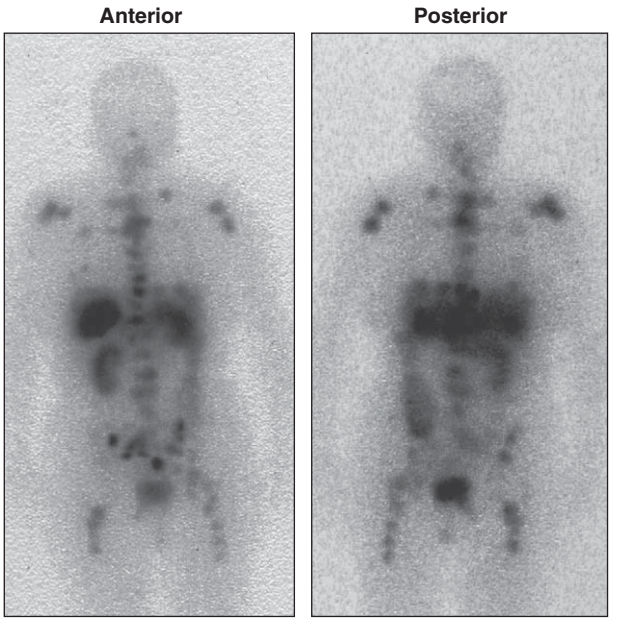

Figure 75-14 • ^{111}In octreotide scan. Patient with metastatic carcinoid with octreotide scan showing bony and visceral metastases with anterior and posterior views.

is an indication for radiation therapy. A trial of whole-abdomen radiation therapy (20–25 Gy)[289] yielded mixed results, with reduction of abdominal pain but less consistent control of the cancer. Radiation therapy should be considered in patients who require local control and palliation.[290]

Antihormonal Therapy

When the symptoms attributed to serotonin are mild, they can be managed successfully over lengthy periods with simple measures, such as administration of opiates and diphenoxylate hydrochloride with atropine. With more severe symptoms, the peripheral serotonin antagonists methysergide and cyproheptadine are effective in controlling diarrhea and, in some cases, malabsorption.[291] Another approach has been the use of agents known to inhibit serotonin synthesis. α-Methyldopa, which partially inhibits the decarboxylation of 5-hydroxytryptophan (5-HTP) to serotonin, has been disappointing, except in patients with the rare 5-HTP-secreting metastatic carcinoid of gastric origin.[292] Parachlorophenylalanine (PCPA) inhibits the enzyme tryptophan 5-hydroxylase, which converts tryptophan to 5-HTP, the immediate precursor of serotonin.[293] Although good to excellent control of diarrhea has been observed, the toxic effects of PCPA, including hypersensitivity reactions and mental aberrations, have limited its clinical value.

Somatostatin inhibits carcinoid flush,[294] but is not practical for therapy because it has a half-life of less than 2 minutes.[295] Synthetic octapeptide analogs of somatostatin, octreotide acetate, lanreotide, and vapreotide have a longer half-lives, and can be given subcutaneously every 4 to 8 hours to maintain the action of somatostatin. As well, the long-acting repetitive, Sandostatin LAR (Novartis), has been shown to be highly effective in control of both carcinoid flushing and diarrhea.[285] Somatostatin influences the inhibition of numerous gastrointestinal hormones, gastric secretion, gastric and small intestinal motility, splanchnic blood flow, pancreatic enzyme secretion, intestinal nutrient absorption, and gallbladder contractility.[296]

Somatostatin analogs have two established uses in carcinoid tumors: chronic treatment of symptoms such as diarrhea and flushing,[297] and treatment of carcinoid crisis.[296] Kvols and associates,[297] in 1986, described the use of the somatostatin analog octreotide in therapy for carcinoid syndrome. Fifty-seven patients with carcinoid tumor and carcinoid syndrome were treated with daily doses of octreotide acetate, ranging from 100 to 1127 μg (mean, 414 μg). Flushing was abolished in most patients, and diarrhea was controlled adequately in approximately 75%. Control of symptoms usually was associated with a decrease in the urinary 5-HIAA level, but reduction in tumor bulk was not seen consistently. The median duration of response to somatostatin analog was 4 months, with some patients escaping control quite early but others continuing for more than 2 years. Increased doses of somatostatin may partially overcome resistance.[298] More recent studies have confirmed that somatostatin improves symptoms but has little effect on tumor regression.[299]

Somatostatin analog usually is well tolerated.[296,297] Minimal irritation at the injection site and alterations in bowel patterns have been observed. Fecal fat excretion may increase, and aberrations in glucose tolerance resulting in hyperglycemia have been observed. Very early studies in the 1980s demonstrated that neostimulated pancreatic enzyme inhibition due to octreotide acetate diminishes after a continued use of octreotide. Clinically significant fat malabsorption is not a widespread problem. We routinely use and recommend pancreatic enzyme supplementation when beginning either subcutaneous octreotide acetate or the long-acting repeatable octreotide.

Long-term therapy may predispose to the formation of gallstones; the drug promotes cholelithiasis by inhibition of cholecystokinin release and a resultant inhibition of gallbladder emptying. Approximately 50% of patients receiving chronic therapy will develop cholelithiasis and should, therefore, undergo elective cholecystectomy at the time of tumor debulking.[300]

Chemotherapy

Because the disease is indolent, little information is available on the role of chemotherapy.[301] Antineoplastic therapy may be called for in patients whose cancers are aggressive, with progressive liver metastases, signs of partial or impending complete intestinal obstruction, or severe symptoms of carcinoid syndrome uncontrollable by other methods. Controlled clinical trials have been difficult to carry out because of the rarity of the tumor, but cooperative study group trials have been useful in assessing tumor responsiveness. In our experience, the less positive the octreoscan and more active the PET scan, the more effective chemotherapy may be.

During the 1970s, systemic therapy with single agents was reported, with 5-FU and streptozotocin shown to be active drugs.[302] The Mayo Clinic experience with more than 200 patients suggests that with single agents the response rates of greater than 10% were seen with only three adequately tested drugs: doxorubicin, 7 of 33 (21%); 5-FU, 5 of 19 (26%); and dacarbazine (DTIC), 2 of 15 (13%).[303] Based on initial observations of patient response to 5-FU and streptozotocin, investigators at the Mayo Clinic studied that regimen and noted an overall response rate of 33% in 43 patients. A larger series of patients was reported in a phase III study by the Eastern Cooperative Oncology Group (ECOG)[304] comparing 5-FU plus streptozotocin to cyclophosphamide plus streptozotocin. Response rates for the two treatment arms were not significantly different (33% vs. 26%, respectively), nor were there significant differences in overall survival. Assuming the 5-FU plus streptozotocin regimen to be standard, the ECOG subsequently reported their trial of this combination, with streptozotocin given less frequently to decrease toxicity, compared with doxorubicin alone.[305] Twenty-three percent of patients in each arm responded, further documenting doxorubicin activity. Most recently, ECOG reported the results of their largest trial of combination chemotherapy.[306] This trial randomly allocated patients with measurable carcinoid tumors to the standard regimen of 5-FU plus streptozotocin (FS) and a new regimen of 5-FU and doxorubicin (FA). Patients who had either renal or heart disease making them ineligible for streptozotocin or doxorubicin-containing therapies were treated with DTIC. Of 208 patients who were eligible and analyzed for response and survival, FA and FS

therapies were associated with response rates of 13% and 16%, respectively, in the randomized group. With DTIC, the response rate was approximately 10%, with no significant differences between previously treated and untreated patients. Although the response rates for FA and FS did not differ, there was a trend toward improved survival in the FS group. The median survival time of the group was 24 months, compared with 16 months for patients receiving FA ($P = 0.11$). This suggestive disparity between response rate and survival time may reflect the fact that reduction in tumor bulk has little correlation with survival in patients with an indolent disease such as carcinoid tumor. Alternatively, it may be true that survival is a better measure of tumor response, with inadequate determination of response by traditional techniques.

Because no highly effective chemotherapy regimen is available, it is clear that patients should be carefully selected for use of cytotoxic chemotherapy in metastatic carcinoid tumor and carcinoid syndrome. Less toxic and more effective palliative therapies for carcinoid syndrome should always be used initially, reserving chemotherapy for those patients who are significantly disabled by unresponsive hormonally related symptoms or those with refractory symptoms due to tumor bulk. Clinical trials of more recently available drugs (taxanes, gemcitabine, camptothecins) need to be carried out. More recent clinical trials suggest potential benefit and possible indications for such anti-agonist compounds such as RAD001 and mTOR inhibitors.[307]

Interferon

Early clinical trials from Sweden suggested a role for low-dose human leukocyte interferon in the treatment of carcinoid tumors.[308] Subsequently, this group reported the results of three consecutive studies using interferon.[301] In the first study, involving 36 patients, an overall response rate of 47% was observed. In the second randomized trial, human leukocyte interferon was compared with FS. No response was observed in the 10 patients treated with chemotherapy, but 5 patients in the interferon-treated group did respond. In the third study, 20 patients were treated with recombinant interferon; an objective response rate of 55% was observed, with the bulk of responses being symptomatic or chemical responses manifested by a decrease in 5-HIAA, rather than by reduction in tumor bulk. The Mayo Clinic subsequently reported the results of their phase II trial of recombinant interferon-α (IFN-α) in 24 patients with malignant carcinoid syndrome.[309] Five patients (20%) with measurable tumor experienced objective tumor regression, and nine patients (37.5%) had a significant reduction in urinary 5-HIAA excretion. Flushing and diarrhea were transiently relieved, with objective responses lasting less than 2 months. The results suggest a limited role for this agent in treating carcinoid tumor. Clinical trials currently are being developed in which chemotherapy and interferons are being combined, although early results do not suggest additional benefit compared to single modalities.[310] Similarly, combinations of octreotide and IFN-α are being investigated to determine whether lower doses of interferon would be effective and whether the tachyphylaxis associated with octreotide could be overcome by the addition of interferon.[311] Patients with carcinoid tumors treated with interferon may develop a wide variety of autoimmune diseases, such as thyroid disease (thyrotoxicosis, hypothyroidism), pernicious anemia, and vasculitis.[312]

Hepatic-Directed Therapy

The results of surgical resection for hepatic metastases and anecdotal reports of hepatic and abdominal radiation in carcinoid tumors have already been described. The Mayo Clinic has investigated the role of hepatic arterial occlusion in metastatic carcinoid and islet cell tumors.[261] Significant improvement in symptoms and reduction in hepatic metastases were noted in 14 patients with carcinoid tumors, but the median length of response was less than 7 months. Mayo Clinic investigators also have examined the role of sequential hepatic arterial occlusion (HAO), followed by systemic chemotherapy with DTIC and doxorubicin alternating with the combination of 5-FU and streptozotocin in carcinoid tumors.[261,313] With 65 carcinoid cases treated, more than two thirds of all patients demonstrated objective regression with either HAO or HAO plus chemotherapy. The median duration of regression was longer in the groups receiving chemotherapy, but this trial was not randomized, and better-risk cases may have been selected for the chemotherapy plus HAO treatment. Other groups are investigating the role of selective hepatic arteriography with sequential hepatic arterial embolization or chemoembolization.[314–316] Significant reduction in the signs and symptoms associated with both carcinoid tumors and islet cell tumors have been reported in the majority of patients so treated. In a study of 15 patients with advanced metastatic carcinoid tumors, hepatic artery chemoembolization improves symptoms and short-term quality of life.[317] Unfortunately, there is a paucity of data on the benefit of either intermittent or prolonged continuous hepatic arterial infusion of chemotherapeutic agents in patients with metastatic carcinoid tumors.

PANCREATIC ISLET CELL TUMORS

The advent of radioimmunoassay (RIA), immunofluorescence, and other techniques for identifying peptide hormones has expanded our knowledge of the prevalence and endocrine effects of islet cell tumors.

The pancreatic islet contains α cells (glucagon), β cells (insulin), and δ cells (somatostatin), as well as enterochromaffin cells (serotonin). These cells are all part of the APUD system, and tumors so derived secrete a wide variety of polypeptides. Some of these peptides share the characteristics and functions of classic hormones: (1) their release follows a physiologic stimulus; (2) they have the ability to effect response in a distant organ; and (3) these effects are mimicked by exogenous infusion of the hormone. By contrast, some abnormal peptides produced by islet cell tumors have no known clinical hormonal effects.[318]

Equally important, these peptide-secreting tumors are, for the most part, nonautonomous. This is thought to be due to tumor cell regulation by somatostatin and its predominant tumor cell receptor somatostatin receptor subtype 2.[319,320] Clinically, in evaluating patients with islet cell tumors, it is important to understand that there appear to be two different types of patients with APUDomas. The first group consists of those patients who experienced their tumors singularly, in the absence of significant personal or family history of endocrine disorders. The second group includes those with clear evidence of an inherited predisposition to multiple neoplasia of the endocrine system in an autosomal dominant pattern. These MEN syndromes have been described earlier.

As with carcinoid tumors, the approach to the patient with an islet cell tumor must be individualized, balancing management of the effects of hormone production with symptoms of tumor bulk. In any individual patient, one or the other management issue may predominate. Treatment should be directed not only by the presence of symptoms, but also by a consideration of the relatively lengthy natural history of islet cell tumors (Fig. 75-15).

Diagnosis

Specific syndromes and diagnostic tests for each of the more common islet cell tumors are discussed separately. However, a few generally applicable principles should be understood. RIA[321] of peptides obtained by selective venous catheterization is most helpful in localizing tumors and may demonstrate the presence of metastatic spread, particularly in patients with gastrinomas (Zollinger-Ellison syndrome). CT scan and arteriography are particularly helpful in tumors greater than 1.0 cm in diameter. However, because many islet cell tumors and their metastases may be small, neither procedure may be adequately sensitive. As with most endocrine neoplasms, islet cell tumors have a rich vascularity, so that "tumor blush" can be seen on

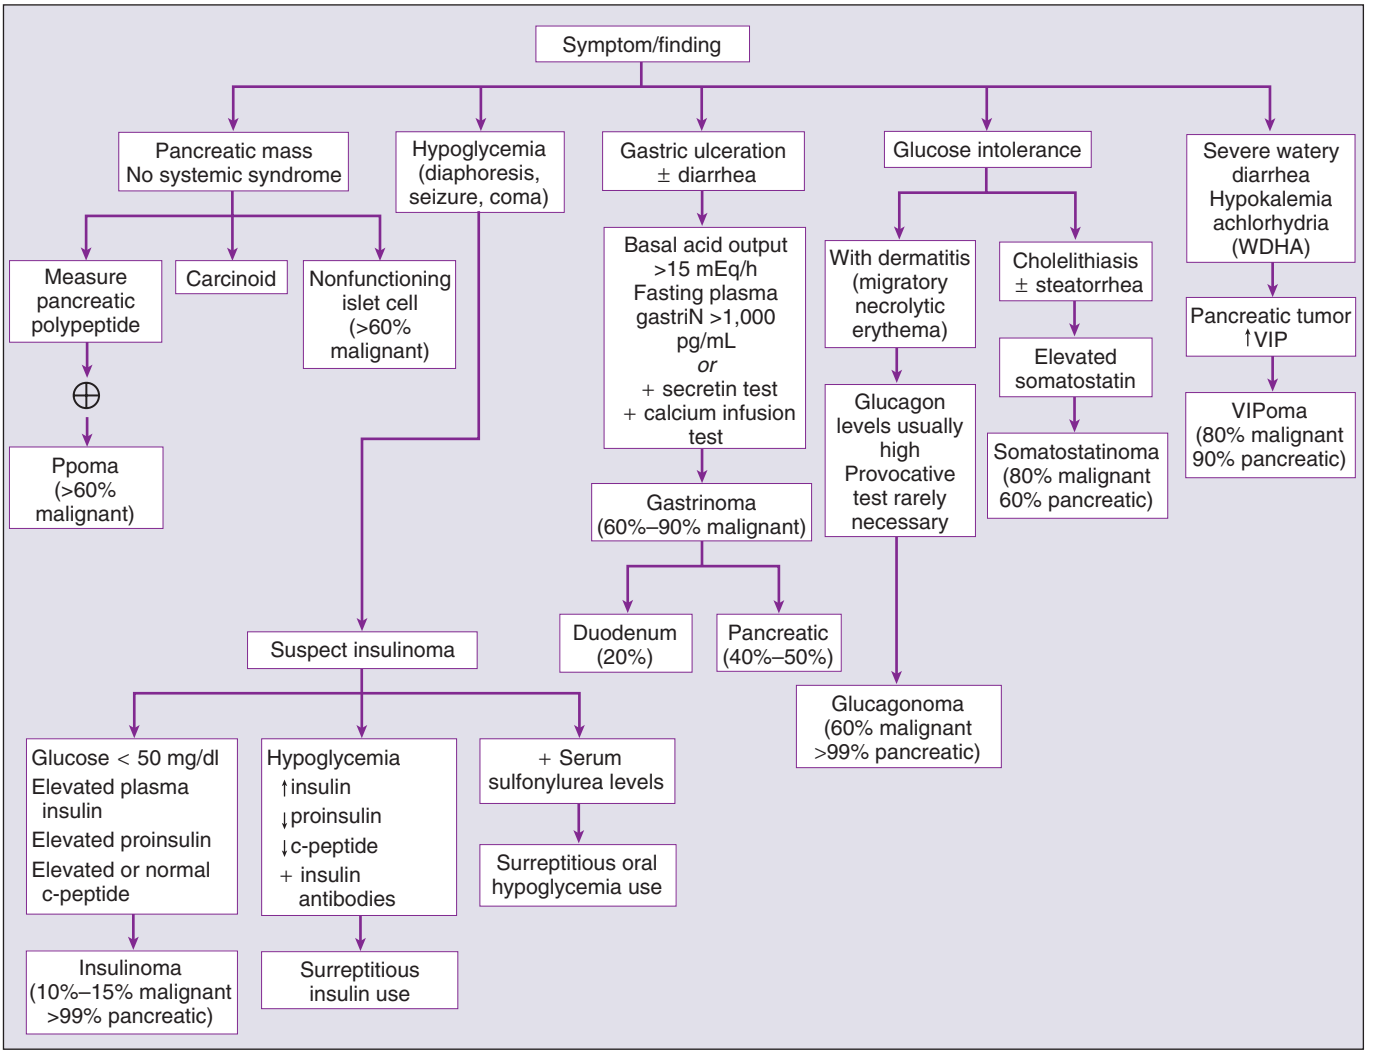

Figure 75-15 • Diagnosis of pancreatic islet cell tumors. Ppoma, pancreatic polypeptide-secreting tumor; VIP, vasoactive intestinal peptide; VIPoma, vasoactive intestinal peptide secreted by a pancreatic islet tumor.

angiography. This sign may be a useful finding in differentiating between endocrine and nonendocrine gastrointestinal tumors. Ultrasonography is of some use in imaging both pancreatic primary tumors and hepatic metastases. Newer imaging techniques are required, therefore, for better diagnosis and staging. For example, MRI has been shown in some studies to be superior to contrast-enhanced CT scans for the identification of all islet cell tumors.[318] The mainstay of diagnosis remains the RIA to detect NSE and chromogranin, which are secreted by these tumors.[255,256]

Insulinoma

The average age of presentation of insulinoma is in the mid-40s, and the sine qua non in diagnosing this syndrome is fasting or inappropriate hypoglycemia accompanied by a relatively high plasma insulin level.[322,323] Other tests have been proposed, including a hypernormal response to tolbutamide, the response of plasma insulin to an infusion of calcium gluconate, and the ratio of proinsulin[323,324] to insulin in the plasma. The key to the diagnosis is a high index of suspicion.

Sporadic insulinomas usually are single and benign; about 10% are malignant.[325] Differentiation of benign from malignant is difficult based on the pathologic features alone, but the presence of metastases defines malignancy. In patients with carcinoma, proinsulin may be increased in plasma[326] or circulating hCG.[327] In both malignant and benign insulinomas, jaundice may occur secondary to biliary tract obstruction from tumors in the head of the pancreas. The typical patient with symptoms of insulinoma has a single small, benign pancreatic nodule. In atypical cases, with multiple primary endocrine tumors, including an insulinoma, MEN-1 syndrome should be suspected.[239]

These tumors usually are imaged with high-resolution, fine-cut CT, MRI, or abdominal ultrasound as the initial study. Although not very sensitive for small, primary tumors, these studies are useful to identify metastatic tumors, if present. If these studies are negative, some authors recommend proceeding with exploration with manual palpation of the pancreas and intraoperative ultrasound, citing success rates greater than 90% at initial exploration.[328] Because insulinomas almost always are confined to the pancreas, selective arteriography and portal venous sampling usually identify the lesion.[325] However, these techniques are technically demanding and not always accurate. Endoscopic ultrasound is being used increasingly to image these tumors. In a prospective series of 37 patients, endoscopic ultrasonography was highly sensitive and specific for pancreatic endocrine tumors, as ultimately confirmed by surgical excision.[329] Endoscopic ultrasound has been reported to be accurate for identifying tumors larger than 5 mm in the pancreatic head.[330] Invasive localization

procedures usually are reserved for patients who present with recurrent or persistent disease.

Surgical resection usually is curative because of the small size and benign nature of insulinomas. As in carcinoid tumor, partial resection may afford palliation in patients whose symptoms are disabling or cannot be controlled with nonsurgical modalities. A patient with unresectable malignant insulinoma and recurrent episodes of hypoglycemia often benefits, during the early stages, from appropriate diet and administration of an insulin antagonist. Frequent feedings between meals and at bedtime are administered with sufficient glucose to control symptoms. Adjustments in the carbohydrate content of the diet may be required, depending on the reactivity of the individual tumor, because the stimulus of a large glucose load may lead to an exaggerated release of insulin.[331] Parenteral glucose supplementation becomes an important adjunct in frequent or sustained hypoglycemic attacks; in emergencies, rapid injection of 50% glucose can be required.

Corticosteroids, human growth hormone (hGH), and glucagon have been useful palliative agents in individual patients.[332,333] However, because of their limited effectiveness, they are best used in combination with other antihormonal measures. Furthermore, glucagon stimulates pancreatic insulin secretion and may cause paradoxic exacerbation of a hypoglycemic episode.

A major advance in the palliation of malignant insulinoma came with the development of diazoxide. Its potent hyperglycemic properties, originally recognized during its use as an antihypertensive agent, have now been extended to the palliation of insulinoma and leucine-sensitive hypoglycemia of infancy.[334,335] Its principal action is to inhibit insulin release directly from the β cell. It also may have an extrapancreatic hyperglycemic effect.[336] Diazoxide is administered orally in divided doses, ranging from 100 to 1000 mg/day. Although the plasma insulin level often can be reduced to a level that causes no symptoms, the tumor will continue to grow and metastasize if malignant, because diazoxide lacks anticancer activity. Diazoxide can cause edema, which can be corrected or prevented with a thiazide diuretic, which also may serve to reinforce the hyperglycemic effects.[323] Octreotide is valuable in the general management of all hormone-producing islet cell tumors and has been found to reduce plasma insulin levels in at least 65% of patients with insulinoma.[337] Octreotide is especially useful when there are insulinoma metastases, because there appears to be upregulation of somatostatin receptor subtype 2 (SST 2) of the metastatic lesions. A caveat remains when using octreotide. Up to 60% of the primary insulin-secreting tumors may not have SST 2 receptors, and hypoglycemia may worsen. Initiation of octreotide acetate requires close monitoring when used in insulinoma therapy.[320]

Chemotherapeutic agents such as streptozocin, 5-fluorouracil, and doxorubicin have been used to treat metastatic insulinomas, but have limited efficacy.[338]

Glucagonoma

Glucagon from pancreatic α cells plays an important role in modulating serum glucose concentrations. Unregulated secretion of glucagon by α-cell tumors[339] produces a distinctive clinical syndrome.[340] A cutaneous rash, described as a necrotizing migratory erythema, is the most characteristic feature.[341] Mild insulin-resistant diabetes and weight loss attributable to the catabolic effects of glucagon also are seen. Glossitis, cheilosis, and venous thromboses can develop. Glucagon inhibits intestinal motility, and the glucagonoma syndrome often includes ileus and constipation. Because symptoms commonly are mild and nonspecific, the tumor often is recognized late, when metastases are present.[340] Most tumors have grown to greater than 4 cm[342] in size at diagnosis, and 50% to 80% are metastatic.[342,343]

The diagnostic test for glucagonoma is the finding of a high plasma glucagon concentration (normal, <60 pg/mL). In patients with glucagonoma, the plasma hormone level typically is markedly elevated and often is greater than 1000 pg/mL.[343] The diagnosis is further suggested by failure of glucose to suppress glucagon, by an abnormal rise in plasma glucagon following infusion of arginine, by the presence of hypoaminoacidemia, and, if tumor is available, immunoperoxidase staining for glucagon. Reviews suggest that the tumor is more common in women and typically presents in the fifth and sixth decades.[344,345] Symptoms persist for many years before the diagnosis is made; survival, even with metastatic disease, may be lengthy. The primary tumor is in the tail or body of the pancreas in 50% of patients and in the head of the pancreas in 8% of patients; the remaining 42% of patients have diffuse involvement. CT scans and MRI are useful in identification of the primary tumor, as is octreoscanning.[346] The tumor is resectable for cure in less than one third of cases,[344] and recurrence after resection, mainly in the liver, is common.

In addition to surgical resection, octreotide produces an improvement of skin rash in up to 90% of patients and complete disappearance of rash in 30%.[347,348] Chemotherapeutic agents may have some activity.

Somatostatinoma

Somatostatin first was identified in pituitary cells, and a role in the regulation of growth hormone secretion was ascribed to it. Subsequently, it was recognized as a hormone of the islet δ cells. Somatostatin may serve as a paracrine regulator of other pancreatic islet cell hormones.[348] Inhibition of secretion of those hormones may account for some of the signs of somatostatinoma. In a review of 20 patients, 11 were noted to present with diabetes, 13 with gallbladder disease, and 7 with diarrhea.[349]

Somatostatinoma occurs most frequently in the head of the pancreas,[350] and as many as 80% of patients have evidence of metastases at diagnosis.[349] Somatostatinomas produce such common symptoms as diabetes (type 2–like diabetes mellitus) and gallbladder disease; therefore, the clinician usually does not consider the diagnosis of somatostatinoma until late in the disease, by which time metastases are likely. Surgical resection usually is not curative.[349,351] Because of the relatively mild hormonally induced symptoms produced by somatostatin, octreotide does not have the same palliative benefit it has in other islet cell tumors. Cytoreductive surgery and chemotherapy may be the most appropriate palliative strategies.

Gastrinoma

Gastrin, the polypeptide hormone normally secreted by the G cell of the gastric antrum, stimulates gastric acid secretion. Tumors of the pancreatic or duodenal wall G cells are responsible for the signs and symptoms of Zollinger-Ellison syndrome, a disorder characterized by hypersecretion of gastrin. First described in 1955,[352] this syndrome is characterized by hypersecretion of gastric acid, severe peptic ulcer disease, and an islet cell tumor of the pancreas. It is estimated that less than 0.1% of patients with peptic ulcer disease have Zollinger-Ellison syndrome.[353]

The hallmark of the gastrinoma syndrome is recurrent peptic ulcer disease in spite of adequate medical or surgical treatment. Intermittent diarrhea, often with steatorrhea, may be present as a result of digestive enzyme inactivation in the small intestine by unbuffered gastric acid. All manifestations of the Zollinger-Ellison syndrome are secondary to hypersecretion of gastric acid.[354] A history of the MEN-1 syndrome has great significance, and gastrinoma may be present in up to 50% of these patients.[355] The combination of high gastric acid secretion and hypergastrinemia is strongly suggestive of gastrinoma, but this combination also can occur in patients with retained gastric antrum following surgery for peptic ulcer (antrectomy and Billroth II gastric resection) and following gastric outlet obstruction. Gastric rugal hypertrophy, multiple ulcers, or ulceration of the small bowel on radiographic studies suggests gastrinoma.[356]

In a review of 60 patients treated surgically for gastrinoma at Ohio State University, Ellison and associates[357] reported that the duration of ulcer symptoms prior to diagnosis averaged slightly more than 4 years. The incidence of MEN was 27%, and a primary tumor was detected in nearly 90% of cases. Gastrinoma can occur not only in the pancreas but also in extrapancreatic locations, including the duodenum, the stomach, and the retroperitoneal lymph nodes. More than one third of patients in the Ohio State series had multiple tumors; metastatic disease in the liver was identified in 20% of patients.[357]

The clinical diagnosis of Zollinger-Ellison syndrome has changed. Although the original case reports stressed the appearance of extensive and multiple gastric ulcers, a heightened index of suspicion and early detection have altered this pattern of disease presentation. The complete diagnosis of Zollinger-Ellison syndrome is based on four steps.[355] The first step is to identify fasting hypergastrinemia in association with a basal acid output greater than 15 mEq/hour. Generally, a gastrin level greater than 1000 pg/mL is pathognomonic. Less convincing elevations in fasting serum gastrin can be further evaluated by the secretin test, in which a peak level of serum gastrin higher than 200 pg/mL over the baseline following administration of secretin is considered diagnostic.[358] The remaining three steps include documentation of peptic ulcer disease, localization of the primary tumor, and assessment of malignancy.[359]

Localization of gastrinomas has been discussed extensively.[360,361] Techniques such as abdominal ultrasonography, CT scan, MRI, selective venous sampling for gastrin, and abdominal arteriography all have a role in the diagnosis and management of this disease. Octreotide scanning is very useful for identifying primary and metastatic lesions,[362] and is valuable as an initial imaging modality. Endoscopic ultrasound also is being used increasingly to identify gastrinomas. Because gastrinomas are so frequently malignant,[363,364] it is necessary to use every diagnostic modality to rule out metastatic disease before planning surgery.

The role of surgery in Zollinger-Ellison syndrome has changed over the past 20 years as a result of the introduction of RIA to diagnose hypergastrinemia and use of histamine H_2-receptor antagonists. The latter therapy has very significantly reduced the need to remove the end organ (the stomach); therefore, few patients will require surgical management to control the signs and symptoms of hypergastrinemia. In addition, gastrinomas are significantly less likely than insulinomas to be isolated, benign, or completely resectable. In a collected series of 457 surgical patients, only 69 patients (15%) were considered to have received surgery with curative intent.[357]

Ellison and associates[357] also analyzed 60 cases from their own institution to determine whether the introduction of the RIA for gastrinoma made earlier diagnosis more likely, with a higher possibility of curative resection. Before the introduction of the assay for serum gastrin levels, 15 of 25 (60%) patients underwent complete excision of all gross tumor. Of the 30 patients who underwent surgical treatment following availability of the assay, 18 (60%) had complete tumor resection. These results indicate no differences in rates of curative resection. However, resectability was associated with prolonged survival, with a 5-year survival rate of 69% in patients with resected tumor, compared with 38% in patients with unresectable disease. The 10-year survival rates were 38% and 9%, respectively. Nearly one half of the deaths were due to the effects of tumor and metastases. These data suggest, but do not prove, that earlier surgical intervention may prevent progression to the complications of bulky malignant tumor in some cases.

Medical management in gastrinoma is directed toward the hypersecretion of gastric acid. Before the introduction of histamine receptor antagonists, the only practical way to treat recurrent duodenal and jejunal ulcers was total gastrectomy. Cimetidine was reported to enhance recovery and make surgery less complicated, and to obviate surgery in some patients.[364] Histamine H_2-receptor antagonists alone or in combination with anticholinergic agents such as propantheline have been successful in producing long-term remissions of peptic ulcer disease complicating gastrinoma.[355] Second- and third-generation histamine H_2-receptor antagonists, such as ranitidine, famotidine, and the ion pump inhibitor omeprazole, have been reported to have progressively superior antisecretory activity, with few failures observed in patients who receive adequate doses.[365] Treatment for symptoms arising from tumor bulk from metastatic gastrinoma are discussed at the conclusion of this section.

Tumors Secreting Vasoactive Intestinal Peptide

In 1958, Verner and Morrison[366] described a syndrome of watery diarrhea, hypokalemia and hypochlorhydria, and metabolic acidosis (the WDHA syndrome), which is due to high circulating levels of vasoactive intestinal peptide secreted by a pancreatic islet tumor (VIPoma). Most studies of VIP infusions in healthy volunteers have supported the concept that the diarrhea in VIPoma patients may be caused directly by elevated circulating levels of vasoactive intestinal polypeptide.[367] Because most patients with this syndrome have metastatic disease at presentation, usually to the liver, management is mainly medical, with chemotherapy or somatostatin analog. Surgical resection is rarely curative. As with carcinoid tumors and other islet cell tumors, however, in patients with locally unresectable disease or those with hepatic metastases, surgical cytoreduction may improve symptom control.

Ghrelin Secreting Tumor

Ghrelin is a 28-amino acid peptide that is secreted in the stomach and stimulates growth hormone release. A recent publication described a patient with hypertension and perspiration and a malignant gastric ghrelinoma with hyperghrelinemia.[368] Although this tumor is exceedingly rare, the expression of ghrelin peptide has now been identified in almost all gastric and intestinal carcinoids, as well as pancreatic neuroendocrine tumors. Its possible role as a tumor marker along with chromogranin A (CGA) in all gastroenteropancreatic neuroendocrine tumors remains to be clarified.

Surgical Management

Pancreatic islet cell tumors present a challenge for the endocrine surgeon. Most are sporadic, but they also can occur as part of the MEN-1 syndrome. Patients with MEN-1 usually develop multicentric tumors that often preclude the ability to perform a curative resection. The commonly occurring islet cell tumors secrete gastrin, insulin, glucagon, pancreatic polypeptide, or somatostatin. These tumors can have profound physiologic effects; even in cases in which complete resection is not possible, tumor debulking may be indicated to alleviate the physiologic effects of hormone secretion.

Gastrinoma

Gastrinomas occur within the pancreas or are found submucosally within the duodenum. Most gastrinomas are located in the "gastrinoma triangle," which is surrounded by the cystic duct superiorly, the second and third portions of the duodenum inferiorly, and the junction of the body and neck of the pancreas medially. Approximately 75% are malignant, with liver metastases a common finding. CT scanning is the best method for evaluating patients for resection. Patients with solitary tumors in the tail of the pancreas can be treated with enucleation or distal pancreatectomy; however, a Whipple procedure may be needed for large or obviously malignant tumors in the head of the pancreas. Duodenal tumors can be resected locally from the wall of the duodenum. It may be necessary to use intraoperative ultrasound, endoscopy with duodenal transillumination, and a longitudinal duodenotomy to identify these tumors. Usually, all enlarged peripancreatic and periduodenal lymph nodes are removed. Occasionally, localized metastases can be resected to control excess gastric

secretion. Patients with unresectable gastrinoma whose acid secretion cannot be controlled medically require a total gastrectomy with esophagojejunostomy.

Insulinoma

Approximately 75% of insulinomas are solitary benign tumors. Preoperative evaluation begins with a double-contrast, fine-cut CT scan. Small tumors that cannot be found by CT scan may be localized preoperatively with transgastric endoscopic ultrasound, which has been reported to have a sensitivity of 83% to 93%.[369] Selective arteriograms with calcium stimulation are used rarely. At laparotomy, the entire pancreas should be exposed by a generous Kocher maneuver. A combination of inspection, palpation, and intraoperative ultrasound will identify most tumors and their relation to the pancreatic duct. Small, benign tumors in any part of the pancreas can be enucleated provided they are not in close proximity to the duct. After enucleation, the pancreatic surface is closed, and the area should be drained because of the possibility of pancreatic fistula.

Larger tumors (≤5 cm) in the head of the pancreas also can be enucleated; however larger tumors in the tail are best treated with a spleen-preserving distal pancreatectomy. Large, potentially malignant, tumors in the head of the pancreas may need a Whipple procedure. Resection of peripancreatic and duodenal nodes also is advised. Some centers now are approaching these tumors laparoscopically. Although feasible, long-term follow up data are needed.[370,371]

Medical Management

Somatostatin Analog

The somatostatin analog octreotide is as useful in the treatment of syndromes associated with ectopic hormone production in islet cell tumors as it is in treatment of carcinoid tumors. In 1985, Santangelo and associates[372] described a single patient with life-threatening pancreatic cholera, successfully controlled by the synthetic somatostatin analog. A later series of patients from the Mayo Clinic significantly supplemented these data; in this series, 24 patients with islet cell tumor were treated.[373] The response to somatostatin analog was prompt and palliated symptoms. However, the median duration of response was only 2.5 months, with only 2 of 24 patients (8%) continuing to benefit beyond 1 year. In another review of 66 cases treated with octreotide, only 8 patients (12%) showed any indication of objective tumor response.[337] The short duration of response and low incidence of objective tumor regression suggest that somatostatin analog in the treatment of metastatic islet cell tumors has a more limited role than in carcinoid tumors. Two recent publications suggest that high-dose octreotide therapy may have additional stabilizing and antiproliferative effects in some patients who suffer malignant, advanced, midgut carcinoid tumors.[374,375] Patients on long-term octreotide therapy should have a cholecystectomy at the time of initial exploration due to the high incidence and morbidity of biliary complications.[300]

Interferon

As somatostatin analogs were being shown to be useful in patients with pancreatic cholera, the first reports of the use of interferon in such patients appeared.[376] In the initial report, two patients with the therapy-resistant pancreatic cholera syndrome were treated successfully with human leukocyte interferon, with reduction in tumor mass in one of the patients. Extending these observations, Swedish investigators reported on 22 patients treated with human leukocyte interferon, with an objective response rate of 77% and a median duration of response of 8.5 months.[301] Most of these responses were documented by decreased hormone production. Only 6 of 22 cases (27%) had objective reduction in tumor bulk. Further evaluation of interferon, with and without chemotherapy, is warranted. The mechanism of action of interferon in islet cell and carcinoid tumors is unknown.

Chemotherapy

As with carcinoid tumors, the use of cytotoxic chemotherapy in a patient with an islet cell tumor is not a first choice for therapy.[377] Chemotherapy usually is attempted in patients with symptoms due to tumor bulk that may not be palliated by cytoreductive surgery or in patients with uncontrolled syndromes of hormone excess. In contrast to carcinoid tumors, islet cell carcinomas generally are more responsive to chemotherapy. The first chemotherapeutic drug to elicit significant attention in the treatment of islet cell tumors was the antitumor antibiotic streptozotocin. This drug has a diabetogenic action in some animals that is correlated with selective uptake of the drug by pancreatic β cells.[377,378] In 1975, Kahn and associates[379] described two patients with pancreatic cholera and islet cell carcinoma successfully treated with intra-arterial streptozotocin. Subsequently, a number of chemotherapeutic drugs were identified as having activity in islet cell tumors. With the identification of 5-FU as a potentially useful drug in these tumors, combination chemotherapy also began to be investigated. In a phase II trial of the combination of 5-FU and streptozotocin, six objective responses were noted in eight patients. In 1980, a larger study from the ECOG was reported, in which streptozotocin alone was compared with streptozotocin plus 5-FU in advanced islet cell carcinomas.[302] The combination was superior to streptozotocin alone in overall rate of response (63% vs. 13%). These responses generally were of long duration and yielded meaningful improvements in performance status and symptoms. The median survival time of patients receiving the combination was 26 months, compared with 16.5 months in the group receiving streptozotocin alone. The combination was associated with a higher degree of nausea and vomiting, myelosuppression, and nephrotoxicity. With the identification of doxorubicin as a potentially useful drug in islet cell tumors,[380] the ECOG also piloted a randomized trial in which doxorubicin plus streptozotocin was compared with the earlier standard of 5-FU plus streptozotocin. Results from this study demonstrate that the doxorubicin plus streptozotocin combination produced objective response in 69% of cases, with a median duration of response in excess of 20 months and a median survival time of 2.2 years.[381] This regimen is superior to the 5-FU plus streptozotocin combination in both tumor response and survival. A study of 12 patients with islet cell carcinomas treated with the combination streptozotocin, doxorubicin, and 5-FU reported a 54% response.[300] However, these were partial responses; no complete responses were found.

A number of other chemotherapy drugs have demonstrated activity in islet cell tumors. Chlorozotocin, an analog of streptozotocin, has been shown to be less nephrotoxic but more myelosuppressive than the parent drug. In phase II trials of chlorozotocin, responses were significant when it was used alone or with 5-FU.[382,383] Unfortunately, chlorozotocin is no longer being produced. DTIC also has activity in islet cell tumors, and this agent is undergoing a prospective clinical trial by the ECOG. Other agents of interest include etoposide and cisplatin, which are active in various neuroectodermally derived tumors. The combination of etoposide and cisplatin has been shown to have activity in small cell lung cancer, and a recent trial demonstrates that more than 60% of anaplastic carcinoid and islet cell tumors respond to this combination, whereas well-differentiated tumors do not respond.[384] A phase II trial with DTIC, 5-FU, and leucovorin reported an overall response rate of 27%; however, 50% of the patients had carcinoid tumors, which, as a subset, demonstrated particularly poor response.[385]

Liver-Directed Therapy

As with carcinoid tumor, islet cell tumors often result in predominantly hepatic metastases, and reduction in tumor bulk in the liver may significantly influence hormone production and quality of life.

For that reason, resection of hepatic metastases is warranted in selected patients. The use of hepatic radiation has been reported only anecdotally. Of two patients treated at the National Cancer Institute, one patient with a VIPoma had significant resolution of watery diarrhea for 25 months; the other, with gastrinoma, had significant diminution in abdominal pain and of gastrin levels.[386] Endocrine and tumor response to hepatic arterial occlusion, with or without chemotherapy, can be impressive. The Mayo Clinic experience documents, in 46 patients with islet cell tumor regression rates of 43% with hepatic artery occlusion alone, versus 78.1% when chemotherapy was included.[261,313] Chemotherapy in addition to hepatic arterial occlusion improved the duration of response, but this was not a randomized comparison. However, both objective tumor responses and hormonal regressions were common, and the increased activity of chemotherapy in these tumors supports the use of systemic therapy with or without HAO techniques. The use of cryosurgery for treatment of hepatic metastases that are resistant to chemotherapy also has been reported.[387] This approach has been reported to be effective in treating symptoms, but effect on survival has not yet been demonstrated.

76 Cancer of the Lung: Non-Small Cell Lung Cancer and Small Cell Lung Cancer

David H. Johnson, William J. Blot, David P. Carbone, Adriana Gonzalez, Dennis Hallahan, Pierre P. Massion, Joe Bill Putnam, and Alan B. Sandler

SUMMARY OF KEY POINTS

Non-Small Cell Lung Cancer

Incidence and Epidemiology

- Non-small cell lung cancer (NSCLC) constitutes 80% to 85% of new cases of lung cancer in North America.
- Its most frequent histologies include adenocarcinoma, squamous cell carcinoma, and large cell carcinoma.
- It is the leading cause of cancer death in the United States for both men and women; it represents one of the most preventable forms of cancer death.
- Tobacco use is considered responsible for 87% of lung cancer deaths use

Screening

- Because it is considered controversial, screening is not recommended by the U.S. Preventive Services Task Force.

Staging Evaluation

- A history and physical examination, and routine hematologic and biochemical testing are done.
- Imaging studies include
  - Computed tomography (CT) scan (with contrast) evaluating lungs, mediastinum, liver, and adrenals
  - Positron emission tomography (PET) useful with clinically early-stage disease
  - If patient has locally advanced or metastatic disease should add magnetic resonance imaging (MRI) of brain
  - If PET not available should add bone scan
- Mediastinal node evaluation includes
  - If disease in early stage (I, II) and PET of mediastinum negative, proceed directly to surgery; if PET positive, proceed to biopsy depending on node location
  - Cervical mediastinoscopy
  - Mediastinotomy
  - Transesophageal endoscopic ultrasound
  - Bronchoscopy
  - If disease is clinically more advanced, use the least invasive biopsy procedure from the foregoing list. At surgery all nodal areas must be sampled at minimum.

Primary Therapy

- Stage I disease
  - Surgery often curative
  - Role of pre- or postoperative therapy unclear
  - Radiation therapy appropriate in selected cases
- Stage II disease
  - Surgery often curative
  - Survival prolonged by postoperative chemotherapy in patients with a good performance status
  - Radiation therapy appropriate in selected cases
- Stage IIIA disease
  - Postoperative chemotherapy useful in resected IIIA if performance status good
  - Role of preoperative chemotherapy with or without radiation therapy for limited-extent stage IIIA unknown except for Pancoast tumors, where it is recommended
- Stage IIIB disease
  - Concurrent chemotherapy combined with irradiation superior to radiation alone; increased toxicity limits this approach in frail patients
  - Malignant pleural effusion treated as stage IV
  - Clinical trials of new approaches deserving of high priority
- Stage IV disease
  - Improvemenet of quality and quantity of life associated with primary chemotherapy with platinum-based doublet
  - No advantage for triplet therapy
  - Non-platinum-based therapy appropriate in selected patients
  - Single-agent therapy reserved for select populations.
  - More clinical trials at this stage clearly needed
- Second- or third-line therapy
  - Further treatment with any of several agents appropriate with progression after chemotherapy if patient sustains a good performance status; docetaxel, pemetrexed, and erlotinib (all approved by US Food and Drug Administration [FDA]).
  - Erlotinib and possibly gefitinib useful in this setting
  - Local recurrence after surgery treatable with combined chemotherapy and radiation after complete restaging

Small Cell Lung Cancer

Incidence and Epidemiology

- Small cell lung cancer (SCLC) accounts for approximately 15% of new cases of lung cancer each year in United States; incidence decreasing
- Subtypes: small cell carcinoma and combined small cell carcinoma (most often combined with squamous cell carcinoma, adenocarcinoma, or large cell carcinoma)

Staging Evaluation

- History and physical examination, routine histologic and biochemical testing
- Imaging
  - CT scan (with contrast) evaluating lungs, mediastinum, liver, and adrenals
  - Brain evaluation (MRI preferred) if neurologically symptomatic
  - Bone scan recommended if signs or symptoms of bone involvement present.
  - PET scan considered investigational
  - Mediastinal node evaluation not required unless as a convenient site for biopsy

- A major task: identifying the presence or absence of M1 disease
- If peripheral smear or hemogram abnormal, bone marrow biopsy may be obtained if no other site of metastatic disease has been confirmed

Therapy

- Limited disease
  - Concurrent etoposide plus cisplatin and radiation to the intrathoracic disease
  - Prophylactic cranial irradiation in complete (or near complete) responders
- Extensive disease
  - Etoposide (or irinotecan) plus cisplatin or carboplatin
  - No evidence a third agent or dose intensification improves outcome
  - Research studies a clear priority given the lack of progress in this arena
- Recurrent disease
  - Second-line therapy useful mainly in individuals who have experienced a longer treatment-free interval and a good performance status
  - Topotecan FDA approved; however, any of several chemotherapy agents offer short-term benefit.
  - Research protocols a preferred choice for individuals with disease recurrence

INTRODUCTION

Although reports of pulmonary malignancies date to antiquity, lung cancer is largely a disease of modern humans. Before 1900 lung cancers were viewed as "matters of medical curiosity not known to be in any degree influenced by medicine and too rare to be of much practical importance".[1] By the mid-twentieth century, however, lung cancer had become epidemic and firmly established as the leading cause of cancer-related death in North America and Europe.[2] It should not be forgotten that lung cancer is potentially one of the most preventable of all of the major malignancies afflicting humanity. Its primary cause is tobacco smoke.[3] King James I was among the first to chronicle the adverse health effects of tobacco smoke,[4] but it was Raymond Pearl's landmark 1938 report that conclusively established the devastating impact smoking has on longevity.[5] It would be another decade before tobacco smoking was firmly established as a causative agent of lung cancer[6,7] and nearly 30 more years before the emergence of the U.S. Surgeon General's initial report of the ill effects of tobacco smoking. Regrettably it would be yet another 3 decades before the tobacco industry publicly acknowledged this obvious truth but only after a long, drawn-out battle of misinformation and deception[8] ironically helped along by the unwitting (perhaps) complicity of physicians.[9] With the belated recognition of the etiologic role of tobacco smoke the incidence of lung cancer started to decline in North America and parts of Europe. For the most part the decline is seen most clearly in men. Only recently has this decline become apparent in women in the United States following a similar decline among men 10 to 15 years ago.[10] In short, the story of lung cancer is replete with controversy,[11] politics,[12] pessimism,[13] and, more recently, guarded optimism.[14] This chapter focuses on our perceptions of current management of lung cancer with an emphasis on advances made over the past 5 years. We refer the reader to previous editions of *Clinical Oncology* for earlier works of historical importance.

EPIDEMIOLOGY

Lung cancer was an uncommon disease in the early part of the twentieth century but then began an epidemic rise to far surpass all other cancers in numbers and rates of death.[15] Indeed, lung cancer is now the second most common cause of death among American men. The increase peaked in the late 1980s among men but did not plateau until around the year 2000 among women. It is estimated that more than 170,000 individuals will be diagnosed with lung cancer in the United States in 2006.[15] Lung cancer is relatively rare in individuals younger than age 40, but rates rise steadily until age 80 and then taper off; the projected lifetime probability of developing lung cancer is estimated to be approximately 8% among males and approximately 6% among females.[16] The incidence of lung cancer varies by racial and ethnic group, with the highest age-adjusted incidence rates among African American men (Fig. 76-1). The excess in age-adjusted rates among blacks occurs only among men, but examinations of recent age-specific rates show that below age 50 mortality from lung cancer is more than 25% higher among black than white women.[16] Incidence and mortality rates among Hispanic, Native, and Asian Americans are only 40% to 50% those of whites. Figure 76-2 shows trends in age-adjusted mortality rates from lung cancers in the United States since 1930.

The trends in overall lung cancer rates mask differences in temporal patterns according to lung cancer cell type. Figure 76-3 shows changes in age-adjusted incidence rates for squamous cell carcinoma and for adenocarcinoma during 1973 to 2003 based on data from nine continuing cancer registries in the National Cancer Institute's (NCI's) SEER program of cancer registration. Among men, squamous cell cancers predominated in the first two thirds of this period. The decline in incidence of lung cancer among men was first apparent for squamous cell tumors, however, with decreases beginning in the early 1980s so that by the mid-1990s rates of squamous cell carcinoma among men had dropped below those for adenocarcinoma, which did not peak until over a decade later. Among women, adenocarcinomas have been more common than squamous cell carcinomas across the 3 decades. The adenocarcinoma excess among women has become more pronounced over time, in that rates of squamous cell cancers increased steadily through the 1980s before

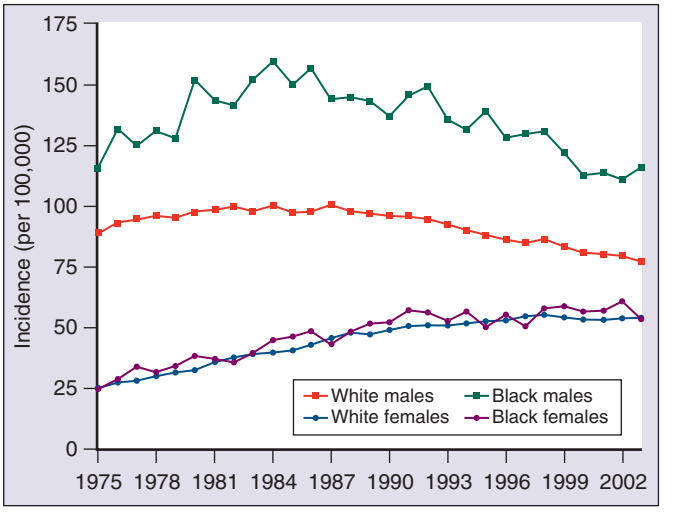

Figure 76-1 • Lung cancer incidence in United States between 1975 and 2003. Age-adjusted to the 2000 U.S. standard population. (Data from National Center for Health Statistics, Centers for Disease Control & Prevention, 2005).

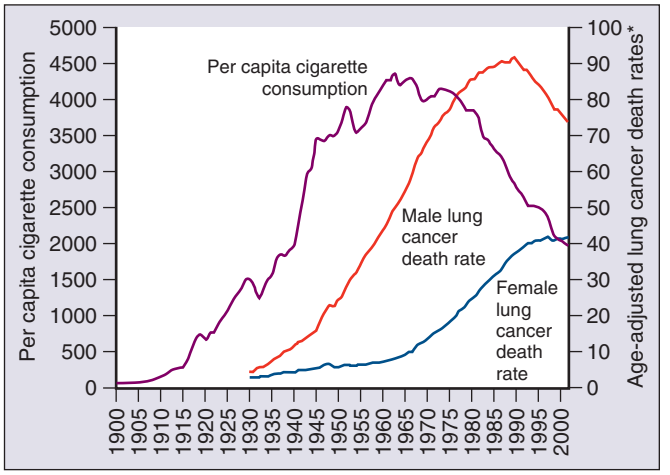

Figure 76-2 • Tobacco use and lung cancer mortality in the United States 1900–2002. *Per 100,000, age-adjusted to the 2000 U.S. standard population.

beginning to decline, whereas adenocarcinoma did not plateau until about a decade later. Although not shown in Figure 76-3, rates of small cell carcinoma, the third most frequent cell type, tended to parallel those for squamous cell cancer among both sexes. Trends for other cell types of lung cancer, including large cell carcinomas and bronchioloalveolar carcinomas, tend to be intermediate between those of squamous cell carcinomas and adenocarcinomas. As discussed later in the chapter, although 5-year relative survival rates for lung cancer have improved over time, the survival rates are low, currently about 15% overall.[16] Some variation exists by sex, race, and cell type, with slightly higher survival among whites than blacks and females than males, but for no group does the overall 5-year relative survival exceed 20%.

Risk Factors

The cause of the large majority (80% to 90%) of lung cancers is cigarette smoking.[17,18] There is a massive compilation of scientific evidence from epidemiologic studies conducted around the world since the 1950s demonstrating the link between smoking and lung cancer. Epidemiologic research has also revealed that several other factors have been implicated as causes of lung cancer, though none to the extent of tobacco.[19,20] Cigarette smokers have been shown to have large increases in the risk of lung cancer. Numerous investigations typically show 10-fold or greater increases in risk of this cancer among smokers as compared with those who have never smoked.[17,18]

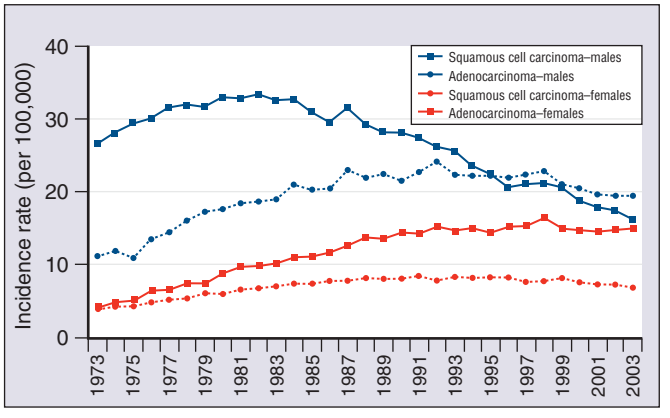

Figure 76-3 • Age-adjusted SEER lung cancer incidence, nine registries.

One of the largest studies is the American Cancer Society's prospective cohort study of over 1 million Americans wherein a greater than 20-fold excess of lung cancer has been observed among men who were current smokers at the start of the follow-up in the early 1980s.[17,18] In contrast, even the most prolonged and intense exposures to asbestos, perhaps the most prominent occupational cause of lung cancer, are associated with no more than about fivefold increases in lung cancer.[21]

Risks of lung cancer are lower among persons who quit smoking than among those who continue smoking.[17,18] The reductions in risk indicate that quitting smoking is beneficial (and conversely that continuing to smoke is harmful). Risk among former smokers on average is less than one half that of those who continue to smoke. In the American Cancer Society cohort study cited discussed earlier, former smokers had a 9-fold increase in lung cancer as compared with men who had never smoked versus the 20-fold excess in those who continued to smoke.[17,18] Such relative reductions have been consistently seen, with the size of the reduction in risk increasing the longer the time period since the person has quit smoking, although generally even long-term former smokers have higher risks of lung cancer than those who never smoked.[17,18]

Cigarette smoking has been shown to increase risk of all the major lung cancer cell types.[17–20] The magnitude of the increase varies by histologic type, however, with highest risks for squamous cell, small cell and large cell carcinomas of the lung. Some early studies tended to show only small increases in risk of adenocarcinoma among smokers, but more recent studies indicate that the excess of lung adenocarcinoma is substantial.[17,18,20]

Cigarette smoke has also been implicated in increasing risk of lung cancer among nonsmokers. A 2006 update of the Surgeon General's report declared that there is sufficient evidence to list passive smoking as an established cause of lung cancer and called for further control of environmental tobacco smoke (ETS) exposures.[22] The risk from ETS is far less than from active smoking, with about a 20% to 30% increase in lung cancer observed among nonsmokers married for many years to smokers, in comparison to the 2000% increase among continuing active smokers. Nevertheless, cancer control activities based on the knowledge that ETS exposure may convey an increased risk of lung cancer have helped reduce exposures in public places and have also provided additional incentive for smokers to quit the habit.

Although cigarette smoking is the dominant cause of lung cancer, several other risk factors for this cancer have been identified.[19,20] These include occupational exposures to asbestos and some other workplace agents, some of which have been evaluated for nearly as long as cigarette smoking. Among the occupational agents considered as known lung carcinogens are arsenic, bischloromethyl ether, hexavalent chromium, mustard gas, nickel (as in certain nickel refining processes), and polycyclic aromatic hydrocarbons.[19,20,23] Several other occupational exposures have been associated with increased rates of lung cancer, but the causal nature of the association is not clear. Epidemiologic studies have attempted to assess the potentially synergistic interrelationship between certain workplace exposures and smoking. Risk of lung cancer among men exposed to asbestos who also smoked was originally thought to be exceptionally high (with early reports of 50-fold or greater excesses compared with unexposed nonsmokers), but recent modeling of larger data pools suggests that asbestos and tobacco combine to enhance lung cancer risk in a less than multiplicative manner.[24] Occupational observations have also provided clues to the mechanisms of lung cancer induction. Risk of lung cancer among asbestos-exposed workers, for example, is increased primarily among those with underlying asbestosis, raising the possibility that the scarring and inflammation produced by this fibrotic nonmalignant lung disease may in many cases (though probably not in all) be the trigger for asbestos-induced lung cancer.[25]

Increased risks of lung cancer have also been associated with other variables. Diet and nutrition are thought to be involved, because numerous investigations have shown somewhat higher risks of this

cancer among those with low fruit and vegetable intake during adulthood.[19,20] The early observational studies led to hypotheses that specific nutrients, in particular retinoids and carotenoids, might have chemopreventative effects for lung cancer. Randomized clinical trials were launched, but hopes were crushed when reports from interventions involving supplementation with β-carotene in trials both in Finland and the United States found increased rather than decreased incidence of lung cancer among those supplemented.[26,27] The current consensus regarding diet and lung cancer remains muddled, with a minor role for nutritional factors probable but difficult to assess epidemiologically. Ionizing radiation has been established as a lung carcinogen, most convincingly demonstrated from studies showing modestly increased rates of this cancer among persons exposed to the atomic bombs of Hiroshima and Nagasaki and large excesses among workers exposed to α-irradiation from radon in underground uranium mining.[19,20] Extrapolations from the high exposures in mines to low-level radon exposures in homes, as well as direct observations from case-control studies assessing measured levels in homes, suggest that prolonged radon exposures above the recommended remedial levels might impart a risk of lung cancer equal or greater than that of ETS.[28] Prior lung diseases such as asbestosis (mentioned previously), chronic bronchitis, emphysema, and tuberculosis also have been linked to increased risks of lung cancer. Although smoking itself is a cause of the chronic obstructive pulmonary diseases (COPDs), the link between chronic bronchitis and emphysema and lung cancer persists after adjustment for smoking, with up to about a doubled smoking-adjusted cancer risk among those with COPD.[19,20,29] Familial clustering of lung cancer has been observed, raising the possibility of inherited traits that may increase risk among some individuals, with risk about doubled in families with prior lung cancer.[19,20] Smoking also clusters within families, so some of the familial aggregation of lung cancer may be smoking-related. Nevertheless, there seem to be multiple genetic factors that help determine the way in which individuals metabolize, detoxify, repair, or otherwise respond to lung carcinogens, including the carcinogens in cigarette smoke, as discussed in more detail later in this chapter.

SMOKING CESSATION

Given the undeniable link between cigarette smoking and lung cancer,[3] it is incumbent upon physicians to promote tobacco abstinence and help their patients who smoke to stop smoking.[30] Smoking cessation, even well into middle age, can minimize an individual's subsequent risk of lung cancer, and stopping before middle age avoids more than 90% of the risk attributable to tobacco.[31,32] By contrast, there is little health benefit realized by simply "cutting back".[33] Among victims of lung cancer, smoking cessation is associated with improved survival,[34–37] fewer side effects from therapy,[38] and an overall improvement in quality of life.[39] It is often forgotten that smoking alters the metabolism of many chemotherapy drugs, potentially adversely altering the toxicities and therapeutic benefits of the agents.[40] Therefore, it is important to promote smoking cessation even *after* the diagnosis of lung cancer is established.[41,42] To do so requires that oncologists be well versed in the treatment of nicotine addiction.[43] Although smoking cessation is extremely difficult, patients with lung cancer tend to be highly motivated and success rates mirror that of other disease states.[44] However, the individual must want to stop smoking and must be willing to work hard to achieve the goal of smoking abstinence. Nicotine replacement therapies, bupropion and varenicline (an $\alpha_4\beta_2$-nicotinic acetylcholine receptor partial agonist), are approved by the U.S. Food and Drug Administration (FDA) as first-line treatments for nicotine dependence.[45] Recently varenicline was demonstrated to be significantly more efficacious than bupropion alone for smoking cessation.[46] Furthermore, prolonged use of varenicline beyond the initial induction phase proved useful in maintaining smoking abstinence.[47] Clonidine and nortriptyline are recommended as second-line treatments.[41] A systematic review of extant smoking cessation studies indicates self-help strategies alone only marginally affect quit rates, whereas individual and combined pharmacotherapies and counseling either alone or in combination can significantly increase rates of cessation.[48]

BIOLOGY OF LUNG CANCER

The specific events that trigger malignant transformation of bronchoepithelial cells are unknown in the vast majority of cases. However, it is clear that exposure to environmental carcinogens, such as those found in tobacco smoke or asbestos fibers, induce or facilitate the transformation (extrinsic component).[49] The contribution of the extrinsic carcinogen on transformation is modulated by variations in genes (intrinsic component) that affect aspects of carcinogen metabolism, such as the conversion of procarcinogens to carcinogens and their subsequent inactivation.[50] These genetic variations occur at relatively high frequency in the population. Their contribution to an individual's lung cancer risk is generally low, but because of their population frequency, their overall impact on lung cancer risk could be high. Epidemiologic studies further suggest that a familial predisposition to lung cancer exists that is independent of tobacco smoke exposure. One study found evidence for an autosomal dominant model linked to 6q23–q25,[51] but other studies have proposed a complex multigene model for inherited risk.[52] A familial clustering of lung cancer cases has been reported with an inherited T790M mutation in the epidermal growth factor receptor (*EGFR*) gene.[53] The identification of individuals at particularly high risk for the development of lung cancer could justify more intense screening regimens, and the identification of the responsible chromosomal loci for lung cancer susceptibility genes could allow the development of specific chemopreventative strategies.

Environmental factors, as modified by inherited modulators, probably affect specific genes by deregulating important pathways to permit the cancer phenotype. Particularly important in lung cancer are acquired abnormalities in the genes encoding ras, Rb, p53, Akt, LKB, and BRAF.[54] However, the single most clinically significant acquired genetic abnormality in lung cancer is the recently described mutation of the *EGFR*.[55–58] These are mutations, primarily in exons 19 (in-frame deletions of four amino acids, LREA) and 20 (L858R point mutants), that result in constitutive signaling and AKT activation,[59] and are associated with very high response rates (60% to 90%) to the specific tyrosine kinase inhibitors (TKIs) gefitinib and erlotinib.[60] Interestingly, almost all of the mutations occur in nonsmokers and adenocarcinomas, and the frequency of mutations is much higher in Asian than Western populations (30% to 70% versus 8%).[61,62] These responses are often dramatic and occur even in heavily pretreated patients, demonstrating that tumors with these mutations are "addicted" to the activation of this pathway. Almost all patients with these impressive responses, however, develop progressive, resistant disease, and about half of these tumors with acquired resistance to TKIs demonstrate a second T790M mutation associated with resistance.[63,64]

Despite the incontrovertable high response rate in patients with *EGFR* mutations, analysis of samples from BR.21, a placebo-controlled randomized clinical trial of erlotinib in second-line non-small cell lung cancer (NSCLC) showed that the presence of an *EGFR* mutation was not associated with prolonged survival,[65] but in univariate analysis amplification of the receptor was associated with improved survival.[66] Interestingly, there was a survival benefit in the entire erlotinib arm compared with placebo, as well as every subset of patients, including smokers and patients with squamous cell cancers,[67] suggesting that variables other than mutation may contribute to clinical benefit, and that this was not necessarily related to objective response rates. Other assays, including serum proteomics, show potential for selecting patients likely to achieve clinical benefit.[68]

It is clear that the vast majority of lung cancers are not driven by single aberrant genes, however, and not all aberrancies are mutations.

Complex networks of genes are finely tuned in normal cells to maintain normal growth, apoptotic responses, and differentiation. These networks can be perturbed at multiple points to deregulate key pathways in lung cancer tumors. A simple example is the mutation of *Rb* and the loss of p16, a regulator of Rb function; NSCLCs disrupt cell cycle control by either mutation of *Rb* or loss of expression of p16, but not both.

Attempts have been made to look at the genome in "comprehensive" ways so as to dissect tumors with common groups of genetic features that might provide biologic or clinical guidance beyond traditional classification by light microscopy. Single-nucleotide polymorphism arrays have been developed that are able to analyze loss or gain of genetic material at very high resolution,[69,70] and cancer genome resequencing efforts are likely to uncover common mutations. Protein expression and therefore function is probably more often modulated by epigenetic alterations than by mutations to cause perturbations in pathway function.[71] Detection of specific promoter methylations may in fact be a useful biomarker of malignancy.[72] These sorts of pathway alterations are more likely to be detected by the analysis of gene expression, protein expression, or post-translational modification-type changes (e.g., phosphorylation) than by gene mutation analysis. High-throughput technologies have been developed for each of these, and they are beginning to be applied to lung cancer. Several studies, for example, have been able to identify prognostically distinct subgroups of lung adenocarcinomas by complementary DNA microarray analysis,[73–75] as well as likelihood of recurrence after surgical resection.[76,77] More important than prognosis, early progress is being made in the analysis of single genes and pathways important for predicting response to targeted therapies, allowing rational individualization of therapy selection. Low expression of the DNA repair gene *ERCC1* has been shown to correlate with poor prognosis in NSCLC but with improved survival after treatment with platinum drugs.[78] For the newer targeted therapies, patterns of gene expression are being developed that may identify those more likely to respond.[79] Even closer to function than gene expression, analysis of protein expression patterns[68,80,81] or even phosphorylation patterns[82] may hold even greater practical promise in the future.

The histologic sequence of events that leads to the various forms of lung cancer is not well understood, and it is clearly different for the various histopathologic entities.[82–85] Current knowledge suggests that squamous cell carcinoma arises in an ordered progression that includes squamous metaplasia and carcinoma-in-situ (CIS). Peripheral adenocarcinomas are thought to arise from atypical adenomatous hyperplastic lesions, but this process is much more obscure largely because this type of lesion is much less accessible by bronchoscopy. Small cell carcinoma might arise from neuroendocrine hyperplasia, but evidence in support of this hypothesis is scarce.

The pathology of premalignancy will be discussed in more detail in the next section, but the molecular biology of premalignancy is of great clinical importance, not only to better understand the process of cancer development, but to provide potential therapeutic targets to intervene in this process and intermediate biomarkers to assess risk and evaluate candidate chemoprevention strategies. Premalignant lesions of the lung have been investigated for molecular alterations in NSCLC, but much less information is available for SCLC.[86] Microdissected specimens derived from normal, hyperplastic, metaplastic, dysplastic, and CIS, as well as invasive neoplastic foci of patients with lung cancer, were studied for gene mutations, promotor hypermethylation, and allele loss. Results obtained thus far suggest that allele loss on chromosome 3p is the earliest event, followed by allele loss/hypermethylation on chromosome 9p and subsequently on chromosome 8p.[85] Loss of heterozygosity at the p53 gene locus (17q13.1) is relatively rare (10%) and occurs predominantly at the dysplasia or CIS stage. Point mutations in the p53 gene[87] and the EGFR gene,[88] however, have been observed in morphologically normal bronchial epithelium obtained from the airways of patients with lung cancer. In contrast, K-ras gene mutations represent a late event, found only in CIS or invasive cancers.[89] In addition to copy number changes and mutations, alterations in the expression of the retinoic acid receptor β (RARβ) have also been used as a molecular marker for premalignancy and as an intermediate biomarker for chemoprevention trials.[90]

The fate of morphologically or molecularly abnormal areas is currently an intense area of research. One study showed that 54% of patients with high-grade dysplastic lesions developed lung cancer within 2 years, but 80% of these arise in a different part of the lung than the CIS.[91] None of the patients with low-grade dysplastic lesions progressed to cancer in this study. Of the low-grade lesions studied, 82% spontaneously regressed, 18% remained unchanged, and none progressed to CIS. Preliminary data also suggest that abnormal regions display reproducible molecular changes on repeat biopsies over time, and that these and additional abnormalities can be observed in tumors arising from these lesions.[92]

Part of the problem with the studies of preneoplasia is that we may be evaluating the microscopic appearance and molecular characteristics of the wrong population of cells. The vast majority of the respiratory epithelium (and most other tissues) is thought to be terminally differentiated and incapable of sustained replication; however, one theory holds that a small subset of the cells have unlimited, but normally tightly regulated, replicative potential. These are the pulmonary "stem cells",[93,94] whose biology is very poorly understood. The stem cell concept may also underlie the failure of standard medical therapies to eradicate lung cancers, even when there is a clinical complete response. The theory is that therapies have been refined to induce measurable reductions in the bulk tumor mass, while true replicative potential exists only in a small subset of "cancer stem cells" that are not effectively targeted by current therapies. Specific isolation of these cells and development of stem cell-targeted therapies may thus not cause rapid tumor regressions but instead result in significantly increased long-term survival.

Understanding of the molecular biology and discovery and validation of reliable biomarkers predictive of relapse, response to therapy, and poor outcome from lung cancer have long been pursued by investigators with the goal of guiding clinicians in selecting treatment for patients. One future approach to improve patient outcome is tailored therapy based on individualized phenotypic or genotypic tumor characteristics. We are now seeing the beginning of this with commercial EGFR mutation screening. Recent technological advances in mutation detection and quantitation of gene expression in minute clinical specimens herald the advent of clinical therapeutic decisions based on the expression of specific therapeutic targets and/or other host and/or tumor characteristics.

PATHOLOGY

The latest World Health Organization (WHO) classification of lung tumors from 2004 is essentially unchanged from the preceding classification from 1999 (Table 76-1).[95,96] The 1999 WHO classification reorganized and introduced several lesions. It defined bronchioloalveolar carcinoma (BAC) as a noninvasive tumor for the first time, and it introduced the concepts of atypical adenomatous hyperplasia and diffuse neuroendocrine hyperplasia as precursors to adenocarcinoma and neuroendocrine tumors, respectively. Since these additions, more studies have focused on evaluation of diagnostic criteria and prognosis of these preneoplastic and in situ lung lesions.

Tissue and Cytologic Diagnosis of Lung Cancer

The diagnosis of lung cancer can be made on tissue specimens such as transbronchial biopsy or resected specimens, or assessment of cytologic specimens such as transbronchial or transthoracic fine-needle aspirates (FNAs), bronchial brushes, bronchial washes, bronchioloalveolar lavage, or sputum cytology. The diagnostic yield depends on several variables including location (accessibility) of the

tumor, tumor size, tumor type, or technical aspects of the diagnostic procedure including the experience level of the bronchoscopist and pathologist.[97] In general, central lesions such as squamous cell carcinomas, small cell carcinoma, or endobronchial lesions such as carcinoid tumors, are more readily diagnosed by bronchoscopic examination, whereas peripheral lesions such as adenocarcinomas and large cell carcinomas are more amenable to transthoracic FNA. Diagnostic accuracy for small cell carcinoma versus non-small cell carcinomas for most specimens is excellent,[98] with lesser accuracy for subtypes of non-small cell carcinoma.[97]

Bronchoscopic specimens include bronchial brush, wash, bronchioloalveolar lavage, and transbronchial FNA. Of these, transbronchial FNA consistently demonstrates the highest sensitivity, surpassed only by the use of a combination of bronchoscopic specimens.[97–101] Overall sensitivity for combined use of bronchoscopic methods is approximately 80%, and together with tissue biopsy, the yield increases to 85% to 90%.[97,98,100] In fact, transbronchial FNA is more often diagnostic that transbronchial biopsy when the lesion of interest is submucosal.[97,102]

Like transbronchial FNA specimens, transthoracic FNA specimens are also very good, yielding diagnostic material in 70% to 95% of cases. Sensitivity is highest for larger lesions and peripheral tumors.[103] In general, FNA specimens, whether transbronchial, transthoracic, or endoscopic ultrasound-guided, are superior to other specimen types.[104] This is primarily because of the higher percentage of lesional tumor cells with fewer confounding conditions such as obscuring inflammation and reactive nonneoplastic cells.

Sputum cytology is inexpensive and noninvasive but has a lower yield than other specimen types due to poor preservation of the cells and more variability in acquiring a good-quality specimen. The yield for sputum cytology is highest for larger and centrally located tumors such as squamous cell carcinoma and small cell carcinoma histology, although occasionally an accurate diagnosis is possible with tumors located more peripherally within the lung.[97] The specificity for sputum cytology averages close to 100%, although sensitivity is generally less than 70%. The accuracy of sputum cytology improves with increased numbers of specimens analyzed; consequently, analysis of at least three sputum specimens is recommended. Sputum cytology also has been extensively studied as a screening tool for early detection of lung cancers with varying success. Sputum cytology is not currently recommended as a routine screening tool, but recent advances in molecular diagnostic techniques may result in a resurgence of this methodology.[105–108]

Precursor Lesions of the Lung

Squamous Dysplasia

The most established carcinoma sequence in lung cancer is that of preinvasive squamous lesions. In response to toxins, normal bronchial epithelium may undergo hyperplasia and squamous metaplasia, then dysplasia (Fig. 76-4), leading to squamous cell carcinoma in situ (Fig. 76-5) and finally to invasive squamous cell carcinoma. Although higher grade lesions such as severe dysplasia or carcinoma in situ are thought to portend a higher risk of development of invasive carcinoma, the progression through these degrees of dysplasia is not necessarily linear, and many preinvasive lesions are reversible or do not progress to invasive carcinoma.[109,110] The 1999 and 2004 WHO classifications of preinvasive lesions detail the microscopic features defined as mild, moderate, and severe dysplasias, and carcinoma in situ. In general, these microscopic features consist of increasing epi-

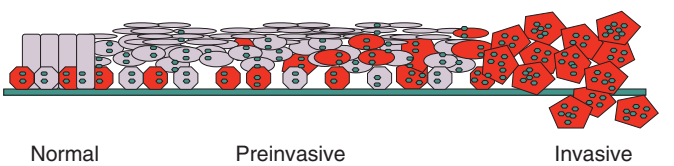

Figure 76-4 • Schematic representation of lung neoplasia showing the transition from normal mucosa to squamous metaplasia, dysplasia, and finally to invasive carcinoma. (Adapted from Massion PP: Genomic alterations in lung cancer. In Pass HI, Carbone DP, Johnson DH [eds]: Lung Cancer Principles and Practice. Philadelphia, Lippincott Williams & Wilkins, 2005, p 89).

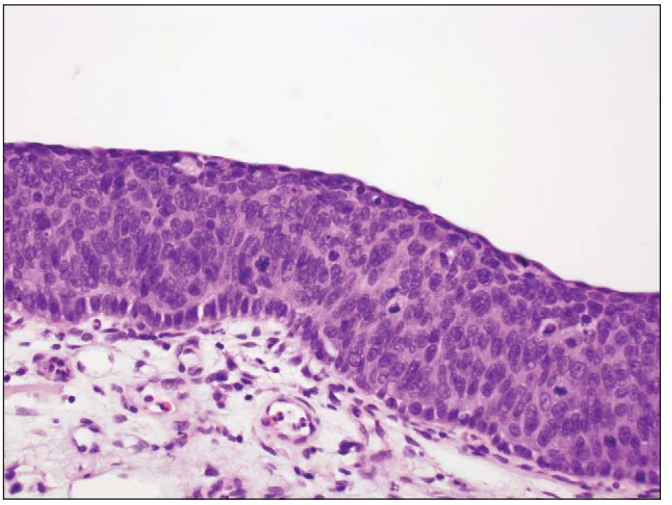

Figure 76-5 • Squamous cell carcinoma in situ. A full-thickness dysplastic squamous epithelium shows disordered cells with high nuclear-to-cytoplasmic ratio and numerous mitotic figures throughout the epithelium.

thelial thickness, cellular crowding and disorganization, and nuclear atypia.[96] Although these changes have been shown to be reproducible among expert lung pathologists, in practice, accurate grading may be hampered by specimen size, quality, and reactive lesions that may mimic dysplasia.[111,112] In general, molecular abnormalities increase with increasing morphologic dysplasia, but some low-grade or even normal epithelium can harbor many molecular abnormalities. In the future a combination of histology and molecular analysis might predict the lesions more likely to progress.[113]

Atypical Adenomatous Hyperplasia

Atypical adenomatous hyperplasia (AAH) is a small noninvasive lesion (usually less than 5 mm) consisting of atypical cells lining the alveoli in the absence of an underlying inflammatory process (Fig. 76-6). These lesions are thought be a precursor lesion to adenocarcinomas of the lung, a theory supported by the detection of molecular abnormalities within AAH similar to those found in adenocarcinomas. AAH is usually an incidental lesion, found either in lung tumor resection specimens or on radiographic imaging.[96] Because these lesions (along with bronchioloalveolar carcinoma) preserve the underlying lung architecture and alveolar spaces, they may appear as "ground-glass opacities" radiographically.[114] Although most often associated with adenocarcinomas of the lung, AAH has also been identified in conjunction with large cell carcinomas, squamous cell carcinomas, and metastatic tumors.[96]

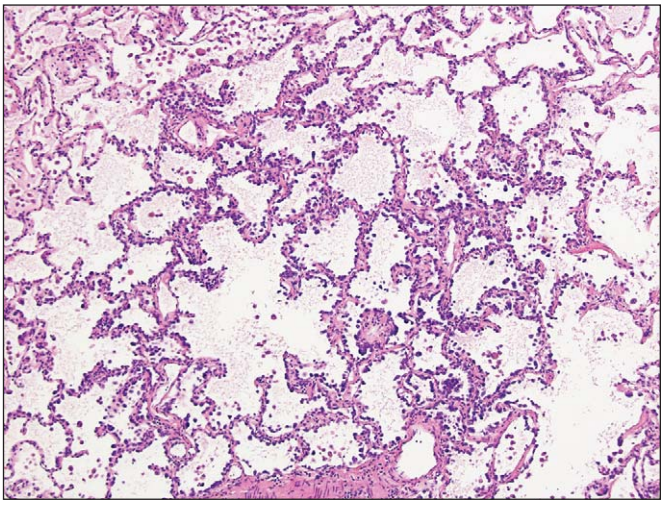

Figure 76-6 • Atypical adenomatous hyperplasia. An area of intact alveolar walls is lined by irregularly spaced enlarged atypical alveolar cells with hyperchromatic nuclei.

AAH differs from BAC in size and in degree of atypia. On a review of tumors identified through spiral CT screening studies performed by the Early Lung Cancer Action Project (ELCAP), a panel of expert lung cancer pathologists identified foci of AAH in roughly 25% of specimens (17 of 65). Six cases originally submitted as AAH (all less than 5 mm) were subsequently determined to be either BAC or invasive carcinoma by the ELCAP review panel based on the degree of atypia or presence of invasion.[115] Thus, it would appear that strict adherence to WHO criteria and additional experience will help to improve consistency in classification of these lesions.

Evaluation of AAH by cytology is difficult, because the atypia is less than that of carcinoma (mimicking many reactive lesions), and is similar to assessment of BAC, in that assessment of the architecture necessary for the diagnosis cannot be performed on a cytologic specimen.

Squamous Cell Carcinoma

Squamous cell carcinoma (Fig. 76-7), which tends to occur centrally and is highly associated with smoking history, is defined as a malignancy showing squamous differentiation. As such, the tumor cells classically contain intercellular bridges and form keratin, although these features may be difficult to identify in poorly differentiated tumors. Histologically, the most common pattern is that of infiltrating nests of malignant squamous cells (Fig. 76-7A), with central necrosis, often resulting in a central cavitation. Several important variants are described, including a papillary pattern (Fig. 76-7C) that can present as an exophytic and endobronchial growth,[116] and a basaloid variant (Fig. 76-7D) that can mimic other basaloid or neuroendocrine tumors histologically.[117] On cytologic evaluation intercellular bridges are not usually identified, but keratin can be clearly seen when present. In addition, the tumor tends to consist of sheets of cells rather than the three-dimensional groups of cells characteristic of adenocarcinomas (Fig. 76-7B).

Squamous cell carcinomas of the lung are morphologically identical to extrapulmonary squamous cell carcinomas; moreover, immunohistochemistry does not clearly distinguish primary from metastatic tumors. Differentiating a primary from metastatic squamous cell carcinoma requires clinical correlation. In rare cases in which the invasive tumor is clearly associated with a squamous cell CIS component or squamous dysplasia, a primary tumor is highly likely. The differential diagnosis of squamous cell carcinoma of the lung includes reactive processes that may result in squamous metaplasia with reactive atypia such as that observed with infection or radiation-induced injury. In these cases, clinical correlation is also essential.

Adenocarcinoma

In North America and Japan, adenocarcinoma is the most common histologic type of lung cancer. As true of other histologies, adenocarcinomas occur predominantly in smokers, although nonsmokers are more likely to develop adenocarcinoma than other lung cancer types. Adenocarcinomas tend to occur more peripherally, but can occur almost anywhere, can be multifocal, or fill an entire lobe. Radiographically they are associated with solid opacities, ground-glass opacities, or mixed patterns, generally correlating with the amount of in situ and invasive components of the tumor.[114,118] On tissue sections the diagnosis is made based on presence of glands (acini), papillary structures, bronchioloalveolar pattern, cellular mucin, or solid pattern if poorly differentiated[96] (Fig. 76-8A–C). A mixture of at least two of these patterns occurs in 80% of adenocarcinomas,[119]

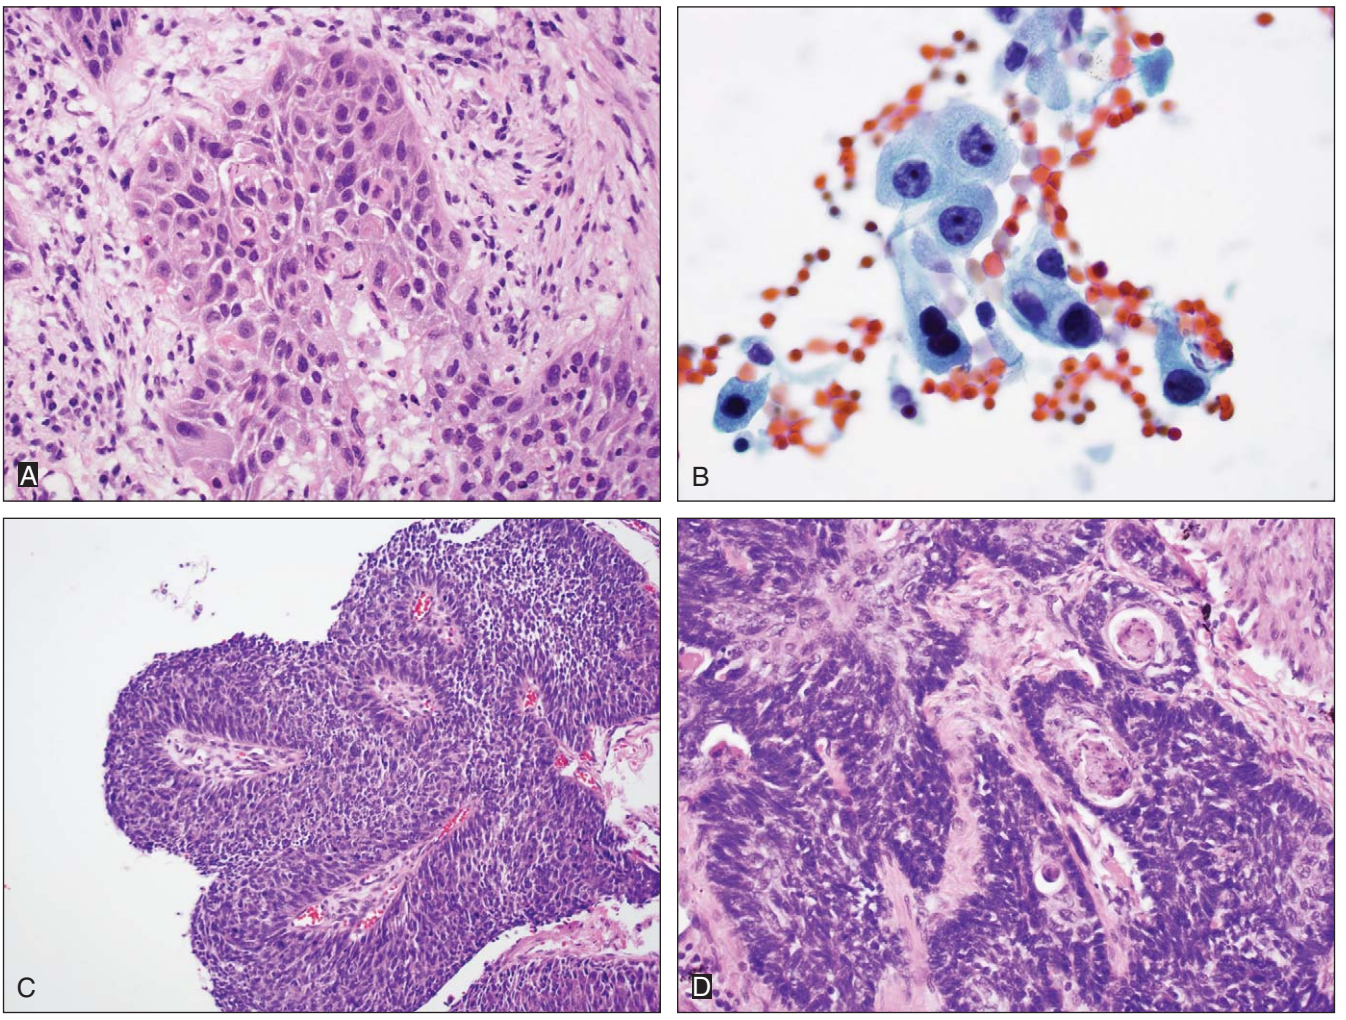

Figure 76-7 • Squamous cell carcinoma. **A,** Histologically, nests of invasive squamous cell carcinoma invade into a fibrous stroma. The tumor cells show an eosinophilic keratinized cytoplasm and intercellular bridges. **B,** Cytologically (Papanicolaou stain), there are malignant squamous cells in clusters with irregular nuclear shape and nuclear chromatin, and abundant "hard" (keratinized) cytoplasm. **C,** The papillary variant of squamous cell carcinoma is an exophytic papillary lesion composed of a malignant squamous epithelium. **D,** The basaloid variant of squamous cell carcinoma consists of invasive nests of basaloid cells demonstrating palisading of tumor nuclei at the periphery and keratinization toward the center of the nests.

and many mixed adenocarcinomas (>20%) show a focal BAC pattern.[115,120] Of these patterns, the solid and micropapillary patterns in adenocarcinomas may predict a worse prognosis.[121–127] On cytologic preparations, three-dimensional groups or glandular and papillary patterns may be identified and are diagnostic of adenocarcinoma (Fig. 76-8D). Variants of adenocarcinomas include signet ring, clear cell, mucinous, and fetal adenocarcinomas. The former three are primarily descriptive, whereas the latter is a distinct but rare tumor occurring in younger smoking patients in the fourth decade and is associated with a better prognosis.[128]

Bronchioloalveolar Carcinoma

Only those adenocarcinomas that show a pure noninvasive bronchioloalveolar pattern are diagnostic of BAC as defined by the WHO[95,96] (Fig. 76-8B). This definition arose out of studies showing that noninvasive tumors less than 3 cm resulted in a 100% 5-year patient survival;[129] in addition, tumors with limited fibrosis, smaller size, and limited invasion have a better prognosis.[129–132] Minimally invasive tumors, though not defined as BAC in the strictest sense, may nonetheless experience an excellent prognosis.[114] BAC is classified as mucinous, nonmucinous (most common), or mixed. Mucinous BACs are more likely to present as multifocal tumors or a lobar consolidation[96] and to show molecular and immunohistochemical features not seen in the nonmucinous type.[133,134]

Cytologically, bronchioloalveolar patterns may be suggested,[135] (Fig. 76-8E), but BAC cannot be definitively diagnosed without evaluation of the tissue architecture necessary to rule out an invasive component. The same is true for small biopsies in which a bronchioloalveolar pattern is seen. Unless the entire lesion can be evaluated for invasion, the diagnosis can only be interpreted as adenocarcinoma with BAC pattern. Because this more strict diagnosis of BAC is fairly recent,[95] pathologists are still refining their interpretation of BAC pattern lesions. Many tumors clinically consistent with BAC may contain areas of microinvasion and subtle papillary patterns that may affect prognosis.[115,136]

The differential diagnosis of adenocarcinoma is broad and includes not only metastatic adenocarcinomas from other sites, but similar-appearing tumors such as mesothelioma. Clinical information including location of the tumor or tumors and history of prior malignancy is the most helpful in differentiating primary from metastatic tumor, but immunohistochemical stains may help narrow the differential

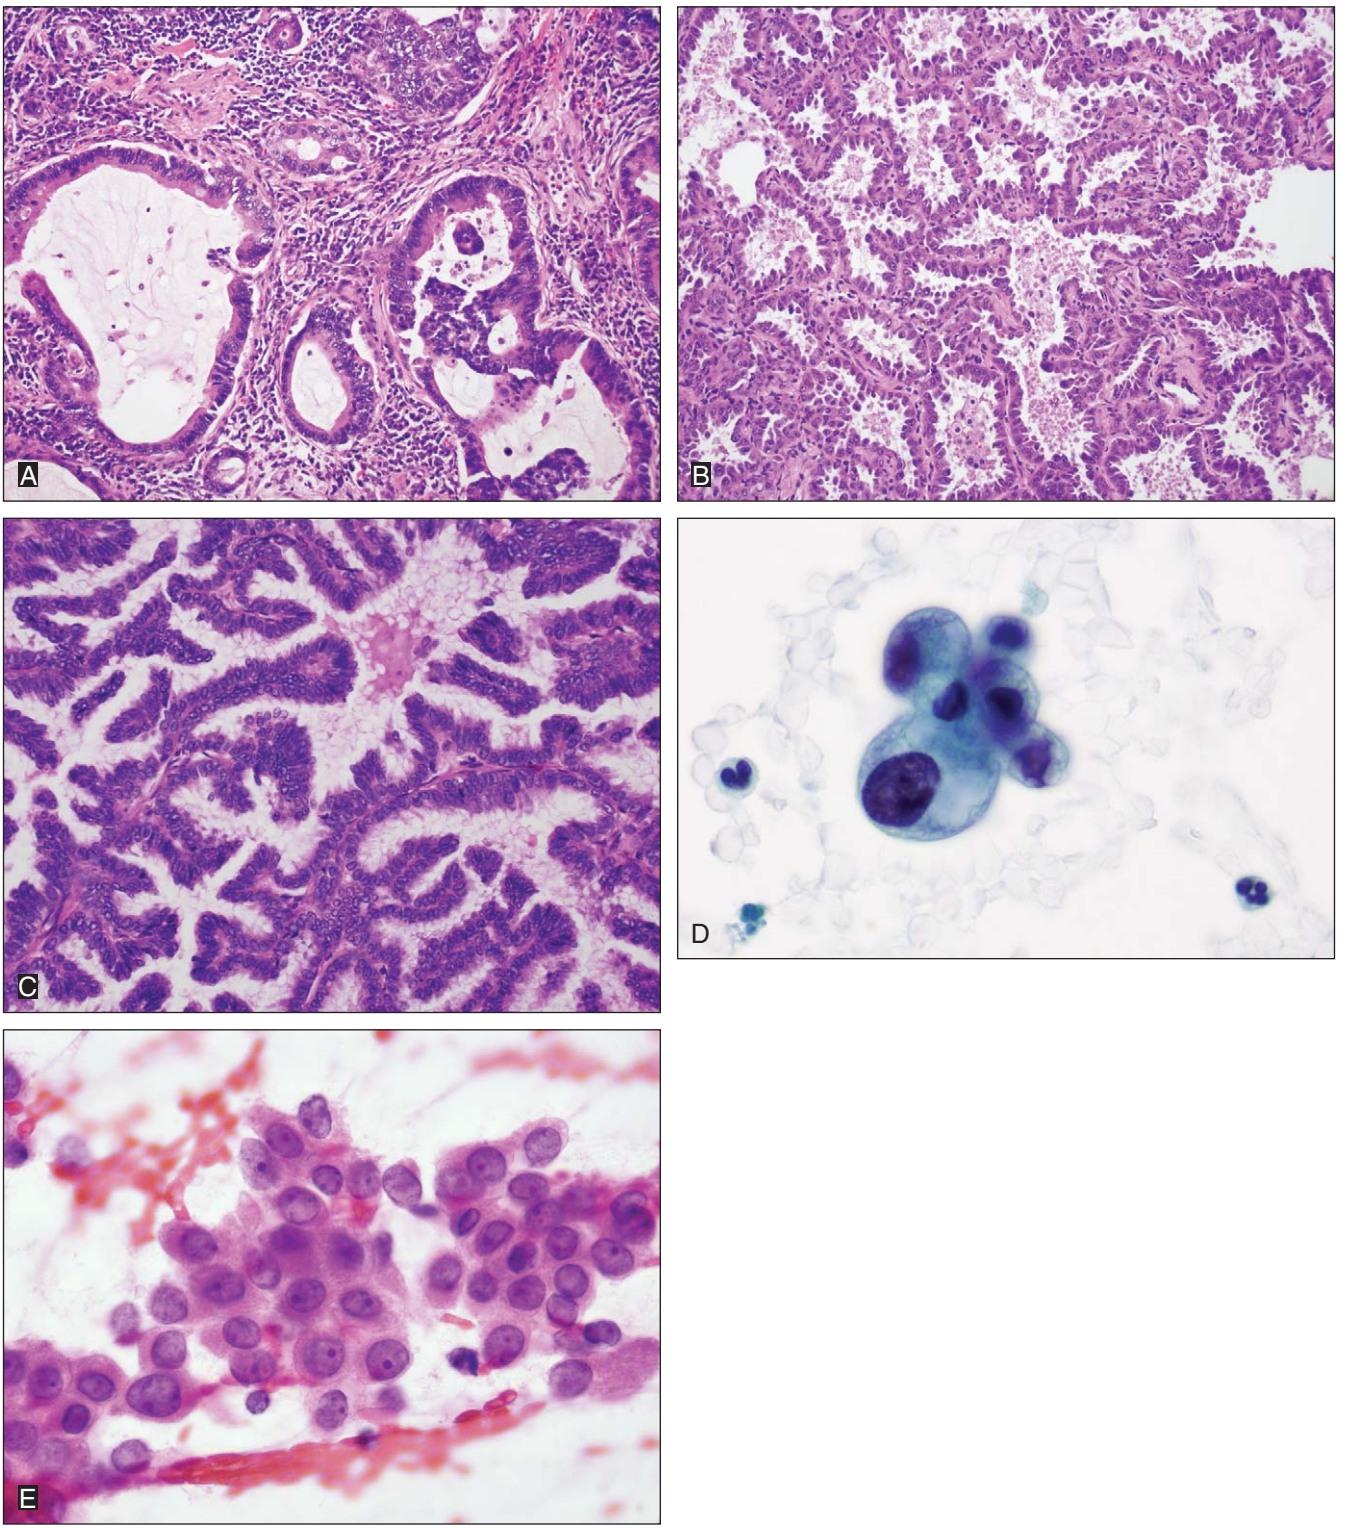

Figure 76-8 • Various patterns of adenocarcinoma. **A,** The acinar (glandular) pattern shows malignant glandular structures invading a fibrous stroma. **B,** The bronchioloalveolar pattern can be pure, as seen in bronchioloalveolar carcinoma (BAC), or mixed with other patterns of adenocarcinoma. It consists of malignant epithelial cells lining alveolar walls without invasion. **C,** Papillary adenocarcinoma shows papillary structures with fibrovascular cores and loss of the underlying alveolar architecture. **D,** Adenocarcinoma by cytology (Papanicolaou stain) shows three-dimensional clusters of malignant cells with vacuolated cytoplasm. **E,** By cytology (H&E stain), the diagnosis of BAC is not definitive but may be suggested by flattened clusters of bland tumor cells with nuclear grooves or inclusions.

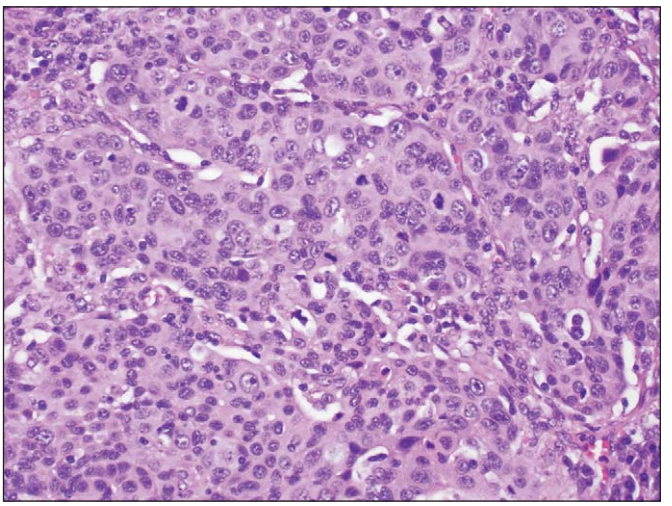

Figure 76-9 • Large cell carcinoma consists of sheets of undifferentiated cells without glandular or squamous differentiation. Prominent nucleoli are seen.

diagnosis when a metastatic lesion is suspected (see the immunohistochemistry discussion that follows).

Large Cell Carcinoma

Large cell carcinomas compose fewer than 10% of lung carcinomas, tend to occur peripherally, and are defined as poorly differentiated carcinomas of the lung composed of larger malignant cells without evidence of squamous, glandular differentiation, or features of small cell carcinoma by light microscopy (Fig. 76-9).[96] These tumors usually consist of sheets of large malignant cells, often with associated necrosis. Cytologically, the tumor is also arranged in syncytial groups and single cells, again without evidence of squamous, glandular, papillary, or features of small cell carcinoma. By electron microscopy, large cell carcinoma may show some evidence of glandular, squamous, or neuroendocrine differentiation, whereas others show none of these.[137] Variants of large cell carcinoma include basaloid carcinoma, which may present as an endobronchial lesion and may resemble a high-grade neuroendocrine tumor, and lymphoepithelioma-like carcinoma, which is similar to the same-named tumor of other sites and is associated with Epstein-Barr virus infection.

Large Cell Neuroendocrine Carcinoma

Large cell neuroendocrine carcinoma (LCNEC) is a subtype of large cell carcinoma that shows neuroendocrine differentiation by light microscopy and accounts for approximately 3% of lung cancers; it is included in the differential diagnosis of neuroendocrine lung tumors (see later discussion). LCNEC is a high-grade carcinoma showing neuroendocrine patterns (formation of rosettes, trabeculae, organoid nests, or perilobular palisading patterns), greater than 10 mitoses per 2 mm^2, and positivity with neuroendocrine markers.[96] LCNEC may be difficult to diagnose cytologically and may be difficult to differentiate from a small cell carcinoma. Cytologic features include evidence of neuroendocrine differentiation (sheets or groups of cells with peripheral palisading or rosette formation, nuclear molding, or immunohistochemical staining with neuroendocrine markers), as seen in other neuroendocrine tumors, but unlike small cell carcinoma, these tumors tend to have larger cells with prominent nucleoli.[96,138–140] LCNEC is an aggressive tumor and shares several molecular abnormalities with small cell carcinoma. The prognosis for these tumors is intermediate between other non-small cell carcinomas and small cell carcinoma.

Small Cell Carcinoma

Small cell carcinoma is a poorly differentiated neuroendocrine tumor that tends to occur centrally and is highly associated with smoking. Incidence rates of small cell carcinoma are higher among men than women,[16] but a higher percentage of lung cancers are of small cell origin among women than men.[141] Small cell carcinoma consists of smaller but obviously malignant cells with little cytoplasm, characteristic finely granular ("salt and pepper") chromatin without prominent nucleoli, and greater than 10 mitoses per 2 mm^2 (Fig. 76-10A).[96] The tumor cells may be arranged in sheets or may show neuroendocrine patterns such as rosettes, trabeculae, or peripheral palisading of cells at the periphery of nests. Often there is necrosis and crushing of tumor cells. The cells are defined as "small," meaning fewer than 21 μm in diameter; however, variation in size is common in these tumors, and the nuclear features are the more characteristic finding,[142] including characteristic "molding" of tumor nuclei.[143,144] The characteristic cytologic features are usually easily identified in well-

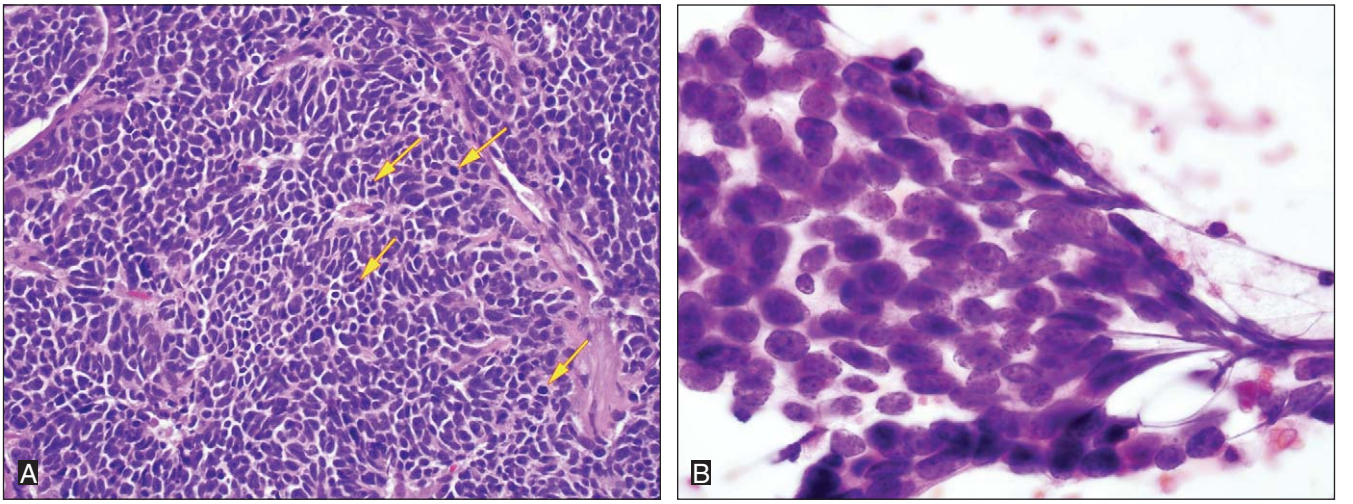

Figure 76-10 • Small cell carcinoma. **A,** A resected small cell carcinoma shows well-preserved tumor cells with little cytoplasm, nuclear molding, and numerous mitotic figures (*arrows*). Note the lack of nucleoli. **B,** By cytology (H&E stain) the nuclear features ("salt and pepper" chromatin pattern), scant cytoplasm, nuclear molding, and crushing of cells in this small cell carcinoma are also evident.

preserved cytologic specimens, but they may be more difficult to differentiate from other round blue cell tumors on ThinPrep cytology[144] or on less well-preserved specimens or small specimens (Fig. 76-10B).[100] As with other histologic types of lung carcinoma, small cell carcinoma may occur alone or combined with other tumors. Combined small cell with LCNEC, large cell carcinoma, adenocarcinoma, and squamous cell carcinoma have all been well documented. The differential diagnosis of small cell carcinoma includes poorly differentiated non-small cell carcinomas and neuroendocrine carcinomas, especially poorly differentiated squamous cell carcinoma and LCNEC, as well as nonepithelial tumors such as lymphoma, small round blue cell tumors, and some sarcomas (e.g., synovial sarcoma).

Typical Carcinoid Tumor

Typical carcinoid tumor is a low-grade neuroendocrine tumor showing tumor cells arranged in organoid nests, trabeculae, or spindled patterns characteristic of neuroendocrine differentiation, but is differentiated from other tumors by its bland uniform cells, lack of necrosis, and no significant mitotic activity (fewer than 2 mitoses per 2 mm^2). Typical carcinoid tumor occurs in nonsmokers, most often as an endobronchial lesion, but can occur more peripherally. Cytologic specimens show uniform low-grade cells with finely stippled ("salt and pepper") chromatin. Although these tumors are known for their excellent prognosis, as many as 10% to 15% can have metastases at diagnosis.[96] A *carcinoid tumorlet* is defined as a carcinoid tumor measuring less than 5 mm. Although tumorlets are usually an incidental finding, tumorlets can be associated with other tumorlets, carcinoid tumors, or neuroendocrine hyperplasia of the bronchial epithelium.[96]

Atypical Carcinoid Tumor

Atypical carcinoid tumor shows neuroendocrine morphology similar to the typical carcinoids, but is a slightly more aggressive tumor, with mitoses in the range of 2 to 10 per 2 mm^2 and higher risk of metastasis (as high as 50% lymph node metastasis at presentation).[96] Cytologically, atypical carcinoids have a similar appearance to typical carcinoids, although tumor cells may show more atypia and nuclear enlargement.[96]

Differential Diagnosis of Neuroendocrine Tumors of the Lung

Neuroendocrine tumors of the lung include a wide variety of lesions from the very bland to the most aggressive pulmonary neoplasms. The four main neuroendocrine tumors of the lung are carcinoid tumor, atypical carcinoid tumor, LCNEC (a type of large cell carcinoma), and small cell carcinoma (Fig. 76-11). In general it is helpful to think of these tumors according to clinical or behavioral characteristics. Carcinoid tumor and atypical carcinoid tumors are less associated with smoking history, tend to occur in younger patients, and are less aggressive, whereas small cell carcinoma and large cell neuroendocrine carcinoma occur in smokers and behave much more aggressively. Differentiating these tumors from one another histologically is usually straightforward based on morphologic features. In some cases, however, there can be overlap in the morphologic features. The WHO classification of these tumors emphasizes mitotic count in differentiating these tumors, and in fact, these criteria are used to define these tumors (Table 76-2). This approach is usually straightforward unless the tissue available is small or in the case of a cytologic specimen. Immunohistochemistry may be performed to support or verify the neuroendocrine nature of the tumor and thus differentiate neuroendocrine tumors from other non-small cell carcinomas.[138]

Immunohistochemistry

The diagnosis of lung cancer most often rests on the morphologic or cytologic features correlated with clinical and radiographic findings. Immunohistochemistry may be used to verify neuroendocrine differentiation within a tumor, or in differentiating primary from metastatic tumor. A summary of commonly used immunohistochemical stains is shown in Table 76-3.[96,117,119,134,138,145–151]

Neuroendocrine markers include neuron-specific enolase, CD56 or neural cell adhesion molecule, synaptophysin, chromogranin, and Leu7. Most often a combination of these stains (e.g., CD56, synaptophysin, and chromogranin) is used to establish a diagnosis.[119] These markers support neuroendocrine differentiation but do not distinguish between specific types of neuroendocrine tumors.

Immunohistochemistry is also helpful in distinguishing primary lung tumors from malignancies metastatic to the lung. This is especially true for distinguishing primary lung adenocarcinomas and metastatic adenocarcinomas. Thyroid transcription factor-1 (TTF-1), identified in tumors of thyroid and pulmonary origin, tests positive in over 70% of pulmonary adenocarcinomas.[151] When present, TTF-1 is a reliable indicator of a primary lung cancer provided a thyroid primary has been excluded. A negative test for TTF-1 does not exclude the possibility of a lung primary, however. Interestingly, TTF-1 also tests positive in neuroendocrine tumors of pulmonary and extrapulmonary origin.[138,146,152,153] Thus, TTF-1 is often used in combination with other immunohistochemical stains to differentiate among various diagnostic possibilities. Individually, TTF-1 and many neuroendocrine markers can show some immunohistochemical positivity in both small cell and non-small cell carcinomas, and have not been shown to be prognostically significant.[154] Cytokeratins 7 and 20, used in combination, also assist in categorizing certain tumors. These stains are not specific for a particular site of origin but can narrow the differential diagnosis.

Although mesothelioma can be easily identified ultrastructurally, it has historically been difficult to differentiate from adenocarcinoma through morphology and immunohistochemical staining. Several markers in the last few years have proven to be more helpful, including CK5/6, calretinin, and Wilms' tumor gene-1,[96] all of which show positivity in mesothelioma.

Molecular Alterations Associated with Lung Cancer Subtypes

The molecular alterations found in lung cancer are varied and not entirely specific to histologic subtype. However, there are molecular abnormalities that are more commonly associated with certain histologies. Examples of a few of the more commonly identified changes are summarized (Table 76-4).[96,148,155–158] Thus far these findings have been of limited value in diagnosis and classification of lung cancer type, but future uses may include lung cancer screening, identifying markers for chemoprevention, and predicting prognosis.[155,157,159] One of the more clinically significant molecular discoveries in the last few years is mutations of the EGFR gene, which were identified in adenocarcinomas of patients showing a response to treatment with TKIs.[55,57] Response to treatment is often associated with the presence of the mutation, and *EGFR* mutations are associated with female gender, nonsmoking status, and adenocarcinoma histology.[57,62] Interestingly, some responders without this mutation have also shown a response.[160] Thus far *EGFR* mutations have been identified in adenocarcinomas of the lung, most often of mixed type with a focal bronchioloalveolar pattern.[161–167] *EGFR* mutations have also been found in AAH but are rare.[167] There is some suggestion that *EGFR* gene amplification by fluorescence in situ hybridization (FISH) or immunohistochemistry may be predictive of response,[168,169] and some agreement between presence of mutation and FISH copy number,[169] and FISH positivity with overexpression by immunohistochemistry.[170,171] However, further study will be needed to determine what

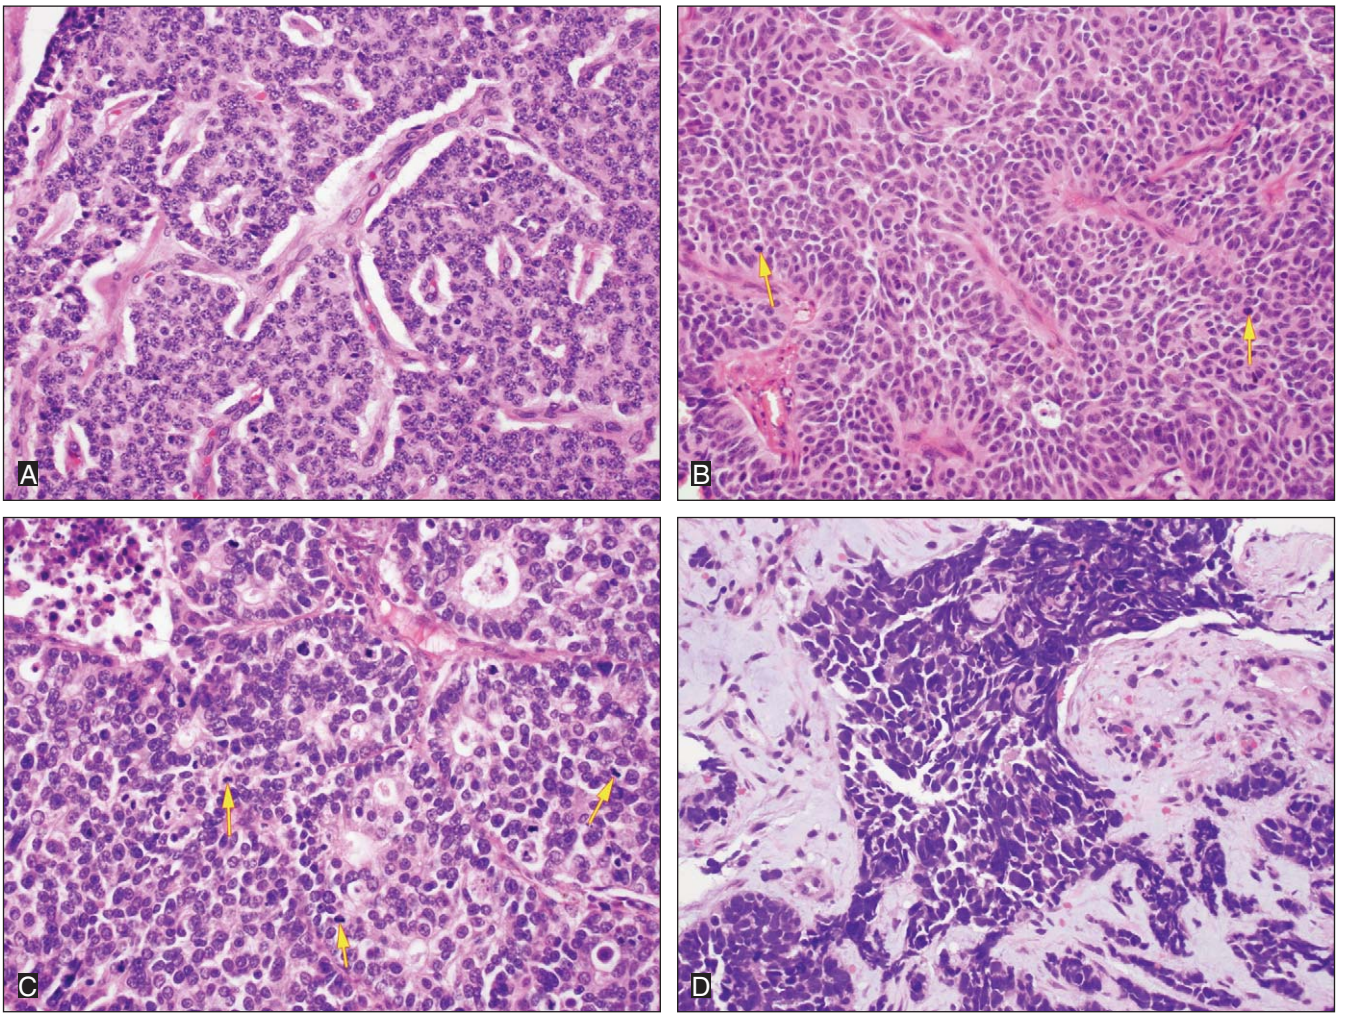

Figure 76-11 • Neuroendocrine tumors of the lung. **A,** A typical carcinoid tumor shows a subtle organoid and trabecular pattern of growth. The tumor cells are uniform with round nuclei showing a neuroendocrine ("salt and pepper") chromatin pattern. No mitoses are identified. **B,** An atypical carcinoid tumor is arranged in sheets with focal palisading of tumor cells, relatively bland neuroendocrine nuclei, and only a few scattered mitoses (*arrows*). **C,** A large cell neuroendocrine carcinoma is arranged in organoid nests and rosettes. Tumor cell nucleoli, necrosis, and abundant mitoses (*arrows*) are readily identified. **D,** A small cell carcinoma shows prominent molding and crushing on a transbronchial biopsy.

Table 76-2 General Histologic Features of Neuroendocrine Tumors

Diagnosis	Morphology	Mitotic Count (per mm^2)
Typical carcinoid tumor	Generally bland neuroendocrine morphology	<2
Atypical carcinoid tumor	Generally bland neuroendocrine morphology with or without focal necrosis	2–10
Large cell neuroendocrine carcinoma	High-grade neuroendocrine carcinoma—larger cells with nucleoli	>10
Small cell carcinoma	High-grade neuroendocrine carcinoma—smaller cells and few nucleoli	>10

Table 76-3 Common Immunohistochemical Markers Used in the Diagnosis of Lung Tumors

Diagnosis	Positive Immunohistochemical Markers
Squamous cell carcinoma	Cytokeratin (CK) cocktail (e.g., AE1/AE3)
	CK5/6
	CK7 rare
Adenocarcinoma including bronchioloalveolar carcinoma, nonmucinous	CK cocktail (e.g. AE1/AE3)
	CK7
	TTF-1
	Neuroendocrine markers rare, e.g., CD56, NSE
Bronchioloalveolar carcinoma, mucinous	CK cocktail (e.g., AE1/AE3)
	CK7
	CK20
	TTF-1 rare
Large cell carcinoma	CK
	TTF-1 rare
	Neuroendocrine markers rare (e.g., CD56, NSE)
Large cell neuroendocrine carcinoma	CK cocktail (e.g., AE1/AE3)
	TTF-1
	CD56
	Chromogranin
	Synaptophysin
Small cell carcinoma	CK cocktail (tends to be patchy)
	TTF-1
	CD56
	Chromogranin
	Synaptophysin
Carcinoid tumor	CK cocktail (e.g., AE1/AE3)
	TTF-1 (weaker than high-grade neuroendocrine tumors)
	CD56
	Chromogranin
	Synaptophysin
Atypical carcinoid tumor	CK cocktail (tends to be patchy)
	TTF-1
	CD56
	Chromogranin
	Synaptophysin
Common differential diagnoses	
Colonic adenocarcinoma	$CK20^+/CK7^-$
Breast, biliary, upper GI adenocarcinoma	$CK7^+/CK20^-$
Urothelial carcinoma	$CK7^+/CK20^+$
Prostatic adenocarcinoma	$CK7^-/CK20^-$
Mesothelioma	Calretinin, WT-1
Malignant melanoma	S-100, HMB-45, Melan-A

GI, gastrointestinal.

Table 76-4 Examples of Common Molecular Alterations in Lung Tumors

Diagnosis	Common Molecular Alterations
Squamous preneoplasia	LOH: 3p, 9p21, 8p21–p23, aneuploidy, methylation
Atypical adenomatous hyperplasia	LOH: 3p, 9p
	Aneuploidy
	K-*ras* codon 12 mutation
Adenocarcinoma	*TP53* mutation
	CDKN2A mutation/inactivation
	K-*ras* (42%) mutation; smokers more common
	EGFR overexpression (40%)
	EGFR mutation
	Her2/neu, COX-2 overexpression
Squamous cell carcinoma	*TP53* mutation
	CDKN2A inactivation
	Allelic loss 3p
	EGFR overexpression (80%)
Large cell carcinoma	K-*ras*, *TP53*, loss *CDKN2A*
Large cell neuroendocrine carcinoma	p53
	BCL-2 overexpression
	Rb mutation
	3p21, FHIT, 3p22–p24, 5q21, 9p21
Small cell carcinoma	Rb mutation (≥80%)
	TP53 mutation (50% to 80%)
	BCL-2 expression
	3p21, FHIT, 3p22–p24, 5q21, 9p21

EGFR, epidermal growth factor receptor; LOH, loss of heterozygosity; Rb, retinoblastoma.

combination of testing will be predictive of response to TKIs or prognosis.[172,173]

EARLY DETECTION AND SCREENING

Early detection is a process that involves screening tests, surveillance, and diagnosis and also implies early treatment,[174] whereas screening is defined as the systematic testing of asymptomatic individuals for preclinical disease.[175] The purpose of screening is to prevent or delay the development of advanced disease in patients with preclinical disease through early detection and treatment. Screening presumes that a test or series of tests will identify asymptomatic persons at risk for a specific disease and that a positive result leads to further testing to establish definitively the presence or absence of disease.[175] The monitoring of these subjects (surveillance) intends to detect the disease early and to treat it early. Under ideal circumstances, early intervention should change the course of the disease once the diagnosis is established, resulting in a decrease in disease-related mortality (the number of disease-specific deaths relative to the total number of persons evaluated). In addition, screening should apply to large populations that would benefit from early detection (therefore with chance of survival greater than 5 years). Finally, screening should cause no harm and be cost effective.[176]

Previous lung cancer screening efforts using periodic chest radiographs coupled with regular assessment of sputum cytology failed to

demonstrate a decrease in lung cancer-related mortality.[177–180] Details of these trials have been extensively reviewed elsewhere.[181] Ironically, more lung cancers were diagnosed in the screening arms of these trials. The lung cancers identified in the screened population were often found at very early stages, allowing more patients in the screened arms to go to definitive surgery. Nonetheless, there was not an improvement in *lung cancer-related mortality*, which is considered a requirement to validate potential screening methods.[181] Several hypotheses have been advanced to explain the findings including flawed trial design, lead-time bias, length time bias, and overdiagnosis bias.[182,183] Briefly, these biases can be defined as follows: *lead-time bias* implies that earlier detection could result in longer survival from the time of diagnosis even if death is not delayed. *Length time bias* occurs when screening examination detects slow-growing cancers. In other words, the slower the growth of the neoplasm, the longer it is present without symptoms and the greater the likelihood of detection. *Overdiagnosis* bias refers to the phenomenon of detecting a lung cancer that would otherwise have remained subclinical before death from other causes. Overdiagnosis is of particular concern in lung cancer screening, because newer screening modalities can identify small nodules of unknown clinical significance. Mayo Clinic investigators found a persistence of excess lung cancer cases in the intervention arm of their original screening after an additional 16 years of follow-up,[183] providing continued support for overdiagnosis in lung cancer screening.

Thus far there is no screening procedure recommended for individuals "at risk" for lung cancer. In 2004 the U.S. Preventive Services Task Force concluded that there is insufficient evidence to recommend screening for lung cancer in asymptomatic individuals at risk for lung cancer (http://www.ahrq.gov/clinic/uspstf/uspslung.htm). Although it is assumed that the higher the risk of cancer the more useful the surveillance program, the field also lacks clear guidelines for the surveillance of "high-risk" individuals. Perhaps the greatest challenge is defining the optimal population to be screened—the population that could best benefit from lung cancer screening.[184] Entry criteria to lung cancer screening trials are still debated and no one has ever shown efficacy of surveillance program for lung cancer. Moreover, the challenges of large population screening programs are considerable and include the potential for diagnostic errors (i.e., false positives) related to pulmonary scarring from smoking or prior infection, areas of inflammation, or other noncancerous conditions as well as the anxiety experienced by the participant, the potential for unnecessary biopsy, surgery or both as well as repeated radiation exposure. Although the amount of radiation exposure engendered by a low-dose spiral CT scan is relatively modest (roughly equal to 10 chest radiographs or one tenth that experienced with a regular chest CT scan), it is not an insignificant issue.[185,186]

High-Risk Population, a Susceptible Subgroup

As noted, a challenging problem in screening for lung cancer is the definition of a "high-risk" population—the population that could best benefit from lung cancer screening.[184] Individuals "at risk" include current and former smokers, those with specific various occupational exposures (e.g., asbestos; see section on Epidemiology), the presence of airflow obstruction, a family history of lung cancer, older individuals, and those with a prior history of a cancer of the aerodigestive tract. Individuals who smoke bathe their entire aerodigestive tract with multiple carcinogens, and it is therefore not surprising that this population experiences a high rate of second primary tumors, estimated to be between 1% and 4% per patient per year.[187–189] However, mere recognition of these features is not sufficient to identify "high-risk" individuals. For example, although smoking is an obvious risk for lung cancer—the cumulative risk of dying from lung cancer for a lifelong smoker is estimated to be approximately 16% in men and approximately 10% in women[31]—the risk of developing lung cancer varies greatly among individual current and former smokers.[190] For example, in the Carotene and Retinol Efficacy Trial, a large, randomized trial of lung cancer prevention, the 10-year cancer risk among current and former smokers ranged from less than 1% to 15%.[190] An example of an individual with a relatively low risk of developing lung cancer would be a 51-year-old woman who smoked one pack per day for 28 years and quit 9 years earlier. By contrast, a 68-year-old man who had smoked two packs per day for 50 years and continued to smoke might have a 15% risk of lung cancer.[190] Both of these individuals would be potentially eligible for screening, and yet the "payoff" would be quite different. This suggests that an accurate risk prediction model may facilitate greatly the admission of subjects in screening (or chemoprevention) trials.[190]

Cytologic atypia in sputum samples reflect the abnormalities that develop in the bronchial epithelium. Moreover, the presence of cytologic atypia has been shown to predict lung cancer risk.[191] The presence of moderate dysplasia or worse cytologic atypia is associated with a increased risk of developing lung cancer in a cohort of heavy smokers with airflow obstruction (adjusted hazards ratio of 2.8).[192] This translates into a cumulative lung cancer incidence of 10% at 3 years and 20% at 6 years. Given the limitations of cytologic evaluation of sputum samples, however, the study of molecular abnormalities in the sputum (e.g., methylation patterns of specific genes involved in lung cancer progression, cytogenetic alterations) may strengthen the assessment of risk for lung cancer in this population.

Molecular epidemiology may be used to identify patients at risk for developing lung cancer through the identification of specific genes, single-nucleotide polymorphisms, or other genetic traits associated with increased susceptibility for lung cancer.[193] Although many genotypes show increased risk (relatively low odds ratios) with lung cancer (e.g., *CYP2A6*, thymidylate synthase, *GSTM1*, *XPA*), their large number and low penetrance make targeted intervention extremely challenging. Assessing genetic susceptibility for lung cancer may allow the identification of susceptible subgroups most likely to represent ideal candidates for early detection. Although autosomal dominant genes have not been found in association with family history of lung cancer, there is epidemiologic evidence demonstrating a 2.5 times increased risk in patients with a family history of lung cancer after controlling for smoking.[194] A recent genomic locus on chromosome 6q23–q25 was identified as a locus of susceptibility with a maximum heterogeneity LOD score of 2.79, 3.47, and 4.26 for families with three, four, or five or more affected individuals.[51] Further complicating the picture is the role of the environment in modifying these specific genes and the interaction of genes between each other and evidence to support a genetic predisposition to smoking addiction.[195,196] If markers of these genetic predispositions can be firmly established, intensive intervention to alter risk factors in these selected populations may alter their clinical outcome.

Imaging Approach

The last decade has witnessed a marked improvement in technology allowing for faster, higher resolution imaging of the chest. The CT scanner first became available in the 1970s but was impractical for screening because of its slow speed and radiation exposure. In the mid-1990s low-dose scanners capable of imaging the chest in less than 15 sec using radiation doses equivalent to 10 radiographs became available, opening the door to their potential use for screening.[197] Moreover, new bronchoscopic methods also demonstrate promise for the detection of preinvasive lesions. Other imaging modalities such as PET scan are able to provide metabolic information on lesions and can be combined with CT scan to give detailed resolution.

Low-Dose Spiral Computed Tomography Scan

In recent years there has been a substantial increase in the use of spiral CT scans to screen for lung cancers in former and current smokers.[174,181] Spiral CT screening allows for a rapid and comprehensive evaluation of the lungs and is attractive because of its potential increased sensitivity, low radiation exposure, and potential cost effec-

Table 76-5 Results of Prevalence and Incidence Screens in Computed Tomography (CT) Screening Trials

Study	Year	No. of Patients Screened	No. of Abnormal CT Scans	Cancers Detected	Stage I Lesions
PREVALENCE CT					
Henschke et al[199]	1999	1,000	233	27 (2.7%)	81%
Sone et al[209]	2001	5,483	676	22 (0.4%)	100%
Swensen et al[210]	2002	1,520	782	22 (1.4%)	59%
Sobue et al[208]	2002	1,611	186	14 (0.9%)	77%
Pastorino et al[200]	2003	1,035	199	11 (1.1%)	55%
Henschke et al[205]	2006	31,567	4186	410 (1.3%)	85%
INCIDENCE CT					
Henschke et al[207]	2001	1,184	63	7 (0.6%)	85%
Sone et al[209]	2001	8,303	518	34 (0.4%)	100%
Swensen et al[210]	2002	1,464	191	3 (0.2%)	0%
Sobue et al[208]	2002	7,891	721	22 (0.3%)	82%
Pastorino et al[200]	2003	996	99	11 (1.1%)	100%
Henschke et al[205]	2006	27,456	1460	74 (0.3%)	86%

tiveness.[174] Many pilot studies using spiral CT scans to screen for lung cancers have shown that this technology can identify a higher percentage of early-stage lung cancer than can conventional imaging studies.[198–200] These results are summarized in Table 76-5 and discussed in detail elsewhere.[174,201,202] Lung cancer prevalence rates range between 0.4% and 2.7%, depending on the population screened. In general, these prevalence rates are significantly higher than that reported using conventional imaging studies. The mean diameter of screened detected cancers ranges between 14 and 21 mm. Incidence rates based on detection of new malignancies at annual repeat screening range from 0.07% to 1.1%.[174,203] Notably, as many as 85% of CT-screened detected lung cancers are clinical stage I lesions. By contrast, only 15% of lung cancers diagnosed through routine clinical care are found to be stage I.[204] Because stage I lung cancer is the most curable form of this disease, a high frequency of detection of stage I tumors is considered a necessary (though not sufficient) indication of a favorable screening outcome.[174] International Early Lung Cancer Action Program (IELCAP) investigators recently reported a 92% 10-year survival rate among screened detected clinical stage I lung cancer patients who underwent surgical resection within 1 month after diagnosis.[205] In a separate report, IELCAP investigators reported that the cancers identified by CT screening met standard criteria for full-fledged aggressive lung cancer.[115] Although these data are intriguing and encouraging, long-term follow-up of these patients will be very important to exclude lead-time bias (simply diagnosing the cancer earlier, but not altering its outcome) as a confounder for an improved survival and a reduced disease-related mortality.

A major challenge confronting advocates of CT screening is the high false-positive rate.[206] On initial screening of at-risk populations, false-positive rates range between 10% and 20% but can be as high as 50%.[207–210] Positive predictive values range from 2.8% to 11.6%.[207–210] False positives can have a substantial impact on patients through the expense and risk of unneeded further evaluation and emotional stress. False-positive rates and positive predictive values are somewhat improved in annual follow-up CT scans, but there is still significant room for improvement. Based on extant data it seems that nodules smaller than 5 mm are unlikely to be cancerous and those 5 to 10 mm in diameter (25% to 40% of noncalcified nodules detected) are of uncertain significance.[211] The management of these patients usually consists of repetitive CT scans over time to see if the nodules grow, attempted FNAs, or surgical resection. PET has limited usefulness in detection of lesions smaller than 1 cm and has proved to be of limited value in adenocarcinoma, particularly of bronchioloalveolar subtype.[212] Each of these is costly, and some have significant morbidity. The impact of waiting to assess nodule growth on patient outcome is also not clear but can only decrease curability. Even for patients with disease that is highly suspicious for lung cancer on clinical grounds, there is a 10% to 20% incidence of "futile thoracotomies" wherein the suspicious lesion is found to be benign, and thus, the patient unnecessarily incurred the morbidity and potential mortality of a thoracotomy.[213–215] Eliminating unnecessary surgery should be one of our priorities, although this may not be feasible without the development of other strategies of early detection.

To address many of these ongoing issues, the NCI initiated the National Lung Cancer Screening Trial (NLST). The NLST is a prospective comparison of spiral CT and standard chest radiograph in 50,000 current or ex-smokers between the ages of 55 and 74 years and is designed to determine the best strategy to reduce lung cancer-related mortality. The NCI estimates that the trial may produce results that could inform policy decisions as early as 2010 (http://www.nci.nih.gov/NLST). A similar study is continuing in Europe comparing CT scanning with standard of care among 20,000 subjects with history of heavy smoking.

Finally, CT scanning has also shown promise in the detection of some preinvasive lesions. High-resolution CT has proven to be sensitive enough to detect ground-glass opacities, some of which may represent inflammatory lesions, BAC, adenocarcinomas, or AAH. AAH is a presumed precursor lesion to adenocarcinoma.[216–219] Because adenocarcinoma is now the most common histologic type of lung cancer in the United States, there is some hope that CT may be able to improve survival for these patients by detecting a precursor lesion before its transformation to invasive carcinoma. Chest CT scanning, however, is not yet sensitive enough to detect preinvasive epithelial lesions of the bronchial tree with squamous differentiation, probable precursors of squamous carcinoma of the lung.

Positron Emission Tomography Scan

Many CT screening protocols now use PET scan as a method of reducing this high false-positive rate. PET scanning attempts to identify malignancy based on glucose metabolism by measuring the

uptake of [^{18}F]fluorodeoxyglucose (FDG). Lung cancers will preferentially take up FDG and appear as a "hot spot". Thus far PET has been used mostly for staging and detection of metastases in lung cancer[220,221] and in the diagnosis of nodules larger than 15 mm in diameter.[200,222] In combination with another imaging modality, PET may provide information about the metabolic state of lung nodules. Combined FDG PET-CT scan has been shown to improve the accuracy of staging in lung cancer compared with visual correlation of PET and CT or either study alone.[223] The added information gained from PET and combined PET-CT may help reduce the high false-positive rates seen in trials using CT alone. A trial of low-dose CT used in combination with PET scan of 1035 patients resulted in only 6 false positives, defined as a surgical biopsy of a benign nodule, out of 27 surgical biopsies of suspicious nodules.[200] There are important limitations to this study, however. First, lung nodules of 5 mm or less in size were followed, with repeat CT in 1 year, and no other intervention. Second, PET scanning was only performed on larger nodules (7 mm or larger). Typically, PET scan has not performed well in the identification of small nodules (<15 mm), so its usefulness in intermediate lesions remains in question, in particular in areas with high prevalence of pulmonary fungal infections.[224] There is no evidence of a survival benefit using PET scan as part of a screening protocol.

Other Imaging Techniques

Fluorescence endoscopy uses differences in the autofluorescence characteristics of normal and neoplastic epithelium to localize lesions. Fluorescence bronchoscopy has been shown to be more sensitive than white-light bronchoscopy in the detection of preneoplastic lesions in many studies, including a randomized trial.[225–228] The randomized trial demonstrated that the use of the laser-induced fluorescence endoscopy procedure resulted in a 46.9% absolute increase in the sensitivity of detecting moderate dysplasia in high-risk patients when compared with white light bronchoscopy, although specificity was worse.[225] Fluorescence bronchoscopy has not been proven as a validated method of early detection of lung cancer, but it is a very important research tool.

New imaging techniques are currently being developed to help improve not only the resolution of current imaging techniques but also to image lesions based on biologic activity. Both magnetic resonance and gamma camera techniques are being tested as molecular imaging tools.[229–231] Near-infrared Raman spectroscopy,[232] optical coherent tomography,[233] and confocal microscopy use optical differences within tissue to allow imaging of individual cell nuclei. This technology is being adapted for use during endoscopic examinations and may be able to provide real-time histologic evaluation of bronchial mucosa.

Blood Biomarkers for Lung Cancer

Although various serum biomarkers have been investigated in lung cancer, none has proved useful in general clinical practice, mainly because of the lack of sufficient sensitivity and specificity. For example, cytokeratin fragment antigen 21.1 (Cyfra-21.1), a marker of cytokeratin,[234–236] carcinoembryonic antigen,[235] and tissue polypeptide antigen[234] were found to have relatively poor sensitivity (31% to 64%) when specificity limits of 95% were set. In addition, most markers reach better sensitivity in advanced-disease stages as compared with stage I lung cancer. Thus, their use for early diagnosis or screening has not had an impact on patient care in the clinic. Blood-derived biomarkers used in combination with other clinical, imaging, or molecular tools might play an important role in early detection, in monitoring response to therapy, in risk assessment of recurrence, and in prognosis.

In conclusion, although no data are available from randomized trials, spiral CT of the chest and autofluorescence bronchoscopy offer excellent sensitivity to detect lung cancer at early stage, even during the preinvasive stage. The high sensitivity of these tests, however, is associated with a low specificity. Better selection of individuals at highest risk of lung cancer, using biomarkers of disease and of genetic susceptibility, may improve their positive predictive values, minimize the false-positive rates and associated unnecessary investigations or treatment, as well as reduce the cost of the early-detection process.

CLINICAL PRESENTATION AND STAGING OF LUNG CANCER

Presenting Signs and Symptoms

Symptoms, signs, and laboratory test abnormalities relating to lung cancer can be classified as those caused directly by the primary lesion, those related to intrathoracic spread or to distant metastasis, and those related to paraneoplastic syndromes.[237–239] The prototypical lung cancer patient is a current or former smoker of either gender, usually in the seventh decade of life, who presents with symptoms attributable to bulky intrathoracic disease (i.e., cough, dyspnea, chest pain, hoarseness, and/or hemoptysis) or distant metastases (e.g., bone pain, central nervous system symptoms, etc).[238,240] Constitutional symptoms may include weakness, anorexia, weight loss, and, rarely, fever.[238,240] Apart from the brevity of symptom duration, these parameters fail to clearly distinguish SCLC from NSCLC or even from neoplasms metastatic to the lungs.[241] Lung cancer arising in a individuals who have never smoked is more common in women and certain ethnic groups and tends to be an adenocarcinoma.[242–245] Such individuals also tend to be slightly younger than their smoking counterparts at the time of diagnosis.[242] However, the clinical presentation of lung cancer in those who have never smoked tends to mirror that of current and former smokers, even though lung cancers arising in lifelong nonsmokers seem to be biologically distinct as suggested by the differing molecular abnormalities found in tumors derived from smokers and nonsmokers.[244] The prognosis of lung cancer in lifelong nonsmokers is generally better compared with cancers in current or former smokers irrespective of stage.[35,242,246] The reason for the improved survival is unclear.

Cough, dyspnea, and chest discomfort are the most common presenting symptoms in lung cancer (Table 76-6).[237] A history of chronic cough with or without hemoptysis in a current or former smoker with COPD aged 40 years or older should prompt a thorough investigation for lung cancer even in the face of a normal chest radiogram.[237] A persistent "pneumonia" without constitutional symptoms and unresponsive to repeated courses of antibiotics also should prompt an evaluation for an underlying cause (e.g., an occult endobronchial lesion), especially if the individual is a current or former smoker. Less frequently individuals present with hemoptysis that rarely is massive and usually described as streaks of fresh or old blood in sputum. The spread of disease within the chest may result in hoarseness secondary to recurrent laryngeal nerve paralysis and less frequently phrenic nerve paralysis. The latter is associated with an elevated hemidiaphragm on standard chest radiogram. Chest wall involvement is commonly accompanied by pain that in turn may serve as a more accurate indicator of chest wall invasion than radiographic studies. Chest wall pain is usually related to either direct invasion of the pleura or chest wall by the primary tumor, or due to a rib metastasis. Tenderness may be elicited at the site of rib involvement and, rarely, a soft-tissue mass can be palpated.[237] The chest pain may have a pleuritic component if there is pleural involvement. The disappearance of pleuritic chest pain may signify the development of a pleural effusion that in turn may cause shortness of breath or worsen existing dyspnea. Venous distension of the neck and chest wall, cyanosis, facial plethora, and upper extremity edema may indicate obstruction of the superior vena cava, which today is most commonly seen with SCLC.[237,247] Although the heart and other mediastinal structures are often involved with tumor at postmortem examination, only rarely does this involvement serve as the source of a presenting symptom.

Approximately one third of patients present with symptoms as a result of distant metastases.[237] The most common sites of distant

Table 76-6 Presenting Sign and Symptoms of Lung Cancer

Symptoms and Signs	Range of Frequency (%)
Cough	8–75
Weight loss	0–68
Dyspnea	3–60
Chest pain	20–49
Hemoptysis	6–35
Bone pain	6–25
Clubbing	0–20
Fever	0–20

Superior vena cava obstruction	0–4
Dysphagia	0–2
Wheezing and stridor	0–2

From Beckles MA, Spiro SG, Colice GL, Rudd RM: Initial evaluation of the patient with lung cancer: symptoms, signs, laboratory tests, and paraneoplastic syndromes. Chest 2003;123:97–104.

metastasis from lung cancer are the bones; liver, adrenal glands, and intra-abdominal lymph nodes; brain and spinal cord; and lymph nodes and skin. Lung cancer can metastasize to virtually any bone, with pain being the primary presenting symptom in as many as 25% of individuals at diagnosis.[237] Similarly, liver metastases are common at initial presentation in both SCLC and NSCLC. However, liver function test results are seldom abnormal until the metastases are numerous and large. Hepatic metastases most commonly produce symptoms of weakness and weight loss. Adrenal lesions, only rarely associated with adrenal insufficiency, and para-aortic lymph node metastases are most commonly seen with SCLC. Intracranial metastases at presentation are most commonly in SCLC and adenocarcinomas of the lung. Presenting symptoms may include headache, nausea and vomiting, focal neurologic symptoms or signs, seizures, confusion, and personality changes.

The stigmata of COPD in smokers may be the only findings on physical examination, or one may detect lymphadenopathy, hepatomegaly, bone tenderness, or abnormal neurologic findings. Digital clubbing and hypertrophic osteoarthropathy may be associated with any histologic subtype of lung cancer but are most frequently associated with squamous cell and adenocarcinoma and least likely to occur in a patient with small cell carcinoma.[237,248] Digital clubbing is more common than hypertrophic osteoarthropathy, which is characterized by painful symmetric arthropathy and periosteal new bone formation of the distal limbs. Its mechanism of development is unknown. In a published series of 111 consecutive lung cancer patients, clubbing was noted in 29% with an incidence of 35% in NSCLC and only 4% in SCLC.[248] As many as 20% of patients present with palpable lymphadenopathy in the supraclavicular fossa during the course of the disease. Subcutaneous metastases while rare may serve as a source of diagnostic material.

Paraneoplastic Disorders

Although many of the symptoms of NSCLC and SCLC are attributable to mass effect and direct impingement upon vital organs, less commonly individuals with lung cancer present with symptoms related to hypercalcemia,[249] hyponatremia,[241,250] Cushing's syndrome,[251] Lambert-Eaton syndrome, and other neurologic disorders.[252–254] These so-called paraneoplastic phenomena can be seen in any histologic type of lung cancer but are most frequently associated with SCLC. In general a majority of these paraneoplastic phenomena fall into endocrine or neurologic categories.[255–257]

Hypercalcemia

Hypercalcemia of malignancy (HCM) is the most common life-threatening metabolic complication of malignancy, affecting approximately 10% to 20% of patients with advanced cancer. Hypercalcemia may be associated with or due to production of a parathyroid hormone-related peptide.[249] The incidence of HCM varies widely by cancer type but occurs most frequently in patients with multiple myeloma and carcinomas of the lung, breast, kidney, and head and neck. With respect to lung cancer, squamous cell carcinoma is the most common histologic subtype. Clinical symptoms of HCM include nausea, vomiting, abdominal pain, constipation, polyuria and thirst, and altered mental status. HCM may lead to renal failure. The early symptoms of nausea, vomiting, and constipation may be easily confused with the initiation of narcotics for pain control. Management of HCM is covered in Chapter 48.

Hyponatremia and the Syndrome of Inappropriate Antidiuretic Hormone

The inappropriate secretion of antidiuretic hormone, or arginine vasopressin (AVP), with its resultant euvolemic, refractory, hypoosmolar hyponatremia, is observed in as many as 15% of individuals with SCLC.[250,258] However, as many as one third of patients with hyponatremia have no evidence of ectopic AVP production.[259] In such cases hyponatremia may be caused by ectopic production of atrial natriuretic peptide (ANP). SCLC is the most common malignant cause of acute or chronic syndrome of inappropriate secretion of antidiuretic hormone (SIADH).[260] The presence of SIADH does not correlate with clinical stage, distribution of metastatic sites, or patient gender, nor does SIADH influence response to chemotherapy or overall survival as an independent variable.[250] As with most paraneoplastic syndromes, the best therapy for SIADH is effective treatment of the underlying SCLC. SIADH typically resolves with 1 to 4 weeks of initiating chemotherapy in the vast majority of cases.[250] While awaiting the effects of chemotherapy, serum sodium can usually be managed and maintained above 128 mEq/L via strict fluid restriction alone.[261] Demeclocycline, which blocks the action of vasopressin at the level of the renal tubule, can be a useful adjunctive measure when fluid restriction alone is insufficient to restore sodium level.[262,263] The starting dose is 150 mg four times a day but may have to be increased to 1200 mg. Tolvaptan, an oral vasopressin V_2-receptor nonpeptide antagonist, also is effective in increasing serum sodium concentrations in patients with euvolemic and hypervolemic hyponatremia.[264] Notably, patients with ectopic ANP secretion do not respond to fluid restriction.[259] In fact, fluid restriction may actually worsen hyponatremia if sodium intake is not concomitantly increased. Accordingly, if hyponatremia fails to improve or worsens after 3 to 4 days of adequate fluid restriction, plasma concentrations of AVP and ANP should be measured to determine whether inappropriate secretion of ADH or ANP is the causative syndrome.[259]

Ectopic Adrenocorticotropic Hormone Production

Cushing's syndrome may be due to ectopic secretion of adrenocorticotropic hormone from a nonpituitary tumor resulting in bilateral adrenocortical hyperplasia and hypercortisolemia.[265] Neuroendocrine lung tumors including SCLC and pulmonary carcinoids account for approximately half of the cases of ectopic tumors producing adrenocorticotropic hormone.[251,266] Although hypercortisolemia has been documented in as many as 50% of SCLC cases, only 2% to 5% of SCLC patients have the characteristic clinical features of Cushing's syndrome.[251] Unlike Cushing's disease, the onset of symptoms in ectopic adrenocorticotropic hormone production is often abrupt because of the characteristic rapid growth of SCLC. Consequently the classical features of Cushing's disease—a buffalo hump, striae, and moon facies—are frequently absent. By contrast, hypokalemic alkalosis, hypertension, hyperglycemia, and, rarely, edema and muscle wasting are common.[251] The effect of Cushing's syndrome on survival is unclear, although some investigators hold that its onset heralds a

more aggressive tumor behavior.[251] Treatment with standard medications, such as metyrapone and ketoconazole, is largely ineffective due to extremely high cortisol levels.[267] Some patients require bilateral adrenalectomy to control symptoms.[265] The most effective strategy for management of the Cushing's syndrome is effective treatment of the underlying SCLC.[251]

Neurologic Paraneoplastic Syndromes

The paraneoplastic neurologic disorders are a diverse group of diseases characterized by the presence of neurologic dysfunction in the setting of a remote cancer.[256,257] They are often the result of production of antibodies that react with both the small cell cancer cells and with normal host tissue. Well-described syndromes include the Lambert-Eaton myasthenic syndrome, paraneoplastic encephalomyelitis and sensorimotor neuronopathy, and paraneoplastic cerebellar degeneration.[254,268] Less frequent abnormalities include subacute sensory neuropathy, autonomic disturbances, myelopathies, progressive encephalopathy, and visual paraneoplastic syndromes.[253,256,269]

Lambert-Eaton myasthenic syndrome is caused by autoantibodies directed against presynaptic voltage-gated P/Q calcium channels.[254,268] The P/Q calcium channel autoantibodies decreases calcium entry into the presynaptic terminal, which prevents binding of vesicles to the presynaptic membrane and acetylcholine release. Individuals with this disorder present with proximal muscle weakness, usually in the lower extremities, occasional autonomic dysfunction, and rarely with cranial nerve symptoms or involvement of the bulbar or respiratory muscles. Depressed deep tendon reflexes are frequently present. As contrasted to individuals with myasthenia gravis, strength improves with serial effort. The diagnosis is confirmed by electrophysiologic testing, which demonstrates small compound muscle action potentials and facilitation with exercise or 20-Hz repetitive stimulation. A serum test for voltage-gated calcium channel antibodies, estimated to occur in 5% of patients with SCLC, is commercially available. Plasma exchange and intravenous immunoglobulin can provide short-term benefit, while 3,4-diaminopyridine, which enhances the release of acetylcholine from presynaptic terminals,[270] prednisone, and azathioprine can provide limited long-term benefit.[271] Some patients who respond to chemotherapy will have resolution of the neurologic abnormalities, and this is the initial treatment of choice.

Paraneoplastic encephalomyelitis and sensory neuronopathies, cerebellar degeneration, limbic encephalitis, and brainstem encephalitis occur in SCLC in association with a variety of antineuronal antibodies such as anti-Hu, anti-CRMP5, and ANNA-3.[253,256,272] These antibodies have been found in as many as 25% of individuals with SCLC though not always in association with a clinically obvious neurologic disorder.[256] These disorders may predate the diagnosis of SCLC.[256] Most paraneoplastic neuropathies are sensorimotor and axonal, symmetric in distribution, and frequently disabling.[256] Limbic encephalitis is characterized by degeneration of neurons in the medial temporal lobe with clinical features that include behavioral changes, hallucinations, short-term memory loss, anosmia, ageusia, and dementia.[273] Symptoms of brainstem encephalitis include vertigo, nystagmus, oscillopsia, ataxia, diplopia, dysarthria, and dysphagia reflecting the predominant involvement of the floor of the fourth ventricle and inferior olives.[274] Some patients develop respiratory insufficiency requiring assisted ventilation. Cerebrospinal fluid studies may show pleocytosis and elevated protein levels. MRI brain scans are typically normal. As with voltage-gated calcium channel antibodies, the presence of anti-Hu antibodies does not correlate with neurologic symptoms nor with an improved prognosis.[272,275]

Paraneoplastic cerebellar degeneration, manifesting with ataxia, dysarthria, and nystagmus, may be associated with anti-Hu, anti-Yo, or P/Q calcium channel autoantibodies.[255,276,277] Patients often present with loss of coordination that usually starts on one side and rapidly progresses over days to weeks to involve both sides equally.[278] Additional presenting symptoms include limb and truncal ataxia, lack of coordination, dysarthria, and nystagmus. More rarely patients experience opsoclonus, myoclonus, memory disturbances, pyramidal signs, sensory disturbances, or hyporeflexia. After progressing for a few weeks, the symptoms stabilize, leaving the person in a severely disabled state. On examination, patients may be unable to stand without assistance because of severe truncal and neck ataxia with markedly ataxic gait. Ocular findings may include horizontal or vertical nystagmus, dysconjugate gaze, ocular dysmetria, and opsoclonus.[277] Speech also can be affected severely, presenting initially as mild dysarthria and progressing to incomprehensible words in severe cases. Mild deterioration of mental status may also be seen, but marked changes in mental status are not compatible with this diagnosis.[277] Treatment may include steroids, plasmapheresis, and chemotherapy.[255,276] However, treatment of the tumor and/or immunomodulation does not alter the course of paraneoplastic cerebellar degeneration but may improve Lambert-Eaton myasthenic syndrome symptoms. Death is frequently due to neurologic complications. Paradoxically, the tumor frequently remains localized to the chest or not detected.[277]

Diagnostic Workup and Staging

Assessment of Intrathoracic Disease

Accurate staging of lung cancer is extremely important, because treatment options and prognosis are dictated by stage.[279] The most significant dividing line is between those individuals who are candidates for surgical resection and those who are inoperable but will benefit from chemotherapy, radiation therapy, or both. Staging with regard to an individual's potential for surgical resection is most applicable to NSCLC. The basis for staging NSCLC is the TNM system (Table 76-7),[280,281] whereas for SCLC a more simplified staging classification is used (described later). Of note, the TNM system is currently undergoing revision.[280] From a practical standpoint, the involvement of disease in the mediastinum, which is reflected in the "N" designator in the system, most often determines the appropriateness of the individual for surgical resection.[279] In other words, individuals with mediastinal node involvement are usually not candidates for surgical resection, although there are selected individuals in whom surgery is appropriate as discussed later in this section. Several noninvasive imaging studies are available to aid in identifying disease both within and outside of the chest. A majority of lung cancers are detected by plain chest radiography (Fig. 76-12). However, the chest radiogram is not sufficiently sensitive to accurately assess the mediastinum. Accordingly, a chest CT scan should be performed in virtually every case of suspected NSCLC. The chest CT scan provides anatomic detail that better identifies the location of the tumor, its proximity to local structures, and whether or not lymph nodes in the mediastinum are enlarged (see Fig. 76-12). Unfortunately, the accuracy of chest CT scanning in differentiating benign from malignant lymph nodes in the mediastinum based on node size is low. The most commonly used size criterion is a short-axis diameter of 1 cm or larger on a transverse CT scan. Whole-body PET scanning provides functional information on tissue activity and is more sensitive and specific than chest CT scanning for staging lung cancer in the mediastinum (Fig. 76-13). In addition, metastatic disease can be detected by PET scan. Still, positive findings of PET scans can occur from nonmalignant etiologies (e.g., infections), so that tissue sampling to confirm the suspected malignancy is strongly recommended.[104,279] MRI can be useful in selected circumstances such as superior sulcus tumors to rule out brachial plexus involvement but in general does not play a major role in NSCLC staging. Of course, abnormalities detected by any of the aforementioned imaging studies are not necessarily cancer. Unless overwhelming evidence of metastatic disease is present on an imaging study, in situations in which it will make a difference in treatment, all abnormal scan findings require tissue confirmation of malignancy so that individuals are not prevented from having potentially curative surgery.[279]

Table 76-7 TNM Staging of Lung Cancer

PRIMARY TUMOR (T)

T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor ≤3 cm and not involving the mainstem bronchus
T2	Tumor is: >3 cm, involving mainstem bronchus ≥2 cm from the carina, invading visceral pleura, or associated with lobar atelectasis or obstructive pneumonitis
T3	Direct invasion of chest wall, diaphragm, mediastinal pleura, pericardium, mainstem bronchus <2 cm from carina, or associated with atelectasis or obstructive pneumonitis of entire lung
T4	Direct invasion of mediastinum, heart, great vessels, trachea, esophagus, vertebrae, carina, or associated with malignant effusion or satellite nodules in the same lobe

REGIONAL LYMPH NODES (N)

N0	No regional nodal metastasis
N1	Metastasis to ipsilateral peribronchial and/or ipsilateral hilar lymph nodes, or intrapulmonary nodes involved by direct primary tumor extension
N2	Metastasis to ipsilateral mediastinal and/or subcarinal lymph nodes
N3	Metastasis to contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene or supraclavicular lymph nodes

DISTANT METASTASIS (M)

M0	No distant metastasis
M1	Distant metastasis present or metastatic nodules in nonprimary tumor lobe(s)

TNM STAGING

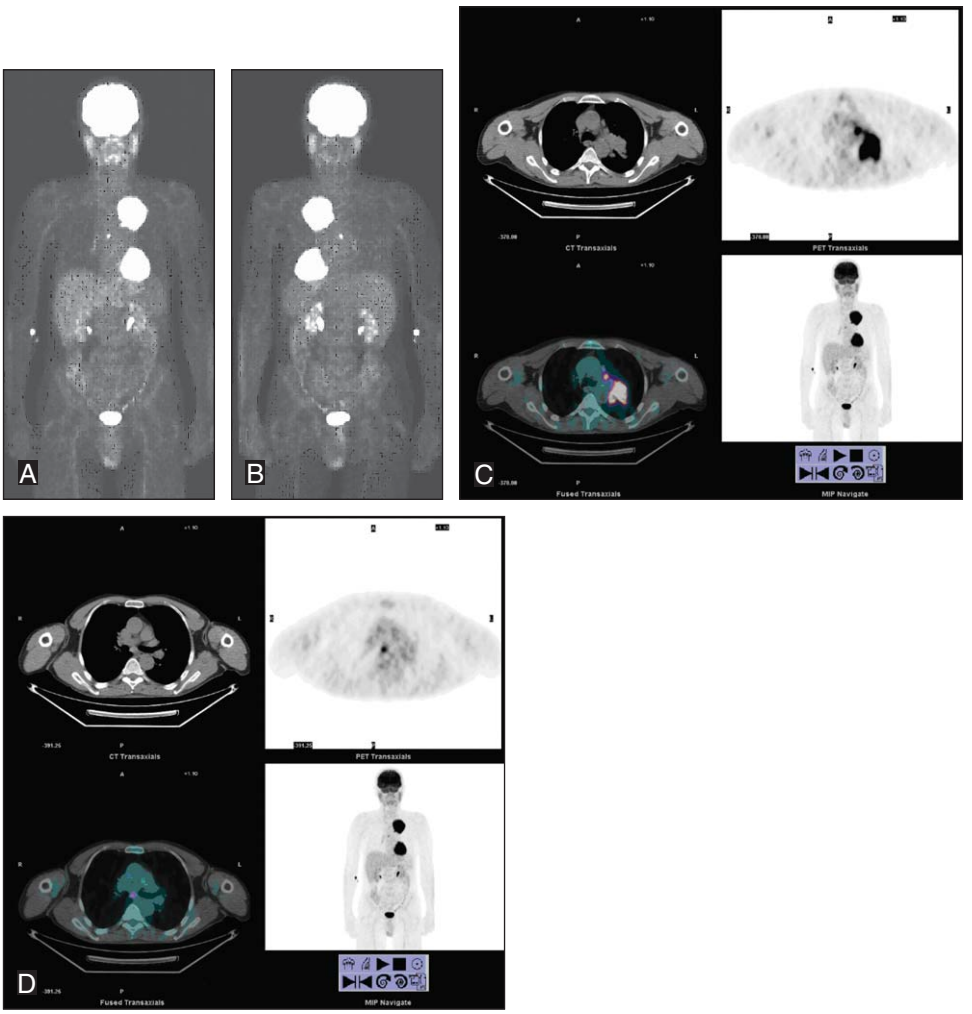

Figure 76-13 • [^{18}F]Fluorodeoxyglucose positron emission tomography with integrated computed tomography. FDG-PET demonstrates (**A**) activity in left upper lobe lesion and (**B**) activity in the subcarinal space. Physiologic uptake is noted in the brain, bones, liver, spleen, kidney, and musculature. Increased activity is also identified at intravenous insertion site, renal collecting system and the bladder. Fused CT/PET images confirm (**C**) lymph node in the anteroposterior window is FDG avid and (**D**) mild FDG uptake in a subcarinal lymph node.

Assessment of Extrathoracic Disease

The best predictor of metastatic disease remains a careful history and physical examination. If signs, symptoms, or findings from the physical examination suggest the presence of malignancy, then sequential imaging, starting with the most appropriate study based on the clues obtained by the clinical evaluation, should be performed. If the findings from the clinical evaluation are negative, then imaging studies such as a CT scan of the head, a bone scan, or an abdominal CT scan are unnecessary, and the search for metastatic disease is complete. Clinical findings suggestive of metastatic disease are listed in Table 76-8.[279] Patients with abnormal clinical evaluations should undergo imaging for extrathoracic metastases. Site-specific symptoms warrant directed evaluation of that site with the most appropriate study (e.g., head CT scan, bone scan, and abdominal CT scan).[279] More controversial is how one should assess individuals with known stage III disease. Because these patients are more likely to have asymptomatic occult metastatic disease, current guidelines recommend a more extensive imaging evaluation to include a head CT scan, an abdominal CT scan, and bone imaging.[279]

Solitary Pulmonary Nodule

The approach to a patient with a pulmonary nodule is based on an estimate of the probability of cancer, determined according to the size of the nodule, the presence or absence of a history of smoking, the patient's age, and characteristics of the nodule's margins on CT imaging.[282] Mayo Clinic investigators reported that clinical charac-

Table 76-8 Clinical Findings Suggesting Metastatic Disease

Symptoms elicited in history	Constitutional: weight loss >10 pounds
	Musculoskeletal: focal skeletal pain
	Neurologic: headaches, syncope, seizures, extremity weakness, recent change in mental status
Signs found on physical examination	Lymphadenopathy (>1 cm)
	Hoarseness, superior vena cava syndrome
	Bone tenderness
	Hepatomegaly (>13-cm span)
	Focal neurologic signs, papilledema
	Soft-tissue mass
Routine laboratory tests	Hematocrit, <40% in men; <35% in women
	Elevated alkaline phosphatase, GGT, SGOT, and calcium levels

GGT, gamma-glutamyltransferase; SGOT, serum glutamic-oxaloacetic transaminase.

teristics (age, cigarette smoking status, and prior cancer diagnosis 5 or more years ago) and three radiologic characteristics (diameter, spiculation, and upper lobe location) were independent predictors of malignancy.[283] An efficient algorithm for assessing these lesions is outlined in Figure 76-14.

NON-SMALL CELL LUNG CANCER

The four major histologic types of lung cancer—squamous cell carcinoma, adenocarcinoma, large cell carcinoma, and small cell undifferentiated carcinoma—together account for more than 90% of lung cancer cases in the United States.[15] The first three are traditionally lumped together into the category of NSCLC. The incidence of NSCLC has been decreasing since the mid-1970s to 1980s among men in North America, northwestern Europe, Australia, and New Zealand, but the age-adjusted rate continues to increase among women in these countries, and among both men and women in southern and eastern Europe.[284] These trends followed changes in smoking behavior. Over time there has been a significant shift in the incidence rates of lung cancer by histologic type. Following a steadily increasing occurrence during the period 1973 to 1987, adenocarcinoma supplanted squamous cell carcinoma as the most frequent form of lung cancer.[285] Several hypotheses have been posited as to the underlying cause of this shift, but recent data suggest that changes in smoking behavior and cigarette design are major contributors.[286]

Presurgical Evaluation

Physiologic Evaluation

The physiologic evaluation must be individualized for each patient but generally emphasizes the pulmonary and cardiac function, and follows a stepwise progression. In some cases, history, physical examination, and routine spirometry are all that is required for physiologic assessment. For many patients further physiologic assessment is indicated before pulmonary resection. The assessment of an individual's ability to tolerate lung resection from a cardiopulmonary standpoint is fundamental to patient selection for surgery. Persons with advanced pulmonary disease and severe pulmonary dysfunction may have prohibitive risk in greater than one third of patients with otherwise resectable disease.[287] The most oncologically sound and perfectly executed operation for lung cancer falls far short of success in the event of a major cardiopulmonary complication or severe long-term functional detriment.

Smoking Cessation

Cigarette smoking is associated with an increase of as much as sixfold in the incidence of postoperative pulmonary complications after surgery.[288] Although there are few studies specific to pulmonary resection, there is evidence that preoperative smoking abstinence of 4 to 8 weeks' duration is necessary to reduce the incidence of complications.[288,289] Interestingly, higher rates of complications occur for

patients who cease smoking within fewer weeks of surgery as compared with those who continue to smoke. In evaluating the current smoker with NSCLC for potential resection, the powerful addictive properties of cigarette smoking must be recognized. Individuals should be offered pharmacologic adjuncts (discussed earlier) and should be enrolled in a formal tobacco cessation program before consideration for resection. Wherever possible, smoking should cease a minimum of 4 weeks before surgery. Whether or not to offer resection to individuals with NSCLC who continue to smoke is a subject of controversy among thoracic surgeons. Whatever a particular surgeon's approach to this group, the significant deleterious effect of cigarette smoking on outcome must be recognized. Furthermore, an individual's success in preoperative tobacco cessation may reflect his or her commitment to recovery and compliance with further therapy.

Nutritional Status

Weight loss and malnutrition are very common among individuals with NSCLC. In a recent study[290] more than 40% of patients undergoing resection for NSCLC had a body mass index and skin fold thickness below the twenty-fifth percentile. Poor nutrition in surgical patients correlates with impaired wound healing and a greater propensity to postoperative infection.[291]

Impact of Age

Advanced age is an independent predictor of mortality after resection for NSCLC.[292] With recent advances in patient selection and perioperative care, however, lung resection may be performed with acceptable rates of morbidity and mortality in patients well beyond the age of 70 years. Advanced age does predict a higher incidence of perioperative cardiovascular complications, but age reflects a surrogate marker for additional comorbidities rather than an independent risk factor.[292,293]

Spirometry and Pulmonary Diffusion Capacity

Spirometry is mandatory for patients under consideration of pulmonary resection for NSCLC and provides an objective assessment of pulmonary function. The forced expiratory volume in 1 sec (FEV_1) is the historical standard to determine suitability for resection; a predicted postoperative FEV_1 ($ppoFEV_1$) can be estimated based on the planned extent of resection:

$$ppoFEV_1 = \text{preoperative } FEV_1 \times (\text{no. segments remaining/total segments}).$$

FEV_1 is an independent predictor of mortality from surgery for lung cancer[294] and serves as the primary determinant of the need for further physiologic assessment before surgery for NSCLC. The criteria of ppo FEV_1 of at least 0.8 L has been widely used in decisions for lung cancer resection.[295] However, an absolute value of FEV_1 predicts postresection pulmonary function less accurately than FEV_1 expressed as a percentage of the expected value for age and size.[296] The use of absolute FEV_1 measurements in patient selection may bias against older individuals, those of small stature, and females.[297] Nevertheless, patients with an absolute FEV_1 of greater than 2.0 L are likely to tolerate pneumonectomy, and those with FEV_1 over 1.5 L have adequate pulmonary reserve for lobectomy.[298,299] Patients deemed unable to tolerate lobectomy from a pulmonary functional standpoint may be candidates for more limited resections, such as wedge or anatomic segmental resection, although such procedures are associated with significantly higher rates of local recurrence and a trend toward decreased survival,[300,301] or from minimally invasive techniques and improved postoperative pain management techniques (patient-controlled analgesia, epidural anesthesia, etc.)

Pulmonary diffusing capacity for carbon monoxide (D_LCO) is an adjunctive test to spirometry and lung volume measurements. D_LCO provides a measurement of the lung surface area available for gas exchange and is determined by measuring expired carbon monoxide levels during controlled exhalation. Variability in the D_LCO may be as much as 12% or greater. The D_LCO measures the rate at which test molecules such as carbon monoxide move from the alveolar space to combine with hemoglobin in the red blood cells. The D_LCO is determined by calculating the difference between inspired and expired samples of gas. D_LCO levels below 50% are associated with increased perioperative risk.[302] A low D_LCO reflects the presence of emphysema, fibrosis, or pulmonary vascular disease. Similar to FEV_1, preoperative D_LCO measurement is most useful when expressed as a percentage of predicted value[297,299,302] and may be used to estimate predicted postoperative D_LCO ($ppoD_LCO$).

Cardiopulmonary Exercise Testing

Cardiopulmonary exercise testing (CPET) can be extremely useful in the evaluation of marginal candidates ($ppoFEV_1$ or $ppoD_LCO$ <40% predicted) or for patients who appear more disabled than expected from simple spirometry measurements.[303,304] Formal CPET includes exercise electrocardiography, heart rate response to exercise, and the measurements of minute ventilation and oxygen uptake per minute. CPET allows a calculation of maximal oxygen consumption (VO_{2max}) and provides insight into overall cardiopulmonary function (the cardiopulmonary axis) that cannot be ascertained from other objective studies. CPET may identify clinically occult cardiac disease and may provide a more accurate assessment of pulmonary function than spirometry and D_LCO, which tend to overestimate functional loss after resection.[303,304] A patient's risk of perioperative morbidity and mortality may be stratified by VO_{2max}. Those with VO_{2max} above 20 mL/kg/min are not at increased risk for complications or death after resection of NSCLC. A level below 15 mL/kg/min is associated with an increased risk, and VO_{2max} less than 10 mL/kg/min indicates very high risk, generally precluding operation.[297,305–307]

Quantitative Perfusion Study

Quantitative radionucleotide perfusion scanning involves the injection of ^{99m}Tc-radiolabeled albumin particles, followed by the visual inspection of planar images. Unlike perfusion scanning in the setting of suspected pulmonary thromboembolism, concomitant ventilation scanning is not routinely performed for preoperative assessment, because studies have demonstrated that both are usually well matched and equally effective in assessing function. Quantitative perfusion provides a measurement of the relative function of each lobe and lung, allowing a prediction of pulmonary function after lung resection:

$$ppoFEV_1 = \text{preoperative } FEV_1 \times (1 - \text{fraction of perfusion to region of planned resection})$$

Quantitative perfusion studies may be useful in selecting patients with marginal pulmonary reserve for resection. Like FEV_1 and D_LCO, quantitative perfusion studies tend to slightly underestimate actual postoperative function, erring on the side of safety in the selection of patients for resection.[308] A recent study compared quantitative perfusion studies to the segment-counting technique and reported no difference in the predictive value for the assessment of postoperative pulmonary function.[296] The study of quantitative perfusion is therefore most useful when there is clinical suspicion that the area of planned resection is not contributing homogeneously to lung function, such as in the setting of heterogeneous emphysema or an obstructive process.

Arterial Blood Gas Analysis

Arterial blood gas analysis is not a mandatory component of preoperative assessment for lung resection. It may be indicated in marginal candidates, or if there is a clinical suspicion of significant hypoxia or carbon dioxide retention.

Informal Exercise Assessment

Observed performance during stair climbing has historically been practiced in the preoperative assessment of patients with lung cancer. Stair-climbing ability has some correlation with values on spirometry[297,309] but perhaps is most correlated with a person's global cardio-

pulmonary status and determination,[309] both of which are fundamental to a successful outcome after surgery. This modality has not been standardized in duration, extent, or technique, and studies thus far represent limited single-institutional experiences. Given the wide availability of more objective and standardized noninvasive tests for cardiopulmonary function, stair-climbing performance should not be used as the sole criterion to determine physiologic suitability for lung cancer resection.

Cardiovascular Status

Cardiovascular evaluation should conform to American College of Cardiology and American Heart Association guidelines for noncardiac surgery.[310] Patients with greater than one major risk factor for coronary artery disease, those with prior cardiac interventions, and those whose functional limitations preclude adequate assessment for angina should be evaluated further. Preoperative electrocardiography should be performed in all patients, and echocardiography is indicated in all patients with a heart murmur, clinical features suggestive of congestive heart failure, or unexplained dyspnea. Echocardiography is also a useful initial evaluation for clinically suspected pulmonary hypertension, which represents a contraindication to lung resection. Pulmonary resection for NSCLC should generally not be undertaken within 6 weeks of an acute myocardial infarction. Patients with a prior history of cerebrovascular events and those with cervical bruits on physical examination should be assessed by carotid Doppler studies and referred for vascular consultation as appropriate.

Effects of Induction Chemotherapy

Patients who have received chemotherapy for NSCLC before surgery typically have more advanced-stage disease and may require greater extent of resection than early-stage disease. There seems to be no significant difference for stage-matched patients who receive induction chemotherapy followed by resection compared to those with resection alone.[311] Malnutrition and current cigarette smoking must be recognized as potentially reversible risk factors for complications after resection and should be modified where possible. It is unclear whether deferral of surgery for any prescribed interval after the completion of chemotherapy may offset some of these deleterious effects. Although induction therapy is not the current standard for NSCLC, many institutions have adopted its use in selected patients with stage IIIA disease. The thoracic surgeon must be aware of the increased attendant perioperative risk, which should be part of the global assessment of a patient's fitness to undergo surgery.

In summary, every person with potentially resectable NSCLC must be carefully assessed by the thoracic surgeon for his or her physiologic fitness to undergo surgery, because patients with severe cardiopulmonary deficiency are at a predictably increased risk for major complications and death after resection. All patients should be assessed for cardiovascular risk using American College of Cardiology and American Heart Association guidelines. Spirometry allows a determination of ppoFEV_1, and D_LCO should be liberally used as an adjunct to spirometry measurements. Patients with a ppoFEV_1 or ppoD_LCO below 40% of expected values should be further evaluated with CPET. At institutions where CPET is not available, supervised stair-climbing assessment may be an acceptable alternative means for assessment. Quantitative perfusion scanning should be considered in patients with marginal ppoFEV_1 or ppoD_LCO, particularly where heterogeneous pulmonary function is clinically suspected. There are several studies reporting acceptable outcomes for lung resection in patients with preoperative measurements well below accepted standards,[312,313] and no single test result should be viewed as an absolute contraindication to surgical resection for NSCLC. Although the physiologic assessment of a patient with normal spirometry and minimal comorbidity is fairly straightforward, patients with marginal preoperative indices must be considered on an individual basis. Surgical decision making in this patient population should incorporate input from the pulmonologist and medical oncologist. The decision whether to pursue lobectomy, limited resection, or primary nonoperative treatment of NSCLC is made best under the guidance of this multidisciplinary team.

Surgical Management of Non-Small Cell Lung Cancer

Since the introduction of the pneumonectomy for extirpation of lung cancer, surgeons and surgical resection have played a pivotal role in the management of early-stage NSCLC.[314] However, in the last 2 decades the management of NSCLC has become a multidisciplinary process involving not only surgeons but also pulmonologists, pathologists, radiologists, radiation oncologists, and medical oncologists. Notably, however, thoracic surgeons retain a key role in the management of all stages of lung cancer from premalignant lesions to the management of selected individuals with advanced stage IV disease.

Surgical management of NSCLC is multifaceted and entails the invasive staging for optimal therapeutic decisions, extirpation of the local disease with mechanical and other physical strategies, alone or in combination with chemotherapy or radiation therapy, and management of the physical sequelae of progressive neoplastic growth with dyspnea from airway compromise, pleural effusion, or other consequences. Fundamentals of surgical management of NSCLC include complete resection of the tumor with negative margins, systematic mediastinal lymph node dissection, and integration of the multidisciplinary team in all but the most early or late stages of disease (i.e., clinical stage IA or metastatic disease, respectively). Ideally NSCLC should be managed by a thoracic surgeon trained in the management of thoracic neoplasms and their sequelae. Both the skill of the surgeon and the volume of procedures performed at a particular facility significantly influence survival following lung cancer surgery.[315,316] Experienced thoracic surgeons working in facilities that perform a high volume of procedures invariably have better outcomes than nonthoracic surgeons and/or thoracic surgeons and nonthoracic surgeons operating in facilities that perform a low volume of lung cancer operations.[315,316] The thoracic surgeon cannot eliminate perioperative risk but can manage it by optimizing patient selection, and various parameters for patient preparation, intraoperative care, and convalescence. Resection of lung cancer can be done with low mortality by experienced thoracic surgeons (i.e., <1.5% mortality rates), as demonstrated in a recently completed multiinstitutional prospective randomized trial of over 1000 patients evaluating mediastinal lymph node dissection versus node sampling.[315]

Although the extant International Staging System is undergoing revision, the current iteration has served surgeons well since its publication in the late 1990s (see Table 76-7).[280] Clear survival differences are demonstrable by stage as determined by differences in tumor size and location, characteristics of hilar, mediastinal, or other nodal groups, and presence or absence of metastatic disease. Patients are selected for a specific treatment on the basis of the clinical stage as determined by the clinician's best and final estimate of the extent of the NSCLC based on all available data before the initiation of definitive therapy. Consequently treatment decisions require accurate and complete staging as an integral component of pulmonary resection for lung cancer. For postoperative treatment decisions, mediastinal lymphadenectomy determines pathologic stage and provides information about potential survival and the need for postresection therapy. The pathologic stage of the tumor most accurately defines the overall and disease-free survival.

Without question, surgical resection of NSCLC provides the best opportunity for cure and offers the greatest potential for prolonged survival.[314] Historically, a pneumonectomy was considered the only procedure that reliably achieved complete resection. However, with the advent of more detailed staging as outlined previously, coupled with more specific survival data, less aggressive surgical resections have been performed for early-stage NSCLC, with improvements in postoperative morbidity and mortality. Currently, patients with stages I, II, and select IIIA (T3N1) NSCLC, as determined by pre-

operative imaging and staging strategies, are candidates for attempting pulmonary resection in the absence of other contraindications to surgery. In some parts of the world individuals with known mediastinal nodal involvement (i.e., N2 disease) also are treated with resection. However, in North America and much of Europe, individuals with known N2 disease are typically treated without primary surgical intervention, although selected patients may undergo surgery as part of a multidisciplinary approach.[314,317] The surgical procedure of choice is a thoracotomy and complete resection to obtain negative surgical margins via lobectomy, sleeve lobectomy, bilobectomy, or pneumonectomy depending on tumor burden and location.[314] Moreover, recent data demonstrate that postoperative chemotherapy is beneficial in selected patients with completely resected stages II and IIIA disease and very possibly in some patents with stage IB disease. The subject of adjuvant and neoadjuvant therapies is covered in greater detail immediately after the following brief overview of the surgical management of some of the more common and not so common presentations of NSCLC.

Occult Lung Cancer

Screening for second aerodigestive malignancies can result in identification of CIS or microinvasive tumor by flexible bronchoscopy. These occult lung cancers (Tx-TisN0M0) occur without symptoms or other radiographic finding and may be treated with endoluminal therapy. However, most patients would be considered for resection with segmentectomy or lobectomy. The choice of anatomic resection must be carefully considered, because field cancerization may exist with many involved areas present. Mucosal ablating techniques include photodynamic therapy, brachytherapy, electrocautery, cryotherapy, and neodymium-yttrium-garnet (Nd-Yag) laser therapy.[318]

Stage I Lung Cancer

Stage I NSCLC includes individuals with a T1 or T2 primary tumor designation and no evidence of hilar or mediastinal nodal disease (N0) or metastatic spread (M0). Medically fit persons with stage I disease should be considered for aggressive local therapy, and curative treatment is possible with 5-year survival rates ranging from 45% to 70% in most series depending in large part on tumor size and whether or not pleural invasion is found.[314,319] Surgical resection is the accepted treatment for individuals with stage I disease.[314,320,321] Only rarely is a pneumonectomy necessary in stage I NSCLC. Lobectomy is usually sufficient to achieve negative surgical margins and is considered the surgical preferred approach, although lesser resections (wedge, segmentectomy, etc.) have advantages in persons with limited pulmonary reserve.[322,323] Compared with a lobectomy, a segmental resection tends to spare pulmonary reserve without significant impairment of survival, although additional local control measures are needed.[324,325] Iodine-125 brachytherapy mesh applied to the suture line may be helpful in decreasing local recurrence.[326,327] Notably, video-assisted thoracic surgery (VATS) techniques have advanced to a common level commensurate with safe anatomic resection of parenchymal neoplasms and lymph node sampling.[328,329] Anatomic resection (open or VATS) is preferred to a wedge resection of NSCLC, because the latter is associated with increased rates of local recurrence.[325] In experienced hands, VATS is associated with low morbidity and mortality, and the risk of intraoperative bleeding or recurrence in an incision is minimal.[328] Moreover, VATS is associated with less postoperative immunosuppression compared with the thoracotomy approach.[330] However, the clinical relevance of better preserved cellular immunity in the early postoperative period is unclear. There are insufficient data to suggest that one method of resection (open thoracotomy, minimally invasive techniques) is superior to another.

Accurate pathologic staging in stage I disease requires adequate segmental, hilar, and mediastinal lymph node dissection.[331,332] The performance of a systematic sampling or full mediastinal lymph node dissection may improve pathologic staging but is unproven therapeutically.[321] Mediastinal lymph node dissection provides for a significantly larger amount of material, which can refine pathologic (nodal) stage determination. On the right side, mediastinal stations 2R, 4R, 7, 8R, and 9R should be dissected; on the left side, stations 5, 6, 7, 8L, and 9L should be dissected. Hilar lymph nodes are typically resected and sent with the specimen, although it is helpful to specifically dissect and label level 10 lymph nodes when possible. On the left side, level 2 and sometimes level 4 lymph nodes are generally obscured by the aorta. Mediastinal lymph node dissection optimizes the accuracy of the pathologic stage and provides information to the clinician as to potential survival and the need for postresection therapy.[331,332] Although the therapeutic benefit of nodal dissection versus nodal sampling remains controversial, in a recent pooled analysis of three trials, 4-year survival was superior in individuals undergoing resection with stage I through IIIA NSCLC who had complete mediastinal lymph node dissection compared with lymph node sampling (hazard ratio [HR] 0.78; 95% confidence interval [CI], 0.65 to 0.93).[333] Moreover, a complete mediastinal lymphadenectomy adds little morbidity to a pulmonary resection for lung cancer.[315] Thus, the recommendation is that patients should have a complete mediastinal node dissection.

Although the cost effectiveness of surveillance is not well established, many surgeons choose to follow patients with resected stage I NSCLC for the development of a second primary tumor.[334,335] About 5% of stage I NSCLC patients will develop a second primary cancer (incidence = 1.99/100 patient-years),[336,337] and surgical intervention in such cases may prove beneficial.[338]

Stage II Lung Cancer

Clinically stage II patients are often misclassified as stage I disease. Stage II NSCLC is a heterogeneous classification covering patients with T1–2N1 or T3N0 tumors. Stage II composes only 5% of all NSCLC based on clinical assessment alone.[339] By definition, patients with tumor invading the chest wall apex, mediastinum, diaphragm, pericardium, phrenic nerve, azygos vein, or right or left pulmonary artery or even the mainstem bronchus have T3 tumors.[339,340] Stage II patients with N1 metastases may require more aggressive surgical strategies to remove all evidence of tumor. For example, one recent retrospective series of 124 patients with T1N1 or T2N1 disease suggested a survival advantage with pneumonectomy compared with a lobectomy in patients with hilar (level 10) lymph node involvement,[341] a finding supported by a lower local recurrence rate in the pneumonectomy patients. The risks of pneumonectomy must be considered for these individuals, because nodal metastasis at level 10 often portends occult distant metastases more so than inadequate local control. The relatively poorer survival as compared with stage I disease had prompted several clinical trials specifically for this subgroup of patients.

Mainstem Bronchus Tumor Less Than 2 Cm from the Carina

Even when the NSCLC lesion is located in the proximal airway a complete resection is feasible in some cases. Although pneumonectomy can be performed, specific techniques that spare noninvolved lung parenchyma are preferred.[314,342] These parenchymal sparing procedures include sleeve resection, bronchoplasty, pulmonary artery sleeve resection, pulmonary arterioplasty, and tracheal resection/reconstruction. Candidates for these procedures must be carefully staged by contrasted CT and bronchoscopy so as to permit surgical airway reconstruction.[314] Bronchial sleeve resection with or without pulmonary artery resection and reconstruction can be accomplished with excellent results and good long-term survival.[343–345] Morbidity, mortality, and functional data suggest that such reconstructions are comparable to lobectomy in terms of pulmonary function. Parenenchymal sparing techniques are infrequently required; however, they may be critical in individuals with marginal pulmonary reserve, and highly desirable in all others. Persons with N2 metastasis should not undergo thoracotomy. Five-year survival with complete resection is approximately 50%.[343–345]

Superior Sulcus Tumors

Superior sulcus tumors are apical masses that often extend to involve the chest wall, upper ribs, vertebral body, brachial plexus, stellate ganglion, or subclavian vascular structures.[346] These tumors account for roughly 3% of all NSCLC and always should be considered for surgery to improve function and relieve pain. Extension of apical tumors into the thoracic inlet may be accompanied by shoulder and/or arm pain, Horner syndrome, and occasionally paresthesias in the ulnar nerve distribution of the hand (fourth and fifth fingers). Patients with all these characteristics may be classified as having Pancoast syndrome.[346,347] Pain arises from involvement of the C8 and T1 nerve roots, whereas Horner syndrome (miosis, ptosis, anhidrosis, and enophthalmos) is caused by sympathetic nerve involvement. Frequently the first, second, and third ribs are involved, requiring resection.[347] Reconstruction of the defect is not required because the scapula and arm protect the defect. CT and MRI are used to assess treatment options. Reportedly, the complete resection (50%) and the 5-year survival (30%) rates for superior sulcus tumors have not changed for over 4 decades.[348] Historically superior sulcus tumors were treated with external beam irradiation (30 Gy) to the primary tumor before resection. However, no prospective trial has proven the benefit of this therapy over surgery alone, and several disadvantages may occur. The usual dose of irradiation is inadequate to completely control most tumors, and accelerated repopulation may occur. If negative surgical margins are not achieved, subsequent attempts to obtain local control via further irradiation can prove problematic. Resection of tumors abutting or invading the brachial plexus after radiation therapy also can be challenging. Finally, definitive postresection radiation therapy can be performed easily. In one retrospective review of 143 superior sulcus tumors, overall 5-year survival was 47% for stage IIB, 14% for stage IIIA, and 16% for stage IIIB superior sulcus tumors. Individuals without gross residual disease after surgical resection who received postoperative radiation therapy with total doses of 55 to 64 Gy had a 5-year survival rate of 82% as compared with the 5-year survival rate of 56% in persons who received 50 to 54 Gy.[349]

Because combined-modality therapy has improved outcome in other subsets of locally advanced NSCLC the North American Intergroup tested the feasibility of induction chemoradiation and surgical resection in superior sulcus tumors with the ultimate aim of improving resectability and survival.[348] Individuals with mediastinoscopy-negative superior sulcus tumors received two cycles of cisplatin and etoposide with concurrent irradiation (45 Gy), followed by resection 3 to 5 weeks later. More than 90% of patients had a complete resection, and postoperative mortality was 2.4%. A complete pathologic response or microscopic residual disease only was noted in 65% of all resected specimens. Two-year survival was 55% for all patients and 70% for patients with an R0 resection. Local failure rates are improved with this strategy. Systemic failure, mostly cerebral metastases, occurs in about 25% of patients. Although this approach has not been compared to surgical intervention with or without postoperative irradiation, it has become the default standard of care for patients meeting the eligibility criteria of this study. Accordingly we believe a multidisciplinary approach is warranted in all cases of superior sulcus tumors with attention to the need for preoperative induction therapy and the use of alternatives to surgery (e.g., definitive chemotherapy and radiation therapy) for medically inoperable patients.

Mediastinal Involvement

Mediastinal involvement is generally identified at the time of operation with tangential involvement of the mediastinal pleura, pericardium, phrenic nerve, or mediastinal fat. Complete resection of the primary tumor en bloc with the mediastinal structure is recommended in an otherwise suitable patient. Unilateral phrenic nerve resection is appropriate if negative margins can be achieved.

Chest Wall Invasion

In the absence of other contraindications to surgery, tumors invading the chest wall should be considered for complete resection. Reconstruction of the chest wall with a muscle flap or patch may also be performed.[350] In the case of pleural invasion and chest wall involvement, en bloc resection is advised over extrapleural resection, because of significantly more favorable survival rates.[350,351] Long-term survival is stage and sex dependent. The best survival is observed in women who have T3N0M0 disease.[351] Persons found to have N2 disease should be managed with multimodality therapy as outlined later in this chapter. Adjuvant irradiation is not recommended for patients with complete resection of T3 chest wall NSCLC but may be considered for local control in patients with positive resection margins.

Stage IIIA Locally Advanced Lung Cancer

Stage IIIA NSCLC constitutes roughly 30% of all NSCLC patients at diagnosis.[317] It is an extraordinary heterogeneous category of patients with metastatic disease to the ipsilateral mediastinal (N2) lymph nodes and also includes T3N1 patients. Approximately one third of stage IIIA patients present with ipsilateral N2 lymph node metastases. Presentations of disease can range from apparently resectable tumors with occult microscopic nodal metastases to unresectable, bulky multistation nodal disease. It is the latter group that constitutes one of the more therapeutically challenging and controversial subsets of NSCLC, with a published 5-year survival of only 23%. Accordingly, the management of IIIA NSCLC patients challenges the surgeon and the multidisciplinary team given the heterogeneity of the local disease and the variable, yet common, occult systemic metastasis.

Clinical staging of stage IIIA typically involves both diagnostic imaging and invasive staging. Invasive staging with pathology examination of lymph node or other tissues further describes the extent of the disease needed to optimally determine treatment decisions. Pathologic staging occurs after resection and typically reveals a spectrum of disease extent. Patients with enlarged mediastinal lymph nodes must undergo mediastinoscopy as node size alone does not predict pathologic findings. Patients with positive N2 nodes determined preoperatively should be referred for definitive chemotherapy and radiation therapy, or entry into a prospective clinical trial (which may or may not evaluate resection as a therapeutic intervention; see later discussion). Resection following chemotherapy and radiation therapy, so-called trimodality therapy, should not routinely take place outside of a clinical trial or without a multidisciplinary plan to include resection established before initiation of therapy.

In each situation a spectrum extends from occult, unrecognized IIIA disease (typically identified after resection such as T3 with N1 nodal involvement, or microscopic N2 disease in the mediastinal lymph node dissection specimen) and single-station N2 disease identified by mediastinoscopy or guided by FDG-PET, to multistation and/or bulky mediastinal N2 disease identified by CT, FDG-PET, or mediastinoscopy. If the surgeon finds involved but resectable mediastinal nodal disease at the time of operation, a complete anatomic resection and mediastinal lymph node dissection is recommended. If the individual has many involved N2 stations, or bulky mediastinal disease, then the decision to proceed with resection must balance risk and benefit (e.g., improved local control). If the patient is at high medical risk for resection (advanced disease with poor predicted survival), then the operation should be aborted and concurrent chemoradiation therapy initiated.

"Incidental" N2 Disease

Despite a careful preoperative staging evaluation, as many as a quarter of patients will be found to have metastases to N2 nodes at the time of thoracotomy.[352–354] Frequently occult N2 disease is identified only at the time of final pathologic examination of the surgical specimen. In other individuals, metastases will be found on intraoperative frozen-section examination of mediastinal nodes. For individuals

with an occult, single-station mediastinal node metastasis recognized at thoracotomy in which a complete resection of the nodes and primary tumor is technically possible, most thoracic surgeons proceed with the planned lung resection and a mediastinal lymphadenectomy. If a complete resection is not possible or there is multistation or bulky nodal disease or extracapsular nodal disease, then the planned lung resection should be aborted. These patients can then be considered for multimodality therapy as described later in this chapter. Although incomplete resection rarely results in long-term survival, collected results indicate that surgery alone in stage IIIA disease (N2 disease) is associated with a 14% to 30% 5-year survival. The best survival is seen in cases with minimal N2 disease and complete resection.[354]

"Clinically Evident" N2 Disease

Individuals with stage IIIA clinically evident N2 disease present more of a problem. Induction chemotherapy (±preoperative radiation therapy) has the theoretical attraction of improving the "resectability" of patients with "bulky" N2 disease stage IIIA (N2) disease based on the premise that improved resection rates would translate into improved overall survival. Both small single-institution studies and multi-institutional trials support this possibility.[355–357] However, such trials are usually inadequately powered to provide definitive proof. Concern vis-à-vis perioperative morbidity has limited this approach to a large extent.[358] More recently data have emerged that suggest induction therapy does not increase the risk of survival complications compared to surgery alone based on a clinical and pathologic stage-specific analysis.[311]

In an important but as yet unpublished North American Intergroup study (INT-0139), individuals with clinical stage IIIA-N2 (T1–3pN2M0) NSCLC, a good performance status (PS) (Eastern Cooperative Oncology Group [ECOG] PS: 0–1) and considered technically resectable at initial evaluation were randomized to induction chemotherapy–radiation therapy followed by surgical resection or chemotherapy–radiation therapy alone.[359] Progression-free survival but not overall survival was improved with resection after induction chemotherapy–radiation therapy. As found in other trials of induction therapy, pN0 status was associated with prolonged survival. Pneumonectomy accounted for 14/15 postoperative deaths and may have compromised overall survival. Thus, the trimodality approach used in this study cannot be considered standard of care for persons with positive N2 disease determined preoperatively. These individuals should be managed with combined chemoradiation therapy as outlined later if they are otherwise physically fit.

A multicenter European trial (EORTC 08941) was designed to determine the optimal local-regional treatment for NSCLC patients with positive N2 involvement.[360] Selected individuals with NSCLC with histologically or cytologically proven stage IIIA (N2) disease were initially treated with three cycles of platinum-based induction chemotherapy. Those individuals who responded to induction chemotherapy were then randomized to a radical resection with lymph node dissection and optional postoperative radiation therapy or thoracic radiation therapy (TRT) alone to a minimal dose of 40 Gy in 2-Gy daily fractions to the mediastinum, with a boost to at least 60 Gy on the involved field. With a median follow-up of 72 months, median (16.4 vs.17.5 months) and 5-year survival rates (16% vs. 13%) were not significantly different between the two arms (HR 0.95, 95% CI 0.75–1.19; $P = 0.6$).

The downstaging of pN2 to pN0 that may occur with induction therapy seems to be important in identifying patients with improved chances for survival. In a phase II trial conducted by the Southwest Oncology Group (SWOG 8805) persons with clinical stages IIIA or IIIB disease received induction chemotherapy–radiation therapy followed by resection. This strategy provided a pathologic complete response in 22% and an overall 3-year survival rate of 27%. Notably, individuals with no residual mediastinal lymph node involvement had a median survival of 30 months compared with 10 months for those with with residual disease ($P = 0.0005$).[361] Whether or not patients without pathologic downstaging of N2 disease should undergo surgery is controversial. In a subset analysis of the aforementioned EORTC study 08941, it was determined that failure to downstage to pN0 after induction chemotherapy portended a worse outcome that may be improved with the application of postoperative radiation therapy. However, surgical resection in this subset of patients was not apparently beneficial.[362] These data warrant prospective validation.

Pulmonary resection after induction chemotherapy–radiation therapy presents several technical challenges. For example, patients who have received in excess of 50 Gy during their neoadjuvant treatment have a higher rate of serious complications such as bronchopleural fistula, prolonged air leak with empyema, and prolonged postoperative ventilation; therefore, the dose should be limited to 45 Gy. The sequelae of chemotherapy–radiation therapy include dense fibrous tissue in the hilum and mediastinum, and tissue planes are often obliterated.

Outside of a clinical trial, individuals with bulky or multistation N2 disease should not be considered for trimodality therapy. These individuals are usually treated with alternatives to resection such as chemoradiation (see later discussion). Trimodality therapy should be used only in rare circumstances. Even if mediastinal nodes are downstaged to pN0 the usefulness of surgical resection remains highly questionable.[363] Moreover, although repeat cervical mediastinoscopy can be performed, the risks of this repeat operation after mediastinal chemoradiation therapy are greater than standard mediastinoscopy. Alternatives to the initial mediastinal staging include esophageal ultrasound and transbronchial ultrasound.[364] Without question, resection should be avoided after induction therapy in persons who have biopsy-proven residual tumor in the mediastinal nodes.

Unresectable N2 Disease

In general, individuals with histologically involved lymph nodes larger than 2 cm in short-axis diameter measured by CT, who have extranodal involvement or multistation disease along with groups of multiple involved smaller lymph nodes, are considered to have bulky, unresectable disease. These individuals are referred for protocols involving chemoradiation as described later in this chapter if they are functionally fit to tolerate the therapy.

Stage IIIB Locally Advanced Lung Cancer

Stage IIIB includes individuals with T4, any N, M0, and any T, N3, M0[365] (e.g., tumor invading into the trachea, carina, esophagus, vertebrae, aorta, vena cava, great vessels, or atrium/cardiac structures; any N3 nodal description; malignant pleural effusion; or more than one nodule in one lobe). Resection with or without neoadjuvant chemotherapy or chemotherapy–radiation therapy is typically reserved for those persons with clinical T4-N0-M0 status in whom the tumor can be removed with negative margins (R0 resection). Survival may approach 25% to 30 % at 5 years for selected patients. Individuals with N3 lymph node involvement are not considered as surgical candidates. For those with unresectable disease, good performance score, and minimal weight loss, treatment with combined chemotherapy and radiation therapy has resulted in better survival than treatment with radiation therapy alone. Multiple daily fractions of radiation therapy have not resulted in improved survival compared to standard fractionation once daily.[365] Concurrent chemotherapy–radiation therapy seems to be associated with improved survival compared with sequential chemotherapy and radiation therapy (see later discussion).[365]

Carinal Resection

Tracheal resection and reconstruction for NSCLC is infrequently performed. More commonly, the extent of the disease requires a nonsurgical approach to include radiation therapy, or chemotherapy and radiation therapy. Palliative techniques include mechanical fulguration, laser ablation, or placement of expandable metal stents. Resection is reserved for localized endobronchial disease of the carina or very distal trachea but is contraindicated in the presence of N2 or N3 disease.[366] Resection of the carina with or without right pneumonectomy is performed with anastomosis between the trachea and the

left mainstem bronchus. Mediastinoscopy is required and reserved until the operation itself is planned so as to avoid any disruption of blood supply and to facilitate mobilization anteriorly. Consistent success requires excellent surgical technique and meticulous attention to detail. Gentle handling of tissue, avoiding disruption of the tracheal blood supply, anastomosis under no tension, and complete resection of the neoplasm with negative margins are necessary.[343,366,367]

Other Mediastinal Structures

Various mediastinal structures may be involved with tumor and may be resected and reconstructed as necessary.[368] The superior vena cava may be resected en bloc with the tumor and reconstructed with primary repair, patch venoplasty, or reconstruction with vascular graft. Limited resection of the left atrium or esophagus for tangential invasion would be appropriate if such resection would provide an R0 resection. The esophageal musculature can be removed, leaving the mucosa intact. Preoperative endoscopy is required for tumors that may abut the esophagus. Resection of the aorta with reconstruction is rarely performed. Individuals with involvement of the vertebral body would require en bloc resection of the tumor and anatomic portion of the lung, with the involved portion of the chest wall and vertebrae.[347] A multispecialty surgical team with thoracic surgery and either neurosurgery or orthopedic surgery, and stabilization of the vertebral column would be needed. Superior sulcus tumors with vertebral invasion can be treated with success.[369] Most patients resected in this small study had received external beam radiation therapy. The absence of perioperative mortality and a 2-year actuarial survival of 54% suggest that benefit can accrue to patients. Tumors that invade the vertebral column can undergo resection with posterior-lateral thoracotomy, lobectomy with en bloc chest wall resection, laminectomy, vertebrectomy, and anterior spinal column reconstruction with methylmethacrylate and spinal instrumentation.[347,369] Additional studies have examined the outcomes of superior sulcus tumors with a T3 or T4 status.[348] Five-year survival was 46% for stage IIB, 0% for stage IIIA, and 13% for stage IIIB.

Other T4 Presentations

Various other clinical presentations are included in stage IIIB NSCLC. These include satellite nodules, and extrathoracic or contralateral nodal metastasis (N3). A satellite nodule is a separate NSCLC of identical histology contained within the same lobe as the primary tumor. These are resectable with good survival. A satellite nodule is a secondary tumor nodule in the same lobe as the primary cancer having histology identical to that of the primary tumor. These are resectable with 5-year survival of 33%.[370] Such individuals should be carefully staged for occult nodal or distant metastasis. Even with treatment, persons with extranodal or contralateral nodal disease typically have poor survival (15% 5-year survival).[371] Although bilateral nodal dissection has been advocated by some Japanese surgeons, the presence of contralateral mediastinal disease or supraclavicular disease suggests a more widely advanced tumor that would be treated with chemotherapy and radiation therapy.[365,372]

Malignant Pleural Effusions

Patients with malignant pleural effusions frequently present with dyspnea, cough, and loss of function.[373] Symptomatic treatment is initially achieved via simple and complete drainage by thoracentesis. Those with a good performance status are subsequently managed like individuals with stage IV disease as described later in this chapter. However, many patients have recurrent effusions in which case treatment options may be much more varied. Treatment for individuals with initial or recurrent malignant pleural effusions should focus on relief of symptoms of dyspnea and restoration of normal activity.[373] The traditional practice of arbitrarily requiring pleural symphysis (obliteration of the pleural space), achieved by in-hospital drainage of the effusion followed by sclerosis with chemical or other agents, may subject the individual to a prolonged hospitalization or other interventions that may significantly reduce quality of life and remaining survival time outside the hospital. Persons with cancer frequently develop recurrent malignant pleural effusions secondary to their disease. In 25% of patients with cancer, malignant cells may not be identified by pathologic examination of the fluid. Median life expectancy in cancer patients with malignant pleural effusion ranges from 3 to 9 months depending upon the histologic subtype of the primary tumor. In one prospective randomized study, the median survival time for all persons with malignant pleural effusions was 90 days.[374]

Treatment options for malignant pleural effusion include thoracentesis or repeat thoracentesis; tube thoracostomy, drainage, and sclerotherapy using talc, bleomycin, or other material; placement of a chronic indwelling pleural catheter[374,375]; and thoracoscopy with drainage and talc insufflation. In the past, successful treatment of malignant pleural effusions required hospitalization for chest tube drainage, sclerosis, and, hopefully, pleural symphysis followed by removal of the drainage catheters. If pleural symphysis could not be achieved during the individual's hospitalization the treatment was considered "failed," and the patient was then treated with the best available means. Pleurodesis was required for discharge. In contrast, today's patient-centered treatment focuses on relief of the patient's symptoms and restoration of normal function. Pleurodesis is not necessarily required to accomplish these goals.[373]

Stage IV Non-Small Cell Lung Cancer

In individuals with metastatic NSCLC, surgery is reserved for palliation of symptoms or resection of metastases with significant local manifestations (e.g., brain metastasis and seizures).[376] Persons with two synchronous nodules of NSCLC with identical histology in different lobes have M1 disease by the current staging system, although it is impossible to exclude synchronous stage I NSCLC by clinical means alone. When doubt exists, the benefit of resection should be considered in selected physiologically fit individuals. Appropriate staging with CT and PET scanning and cervical mediastinoscopy is required. If there is no evidence of nodal or other metastatic disease, and the nodules are completely resectable with an appropriate risk-to-benefit ratio, then resection could be considered.[377,378]

Brain metastases are often seen in individuals with NSCLC, and although they are frequently multiple, a subset of patients with a solitary brain metastasis (with controlled primary tumor) is occasionally encountered in clinical practice. Patients with isolated brain metastases may do well with resection of the symptomatic lesion.[379,380] Although treatment of a solitary brain metastasis is usually surgical whenever possible, the development of new stereotactic techniques of radiation therapy using a linear accelerator or the gamma knife provides new potential treatment options.[381] Before resection all patients should have additional staging to include CT and PET scans. In those considered as candidates for resection, cervical mediastinoscopy should also be performed even if the preoperative CT reveals no enlarged nodes, and the PET demonstrates no FDG-avid lesions. The primary lung tumor is then treated according to T and N stage.[379,380] Survival may range between 20% and 40% at 5 years.

Hematogenous metastases to the adrenal gland and elsewhere, in general, portend a poor survival, and although isolated reports of resection have occurred, this treatment strategy is not uniformly successful.[376,382–384] Resection of metastatic lung cancer with curative intent is not recommended, because adrenal and other extrathoracic metastases represent systemic metastases.[382] The curious survival advantage seen in some patients may be related to overdiagnosis bias in individuals with early primary-stage disease.

Experimental Surgical Techniques

Experimental techniques for treatment of parenchymal NSCLC in medically inoperable individuals include radiofrequency ablation and stereotactic thoracic radiation.[385,386]

Second Primary Tumors or Metastasis

Recurrent tumors may be resected safely and with good survival. Generally, lung cancer that recurs with identical histology within 2

years is considered a metastasis; lung cancer that recurs after 2 years is considered a second primary. Patients with resection of second (metachronous) primary lung cancers can have up to 5-year survival of 40% after resection that is based on the T and N status of the second primary.[336,338,387] A completion pneumonectomy, if required, can be performed safely, with good local control achieved, and as much as a 25% 5-year survival.

In summary, the thoracic surgeon must balance the risks from mechanical extirpation of lung cancer (local disease control, pain relief, improved survival) and the benefits of improvement in survival and quality of life. Typically, when the risks are high, resection is not considered; however, in some high-risk patients risk may be successfully managed with good local control and survival.[314] Resection of NSCLC can be performed safely in most individuals who meet certain minimal physiologic thresholds. Consistency of approach, application of proven intraoperative and perioperative techniques, completeness of resection, and adequacy of mediastinal lymph node dissection all benefit the patient in optimizing local control and subsequent therapeutic decisions. Selection of optimal surgical treatment for individuals with NSCLC requires excellent pretreatment staging and clinical evaluation with discussion of all therapeutic possibilities by the integrated multidisciplinary care team: thoracic surgeon, pathologist, pulmonologist, radiation oncologist, medical oncologist, and allied specialties. Individuals with advanced-stage lung cancer (i.e., stage IIIA or greater, biopsy-proven N2, etc.) inconsistently benefit from resection alone, because the risks of resection frequently do not exceed the benefits.[314] In selected individuals resection of advanced-stage lung cancer may be desirable for local tumor control (alone or as part of a multidisciplinary treatment plan), palliation of symptoms, improved quality of life, and the potential for improved survival. Few prospective multi-institutional clinical trials have specifically addressed surgery compared to other therapies for early-stage disease. Future clinical trials should consider accurate and noninvasive measures of local control and recurrence, specific measures of response, quality-of-life measures, as well as overall and disease-free survival.

Adjuvant Chemotherapy

Until recently convincing evidence supporting the routine use of postoperative adjuvant chemotherapy in resected NSCLC was lacking. Notably, an evaluation of adjuvant studies completed before 31 December 1991 was included in a landmark 1995 meta-analysis of 52 randomized chemotherapy trials in NSCLC.[388] Globally no improvement in overall survival was identified following postoperative chemotherapy. However, when the data were analyzed by composition of the adjuvant chemotherapy regimen, there was a nonsignificant 13% reduction in the risk of death observed with platinum-based regimens that translated into an absolute survival benefit of 5% at 5 years ($P = 0.08$).[388] The magnitude of the survival benefit was similar to that observed with adjuvant chemotherapy in early-stage breast cancer,[389] prompting several groups to initiate a new series of adjuvant trials in NSCLC using a newer and more efficacious generation of platinum-based chemotherapy regimens.[390–396] A few of the recent studies also permitted the use of postoperative radiation therapy. Meta-analyses of these data estimate a relative risk reduction in mortality of 11% to 13% at 5 years.[397–399] Collectively the results of these trials clearly support the use of postoperative therapy in individuals with good performance status with stage II or IIIA NSCLC (Table 76-9).[400–402]

Much less clear and far more controversial is the role adjuvant chemotherapy plays in the management of individuals with resected stage I NSCLC.[401–403] The controversy stems in part from subgroup analyses of recently completed adjuvant trials data that suggest stage I patients do not obtain a meaningful survival improvement following postoperative chemotherapy.[393,394] This is somewhat surprising, in that extrathoracic metastases are the most common site of recurrence in resected individuals with stage I disease,[404] and one would predict a favorable effect with systemic therapy. Nonetheless, the verisimilitude of the subgroup analyses was bolstered by the negative results of a Cancer and Leukemia Group B (CALGB 9633) phase III trial that specifically addressed the utility of adjuvant chemotherapy in stage IB NSCLC.[395,405] Although the initial report of the CALGB

†2-year survival.

study indicated that postoperative carboplatin and paclitaxel imparted a significant survival advantage compared with no adjuvant therapy,[405] the survival benefit was no longer apparent upon longer follow-up.[395] Five of the adjuvant chemotherapy trials listed in Table 76-9 were included in a recent meta-analysis[390,391,393,394,396]—the so-called Lung Adjuvant Cisplatin Evaluation (LACE) analysis.[398] Despite the increased statistical power, there was not a survival benefit among individuals with stage I NSCLC. In fact, there was a trend toward detriment with treatment in persons with stage IA disease. The effect of adjuvant chemotherapy in stage IB disease seemed to be neutral.

Three of the post-1995 meta-analysis adjuvant trials specifically addressed the question of postoperative chemotherapy in resected stage I NSCLC,[392,395,406] whereas a fourth study was limited to persons with stages IB and II disease.[393] None of the stage I-only adjuvant trials was included in the LACE meta-analysis.[398] Two of these trials demonstrated a statistically significant improvement in survival in stage I individuals given adjuvant chemotherapy.[392,406] Only the CALGB 9633 proved negative for a survival improvement, although interestingly disease-free survival was statistically significantly improved with chemotherapy.[395] Collectively the data derived from studies confined to stage I NSCLC suggest there may be some patients with stage I disease who benefit from adjuvant chemotherapy. This is not too surprising, because stage I NSCLC is a heterogeneous disease that in some circumstances carries a prognosis that rivals that of stage II or stage IIIA disease (e.g., large primary lesions >5 cm; visceral pleural involvement).[407,408] Adjuvant therapy may be appropriate for such individuals, provided he or she understands the risks of treatment. Our approach to resected stage I NSCLC is outlined in the accompanying algorithm (Fig. 76-15).

There are several promising technologies on the horizon that may soon permit oncologists to prospectively assign persons with NSCLC into "good" or "bad" survival categories and help guide treatment decisions.[76,78,81] However, until these newer technologies are proved to be reliable predictors of treatment response and survival, clinical judgment is still required when making a decision to offer adjuvant chemotherapy to individuals with resected NSCLC. Most experts agree that adjuvant therapy should be limited to those with a good performance status (i.e., ECOG PS = 1), few comorbidities, and a relatively short postoperative recovery period (i.e., <8 weeks).[400–402]

Adjuvant Radiation Therapy

Individuals with resected node-negative lung cancer do not benefit from adjuvant radiation therapy.[4,409–411] Likewise, randomized trials studying the efficacy of adjuvant radiation therapy after surgical resection of persons with N2 disease have shown no improvement in survival.[411,412] A recent clinical trial studied overall survival, progression-free survival, and toxicity associated with concurrent paclitaxel plus carboplatin and TRT for patients with completely resected stage II and IIIA NSCLC.[413] Eighty-eight eligible individuals had surgical resection for pathologic stage II or IIIA disease and received postoperative paclitaxel and carboplatin. Concurrent TRT at 50.4 Gy in 28 fractions for 6 weeks was given. A boost of 10.8 Gy in six fractions was given for extracapsular nodal extension or T3 lesions. The median overall survival time was 56.3 months, with 1-, 2-, and 3-year survival rates of 86%, 70%, and 61%, respectively. Local failure was a component of first failure in 15% of these individuals. Our current practice is to consider postoperative radiation therapy when surgical resection is incomplete (positive surgical margins), surgical margins are close (≤1 mm), or when there is extracapsular extension from lymph node metastases.

Neoadjuvant Chemotherapy

Neoadjuvant or induction chemotherapy offers several potential advantages compared with adjuvant chemotherapy, such as improved compliance and drug delivery, early control of micrometastases, and reduction of the primary tumor size before surgery, thus allowing for more conservative and possibly complete resection of the tumor.[414–416] Several phase II clinical trials have shown that induction chemotherapy is safe and feasible, with no significant increase in surgical complications, and results in favorable survival rates in persons with resectable NSCLC (see reviews[414–416]). Improved survival is seemingly greatest in individuals in whom a complete pathologic response is achieved.[417] Randomized neoadjuvant chemotherapy trials, however, have revealed conflicting results.[418,419]

Initial enthusiasm for neoadjuvant chemotherapy originated in part with the publication of two small randomized trials conducted exclusively in persons with N2-positive stage IIIA NSCLC.[356,357] Although these trials closed prematurely as a result of accrual problems, both studies yielded a positive survival advantage with neoadjuvant therapy. Subsequently, two larger phase III trials were undertaken in an attempt to validate these results and extend the observation with earlier stage, resectable NSCLC.[355,420] The first of these was conducted by the French Thoracic Cooperative Group in which individuals with stage I through IIIA NSCLC were randomized to surgery or surgery combined with two cycles of neoadjuvant mitomycin, ifosfamide, and cisplatin.[355] Two cycles of postoperative mitomycin, ifosfamide, and cisplatin were administered to responding individuals. In addition, persons with pathologic T3 or N2 disease or incomplete resection received postoperative radiation therapy. There was a statistically non-significant 3.8% (95% CI, 1.3% to 25.1%) improvement in 1-year survival increasing to 8.6% (95% CI, 2.64% to 24.4%) survival benefit at 4 years in persons treated with preoperative chemotherapy. This benefit, however, was seemingly limited to persons with N0 and N1 disease (relative risk [RR], 0.68, 95% confidence interval [CI], 0.49–0.96, $P = 0.027$).[355] Neoadjuvant chemotherapy was associated with nonsignificant higher perioperative mortality (9% vs. 5%), a problem not reported by others.[311,356,357] Complicating the interpretation of these data were potentially important differences in the patient characteristics and treatment of the two arms. For example, almost twice as many patients in the chemotherapy arm had N2 disease (40% vs. 28%), whereas almost twice as many patients in the surgery-alone arm

received postoperative radiation therapy (48% vs. 28%). These differences may or may not have contributed to the overall outcomes.

A U.S. Intergroup study (S9900) enrolled individuals with clinical stages IB through IIIA NSCLC (T2N0, T1–2N1, and T3N0–1) into a randomized study of surgery alone or surgery preceded by three cycles of paclitaxel and carboplatin.[420] Individuals with superior sulcus tumors were excluded. The study was closed prematurely with the recognition that postoperative adjuvant chemotherapy imparted a survival benefit in this group of individuals with NSCLC (discussed earlier). Neoadjuvant paclitaxel and carboplatin yielded an objective response of 40%. Although progression-free and overall survival tended to favor the neoadjuvant chemotherapy arm, these differences were not statistically significant (median and 2-year survivals were 42 months and 68% with neoadjuvant chemotherapy vs. 37 months and 64% with surgery alone; $P = 0.47$). There were six treatment-related deaths within 30 days of surgery in the neoadjuvant arm compared with three deaths in the surgery-alone arm.

A recent literature-based meta-analysis examined the role of induction chemotherapy in early-stage NSCLC.[419] The analysis involved all randomized studies conducted between 1965 and 2004 published in English or French. The overall hazard ratio was 0.66 (95% CI, 0.48–0.93) in favor of the addition of induction chemotherapy to a standard surgical procedure. Although the trend was in favor of neoadjuvant chemotherapy in stage III disease (HR = 0.65; 95% CI, 0.41–1.04), it was not statistically significant. By contrast, a second meta-analysis evaluating trials published between 1994 and 2004 failed to note a survival advantage for persons with resectable NSCLC who had preoperative chemotherapy.[421]

At the present time the role of induction chemotherapy remains ill-defined. Similar to other solid tumors (e.g., breast cancer), neoadjuvant chemotherapy may ultimately prove useful in rendering a marginally resectable lesion more amenable to definitive resection but without imparting a positive survival benefit. Only prospective trials will answer this question. However, defining the optimal candidate for preoperative versus postoperative chemotherapy comparative trials will prove challenging. Our approach has been to treat individuals with clinical stage I and II disease with surgery and to administer postoperative adjuvant chemotherapy to those who are appropriate candidates as described previously. Individuals with so-called marginally resectable lesions are assessed on a case-by-case basis. We are more inclined to administer neoadjuvant chemotherapy to those with minimal involvement of N2 lymph nodes. Persons with multiple positive N2 disease are not thought to be candidates for surgery and are treated with concurrent chemotherapy–radiation therapy as discussed later.

Neoadjuvant Chemotherapy–Radiation Therapy

The addition of TRT to preoperative chemotherapy further increases the frequency of pathologic clearance of mediastinal lymph nodes, suggesting that trimodality therapy (i.e., neoadjuvant chemotherapy–radiation therapy followed by surgery) might be superior to a bimodality approach.[416] To address this possibility several investigators have conducted trials combining induction chemotherapy with radiation given either sequentially or concurrently before surgery for individuals with stage III NSCLC (see review[416]). A variety of cisplatin-based chemotherapy regimens have been administered in combination with various total doses of TRT (typically 30–45 Gy) given once or twice daily, and some trials even included stage IIIB patients (excluding pleural effusions). For example, SWOG investigators administered concurrent TRT (45 Gy) with two cycles of induction cisplatin plus etoposide to 126 patients with biopsy-proven stage IIIA (N2) or IIIB NSCLC.[361] Persons who experienced an objective response or stable disease were taken to definitive resection. The objective response rate to induction was 59%, and 29% had stable disease. Resectability was 85% for the IIIA group and 80% for the IIIB group. Although 13 treatment-related deaths (10%) were observed, 3-year survival rates were 27% and 24%, respectively, for stage IIIA (N2) and IIIB disease. As noted by others, the strongest predictor of long-term survival after thoracotomy was absence of tumor in the mediastinal nodes at surgery (3-year survival: 44% vs. 18%; $P = 0.0005$).

The phase II trials of preoperative chemoradiation yielded results that were similar to the induction chemotherapy-alone trials in terms of response, resection, and survival rates.[416] The need for surgery also in the treatment of individuals with N2-positive stage IIIA NSCLC has not been fully determined. Intergroup trial 0139 was designed to address this controversy and prospectively compared preoperative concurrent chemotherapy–radiation therapy to concurrent chemotherapy–radiation therapy alone.[359] Eligible patients had a good performance status (0–1) and proven involvement of N2 nodes with no evidence of metastatic disease. All study participants received cisplatin and etoposide with concomitant TRT to 45 Gy starting day 1. The trimodality group went to a resection if there was no evidence of disease progression with induction therapy and then received two additional cycles of etoposide and cisplatin (EP). The bimodality group continued with TRT to a total dose of 61 Gy with EP for two additional cycles. Although progression-free survival was superior following trimodality therapy, this did not translate into an improvement in 5-year survival (27.7% vs. 20.3%; $P = 0.10$). There were 16 treatment-related deaths in the trimodality arm (10 within 30 days of surgery) and 4 treatment-related deaths in the bimodality arm. Postoperative mortality was particularly high in those requiring simple or complex pneumonectomy. Improved long-term survival was observed in persons with downstaging from positive to N2 to N0 disease at surgery (5-year survival: pN0 = 41%; pN1–3 = 24%; no surgery = 8%; $P < 0.0001$). This is similar to several smaller studies that have highlighted the importance of N0 disease at the time of resection following neoadjuvant chemotherapy–radiation therapy.[416,417]

Although these data are intriguing, there remain no data that definitively prove that radiation therapy improves outcome over chemotherapy and surgery, or that surgery adds to the therapeutic efficacy of chemotherapy and radiation therapy.[416] The subsets for which trimodality treatment is preferred include patients with T4N0–1 disease and superior sulcus tumors. Cancers located in the superior sulcus are difficult to resect and frequently have residual disease after resection. For these reasons, neoadjuvant chemotherapy–radiation therapy is indicated before thoracotomy.[348] Our current practice is to only use neoadjuvant chemotherapy and radiation therapy when this therapy is needed to facilitate resection of locally extensive tumors such as superior sulcus tumors. Moreover, a strong statement can be made that patients who will require a pneumonectomy should NOT be considered for a trimodality approach and should be treated with concurrent chemotherapy–radiation therapy.

Treatment of Locally Advanced Unresectable Non-Small Cell Lung Cancer

Locally advanced NSCLC consists of stages IIIA (T3N1M0 or T1–3N2M0) and IIIB (T4NanyM0 or TanyN3M0) and is considered unresectable in all but the most unusual of cases.[317,365,372] Nonetheless, with the exception of the subset of persons with malignant pleural effusion, individuals with stage III lung cancer are treated with curative intent.[317,365] Individuals with malignant pleural effusion preferentially are treated with chemotherapy (see later discussion; metastatic disease). Until the 1980s radiation therapy alone had been the standard of care for locally advanced NSCLC despite dismal survival results.[422–424] Using standard traditional radiation doses and technique, survival rates of 40%, 15%, and 5% were achieved at 1, 2, and 5 years respectively.[422–424] During the early 1990s, however, results of many randomized phase III studies shifted the standard toward concurrent chemoradiation therapy.[424] The key trials that led to the evolution in treatment of locally advanced NSCLC are described later. In addition, recent technologic advances in radiation therapy and novel chemotherapeutic approaches have provided pre-

liminary data for further improving clinical outcome while minimizing the morbidity associated with the therapy.[423]

Sequential Chemoradiation versus Radiation Alone

With sequential chemoradiation, full doses of both modalities can be delivered without compromise of either. The rationale behind the sequential combination of chemotherapy and radiation therapy is based on the premise that radiation therapy addresses the local-regional disease whereas chemotherapy acts systemically to eradicate micrometastases. The first large-scale trial to demonstrate a survival benefit with sequential chemoradiation therapy compared to standard radiation therapy alone was conducted by the Cancer and Leukemia Group B (CALGB); (Table 76-10).[425] These investigators administered cisplatin and vinblastine before standard TRT (i.e., 60 Gy over 6 weeks) and observed an improvement in median and long-term survival (23% vs. 11% at 3 years). These findings were later validated by a North American Intergroup trial (Radiation Therapy Oncology Group [RTOG] 88–08) in which persons with unresectable NSCLC were randomized to one of two radiation-alone arms (daily to 60 Gy or twice daily to 69.6 Gy), or to a third arm of induction chemotherapy with cisplatin and vinblastine followed by daily radiation therapy to 60 Gy.[426,427] Similar to the CALGB trial, there was a statistically significant improvement in median survival with sequential chemoradiation therapy, compared with those of the two arms using radiation therapy alone (see Table 76-10). These in addition to other landmark trials consistently demonstrate a significant survival benefit with the addition of induction chemotherapy over conventional or hyperfractionated irradiation alone. Induction chemotherapy seems to reduce the number of distant relapses, which translates into a modest benefit in survival. As a result of these studies, sequential chemoradiation became the basis for comparisons in clinical trials of the 1990s.

Sequential versus Concurrent Chemoradiation Therapy

The mechanism of chemotherapeutic radiosensitization is thought to be direct inhibition of repair of radiation-induced damage; elimination of radioresistant, chemosensitive clones; and/or suppression of interfraction tumor repopulation.[428] Concurrent chemoradiation addresses both distant and local-regional disease simultaneously. The two modalities should act synergistically on tumor clonogens susceptible to both modalities and in a complementary fashion on local-regional clonogens that are susceptible to only one of the modalities. The superiority of concurrent chemotherapy with radiation therapy compared with sequential chemotherapy followed by irradiation was conclusively demonstrated in large multicenter trials.[429–431] In the first of these trials, Japanese investigators randomized individuals with locally advanced NSCLC to receive either concurrent or sequential chemoradiation therapy.[431] Chemotherapy consisted of mitomycin (8 mg/m^2 days 1 and 29), vindesine (3 mg/m^2 days 1, 8, 29, and 36), and cisplatin (80 mg/m^2 days 1 and 29). TRT (56 Gy) was administered as a split course in the concurrent arm but was given continuously in the sequential arm. Overall response rate and survival were statistically significantly improved with concurrent chemotherapy–radiation therapy (Table 76-11). The survival benefit seemed to be due primarily to improved local tumor control based on a marked improvement in local failure-free survival (30 vs. 11 months), whereas

distant failure rates were similar at approximately 50%. These findings recapitulate earlier reports of improved local tumor control without improvement in the rate of distant metastasis when cisplatin is administered with split-course radiation therapy.[432]

The RTOG addressed the question of sequential versus concurrent chemotherapy–radiation therapy in study 9410.[429,433] The trial also included a third arm designed to assess the value of twice-daily irradiation in conjunction with chemotherapy. Chemotherapy consisted of cisplatin and vinblastine. The twice-daily radiation therapy arm demonstrated improved local control without improving survival, whereas the concurrent chemotherapy–radiation therapy arm was superior to the sequential treatment in terms of local control, median survival (17.0 vs. 14.6 months; $P = 0.0038$), and 4-year survival rate (21% vs. 12%; $P = 0.046$; see Table 76-10). Acute grade 3 to 5 toxicities were more frequent in the two concurrent chemotherapy–radiation therapy arms. However, the differences in late effects were not statistically significant.

French investigators also compared sequential and concurrent chemotherapy–radiation therapy in individuals with unresectable stage III NSCLC.[430] Sequential therapy consisted of three cycles of cisplatin (120 mg/m^2) every 3 weeks and weekly vinorelbine (30 mg/m^2 per week) followed by TRT (66 Gy in 33 fractions), whereas the concurrent arm used the same radiation therapy with simultaneous initiation of daily cisplatin (20 mg/m^2 daily) and etoposide (50 mg/m^2 per day) on days 1 to 5 and 29 to 33. The concurrent arm then received two courses of consolidation therapy with cisplatin (80 mg/m^2) and vinorelbine (30 mg/m^2 per week). Treatment-related deaths (10 vs. 3) and WHO grade 3 to 4 esophageal toxicity (32% vs. 3%; $P < 0.0001$) were significantly more frequent in the concurrent arm than in the sequential arm. Median survival (16.3 vs. 14.5 months) and 4-year survival rates (21% vs. 14%) were not statistically significantly different; this result the investigators attributed to insufficient powering of the trial (see Table 76-11). However, an alternative explanation might be the excess of toxic deaths in the concurrent arm, which in turn may be attributable to the dose and scheduling of cisplatin and vinorelbine. Less life-threatening toxicity has been observed with different doses and scheduling of these agents without an apparent compromise in overall efficacy.[424]

These and similar trials[434] consistently demonstrate a survival advantage for the concurrent chemotherapy–radiation therapy as opposed to the sequential use of chemotherapy followed by TRT but always with an increase in host toxicity—most specifically with respect to an increase in treatment-related esophagitis. Of concern is the modest but clinically meaningful increase in treatment-related deaths accompanying concurrent chemotherapy–radiation therapy in some of the aforementioned trials. Nonetheless, the results from these trials established concurrent chemoradiation therapy as the current standard for locally advanced NSCLC in good-performance-status patients with limited comorbidities.

Concurrent Chemoradiation Therapy with Consolidation or Induction Chemotherapy

Building on the survival benefits achieved with concurrent chemotherapy–radiation therapy in locally advanced NSCLC, SWOG investigators conducted a series of sequential phase II trials designed to assess the benefit of consolidation therapies in locally advanced NSCLC (Table 76-12). The first of these trials, S9019, assessed the feasibility and impact on long-term survival of full-dose cisplatin and etoposide given during and after full-dose TRT (61 Gy).[371] The study enrolled only individuals with pathologically confirmed stage IIIB NSCLC and yielded a median survival time of 15 months and 5-year survival of 17%. In a follow-up study (S9504), 83 individuals with pathologic stage IIIB NSCLC were treated with the same regimen of cisplatin and etoposide with concurrent TRT followed by docetaxel.[435,436] With a median follow-up of 71 months, median survival time was 26 months, and the 5-year survival rate was 29%. Long-term survival compared favorably with the data from the SWOG S9019 study. Despite a lack of phase III confirmatory data, this regimen became the reference arm for a third SWOG trial (S0023) in which patients were randomized to gefitinib, an inhibitor of the EGFR tyrosine kinase, or a placebo.[437] Notably, the median survival of patients randomized to gefitinib was dramatically lower than that of patients given a placebo (19 vs. 29 months; $P = 0.09$). This trial was closed early, because gefitinib was deemed unlikely to improve overall survival. At the same time SWOG S0023 was under way, the Hoosier Oncology Group (HOG) undertook a phase III trial (LUN-01–24) designed to confirm the results of SWOG trial S9504 (i.e., to evaluate the role of consolidation docetaxel in individuals with unresectable stage III disease).[438] In the HOG study, persons with stage III NSCLC and no evidence of local disease progression or distant metastases were randomized to receive docetaxel or observation after completing concurrent cisplatin and etoposide with TRT. The HOG trial recently closed on the recommendation of a Data and Safety Monitoring Committee as a consequence of a statistical improbability that the docetaxel arm would yield an increase in overall survival. (Overall median survival = 21.15 months; median survival for those taking docetaxel = 21.6 months vs. 24.2 months for those in the observation arm; $P = 0.94$.)[439]

In contrast to SWOG, CALGB investigators opted to evaluate the role of induction chemotherapy with concurrent chemotherapy–radiation therapy based on their long-standing interest in the use of induction chemotherapy.[440] In CALGB 39801 individuals with unresectable stage III NSCLC were randomized to immediate concurrent

chemotherapy–radiation therapy (i.e., carboplatin AUC = 2 and paclitaxel 50 mg/m^2 each given weekly during 66 Gy TRT; 182 patients) or two cycles of induction carboplatin (AUC 6) and paclitaxel (200 mg/m^2) followed by concurrent chemotherapy–radiation therapy.[441] There were no differences in survival outcomes (median and 1-year survival of 11.4 and 14.6 months and 48% to 58% respectively; $P = 0.154$), although follow-up is short (see Table 76-12). Curiously, the results of both arms were somewhat inferior to historical controls and the results in the control arms of the studies listed in the preceding section. Nonetheless, the results of this study suggest that induction chemotherapy before concurrent chemoradiation is not beneficial.

The American College of Radiology conducted a randomized phase II study designed to determine the optimal sequencing and integration of chemotherapy with standard daily TRT in individuals with locally advanced unresectable stages IIIA and IIIB NSCLC.[442] This trial, better known as the Locally Advanced Multimodality Protocol (LAMP) study, randomized patients to induction chemotherapy followed by irradiation (arm A), induction chemotherapy followed by concurrent chemoradiation (arm B), or chemoradiation followed by consolidation chemotherapy (arm C; see Table 76-12). Participants received full systemic doses of carboplatin and paclitaxel as induction or consolidation therapy and weekly low doses of carboplatin and paclitaxel during concurrent chemotherapy–radiation therapy. All patients received TRT to 63 Gy. The LAMP trial suffered from poor accrual and was terminated before enrolling the target number of patients. Nonetheless, LAMP is the only large trial directly comparing induction and consolidation chemotherapy in the setting of concurrent chemoradiation. With a median follow-up time of more than 3.5 years, median overall survival was virtually identical in the induction arms (arm A 13.1; arm B 12.7 months) and longest with the concurrent chemotherapy–radiation therapy–consolidation approach (16.3 months). Toxicity, however, was greater in the latter arm. The results of the LAMP trial suggest a benefit of consolidation chemotherapy following concurrent chemotherapy–radiation therapy,[442] although these results can hardly be considered definitive because of inadequacies in the study design and imbalances in prognostic factors among the three arms.[424] Likewise, the role of consolidative docetaxel after full-dose EP and concomitant chemoradiation therapy is not supported by phase III data.[438] Neither docetaxel nor gefitinib is recommended as consolidation therapy following concurrent chemotherapy–radiation therapy for locally advanced NSCLC given the lack of a survival advantage and an increase in toxicity. Further studies are necessary to fully define the optimal administration of concurrent chemotherapy–radiation therapy with or without induction or consolidation chemotherapy.

Optimal Chemotherapy Regimen in Stage III Non-Small Cell Lung Cancer

There is a paucity of data comparing different chemotherapy regimens in the setting of locally advanced NSCLC. For many theoretical reasons a regimen that includes cisplatin may be superior to a non-platinum-containing regimen. However, questions remain as to whether a low-dose platinum regimen is actually equivalent to a full-dose cisplatin-based regimen given concurrently with radiation therapy. One regimen that has consistently stood the test of time consists of that first used in SWOG trial S9019.[371] The SWOG approach consists of two cycles of induction EP administered concurrently with once-daily TRT (45 Gy). In the absence of progressive disease, radiation therapy is continued to a total dose of 61 Gy after which two additional cycles of EP are delivered. An alternative approach is to use the LAMP regimen of concurrent low-dose weekly carboplatin plus paclitaxel with radiation therapy followed by two additional cycles of full-dose consolidation carboplatin plus paclitaxel chemotherapy.[442] The decision to use one particular regimen over others is often made on the basis of secondary factors such as cost, logistical convenience, ease of administration, toxicity profile, patient preference, and physician experience.

Modulation of Concurrent Chemoradiation Therapy Toxicity

Although concurrent chemoradiation provides a significant survival benefit in locally advanced NSCLC, it comes at the cost of increased toxicity.[443–445] Radioprotectors are an attractive way to reduce the morbidity associated with combined-modality therapy and thereby may allow radiation therapy dose escalation to improve local control and survival. Amifostine is a candidate drug and acts primarily by scavenging free radicals released during the interaction of ionizing radiation and water. It theoretically protects normal tissue preferentially, thus increasing the therapeutic window. Thus far four randomized studies have been performed with amifostine in the setting of lung cancer with divergent results.[446–449] The largest of these trials was conducted by RTOG (RTOG 98–01).[449] All patients enrolled in the RTOG study received induction and concurrent carboplatin and paclitaxel with hyperfractionated radiation therapy (69.6 Gy) with or without amifostine. The primary endpoint was the frequency of grade 3 or higher esophagitis, a common toxicity of concurrent chemoradiation administration. However, no difference in the rate of grade 3 or higher esophagitis was detected, and there was a significant increase in the rate of nausea and vomiting, cardiovascular toxicity, and infection and febrile neutropenia with amifostine. Individuals given amifostine reported subjective improvement in swallowing and improved pain control, but quality-of-life measures were not statistically different nor was there an improvement in treatment compliance or survival. These data coupled with negative results achieved in other settings in which concurrent chemoradiation therapy is used[450] suggest that further study of this approach using amifostine is unlikely to be productive. However, some experts believe improved schedules of amifostine administration (such as more frequent dosing closer to the treatment time) could yield improved results.[446,447] The cost-to-benefit ratio of such frequent, strict dosing of this expensive drug in routine clinical practice has not been adequately studied, and thus we believe there is no compelling reason to use amifostine in this setting.

Molecular-Targeted Combined Modality Therapy

Molecular-targeted therapy is a novel strategy evolving from our increasing understanding of the underlying pathways and key molecules involved in tumor growth and progression. Theoretically, the specificity of molecular-targeted therapy should improve the therapeutic window by affecting the tumor cells and sparing normal cells. EGFR is an important mediator of growth factor signaling pathways that affect normal cell proliferation, motility, adhesion, and survival, as well as angiogenesis. EGFR is highly expressed in many solid tumors, and there have been reports correlating overexpression of EGFR with poor prognosis. Gefitinib, an inhibitor of EGFR tyrosine kinase activity, was the first targeted agent to be approved for the treatment of third-line NSCLC. As noted previously, SWOG investigators evaluated the potential benefit of maintenance therapy with gefitinib in locally advanced NSCLC in trial S0023.[437] An interim analysis prompted study closure when it showed that the gefitinib arm had no possibility of improving overall survival or progression-free survival compared with placebo. University of Chicago investigators are conducting a randomized phase II trial evaluating another EGFR-TKI, erlotinib, in a concurrent fashion with chemoradiation therapy consisting of either EP and radiation therapy followed by consolidation docetaxel for three cycles or induction chemotherapy with paclitaxel and carboplatin followed by concurrent chemoradiation consisting of weekly paclitaxel, carboplatin, with daily erlotinib.[451]

Another promising targeted agent is cetuximab, a chimeric antibody to IgG1 subclass with fivefold greater affinity than the murine monoclonal antibody. It works by blocking the binding of ligand to EGFR and suppressing the downstream activity. In individuals with squamous cell carcinoma of head and neck cetuximab combined with

radiation therapy improved overall survival,[452] prompting similar studies in locally advanced NSCLC. In a recently completed RTOG phase II trial (RTOG-0324) cetuximab was combined with carboplatin and paclitaxel and daily fractionated radiation therapy.[453] The study has completed planned accrual and is awaiting maturation.

Metastatic Non-Small Cell Lung Cancer

Before the widespread use of chemotherapy, individuals with metastatic NSCLC experienced a median survival of 4 to 5 months and 1-year survival rates of approximately 10% when managed with supportive care alone.[454,455] Moreover, with rare exception, clinical trials conducted during the 1970s and 1980s comparing chemotherapy to best supportive care failed to provide definitive evidence supporting the use of chemotherapy for individuals with advanced NSCLC. The failure to demonstrate a survival benefit was attributed to a lack of effective treatment and to the intolerable side effects of the agents available. However, the statistical power of these studies was inadequate to detect a modest improvement in survival. To remedy this shortcoming a landmark meta-analysis of the extant data was undertaken.[388] No survival benefit was observed with chemotherapy regimens composed of alkylating drugs or vinca alkaloids. However, the meta-analysis also included eight trials involving nearly 800 patients who received cisplatin-based chemotherapy versus supportive care alone. In these trials the hazard ratio for death was 0.73 in favor of cisplatin-based chemotherapy ($P < 0.0001$), corresponding to a 1.5-month increase in median survival time and a 10% increase in survival at 1 year. For most oncologists these data firmly established the survival benefits of platinum-based chemotherapy. Numerous subsequent studies confirmed this survival advantage and also convincingly demonstrated an improvement in quality of life compared with supportive care alone and the cost effectiveness of chemotherapy as well.[456,457]

Platinum-based chemotherapy assessed in the aforementioned meta-analysis mainly consisted of drug combinations consisting of older or second-generation cytotoxic agents (e.g., etoposide or vinca). These older drugs were associated with significant side effects that may have contributed to a less than optimal outcome. Beginning in the 1990s newer and less toxic chemotherapy drugs such as gemcitabine, vinorelbine, paclitaxel, and docetaxel were shown to possess good single-agent activity against advanced NSCLC and, in some instances, to impart a survival benefit compared with supportive care alone.[458,459] Subsequently these third-generation drugs were compared as single agents to older platinum-based combinations containing second-generation drugs (e.g., etoposide, vindesine, etc.) and platinum-based doublets containing third-generation drugs (see reviews[460,461]). For the most part third-generation agents used alone seemed to perform as well as the older platinum-based doublets in terms of overall survival but proved inferior to platinum-based doublets containing the newer third-generation drugs.[460,461] This observation was later borne out in a meta-analysis of studies conducted between 1994 and 2003 involving third-generation drugs as single agents or in combination with platinum.[462] Platinum-based doublets using third-generation agents produced a twofold higher overall response rate than the new agent alone (OR = 2.32; 1.68–3.20) and a 13% prolongation of survival (HR = 0.87; 0.80–0.94, $P < 0.001$). Despite significant increases in the frequencies of various toxic effects in patients receiving newer platinum-based doublets, no significant difference in treatment-related mortality was observed.

Newer versus Older Platinum-Based Doublet Drug Combinations

As the newer third-generation drug combinations emerged they naturally led to randomized phase III trials aimed at defining an optimal platinum-based doublet therapy regimen in advanced NSCLC. Several of these important trials are listed in Table 76-13. For example, the ECOG conducted a landmark phase III trial in which chemotherapy-naive individuals with advanced NSCLC were randomized to receive cisplatin plus paclitaxel as the reference standard based on earlier work from an earlier ECOG study[463] or to one of three experimental arms: cisplatin plus gemcitabine, cisplatin plus docetaxel, or carboplatin plus paclitaxel.[464] Overall response rates and survival, however, did not differ significantly between the reference regimen of cisplatin plus paclitaxel and the three investigational arms. Similar results have been reported by other groups.[465,466] Although response rates and survival times differ slightly among these trials, the

Table 76-13 Phase III Trials with Third-Generation Drugs in Advanced Non-Small Cell Lung Cancer

				Survival	
Group	**CT**	**No. of Patients**	**RR (%)**	**Median (mo.)**	**1 Yr (%)**
ECOG[464]	Paclitaxel/cisplatin	288	21	7.8	31
	Gemcitabine/cisplatin	288	22	8.1	36
	Docetaxel/cisplatin	289	17	7.4	31
	Paclitaxel/carboplatin	290	17	8.1	34
EORTC[480]	Paclitaxel/cisplatin	159	31	8.1	35
	Gemcitabine/cisplatin	160	36	8.8	31
	Gemcitabine/paclitaxel	161	27	6.9	26
ILCP[662]	Vinorelbine/cisplatin	201	30	9.5	37
	Gemcitabine/cisplatin	205	30	9.8	37
	Paclitaxel/carboplatin	201	32	9.9	43
SWOG[465]	Paclitaxel/carboplatin	206	25	8.0	38
	Vinorelbine/cisplatin	202	28	8.0	36
TAX-326[468]	Cisplatin/vinorelbine	394	25	10.1	41
	Cisplatin/docetaxel	406	32	11.3	46
	Carboplatin/docetaxel	404	24	9.4	38

RR, response rate.

differences are relatively minor and mainly attributable to subtle but important differences in the characteristics of the various study populations.[467] For example, in the TAX-326 study, approximately one third of the participants had stage III disease, compared with fewer than 20% stage III disease in the other large trials.[468] Because individuals with stage III disease tend to live longer, this difference introduces a potential bias and makes it difficult to compare across trials (although within the trials the balance of stages was similar between the randomized arms). Collectively these data indicate platinum-based doublets using third-generation agents represent the standard of care in individuals with advanced NSCLC.[454,469] No clinically significant differences among the common regimens have emerged.

Triplet versus Doublet Platinum-Based Drug Combinations

Given that the third-generation chemotherapy agents often have nonoverlapping toxicity profiles, triplet chemotherapy regimens have considerable theoretical appeal. Several phase II and III trials have demonstrated the tolerability and activity of various triplet combinations.[460] However, although response rates and progression-free survival often improved with the addition of a third agent, overall survival was rarely impacted in a positive manner. Not surprisingly, however, toxicity and cost increased with the addition of a third agent. Two recent meta-analyses revealed a statistically significant improvement in response rate favoring the three-drug regimen.[470,471] However, the improvement in response rate did not translate into an improvement in survival. Moreover, toxicity was greater with triple-drug therapy as compared with doublet therapy.[461,471] Accordingly, triplet-drug chemotherapy is not recommended outside the confines of a clinical trial.

Duration of Therapy

How long one should administer chemotherapy in advanced NSCLC is a subject of ongoing debate.[461] American Society of Clinical Oncology practice guidelines for advanced NSCLC recommend cessation of first-line chemotherapy at four cycles in patients who are not responding to treatment and recommend no more than six cycles in responding patients.[472] These recommendations are based on limited data. A seminal study randomized individuals with advanced NSCLC to three versus six cycles of mitomycin, vinblastine, and cisplatin.[473] The dose of cisplatin was 50 mg/m^2, considered by some experts to be a low and possibly less effective dose of this agent (although this concern is not borne out in prospective trials; see Gandara and colleagues[474] and Klastersky and associates[475]). Median survival (6 vs. 7 months) and 1-year survival rates (22% vs. 25%; $P = 0.2$) were essentially identical in the two arms of the trial, as were the median durations of symptom relief (4.5 months in both arms). Quality-of-life parameters also were the same or improved for patients randomized to only three courses, including a significant decrease in fatigue ($P = 0.03$) and a trend toward decreased nausea and vomiting ($P = 0.06$). A second trial compared four cycles of carboplatin and paclitaxel to continuous treatment with these agents until disease progression in individuals with stages IIIB or IV NSCLC. Among individuals allocated to four cycles, 57% completed the intended course of chemotherapy. The median number of courses delivered in the continuous treatment arm was four, with 42% receiving five or more cycles of carboplatin and paclitaxel. Overall response rates (22% and 24%; $P = 0.80$), median survival (6.6. and 8.5 months), and 1-year survival rates (28% vs. 34%; log-rank $P = 0.63$) were not statistically different. Except for neuropathy, hematologic and non-hematologic toxicity rates were similar between the two arms. There were no differences in quality-of-life parameters. The frequency of patients who received second-line therapy was identical in the two groups as well (42% vs. 47%; $P = 0.42$). Collectively these indicate that treatment beyond three or four cycles of platinum-based therapy is of limited or no benefit in individuals with advanced NSCLC.[461,476]

Cisplatin versus Carboplatin

One of the more enduring controversies surrounding the treatment of persons with metastatic NSCLC is whether cisplatin-based chemotherapy is superior to carboplatin-based chemotherapy.[477] The ongoing controversy is fueled in part by a lack of a direct comparison of these agents. However, two recent randomized trials in advanced NSCLC suggest that carboplatin-containing doublets are inferior to cisplatin-based doublets in terms of overall survival when third-generation drugs are used.[468,478] A meta-analysis of extant data lends further support to this possibility.[477] Among eight trials (involving nearly 3000 patients) that directly compared a cisplatin-based doublet with a carboplatin-based doublet, five investigated drug regimens containing a third-generation agent. Taking into account all eight studies, cisplatin-based chemotherapy produced a statistically significant higher response rate but no survival advantage (HR = 1.050; 0.907–1.216; $P = 0.515$). However, a subgroup analysis of the five trials that used third-generation platinum-based doublets revealed that cisplatin plus a newer agent yields an 11% longer survival than carboplatin plus the same newer agent (HR = 1.106; 1.005–1.218; $P = 0.039$). Cisplatin-based chemotherapy more frequently induced grade 3 or higher nausea and vomiting, whereas grade 3 or higher thrombocytopenia was more frequent during carboplatin-based chemotherapy. There was not a significant difference in treatment-related deaths (3.9% vs. 2.9%, respectively). Given the palliative nature of chemotherapy for advanced disease, however, the modest survival benefit derived from cisplatin-based therapy may be offset by the increase in host toxicity. Accordingly, it is reasonable to consider substituting carboplatin for cisplatin in selected circumstances where the toxicities of cisplatin could be particularly problematic (i.e., pre-existing neuropathy, hearing difficulties, renal dysfunction, etc.). The situation in early-stage disease may be quite different (discussed earlier).

Platinum-Containing versus Non-Platinum-Containing Chemotherapy

Improvement in survival is a crucial factor in choosing chemotherapy, but serious consideration also should always be given to other factors, such as tolerability, quality of life, convenience, and cost.[472] These factors have led to the investigation of non-platinum-containing chemotherapy regimens. Given the activity and tolerability of newer non-platinum drugs (e.g., gemcitabine, vinorelbine, paclitaxel, docetaxel, oxaliplatin),[479] there has been considerable interest in developing non-platinum-based chemotherapy regimens.[469] However, many of these data are from phase II studies and must be interpreted with some degree of caution. This is particularly relevant given that a recent European phase III trial suggested non-platinum-based chemotherapy might be less efficacious than platinum-based chemotherapy.[480] Moreover, a recent meta-analysis analyzed 1-year survival using data obtained from 37 randomized phase II and phase III trials that compared platinum- to non-platinum-based chemotherapy regimens.[481] Collectively these trials enrolled more than 7600 patients. The analysis found that platinum-based chemotherapy was associated with a 62% increase in the odds ratio for response (OR, 1.62; 1.46–1.8; $P < 0.0001$) and a 5% increase in the 1-year survival rate (34% vs. 29%; OR, 1.21; 1.09–1.35; $P = 0.0003$). However, compared to third-generation-based combination regimens there was not a statistically significant increase in 1-year survival with platinum-based therapies (35% vs. 36%, respectively; OR, 1.11; 0.96–1.28; $P = 0.17$) when single-agent trials were excluded. In addition, the toxicity of platinum-based regimens was significantly higher for hematologic toxicity, nephrotoxicity, and nausea and vomiting, but not for neurotoxicity, febrile neutropenia rate, or toxic death rate.

This aforementioned meta-analysis has been criticized for the inclusion of single-agent comparisons as well as phase II trials regarded as too small to provide reliable survival data.[482] The criticism prompted a second meta-analysis restricted to phase III trials that compared

platinum-based doublets to non-platinum-based doublet therapies.[482] The latter analysis involved 14 phase III trials that compared platinum-based to non-platinum-based regimens using survival at 1-year as the endpoint of interest. The analysis included nearly 6000 patients. The results revealed a statistically significant benefit in the reduction of death for the platinum-based regimens at 1 year (OR, 0.88; $P = 0.044$) and a lower risk of being refractory to chemotherapy with platinum-based chemotherapy (OR, 0.87; 0.73–0.99; $P = 0.049$) (an issue of potential greater importance when chemotherapy is used in the adjuvant setting; see earlier discussion). The risks of grades 3 and 4 gastrointestinal and hematologic toxicities were substantially higher with platinum-based chemotherapies, although this was not associated with a significant increase in the risk of febrile neutropenia (OR, 1.23; 0.94–1.60; $P = 0.063$). There was, however, a trend toward an increase in treatment-related deaths on the platinum-based regimens (1.9% vs. 1.3%; $P = 0.08$). Based on these data non-platinum-containing regimens do have activity that is similar to that of platinum-based regimens. Although arguably somewhat less effective than platinum-based therapy, some non-platinum-based chemotherapy regimens seem appropriate for patients in whom platinum-associated toxicities are a major concern.

Chemotherapy for Palliation of Symptoms

The notion that chemotherapy can be used primarily for palliation purposes is an anathema to many nononcologists. However, several investigators have shown that cytotoxic chemotherapy is associated with symptom improvement even in the absence of a classic tumor response.[483] Symptomatic response is usually achieved within the first or second course of chemotherapy in responding patients. Nonetheless, some practitioners shy away from recommending platinum-based palliative chemotherapy because of the toxicities known to accompany platinum agents. Newer agents such as gemcitabine and vinorelbine can be used with beneficial effect. For example, in one study patients given gemcitabine were far less likely to require palliative radiation therapy at 2 months than those treated with supportive care alone (7% vs. 42%).[484] The median time to receiving palliative radiation therapy was 7 months for patients receiving gemcitabine versus 1 month for patients treated with best supportive care alone. Duration of symptom relief achieved varied considerably but resulted in a median relief of 3–5 months for dyspnea, cough, and chest pain and 2–3 months for anorexia and hemoptysis.[485] Symptomatic relief derived from chemotherapy is not limited to first-line therapy. In individuals with recurrent NSCLC second-line docetaxel provided greater improvement in tumor-related symptoms, including asthenia, pain, and pulmonary and neurologic symptoms compared with supportive care as well as a survival benefit.[486]

Elderly Patients

Lung cancer is primarily a disease of older individuals; the median age at diagnosis is 68 years and as many as 40% of patients may be 70 years old at diagnosis.[487] Because older people with NSCLC tend to have substantial comorbidities, many oncologists are often reticent to administer standard chemotherapy regimens fearing excessive toxicity.[487,488] However, when deciding a treatment strategy the biologic rather than the chronologic age should be carefully assessed, and treatment should only be modified or withheld for very good reason.[489] This applies equally to surgery and radiation therapy as well as chemotherapy, in that numerous prospective studies have clearly demonstrated the benefits of chemotherapy in the elderly. Randomized trials have confirmed the superiority of single-agent vinorelbine to supportive care and to combination therapy with vinorelbine and gemcitabine.[490,491] In addition, retrospective analyses of many cooperative-group phase III studies indicate that patients aged 70 years and older experience survival and quality-of-life benefits similar to that of their younger counterparts.[464,466,468,492] Recently a panel of international experts in geriatric oncology was convened to develop guidelines for the treatment of elderly patients with NSCLC.[488] The panel recommended single-agent chemotherapy with a third-generation agent (vinorelbine, gemcitabine, docetaxel, or paclitaxel), as an option for elderly individuals with advanced NSCLC. Several variables must be considered when selecting a particular drug, including the expected toxicity profile of the agent, pharmacokinetics, organ function, and comorbidities as well as the patient's preferences. The expert panel indicated that a platinum-based chemotherapy represented a valid option in older patients with a good performance status and adequate organ function. Appropriate supportive care measures (e.g., growth factors) were encouraged in older patients suffering from comorbidities and disease symptoms. Finally, as is true of lung cancer patients of any age, the expert panel noted that supportive care alone represented an appropriate management plan for patients who are not suitable for active treatments.

Patients with Poor Performance Status

Retrospective reviews of early clinical trials in advanced NSCLC identified poor performance status (i.e., ECOG PS 2) as a strongly negative prognostic variable.[493] The use of chemotherapy in patients with PS 2 is controversial, because the survival benefit derived from cisplatin-based chemotherapy seems to be confined to those with PS 0 to 1.[494] Not surprisingly, what happens in clinical practice is fairly inconsistent.[495] Data derived from pooled studies suggest that patients with PS 2 do experience improved quality of life with chemotherapy even if a survival benefit is not obtained.[496] Monochemotherapy with one of the third-generation cytotoxic agents (e.g., vinorelbine, gemcitabine, or a taxane) or newer formulations of these agents (e.g., paclitaxel, poliglumex) may provide clinical benefit with less toxicity, whereas newer combination regimens seem to improve survival albeit quite modestly.[466] In addition, the oral EGFR inhibitors gefitinib and erlotinib have demonstrated promising activity in persons with advanced NSCLC who have previously received chemotherapy (see later discussion). The favorable toxicity profile of these agents makes them an attractive option for patients with PS 2 as well. A cautionary note is warranted, however. In a randomized phase II trial, patients with PS 2 seemed to fare better with standard doublet chemotherapy than with single-agent erlotinib as initial therapy.[497] Thus, caution is warranted in selecting initial treatment for patients with PS 2 or greater. There remains a critical need for novel therapeutic strategies for all persons with NSCLC and especially for those with a poor PS.

Second-Line Therapy

As first-line chemotherapy regimens improve, a substantial number of patients will maintain a good performance status and a desire for further therapy when they develop recurrent disease. Numerous trials of single-agent and combination therapies have been performed; the results of more than 50 trials have been summarized elsewhere.[498] At present only three drugs are approved by the FDA for second-line therapy of NSCLC in the United States, including docetaxel, pemetrexed, and erlotinib. In general these agents have similar overall response rates of around 5% to 10% (depending on the patient's prior exposure to taxanes and platinum) and yield median survivals of 6 to 8 months (Table 76-14). However, the available drugs have distinct toxicity profiles that can influence their use in the second-line setting.[499] In a prospective comparison of docetaxel and pemetrexed, for example, overall response rates (9.1% vs. 8.8%; $P = 0.105$), median time to progression (3.5 vs. 3.4 months), and median survival times (8.3 vs. 7.9 months) were not significantly different (see Table 76-14).[500] However, patients receiving docetaxel were much more likely to experience grade 3 or 4 neutropenia (40.2% vs. 5.3%; $P < 0.001$), febrile neutropenia (12.7% vs. 1.9%; $P < 0.001$), neutropenia with infections (3.3% vs. 0.0%; $P = 0.004$), hospitalizations for neutropenic fever (13.4% vs. 1.5%; $P < 0.001$), hospitalizations due to other drug-related adverse events (10.5% vs. 6.4%; $P = 0.092$), use of granulocyte colony-stimulating factor support (19.2% vs. 2.6%; $P < 0.001$), and all-grade alopecia (37.7% vs. 6.4%; $P < 0.001$)

Table 76-14 Phase III Trials of Docetaxel and Pemetrexed in Recurrent Non-Small Cell Lung Cancer

	SHEPHERD ET AL[486]				HANNA ET AL[500]	
		DOCETAXEL			DOCETAXEL	PEMETREXED
	BSC	**Overall**	**75 mg/m²**	**100 mg/m²**	**75 mg/m²**	**500 mg/m²**
RR	0%	5.8%	5.5%	6.3%	8.8%	9.1%
TTP	1.6 mo	2.5 mo	2.5 mo	2.5 mo	3.5 mo	3.4 mo
MST	4.6 mo	7.0 mo	7.5 mo	5.9 mo	7.9 mo	8.3 mo
1 Yr	19%	29%	37%	29%	29.7%	29.7%

BSC, best supportive care; MST, median survival time; RR, response rate; TTP, time to progression.

compared with patients receiving pemetrexed. Thus, based on the current available data, the efficacy of these three drugs is similar in a general patient population, but their toxicity profiles differ substantially. Hematologic toxicity is greater for docetaxel compared with pemetrexed and erlotinib, whereas nonhematologic toxicity, namely rash and diarrhea, is greater with erlotinib. For smokers who derived benefit from first-line chemotherapy and maintain a good performance status (i.e., ECOG PS 0–1), a trial of pemetrexed is reasonable. Erlotinib should be strongly considered as second-line treatment in those who have never smoked, including those who failed to benefit from first-line chemotherapy. Most of the survival benefit for any of these agents is realized in those patients who maintain a good performance status.

Epidermal Growth Factor Receptor Inhibitors

EGFR overexpression occurs in a variety of solid tumors including NSCLC and is associated with a poor prognosis in some retrospective reports.[60,501] When stimulated, the transmembrane receptors trigger a cascade of intracellular signaling that affects cellular proliferation and apoptosis. Strategies to target the EGFR include use of TKIs, monoclonal antibodies, antisense oligonucleotides, and ligand-toxins or immunoconjugates.[501] Thus far the EGFR inhibitors used in the treatment of NSCLC fall into two main categories: monoclonal antibodies to the extracellular domain of the EGFR (cetuximab and panitubimab) and small molecules that are inhibitors of the intracellular tyrosine kinase domain by interfering with autophosphorylation by adenosine triphosphate (gefitinib and erlotinib). Gefitinib, erlotinib, and cetuximab have demonstrated modest activity in phase II studies conducted in unselected individuals with recurrent NSCLC.[502–504] However, only erlotinib is approved by the FDA for the treatment of NSCLC based on the results of a randomized placebo-controlled trial in which erlotinib demonstrated a statistically significant survival benefit in persons with recurrent NSCLC.[65]

Table 76-15 Phase III Trials of Erlotinib and Gefitinib in Recurrent Non-Small Cell Lung Cancer

	BR.21[65]		ISEL[505]	
	Erlotinib	**Placebo**	**Gefitinib**	**Placebo**
RR	8.9%	<1%	8%	1%
Stable disease	35%	27%	32%	31%
TTP	2.2 mo	1.8 mo	3.0 mo	2.6 mo
MST*	6.7 mo	4.7 mo	5.6 mo	5.1 mo
1-yr survival	31.2%	21.5%	27%	21%

MST, median survival time; RR, response rate; TTP, time to progression.

Patients enrolled in the erlotinib trial all had received prior platinum-based chemotherapy and/or were considered ill-suited for further chemotherapy. A trial of similar design failed to demonstrate a survival advantage with gefitinib, although the trends in time to progression and overall survival favored the EGFR TKI arm[505] (Table 76-15).

Notably, the start of the aforementioned placebo-controlled phase III trials predates the discovery of somatic mutations in the EGFR gene that seem to associate with clinical responses to EGFR TKIs but not to the monoclonal antibodies cetuximab and panitubimab targeting EGFR and its ligands.[55,57,58,60] The clinical relevance of these *EGFR* mutations, however, remains unclear. For example, many different mutations have been reported. Thus far four of the described mutations associate with tumor response (validated from in vitro studies or from actual tumor responses in human patients) including point mutations in exons 18 (G719A/C) and 21 (L858R and L861Q) and in-frame deletions in exon 19 that eliminate four amino acids (LREA) just downstream of a critical lysine residue at position 745 (Fig. 76-16).[60] Three mutations, an exon 19 point mutation (D761Y), an exon 20 point mutation (T790M), and an exon 20 insertion (D770_N771insNPG) are associated with drug resistance.[60] Notably, mutations in *KRAS* also are associated with a lack of sensitivity to EGFR TKIs.[506] The most common of these four drug-sensitive mutations are exon 19 deletions and the exon 21 L858R substitution that together account for 85% to 90% of *EGFR* mutations in NSCLC.[62] The existing data show an approximate 75% response rate to EGFR TKIs in tumors with drug-sensitive mutations versus a less than 10% response in tumors with wild-type EGFR. However, the presence of mutations failed to correlate with survival benefit in the erlotinib placebo-controlled trial.[66] By contrast, amplification of the EFGR gene as detected by FISH did correlate with survival outcome in the placebo-controlled erlotinib and gefitinib trials.[66,507] In cell lines *EGFR* mutations are often accompanied by gene amplification. Indeed, in most studies, amplification of *EGFR* has been associated with mutations in *EGFR*.[508] It has been suggested that the failure of *EGFR* mutations to correlate with survival outcome in the erlotinib trial is due to inadequacies of technique used to assess for mutations in this pivotal trial.[173,509] Moreover, whereas *EGFR* mutations and increased copy number have been treated as separate molecular events thus far, accumulating data suggest that they are not mutually exclusive.[173]

Individuals with gastrointestinal stromal tumors harboring mutations in *KIT* exon 11 have a significantly longer overall survival when compared with persons with mutations in *KIT* exon 9.[510] Similar observations have been made in NSCLC; individuals with tumors harboring *EGFR* exon 19 deletions have a longer overall survival when compared with persons with *EGFR* L858R (34 vs. 8 months; log-rank, $P = 0.01$).[511] The molecular basis for this observation is not known, although kinetic analyses of EGFR-mutant proteins suggest that the off-rate for erlotinib may be slower for the deletion mutant, compared with the L858R mutant, thereby prolonging the duration of erlotinib binding to the deletion mutant.[512]

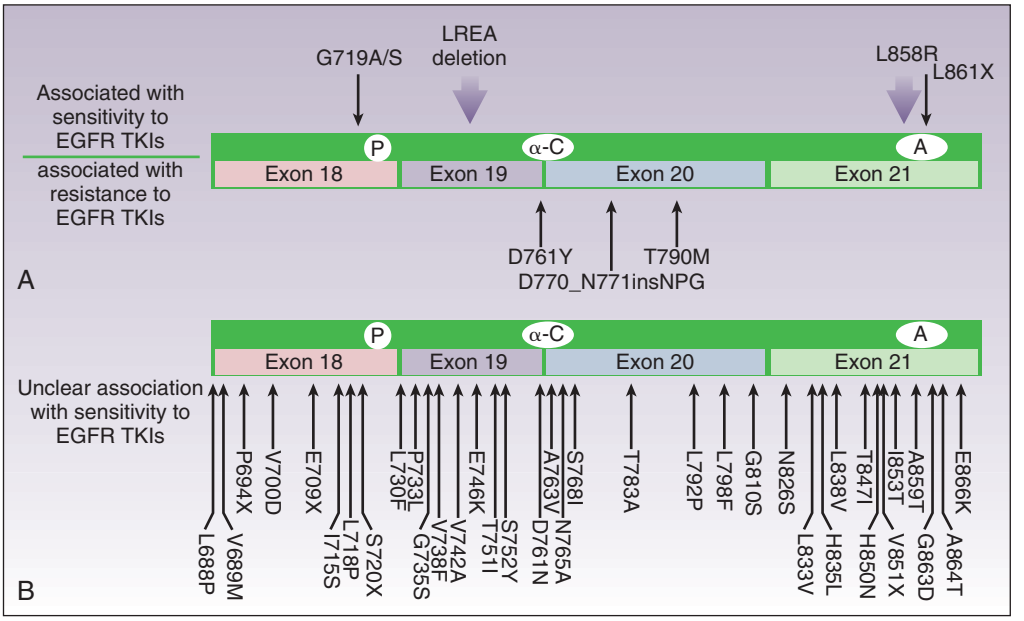

Figure 76-16 • Schematic diagram of reported mutations in *EGFR* in NSCLC tumors. **A,** Mutations associated with sensitivity to gefitinib or erlotinib (*top*). The relative frequencies of mutations are indicated by size of arrows. Mutations associated with resistance to gefitinib or erlotinib (*bottom*). **B,** Mutations isolated from NSCLC tumors with unclear association with response to erlotinib or gefitinib. (Reproduced with permission from Riely GJ, Politi KA, Miller VA, Pao W: Update on epidermal growth factor receptor mutations in non–small cell lung cancer. Clin Cancer Res 2006;12: 7232–7241.)

Despite an initial response to EGFR TKIs, individuals with *EGFR* mutations rarely achieve a complete pathologic response, and with continued treatment tumors typically develop resistance to gefitinib or erlotinib.[60] The mechanisms of this acquired resistance are only now being defined. Studies of tumor material taken from individuals with initial responses to EGFR TKIs and subsequent progression have identified additional mutations in *EGFR* in specimens with acquired resistance.[63,64] The major lesion identified thus far is an EGFR T790M mutation reported to occur in approximately half of the published cases.[60,63,64] This T790M substitution in EGFR is predicted to block binding of erlotinib or gefitinib to the kinase adenosine triphosphate-binding pocket.[63,64]

Routine testing for *EGFR* mutations is not recommended, although there are several ongoing trials testing the practicality and value of such an approach.[60] These studies should help determine the importance of mutation testing in selecting therapy for subsets of patients with lung cancer, providing prospective data on response rates, time to progression, and survival with and without mutations treated with either gefitinib or erlotinib. From a practical standpoint, the extant data suggest that there may be a subgroup of persons with NSCLC that preferentially respond to EGFR TKIs, including those with adenocarcinomas (especially adenocarcinomas with bronchioloalveolar features), those who have never smoked, patients of Asian ethnicity, and females.[60,501] Investigators at Memorial Sloan-Kettering Cancer Center developed a response and survival prediction model shown in Table 76-16.[513] Data developed after the development of this model suggest that bronchioloalveolar carcinoma per se is not predictive of responsiveness to EGFR TKIs.[62] Instead, it seems that the more responsive histology is adenocarcinoma with BAC-like features (as described previously). The model also ignores a patient's ethnicity, which seems to play a substantial role in the likelihood of response to these agents.[62] Nonetheless, the prediction model developed by the Memorial investigators provides practical clinical guidance as to a patient's likelihood of deriving benefit from an EGFR TKI like gefitinib or erlotinib. Once an EGFR TKI is administered individuals with responding tumors often experience marked and rapid tumor regression, often within days of starting treatment (Fig. 76-17). Moreover, a growing body of evidence suggests that these clinical features tend to be associated with the presence of *EGFR* somatic mutations.[62] Prospective trials utilizing the clinical parameters to select patients are under way. SWOG investigators completed one such trial using gefitinib in patients with chemonaive or recurrent BAC.[514] The overall response rate was 17% among previously untreated individuals and 9% among pretreated individuals. Median survival was 13 months, with a 23% 3-year survival. Toxicity consisted mainly of rash and diarrhea, but 2% of patients died of presumed interstitial lung disease. Such trials have raised the question of whether patients who fit these specific criteria should be considered for first-line therapy with an EGFR TKI.[60]

Table 76-16 Response and Survival with Epidermal Growth Factor Receptor Tyrosine Kinase Inhibitors

Positive Predictive Factors	RR (%)	MST
Never smoker	56	14+ mo
BAC-like features		
Female

Epidermal Growth Factor Receptor Tyrosine Kinase Inhibitors with Combination Chemotherapy

Thus far, attempts to move EGFR TKIs into front-line therapy of advanced NSCLC have concentrated on combining these agents with standard chemotherapy[515–517] (Table 76-17). Each of the completed studies was designed with the knowledge that gefitinib and erlotinib had demonstrated impressive antitumor activity in individuals with refractory, advanced NSCLC with only modest toxicity, and was based on the premise that these drugs could enhance the cytotoxic effects of standard chemotherapy agents, as shown in preclinical studies.[518,519] Unfortunately none of the studies yielded a survival improvement with EGFR TKIs. There are several potential explanations for the failure of EGFR TKIs to effect survival benefit when combined with chemotherapy. For example, it is certainly possible

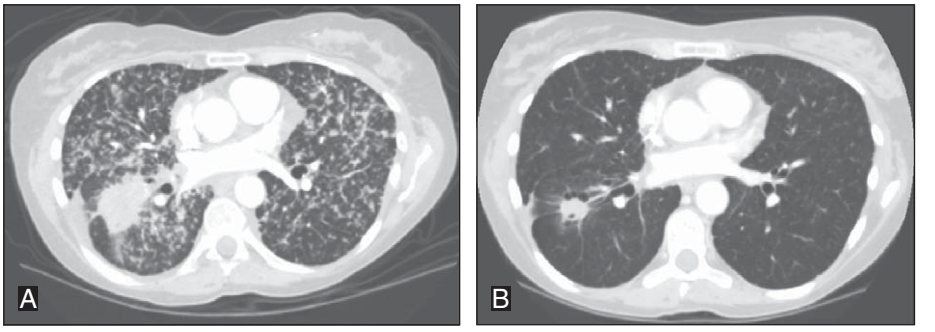

Figure 76-17 • Chest CT scans of a 60-year-old female who had never smoked with adenocarcinoma before (**A**) and after 28 days of erlotinib therapy (an EGFR TKI) (**B**). The patient had a mutation in exon 19 of the *EGFR* gene.

that more careful patient selection might have led to a better outcome (see later discussion). In none of these studies were patients selected based on EGFR expression, somatic mutations, or any other putative marker of efficacy. Some experts also have speculated that EGFR inhibitors act mainly by reducing proliferation in wild-type EGFR tumor cells. Because proliferating tumor cells are those most affected by chemotherapy, an antagonistic effect between EGFR TKIs and chemotherapy may occur.[509] Interestingly, neither *EGFR* mutations nor amplification seemed to identify distinct subsets of NSCLC with an increased response to gefitinib in the phase II/III randomized trials, nor did the combination of gefitinib with chemotherapy improve survival in individuals with these molecular markers.[520] Notably, however, patients who had never smoked who were treated with erlotinib and chemotherapy seemed to experience an improvement in survival in a preplanned subset analysis.[517] Never smoking has been associated with a greater probability of response to EGFR TKIs and may represent a surrogate marker for the presence of *EGFR* mutations.[521] Nonetheless, neither erlotinib nor gefitinib combined with standard chemotherapy regimens confers a survival advantage over chemotherapy alone in unselected patients with previously untreated advanced NSCLC.[517] Consequently, at present, concurrent chemotherapy with an EGFR TKI is not recommended as routine therapy.

Vascular Endothelial Growth Factor Inhibitors

Inhibition of angiogenesis has been a major thrust of new drug development in many solid tumors including lung cancer. Bevacizumab is a recombinant humanized monoclonal antibody to the vascular endothelial growth factor (VEGF) that has shown great promise in the treatment of breast and colon cancer. In a randomized phase II trial, bevacizumab combined with carboplatin and paclitaxel seemed to improve both overall response rates and times to disease progression.[522] However, bevacizumab engendered a high rate of life-threatening pulmonary hemorrhage that was observed primarily in individuals with squamous cell carcinomas. The ensuing ECOG phase III trial was therefore limited to individuals with NSCLC of nonsquamous histology, no history of hemoptysis, and no brain metastases to limit the potential for serious bleeding.[523] Patients assigned to the bevacizumab group experienced an improved response rate (35% vs. 15%; $P < 0.001$), progression-free period (6.2 vs. 4.5 months; HR = 0.66; $P < 0.001$), and overall survival (12.3 vs. 10.3 months; HR = 0.79; $P = 0.003$). However, these benefits came at a cost, including a greater number of treatment-related deaths (15 vs. 5) and a higher rate of clinically significant bleeding (4.4% vs. 0.7%; $P < 0.001$). Nonetheless, the substantial improvement in overall survival indicates that bevacizumab plays a key role in the management of selected patients with NSCLC with metastatic disease.

Lung Cancer Vaccines

There are many diverse approaches to attempting to harness the specificity and generality of the immune system in the fight against cancer, and most of them remain theoretical or relevant only in animal studies. However, despite some remarkable failures,[524] several recent studies suggest that real progress is being made in the development of immunotherapeutic strategies for lung cancer. The most promising approaches can be divided into three main groups: (1) whole-cell vaccines, where either autologous or allogeneic tumor cells are used as the source of a mixture of potential, primarily undefined,

Table 76-17 Results of Phase III Trials Combining Chemotherapy and Epidermal Growth Factor Receptor Tyrosine Kinase Inhibitors

tumor antigens; (2) defined-antigen vaccines using synthetic protein or peptide antigens; and (3) immunostimulatory preparations without administered tumor antigens.

WHOLE-CELL VACCINES. The clinically apparent diversity of lung cancers suggests that the best source of tumor antigens might be the patient's own tumor, killed and formulated into a vaccine in a manner that allowed the induction of a specific, effective immune response directed at the residual live tumor in the patient. This theoretically attractive but practically difficult approach was tested in a vaccine based on the concept that tumor cells engineered to express large amounts of the cytokine granulocyte-macrophage colony-stimulating factor were very effective at inducing tumor-specific immunity.[525] In this trial patients with resectable tumor deposits had their own tumor cells engineered to overexpress this cytokine formulated into a vaccine and injected intradermally, and durable, complete responses were observed in 3 of 33 patients treated.[526] This approach was dropped for commercial development, however, because of the practical difficulties in harvesting and processing autologous tumor to prepare the vaccine, but despite this was the first trial to show objective responses to vaccine therapy alone in individuals with lung cancer.

A similar study used a mixture of four allogeneic lung cancer tumor cell lines engineered to overexpress antisense transforming growth factor-β2 (TGFβ), a potent immunosuppressive cytokine, to treat individuals with advanced lung cancer.[526] In this randomized phase II testing three different doses of the vaccine, a 15% partial response rate was observed and the survival of the higher dose groups was statistically significantly longer than that of the lowest dose group (52% vs. 20% 2-year survival). Because all patients in this study received the same vaccine, it is much more amenable to commercial-scale manufacture and is currently being tested in a phase III trial.

DEFINED-ANTIGEN VACCINES. Proteins that are somatically mutated in the development of the cancer and thus absolutely specifically expressed in the cancer and not in normal tissues also present an attractive target for immunotherapy, and one trial immunized patients with synthetic peptides custom-made to match the mutated ras or p53 protein products present in each patient's tumor.[527] In this study specific immune responses were observed, and survival was prolonged in the individuals who achieved such a response, but no objective responses were observed. Instead of using a custom-made mutant oncogene peptide, it is possible to target nonmutated p53 peptides based on the overexpression of the protein frequently observed in lung cancer. In fact, an objective response and improved clinical outcomes compared with historical controls were also observed in a trial immunizing persons with SCLC using a vaccine targeting overexpressed wild-type p53.[528]

An approach that is much more practical for commercial development is to find a tumor antigen that is frequently expressed in lung cancer and formulate this antigen into a vaccine. Two such examples in large-scale clinical development now are those based on the MUC and MAGE antigens, both frequently overexpressed in lung cancer. The BLP-25 vaccine is a MUC lipopeptide that was given to persons with advanced NSCLC with responding or stable disease after chemotherapy or chemoradiation therapy.[529] In a subset analysis of stage IIIB patients who received radiation therapy for local-regional disease (no pleural effusion) there was a trend toward an improved survival compared with nonvaccinated patients. In another study a vaccine based on the MAGE antigen was given as adjuvant therapy to individuals with completely resected disease,[530] and a strong trend toward an improved survival was observed in a planned interim analysis.

IMMUNOSTIMULATORY APPROACHES. Because cancers develop and become clinically evident despite an apparently intact immune system in the majority of individuals, there must be mechanisms by which cancers avoid an effective immune response. One of the factors that cancers make to suppress effective responses is TGFβ, as discussed previously, but another is VEGF.[531] With the recent approval of bevacizumab, combinations of anti-VEGF with immunotherapy are being tested in early-phase clinical trials.

It is clear that prokaryotic DNA, specifically unmethylated DNA, is recognized as foreign by a primitive component of the eukaryotic cell involving the TLR-9 receptor. This observation has led to the development of TLR-9 agonists to activate innate and adaptive immune induction. In one randomized phase II trial a TLR-9 agonist, PF-3512676, was given in combination with chemotherapy versus chemotherapy alone in a randomized, placebo-controlled design, and a significant increase in response rate was observed (Pfizer, unpublished data). This is currently being tested in a large phase III trial.

There are therefore suggestions of clinical activity for vaccines in lung cancer, and this has stimulated resurgent interest by pharmaceutical companies and large-scale clinical development in lung cancer. The true extent and potential for lung cancer immunotherapy remains to be elucidated, however.

In summary, for much of the twentieth century advances in the systemic treatment of advanced NSCLC were considered modest at best.[455,532] In fact as recently as 1998 the noted oncologist B.J. Kennedy derisively commented on the "snail's pace" of progress in the management of late-stage NSCLC.[13] Much has changed since Dr. Kennedy's scholarly rebuke. It is now well established that modern chemotherapy can prolong survival of individuals with NSCLC in the late stages of disease as well as improve the symptoms and quality of life in a cost-effective manner.[454,455] It is now well accepted that doublet platinum-based chemotherapy with a third-generation drug is the preferred treatment for physically fit patients with advanced NSCLC. No single regimen stands apart as the optimal program for all patients. Non-platinum therapy is a reasonable alternative approach in selected circumstances where cisplatin or carboplatin is not appropriate. Subtle differences among the extant regimens allow clinicians flexibility to choose among toxicity profiles, convenience, and cost. For a subset of patients, namely those with adenocarcinoma, no brain metastases, and no hemoptysis, the addition of bevacizumab to chemotherapy is warranted based on a significant improvement in overall survival. Whether the addition of bevacizumab to doublets other than carboplatin and paclitaxel is beneficial remains to be determined. The available data indicate that no more than three to six cycles of chemotherapy regimen are required to achieve optimal survival results and minimize host toxicity. Second-line chemotherapy is beneficial in term of survival, quality of life, and cost. Older patients who are physically fit should be treated in a manner that mirrors that of their younger counterparts. Older patients who are not physically fit and patients with a poor initial performance status may be candidates for monotherapy with a third-generation drug or possibly one of the newer so-called targeted agents (e.g., erlotinib). Finally, all therapy in the setting of metastatic disease is ultimately palliative. Consequently treatment decisions must be tempered by this sobering reality.

SMALL CELL LUNG CANCER

The absolute incidence of SCLC increased at an annual rate of 6.5% until 1982, continued to increase at an annual percentage change rate of 1.2% between 1982 and 1989, and since 1990 has decreased at a statistically significant rate of 2.4% per annum[533] (Fig. 76-18). SCLC now constitutes approximately 13% of all newly diagnosed lung cancers in the United States,[533] a marked decline from previous estimates of 20% to 25% noted 2 decades ago.[238] The change in the incidence of SCLC is most evident in men but has recently shown a favorable downward trend among women as well.[286] The declining SCLC incidence is a direct result of reduced smoking among U.S. adults.[286,534] It is estimated that without these reductions in smoking, there would have been virtually no reduction in overall cancer mortality in either men or women since the early 1990s.[535] Nonetheless,

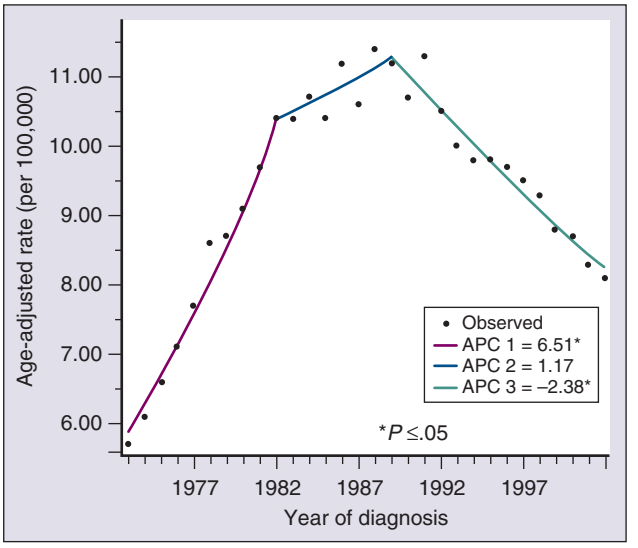

Figure 76-18 • Annual percentage change in the diagnosis of small cell lung cancer in the United States over the last 30 years. (Reproduced with permission from Govindan R, Page N, Morgensztern D, et al: Changing epidemiology of small-cell lung cancer in the United States over the last 30 years: analysis of the surveillance, epidemiologic, and end results database. J Clin Oncol 2006;24:4539–4544.)

the natural history of untreated SCLC remains extremely poor with median survival of only 2 months for metastatic SCLC and less than 3 to 4 months for disease confined to the thorax.[536] Although SCLC was once considered highly curable, in fact, the median survival and the proportion of long-term survivors of patients treated with chemoradiation for limited-stage SCLC and stage III NSCLC or extensive-stage SCLC and metastatic NSCLC are essentially identical.[239] The time required for treatment-resistant clones to cause a fatal outcome is similar for SCLC and NSCLC. Both are virulent epithelial neoplasms that respond somewhat to radiation therapy and chemotherapy.[239]

Small Cell Lung Cancer Staging

The TNM staging system is rarely used to stage SCLC. Instead, SCLC is staged using the Veterans Administration Lung Study Group system mainly because of its simplicity and clinical utility.[537] Approximately one third of individuals with SCLC present with limited-stage disease, defined as tumor confined to one hemithorax that can be encompassed within a single tolerable radiation therapy portal. This definition becomes somewhat problematic, however, when applied to the staging of patients with local-regionally advanced disease manifested as the presence of an ipsilateral pleural effusion, contralateral supraclavicular lymphadenopathy, or contralateral mediastinal lymphadenopathy.[538] Extensive-stage disease is any disease beyond these boundaries. Metastatic disease may involve the liver, adrenals, bone, brain, supraclavicular or retroperitoneal lymph nodes, pleura, contralateral lung, soft tissues, and bone marrow. The diagnosis is usually established via fiberoptic bronchoscopy or via transthoracic needle biopsy.[238] Only rarely is the diagnosis established on the basis of larger biopsy specimens. Histologically small cell carcinoma consists of small round, oval, and spindle-shaped cells with scant cytoplasm, ill-defined borders, finely granular nuclear chromatin, prominent nuclear molding, and a high mitotic rate and absent or inconspicuous nucleoli.[142,539]

In addition to a history and physical examination, individuals with SCLC should undergo routine hematologic and serum chemistry tests and a chest CT study. The chest CT scan is customarily extended caudally to encompass the liver and adrenal glands given the frequency of involvement of these organs. A radionuclide bone scan is indicated in persons with bone pain. Neurologic findings should prompt appropriate imaging studies of the brain or spinal cord (i.e., CT or MRI scans). For a person with an abnormal complete blood count or peripheral blood smear that cannot be otherwise explained, bone marrow biopsy should be considered, particularly if there is no other site of extensive-stage disease. In general, however, a bone marrow assessment is rarely required.[540] Once a patient is found to have unequivocal evidence of metastatic involvement confirming extensive-stage disease, no further workup is necessary unless the patient is being considered for a clinical trial requiring more rigorous staging. This stepwise approach minimizes the cost of the staging assessment without compromising patient care.[541]

The role of PET with FDG in the staging of SCLC is not fully defined.[542,543] In one recent report just 1 of 120 patients was incorrectly staged by FDG-PET, as a result of failure to detect brain metastases.[543] Similarly, in a small prospective trial FDG-PET scans identified metastatic lesions in individuals who were thought to have limited-stage disease by standard staging methods.[542] Thus, it would seem that FDG-PET may reduce the number of tests and invasive procedures required to optimally stage patients and could impact patient management by altering radiation portals in persons with limited-stage disease.[544]

Prognostic Factors

Several pretreatment factors are reported to have prognostic significance in SCLC (Table 76-18).[545–549] The most consistent of these are stage and performance status. The importance of stage has already been mentioned, but it is perhaps worth noting that patients with a single metastatic site will often fare better than the typical extensive-stage patient with many metastatic sites.[550] Patients with poor performance status are less likely to respond favorably to chemotherapy and are more likely to experience major clinical toxicity.[551] Nonetheless, as discussed elsewhere, poor performance status per se does not automatically exclude a patient from consideration to receive combination chemotherapy, in that the occasional patient will experience substantial clinical improvement and survival benefit.[552,553] Female gender has been shown consistently to be a favorable prognostic factor in SCLC.[554] Women enjoy higher overall response rates and longer survivals compared with their male counterparts but do so at the cost of greater treatment-related toxicities. Substantial weight loss (≥10% of body weight) is an independent adverse prognostic factor,[555] as is a high serum lactate dehydrogenase in persons with extensive-stage disease.[545] Hypoalbuminemia, hyponatremia, elevated alkaline phosphatase, and leukocytosis are associated with an adverse outcome in some studies, but these findings are inconsistent from study to study.[546,547,555,556]

Table 76-18 Favorable Prognostic Factors in Small Cell Lung Cancer

Consistently Reported	Inconsistently Reported
Limited-stage	Single metastatic site
Good performance status	Absence of pleural effusion
Female sex	Absence of brain metastasis
Normal lactate dehydrogenase	Absence of liver metastasis
	Age <40 yr
	Normal serum sodium
	Normal liver function

Small Cell Lung Cancer Treatment

Chemotherapy Overview: The Emergence of Etoposide and Cisplatin

For more than 3 decades combination chemotherapy has served as the foundation of SCLC therapy.[238,239] In the earliest phase of SCLC clinical investigation combination regimens typically included alkylating agents such as cyclophosphamide or anthracyclines such as doxorubicin (Adriamycin). Common drug combinations included cyclophosphamide, doxorubicin, and vincristine (CAV) or its variant CAE in which etoposide is substituted for vincristine.[557] Over the past 2 decades, however, platinum-based chemotherapy has supplanted these older regimens in part because of an increase in overall response rates and greater survival without a perceptible increase in the frequency of toxic death.[558] Specific interest in the combination of etoposide and cisplatin (EP) was stimulated initially by the observation that the regimen could produce tumor regression in persons whose cancers had progressed following initial drug treatment with a cyclophosphamide-based regimen.[559–561] In many subsequent comparative studies and in meta-analyses,[562–565] EP has been found to consistently outperform CAV or similar regimens in terms of survival benefit, reduced host toxicity, or both. The consistent performance of EP over nearly 2 decades of clinical trials coupled with the added benefit of its compatibility with TRT (see later discussion) has rendered this regimen the treatment of choice for most individuals with SCLC irrespective of initial stage.[238,239] EP has been described as "[o]ne of the best bargains for state of the art cancer care".[239]

Although EP is widely regarded as the gold standard for the treatment of SCLC, the optimal dose and scheduling of these agents are not well defined.[239] Etoposide has greater efficacy in SCLC when given over multiple days as compared with a dose administered on a single day[566] and is usually administered cyclically over 3 to 5 days. Cisplatin is not schedule dependent but nonetheless is sometimes administered as a split dose to lessen its gastrointestinal and renal toxicities. Increasing doses of etoposide does effect higher complete response rates but has no impact on overall response rates.[567] By contrast, complete or overall responses are not affected by cisplatin dose per cycle, and there is no correlation between survival and dose per cycle of either agent.[567] These data suggest minor variations in the dosing and scheduling of EP have little impact on survival (at least in persons with extensive-stage SCLC). Individuals with limited-stage SCLC given EP using any of the common regimens listed in Table 76-19 should experience complete-response rates of 80% or higher, a median survival of approximately 18 months, and a 5-year cancer-free survival of up to 25%.[568] In persons with extensive-stage SCLC EP is associated with a complete-response rate of more than 20% and median survivals of 7 to 9 months; in addition, 2% of patients will be alive and without cancer at 5 years.[569] The death rate related to EP therapy should be under 2%.[239]

Extensive-Stage Small Cell Lung Cancer

A multitude of therapeutic strategies have been evaluated as a means of improving response rates and overall survival in extensive-stage SCLC.[238,239,557] For the most part these efforts used older alkylating- or anthracycline-based chemotherapy regimens and were uniformly ineffective as reviewed in detail elsewhere.[238,239,557] Attempts to enhance the therapeutic efficacy of the EP regimen have focused on the addition of a third active agent,[570–574] substitution of a newer active agent for etoposide,[575–577] dose intensification,[578] weekly administration of EP with additional active agents,[579,580] integration of putative alternating non-cross-resistant regimens,[562,564] and use of maintenance or consolidation chemotherapy.[581] Unfortunately, none of these strategies has yielded a consistent or clinically meaningful prolongation of survival, nor has host toxicity been consistently or meaningfully reduced relative to a standard EP regimen.[238,239]

Additional Active Agents with Etoposide and Cisplatin

Combining agents with differing mechanisms of action and nonoverlapping toxicities is a time-honored approach to incremental improvement in cancer therapy and a strategy used by several investigative groups (Table 76-20). One of the earliest attempts to use this approach to improve EP was undertaken by a group of HOG investigators.[570] In a phase III trial the HOG investigators compared EP to EP plus ifosfamide. Although the addition of ifosfamide to EP yielded a statistically significant survival benefit (median survival 7.3 vs. 9.0 months; 2-year survival 5% vs. 13%; $P = 0.045$), most experts have viewed the modest survival gain as insufficient to change clinical practice given the added cost and accompanying increase in host toxicity.[239]

The addition of paclitaxel to EP failed to improve overall survival in extensive-stage SCLC (median survival 9.9 vs. 10.6 months; $P = 0.169$) and was accompanied by an increase in renal toxicity, motor-sensory neuropathy, and hearing loss.[572] There was also a tripling of the toxic death rate (6.5% vs. 2.4%), even with the addition of granulocyte colony-stimulating factor support.[572] Similar uninspiring results were reported in a Greek Lung Cancer Cooperative Group randomized trial of EP plus paclitaxel versus EP that was closed early because of unacceptable toxicity in the three-drug arm.[571]

Using a different approach, ECOG investigators treated individuals with extensive-stage SCLC with four courses of induction EP.[574] Persons with stable or responding disease were then randomized to observation or consolidation therapy using four cycles of single-agent topotecan. Progression-free survival was statistically superior for the topotecan arm (3.6 vs. 2.3 months; $P < 0.001$), but there was no difference in median survival (8.9 vs. 9.3 months; $P = 0.43$), and topotecan added substantial toxicity. It is noteworthy that even when individuals with extensive-stage SCLC were selected for chemoresponsive biology (i.e., only patients without progressive disease were

Table 76-19 Dose and Schedule of Etoposide and Cisplatin Administration in Small Cell Lung Cancer

	EP + topotecan*	112	9.3 mo	25%‡	
Pujol et al[573]	EP	109	9.3 mo	29%	
	EP + epidoxorubicin + cyclophosphamide†	117	10.5 mo	40%	0.0067

EP, cisplatin + etoposide; MST, median survival time.
*Topotecan administered as consolidation therapy in patients with responding or stable disease.
†Toxicity-related death rate = 9%.
‡One-year survival from time of randomization (overall 2-year survival = 35%).

randomized), maintenance treatment beyond four cycles of EP with putatively non-cross-resistant properties failed to improve survival.[239]

Finally, a French group conducted a trial that compared EP to EP plus cyclophosphamide and epirubicin and reported a modest but statistically significant improvement in median survival (10.5 vs. 9.3 months; $P = 0.0067$).[573] The survival benefit, however, was accompanied by a marked increase in overall toxicity that included a trebling of the rate of documented infections and a near doubling of the toxicity-related death rate.

In summary, the addition of a third (or more) active agent to EP has thus far proved ineffective as a means of improving survival and is generally associated with increased toxicity.[571–574] Outside of a clinical trial setting, such an approach is to be discouraged.

Active Agents Substitutions in Etoposide and Cisplatin

The substitution of an active agent for etoposide or cisplatin presumes the newer agent will enhance survival, reduce host toxicity, or both. Japanese investigators took this approach in a trial that prospectively compared EP to a regimen consisting of irinotecan and cisplatin (IP); (Table 76-21).[577] The IP regimen consisted of irinotecan 60 mg/m^2 on days 1, 8, and 15 and cisplatin 60 mg/m^2 on day 1 every 4 weeks, whereas EP was administered as follows: etoposide 100 mg/m^2 days 1 through 3 with cisplatin 80 mg/m^2 on day 1 every 3 weeks. The trial was stopped early when an interim analysis revealed that the IP combination had demonstrated survival superiority (median survival 12.8 vs. 9.4 months, respectively; $P = 0.002$). At 2 years the percentage of patients surviving was 19.5% versus 5.2% in favor of the IP arm. The verisimilitude of these results was bolstered by the view that the survival of EP-treated patients was characteristic of this regimen. Severe or life-threatening myelosuppression was more frequent in the EP group than in the IP group, whereas severe or life-threatening diarrhea was more frequent in the IP group compared with those given EP. The authors concluded that IP "is an attractive option for patients with metastatic small-cell lung cancer who have a good performance status."

More recently an American group undertook a confirmatory trial but used a slightly different schedule and dosing of the IP regimen (irinotecan 65 mg/m^2 plus cisplatin 30 mg/m^2 days 1 and 8 every 3 weeks).[576] In keeping with the Japanese trial, grades 3 or 4 anemia, thrombocytopenia, neutropenia, and febrile neutropenia were less common in IP-treated patients, whereas grades 3 or 4 diarrhea and vomiting were more frequent as compared with EP-treated patients. However, in contrast to the Japanese experience, there was no significant difference in response rates (48% vs. 43.6%), median times to progression (4.1 vs. 4.6 months), or median survival (9.3 vs. 10.2 months; $P = 0.74$; see Table 76-21).[576] These investigators determined that IP and EP are therapeutically equivalent and distinguishable only by modest differences in toxicity profile. They have further suggested that IP might be useful when it is anticipated that hematologic toxicity will be a limiting toxicity or when the toxicity is found to be severe during the early cycles of EP.[576]

Given the divergent survival results of the preceding studies, the SWOG initiated a third phase III study that compares IP with EP (S0124). The SWOG trial uses the same IP regimen and study design used in the Japanese study under the presumption that a change in

Table 76-21 Etoposide Drug Substitution Trials in Small Cell Lung Cancer

Reference	Regimen	No. of Patients	MST	1-Yr Survival	*P* Value

EP, etoposide + cisplatin; MST, median survival time; P, cisplatin.

the IP dose and scheduling may account for the negative outcome of the North American study. A more likely explanation resides in the ethnic differences between Asians and Caucasians in the enzymes responsible for irinotecan metabolism.[582] This possibility will be addressed in the SWOG trial that includes pharmacogenomic endpoints (e.g., UGT1A1 polymorphisms) and markers of drug resistance (e.g., ERCC-1 and XRCC-1).

A third attempt to incorporate a topoisomerase I poison into frontline therapy was undertaken by a multinational group that randomized individuals with extensive-stage SCLC to EP or oral topotecan and cisplatin.[575] However, like irinotecan, topotecan did not improve response rates, median time to progression, or overall survival (see Table 76-21). Therefore, the combined data from North America and Europe indicate that the substitution of topoisomerase I inhibitors for etoposide in a platinum protocol is unlikely to displace EP as standard therapy for extensive-stage SCLC in patients of European descent.[239] There may be ethnic and pharmacogenetic differences that favor the IP regimen in patients from Japan and perhaps other Far East countries.[582]

Carboplatin is an active agent against SCLC, with less toxicity and better tolerance than cisplatin.[583] It is also well tolerated when combined with etoposide.[584] The Hellenic Co-operative Oncology Group prospectively compared EP to etoposide plus carboplatin and reported comparable response rates and survival.[585] However, the trial was not adequately powered to discern noninferiority.[586] Nonetheless, these data are frequently cited as justification for the substitution of carboplatin for cisplatin.

Other newer agents such as pemetrexed and amrubicin are under active investigation as possible substitutions for etoposide.[587,588] In general the survival data from these preliminary studies do not suggest these newer agents represent a true major breakthrough.

Etoposide and Cisplatin Dose Intensification

Previous efforts to improve outcome in extensive-stage SCLC through dose intensification were conducted primarily using older alkylating agent or anthracycline-based regimens, and all failed.[238,239] So it is with the EP regimen. In a prospective trial conducted at the NCI, standard-dose EP (etoposide 80 mg/m^2 days 1–3 and cisplatin 80 mg/m^2 day 1 every 3 weeks) was compared to high-dose EP (etoposide 80 mg/m^2 days 1–5 and cisplatin 27 mg/m^2 days 1–5 every 3 weeks for two cycles) in persons with extensive-stage SCLC and good performance status.[578] Although patients in the high-dose EP arm received 68% higher doses and a 46% higher dose-rate intensity, complete response rates (23% vs. 22%; $P = 0.99$) and median survival durations (10.7 vs. 11.4 months; $P = 0.68$) were identical. Leukopenia, thrombocytopenia, febrile neutropenia, and weight loss were all significantly more common in patients randomized to receive high-dose compared with standard-dose EP. Notably, grade 4 leukopenia and thrombocytopenia were infrequent (2% of patients) in the standard-dose EP arm. Although trials of high-dose chemotherapy with stem cell support for SCLC are still under way in Europe,[589] the failure of this approach to overcome drug resistance in other epithelial cancers coupled with the substantial added costs in financial and logistic terms limits this line of investigation to a few enthusiasts. The NCI data, in conjunction with additional supporting data,[562,564] strongly suggest that drug regimens with severe hematologic toxicities are simply not necessary to yield optimal therapeutic results. Recent advances in antiemetic therapy and intravenous hydration regimens suitable for the outpatient clinic can ameliorate the nonhematologic toxicities associated with cisplatin and further enhance the therapeutic index of EP.[238,239]

Weekly Administration of Etoposide and Cisplatin with Additional Active Agents

In general weekly chemotherapy programs combined EP with the active agents used in older cyclophosphamide- and anthracycline-based regimens (i.e., CAV or CAE). A popular regimen for a short period of time was the CODE regimen (EP with doxorubicin and vincristine). CODE was unique in that it combined drug diversity with dose intensity.[239] Unfortunately the approach proved excessively toxic, even in a select group of individuals with extensive-stage SCLC and good performance status, and was no more effective than standard dose and scheduling of alternating EP with CAV.[580] Notably, in extensive-stage SCLC, alternating EP with CAV is not more effective than EP alone.[562,564] Likewise, efforts to interdigitate topotecan and paclitaxel with EP have proved unsuccessful, with no survival improvement but substantially increased myelosuppression.[590] In short, weekly chemotherapy administration is not recommended in the care of patients with extensive-stage SCLC.

Maintenance Therapy

Several randomized trials of maintenance therapy have been carried out since 1980.[591,592] With rare exception,[593] no survival advantage was observed in any of the individual published trials.[592] Highly instructive in this regard is a trial conducted more than 2 decades ago in which individuals with SCLC were treated with induction EP chemotherapy and, where appropriate, thoracic and cranial irradiation depending on initial stage.[581] Only the patients responding to induction EP were randomized to either observation or up to 10 cycles of maintenance CAV chemotherapy. Maintenance therapy with CAV yielded no survival advantage, although there was considerable increased host toxicity. A recent meta-analysis of 14 maintenance chemotherapy trials suggested that there may be a modest survival improvement with maintenance therapy.[591] However, the studies included in this analysis go back to the early 1970s in some instances, and individual patient data were not used. Thus, the clinical relevance of this report is questionable.

Marimastat, an orally administered synthetic inhibitor of matrix metalloproteinases, has been evaluated as maintenance therapy in a placebo-controlled trial.[594] Eligible patients first received four or more cycles of an induction chemotherapy regimen, and only those who achieved a complete or partial remission were randomized. The choice of induction therapy and the decision to use radiation as part of the induction regimen were left to the discretion of individual investigators. Median times to progression (4.3 vs. 4.4 months; $P = 0.81$) and median survivals (9.3 vs. 9.7 months; $P = 0.90$) were identical for marimastat and placebo-treated patients. Quality of life, however, was considerably worse on the marimastat arm at both 3 and 6 months because of substantial side effects. Thus, treatment with marimastat after induction therapy for SCLC did not improve survival and imparted a negative effect on quality of life.

Collectively these data suggest that a plateau has been reached in the management of extensive-stage SCLC using classical cytotoxic agents similar to that observed in metastatic NSCLC.[238,239]

Limited-Stage Small Cell Lung Cancer

Median survival of persons with limited-stage SCLC treated on the control arms of NCI-sponsored randomized trials initiated between 1972 and 1981 was just 12.0 months (range, 10–16 months) compared to a median survival of 17.0 months (range, 11–20 months; $P < 0.001$) in trials carried out between 1982 and 1992.[568] Thus, in contrast to the modest survival progress made in extensive-stage SCLC over the past 2 decades, the survival of individuals with limited-stage SCLC has improved substantially.[238,239,568,595] The relative contribution of improved therapeutic options, better supportive care, and/or stage migration to the observed survival prolongation is difficult to assess from the available literature. However, it is noteworthy that among persons with limited-stage SCLC treated within the context of these U.S. cooperative group trials, some modification in radiation therapy accounted for the improved survival noted in all five of the positive studies, suggesting that modifications in the delivery of irradiation played a prominent role in the survival advances.

In none of the NCI-sponsored randomized trials carried out between 1972 and 1992 did a change in chemotherapy alone account for an obvious survival improvement.[568] However, in subsequent trials EP has demonstrated a survival advantage in limited-stage SCLC compared with older chemotherapy regimens.[565] A Norwegian group randomized limited-stage and extensive-stage SCLC patients to receive EP or a regimen of cyclophosphamide, epirubicin, and vincristine (CEV), the European equivalent of CAV.[565] Among the entire study cohort, survival at 2 and 5 years was significantly better in the EP arm (14% vs. 5%) compared with the CEV arm (6% vs. 2%; $P = 0.0004$). Among the patients with limited-stage disease, EP plus TRT conferred a clear survival advantage compared with patients treated with CEV plus TRT (median survival 14.5 vs. 9.7 months), with 2- and 5-year survival rates of 25% and 10% versus 8% and 3% in the EP and CEV arms, respectively ($P = 0.0001$).[565] In light of these results, EP is now considered the preferred chemotherapy regimen for limited-stage SCLC in virtually all parts of the world.

Attempts to improve upon the results achieved with standard EP regimens and TRT in limited-stage SCLC have used drug substitutions or dose intensification.[596,597] Both strategies yielded improved survival compared with standard combined-modality therapy with EP alone, but a closer look at the data reveals median and long-term survival rates in the standard treatment arms that are clearly inferior to what is usually obtained with concurrent EP and TRT.[596,597] The explanation for this disparity is not clear, although both studies delayed TRT until after administration of the modified chemotherapy program. The need to delay TRT in these studies suggests that these therapeutic strategies may be incompatible with optimal delivery of TRT.[239] Although it is possible there were differences in the prognostic factors or staging methods used in these trials that rendered the participants markedly different from the participants in other recently published studies,[239] this does not seem to be the case. Moreover, the changing demographics of individuals with SCLC do not seem to be particularly conducive to wide-scale use of increasingly toxic combined-modality approaches.[598] Accordingly, these data fail to establish a new treatment standard in limited-stage SCLC as outlined following.

Combined-Modality Therapy for Limited-Stage Small Cell Lung Cancer

Meta-analyses of the individual trials comparing chemotherapy alone to chemotherapy plus TRT show a modest improvement in survival rates in patients on combined-modality therapy.[599,600] The overall relative risk of death in the combined-modality group as compared with the chemotherapy group is 0.86 (95% CI, 0.78–0.95; $P = 0.001$), that is, a 14% reduction in the mortality rate.[599] During the initial 12 months individuals irradiated after diagnosis seem to do slightly less well than nonirradiated patients, but by 1 year a survival benefit emerges that persists beyond 5 years.[239] At 3 years 8.9% of the chemotherapy-only group is alive compared with 14.3% of the combined-modality group. At 2 years local failure rate is 23% for irradiated patients and 48% for nonirradiated patients ($P = 0.0001$).[599] Combined therapy is accompanied by a 1% increase in treatment-related deaths.[239] Because a majority of the trials included in these meta-analyses involved non-platinum-based chemotherapy regimens, it is likely the meta-analyses underestimate the absolute benefit of combined-modality therapy in individuals with limited-stage SCLC and good performance status, because platinum-based therapy allows for easier integration of full-dose chemotherapy and radiation therapy.[239,601] Although these data clearly establish combined-modality therapy as the preferred treatment for patients with limited-stage SCLC and a good performance status, there are unanswered questions relating to the optimization of TRT including timing and sequencing of TRT, optimal total dose, fractionation, and volume of irradiation.[239,595] These issues are covered in the following sections.

Timing of Thoracic Radiation Therapy

Two literature-based meta-analyses addressed the question of optimal timing of TRT in limited-stage SCLC.[602,603] These analyses differ in their definition of early versus late TRT. One defined early chest irradiation as starting within 30 days after the start of chemotherapy and identified eligible studies according to the Cochrane Collaboration Guidelines.[602] Altogether seven trials met the inclusion criteria, most of which used platinum-based chemotherapy regimens.[604–610] Overall survival at 2 or 5 years was not significantly different between early or late TRT, nor was there a significant effect on local tumor control comparing early and late radiation therapy.[602] However, the elimination of one trial that used a non-platinum therapy[611] resulted in a significantly higher 5-year survival when TRT was started within 30 days of starting platinum-based chemotherapy.[602] The survival benefit was even more pronounced when the overall treatment time of TRT was less than 30 days (see later discussion). The second meta-analysis included randomized trials addressing timing of TRT published after 1985 and defined early TRT as beginning before 9 weeks after the initiation of chemotherapy and before the third cycle of chemotherapy.[603] Late TRT was defined as beginning 9 weeks or more after the initiation of chemotherapy or after the beginning of the third cycle of chemotherapy. The 2-year overall survival risk ratio of 1.17 (an absolute 5% survival benefit) favored early radiation therapy (Fig. 76-19).[603] Patients treated with platinum-based chemotherapy and early TRT experienced a significant survival benefit at both 2 (RR, 1.30; 95% CI, 1.10–1.53; $P = 0.002$) and 3 years (RR, 1.35; 95% CI, 1.07–1.70; $P = 0.01$), whereas patients treated with non-platinum-based regimens derived no survival benefit from early TRT. There was also a significant survival benefit associated with early TRT among patients treated with hyperfractionated radiation

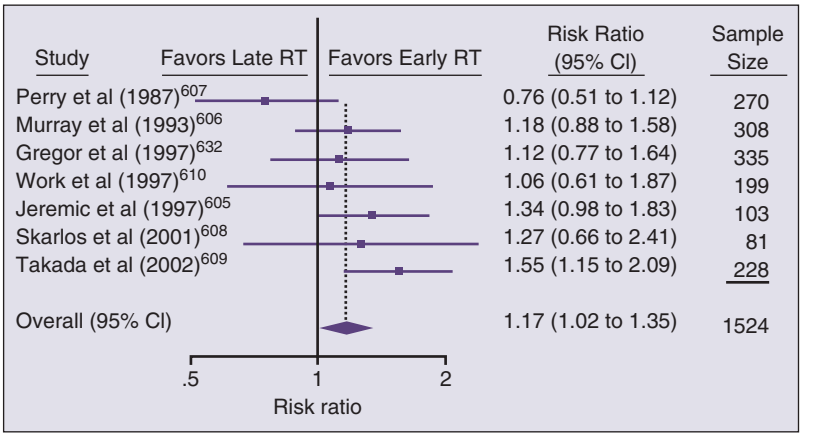

Figure 76-19 • Two-year overall survival risk ratio forest plot for early versus late thoracic radiation therapy. (Reproduced with permission from Fried DB, Morris DE, Poole C, et al: Systematic review evaluating the timing of thoracic radiation therapy in combined modality therapy for limited-stage small-cell lung cancer. J Clin Oncol 2004;22:4785–4793.)

(RR, 1.44; 95% CI, 1.17–1.83; $P = 0.001$ and RR, 1.39; 95% CI, 1.02–1.90; $P = 0.04$, respectively). Patients treated with once-daily irradiation derived no survival benefit from receiving early TRT.

Collectively these data support a small but significant improvement in 2-year overall survival with early TRT in limited-stage SCLC. The greatest difference occurs with platinum-based chemotherapy and hyperfractionated TRT.[603] Both meta-analyses indicate that early combined-modality therapy extracts a price, however, in that severe esophagitis and leukopenia are more frequent and there is a trend toward a higher incidence of severe pneumonitis.[602,603]

Duration of Combined-Modality Therapy

It has been suggested that repopulation of clonogenic tumor cells triggered by one or two cycles of chemotherapy can inhibit the effectiveness of subsequent TRT and may contribute to treatment failure.[612] In other words, the time interval from the start of any treatment in limited-stage SCLC until the end of radiation therapy (known as SER) may have a major bearing on response and survival rates.[613] In a recent analysis of SER, a shorter SER interval was associated with significantly higher 5-year survival (RR, 0.62; 95% CI, 0.49–0.80; $P = 0.0003$). When the SER was less than 30 days, survival improvement was more than 20%. For each week SER is extended beyond 3 weeks there was a decrement in the 5-year survival rate of approximately 1.8% per week. However, improved survival was gained at the expense of greater toxicity mainly as a higher incidence of severe esophagitis. Curiously the study failed to identify a significant relationship between SER and local failure rates, although this is probably attributable to problems in assessing local failure rates in clinical trials. These data indicate that the total time in which the entire combined-modality treatment is delivered is critical in determining survival outcome in limited-stage SCLC.[612,613] This might be achieved in a variety of ways including delivering TRT early as discussed previously and/or through other means such as hyperfractionation.

Fractionation of Thoracic Radiation Therapy

Conventional radiation therapy fractionation can be modified by hyperfractionation (radiation therapy given more than once a day), acceleration (shortening of the overall treatment time), or both.[595] A potential advantage of accelerated radiation therapy is a shortening of SER and the avoidance of accelerated tumor cell repopulation and the attendant detrimental effects.[602] Repopulation of surviving tumor cells may occur between dose fractions of either radiation therapy or chemotherapy and effectively decreases tumor cell kill.[612] Multiple small fractions of radiation therapy or hyperfractionation may be useful, because the radiation dose-response curves for SCLC cell lines lack a shoulder,[614] meaning that even at relatively low doses per fraction, tumor cells are killed exponentially. By contrast, lower radiation dose fractions spare cell populations that have a shoulder as is true of most normal tissues. For these reasons, multiple small fractions of radiation therapy can kill small cell cancer cells while reducing permanent damage to normal tissues lessening the risks of late effects of radiation.

Two U.S. cooperative groups performed randomized trials comparing hyperfractionated with conventional once-daily fractionated TRT in individuals with limited-stage SCLC.[601,615] The results of these studies are seemingly contradictory (Table 76-22). ECOG investigators compared twice-daily irradiation (45 Gy in 1.5-Gy fractions twice daily) to standard once-daily radiation therapy(45 Gy in 1.8-Gy fractions) starting with the first cycle of EP chemotherapy.[601] With a median follow-up of almost 8 years, the median and 5-year survival rates favored patients treated twice daily. There was a higher rate of severe esophagitis in the twice-daily treated arm but little in the way of increased toxicity otherwise. A North Central Cancer Treatment Group (NCCTG) trial, however, found no survival benefit with twice-daily TRT as compared to conventional once-daily TRT.[615] There are important differences in the design of these two trials that may have impacted outcome. In the NCCTG trial all patients initially received three cycles of EP. Only patients without significant progression were randomized to once- or twice-daily TRT, thereby delaying irradiation until the fourth and fifth cycles of chemotherapy.[615] The lengthy delay in TRT administration may have allowed chemotherapy-resistant clones to develop.[612] Further confounding the interpretation of the NCCTG data, the total duration of TRT was not different in the hyperfractionated scheme, because these investigators included a mid-course interruption in the twice-daily arm. In effect this mid-course interruption negated the planned overall acceleration in the hyperfractionated arm, potentially permitting tumor repopulation to take place.[616]

Dose of Thoracic Radiation Therapy

Another unresolved issue is the optimal dose of TRT in limited-stage SCLC. Historically, relatively lower doses of TRT have been used, mostly because of a perceived greater intrinsic radiosensitivity.[239] However, low-dose schedules are associated with a high rate of local failure, suggesting that dose escalation of radiation therapy to levels employed in NSCLC might be beneficial. There is surprisingly little evidence that higher doses of TRT can improve survival because of a paucity of prospective randomized trials addressing the optimal TRT dose question.[239,595] Retrospective studies do suggest that TRT doses greater than 50 Gy translate into improved progression-free survival.[617,618] Some U.S. cooperative groups have escalated TRT doses to 60 Gy and higher, paralleling the doses used in locally advanced NSCLC,[239,595] with individual investigators increasing radiation therapy doses to as high as 70 Gy in 35 fractions over 7 weeks.[618] However, none of these efforts seems to provide survival results superior to the dose and schedule used in the aforementioned ECOG trial (i.e., 45 Gy delivered over 3 weeks).[601] Moreover, the increased treatment times required by the high-dose treatments administered over 6 to 7 weeks are associated with a longer SER. Longer SER is generally associated with a less favorable outcome as outlined previously. In addition, protracted TRT will necessarily overlap with more chemotherapy cycles that in turn will probably result in more frequent dose reductions and treatment delays, further compromising chemotherapy delivery.[239] Ideally, TRT doses of 60 Gy or more should be evaluated against the twice-daily schedule

Table 76-22 Hyperfractionated Thoracic Radiation Therapy in Small Cell Lung Cancer: Randomized Phase III Trials

Group	No. of Patients	TRT Schema	MST (mo.)	5-Yr Survival (%)
ECOG[601]	211	45 Gy, 1.5 Gy twice daily, wk 1–3	23	26
	206	45 Gy, 1.8 Gy daily, wk 1–5	19	16
NCCTG[615]	130	48 Gy, 1.5 Gy twice daily, wk 13–14; 17–18	20.6	22
	131	50.4 Gy, 1.8 Gy daily, wk 13–18	20.6	21

MST, median survival time; TRT, thoracic radiation therapy.

used by ECOG investigators to clearly define "a dose effect" in the management of limited-stage SCLC.[239,595] Unfortunately no such study is under way or planned.

Target Volume for Thoracic Radiation Therapy

Two issues tend to dominate the debate surrounding optimal target volume: the need to electively irradiate lymph nodes and the decision to treat the pre- or postchemotherapy volume of disease if TRT is to be delayed. With modern planning capabilities many experts feel that the irradiation portal should be confined to clinically palpable nodes in the supraclavicular fossa, disease found by bronchoscopy and lymph nodes that measure ≥1 cm on CT scans.[239] Larger treatment ports increase exposure to the esophagus, lung, and other sensitive normal tissues and increase normal tissue toxicities (e.g., esophagitis and pneumonitis).[239] However, limited-stage SCLC can present as a large mediastinal mass. This presents a challenge for radiation dosimetry planning, because the thoracic spine dose must be held to less than 46 Gy, and the volume of lung receiving 20 Gy (V20) must be less than 30% of the entire lung volume. The volume of the radiation should include areas of bulky lymph nodes along with the primary neoplasm so as to reduce esophagitis and pneumonitis.[239] When initial bulk of tumor is too large to reasonably treat with a radiation port, two cycles of chemotherapy may reduce the volume sufficiently with radiation ports that do not excessively irradiate the lungs.[619] Recent studies have explored the feasibility of using intensity-modulated radiation therapy to treat these large mediastinal masses to higher doses. For example, non-coplanar (parasagittal) fields can be used to minimize the volume of lung treated. Intensity-modulated radiation therapy can be considered if the volume of lung receiving 20 Gy is less than 30% and if patients have FEV_1 exceeding 1 L. Otherwise, anteroposterior/posteroanterior fields should be considered to 39 Gy followed by oblique (off spinal cord) fields.

On the basis of the extant data we believe that concurrent twice-daily TRT (45 Gy in 3 weeks) beginning with the first cycle of EP chemotherapy represents the "gold standard" for combined-modality treatment in patients with limited-stage SCLC and good performance status.[601] Higher dose once-daily fractionated TRT may be equivalent to this approach, but prospective randomized data supporting this supposition are lacking. In circumstances where the early application of TRT would necessitate treating an excessively large volume, delaying TRT until one or two cycles of chemotherapy seems justified.[602] The treatment portal should then be limited to the postchemotherapy tumor volume to minimize toxicity to normal tissues.[619]

Surgery in Small Cell Lung Cancer

The role of surgery for SCLC has come full circle in the past 4 decades. The disease has been thought of as systemic from the outset, and chemotherapeutic treatment has long been standard. In the mid-twentieth century, however, the British Research Medical Council randomized individuals with SCLC to surgery or TRT.[620] The patients on the surgical arm had worse survival, but neither arm did particularly well, with less than 5% of patients alive at 5 years. Subsequently, The VA Surgical Oncology Group entered more than 2000 patients in a study looking at the role of adjuvant chemotherapy after resection of NSCLC.[621] A total of 148 individuals with SCLC were incidentally entered in the study, and those with early-stage disease enjoyed superior survival.

Surgery for early-stage small cell carcinoma, particularly those cancers presenting as small single pulmonary nodules, may be more appropriate, as these tumors may be biologically distinct from more advanced disease.[622–624] For example, in a retrospective study, Roswell Park Cancer Institute investigators identified a small number of individuals with SCLC whose lesions were "isolated". These persons did not receive "prompt" diagnosis or treatment of their cancers. Moreover, extremely slow growth of the tumors was documented ranging from 14 to 40 months, and no lymph node involvement or metastatic disease was found at the time of surgery. Thus, this experience is not characteristic of SCLC in general. Nonetheless, other studies of resection for individuals with T1N0M0 tumors have suggested a 50% to 80% 5-year survival rate, although it is extremely rare for patients to fall into this category.[625] In the early 1990s University of Toronto investigators reviewed a 15-year surgical experience with SCLC at that institution.[625] They reported that resection improved control at the primary site, and a significant proportion of patients with stage I (N0) disease achieved long-term survival and cure with combined-modality therapy including surgery. Moreover, patients with stage II and IIIA SCLC had survival durations similar to patients with stage IIIA NSCLC who were treated surgically.[625]

There may be other circumstances where one might consider performing surgery with or without systemic therapies in selected individuals with SCLC.[623] First, small cell cancer treated with chemotherapy plus radiation therapy still has a high local recurrence rate. Surgery for other thoracic malignancies, particularly esophageal cancer, affords significant improvement in local control, even when added to radiation therapy. Second, surgery immediately puts the patient into a "no clinical evidence of disease" category, and both chemotherapy and radiation therapy work better on small-volume or microscopic disease. Finally, mixed-histology SCLCs contain non-small cell elements that may be less responsive to irradiation or chemotherapy. NSCLC is relatively resistant to chemotherapy, and surgery is the best curative option for this disease.[626] Therefore, an argument could be made for resection of residual disease after chemotherapy, especially if the remaining element represents a non-small cell fraction. There has been one randomized study testing this role for surgery in SCLC.[627] The Lung Cancer Study Group gave individuals with limited-stage SCLC standard chemotherapy for five cycles, followed by prophylactic cranial irradiation (PCI) and TRT; the patients were also randomized to receive or not receive surgery. It is interesting to note that 9% of individuals who did undergo surgery had residual non-small cell elements. Actuarial 2-year survival was identical on the two arms at 20%; thus, no survival benefit was demonstrated for surgery. However, this study excluded persons who would have fallen into the extremely limited T1N0M0 or T2N0M0 non-small cell staging schema—the ones who had shown the most benefit from surgery in earlier studies. Thus, this trial does not definitively exclude a role for postinduction surgery in SCLC, although admittedly such an approach is likely to be exceedingly uncommon in clinical practice.

In summary, the benefits of surgical resection in SCLC are mainly seen in persons with TNM stage I disease with peripheral tumors and no nodal involvement, and who are able to tolerate the procedure. Adjuvant chemotherapy should be offered postoperatively.

Prophylactic Cranial Irradiation

The need for PCI in individuals with limited-stage SCLC had long been an area of controversy.[628,629] This issue is critical in the management of limited-stage disease for two key reasons: the central nervous system has long been considered a sanctuary site from many chemotherapeutic agents, and the brain is a common site of metastasis in this cancer. Limited-stage SCLC successfully treated with induction chemotherapy plus radiation therapy is estimated to have a 50% to 67% chance of relapse in the brain, with one third of these patients having disease solely in the central nervous system.[630] A meta-analysis of seven randomized trials published in 1999 demonstrated a significant benefit to PCI.[631] Patients who received PCI were 5.4% more likely to be alive at 3 years, had a 54% reduction in the risk of brain metastases, and a 25% increase in disease-free survival.[631] Although there has been some concern that PCI can lead to late cognitive impairment, no detectable difference in post-treatment cognitive impairment or quality of life is found at 1 year after treatment.[632] Because the overall benefits seem to outweigh the risks,[628] current guidelines recommend PCI for all patients with a good

performance status who have attained remission after induction chemotherapy plus radiation therapy.[631,632] This includes individuals with extensive-stage disease in complete remission, although the benefit for this subset of patients is not as clear-cut.[631] PCI should be given sequentially, rather than concurrently, to avoid additional toxicity.[633] Typically patients receive 25 to 36 Gy in 10 to 18 fractions.[239]

Elderly Individuals with Small Cell Lung Cancer and Poor Performance Status

The proportion of people 70 years of age and older that has limited-stage SCLC has increased from 32% in 1985 to 45% in 2000.[598] This percentage is likely to increase in the coming decade as members of the post-World War II "baby boomer" generation enter into their sixth and seventh decades of life. Given the lengthy smoking history in the majority of persons with SCLC, many also suffer from the cardiovascular and pulmonary sequelae of smoking, which can negatively impact performance status. In turn, impaired performance status associates with greater treatment-related toxicity, as does the abnormal cardiac, liver, or renal function often observed in the elderly.[634,635] As a result, curative chemotherapy is often not even attempted in the elderly with a wide variety of malignancies.[636] Age alone, however, is not a sufficient reason to deny an elderly patient potentially curative or appropriate palliative therapy. At one point it was assumed that single-agent cytotoxic therapy might afford a measure of palliation in such individuals without engendering the toxicity associated with combination chemotherapy while simultaneously preserving a survival benefit. However, in two randomized trials that compared single-agent oral etoposide with combination-chemotherapy regimens, persons assigned to combination regimens not only lived longer but also had fewer side effects.[552,553] Given these findings, intravenous combination chemotherapy is considered the standard treatment in this setting. Among elderly individuals with limited-stage SCLC and a good performance status, the standard combined-modality approach remains the preferred option.[615,637] When the tolerability of standard-dose EP is deemed to be problematic, options include dose reduction, substitution of carboplatin for cisplatin,[585,638–640] or possibly a combination of low-dose cisplatin, doxorubicin, vincristine, and etoposide.[641] Selected, fit older patients are as able as younger patients to tolerate chemotherapy, although their management may require more attention to supportive care.[642]

Second-Line Chemotherapy in Small Cell Lung Cancer

There is no best salvage regimen or drug for recurrent or resistant SCLC.[643] Topotecan is the only agent approved by the FDA for use as second-line chemotherapy in SCLC.[644,645] It is associated with a modest prolongation of survival and quality-of-life benefit whether given intravenously or orally.[646] Other agents such as paclitaxel,[647,648] oral etoposide,[649] irinotecan,[650] and amrubicin[651] are useful in this setting as well. From a practical standpoint, the most important influences on the decision to administer second-line therapy are the person's current performance status, the level of sensitivity to induction therapy, and the interval from prior therapy. Patients with a good performance status, sensitivity to prior therapy, and a progression-free period of more than 3 months are much more likely to respond to second-line treatment. Retreatment with the induction regimen or one of the agents listed previously is appropriate for individuals meeting these criteria. For all others, second-line therapy tends to be a process of "trial and error" of single agents or combinations.[643] Paclitaxel-containing regimens may be especially useful in individuals without prior response or a very short treatment-free interval after initial first-line treatment, especially if non-platinum therapy is used as induction therapy.[647,648] Radiation therapy can be an effective treatment for palliation of specific symptoms and isolated intrathoracic relapses.[643]

Novel and Targeted Therapy in Small Cell Lung Cancer

In contrast to NSCLC, *EGFR* mutations are virtually never found in SCLC.[62] Notably, however, two independent groups found *EGFR* mutations in females who had never smoked and who were diagnosed with SCLC.[652,653] Both patients were initially diagnosed as having an adenocarcinoma and were treated with an EGFR TKI (gefitinib or erlotinib). Subsequent analyses of tumor material obtained at the time of disease progression or at postmortem revealed SCLC with an *EGFR* mutation. In both cases the mutation involved exon 19. It is unclear whether these women originally had a combination of SCLC and NSCLC or whether the NSCLC transdifferentiated to SCLC after prolonged treatment with erlotinib.[653] Nevertheless, these data suggest that *EGFR* mutations may be important in the rare circumstance where SCLC develops in a person who has never smoked. Although extremely rare in nonsmokers, SCLC is found in nearly 3% of women with lung cancer who had never smoked.[245] Additional novel targeted agents investigated in SCLC include inhibitors of matrix metalloproteinases,[594] c-kit,[654] farnesyl transferase,[655] proteasome inhibitors,[656] and mTOR,[657] conjugated antibodies against CD56,[658] bcl-2 antisense oligonucleotide[659] and anti-idiotype vaccines.[524] Essentially all these efforts have proved negative or inconclusive.[660] Antiangiogenesis agents such a bevacizumab are worthy of additional study given recent successes in NSCLC[523] and other solid tumors.

77 Tumors of the Pleura and Mediastinum

Mika A. Sovak, Seena C. Aisner, and Joseph Aisner

SUMMARY OF KEY POINTS

Malignant Pleural Mesothelioma

Epidemiology

- Malignant mesothelioma is a rare disease closely associated with asbestos exposure (all fiber types).
- Based on the prior use of asbestos, more than 8 million people are exposed and at risk in the United States.
- More than 3000 cases are estimated to be diagnosed in the United States annually, with the incidence still increasing.
- It is more likely to be seen in men and more likely to occur on the right side.
- Three subtypes exist: epithelial, fibrosarcomatous, and mixed.

Differential Diagnosis

- The epithelial form must be distinguished from metastatic adenocarcinomas.
- To establish the diagnosis, a generous tissue biopsy or cell block is needed so that a battery of tests may be performed, including histochemistry and immunohistochemistry.
- Immunohistochemistry now can be defining.
- Electron microscopy often is helpful; normal adjacent lung for fiber count is helpful.

Staging Evaluation

- Take a medical history and a complete occupational history, and perform a physical examination.
- Obtain computed tomography (CT) scan of chest and abdomen and a positron emission tomography (PET) scan to define the extent of disease and of mediastinal involvement.
- Focus on potential operability: CT scan of chest, bone scan, and pulmonary and cardiac function tests.
- Evaluation can be abbreviated if disease is not operable; CT scan is the best modality for following the disease.
- Use new TNM staging system.

Primary Therapy

- Therapeutic interventions are limited; consider referral to a specialty center.
- Assess symptoms carefully, and discuss risk-benefit ratio for any therapy, especially in patients with compromised performance.
- For operable disease, perform either pleural stripping with postoperative irradiation or extrapleural pneumonectomy. The role of adjuvant therapies is not certain.
- Intrapleural therapies are possible only in early disease.
- Consider radiation therapy to incision sites and needle traces to prevent growth.
- Radiation therapy may be used as a postoperative adjuvant or for symptom control.
- Chemotherapy: pemetrexed plus cisplatin; high-dose methotrexate; gemcitabine plus cisplatin; new agents remain justified.

Metastatic Tumors of the Pleura

Incidence

- Occurrence is related to the incidence of primary tumors.
- Metastases are seen most commonly with lung, breast, lymphoma, gastric, colon, melanoma, ovary, and prostate tumors.

Differential Diagnosis

- Cytology often is able to diagnose malignancy—cell block for immunohistochemistry (adenocarcinoma vs. other). Metastases should be distinguished from primary tumors, especially in high-risk individuals.
- Mucin positivity virtually excludes mesothelioma.
- Primary source identification could help to define treatment for the underlying primary disease.

Staging

- Metastatic disease, by definition (M1).

Primary Therapy

- Drain effusions for symptom control and treat the underlying primary neoplasm.
- For recurrent effusions, drain and sclerose using talc. Antibiotics (minocycline), chemotherapy (bleomycin), or biologics (*Corynebacterium parvum* [interferon {IFN} or IL-2]) have been used.

Secondary Therapies

- For highly selected patients, consider pleurectomy if effusion is resistant and the prognosis is reasonable.

Mediastinal Neoplasms

General

- Tumors are categorized or catalogued by anatomic compartments: anterior, middle, and posterior.
- Anterior compartment tumors are predominantly thymomas, lymphomas, and germ cell tumors.
- Middle compartment tumors are myxomas and malignant tumors and cysts of the heart and pericardium, including angiosarcomas, rhabdomyosarcomas, mesotheliomas, fibrosarcomas, lymphomas, extraskeletal osteosarcomas, neurogenic sarcomas, malignant teratomas, thymomas, leiomyosarcomas, liposarcomas, and synovial sarcomas.
- Posterior compartment tumors are neural crest tumors: peripheral neuroectodermal tumor (PNET), neuroblastoma, ganglioneuroma, pheochromocytoma, schwannoma, and neurofibroma.

Tumors of the Anterior Mediastinum

Epidemiology

- Thymoma
  - Twenty percent of all mediastinal tumors in adults
  - Equal male/female distribution

- Most common in the fifth and sixth decades of life
- More aggressive in children
- A possible association with Epstein-Barr virus (EBV) exists.
- Complications include myasthenia gravis, red cell aplasia, and hypogammaglobulinemia.

- Lymphoma
  - Lymphomas commonly include Hodgkin and non-Hodgkin lymphomas.
- Germ cell tumors
  - Anterior mediastinal tumors form 1% of all germ cell neoplasms and are related to malignant transformation of mediastinal germinal elements.
  - Malignant forms seen are predominantly similar to those of testicular germ cell tumors.

Differential Diagnosis

- Thymoma
  - To establish diagnosis, a generous tissue biopsy is needed for special stains and definition of architecture.
  - Subtypes include lymphocytic, epithelial, thymic carcinoma, and thymic carcinoid.
- Lymphoma
  - To establish diagnosis, sufficient material is needed for flow cytometry for immunophenotyping.
  - Tissue biopsy is helpful for special stains to define nodal architecture and cellular types.
  - Flow and biopsy should be reviewed by a pathologist with experience in lymphomas.
- Germ cell tumors
  - In the presence of appropriate biomarkers, fine-needle biopsy can establish diagnosis.
  - Subtypes (seminomatous and nonseminomatous) could require more generous tissue samples in the absence of biomarkers.

Staging and Evaluation

- Thymoma
  - Take history and perform physical examination, complete blood count, serum protein electrophoresis, and chest CT scan (role of MRI scans is not yet clear).
- Lymphoma
  - Take history and perform physical examination.
  - The remaining steps of staging and evaluation are described in the chapters on Hodgkin's and non-Hodgkin's lymphoma.
- Germ cell tumors
  - Take history and perform physical examination, chest CT scan, α-fetoprotein (AFP), β-human chorionic gonadotropin (HCG), and lactate dehydrogenase (LDH).

Primary Treatment

- Thymoma
  - Perform complete surgical resection.
  - If residual disease exists after surgery, add radiation therapy. The role of chemotherapy is not established; if the tumor is nonresectable, use radiation therapy.
  - The role of neoadjuvant therapies is not well defined.
- Lymphoma
  - Therapeutic approaches are defined in the chapters on lymphoma.
- Germ cell tumors
  - Therapeutic regimens generally follow the approaches outlined for poor-prognosis testicular germ cell tumors, with primary and secondary chemotherapy regimens and autologous bone marrow transplantation.

Tumors of the Middle Mediastinum

Incidence

- These are all very rare tumors.
- More than half are benign atrial myxomas; malignant tumors of the heart are very rare.
- Malignant tumors can originate from or metastasize to the pericardium. Other mediastinal structures can be involved depending on site and histology.
- Too few cases of pericardial mesothelioma exist to draw any inferences about an association with exposure to asbestos.

Differential Diagnosis

- Myxomas are suspected from patterns of congestive failure or embolic disease; excisional biopsy often is based on angiographic studies.
- Malignant tumors sometimes can be biopsied through bronchoscopy or via thoracoscopy. Generous amounts of tissue often are needed to define histology. Pathology experience with soft tissue tumors usually is helpful.

Staging and Evaluation

- A careful history and a physical examination are needed.
- Myxomas are best seen by cardiac catheterization. MRI might also be useful.
- Malignant tumors are best visualized by CT or MRI scan.

Primary Treatment

- Perform surgical excision of myxomas and soft tissue tumors; radiation therapy or chemotherapy have no defined role in the absence of metastases.
- Treat the underlying primary malignancy in the case of metastatic disease.

Posterior Mediastinal Tumors

Incidence

- These are rare tumors mostly originating from the neural crest; others (rarely) include lymphoma and soft tissue tumors.

Differential Diagnosis

- Tumors are in two basic groups: (1) neuronal origin, including the nerve ganglion cells (neuroepithelioma, neuroblastoma, ganglioneuroblastoma, and ganglioneuroma) and neuroendocrine cells (e.g., pheochromocytoma, paraganglioma, and medullary thyroid carcinoma); and (2) neural sheath cells or Schwann cells, including schwannoma and neurofibroma.
- Most tumors are benign.
- Adequate tissue samples are needed to perform special stains, electron microscopy, and possible cytogenetics (peripheral neuroectodermal tumors).

Staging Evaluation

- Perform CT scans; test for metanephrines in the case of labile hypertension.

Primary Treatment

- Perform surgical resection; local recurrence is likely with incomplete resection.
- Roles of radiation therapy and chemotherapy are not well defined.

PRIMARY TUMORS OF THE PLEURA

Benign and malignant primary tumors of the pleura constitute a group of unusual and rare diseases. In contrast, metastases to the pleura are a relatively common manifestation of many cancers. The diagnosis and management of the benign and malignant tumors of the pleura present important but often difficult challenges for clinicians.

Primary tumors of the pleura can originate either from the surface of the mesothelium or from the submesothelium. These various rare

Table 77-1 Classification of Tumors of the Pleura

Localized	Diffuse
MESOTHELIAL (PLEURAL)	
Adenomatoid tumor	Epithelia malignant mesothelioma
Cystic mesothelioma	Tubulopapillary
Benign papillary mesothelioma	Nonglandular (solid)
Mesothelioma of the atrioventricular node	Sarcomatous (fibrous)
	Biphasic (mixed)
	Undifferentiated
SUBMESOTHELIAL (SUBPLEURAL)	
Fibroma (localized mesothelioma)	Angiosarcoma
Fibrosarcoma (localized malignant fibrous mesothelioma)	
Angioma	
Angiosarcoma	

tumors can present as either localized or diffuse (Table 77-1). With the exception of the localized malignant soft tissue tumors, most of the localized tumors tend to behave in a benign manner, whereas the diffuse tumors tend to be more malignant in their behaviors. The usual approach to localized tumors is surgical excision, including the chest wall as needed. The role of adjunctive radiation therapy to augment local control is not well defined. For the localized soft tissue sarcomas, excision still remains the treatment of choice. In one review of 82 malignant localized tumors, 37 (45%) were cured by simple excision.[1] Because of the rarity of these tumors, studies of postoperative therapy are lacking, and there is no convincing evidence for the role of any adjunctive postoperative therapy.

Benign Mesothelioma

Benign (localized) tumors arising from the mesothelium have been described as arising from the pleura, the peritoneum, the tunica vaginalis testis, the atrioventricular (AV) node, the mediastinum, the liver, and the adrenal gland.[2–8] These tumors tend to grow to considerable size and produce symptoms by the effect of their mass, such as compression or blockage of adjacent structures. The most common approach to treatment is surgical excision. Local recurrences are prominent in cases of incomplete resection. These tumors are believed to originate from the mesothelial cells; however, there remains some uncertainty regarding the origin of AV node mesotheliomas, which might arise from submesothelial mesenchymal cells.

Benign fibrous tumors of the pleura are believed to arise from submesothelial fibrous tissue and thus have been called submesothelial fibromas, localized fibrous mesotheliomas, or solitary fibrous tumors of the pleura.[9–11] These tumors are considerably less common than malignant mesotheliomas, with no defined association with asbestos exposure. They can present as very large, pedunculated intrathoracic masses and sometimes are seen with hypertrophic pulmonary osteoarthropathy or serosanguineous effusions. These tumors rarely invade the visceral pleura and, therefore, produce clear margins between the tumor and the compressed lung. Diagnostic imaging with either computed tomography (CT) or magnetic resonance imaging (MRI) scans tends to be highly suggestive of the tumor, and complete surgical resections thus are possible, although chest wall resections could be required. Definitive diagnosis and exclusion of malignant mesothelioma must be based on histologic confirmation and immunohistochemical staining (CD 34+), however.[12] Local recurrences can be seen late and can result in fatality, although curative re-excision often is possible.[11,13]

Malignant Pleural Mesothelioma

Epidemiology

Before 1960, the existence of mesothelioma as a distinct pathological entity was still debated. In 1960, Wagner and colleagues[14] initially reported 33 cases and then added 14 additional cases of mesothelioma diagnosed in a South African asbestos (crocidolite) mining community, where patients were exposed to asbestos. Selikoff and coworkers[15] noted an association between asbestos exposure and mesothelioma among pipe fitters, and these observations were followed by reports of mesotheliomas among asbestos workers in other parts of the world.[16,17] Malignant mesothelioma of the pleura, peritoneum, and tunica vaginalis testis now are well recognized as being associated with asbestos exposure, with other potential causal factors including prior radiation therapy, extravasated Thoratrast, and certain other fibers with physical properties similar to asbestos, such as zeolite and erionite.[18] Current estimates suggest that about 3000 new cases of mesothelioma are seen annually in the United States.[19] The frequency with which malignant mesothelioma can be linked to asbestos exposure varies somewhat according to the geographic location. On the east and west coasts of the United States, the association approaches nearly 80%, whereas in the Midwestern states, the association is seen about 60% of the time.[20] The exact incidence and death rate from malignant mesothelioma remain difficult to estimate, due in part to the continued coding of mesothelioma as lung cancer. Although the incidence of mesothelioma continued to rise throughout the 1980s, reflecting a marked increase in the use of asbestos since World War II, more recent studies suggest a declining incidence in the United States, perhaps a result of governmental regulations instituted in the 1970s.[21–23] However, the incidence worldwide is expected to continue to rise for at least the next 10 to 20 years.[24]

Reflecting the association with asbestos exposure in the workplace, malignant mesothelioma is seen more commonly in men than in women. Furthermore, because of the long latent period in its development, the incidence rises with age, and the median age at presentation is greater than 65 years. Mesothelioma has been reported as a consequence of household exposure among family members of asbestos workers, however, and in young adults as a consequence of household or neighborhood exposure.[24] The risk of mesothelioma thus is not limited to those who are directly involved with the mining, milling, or application of asbestos but also extends to those who are in proximity to the use of the asbestos material or are exposed to it when it is carried home in clothing or hair.

Asbestos is a group of mineral silicate fibers that are found widely throughout the world, with mining activity in Canada, China, Russia, South Africa, and the United States.[25] Because of its superior fire-resistant qualities, it was used extensively in the shipping and construction industries. Two major forms of asbestos exist: a serpentine form (chrysotile) and the thin, rodlike amphiboles (crocidolite, amosite, anthophyllite, tremolite, and actinolyte).[25] The carcinogenic effects of asbestos are believed to be a function of their physical rather than chemical properties, with amphiboles potentially being the more carcinogenic form.[24,26,27] Asbestos fibers separate easily to form numerous minute strands. The small, inhaled fibers, which are not cleared by mucociliary action, migrate distally through the endothelial lining and into the interstitial tissues, where they accumulate in the lower third of the lungs and then penetrate into the visceral pleura. The fibers are ingested by macrophages, which often are damaged in the process, leaking lysosomal enzymes, cytokines, superoxides, and other free radicals. The asbestos fibers thus produce inflammatory and fibrotic reactions.[28] The fibers also can carry absorbed carcinogens, which might contribute further to the carcinogenic process.

The number of asbestos-exposed individuals rose throughout most of the 20th century as a consequence of increased asbestos mining and

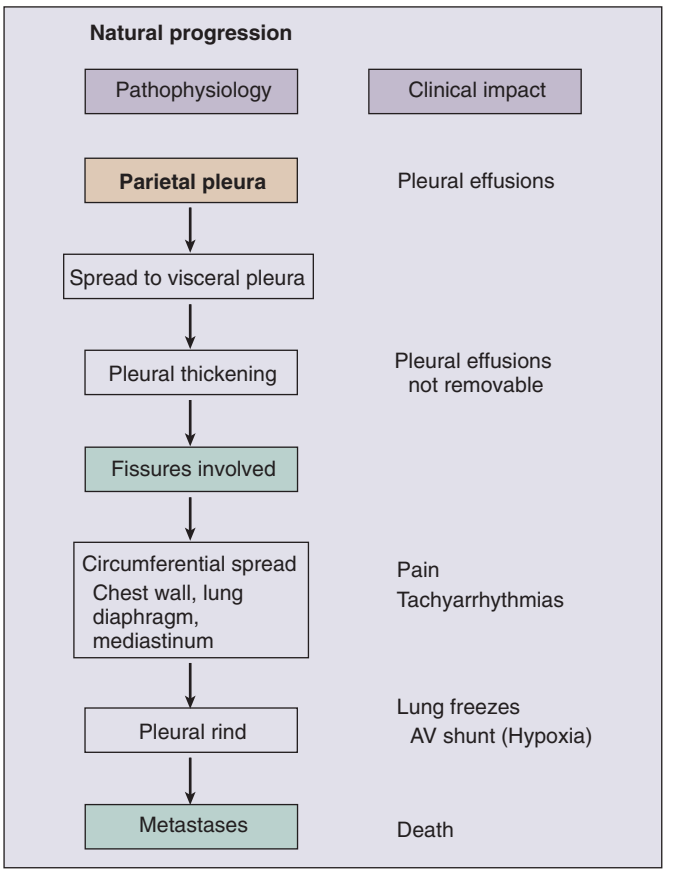

Figure 77-1 • Outline of the progress of the natural history of malignant pleural mesothelioma and the approximate clinical events and findings at various stages of evolution.

use. Despite the large number of exposed individuals, mesothelioma remains a fairly rare cancer, leading some observers to argue that additional factors, such as accumulating genetic alterations or viruses, could contribute to the causation. Advances in molecular technology now allow the identification of various oncogenes, tumor suppressor genes, and signaling pathways, which are perturbed in cases of mesothelioma. One hypothesis suggests that simian virus 40 (SV-40) might play an important etiologic role.[29] Based on experimental findings of SV-40-associated mesotheliomas in hamsters, several investigators performed polymerized chain reaction (PCR) analysis in human mesothelioma specimens and found SV-40 sequences in 40% to 50% of the specimens.[30–34] This hypothesis is of considerable concern, because as many as 32 million adults in the United States were vaccinated with polio vaccine contaminated with infectious SV-40.[35] However, a clear etiologic link remains to be proven.[36,37] Nonetheless, if this hypothesis is correct, malignant mesothelioma could become a far more common cancer, and further study of the molecular mechanisms of pathogenesis are needed urgently.

Clinical Presentation and Diagnosis

Most commonly, signs and symptoms associated with pleural effusion, such as shortness of breath, dyspnea on exertion, or nonpleuritic chest wall pain, bring patients to medical attention. Other common features at presentation include fever of unknown origin, sweats, a declining performance status, and weight loss.[38] Physical examination usually discloses unilateral shifting dullness, and chest roentgenograms show a large pleural effusion, more often involving the right side. Roentgenograms also might show evidence of asbestos exposure, such as pleural plaques or calcifications in the diaphragm, although asbestosis is not a necessary precondition. With the recent emphasis on asbestos-associated illness, increased surveillance occasionally identifies asymptomatic individuals with an incidental effusion on chest x-ray.[39] CT scans of the chest, however, are far more sensitive and are used to assess the extent of disease. Pleural thickening with involvement of the interlobar fissures and atelectasis are evident early on CT scan.[40] Thrombocytosis, disseminated intravascular coagulation, thrombophlebitis, pulmonary emboli, and Coombs-positive hemolytic anemia also have been reported.[38,41–43] The median duration of survival ranges from 4 to 18 months in most reported series. Prognostic factors at presentation that are associated with a better survival include the following[44,45]:

- Younger age
- Good performance status
- Stage
- Epithelial histology
- Lack of chest pain
- Normal platelet count

Figure 77-1 outlines the natural progression and associated clinical findings of malignant pleural mesothelioma. As mesothelioma progresses, the tumor obliterates the pleural space, encasing the lung and invading lung parenchyma as well as adjacent organs, with distant metastases developing only late in the course of the disease (Fig. 77-2). The tumor can grow along thoracentesis, chest tube drainage, or thoracotomy tracts in 10% or more of cases, and direct extension into esophagus, ribs, vertebrae, nerves, and the superior vena cava can cause dysphagia, chest pain, cord compression, plexopathy, Horner's syndrome, or superior vena cava syndrome.[18,46] Direct extension also occurs commonly into the pulmonary parenchyma, the chest wall, into the mediastinum, and through the diaphragm into the abdominal cavity (Figs. 77-2 through 77-4). Mediastinal and cervical lymph nodes also can be involved. As the disease progresses, loss of diaphrag-

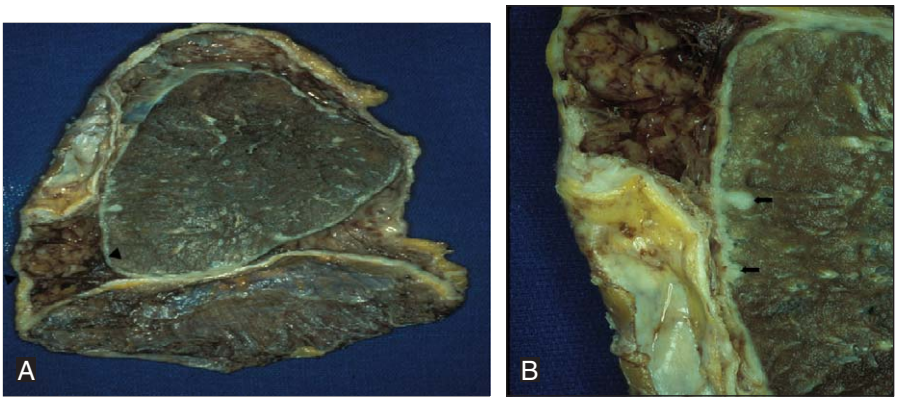

Figure 77-2 • **A,** Resected lung and diaphragm showing thick rind of tumor *(arrowhead)* encasing entire lung and trapping its function. **B,** Extension of the pleural tumor *(arrows)* into adjacent lung from the visceral pleura. Attempts to remove the visceral pleura obviously would leave residual tumor on the pulmonary surface. (Courtesy of S.C. Aisner, MD.)

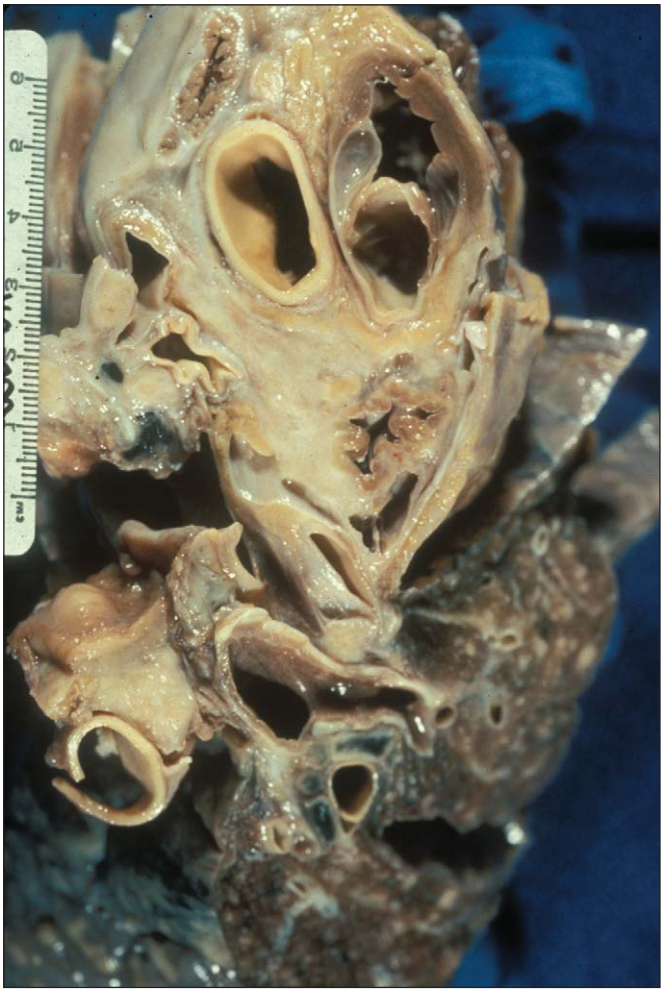

Figure 77-3 • Autopsy specimen showing extension of the mesothelioma into the mediastinum, trapping the heart, great vessels, and airways. (Courtesy of S.C. Aisner, MD.)

matic and intercostal muscle movement, chest contraction, and scoliosis also develop. Symptomatically, as the disease advances, patients complain of fatigue and dyspnea out of proportion to chest x-ray findings due to the shunting of poorly aerated blood in the trapped lung.

Most patients undergo repeated thoracenteses with negative or indeterminate cytology despite active tumor, because pleural effusions often produce atypical mesothelial cells that confound diagnosis. Needle biopsies might disclose tumor; however, pathologic distinction from adenocarcinoma can be difficult on the small specimens obtained. Thoracoscopy and pleuroscopy have been successful in obtaining adequate tissue samples.[47] Boutin and Rey[48] showed that thoracoscopy can be nearly 95% as accurate as diagnostic open thoracotomy. In early disease, discrete nodules and coalescent plaques are seen on the visceral and parietal pleura at the time of surgery. In more advanced disease, the pleural space is obliterated by a thick cake of tumor (see Fig. 77-2). Generous samples usually are taken for diagnosis. In view of the highly litigious nature of the disease, and although it is probably irrelevant, samples of uninvolved lung probably should be obtained as well for counting asbestos fibers.[49]

Pathology

Three histologic subtypes of mesothelioma usually are described: epithelial, sarcomatous, and mixed (epithelial/sarcomatous). Most mesotheliomas occur in the epithelial form, and these can exhibit papillary, solid, tubular, or vacuolated patterns. The sarcomatous form appears similar to a fibrosarcoma, with predominantly spindle-shaped or ovoid cells. The mixed or biphasic form demonstrates both epithelial and sarcomatoid elements. The finding of both elements on histology is usually diagnostic of malignant mesothelioma.

Metastatic adenocarcinoma can be difficult to distinguish grossly and histologically from epithelial mesothelioma. Historically many different modalities have been used to distinguish these entities (Table 77-2). Today, however, the diagnosis often can be made using immunohistochemical analysis (mesotheliomas are calretinin, WT-1, and cytokeratin positive and CEA negative).[24,50,51] Table 77-2 lists some of the differences seen among the various histochemical, immunohistochemical, and electron microscopy studies performed to distinguish mesothelioma from adenocarcinoma. The sarcomatous form should be distinguished from other soft tissue sarcomas.[52] Electron microscopy remains the major reference method for defining the diagnosis of malignant mesothelioma, although it is not used frequently in view of the immunohistochemistry.[53,54]

Staging

Staging systems usually are developed to help define comparable groups for therapy and prognosis, and thus provide a more accurate method for comparing results. To date, there is no uniformly accepted staging system that accomplishes these goals in the staging of mesothelioma. The first staging system proposed by Butchart and colleagues[55] did not uniformly predict survival outcomes, did not provide tumor or organ invasion descriptions, and provided only vague statements about lymph node and chest wall involvement. Based on the large surgical experience at the Brigham and Women's Hospital and Dana Farber Cancer Institute, a clinical, postoperative staging system was proposed (Table 77-3).[56] After several attempts to develop a TNM-based staging system that considered the influence of regional lymph nodes and the extent of local invasion, the International Mesothelioma Interest Group (IMIG) organized a consensus TNM staging system, which forms the basis of the current AJCC Staging system (Table 77-4).[57]

Imaging Studies

Chest x-rays usually are obtained when a patient presents with shortness of breath or chest pain, and most typically demonstrate a pleural effusion. In addition, pleural plaques or calcifications in the diaphragm denote asbestos exposure, although they are found in fewer than 20% of patients with mesothelioma. Abnormal chest x-ray findings are followed by CT scans, the most widely used imaging technique, which can provide details of the extent of disease as it progressively encircles and traps the lung (see Figs. 77-1 and 77-2), extends into the fissures and along the pericardium, and invades the chest wall, diaphragm, and mediastinal structures.[58] The CT scan also can define enlarged mediastinal lymph nodes, a finding that carries an adverse prognosis. Other technologies also have been applied to imaging. MRI theoretically can improve differentiation between tumor and surrounding normal tissue. This could be of particular value in evaluation of penetration into the mediastinal structures, chest wall, and diaphragm. One small study, however, compared the staging information derived from CT and MRI scans and concluded that the two techniques offer approximately equivalent information.[59] Thus, it usually is not necessary to use both techniques. In recent years, PET scanning has offered the ability to identify tumors based on their metabolism of 18-F fluorodeoxyglucose (FDG). Preliminary studies suggest that PET scans may be most useful in the identification of mediastinal and distant mestastases and defining prognosis,[60–62] and further studies may prove that PET scanning is a valuable adjunct to CT or MRI scanning.

Table 77-3 Brigham and Dana Farber Cancer Institute Revised Postoperative Staging System for Malignant Mesothelioma

Stage	Definition
I	Disease completely resected within the capsule of the parietal pleura without adenopathy. Ipsilateral pleura, lung, pericardium, diaphragm, or chest wall disease limited to previous biopsy sites.
II	All of stage I with positive resection margin and/or intrapleural adenopathy.
III	Local extension into the chest wall or mediastinum; into the heart or through the diaphragm or peritoneum; or with extrapleural lymph node involvement.
IV	Distant metastatic disease.

Brigham, Brigham and Women's Hospital; DFCI, Dana Farber Cancer Institute.

Surgery

The first decision point in the management of mesothelioma is resectability of disease (Fig. 77-5). Because of the rarity of the disease and the highly selected nature of the patients entered into surgical trials, the role of surgery in mesothelioma for any reason other than biopsy remains controversial. Although pleurectomy can reduce the recurrence of effusions in most patients, surgery has little role in the palliative management of mesothelioma, and many clinicians advocate pleurodesis and supportive care.[63] With the recognition of the risk of disease in asbestos-exposed individuals, however, many patients now are found with earlier stages of mesothelioma, and such patients could have longer survival times. Thus, surgical excision could be a reasonable approach among patients whose disease is confined to the pleural space. Before considering aggressive surgery, bronchoscopy should be performed to define the anatomy and eliminate the possibility of endobronchial disease. Endobronchial tumor is likely to be a result of primary lung cancer rather than mesothelioma.[64] Because of the progressive nature of mesothelioma and the extent of surgery needed to eradicate the disease, any patient being considered for radical surgery must be able to withstand possible pneumonectomy and prolonged anesthesia. Careful evaluation of cardiac and pulmonary functions are thus critical.[65] For therapeutic approaches, three surgical techniques have been advocated: pleurodesis, pleurectomy (decortication), and extrapleural pneumonectomy (EPP). There are no comparative studies of these approaches, and patients treated often are highly selected for the various procedures. Thus, the studies of the different approaches often contain patient groups with highly different prognostic factors and so cannot be compared.

Pleurodesis usually is performed for palliation and is accomplished alone or with a partial pleurectomy by means of video-assisted thoracoscopic surgery (VATS) and the insufflation of sclerosing agents, such as talc.[66] This approach can control pleural effusions in about 90% of cases but does not offer any opportunity for cytoreduction of tumor. Advocates of this approach cite the lack of definitive data favoring more aggressive debulking procedures and the relative sparing of postoperative complications. This technique produces median survivals that recapitulate the natural history of the tumor, however, and it further complicates any subsequent attempt to perform a cytoreductive procedure.[66] Nevertheless, this approach could be the most appropriate for those with significant comorbid disease or those with adverse surgical prognostic factors.

Pleurectomy or decortication has been advocated by a number of investigators, with the median survival in these series ranging from 6.7 to 21 months (Table 77-5).[67–78] This approach also has been used to control effusions (including cases of pleurodesis failure) and has achieved control of effusions in more than 80% of cases. With this

Table 77-4 International Mesothelioma Interest Group Staging of Mesothelioma

PRIMARY TUMOR AND EXTENT (T)	
Tx	Primary tumor cannot be assessed.
T0	No evidence of primary tumor.
T1	Tumor involves ipsilateral parietal pleura, with or without focal involvement of visceral pleura.
T1a	Tumor involves ispilateral parietal (mediastinal, diaphragmatic) pleura. No visceral pleura involved.
T1b	Tumor involves ipsilateral partietal (mediastinal, diaphragmatic) pleura with focal involvement of visceral pleura.
T2	Tumor involves any of the ipsilateral pleural surfaces and one or more of the following: confluent visceral pleura and fissure, diaphragmatic muscle, ipsilateral lung parenchyma.
T3*	Tumor involves any of the ipsilateral pleural surfaces and one or more of the following: endothoracic fascia, mediastinal fat, solitary ipsilateral chest wall, soft tissues, nontransmural invasion of the pericardium.
T4†	Tumor involves any of the ipsilateral pleural surfaces and one or more of the following: diffuse chest wall invasion, rib involvement, invasion through diaphragm, invasion through pericardium, positive pericardial effusion cytology, involvement of myocardium, involvement of any mediastinal organ, contralateral pleura, invasion of spine, or invasion of brachial plexus.
LYMPH NODES (N)	
Nx	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastases.
N1	Metastases in ipsilateral bronchopulmonary or hilar lymph nodes.
N2	Metastases in subcarinal lymph nodes or in ipsilateral mediastinal or internal mammary lymph nodes.
N3	Metastases in contralateral mediastinal internal mammary, or hilar lymph nodes or any supraclavicular, or scalene lymph nodes.
METASTASES (M)	
Mx	Distant metastases cannot be assesed.
M0	No (known) distant metastases.
M1	Distant metastasis.

technique, the pleura are stripped from the apex of the lung to the diaphragm, removing pericardium and parietal pleura in the course of dissection. Clean separation of lung and visceral pleura often is difficult because of the pattern of growth. The diaphragmatic pleura usually cannot be completely resected, which eventually leads to a very high local recurrence rate. Chest tubes are placed to drain blood and to manage any possible bronchopleural fistulae. Operative mortality from pleurectomy usually is quite low (1.5%–5%), but complications include bronchopleural fistulae, hemorrhage, and subcutaneous emphysema. Of considerable interest is the impact of histological subtype on the outcome. In most surgical series in which subtype is specified, the median survival duration for the epithelial subtype is two- to threefold greater than for the sarcomatous form, and the mixed subtype shows an intermediate survival. Investigators at Memorial Sloan-Kettering Cancer Center published some of the largest experiences with this technique when combined with external beam with or without interstitial irradiation, or in combination with postoperative intrapleural therapies and irradiation.[64,69,72] In their experience with 95 patients (see Table 77-5), a select group of 27 patients who had the epithelial subtype and who did not require an implant had a median survival of 22.5 months and a 2-year survival rate of 41%. Wanebo and colleagues[76] also evaluated their surgical pleurectomy series by histologic subtype and found that those patients with the epithelial form had a better survival than those whose tumor showed the fibrosarcomatous form. The relatively poor results (with a median of 6.7 months survival) that were reported by Lewis and coworkers[71] were derived from an older group of patients. DaValle and associates[68] advocated the use of extrapleural pneumonectomy for patients with minimal invasion of the visceral pleura (free pleural space without tissue invasion) as an approach for possible cure, because the survival with pleurectomy was not striking (a median of 11.2 months). Although no studies have directly compared the various surgical approaches, the reported median survival for pleurectomy appears similar to the medians reported for even more aggressive surgical approaches.

EPP is a more aggressive, extirpative procedure in which the parietal pleura, lung, pericardium, and diaphragm are resected en bloc. A graft to prevent herniation of the abdominal contents replaces the diaphragmatic defect. To prevent cardiac herniation, the right pericardium also often is reconstructed. A thoracoabdominal approach allows for easier access for the resection of the diaphragm. DaValle and colleagues[68] advocated extrapleural dissection to the hilum, early entry into the pericardium retrosternally to accomplish intrapericardial pneumonectomy, and use of double-lumen anesthesia. With either approach, intercostal chest tubes usually are placed to drain blood and fluid, and to treat possible bronchial air leaks. The trials reporting extrapleural pneumonectomy show median survival ranging from 4 to 20 months (Table 77-6).[55,56,68,73,79–83] Because of the extent

of the procedure and the learning curve, the early studies showed postoperative mortality as high as 31%. With increasing experience, more recent studies demonstrate operative and postoperative mortality below 4%. Serious complications have been reported in as many as 25% of patients, including bronchial leaks, empyema, vocal cord paralysis, chylothorax, arrhythmias, and respiratory insufficiency.[84] Recent studies with careful preoperative screening also have reduced these postoperative complications.[85] The evolution of this approach is demonstrated in Table 77-6 by the increasing median survival and decreasing surgical mortality. Rusch and coworkers[81] reported a 2-year survival of 33% with a 10-month median survival in 20 patients, whereas Sugarbaker and associates[56] reported a 38% 2-year survival and 19-month median survival for those patients undergoing EPP. The surgical mortality reported in the two studies was 15% and 3.8%, respectively. These latter two studies probably are representative of modern selection criteria and contemporary surgical management. Both studies also offer the details of treatment failure sites. In contrast to the pleurectomy series, some of the reports of extrapleural pneumonectomy showed a small percentage of 5-year survivors. Although the degree of surgery, the selection criteria, and the possible stage shift biases preclude definitive statements, overview of the sites of treatment failure and long-term outcomes suggest that extrapleural pneumonectomy could alter the natural history of pleural mesothelioma.

Surgical Prognostic Factors

Results from both pleurectomy and EPP series suggest that certain pre- and postoperative factors carry important prognostic information that can help select appropriate surgical candidates. These factors include the following:

- Subhistologies (epithelial vs. other types)
- Preoperative tumor bulk
- Mediastinal lymph node involvement
- Resection margins
- Invasion beyond the pleural envelope.

Among those studies that specify subhistology, nearly all show that patients with the sarcomatous and mixed forms of mesothelioma have a significantly worse disease-free and overall survival than those with the epithelial form.[56,78,86] These data strongly suggest that patients with sarcomatous or mixed subhistology should be offered palliative therapies such as pleurodesis and be spared the operative consequences of aggressive surgical procedures. Similarly, mediastinal lymph node involvement defines an adverse prognosis.[56,86] Because patients with mediastinal lymph node involvement have a significantly decreased survival, preoperative staging probably should assess the mediastinum. Whether this dictates a preoperative mediastinoscopy, or whether imaging techniques such as FDG-PET scanning can provide adequate preoperative assessment, remains to be determined. Other factors that can predict survival include penetration through the diaphragm, extension to other extracapsular sites, and large preoperative tumor volume.[56,86] These surgical prognostic factors suggest that further revision of the staging systems could be required to better define which patients are most likely to benefit from surgical approaches. An alternative, postoperative, functional staging system based on the surgical experience at Brigham Hospital and Dana-Farber Cancer Institute is shown in Table 77-3.

Radiation Therapy

The diffuse nature of the disease and toxicity of tumoricidal doses of irradiation to vital organs, including the lung, heart, and liver, limit the utility of radiation therapy in the treatment of mesothelioma. Radiation therapy alone has not resulted in a survival benefit, though its role in the palliation of localized pain or in combination with other treatment modalities remains promising.[87,88] Seeding along biopsy or chest tube tracts can result in painful chest wall masses. Prophylactic radiation to these tracts or radiation of these masses once they recur may provide temporary pain relief.[89–91] In one report, 21 Gy delivered in three fractions prevented the recurrence of tumor in the wound after thoracoscopy or thoracotomy in 20 patients, whereas 8 of 20 (40%) patients not undergoing radiation developed tumors at the wound site.[90] The addition of radiation therapy to pleurectomy to reduce local recurrences has considerable appeal because of the high local recurrence observed with this surgical technique, and the addition of radiation therapy to EPP also might be better tolerated because the underlying lung has been removed. Alberts and colleagues[92] compiled the treatment outcomes for 262 patients treated between 1965 and 1985 with either chemotherapy, radiation therapy (RT), both chemotherapy and RT, or decortication plus RT and chemotherapy. The median survival of 9.6 months was similar for all groups. Only a small group of patients treated with doxorubicin and irradiation with 10 Gy every 6 weeks for four courses appeared to show prolonged survival, with a median survival of 22.6 months.

Chemotherapy

SINGLE AGENTS. In the past, the role of chemotherapy for malignant pleural mesothelioma was difficult to assess because of the small numbers of patients entered into individual chemotherapy trials, the pessimism regarding treatment, the difficulty in assessing response, and the bias associated with reporting predominantly positive results. Thus, much of the older data regarding single-agent and combination chemotherapy activity was derived from summary overviews of small pilot trials or from chemotherapy trials of soft-tissue sarcomas.[93] Since 1990, however, both the incidence and the accuracy of diagnosis have increased, thus permitting larger disease-specific trials to occur. The advent of CT and MRI has further allowed for assessment of response using rind thickness as a criterion. Table 77-7 shows the activity of various chemotherapy agents, based on trials of adequate size that include 14 or more patients.[94–147] At one time, the anthracyclines were considered the mainstay of chemotherapy for mesothelioma. However, adequately sized trials have proven this class of drugs to have only modest activity, and their use has essentially ceased. Among the alkylating agents, one trial of mitomycin C suggested a response rate of 21%. The platinums (cisplatin and carboplatin) show only modest response rates of 14% and 11%, respectively, but their value could reside in their ability to synergize with other agents. The camptothecins, taxanes, and vinca alkaloids have been disappointing as single agents. In contrast, the antimetabolites, specifically antifolate compounds, are of considerable interest, especially because recent studies have shown enhanced folate expression in human mesotheliomas and potentially unique transport

mechanisms for pemetrexed.[148,149] Solheim and associates[119] showed that high-dose methotrexate had an appreciable response, with a 37% response rate. Vogelzang and colleagues[120] reported a 12% response rate for trimetrexate, and Kindler and coworkers[121] reported a 25% response with the antifolate agent, edetrexate. Another antifolate agent, pemetrexed, showed modest activity of 14% as a single agent, but provided both improved response and improved survival when added to cisplatin compared to cisplatin alone.[115,122]

COMBINATION CHEMOTHERAPY. The vast majority of combination chemotherapy regimens tested with adequate sample size are either anthracycline- or platinum-based (Table 77-8). Similar to the data on single agents, the early studies of combination chemotherapy suffered from small and often inadequate trials, and the various trials are difficult to compare because of issues concerning disease subgroups, pretreatment characteristics, and prior therapies. These make the survival data difficult to interpret, and for this reason, responses rather than survival are evaluated. More recent studies include more appropriate numbers of patients and modern response criteria, thus allowing for a better assessment of activity. Recently tested combination regimens are listed in Table 77-8.[115,122,150–181]

Most recent trials of combination chemotherapy are platinum based and show a somewhat greater response to therapy than prior combinations. Whether this apparent improvement in response is an artifact of patient selection, earlier treatment, or better agents remains uncertain, but it is illustrated in the recent single-agent data for cisplatin, which was part of a randomized trial and showed a 16.7% response rate.[115] An interesting model of human mesothelioma transplanted onto nude athymic mice suggested that the combination of cisplatin and mitomycin C is highly synergistic.[182] A prospective randomized phase II study by the Cancer and Leukemia Group B (CALGB) showed a response of 26% when the stable disease category was included, but the response rate declined to less than 20% if only objective criteria were considered.[156] Two combination chemotherapy regimens appear to show significant promise, and both focus on an antimetabolite plus cisplatin (see Table 77-8). Several phase II trials have shown reproducible responses for the combination of cisplatin and gemcitabine, with potential schedule-dependent differences. The combination of cisplatin and pemetrexed showed activity in a phase I study and led to the large, randomized trial of this combination vs. cisplatin alone.[183] The response rate for this combination was 41.3%, compared with 16.7% for cisplatin alone, and the combination showed significant superiority in terms of both time to progression and overall survival.[115] This trial led to a new standard of therapy for malignant pleural mesothelioma that will clearly be the basis for comparison for new treatments.[184]

Intrapleural Therapy

Another approach to the treatment of pleural mesothelioma has been the instillation of therapeutic agents into the pleural space. Because mesothelioma develops superficially along pleural and peritoneal cavities, intracavitary instillation of chemotherapy, radioisotopes, or biologics potentially could treat the superficial disease. Anecdotal reports of prolonged survival with certain radioisotopes also has stimulated interest in this approach.[185,186] High intracavitary concentrations of chemotherapeutic agents potentially could capitalize on any dose-response relationships for the agents. This approach is limited, however, by the propensity of the pleural space to become progressively obliterated with advancing disease, and even in early disease the intracavitary chemotherapy penetrates only a very shallow level of the tumor. Thus intrapleural therapies have limited applications, only to either very early disease or post-debulking surgical procedures.

Cisplatin is the agent that has been most extensively studied for intracavitary use.[187–189] Pharmacokinetic studies of its intracavitary use show that exposure and peak levels are much greater than for intravenous administration of cisplatin. This approach has not met

with the same degree of success as has been seen with intraperitoneal administration of cisplatin for peritoneal mesothelioma.[189] The role of other agents, such as doxorubicin, cytosine arabinoside, and mitomycin-C by the intracavitary route, is not well established. Various permutations of this approach currently are under investigation, including hyperthermic perfusion.[190] Given the complexity of such maneuvers, it is unlikely that this approach will become well established unless a significant benefit occurs, which has yet to be demonstrated.

Biologic and Targeted Therapies

Another approach to treating mesothelioma has been the exploration of several biologic response modifiers, including the interferons, other cytokines such as IL-2, gene therapy, and vaccines.[152,161,191–204] Some of the various biological agents tested either systemically or intrapleurally are shown in Table 77-9. In addition, studies of cancer cell biology have identified various molecular targets that control growth and proliferation pathways; these studies have opened new vistas for therapeutic intervention. Tissue and molecular technology even offer the possibility of specifically phenotyping a given tumor for its molecular targets.

The interferons (IFNs) have been tested extensively because preclinical studies showed that malignant mesothelioma cell lines are susceptible to IFN-α alone and that this effect is enhanced in combination with other cytokines (e.g., IFN-γ and tumor necrosis factor [TNF]) and with chemotherapy.[202,203] Additionally, IFNs offer the possibility of improving immune recognition of the tumor. These data have served as the rationale for clinical trials with the IFNs (see Table 77-9), which mostly have been disappointing and have produced considerable systemic toxicities, including fever, nausea, vomiting, chill, myalgias, and anorexia. Intrapleural therapy also has produced some empyema. Intrapleural IFN-γ, however, is worthy of notice. Boutin and colleagues[205] performed pleuroscopy upon recognizing effusion in asbestos-exposed individuals and instilled IFN-γ if tumor was identified. Pleuroscopy was repeated for subsequent evaluation. The overall response rate was 20%, but those patients with stage IA disease had a 45% response, with eight confirmed complete responses and a prolonged disease-free survival. These data served as part of the impetus for the IMIG revision of the staging system.[57] Interleukin 2 (IL-2) also was shown to have an antiproliferative effect on mesothelioma cell lines.[172] Two small studies of intrapleural IL-2 produced responses of 55% and 19%, respectively (see Table 77-9), but showed considerable systemic toxicities.[199,200] Intramuscular administration of TNF plus IFN-γ and intralesional administration of GM-CSF produced disappointing results and considerable toxicity (see Table 77-9).

The biologic agents also were combined with chemotherapy, and most of these trials combined chemotherapy agents with IFN-α (see Table 77-8). Doxorubicin plus IFN-α produced a modest response with unacceptable toxicity.[151] Two different doses of IFN-α plus 60 mg/m^2 cisplatin produced responses of 25% and 30%, respectively.[161,162] The toxicities—which included nausea, vomiting, fever, anorexia, and asthenia—were unacceptable, however. Carboplatin plus IFN-α produced a 7% response, but the carboplatin was dosed by body surface area.[176] A trial of IFN-α plus mitomycin and cisplatin produced a response in 6 of 43 patients (14%), including complete response in 2 patients (5%).[168,169] The combination of high-dose methotrexate and systemic IFN-α and IFN-γ produced a 29% response, similar to that seen for high-dose methotrexate alone.[180] Given the significant systemic toxicities of this combined

approach, further studies await better chemotherapy and biotherapy combinations.

GENE THERAPY. Another approach for biotherapeutics has been the use of gene therapies. Because early tumors are relatively localized, gene therapy via the pleuroscope has been tested by investigators at the University of Pennsylvania.[206] They used replication-defective adenovirus containing HSV-tk (a viral protein sensitive to gancyclovir) to test the concept that insertion of the HSV-tk genome into the tumor cells would make the transfected tumor cells (in contrast to normal mammalian cells) lethally susceptible to gancyclovir. Only a small percentage of screened patients were eligible, and 26 patients were treated intrapleurally with escalating doses of virus. Gene transfer was seen in 17 patients, humoral and cellular immune responses were seen, and two patients achieved either a response or a prolonged disease-free survival. The median survival was 11 months, and further studies are in process, although the issues of generalized inflammatory responses remain of some concern. Other gene therapy approaches, such as inserting cytokines onto viral vectors and tumor vaccines, also are under development.[207]

TARGETED THERAPIES. The identification of specific molecular targets that control tumor cell growth, replication, and metastases has led to the identification of agents that target these molecular abnormalities specifically. Antibodies and specific tyrosine kinase inhibitors (TKIs) have been developed that target the epidermal growth factor receptor (EGFR), vascular endothelial growth factor (VEGF), and platelet-derived growth factor (PDGF). EGFR is overexpressed in many human epithelial tumors, including mesothelioma.[203] Interfering in this signaling pathway could influence growth, angiogenesis, and apoptosis. Inhibition of VEGF also could inhibit angiogenesis. PDGF is believed to be an important autocrine growth factor for growth of mesothelioma.[203] Thus, interfering with this autocrine loop could inhibit growth. The initial trials of some of these agents, however, have shown disappointing results so far. Gefitinib, an EGFR TKI, was tested by the CALGB, and one response (2%) was seen among 43 patients.[146] Imatinib, a PDGF TKI, produced no responses among 25 patients.[147] Multi-target agents that inhibit both vascular endothelial growth factor receptors involved in angiogenesis, as well as PDGF, also have been tested. Two such agents, sorafenib and vatalanib, have only moderate activity (4% and 11% response rates, respectively).[208,209] However the optimal use of these agents most likely depends on finding the correct biological indicators of the responses, and studies are ongoing.

Combined-Modality Therapies

Another approach to the treatment of mesothelioma is to combine or sequence several treatment modalities to reduce both local and distant recurrences. Thus surgery, radiation therapy, chemotherapy, and biologics might be combined in various groupings.

Because of the advanced stage of disease at presentation in the United States, most patients are not candidates for surgical resection. Thus, one possible approach is the use of chemotherapy with radiation therapy. There is, however, only limited experience with this approach, despite the recognized potential of many agents such as cisplatin to act as radiosensitizers. Doxorubicin plus radiation therapy was studied in two small trials.[150,210] A small subgroup of patients from the large series reported from South Africa was treated with doxorubicin and radiation therapy.[92] Compared with most of the patients in the report, this subgroup appeared to show a prolonged survival (median survival of 22.6 months). Drawing a conclusion about outcomes in a small, highly selected subgroup, however, is difficult at best.

Several trials have added either interstitial or external beam irradiation to pleurectomy, as described in the earlier section on radiation therapy. Rusch reviewed the multimodality experience at Memorial Sloan-Kettering Cancer Center.[211] One hundred five patients underwent pleurectomy followed by interstitial and external beam irradiation. The median survival was 12.5 months, and those with early disease and epithelial histology demonstrated better survival. Another approach to postoperative irradiation is the use of photodynamic therapy (PDT) to the interior of the pleural or thoracic cavity. After a debulking procedure such as a pleurectomy or EPP, a diffusing solution is placed in the hemithorax, and a unique wavelength (usually red) light is used to activate the dye. Moskal and colleagues[212] treated 40 patients (24 with advanced disease) using surgical debulking and PDT. Although the median survival was 15 months for those who survived surgery, the patient with Butchard stage I disease survived for 36 months. Pass and coworkers[213] tested PDT as part of a complex, randomized, postoperative chemoimmunotherapy protocol. Sixty-three patients were randomized to receive cisplatin, tamoxifen, and IFN-α with or without PDT after maximal cytoreductive surgery. The two treatment arms were comparable in terms of local failure rate, time to progression, and median survival. Further studies using this approach do not seem likely.

In the United States, most patients, even among the patients in whom surgical resection is attempted, usually have disease beyond the parietal pleura. Thus adjuvant therapies to improve local control and prevent systemic recurrence often are attempted. Rusch and coworkers[214] followed pleurectomy with intracavitary cisplatin and mitomycin-C to assess the pharmacokinetic behavior of these agents. The investigators observed a high intracavitary concentration of drug with adequate plasma levels and systemic chemotherapy toxic effects. Postoperative systemic cisplatin and mitomycin-C chemotherapy also were added subsequently. Thirty-six patients were enrolled; of these, 28 underwent surgical debulking, and 23 went on to postoperative therapy. The median survival was 17 months. Rice and associates[73] used a similar approach for 19 patients, and the median survival was 13 months. A variation of this postoperative intrapleural therapy tested hyperthermic perfusion with cisplatin,[215] cisplatin plus mitomycin,[216] or cisplatin plus doxorubicin.[190] Although these studies showed that this approach is feasible, the clinical complexity and toxicity remain difficult to justify on the basis of the early results.

Sugarbaker and coworkers[56] built a trimodality therapy program using EPP followed first by various chemotherapy regimens (cyclophosphamide plus doxorubicin plus or minus cisplatin or carboplatin plus paclitaxel) and then by subsequent (or concurrent) external beam chest irradiation. One hundred eighty-three patients were entered into the sequential studies, and there were seven postoperative deaths. The median duration of survival (excluding the seven postoperative deaths) was 19 months. Epithelial histology, negative mediastinal lymph nodes, tumor confined to the pleural envelope, and negative resection margins were all highly favorable prognostic factors. This subset analysis led to the Brigham/Farber postoperative staging system (see Table 77-3). The subgroup that satisfied these prognostic factors (Brigham/Farber stage I) had a median duration of survival of 51 months and 2- and 5-year survivals of 68% and 46%, respectively. Whether this represents lead-time bias is unclear, however. Newer chemotherapeutic agents such as gemcitabine plus cisplatin, or pemetrexed plus cisplatin, also are being incorporated into trimodality regimens as neoadjuvant therapy, and studies are ongoing.[217,218] The results of these trials argue that careful staging and preoperative patient selection will be crucial in determining which patients may benefit the most from aggressive therapy.

METASTATIC TUMORS OF THE PLEURA

Metastatic tumors in the pleura are far more common than primary pleural tumors. Clinically, patients with these tumors present in a manner similar to those who have primary tumors in the pleura, with effusions, dyspnea, cough, atelectasis, and (less often) pain and fever. Symptoms related to the primary site of tumor are seen in nearly half

of the patients, and the prognosis with metastatic disease to the pleura is related most to the ability to control the underlying primary tumor. Compromised performance status and weight loss are adverse prognostic features. The pleura can be the site of metastases from many cancers, but the most common origins are tumors of the lung, breast, stomach, colon, ovary, prostate, and thyroid, and melanoma and lymphoma/leukemia, with tumors of the lung and breast most common in men and women, respectively.[219,220] Most often, the primary site of disease becomes clinically evident or is found easily after the history, physical examination, and roentgenographic studies.

Diagnosis

The most effective means to deal with symptomatic pleural disease is to exercise effective treatment of the underlying disease. However, even when metastatic tumors are resistant to therapy, palliation of symptoms is of utmost importance. This includes radiation therapy for localized painful areas, therapeutic thoracentesis, sclerosis, or pleurodesis, and pleural resection in selected cases. The choice of therapeutic options must be based on a realistic appraisal of the patient's disease and prognosis, the potential risks and benefits of each procedure, and a careful assessment of the goals of therapy.

For patients who present with pleural effusion, a diagnostic thoracentesis can provide sufficient material to determine whether it is malignant, and help identify the primary site of disease if not clinically evident. Evaluation of the pleural fluid with cytology, histopathology, and immunohistochemistry can be important in suggesting an area of primary tumor, although up to 35% of initial specimens will be nondiagnostic, thus necessitating repeat thoracentesis.[221] Molecular analysis of pleural fluid for tumor markers or epigenetic changes associated with cancer, such as DNA hypermethylation, may improve diagnostic capabilities and is a promising area of research.[222–224] If histology suggests an adenocarcinoma, then appropriate diagnostic pathology studies should be performed to exclude an epithelial form of malignant mesothelioma, because patients with early mesotheliomas could be candidates for various aggressive therapies. Exclusion of nonmalignant causes of the effusion (e.g., parapneumonic effusions, pulmonary embolism, congestive heart failure), or causes accompanying disease or its treatment (e.g., superior vena cava syndrome, chylothorax from lymphatic obstruction trapped lung) can have important implications for therapy.

If thoracentesis or small-needle biopsies provide inadequate diagnostic material, a complete thoracentesis (i.e., dry tap) may be required to harvest enough freshly shed tumor cells to assist in diagnosis, as well as providing a potential therapeutic maneuver, because some effusions will not recur or will recur only slowly. Caution must be exercised when performing a thoracentesis to near dryness, however, as this approach increases the risk of pneumothorax, and removing a large effusion increases the risk of postexpansion pulmonary edema.[225,226] Draining the effusion to dryness might thus require multiple sequential attempts. If repeated thoracenteses are needed for symptom control, more aggressive procedures (e.g., pleurodesis or pleural resection) may be appropriate.[227,228]

Symptom Management

Pleural Sclerosis and Pleurodesis

One of the standard approaches in the treatment of recurrent symptomatic pleural effusions is obliteration of the pleural space by inciting irritation or inflammation of the pleural surfaces, resulting in fibrosis and adherence. Techniques to accomplish this have included repeated thoracentesis, chronic tube drainage, instillation of various agents, or partial pleurectomy.[229–234] The procedure most commonly used is chemical pleurodesis. Several important issues surround this procedure: drainage of the effusion, choice of sclerosing agent, and management of the side effects of both in these patients, who already are suffering from significant respiratory compromise. Until recently, drainage usually was accomplished through a large-bore (28–32F) chest tube evacuated through a water seal by gravity or suction, a procedure that is associated with significant patient discomfort.[235] Effective drainage (and pleurodesis) can alternatively be achieved via small-bore (10–12F) catheters, which may be better tolerated by the patient.[236–239] Regardless, the use of intravenous pain medication and/or sedatives should be strongly considered as premedication for both placement of the chest tube and instillation of sclerosing agent. Both relief of dyspnea and lung re-expansion should be demonstrated before proceeding to pleurodesis. If thoracentesis fails to re-expand the lung, pleurodesis is unlikely to be successful, and a chronic small-bore indwelling catheter (e.g., Pleurx) may allow symptomatic relief.

Which sclerosing agent is optimal is debatable, because studies in this area are hampered by heterogeneous patient populations, differences in the definition of response to treatment, and the various techniques used. The many and various agents used include talc; antibiotics such as tetracycline, doxycycline, and minocycline; the antiparasitic agent quinacrine; various chemotherapeutic agents; biological substances such as interferon-β, IL-2, and *Corynebacterium parvum*; and radioisotopes.[233,240,241] Thoracoscopic drainage and talc pleurodesis have been studied extensively and have been shown to be highly effective (93%) in achieving control of effusions.[237–239,242–258] Several antibiotics have been tested as sclerotic agents, including tetracycline and doxycycline. In the United States, parenteral forms of tetracycline are no longer available, and some investigators substituted doxycycline. Pain is a fairly significant side effect in the use of the antibiotics, and many clinicians add xylocaine into the pleural cavity before or during the instillation of the antibiotic. Xylocaine, however, is recognized as paralyzing both leukocytes and monocytes, and to the degree that these cells are helpful in the etiology of sclerosis, the effect of instilling the topical anesthetic on the effectiveness of sclerosis has not been studied adequately.[259] Chemotherapeutic agents also have been used as intrapleural therapies with some success, although many were associated with significant side effects, including severe pain (nitrogen mustard, doxorubicin) and myelosuppression (nitrogen mustard, mitomycin-C).[230,233] Ruckdeschel and coworkers performed a randomized study of tetracycline vs. bleomycin and concluded that there appeared to be an advantage for the bleomycin, with less frequent recurrences of effusions.[260] The pain associated with bleomycin was less severe than with tetracycline, although many patients experienced some febrile response. Bleomycin remains the most commonly used chemotherapeutic agent for sclerosis. However in comparison trials, talc appeared to be more effective than bleomycin or tetracycline, and most investigators believe that talc probably is the most effective agent.[233,248,249,258,261] Talc has thus become the dominant approach to pleurodesis.

The use of biologic agents such as *Corynebacterium parvum*,[262–269] OK-432 (lyophilized *Staphylococcus pyogenes*),[270] interferon-α,[271] interferon-β[193], and recombinant IL-2[199,272,273] is limited, given their disappointing efficacy, significant side effects, or the need for multiple instillations. Among the other agents tested, quinacrine was used in the past with some modest success; however, fever, pain, hypotension, hallucinations, and anecdotal reports of sudden death essentially removed this agent from use.[274–276] The use of radioactive isotopes such as P^{32} and Au^{198} in patients is somewhat onerous, and they have been used with only disputable success.[277,278]

A last option for the control of recurrent pleural effusions is thoracotomy and limited pleural stripping or pleurectomy, thereby achieving a mechanical form of pleurodesis. Although this procedure is highly successful in achieving control of pleural effusions, it is of limited potential application because of the high morbidity (23%) and mortality (18%) associated with it, even in experienced hands.[77,279] However more recent studies suggest that the use of VATS can reduce

these complications significantly.[231,234] Nevertheless, pleurectomy should be reserved for the unique ambulatory patient with an otherwise "good" prognosis whose effusion cannot be controlled with less aggressive techniques.

Future Studies

Although the therapy for metastatic effusions is difficult, and the prognosis for patients with these metastases is poor, further studies are of some importance because of the symptoms involved, the cost of care, and the need to maintain quality of life as long as possible. Thus outpatient programs for pleural drainage and research into sclerosing agents with minimal side effects are important areas of development. Another area of further development includes the use of talc insufflation at the time of initial diagnosis, when the thoracoscope is used for intrapleural biopsies.

In some cases a more aggressive surgical procedure such as pleuroscopy may be necessary to obtain a diagnosis. This procedure has a diagnostic accuracy of 90%, and has the added benefit that pleurodesis can be performed at the same time if malignancy is detected.[280,281]

MEDIASTINAL TUMORS

General

The mediastinum is a complex space in the center of the chest, bounded by the thoracic inlet superiorly, the diaphragm inferiorly, the sternum anteriorly, the spine posteriorly, and the mediastinal pleura bordering each lung laterally. A number of tumors, both benign and malignant, are known to occur in this area, which is divided anatomically into anterior, middle, and posterior compartments, each extending from the thoracic inlet to the diaphragm. These tumors often are difficult to differentiate, either clinically or with available imaging techniques. The anterior mediastinum encompasses the space between the sternum anteriorly and the anterior pericardium posteriorly and contains the thymus gland, lymph nodes, and mesenchymal tissues. The middle mediastinum contains the heart and great vessels, the trachea and esophagus, the vagus and phrenic nerves, and most of the mediastinal lymph nodes. Finally, the posterior mediastinum is bounded by the posterior aspect of the pericardium and trachea anteriorly and the vertebral bodies to the costovertebral sulci posteriorly, and it includes the paraspinal tissues along with sympathetic and peripheral nerves. Occasionally, a distinction is made for the superior mediastinum, which is part of the anterior mediastinum residing behind the manubrium sterni, extending from the suprasternal notch to the angle of Lewis.

Tumors of the mediastinum usually are categorized according to their specific histologic subtype and anatomic location (Table 77-10). Only one third of all primary mediastinal masses are malignant, but they include a wide variety of neoplasms. The location and site of the tumor often provide valuable clues toward making a clinical diagnosis. The clinical presentation of these tumors is shown in Table 77-11.

Thymomas, lymphomas, and germ cell tumors account for most of the anterior mediastinal masses. In a series of 41 patients with isolated anterior mediastinal masses, the pathological diagnosis was lymphoma in 13 patients, thymoma in 11, germ cell tumor in 6, carcinoid in 2, bronchogenic carcinoma in 2, and benign process in the remaining 7 patients.[282] The middle mediastinum is the site of lymphoid malignancies in addition to the neoplasms that are related to metastases from visceral organs (e.g., lung cancer). Most neurogenic tumors are located in the posterior mediastinum. These generalizations according to anatomic site, however, are clinically helpful but not uniformly accurate because of the exceptions to these guidelines. A number of rare tumors, such as carcinoids, neoplasms of mesenchymal origin, melanomas, and undifferentiated carcinomas are known to occur in the mediastinum without any regular compartmental localization.

The substernal thyroid extends downward from the thyroid and does not arise in the mediastinum, although it can first present as a mass in the anterosuperior compartment and can result in symptoms due to compression of the structures in the thoracic inlet, such as the

Table 77-10 Classification of Mediastinal Tumors by Location

ANTERIOR MEDIASTINUM
Thymoma
Thymic carinoma
Thymic carcinoid
Mediastinal germ cell tumors
Hodgkin's disease
Non-Hodgkin's lymphoma
MIDDLE MEDIASTINUM
Angiosarcoma of heart
Rhabdomyosarcoma of heart
Fibrosarcoma

trachea, esophagus, superior vena cava, and other neurovascular structures.[283] Most substernal thyroids are benign, but occasionally carcinoma can be detected in the substernal goiter. Substernal thyroid can be detected by radioactive iodine scanning and usually is excised using a cervical approach, but in certain cases, median sternotomy could be required.

Approach to Obtaining Diagnostic Material

Transthoracic needle biopsy (aspiration biopsy or true-cut needle biopsy) of a mediastinal mass can be used to obtain tissue, and imaging techniques such as CT, MRI, fluoroscopy, or ultrasound have made these procedures safe and effective.[270,284,285] These small-volume biopsies are of value only in certain specific situations, however.[270,285,286] Because of the need to establish a definitive diagnosis, thymoma, lymphoma, and other neoplasms might not be categorized reliably by small tissue samples obtained by transthoracic needle aspiration and/or biopsy. In contrast, metastatic carcinoma and germ cell tumors can be diagnosed with a high degree of specificity and sensitivity (Table 77-12).[287] The pneumothorax rate with transthoracic needle biopsy varies from 11% to 34% in reported studies.[285,286] This procedure should not be performed if the lesion is suspected of being vascular or if the patient has a history of bleeding disorders or previous pneumonectomy.

When needle aspiration or biopsy is not feasible or is unlikely to yield sufficient material, mediastinoscopy or anterior mediastinotomy can provide adequate material for definitive histologic diagnosis, cell-surface marker studies, and flow cytometric and cytogenetic studies.[287] Thoracotomy has given way to VATS thoracoscopsy, which is being used increasingly for diagnosis and staging of mediastinal and intrathoracic masses.[288] Bronchoscopy and esophagoscopy are of limited value for mediastinal masses and should be reserved for patients with apparent involvement of the aerodigestive tract.

TUMORS OF THE ANTERIOR MEDIASTINUM

Imaging modalities for the diagnosis of mediastinal tumors are presented in Box 77-1.

Thymoma

Thymoma is the most common cause of anterior mediastinal masses in adults (Tables 77-10 and 77-13). Thymomas are derived from thymic epithelial cells demonstrating a spectrum of histologic patterns that encompass both epithelial and lymphocytic components in varying proportions.[289] The epithelial cells are embryologically derived from the lower portion of the third pharyngeal pouch and are believed to be responsible for the neoplastic element in thymomas. The lymphocytes associated with both the normal thymus and thymomas are predominantly immature T lymphocytes and demonstrate TdT postivity.[290,291] Immunoglobulin and T-cell receptor gene studies failed to show genotypic evidence supporting the neoplastic nature of the lymphocytic component.[292]

Although thymomas initially were classified according to their proportion of epithelial and lymphocytic components, this classification repeatedly showed a lack of clinical relevance to patient response and survival.[293–295] In the mid-1980s, Marino and Muller-Hermelink[296] revised this traditional classification based on the

Box 77-1. AN APPROACH TO THE DIAGNOSIS OF MEDIASTINAL TUMORS BY IMAGING STUDIES

Chest radiography
- Essential for diagnosis of mediastinal tumors

Computed tomography scan with contrast
- Imaging modality of choice and "gold standard" for noninvasive evaluation
- Differentiates mediastinal masses from vascular and cystic lesions
- Delineates the compartment involved
- Defines the mass in relationship to adjacent tissues
- Valuable in determining the best approach for diagnostic biopsy of the mediastinal mass

Magnetic resonance imaging
- Modality of choice for evaluating posterior and superior mediastinal masses, chest wall abnormalities, and diaphragmatic processes
- Study of choice for detecting masses adjacent to the spinal cord and vertebral bodies
- Defines the characteristics of neurogenic tumors and neural cysts
- Defines intracardiac masses with gating studies
- Unique image reconstruction with coronal and sagittal views
- Avoids use of iodinated contrast and ionizing radiation
- Might help to distinguish residual tumor from fibrosis
- Should be reserved for specific situations described, until spatial resolution limitations are overcome

Intraesophageal ultrasonography
- Eliminates the lungs as a source of interference and thus is useful for imaging cysts

Radionuclide scanning
- I-scanning for thyroid neoplasms or goiter (must be performed before intravenous administration of contrast for CT because the iodine load will interfere with normal thyroid uptake of radioactive iodine)
- I-labeled MIBG scanning for pheochromocytoma

Double isotope (technetium and thallium) subtraction imaging for parathyroid tumors

Gallium scanning for lymphomas and Hodgkin's disease

Positron emission tomography (PET) scanning for Hodgkin's and non-Hodgkin's lymphomas

Table 77-13 Thymic Tumors

Thymoma
Thymic carcinoma
Thymic lymphoma
Thymic Hodgkin's disease
Thymic carcinoid
Thymic germ cell neoplasm
Thymic lipoma
Thymic cyst
Thymic myoid tumor
Thymic histiocytic tumor

Table 77-14 Staging of Thymoma

Stage	Definition
I	Macroscopically, completely encapsulated; microscopically, no capsular invasion
IIa	Macroscopic invasion into surrounding fatty tissues or mediastinal pleura
IIb	Microscopic invasion into the capsule
III	Macroscopic invasion into the neighboring organ (i.e., pericardium, great vessels, or lung)
IVa	Pleural or pericardial dissemination
IVb	Lymphogenous or hematogenous metastases

subtyping of tumors according to their microscopic resemblance to the normal thymic epithelial cells and thymic cortex. The 1999 WHO classification of thymomas further modified the Muller-Hermelink classification, adding thymic carcinoma to the classification schema, simplifying the terminology, and providing prognostic relevance.[297,298] Typically, thymomas are solid tumors covered by a thick, fibrous capsule (Fig. 77-6). The cut section reveals tan, fleshy lobulations divided by fibrous septae. Cystic degeneration, calcification, and focal hemorrhage may be seen.[289]

Histologically, thymomas are classified according to their cytologic appearance in association with the proportion of lymphocytes present.[289] These tumors typically are bland in appearance and can demonstrate mild to moderate cellular atypia. Thymic carcinomas, on the other hand, appear cytologically malignant with marked nuclear atypia and demonstrate a high correlation between cytologic malignancy and clinical outcome.[297]

The staging system used for thymoma as proposed by Masaoka is outlined in Table 77-14.[299] Tumor staging is considered the most significant prognostic factor in determining patient survival. Thymoma spreads via direct extension through its capsule into adjacent structures such as lung, mediastinal soft tissue, or pleura and can metastasize distantly. The extent of capsule invasion and the involvement of thoracic and extrathoracic structures determine the stage, which is correlated to the risk of recurrence and survival.[299,300] Thus extensive tissue sampling of the resected tumor is essential to define microscopic and macroscopic invasion through the fibrous capsule. Other prognostic factors include the completeness of excision, tumor size, histologic typing, involvement of the great vessels, and performance status.[301–304]

Epidemiology

Thymomas constitute 20% of all mediastinal masses in adults. In general, they occur with about the same frequency in males and females, and there is no predilection for a particular race or geographic distribution. They are most commonly seen in the fifth and sixth decades of life.[305,306] A recent study indicated that in thymomas found to have capsular invasion, there is a predilection for males and persons of Asian or Pacific Island descent.[307] Thymomas are extremely rare in children, but when they occur, they present as highly aggressive tumors with a high mortality rate.[308]

Clinical Manifestations

In 30% to 50% of cases, thymomas present as an asymptomatic anterosuperior mediastinal mass seen on a chest radiograph (Fig. 77-7). When symptomatic, patients usually present with cough, chest pain, dyspnea, dysphagia, fever, weight loss, or anorexia.[306] A number of associated conditions are seen in patients with thymoma, including myasthenia gravis, red cell aplasia, hypogammaglobulinemia, polymyositis, and (rarely) systemic lupus erythematosus, rheumatoid arthritis, thyroiditis, hyperthyroidism, and other cytopenias.[309] When an anterior mediastinal mass is present with myasthenia gravis, red cell aplasia, or hypogammaglobulinemia, the diagnosis of thymoma is essentially established.

Myasthenia gravis is an acquired autoimmune disorder caused by circulating acetylcholine receptor antibodies, resulting in acetylcholine receptor deficiency at the motor end-plate.[310] Two thirds of patients with myasthenia gravis have thymic lymphoid hyperplasia,

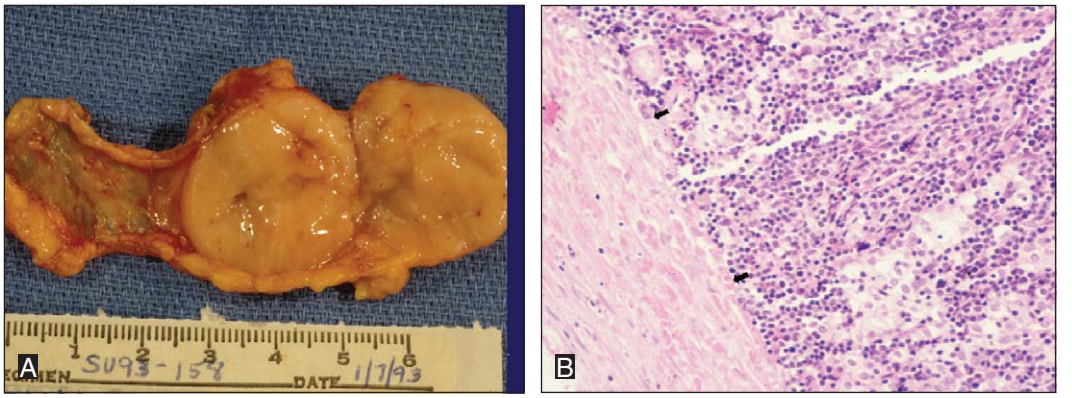

Figure 77-6 • **A,** Gross anatomy of a bisected thymoma demonstrating a complete capsule. **B,** Microscopic demonstration of a thick capsule *(arrows)*. (Courtesy of S.C. Aisner, MD.)

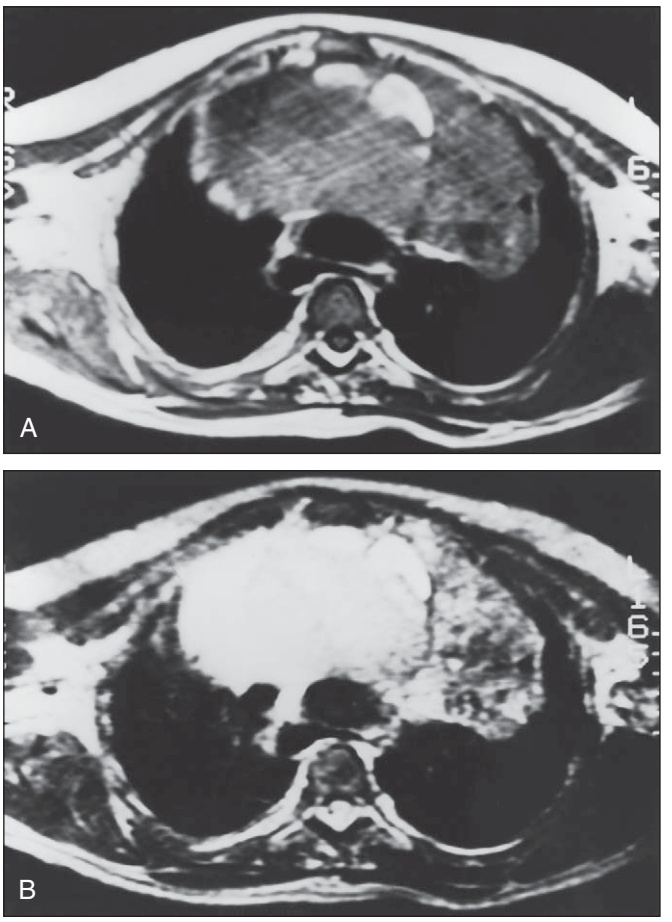

Figure 77-7 • Anterior mediastinal mass that was determined on biopsy to be thymoma. **A,** Axial T_1-weighted MRI through the upper chest showing a large anterior mediastinal mass that extends laterally to both hemithoraces. **B,** Axial T_2-weighted MRI of the same mass, illustrating enhancement compatible with thymoma.

and 8.5% to 15% have thymoma.[299,311] In keeping with this correlation, one third of patients with thymoma have myasthenia gravis.[299,311,312] Thymomas with concurrent myasthenia gravis tend to be less aggressive tumors than those without this associated disorder, and histologically, the tumors tend to have a greater lymphocyte-to-epithelial cell ratio.[313,314] Myasthenia gravis can involve the external ocular muscles selectively, with the patient presenting with diplopia and ptosis. When the other bulbar muscles are involved, the presenting symptoms can include difficulty with deglutition, slurred speech, and loss of facial expression. The general voluntary muscle system can be affected, either alone or with the involvement of the external ocular and bulbar muscles, resulting in fatigability of the limb muscles. The proximal muscles are more severely affected than the distal ones. In advanced cases, the weakness is universal, and the grade of dyspnea depends on the severity of the disease. Progression is most rapid during the first few years, and most deaths caused by myasthenia gravis occur within the first 3 years after diagnosis.[311]

The anticholinesterase test usually is diagnostic for myasthenia gravis. Administration of edrophonium results in rapid (although transient) clinical improvement, with objective response assessed by degree of ptosis, range of ocular movements, and the force of the hand grip. Electromyography performed with supramaximal stimulation of a motor nerve at 2 to 3 Hz results in progressive decrement of the amplitude of the evoked compound muscle action potential from the first to the fifth response. Other diagnostic studies include serologic tests for acetylcholine receptor antibody, C_3 localization of immune complexes at the end-plate in cryostat sections, and electrophysiologic studies of neuromuscular transmission.[315]

The initial current therapy of myasthenia gravis includes anticholinesterases and, alternately, prednisone. Pyridostigmine-bromide is widely used because of its longer duration of action and reduced muscarinic effects compared with neostigmine bromide.[316] The identification of thymoma in patients with myasthenia gravis represents an absolute indication for thymectomy. Although most patients experience some improvement in the thymoma-associated myasthenia gravis symptoms, complete remission of the associated myasthenia gravis symptoms can be expected in only a minority of patients.[317,318] Conversely, more than 75% of all patients with myasthenia gravis without thymoma show some improvement with thymectomy.[319] All thymus tissue, not only the thymoma, should be removed at the time of thymectomy, because residual thymus tissue can lead to persistence of the autoimmune disorder.[320] Other therapies for myasthenia gravis include immunosuppressive agents (e.g., azathioprine and plasmapheresis) in fulminant cases.

Red Cell Aplasia

As many as 5% to 10% of patients with thymoma may have isolated red cell aplasia, which is characterized by an almost total absence of red cell precursors in the bone marrow and reticulocytes in the peripheral blood. One third of these patients also have reduced counts of both leukocytes and platelets. The exact etiology of this disorder is not known, but it has been reported to occur together with myasthenia gravis and thymoma, which suggests an autoimmune mechanism.[321] Thymectomy results in improvement in approximately 30% of these patients.[322]

Hypogammaglobulinemia

Hypogammaglobulinemia is seen in about 5% of patients with thymoma. Both cellular and humoral immunity are decreased in these patients. Only occasional remissions in hypogammaglobulinemia have been seen after thymectomy.[322]

Management of Thymoma

Surgical resection is the principal treatment modality for thymoma. All normal thymic tissue, including the perithymic fat, should be removed, especially if there is an associated autoimmune disease.[320] The usual surgical approach is by median sternotomy, but it can depend on the extent of the disease; more extensive resections might be required, including partial or total pneumonectomy or pericardiectomy.[323,324] Postoperative adjuvant radiation therapy is recommended for those patients found at the time of surgery to have invasive disease or thymic carcinoma, because such therapy leads to definite improvement in long-term survival, as shown by the results of randomized studies.[323] Patients with incompletely resected or unresectable disease also are candidates for radiation therapy. A dose of 30 to 60 Gy has been recommended. Even after whole mediastinal irradiation, recurrences have been seen in the pleural cavity.[305,325] The role of radioisotope implants in areas of unresected tumor is not clear. Occasional responses of myasthenia gravis to radiation therapy have been noted in patients with persistent myasthenia gravis after thymectomy.[326]

Chemotherapy achieves only moderate responses for patients with recurrent or metastatic disease.[327] Agents with some degree of activity include cisplatin, doxorubicin, procarbazine, cyclophosphamide, ifosfamide, and corticosteroids. Only octreotide, cisplatin, and ifosfamide have completed phase II testing.[328–330] Anecdotal reports of responses to corticosteroids exist.[331] Chemotherapy combinations usually produce higher response rates. Cisplatin-based combinations have been tested most extensively.[332–335] Fornasiero and colleagues[333] reported a 92% response rate in 37 patients with cisplatin, doxorubicin, vincristine, and cyclophosphamide. Loehrer and coworkers[330] reported a 50% response among 29 patients using cisplatin,

doxorubricin, and cyclophosphamide. In another report, Park and associates[336] reported a 64% response rate with a similar regimen, with or without prednisone. The European Organization for Research and Treatment of Cancer (EORTC) reported a 56% response rate among 16 patients treated with cisplatin and etoposide; the addition of ifosfamide was not beneficial.[337] A recent trial by Loehrer and colleagues[330] added ifosfamide to this regimen and demonstrated similar response rates. Thymic tumors have demonstrated a high uptake of indium-labeled octreotide (^{111}In-DTPA-D-Phe^{1}), which could be useful for imaging, but which in combination with prednisone has demonstrated complete and partial responses in patients with advanced disease.[330,338] These results indicate that thymoma could, in fact, be a chemosensitive tumor, and thus the role of chemotherapy in the adjuvant and neoadjuvant settings and in advanced disease must be further defined.

Thymic Carcinoma

Thymic carcinomas are epithelial neoplasms of the thymus that are characterized by a high degree of cytologic atypia. These tumors, unlike thymomas, express highly aggressive behavior and thus should be classified separately. Thymic carcinoma includes a heterogeneous group of neoplasms, of which more than half are undifferentiated carcinomas. Other tumor subtypes include squamous cell carcinoma, spindle cell carcinoma, lymphoepithelioma-like carcinoma, mucoepidermoid carcinoma, basaloid carcinoma, clear cell carcinoma, and adenoid cystic tumor.[339,340] Unlike their thymoma counterpart, thymic carcinomas lack immature T lymphocytes and are TdT negative.[341] Additionally, thymic carcinomas express the cytokeratin marker CD5, which is helpful in distinguishing these tumors from nonthymic epithelial malignancies.[342]

These tumors usually present in adult men and are seen only rarely in children. Symptoms include weight loss, shoulder discomfort, cough, and dyspnea. Paraneoplastic syndromes usually are not associated with thymic carcinoma. Well-differentiated thymic carcinoma has been reported in association with myasthenia gravis.[341] The spindle cell variety generally is an aggressive subtype, with mortality rates of up to 50% within 5 years.[340,343,344] There is increasing evidence that Epstein-Barr virus (EBV) might play a role in the development of a lymphoepithelioma-like carcinoma of the thymus gland, as is seen in nasopharyngeal carcinomas. EBV nuclease antigen has been detected in tumorous cells, and Southern blot analysis has demonstrated the EBV viral genome in the cells of thymic lymphoepithelioma-like carcinoma.[345] Although EBV-associated lymphoepitheliomas of the nasopharynx often are treated successfully, the thymic counterpart appears to have a poor prognosis, probably because it usually has become very large by the time it is discovered.[340] Other forms of thymic carcinoma just mentioned are rare. CT scans usually show an anterior mediastinal mass infiltrating along the pleura or mediastinum with necrosis or calcification.[346]

Thymic carcinomas are aggressive and highly lethal tumors. Usually, patients present with advanced-stage disease and are candidates for multimodality treatment, including surgery, radiation therapy, and chemotherapy.[305,347] The combination of cisplatin, vinblastine, and bleomycin as used in the treatment of germ cell tumors has been applied to these neoplasms.[347]

Thymic Carcinoid

Thymic carcinoid (see Chapter 75) arises from the neuroectodermal cells of foregut origin within the thymus and is an amine precursor uptake and decarboxylase (APUD) tumor, usually not associated with the classical carcinoid syndrome seen in carcinoids arising from the midgut.[348] These thymic carcinoids usually are locally invasive but can metastasize to bone, lymph nodes, skin, and liver.[349] In a large review of mediastinal thymic carcinoids, patients with three types of thymic carcinoid were identified.

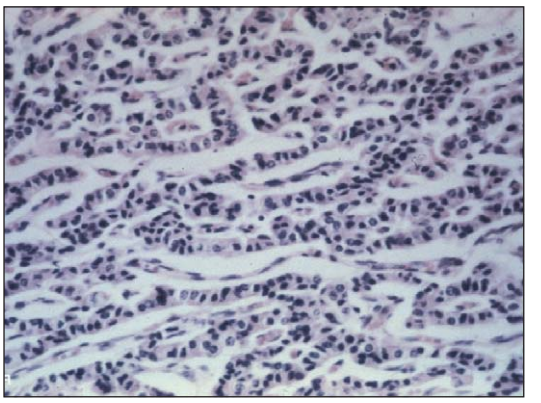

Figure 77-8 • Microscopic view of thymic carcinoid with ribbon pattern of tumor, typical of mediastinal carcinoid. (Courtesy of S.C. Aisner, MD.)

1. Thymic carcinoid associated with Cushing's syndrome or other endocrinopathies (38%; age range 9–48 years).
2. Thymic carcinoid without other endocrinopathies (44.5%; age range 21–87 years).
3. Thymic carcinoid with multiple endocrine neoplasia, type I or II (17.5%; age range 30–46 years).[350]

Cushing's syndrome due to adrenocorticotropic hormone production by tumors is seen most often in children with thymic carcinoid.[351,352] Compared with bronchial carcinoid tumors, thymic carcinoid tumors are a much less common cause of ectopic corticotropin syndrome.[353] Macroscopically, thymic carcinoids resemble thymomas but usually are not encapsulated. On histopathologic examination, thymic carcinoid is characterized by formation of tumor cells arranged into organoid clusters with tumor rosettes and ribbons (Fig. 77-8). The vast majority of cells are positive for neuroendocrine markers such as chromagranin and synaptophysin, which are useful in confirming the diagnosis.[354] Wide excision, when possible, is the mainstay of treatment.[349] The roles of postoperative radiation and chemotherapy are not known, but patients with unresectable or persistent tumors probably should be treated with radiation therapy. Control of hypercortisolism with metyrapone in patients with ectopic corticotropin syndrome is an important part of management.[351]

Mediastinal Germ Cell Tumors

Primary germ cell tumors constitute approximately 10% to 15% of all mediastinal neoplasms.[355] These tumors, although histologically similar to testicular neoplasms, are recognized as distinct entities with separate clinical and biological behaviors (see Chapter 90). They initially were thought to represent metastasis from occult testicular primary lesions, based on the presence of testicular scars representing healed tumors.[356] Malignant transformation of germinal elements in the mediastinum without a primary gonadal tumor has now been well established, however, as isolated mediastinal metastasis from gonadal germ cell tumors rarely occurs. Autopsy series have failed to confirm the presence of either testicular occult primary tumors or fibrous scars in most of the cases with extragonadal germ cell tumors.[357,358] In addition to the mediastinum, other common sites of extragonadal germ cell tumors have been located along the body midline and identified in the pineal gland, sacrococcygeal region, and retroperitoneum.[359] This finding could be due to either abnormal migration of germinal elements to these areas during embryogenesis or their widespread distribution during early development.[360]

Epidemiology

The mediastinum is the most common site of extragonadal germ cell tumors in young adults.[361,362] They can be benign or malignant.

Benign germ cell tumors show no predilection for sex, whereas malignant mediastinal germ cell tumors occur almost exclusively in men.[362] The racial distribution of mediastinal germ cell tumors is unknown, unlike the distribution of gonadal germ cell tumors, which are seen most commonly among whites. There is some evidence that extragonadal germ cell tumors—especially mediastinal tumors—might occur with higher incidence among blacks and Hispanics. The mediastinal nonseminomatous germ cell tumors have been recognized recently in association with Klinefelter's syndrome, with characteristic clinical features and cytogenetic abnormality 47XXY.[363] Whether the chromosomal abnormality seen in Klinefelter's syndrome plays a role in the development of these tumors is not known, but approximately 20% of patients with nonseminomatous germ cell tumors have Klinefelter's syndrome.[364] Systemic mast cell disease with circulating heparin-like anticoagulant has been reported in association with mediastinal germ cell neoplasms.[365] Acute nonlymphocytic leukemia and malignant histiocytosis also are known to occur in association with nonseminomatous mediastinal germ cell tumors; these clearly are not attributable to the therapy but seem to arise from a common progenitor.[366]

All histologic variants of germ cell tumors arise in extragonadal sites such as the mediastinum and are identical to those seen in the testes. This finding is compatible with the embryologic concept that extragonadal germ cell tumors arise from primordial germ cells in the yolk sac or urogenital ridge that have failed to migrate into the scrotum. Benign teratomas are the most common germ cell tumors seen within the mediastinum, in both children and adults.[367,368] These tumors contain elements from all three germ layers: ectoderm, mesoderm, and endoderm. Seminoma is the most common malignant variety of germ cell tumor in the mediastinum, with an incidence of 40%.[369] Other subtypes include embryonal carcinoma, teratocarcinoma, choriocarcinoma, and endodermal sinus tumors, with pure and mixed forms of each type.[370] In a report of 11 cases of primary mediastinal germ cell tumors from a single institution, 4 were seminomas, 3 were mixed germ cell tumors, 2 were embryonal carcinomas, and 2 were teratocarcinomas.[371]

Clinical Presentation

The benign forms often do not give rise to any symptoms and are discovered incidentally on chest radiographs obtained for other reasons. If symptoms do occur, they usually are due to the enlarging mass in the anterior mediastinum (Fig. 77-9).[368] On the other hand, almost all patients with malignant extragonadal germ cell tumors present with chest pain, cough, dyspnea, and constitutional symptoms such as fever, weight loss, and anorexia. Nonseminomatous tumors grow rapidly and metastasize early.[370] Occasionally, these patients develop superior vena cava syndrome or present with symptoms related to the site of metastasis, the most common of which are lungs, liver, bone, and brain.

The anterosuperior mediastinum is the most common site of mediastinal involvement, with rare presentation in the posterior compartment. Useful imaging studies include CT scans of the thorax to gauge the extent and characteristics of mediastinal involvement. Abdominal CT scans can detect the presence of liver metastasis or retroperitoneal disease. A testicular primary tumor should be suspected if significant retroperitoneal disease is found. Elevation of β subunit of human chorionic gonadotropin (hCG) and α-fetoprotein (AFP) suggest the malignant, nonseminomatous nature of these tumors. The incidence of elevated AFP is higher in patients with mediastinal, nonseminomatous germ cell tumors than in those with primary metastatic testicular tumors. Choriocarcinomas can produce both hCG and gynecomastia, which can be seen on initial presentation.[372] Elevation of lactic dehydrogenase is seen in 80% to 90% of patients with either seminomatous or nonseminomatous tumors. Serum markers, when present, are used both to assess response to treatment and to detect early recurrence.[373] Fluorescence in situ hybridization (FISH) has permitted specific recognition of a genetic marker i(12p) for germ cell tumors.[374] The fluorescent signal at the centromere of the i(12p) is larger than that obtained from a normal chromosome 12 centromere using a probe specific for chromosome 12 centromeric DNA.[374] Presence of the i(12p) or excess 12p copy numbers tends to be associated with complete response to chemotherapy and long-term disease-free survival.[375]

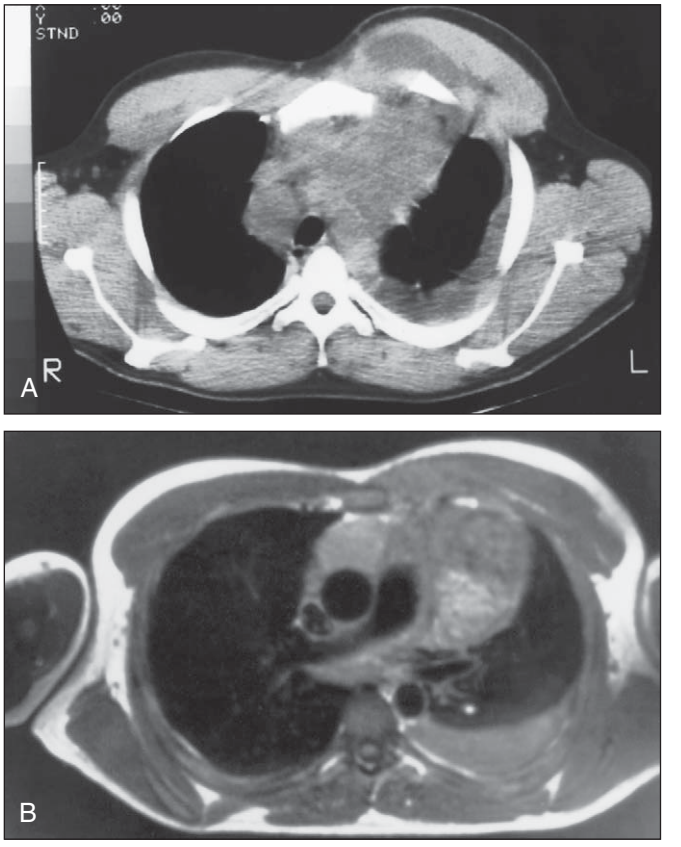

Figure 77-9 • Anterior mediastinal mass-germ cell tumor. **A,** Unenhanced CT image of the chest at the level of the aortic arch showing a large anterior mediastinal mass that extends to the left to or through the chest wall. Note the extension of the pectoralis minor and the bulge of the pectoralis major anteriorly. Paratracheal adenopathy is evident on the right, as is a moderate left pleural effusion. **B,** T_1-weighted MR image at the same level, clearly demonstrating extension of the mass into the chest wall.

Establishment of a definitive histopathologic diagnosis is crucial for the management of these patients. The classic presentation is a young adult with an anterosuperior mediastinal mass and a characteristic marker profile. Percutaneous imaging-guided fine-needle aspiration of the anterior mediastinal mass often establishes the diagnosis of germ cell neoplasms, but definitive tissue diagnosis is best obtained by parasternal mediastinotomy. If considerable risk is involved with surgical intervention for diagnosis because of a patient's poor overall condition, and if there is a high index of suspicion with elevated markers, management can be initiated with chemotherapy without a diagnostic biopsy.[359]

Benign Mediastinal Germ Cell Tumors

Benign mediastinal teratomas are treated exclusively with surgical resection, which results in cure; there is no role for adjuvant therapies after surgical resection.[376] Lewis and coworkers[368] reported a series of 69 patients from the Mayo Clinic with benign mediastinal teratoma, 64 of whom are long-term survivors. The five remaining patients died either from surgical complications or from unknown causes.

Mediastinal Seminoma

Mediastinal seminomas tend to be slow-growing and can reach considerable size with few or no symptoms. Traditionally, the disease was treated with supradiaphragmatic irradiation because of the tumor's radiosensitivity.[377] Large masses might require large fields of irradiation, however, which can cause considerable compromise to surrounding organs. Several trials, therefore, have tested the role of cisplatin-based chemotherapy and have found significant activity and long-term disease control.[359,378,379] Either approach offers the possibility of disease control. Depending on the individual characteristics of the patient and the comorbid diseases, small tumors might be considered for radiation therapy, whereas larger tumors most likely would be best treated with initial cisplatin-based chemotherapy. Surgical excision or management does not appear to play a role in the management of this disease.[359] Whether cisplatin-based chemotherapy or radiation therapy alone followed by chemotherapy at recurrence should be considered as the optimum treatment for mediastinal seminoma is still open to question; both result in comparable long-term survival rates. For patients who have bulky mediastinal disease or extramediastinal involvement, there is substantial evidence that cisplatin-based chemotherapy might be superior.

Mediastinal Nonseminomatous Germ Cell Tumors

Cisplatin-based chemotherapy is the cornerstone of management of mediastinal nonseminomatous germ cell tumors.[380–382] Overall, the prognosis of mediastinal nonseminomatous germ cell tumors is poor compared with that of their testicular counterparts, and they have the worst survival characteristics of all the nonseminomatous germ cell tumors.[383] In an old series from Memorial-Sloan Kettering Cancer Center before the advent of cisplatin, only 5% of patients survived beyond 17 months with surgical resection followed by radiation therapy.[362] A French multicenter retrospective study reported a 53% 2-year projected survival rate and a median survival of 28 months for patients with mediastinal nonseminomatous germ cell tumor using cisplatin-based chemotherapy followed by resection of residual tumor, if present.[379] Complete response rates with cisplatin-based therapy have ranged from 50% to 70% in most series, with a long-term survival of approximately 50%.[380,381] Second-line chemotherapy combinations for patients with resistant or recurrent disease generally have yielded poor results.[384,385] These patients, therefore, either should be entered into clinical trials with investigational agents in an effort to identify new active agents in this disease, or should be treated with high-dose therapy followed by peripheral blood stem cell or autologous bone marrow transplantation.[386] Chemotherapy in general and salvage chemotherapy specifically tend to be less effective for the management of patients with mediastinal germ cell tumors than of patients with their testicular counterparts.[387]

Mediastinal Hodgkin's Disease

Approximately one half of patients with Hodgkin's disease have mediastinal involvement, usually in the anterior compartment, either as a component of widespread disease or presenting solely as a mediastinal mass (see Chapter 111). The most common histologic subtype with mediastinal involvement is nodular sclerosis, which is seen predominantly among young women.[388] The diagnosis usually is made from biopsy of a cervical lymph node and rarely requires biopsy of the mediastinal mass. The extent of mediastinal and pulmonary involvement can be gauged better with CT and MRI scans than with plain chest radiograph (Fig. 77-10).[389] The CT scan also is useful in planning the radiation fields. Approximately 40% of cases also have involvement in the form of hilar adenopathy and lung nodules. Pleural and pericardial effusions, although less common, are known to occur.[390] In cases of bulky mediastinal disease, acute tracheobronchial obstruction can occur during anesthesia.[391] Management of mediastinal Hodgkin's disease is based on the bulk of the tumor and the extent of parenchymal lung involvement.

Pulmonary extension significantly increases the risk of relapse and decreases the overall survival. In a study reported by the Baltimore Cancer Research Center, small-volume mediastinal involvement with early-stage (stage I or II) Hodgkin's disease was treated successfully with upper-mantle radiation therapy alone.[392] For those with large mediastinal masses or pulmonary extension, radiation therapy alone was associated with 38% disease-free survival at 10 years; combined chemotherapy and irradiation resulted in 88% disease-free survival at 10 years.[392] The risk of relapse at the margin of the irradiation field was increased when a "shrinking field technique" was used to decrease the incidence of pulmonary complications in patients with large mediastinal masses treated with radiation therapy alone. Although salvage chemotherapy can be useful in patients who fail to achieve a complete response to radiation therapy alone, the results are inferior when compared with combined-modality treatment. Combined-modality therapy also was superior to chemotherapy alone as reported in various studies for patients with large mediastinal masses due to Hodgkin's disease. Currently, therefore, the standard of care for patients with large mediastinal masses is combined chemotherapy and irradiation.

Gallium scans, and both CT and PET scans, have been used for detection of viable Hodgkin's disease in the mediastinum after chemotherapy or combined-modality therapy.[393–395] According to the results of a recent study, the value of these studies is limited in predicting disease sterilization, although a few patients have benefited from treatment modification due to abnormal activity seen on these scans.[393,395]

Mediastinal Non-Hodgkin's Lymphoma

Mediastinal non-Hodgkin's lymphomas have a wide clinical spectrum, ranging from nodal involvement as a part of generalized disease to bulky anterior mediastinal mass resulting in symptoms of compression of other structures such as the pericardium, heart, lungs, or great vessels (including the superior vena cava; see Chapter 112). The most common symptoms of bulky mediastinal disease include chest pain, dyspnea, sternal tenderness, superior vena caval compression syndrome, and pleural or pericardial effusions.[388,396] Constitutional symptoms such as fever, weight loss, and anorexia occur in 50% of patients and are associated with a poorer prognosis than disease without these symptoms.[397] In isolated mediastinal involvement, thoracotomy or mediastinotomy could be required for obtaining adequate diagnostic material. Complete staging evaluation is required, because extensive involvement of other organs is seen frequently. The two most common subtypes of non-Hodgkin's lymphoma that are seen predominantly in the mediastinum include diffuse large cell lymphoma.

Diffuse large cell lymphoma can present as an anterior mediastinal mass. Mediastinal presentation is more common among young females, with a median age of about 30 years. The disease usually is bulky and extends from the mediastinum into contiguous structures such as pleura, pericardium, and lung. Pleural and pericardial effusions are known to occur in nearly one third of patients. Bone marrow and central nervous system involvement usually are not seen at presentation. These are predominantly B-cell neoplasms, with the dominant phenotype reported to be CD19+, CD22+, CD37+, CD21–, CD30–, CD10–, CD5–, and immunoglobulin negative.[398,399]

Lymphoblastic lymphoma is a distinct entity that presents as an anterior mediastinal mass in older children and young adults. It is seen predominantly in males and is clinically and immunologically similar to acute lymphoblastic leukemia. The cell of origin is the T cell or middle or late thymocyte in most cases, but rarely, it may be of the pre-B cell or null cell types. Immunophenotyping reveals E rosette+, T6+, T4+, T8+, T1+, and T3+. On histopathology exam-

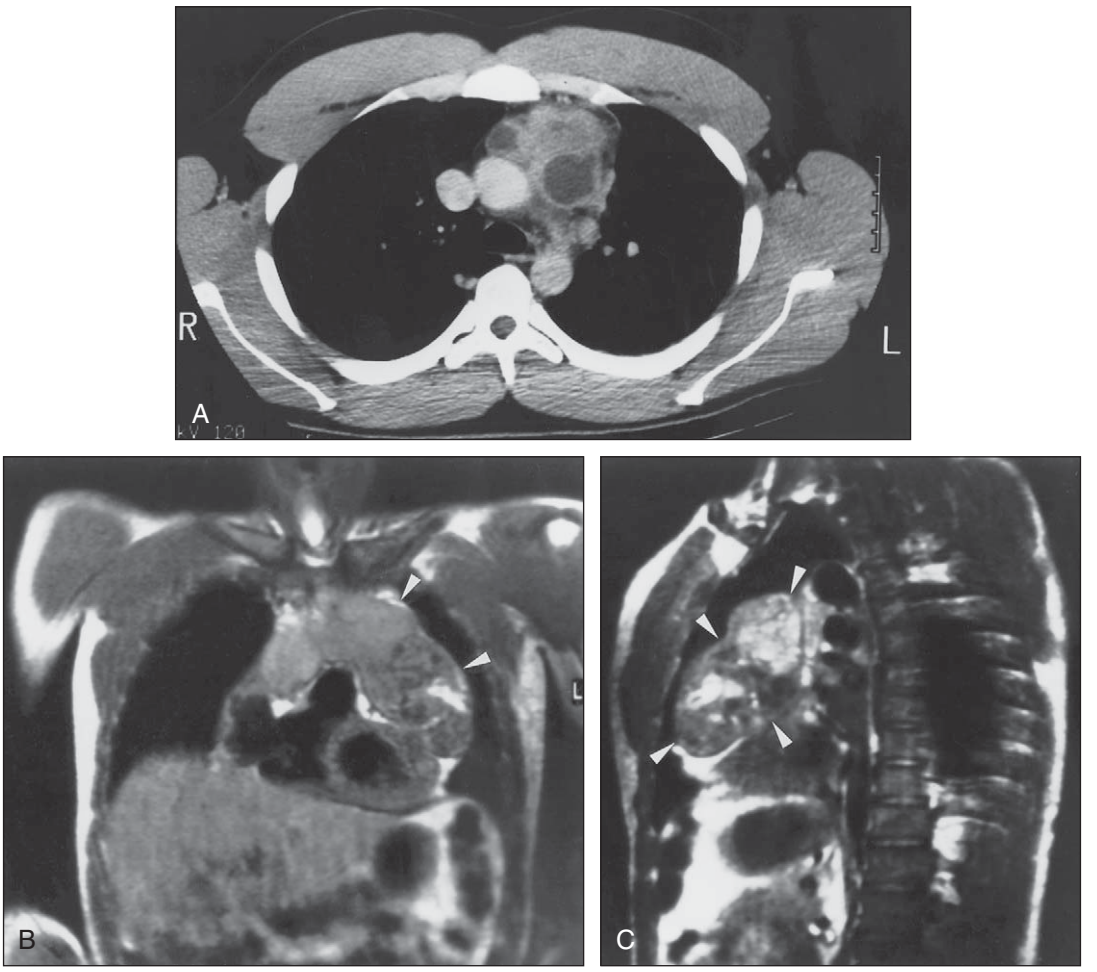

Figure 77-10 • Anterior mediastinal mass that was determined to be Hodgkin's disease. **A,** Enhanced CT image of the chest at the AP window showing a large mixed solid and cystic mass with extension to the left. **B,** Coronal T_1-weighted MR image of the chest showing the large mediastinal mass *(arrowheads)* with extension to the left. **C,** Sagittal T_1-weighted MR image of the chest showing the large mediastinal mass with areas of mixed signal corresponding to the mixed solid and cystic areas.

ination, cells have convoluted or nonconvoluted nuclei with fine chromatin without nucleoli. The histology-stained section gives a "starry sky" appearance. Staining with terminal deoxynucleotidyl transferase (TdT) usually is positive. Clinically, these cases present as a thymic mass with paracortical involvement of the thymus-dependent lymph nodes. There is a high incidence of meningeal spread and involvement of the bone marrow, peripheral blood, and testes. Cells obtained from cerebrospinal fluid should be stained with TdT.[400]

The management of lymphoblastic lymphoma is essentially similar to that of acute lymphoblastic leukemia. The response to chemotherapy usually is rapid.[401,402] Earlier regimens, such as CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), produced low complete remission rates and substantially fewer survivors.[403] Intrathecal therapy with or without craniospinal irradiation is applied early in the treatment course to prevent central nervous system relapse.[402–404] There is no evidence that radiation therapy in addition to chemotherapy improves survival, but it should be initiated if the patient is in severe distress and objective improvement is not seen quickly with chemotherapy.

TUMORS OF THE MIDDLE MEDIASTINUM

Malignant tumors of the heart and pericardium are rare entities. Approximately 75% of all cardiac tumors are benign, and more than half of these are myxomas (Fig. 77-11). Other malignant tumors and cysts of the heart and pericardium include angiosarcoma, rhabdomyosarcoma, mesothelioma, fibrosarcoma, lymphoma, extraskeletal osteosarcoma, neurogenic sarcoma, malignant teratoma, thymoma, leiomyosarcoma, liposarcoma, and synovial cell sarcoma.[405] In a series recently reported by Chen and coworkers,[406] 79 patients with cardiac tumors were seen at the Shanghai Institute from 1957 to 1988. Of these, 49 patients had benign and 30 had malignant tumors. All except two of the benign tumors were myxomas, and 86% of these were located in the left atrium. Among the 30 malignant tumors, 15 were secondary metastases, 3 were lymphomas, 2 were mesotheliomas, 2 were malignant myxoma, 1 was angiosarcoma, 1 was rhabdomyosarcoma, 1 was leiomyosarcoma, 1 was fibrosarcoma, and 4 were undiagnosed. Metastatic tumors to the heart and pericardium can result from direct extension from the mediastinal lymph nodes or hematogenous dissemination of tumor. Metastatic renal cell carcinoma has been demonstrated to grow into the right atrium from the vena cava without myocardial infiltration, and such tumors occasionally have been surgically resected.[407] The manifestations of cardiac and pericardial tumors are varied and depend on mass effect, local invasion, embolization, and systemic constitutional symptoms.[408] Pericardial involvement can result in severe substernal chest pain due to pericarditis with frequent effusion or tamponade (Fig. 77-12). Other manifestations include congestive heart failure, pulmonary

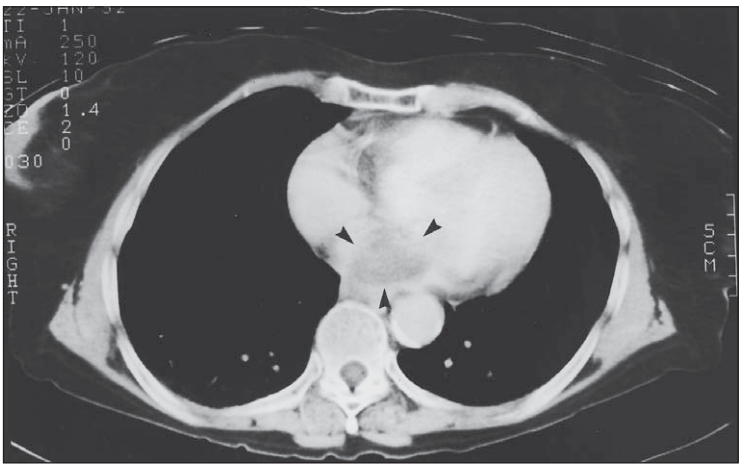

Figure 77-11 • This middle mediastinal mass represents a left atrial myxoma. Enhanced CT image through the heart showing a left atrial defect *(arrowheads)* with lower attenuation than the surrounding contrast-filled atria and ventricles.

hypertension, and dysrhythmias. Diagnostic procedures include echocardiography and CT of the chest in addition to chest radiographs and electrocardiograms.[408] CT with contrast can detect the intracavitary filling defect and its relationship to cardiac chambers and invasion. More recently, MRI has been used to localize intracardiac tumors, to assess their vascularity, and to distinguish them from cardiac metastasis.[409] Cardiac catheterization is able to detect mass effects resulting in compression or deformity of various chambers, intracavitary filling defects, myocardial motion abnormalities, or pericardial effusion. Angiosarcoma and rhabdomyosarcoma are the two most common malignant cardiac tumors.[405,410,411] Microscopically, angiosarcomas contain foci of solid areas and spindle cells forming vascular channels, while rhabdomyosarcomas contain rhabdomyoblasts, but in both types of tumors, there can be high degrees of anaplasia and pleomorphism with necrosis and hemorrhage. Most patients with malignant cardiac tumors survive less than a year from diagnosis. Local excision of intracardiac tumors occasionally is successful, but the patients usually are left with residual disease.[412] Radiation and chemotherapy have been tried but are of limited value in these cases. Cardiac transplantation might result in improved survival in patients with inoperable cardiac tumors, but definitive data are lacking.

Malignant Mesothelioma of the Pericardium

Malignant mesothelioma originating on the pericardium is an exceptionally rare tumor; just over 100 cases (including children) have been reported in the literature.[413] Because of the rarity and age distribution of these tumors, no association has been made with asbestos exposure in most of the reported cases. The clinical presentation can include mediastinal mass, pericardial effusion, congestive heart failure, or tamponade.[413–416] Diffuse involvement of the pericardium with invasion of myocardium and mediastinal structures often is seen. The diagnosis of this tumor is rarely made or suspected before surgery or autopsy.[417–419] Surgical excision is rarely complete, and most cases rapidly become fatal. The role of radiation therapy or chemotherapy is not known.

POSTERIOR MEDIASTINAL TUMORS

Malignant Neural Crest Neoplasms

The overall incidence of tumors arising from the neural crest is low, but they are the most common tumors found within the posterior mediastinum (Fig. 77-13).[420] The neurogenic tumors encompass a

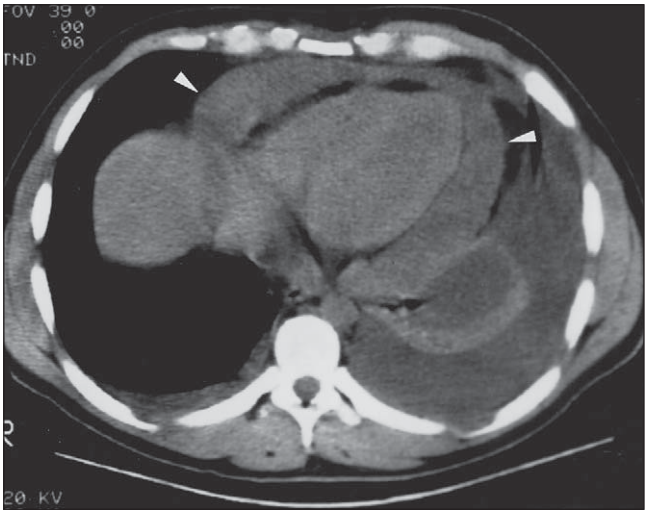

Figure 77-12 • The middle mediastinal mass was found to be malignant pericardial effusion. Enhanced CT image showing a large pericardial effusion *(arrowheads)* and bilateral pleural effusions, greater on the left than on the right. The collapsed left lower lobe is seen extending into the effusion at the left base.

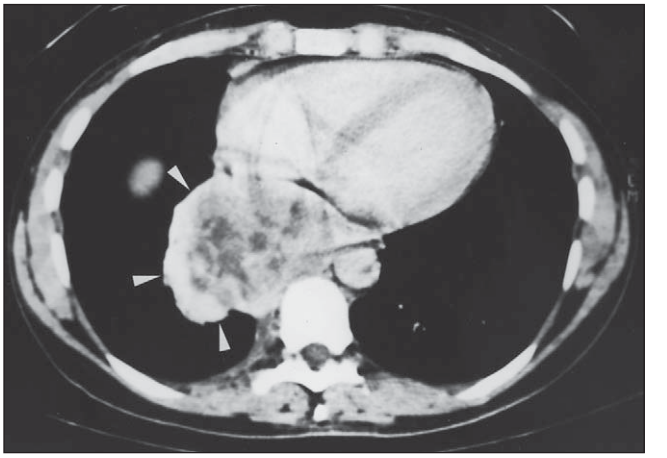

Figure 77-13 • Posterior and middle mediastinal mass that was found to be a neurogenic tumor. Enhanced CT image of the lower chest just above the level of the diaphragm showing a large mass *(arrowheads)* in the posterior mediastinum extending to the middle mediastinum with variable CT attenuation. Comparison with prior unenhanced CT image showed a strong enhancement of the mass.

wide and complex spectrum of neoplasms that occur in both children and adults. These tumors can range in their usual clinical behavior from benign (schwannoma) to highly aggressive (neuroblastoma). They commonly are solitary and asymptomatic but can cause constitutional symptoms such as cough, dyspnea, and pain with tumor enlargement. Children are more likely than adults to present with malignant disease with metastasis. Mediastinal tumors of the neural crest can be divided into two groups. One group of tumors arises from the neuronal cells, which include the nerve ganglion cells (ganglioneuroblastoma and ganglioneuroma) and the neuroendocrine cells (e.g., pheochromocytoma, paraganglioma). The second group arises from the neural sheath cells or the Schwann cells and includes schwannoma and neurofibroma.

Peripheral Primitive Neuroectodermal Tumor

Peripheral primitive neuroectodermal tumor (PNET; peripheral neuroepithelioma, Askin tumor, extraosseous Ewing's sarcoma) of the thorax can present either as a pleural-based mass or as a paraspinal posterior mediastinal mass. The clinical picture varies depending on the presence or absence of pleural effusion, rib destruction, or epidural spinal cord compression.[421] High fevers with other constitutional symptoms are usual accompaniments. These tumors usually occur in children or young adults and occur equally in males and females.[422] Histologically, these tumors are lobulated and have small, blue round cells with occasional rosettes. Electron microscopy reveals dense, neurosecretory granules and neurofilaments. The cells stain strongly for the antibody O13, demonstrating membranous positivity.[423] PNETs also may stain for neuron-specific enolase, synaptophysin, and Leu-7. They demonstrate high levels of choline-acetyl transferase but are devoid of catecholamine enzymes seen in neuroblastomas, such as dopamine decarboxylase and tyrosine hydroxylase.[421,424] Cytogenetically, PNETs demonstrate a consistent pattern of chromosomal translocation: rcp (11;22) (q24;q12).[425] Whether the altered regulation of synthesis of the proteins encoded by the cellular protooncogenes at the site of chromosomal translocations contributes to malignant transformation is not entirely clear.[426] Fluorescence in situ hybridization (FISH) probes directed at the EWS gene rearrangement now can be performed accurately on fixed and paraffin-embedded tissue.[427] In the past, a multimodality approach was used for the management of PNETs, but the median survival was only about 8 months despite the aggressive therapies. Radiation therapy (45–55 Gy) could produce shrinkage, but local recurrence was common. Metastases to the lung, bone, and bone marrow occurred with regularity.[428] Chemotherapy combinations of cyclophosphamide, doxorubicin, and vincristine (CAV) or CAV with actinomycin-D were used with some success, both as neoadjuvant therapy prior to local radiation therapy and wide surgical excision and to treat advanced metastatic disease.[421,429] High-dose chemotherapy with total body irradiation and autologous bone marrow transplantation was also attempted.[430] Recently, the combination of etoposide and cisplatin has shown somewhat better success in the treatment of this tumor, although large masses still are likely to recur and could require radiation therapy as part of combined modality therapy.[431]

Neuroblastoma, Ganglioneuroblastoma, and Ganglioneuroma

Neuroblastoma, ganglioneuroblastoma, and ganglioneuroma occur in children, although there are rare reports of these tumors arising in adults.[432–434] These tumors differ from each other only in terms of their degree of differentiation, with neuroblastoma being a high-grade, undifferentiated neoplasm and ganglioneuroma being a benign tumor possessing mature ganglion cells. Occasionally, these tumors present as masses in the posterior mediastinum rather than in their usual abdominal or widely disseminated presentation. When present in the thorax, these tumors are reported to have a better prognosis, possibly because of early detection due to the occurrence of symptoms.

Neuroblastoma

Neuroblastoma is the most common cause of mediastinal neurogenic mass in children and is a highly aggressive tumor thought to arise from primitive neural crest-derived cells called neuroblasts.[435,436] A thoracic presentation accounts for 15% of all cases of neuroblastoma, although it is seen predominantly in the very young. More than half of patients with mediastinal presentation already have disseminated disease.[437] The most common sites of metastatic involvement include lymph nodes, bone, liver, and subcutaneous tissues. The signs and symptoms depend on the site of dissemination. Mediastinal neuroblastoma usually occurs in the posterior compartment and usually is seen as an incidental finding on a chest radiograph obtained for other reasons. Occasionally, patients can present with cough, dyspnea, malaise, and spinal cord compression. Bone marrow involvement is common. The presence of the opsoclonus polymyoclonus syndrome—characterized by acute cerebellar and truncal ataxia and dancing eyes—could indicate a favorable prognosis. Amplification of n-myc has been seen in neuroblastoma and is associated with early disseminated disease.[438,439] DNA content assessed by flow cytomety also can be clinically useful as a predictor of response in unresectable disease.[438] A number of specific genetic changes, including a deletion in the short arm of chromosome 1 (1p-) and abnormalities in chromosome 17, have marked neuroblastoma as a paradigm for the study of molecular changes and cancer.[440] Therapy usually consists of a multidisciplinary approach, with surgery for localized disease and chemotherapy being the mainstay of treatment for those with disseminated disease.

Pheochromocytoma

Pheochromocytoma, a tumor of the autonomic nervous system, is a form of paraganglioma that both secretes and stores catecholamines. Extra-adrenal presentations are unusual, but the posterior mediastinum is the usual site of occurrence of intrathoracic pheochromocytoma. Pheochromocytomas also have been reported to occur in the middle mediastinum, with involvement of the cardiac atria and arch of the aorta.[19] The vast majority of all mediastinal pheochromocytomas are clinically benign but share histological similarities with their malignant counterparts.[441] Nuclear atypia and pleomorphism are the hallmarks of both benign and malignant tumors. Membrane-bound dense core neurosecretory granules (150–250 nm) are seen routinely with electron microscopy.[442] On immunohistochemical analysis, pheochromocytomas demonstrate neuron-specific enolase, chromagranin, synaptophysin, and corticotropin-like reactivity.[441,443,444] Metastatic disease is the only reliable benchmark for defining malignancy.[445] The malignant forms also can be locally aggressive and can metastasize to bone, lymph nodes, liver, lung, and brain. Clinically, patients with pheochromocytomas present with symptoms of catecholamine excess such as persistent hypertension, palpitations, headache, perspiration, orthostasis, chest pain, and constitutional symptoms.[446] Occasionally, cardiomyopathy can result from catecholamine excess. In addition to the usual diagnostic tests for mediastinal tumors, specific studies include measurement of urine and plasma catecholamines, ^{131}I-MIBG [I-131-meta-iodobenzylguanidine], scintigraphy, and pharmacologic tests using provocative agents such as glucagon, tyramine histamine, or suppressive agents (e.g., phentolamine and clonidine).[447]

Pheochromocytomas are managed with surgical resection, which can result in cure in some cases. Pharmacologic adrenal blockage preoperatively is achieved with phenoxybenzamine and subsequent beta-adrenergic blockade with propranolol, while short-acting phentolamine is reserved for management if hypertension arises. Sometimes a-methyl tyrosine may be used to decrease catecholamine synthesis. The 5-year survival of patients with malignant mediastinal

pheochromocytomas approaches 50%. The role of radiation therapy after surgical resection of malignant forms is not clear, although these tumors are relatively sensitive to radiation.[446] A number of chemotherapeutic agents have been tried for malignant pheochromocytoma with limited success; these include cyclophosphamide, vincristine, doxorubicin, dacarbazine, methotrexate, and streptozotocin.[448–450] Conceptually, ^{131}MIBG with high specific activity could have a therapeutic role in the management of malignant pheochromocytomas.[447,451]

Schwannomas and Neurofibromas

Schwannomas and neurofibromas derive from neural sheath cells (see Chapter 70). Together, they form a group with the highest incidence among all mediastinal tumors in adults and are the most common tumors seen in association with Von Recklinghausen's disease.[452,453]

Schwannoma and Malignant Schwannoma

Schwannoma (neurilemmoma) is a benign, encapsulated nerve sheath tumor that usually is solitary except when seen in association with neurofibromatosis (NF-1).[454] Schwannomas arise from Schwann cells of the cranial, spinal, or peripheral nerves.[453] The lung and heart are other sites of intrathoracic involvement.[455,456] Schwannomas tend to be slow-growing tumors, usually in the right side of the upper posterior mediastinum, and they rarely extend into the intervertebral foramina. Clinically, they usually do not cause any symptoms until, in rare cases, there is involvement of the vagus or phrenic nerve. On histopathologic examination, these tumors demonstrate an alternating pattern of palisading spindle cells (Antoni A) and loose myxoid hypocellular areas with scattered spindle cells (Antoni B). Immunohistochemistry demonstrates strong S-100 positivity.[457] They can be treated with simple surgical resection without sacrificing neural structures.[458]

Malignant schwannomas or malignant peripheral nerve sheath tumors are aggressive spindle cell neoplasms most commonly arising from nerve trunks in the posterior mediastinum or in the vagus or other peripheral nerves. They rarely result from malignant transformation of their benign counterpart but can arise from either degeneration of neurofibroma in neurofibromatosis (NF-1) or within the field of prior radiation therapy.[459,460] On histologic examination, these malignant tumors demonstrate a variably cellular spindle cell and myxoid neoplasm. Mitotic figures are seen easily. Occasionally, mesenchymal elements such as fat, cartilage, bone, and muscle are seen in malignant schwannomas.[461,462] In one study, MRI and pathologic correlation showed that a nonhomogeneous, high-intensity appearance of schwannomas on T_2-weighted images corresponded to alternating Antoni A and Antoni B areas, whereas a central, very-high-intensity region was noted in areas of cystic degeneration.[462] Immunohistochemical studies show S-100 variable positivity.[463] Clinically, in addition to symptoms due to mass effect, patients can present with pain and constitutional symptoms such as fatigue, weight loss, anorexia, and, occasionally, fever. The tumor advances locally, invading nearby structures such as the heart, great vessels, and vertebral bodies, and it can extend into the intervertebral foramina. Lung, liver, bone, skin, and serous surfaces are common sites of metastases. Surgical resection is the primary treatment.[464] The role of adjuvant radiation therapy is not well defined. This family of malignant tumors tends to be very resistant to chemotherapy, although some anecdotal responses have been seen with novantrone plus vinblastine and the combination of cyclophosphamide, ifosphamide, doxorubicin, dacarbazine, and vincristine.[465,466]

Neurofibromas

Neurofibromas also are believed to originate from the Schwann cell and, like schwannomas, they usually are solitary masses except when seen in association with neurofibromatosis (NF-1), tuberous sclerosis, Sturg-Weber syndrome, or von Hippel-Lindau disease.[467,468] They are slow-growing, benign tumors and can arise from any nerve. Clinically, they usually are asymptomatic until there is interspinal extension, resulting in signs of epidural cord compression. On histologic examination, the solitary forms are unencapsulated and consist of elongated wavy spindle cells separated by collagen and mucoid material. The plexiform variety, seen in patients with NF-1, involves expanded nerve trunks in a neurofibromatous background. Malignant transformation has been reported and is a serious complication of this disease.[453,469] On T_2-weighted MRI, high-intensity regions in the periphery of neurofibromas correspond to myxoid degeneration, and curvilinear or nodular areas of low signal intensity correspond to collagenous fibrous tissue. On immunohistochemistry, neurofibromas show S-100 reactivity and demonstrate the presence of cholinesterase. Surgical resection is the treatment of choice.

78 Cancer of the Esophagus

Lawrence R. Kleinberg, Malcolm V. Brock, Sanjay B. Jagannath, and Arlene A. Forastiere

SUMMARY OF KEY POINTS

Classification

- Esophageal cancer is subdivided into the following four groups: epithelial tumors, metastatic tumors, lymphomas, and sarcomas.
- Cancers of epithelial origin, predominantly squamous cell carcinomas and adenocarcinomas, are the most common; other histologic types are rare.

Incidence

- Within the United States, the incidence of esophageal cancer in people younger than 80 years is 3.2 per 100,000 persons.
- Historically and internationally, squamous cell tumors are the most common histologic type; however, a dramatic increase in the incidence of adenocarcinoma has been documented in the United States, the United Kingdom, and western Europe.

Pathogenesis

- Exact etiology is unknown.
- The data support the hypothesis that epithelial tumors arise as a result of chronic irritation from a wide variety of sources, including gastric contents in chronic reflux and known carcinogens.
- A strong association of Barrett's esophagus and adenocarcinoma is seen, but a benefit to screening endoscopy for those who are at risk for or have known Barrett's esophagus is unknown, as the overall risk of cancer-related mortality is low. Studies with longer-term follow-up are needed to clarify this issue. Other identified risk factors are gastroesophageal reflux disease, obesity, and smoking.
- Squamous cell carcinoma is associated with smoking as well as alcohol use, and the declining incidence has paralleled the decline in smoking.
- Point mutations, increased copy number, and promoter region hypermethylation all appear to be important in the progression to malignancy.

Diagnosis and Staging

- Symptoms and demographics will strongly suggest the diagnosis.
- Endoscopy is the best screening examination, but esophagram may also be utilized.
- Diagnosis is made by endoscopy with cytology and biopsy of tumor.
- Transesophageal ultrasound should be used to assess T and N stage to guide optimal definitive therapy.
- Computed tomography (CT) of the chest and abdomen is useful in screening for metastatic disease.
- Positron emission tomography (PET) scan is useful to detect additional cases of metastatic disease before costly and toxic definitive therapy. PET may be superior to endoscopic ultrasonography in detecting intra-abdominal lymph nodes but not periesophageal nodes adjacent to the primary tumor.
- Additional studies include laparoscopy, thoracoscopy, bone scan, and CT of the brain when indicated by clinical circumstances.

Treatment

- Treatment of premalignant dysplasia is guided by grade of histology. Low-grade dysplasia should be closely followed by endoscopy. High-grade dysplasia is treated with esophagectomy, although close follow-up or endoscopic treatments might be appropriate for selected patients.
- Selection of appropriate treatment for carcinoma depends on tumor stage and patient performance status.
- Surgery is an accepted single-modality therapy for patients with localized disease (T1 to 3 N0 to 1 M01a). The selection of surgical approach depends on location and experience, but no approach has been demonstrated to lead to superior cure rates.
- Combined chemoradiation leads to prolonged median survival and long-term survival compared with radiation alone, at the price of increased toxicity. This represents a potentially curative alternative to surgery for squamous cell cancers and is appropriate for most unresectable T4 N(any) M0 lesions of either histology. As most patients treated on prospective chemoradiation trials had squamous cell carcinomas, the benefits of nonoperative management for adenocarcinoma are not known.
- Randomized trials have not confirmed a survival benefit with surgery added to chemoradiation in squamous cell carcinoma, but there was a significant local control benefit.
- Accumulating evidence, including multiple modestly powered randomized trials and meta-analyses, suggests that combination therapy with preoperative chemoradiation followed by surgery improves local control and may increase survival compared with surgery alone.
- Postoperative adjuvant chemotherapy or chemoradiation is less well studied in esophageal cancer, but trials in gastric cancer, including gastroesophageal junction adenocarcinoma, have demonstrated a benefit.
- Combined modality chemotherapy regimens frequently include 5-fluorouracil and cisplatin agents; other commonly used regimens include taxanes and irinotecan.
- Endoscopic palliative therapy includes laser or electrical fulguration, photodynamic therapy, or stenting. Except for very superficial lesions, these therapies are not alternatives to surgery, as they do not address deeper disease or lymphatic spread.
- Radiation therapy, with or without chemotherapy, may be used to palliate local symptoms.
- Chemotherapy may be used for metastatic disease, but response rates and duration of response are modest for most patients. Clinical trials are recommended.

INTRODUCTION

Carcinoma of the esophagus is a devastating disease associated with poor survival outcome and with adverse affects on swallowing and quality of life. Although esophageal cancer is an aggressive malignancy that usually presents in a locally advanced stage, significant progress has been made in the treatment of this disease, including expanded treatment options, decreased surgical morbidity and mortality, and improvements in identifying patients who are at risk. These advances are resulting in incremental improvements in outcome, but there remains considerable controversy over the optimal management under individual scenarios. The emphasis of this chapter is on selecting the appropriate options in the curative and palliative management of esophageal cancer.

CLASSIFICATION AND LOCATION

Esophageal cancer (Table 78-1) is classified on the basis of histologic appearance and cell of origin, as follows: (1) epithelial tumors, (2) metastatic tumors, (3) lymphomas, and (4) sarcomas. Cancers of epithelial cell origin, predominantly squamous cell carcinoma and adenocarcinoma, are the most common.

Squamous cell cancer usually occurs in the middle third of the esophagus. In a collective review of over 28,000 cases of squamous cell cancers, Postlethwait[1] estimated the ratio of upper, middle, and lower cancers to be 15 : 50 : 35, respectively. Adenocarcinoma, on the other hand, is most common in the lower third of the esophagus. In a collective review of 4783 cases of esophageal adenocarcinoma, Ming[2] noted an upper esophageal location in 4%, middle in 18%, and lower in 67%. Of the rare primary histologic types, 95% of small cell cancers occur in the middle and lower thirds; both malignant melanoma and choriocarcinoma tend to occur in the lower third. Esophageal sarcomas may occur anywhere along the esophagus, as is the case for esophageal lymphomas or metastases from other primary cancers.

INCIDENCE

Tumors of the esophagus other than squamous cell carcinoma and adenocarcinoma are very rare. This chapter therefore focuses on esophageal squamous cell carcinoma and adenocarcinoma. Epidemiologic data show that the incidence of esophageal cancer varies considerably from one country to another and often within a single country. The geographic diversity of esophageal cancer worldwide, of which over 90% are squamous cell cancers, underscores the multifactorial etiologies of this group of diseases. In the United States and other Western industrialized countries,[3–8] however, there has been a slight decline in squamous cell esophageal cancer over the past three decades and a dramatic rise in adenocarcinoma of the distal esophagus and gastroesophageal (GE) junction. This histology has increased in incidence approximately sixfold and, since the mid-1990s, has been the predominant esophageal cancer in Caucasians.[7] The absolute incidence in the United States has increased from 3.8 per million in 1973–1975 to 23.3 per million in 2001, according to the National Cancer Institute's Surveillance, Epidemiology and End Results database.[7] This rate of increase exceeds that of all other cancers, including lung, breast, prostate, and melanoma. Adenocarcinoma is much less common in African Americans but has increased from 0.4 per 100,000 to 0.9 per 100,000, and 0 to 0.2 per 100,000 in females. Obesity and gastroesophageal reflux disease (GERD) appear to contribute to this rise in adenocarcinoma incidence. In contrast, the incidence of squamous cell carcinoma decreased in all of these groups during this period, perhaps owing to a decline in the prevalence of smoking and increased consumption of fresh fruits and vegetables.[9]

Table 78-1 Classification of Esophageal Cancer

EPITHELIAL
Squamous cell carcinoma
Ordinary squamous cell
Verrucous squamous cell
Spindle cell (carcinosarcoma)
Adenocarcinoma
Ordinary
Adenoacanthoma
Mucoepidermoid
Adenoid cystic
Small cell
Melanoma
Choriocarcinoma
METASTATIC DISEASE
Lymphoma
Sarcoma

PATHOGENESIS

Data support the hypothesis that epithelial esophageal tumors arise as a result of chronic irritation and inflammation of the esophagus leading to a sequence of genetic alterations in the damaged epithelium and histologic changes of dysplasia to carcinoma. The geographic and demographic distributions of esophageal cancer vary widely. Whether this variance can be explained solely by environmental factors or whether a genetic component exists as well is conjectural. The most commonly reported irritants include tobacco, alcohol, dietary factors, lye, radiation, and refluxed bile salts and gastric contents. There are important differences between the risk factors, histologic progression, and molecular events that support the concept that squamous cell carcinoma and adenocarcinoma should be considered as separate entities with potential to respond differently to newer treatment approaches. These differences are highlighted in the following sections.

Clinical Risk Factors

Tobacco smoking is a proven etiologic factor in the development of squamous cell esophageal cancer for both men and women according to epidemiologic studies from various countries worldwide. This relationship is dose-dependent, and the risk of esophageal cancer decreases with smoking cessation. Smokeless tobacco products have also been shown to correlate with an increased risk of cancers of the mouth, larynx, throat, and esophagus.[10] There is also a multiplicative interaction of alcohol intake and tobacco use.[11–14] In a study from Taiwan, the strongest risk for squamous esophageal cancer was alcohol consumption, with a 13.9-fold increased risk, while combined exposure with smoking increased the risk to nearly 20-fold.[11]

A prospective study of tobacco, alcohol, and risk of esophageal squamous cell carcinoma and adenocarcinoma in the United States found an increased risk of squamous cell carcinoma among current smokers compared with nonsmokers (hazard ratio (HR): 9.27, 95% confidence interval (CI): 4.04, 21.29) and also an increased risk for adenocarcinoma (HR: 3.70, 95% CI: 2.20, 6.22). For people who drink more than three alcoholic beverages a day compared to one drink, there was increased risk of esophageal squamous cell carcinoma but not adenocarcinoma of the esophagus, GE junction, or cardia.[13] The association of adenocarcinoma with smoking, though much less

striking than that of squamous cell carcinoma, appears to remain elevated for more than 30 years after smoking cessation.[15]

Other factors that are associated with an increased risk of squamous cell esophageal cancer are lye ingestion, radiation therapy (RT), achalasia, Plummer-Vinson syndrome, and previous head and neck squamous cell cancer. The interval between injury and the development of cancer may be considerable in patients who sustain lye ingestion or are irradiated.

Nutritional and dietary factors have been evaluated in an attempt to explain the worldwide variability in the incidence of squamous esophageal cancer. Ghadirian and colleagues[16] reported that the populations with the highest incidence of esophageal cancer shared dietary characteristics, including a rapidly consumed high-starch diet with few or no fruits and vegetables. Many dishes consist of granular foods or foods that are served quite hot, both of which irritate the esophagus.[16] Associations between fruit and vegetable intake and esophageal cancer risk have been found for both squamous cell carcinomas and adenocarcinomas of the esophagus and aerodigestive tract cancers in general,[17,18] some data suggesting that this relationship might vary according to histologic type.[19] For example, risk factors for esophageal, gastric cardia, and noncardia gastric cancers in Linxian, China, which has one of the highest rates of these cancers in the world, were prospectively evaluated in a population-based study of over 25,000 adults performed by the National Cancer Institute.[20] After 15 years of follow-up, improved socioeconomic status seemed to be a common factor for lowering risks for all three sites. Protective factors for esophageal squamous cell cancer included formal education; water piped into the home; and increased consumption of meat, eggs, and fresh fruits. A study in Sweden that controlled for other risk factors assessed the importance of three diets as a risk factor: "healthy diet" (high in vegetables, tomatoes, fruits, fish, and poultry), "Western diet" (high in processed meat, red meat, sweets, high-fat dairy, and high-fat gravy), and "alcohol drinker" (high in intakes of beer, liquor, and French fries). A Western diet was associated with increased risks of gastric cardia adenocarcinoma (high third tertile versus low first quartile, odds ratio [OR]: 1.8, 95% CI: 1.1 to 2.9, *P* for trend: 0.04) and esophageal adenocarcinoma (high third tertile versus low first tertile, OR: 1.6, 95% CI: 0.9 to 3.1, *P* for trend: 0.13), whereas a dietary pattern characterized by high beer and liquor intake (alcohol drinker) significantly increased the risk of squamous cell carcinoma of the esophagus (third tertile versus low first tertile, OR: 3.5, 95% CI: 1.9 to 6.3, *P* for trend: <0.0001).[21]

The increased risk of adenocarcinoma over the past several decades, primarily in Western nations and among white males, is attributable to a combination of factors, including obesity,[22] diets low in vegetables and high in processed and red meat, and a close association with GERD and Barrett's esophagus (BE).[23,24] Obesity, defined as a body mass index of 30 or greater, is a strong risk factor for esophageal adenocarcinoma, as is demonstrated in epidemiologic studies in the United States and Sweden.[14,22] The relative risk of adenocarcinoma was increased 7.6-fold for obese individuals compared to lean individuals (body mass index <22) in a study from Sweden.[14] This has clear implications for the increasing obesity rates in the United States and could in part explain the rising incidence of esophageal adenocarcinoma. The exact mechanism for this association of obesity is not understood but might reflect an increased propensity for GERD.

Further study to identify the individuals who are at highest risk and to understand the molecular progression from BE to dysplasia and invasive malignancy could lead to effective strategies for screening or prevention. Squamous cell carcinoma generally arises in a sequence through normal epithelium to atypia onto malignancy. The initial change is characterized by epithelial proliferation, followed by development of dysplasia, then carcinoma in situ. Esophageal adenocarcinoma frequently arises in BE, a metaplastic columnar epithelium that develops in the esophagus, generally as a result of injury from chronic reflux. As is described in the following sections, there is then progression through low- and high-grade dysplasia to invasive malignancy, which may be within or adjacent to dysplastic columnar epithelium or may replace it.

Adenocarcinoma: Role of Gastroesophogeal Reflux Disease and Barrett's Esophagus

Gastroesophageal reflux disease is a well-established risk factor for esophageal adenocarcinoma.[23,24] A population-based case-control study that was performed in Sweden demonstrated a relative risk of 7.7 for development of esophageal cancer in patients with chronic reflux disease.[23] With longstanding, severe symptoms, the relative risk was 43.5. Similar increases in risk were not observed for esophageal squamous cell carcinoma or adenocarcinoma of the gastric cardia. Interestingly, the increased risk of esophageal carcinoma existed whether or not BE could be identified, leading the authors to speculate that GERD might cause esophageal adenocarcinoma by a mechanism independent of BE. An alternative explanation might be that the area of BE in these patients was overgrown by tumor.[25] It remains controversial whether treating reflux in the setting of BE will significantly reduce or eliminate the risk of adenocarcinoma. The role of screening for BE is unknown.[26] According to the American College of Gastroenterology practice guidelines, a one-time endoscopic examination could be prudent to rule out BE in patients with chronic GERD, especially in the highest-risk population: white males. The value of this approach has been questioned by those who point out that BE is uncommon, progression to malignancy is infrequent, and the effect on overall population mortality appears quite low. These data are summarized following, and screening with endoscopy is further discussed later in this chapter.

There is a clear relationship between BE and dysplasia and neoplasm.[27] BE refers to a condition in which the normal stratified squamous mucosa is replaced by columnar-lined epithelium that extends upward from the esophagogastric junction. Various lengths of esophagus may be involved. The condition is an acquired, metaplastic process that develops in response to an esophageal mucosal injury that heals in the setting of the inflammatory stimulus of continued GE reflux. BE may progress to dysplasia and then malignancy as the dysplastic epithelial cells accumulate genetic alterations.

The incidence of BE is not known, although reports range from 1% to 2% of the general population. Miros and colleagues[28] prospectively followed 81 patients with BE. Three patients developed adenocarcinoma: two with antecedent high-grade dysplasia and one with low-grade dysplasia. No patient without dysplasia developed adenocarcinoma. The length of time for the progression from high-grade dysplasia to adenocarcinoma is unknown. Because the lifetime risk may be as high as 8% to 15% or 0.5% to 1% per 50 patient years, many advocate lifelong endoscopic surveillance for patients with Barrett's mucosa with the goal of treating dysplastic changes and thereby reducing the risk of developing adenocarcinoma. Indeed, tumors that are discovered during surveillance appear to be of an earlier stage and therefore to have a higher chance of cure.[29,30] Still, it is not certain whether surveillance reduces mortality; the overall risk of death from esophageal cancer is relatively low even in this high-risk population.[26,31,32]

Several centers have reported results of endoscopic screening that suggest that progression of BE to esophageal cancer might be less common than was originally thought, at least in the short term. A Veterans Administration study of patients requiring therapy for reflux disease found a 0.4% per patient-year risk in patients with BE and 0.07% per year in those without BE.[33] A study of 60 patients with a new diagnosis of BE followed for a median of 10 years (range: 5 to 15 years) demonstrated that 3% developed esophageal cancer and 15% developed other cancers, with no significant difference in life expectancy compared with the general population.[31] There is uncertainty about the actual risk of esophageal adenocarcinoma in individuals with GERD, estimates ranging from a 30-fold to a 125-fold increase in risk. In the setting of confirmed BE and surveillance,

progression to esophageal adenocarcinoma is estimated as 1 per 250 patient-years, or 0.4% per year. These uncertainties are in part due to the problem of sampling error when biopsies are performed during endoscopy and to a high degree of interobserver variability in dysplasia grading.[34] Thus, the current method for detecting esophageal cancer early in at-risk individuals through endoscopic screening and biopsy has low sensitivity and is controversial.

Approximately two thirds of patients who develop adenocarcinoma have histologic evidence of BE[35–37]; however, an estimated 40% will give no clear-cut history of GERD. Thus, screening endoscopy of individuals with symptomatic GERD will still miss the substantial proportion of individuals who do not report reflux symptoms.[38]

Although there has been much progress in unraveling the relationship between Barrett's mucosa, dysplasia, and esophageal adenocarcinoma, there are still many unanswered questions, such as why Barrett's mucosa is seen in such a specific demographic pattern, and what is the trigger to initiate the progression to dysplasia and carcinoma.

Molecular Progression to Adenocarcinoma

Molecular genetic data support the histologic observation that there is a progression from normal epithelium to BE to dysplasia to adenocarcinoma.[39,40] Although a clearly defined sequence of genetic alterations leading to adenocarcinoma has not been defined, an accumulation of abnormalities has been identified in a wide range of genes that regulate proliferation, apoptosis, invasion, metastasis, angiogenesis, growth, and cell cycle regulation. Tumor suppressor genes such as p53 and p16 have been implicated as early events, as loss of cell cycle checkpoints may be permissive for genetic instability, allowing later transformation in the metaplasia-dysplasia-adenocarcinoma sequence.[39,41,42] Moskaluk and colleagues[43] performed immunohistochemical staining for p53, an important regulatory gene in cell cycle control and apoptosis, and p21/WAF1, a cyclin-dependent kinase inhibitor, in 98 adenocarcinoma esophagectomy specimens. They found similar p53 and p21 WAF1 expression in adenocarcinoma specimens with and without associated Barrett's mucosa, and they concluded that the molecular mechanism of carcinogenesis for these two groups is the same. Wu and colleagues[44] investigated DNA replication errors and allelic losses of chromosomes 17p, 18q, and 5q in esophageal adenocarcinoma (without associated Barrett's mucosa), Barrett's adenocarcinoma, and Barrett's mucosa with dysplasia. More recently, Barrett and colleagues[45] have reported that alteration in p53 and p16 are generally seen throughout an area of Barrett's abnormality, suggesting that these abnormalities were inherent in the original clonal development of BE. Additional mutations involving loss of heterozygosity at 5q, 13q, or 18q occurring in no particular order appeared to be important in the bifurcation into aneuploidy and onto progression into neoplasm.[45] Wong and colleagues[46] focused on the role of p16 inactivation and found that more than 85% of BE clones had inactivation of one or both p16 alleles by loss of heterozygosity (53%), hypermethylation (61%), and point mutation (15%). The loss of cell cycle regulation from these early changes may promote DNA instability, leading to additional changes required for progression to malignancy. Interestingly, in patients with Barrett's mucosa that harbor p16 +/− or p16 −/− alterations, the prevalence of other abnormalities, including 17p (p53) LOH, aneuploidy, or tetraploidy, can be 44% higher than that in patients without any p16 loss in their esophageal mucosae. In addition, the median length of Barrett's mucosa increased from 1.5 in patients without p16 loss to 6.0 to 8.0 cm in those with p16 abnormalities. This again suggests that p16 might be an important step in the field change leading to Barrett's epithelium and invasive cancer.[46]

There appears to be a diversity of molecular abnormalities in esophageal cancer that are caused by actual genetic mutations, epigenetic inactivation, and altered cell regulation. Lagarde and colleagues have reviewed many of the abnormalities of in gene expression in esophageal cancer, which occur in a wide variety of genes, such as cyclin D1, EGFR, Her-2/Neu, APC, TGF-β, Endoglin, CTGF, P53, Bcl-2, NF-kappaB, Cox-2, E-cadherin, beta-catenin, uPA, MMP-1,3,7,9, the TIMP family, T(h)1/T(h)2 balance, CRP, and PTHrP.[41,47] The method of identifying and codifying alterations in these genes into a clinically useful paradigm has not yet proved superior to standard histology for predicting outcome, but more complex analyses using sophisticated molecular techniques such as genomic arrays could be helpful in the future. In the meantime, new molecular abnormalities continue to be identified.[48]

In the last decade, epigenetic modifications have emerged as heritable and fundamental features of most malignancies.[49] The best-studied epigenetic modification of the DNA is promoter region hypermethylation, an epigenetic modification that is associated with gene inactivation. A meaningful understanding of the molecular events that lead to progression to adenocarcinoma will likely require a greater understanding of this phenomenon as it occurs at least as frequently as point mutation. DNA hypermethylation is biologically important in development where it is associated with the inactivation of genes on the X chromosome. In oncogenesis, hypermethylation is often associated with inactivation of tumor suppressor genes, of genes that suppress metastasis and angiogenesis, as well as of genes that repair DNA. Methylation of DNA occurs mostly at CpG sites in the genome and is catalyzed by a family of three active DNA methyltransferases that transfer a methyl group from S-adenosyl-methionine to cytosine to form 5-methylcytosine. Because this reaction can be blocked effectively by a drug, 5-azacytidine, which acts as an irreversible inhibitor of the DNA methyltransferases, the therapeutic potential inherent in reversing DNA hypermethylation is significant.[50]

In esophageal adenocarcinoma, CpG-island methylation at CDKN2A/p16INK4a has been implicated in the progression of BE to malignancy with 38% of premalignant and malignant lesions demonstrating this abnormality. Eads and colleagues[51,52] reported results for 31 normal esophagus specimens and 22 adenocarcinoma specimens. The following genes were observed to be methylated in a substantial portion of esophageal cancer specimens but less often in normal esophagus from the same patients (percent tumor versus percent normal specimens): CDKN2a/p16 (41% versus 0%), ESR1 (86% versus 0%), MYOD1 (45% versus 0%), TIMP3 (86% versus 19%), APC (68% versus 3%), and CALCA (50% versus 13%). Others have found that CDH1 is methylated with substantially greater frequency in adenocarcinoma than in normal esophagus, BE, or dysplasia. In contrast to colon cancer, in which point mutations of CDKN2a/p16 are frequent, such mutations are rarely found in esophageal adenocarcinoma, and methylation predominates. Hypermethylation of various genes is also prevalent in esophageal dysplasia. Of note, APC was found to be methylated in normal stomach in 12 of 12 specimens.[52] MGMT was methylated in 55% of normal esophagus specimens, 73% of adenocarcinoma specimens, and 25% of stomach specimens. Hypermethylation of nel-like 1 gene[53] and DAPK[54] is uncommon in normal esophagus but is found in 40% to 60% of BE, dysplasia, and esophageal adenocarcinoma specimens and is associated with poorer prognosis, whereas MGMT hypermethylation has not been associated with prognosis.[53,55,56]

A study at Johns Hopkins found methylation[57] frequencies of the genes APC (68%), E-cadherin (66%), O6-methylguanine DNA methyltransferase (56%), ER (51%), p16 (39%), DAP-kinase (19%), and TIMP3 (19%).[57] Analysis of DNA methylation of these genes individually showed only trends toward diminished survival, whereas patients whose tumors had more than 50% of their gene profile methylated had both significantly poorer survival ($P = 0.04$) and earlier tumor recurrence ($P = 0.05$) than those without positive methylation. By multivariate analysis, the hazard ratios (HRs) with positive methylation status were more powerful predictors of survival (HR: 2.7 [1.14 to 6.45, 95% CI]) and tumor recurrence (HR: 2.5 [1.11 to 5.6]) than was age (HR: 2.03 and 1.96, respectively) or stage (HR: 1.48 and 1.67, respectively).

Molecular Steps to Squamous Cell Carcinoma

Gene expression profiling studies have delineated some important differences between adenocarcinoma and squamous cell carcinoma. A comparison of adenocarcinoma, squamous cell carcinoma, BE, and normal esophagus suggested that both histologies had upregulation of genes commonly involved in carcinogenesis such as cell cycle regulators, extracellular matrix genes, immune response genes, kallikreins, and serine protease inhibitors with downregulation of genes related to calcium ion binding and gap junctions.[58] Despite these similarities, other aspects of the gene expression profile of squamous cell carcinoma were more closely related to normal esophagus, whereas adenocarcinoma was more closely related to the profile identified in BE.

As with adenocarcinoma, there exists great complexity in the molecular events that are involved in progression to squamous cell carcinoma. Loss of heterozygosity of Rb, p53, and CDKN2A/p16INK4a has been identified as a common event. Methylation, although less well studied in squamous cell cancer than in adenocarcinoma, appears to play an important role.[59] At Johns Hopkins, Guo and colleagues used a panel of methylation markers, including p16, MGMT, MLH1, APC, BRAC1, RAR, CDH1, and DAPK, to suggest that there was a tendency for each of these genes to be methylated at higher frequencies as the grade of the lesion increased through dysplasia to malignancy.[59] The conclusion was that accumulation of DNA methylation changes suggests epigenetic progression and that this progression parallels visible histologic changes that are observed as squamous dysplasia progresses to frank carcinoma. In this study, the most commonly methylated gene was p16 (52%). Interestingly, the rates of methylation for more than one and two genes was 29% and 0%, respectively, for normal esophagus; 56% and 56%, respectively, for high-grade dysplasia; and 91% and 70%, respectively, for carcinoma.[59] Wu has extensively reviewed methylation of individual genes in adenocarcinoma and squamous cell carcinoma, but the limitations of the currently available data do not allow for definitive identification of any differences.[60] Ischii and colleagues[61] have also reported that for a large panel of promoter regions, there was a higher tendency toward methylation of many of the candidate genes in carcinoma and intraepithelial neoplasm than in the adjacent nonepithelial neoplasm. The data from Ishii and colleagues corroborate the findings of Guo and colleagues of an accumulating progression of DNA methylation changes on top of a background of low-level DNA methylation in nonneoplastic esophageal epithelium.[61,62] Interestingly, in the same study, p53 mutations occurred almost exclusively in intraepithelial neoplasm (57%) or carcinoma (63%) and in only 4% of adjacent nonneoplastic mucosa.

The possibility of detecting hypermethylated DNA in circulating plasma and serum has also been investigated in squamous cell cancer. This ultimately could play a role in early detection and/or following response to therapy. For example, in one study, hypermethylation of the APC gene in tissue occurred in 48 of 52 patients (92%) with esophageal adenocarcinoma, in 16 of 32 patients (50%) with esophageal squamous cell carcinoma, and in 17 of 43 patients (39.5%) with Barrett's metaplasia but not in matching normal esophageal tissues.[62] In the plasma of these patients, hypermethylated APC DNA was observed in only 13 of 52 adenocarcinoma patients (25%) and in 2 of 32 squamous cell carcinoma patients (6.3%). High plasma levels of methylated APC DNA were statistically significantly associated with reduced patient survival in this study ($P = 0.016$).[62] In another study, aberrant promoter methylation of the p16 gene was detected in the tumor tissue of 31 of 38 patients (82%) with esophageal squamous cell cancer.[63] In subsequent testing for p16 promoter methylation in the paired serum DNA of 31 patients with a p16 methylated in the primary tumor, only 7 of these 31 patients (23%) had the same methylation changes in the serum DNA.[63] In another analysis, preoperative blood samples were obtained from 44 esophageal squamous cell cancer patients and were subjected to CEA-specific reverse transcriptase polymerase chain reaction assay and methylation-specific polymerase chain reaction (MSP) assay for p16, E-cadherin, and RAR-β gene methylation. Circulating tumor cells were detected in 12 patients (27%), and 14 patients (32%) had aberrant methylation in the promoter region of at least one gene (6, 4, and 4 patients for p16, E-cadherin, and RARbeta, respectively). No abnormality was detected by either assay in control plasmas. Altogether, 23 patients (53%) had a positive result with either molecular assay.[64]

OVERVIEW: THE CHOICE OF THERAPY

The primary goals of therapeutic interventions for esophageal cancer are to relieve symptoms (predominantly dysphagia) and to treat the underlying cancer. An ideal therapy would accomplish both, safely and effectively. Currently, three main treatment strategies exist. The first utilizes endoscopic palliative techniques to control the tumor locally for the purpose of palliation, the second uses single modalities (e.g., surgery, radiation, or chemotherapy), and the third involves intensive combination therapies aimed at cure. There is substantial controversy about the optimal management of curable (localized) esophageal cancer; the treatment options include surgery alone, chemotherapy followed by surgery or adjuvant chemotherapy after resection, chemoradiation followed by surgery, and definitive chemoradiation. Radiation alone as definitive treatment aimed at cure is inferior to combined chemoradiation for locally advanced disease and should be considered only when the other options are not feasible. Similarly, RT used in the adjuvant or neoadjuvant setting has not been shown to improve outcome. These options and the supporting data are summarized in Table 78-2. The survival outcome of patients with localized disease who were enrolled in selected randomized controlled trials is summarized in Table 78-3 according to treatment group. The median survival ranges from 9.0 months for patients in RT-alone control groups to as long as 19 months for those receiving preoperative chemoradiation. A statistically significant 10% to 15% improvement in survival rate with any of these approaches would be of major importance. As Table 78-3 shows, the median survival rates with surgery, definitive chemoradiation, and preoperative chemotherapy or preoperative chemoradiation do not clearly differ, although selection factors might have varied substantially among the trials.

Surgery is a standard treatment option, and there are substantial data, although not a definitive randomized controlled trial, supporting the hypothesis that preoperative chemoradiation (trimodality therapy) improves outcome over that achievable with surgery alone. Preoperative chemotherapy has been evaluated in randomized controlled trials with conflicting results among U.S. and non-U.S. trials. It is not a standard of care or common practice in the United States. On the other hand, definitive chemoradiation is a potentially curative alternative to surgery and is indicated for patients with unresectable primary tumors or inoperable disease due to medical comorbidities.

Given the lack of comparative data to demonstrate the superiority of any of one approach for resectable disease, clinical decision making for optimal management is complex and controversial. Surgery as a single therapeutic modality is the appropriate management for early-stage disease (stages I and IIA); however, for more advanced disease (stages IIB, III, and IVA), combined-modality therapy, specifically preoperative chemoradiation with its associated risks of toxicity but potential for improved long-term survival, is frequently utilized. (See Table 78-4 for stage definitions.) The available data from phase II trials, underpowered phase III trials, and meta-analyses indicate improved local control and suggest a survival benefit on the order of 10%. However, an adequately powered, randomized controlled trial has not been conducted to validate the observations from phase II clinical trials, and it is unlikely that such a trial will be performed in the United States. Commonly used preoperative chemoradiation regimens are associated with substantial toxicity; therefore,

Table 78-2 Options in the Therapy of Esophageal Carcinoma

Treatment	Recommendation
SINGLE MODALITY	
Surgery	• Accepted standard for resectable AC and SCCa
Radiotherapy	• Recommended for high-grade dysplasia and stage I carcinoma
	• Definitive treatment of inoperable patients unsuitable for chemoradiation
	• Palliation of obstructive symptoms
COMBINED MODALITY	
Definitive chemoradiation	• Inoperable SCCa and selected resectable SCCa
Preoperative chemotherapy	• Inoperable AC
Preoperative chemoradiation	• Investigational
	• Preferred approach for resectable SCCa and AC
POSTOPERATIVE ADJUVANT THERAPY	
Following preoperative chemotherapy or chemoradiation	• No demonstrated benefit
Following surgery alone	• R0 resection: no demonstrated benefit for adjuvant radiotherapy, chemotherapy, or chemoradiation for SCCa; potential benefit for AC based on gastric trial data
	• Microscopic or gross residual tumor: consider chemoradiation in good performance status patients or radiation indicated

AC, adenocarcinoma of the distal esophagus and gastroesophageal junction; SCCa, squamous cell carcinoma.

trimodality therapy should be used cautiously in patients with poor performance status or comorbid conditions that increase the risk of life-threatening toxicity. There are no data to support the notion that chemoradiation is useful to convert an unresectable lesion into a resectable lesion.

Preoperative chemotherapy has less associated toxicity than does preoperative chemoradiation and is the favored combined modality approach in the United Kingdom, stemming from a survival benefit that was demonstrated in a randomized controlled trial conducted in the United Kingdom by the Medical Research Council (MRC).[65] By contrast, a similarly designed U.S. Intergroup trial found no advantage over the surgery control group; hence, this approach is considered experimental in the United States.[66]

Definitive chemoradiation eliminates the risk of surgery but at the cost of inferior local control and disease-free survival compared to trials of trimodality therapy.[67] In evaluating clinical trial results, though, it is important to consider selection factors that might be at work: chemoradiation may be selected for patients with more advanced lesions, unresectable disease, or with significant comorbid disease leading to inoperability, a population that is less likely to achieve long-term survival. Definitive chemoradiation has been studied in patients with esophageal squamous cell carcinoma, a population with a high prevalence of cardiopulmonary and hepatic disease from excessive tobacco and alcohol use, which increases operative risks. In contrast, nonsurgical treatment aimed at cure has not been adequately tested in patients with resectable adenocarcinoma and therefore cannot be recommended for this histology.

The role of adjuvant therapy after complete surgical resection has not been as well studied as preoperative therapies. For patients who are undergoing immediate surgery, data to support adjuvant chemoradiation is extrapolated from gastric trials that included a minority of patients (about 20%) with GE junction primaries. At best, these data showing significant improvement in survival for patients with gastric cancer but not powered to look at site-specific subsets provide a rationale for additional treatment for resected patients with adenocarcinoma of the distal esophagus or GE junction, stages IIB, III, or IVA. Adjuvant RT has been studied and shown not to be beneficial, whereas there are insufficient data on adjuvant chemotherapy to recommend its use. In patients who are undergoing primary surgery with microscopic or gross residual disease, postoperative chemoradiation should be considered if it is tolerable.

When palliation of obstructive symptoms rather than cure is the goal, several options exist. These include RT with or without chemotherapy and the endoscopic therapies of stent placement, laser therapy, and photodynamic therapy (PDT). The choice of palliative treatment is influenced by the severity of symptoms, patient performance status, expected survival time, and physician expertise. When survival expectations exceed a few months, palliation with radiosensitizing chemotherapy and concurrent radiation limited to the tumor bulk may provide more durable symptomatic relief. RT may also be added after endoscopic palliation to increase the durability of local palliation for patients who are likely to survive more than 3 to 6 months.

For metastatic disease, chemotherapy is indicated, with the goal of improving survival and preventing or treating symptoms at all locations. Given the modest response rate and brief duration of response with available regimens, chemotherapy alone has limited ability to effectively palliate obstructive symptoms.

DEFINITIVE TREATMENT OPTIONS

Diagnostic Evaluation

The most common presentation of esophageal carcinoma includes solid food dysphagia and weight loss of several months' duration. Other presentations that occur with esophageal adenocarcinoma in particular include chest pain in the absence of myocardial ischemia and anemia from a chronic gastrointestinal (GI) bleed from the mucosal lesion. These clinical signs and symptoms should prompt endoscopic evaluation and diagnostic imaging. The diagnosis is usually evident by the characteristic narrowing of the esophagus on barium esophagram, but endoscopy and biopsy are essential for histopathologic diagnosis. Endoscopic biopsies and brushings of the lesion will yield the diagnosis in more than 90% of patients. Multiple biopsies might be necessary to obtain the diagnosis of an invasive malignancy that is submucosal or necrotic.[68] A diagnosis of in situ carcinoma in the face of a large lesion seen on radiographic studies should not be accepted, and biopsy should be repeated.

Once the pathologic diagnosis has been established, evaluation to determine the extent of disease should include a computed

tomography (CT) scan of the chest and complete abdomen. The chest CT is useful for evaluating lung parenchyma and mediastinal structures.[69] Lymph nodes that are more than 1 cm in diameter or have necrotic centers suggest metastatic involvement. The chest CT also is helpful for assessing aortic or pericardial invasion of tumor that would preclude esophagectomy. In contrast, the actual length of the esophageal lesion is better assessed on the barium esophagram.

The accuracy of identifying metastases to the liver and celiac axis by abdominal CT depends on the bulk of the disease. Small liver metastases, peritoneal studding, and abdominal nodes will often be undetectable.[69–75] For squamous cell lesions of the upper and mid-thoracic esophagus, a CT scan of the upper abdomen that includes the liver and adrenals is sufficient. For the patient with an adenocarcinoma of the distal esophagus, GE junction or cardia, a complete abdominal-pelvic CT is necessary to visualize potential areas of nodal metastases. Cancers of this histologic type are more likely to metastasize early to periaortic lymph nodes. A complaint of back pain might signal the presence of enlarged retroperitoneal nodes.

Positron emission tomography (PET) scanning enables the identification of metastatic disease in patients who might otherwise inappropriately receive definitive local therapy and therefore is now considered a standard if not mandatory staging test. Prospective studies [76,77] demonstrated that PET will detect unsuspected metastatic disease in approximately 15% of patients after all other staging tests are completed, although it is not as useful as other techniques in identifying involved regional nodes. A prospective study of 79 patients[76] found that the specificity and sensitivity of PET for identifying stage IV disease was 90% and 74% versus 47% and 78% for the combination of CT and endoscopic ultrasonography (EUS), with an overall accuracy of identification of stage IV disease of 82% versus 64% ($P = 0.004$). Furthermore, when PET was added to CT and EUS, 22% of patients had a change in stage that altered their planned treatment (15% upstaged to incurable stage IV disease, and 7% downstaged to a stage at which curative therapy would be appropriate). Other investigators have confirmed that PET scanning will change management from curative to palliative in 10% to 20% of patients while also occasionally demonstrating that suspicious findings on other staging tests did not represent metastatic disease.[78–80] Combined PET and CT imaging allows viewing of both sets of images in register and is optimal for accurate identification of smaller-volume metastatic tumor.[81,82]

A bone scan is recommended for patients with an elevated alkaline phosphatase level or symptomatic painful areas, although this might not be necessary when a PET scan is performed. Bone metastases are infrequent as the initial site of metastases, but they do occur, more commonly in patients with adenocarcinoma. Evaluation for tracheal involvement with bronchoscopy is necessary for all lesions located at or above the carina.

Accurate determination of the extent of disease has a major impact on therapeutic decision making for single-modality versus multimodality treatment or curative versus palliative intent; therefore, it is essential that comprehensive staging be performed. A substantial literature now exists regarding transesophageal ultrasound (EUS), laparoscopy, and thoracoscopy. The largest and earliest experience was with EUS.[83–87] Recent surveys of the literature indicate an accuracy for T stage of approximately 85% and an accuracy of approximately 75% for N stage. The accuracy for N stage is increased to 85% if fine-needle aspiration biopsy is included.[88,89] EUS is not a reliable technique for diagnosing liver and peritoneal metastases because of the limited depth of penetration of ultrasound.[89]

The indications for minimally invasive staging techniques are not yet fully defined. Laparoscopic evaluation of abdominal lymph nodes can be achieved with minimal risks when high-yield staging information is not obtainable with standard imaging studies. The staging accuracy of laparoscopy for nodal involvement exceeds 95%.[72–75,90–92] Unsuspected findings such as liver metastases or peritoneal studding that alter treatment occur in 12% to 17% of patients studied.[72–74,90,93] Laparoscopy appears to be most useful for evaluating intra-abdominal spread of disease in patients with a bulky distal third or GE junction primary and/or celiac adenopathy. Small hepatic metastases and peritoneal carcinomatosis that are below the limit of resolution of CT and PET imaging may be detected. Laparoscopy is commonly performed at the time of jejunostomy tube placement for patients who are planning to receive preoperative chemoradiation. Thoracoscopy also has a high level of accuracy: 95% in detecting regional nodal involvement compared with surgical staging.[71,90,94]

Surgery Alone

Esophagectomy with reconstruction has a clear goal of both achieving local tumor control and restoring swallowing function. Esophageal surgical intraoperative risks, postoperative complications, and length of hospitalization have all decreased over the past decade to acceptable levels that are now compatible with those of other major oncologic resections.[95–100] Whether surgical resection is performed as the sole therapy or as part of a combined approach, the surgical principles and techniques are the same. A combination of concurrent chemotherapy and radiation without surgery is a potentially curative alternative for patients who refuse surgery, who are at high risk for surgery, who have unresectable tumors, or who have upper esophageal lesions for which resection might also require laryngectomy. A so-called palliative esophagectomy to restore swallowing function but with little or no change of long-term survival due to the extent of disease is rarely acceptable treatment and usually should not be contemplated. The standard operation in the United States to resect an esophageal cancer includes resecting the involved portion of esophagus, the proximal stomach, and the regional lymph nodes, as illustrated in Figure 78-1. The surgical resection is therefore properly termed a

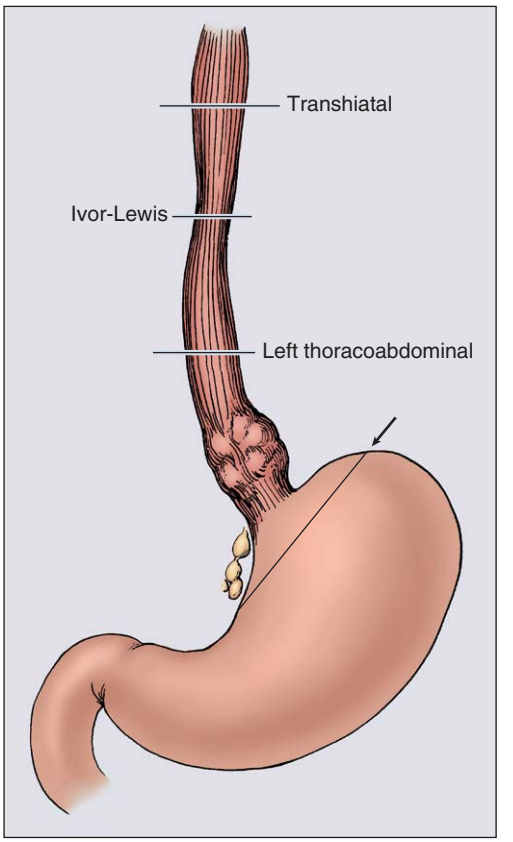

Figure 78-1 • Regardless of the surgical approach used, a partial esophagogastrectomy is performed to resect esophageal tumors. Depending on the approach, different lengths of esophagus are removed.

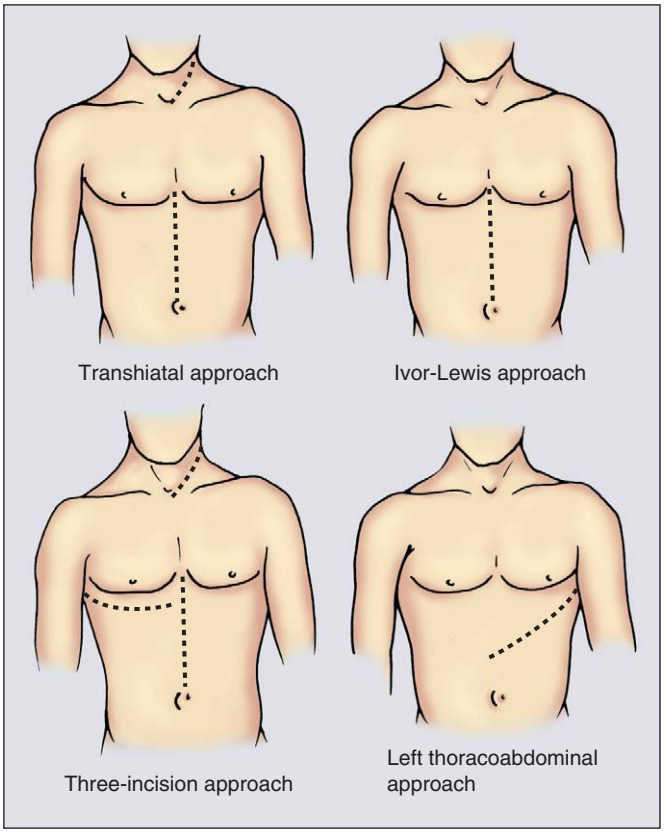

Figure 78-2 • The different incisions used to perform partial esophagogastrectomy are depicted.

partial esophagogastrectomy with regional (or one field) lymphadenectomy. The resected esophagus is replaced with a conduit, usually the stomach or segments of the small or large intestine, which are in turn mobilized as a vascularized pedicle and anastomosed to the remaining proximal esophagus.

A number of incisional approaches are used to perform a partial esophagogastrectomy, including the transhiatal, Ivor-Lewis, left thoracoabdominal, and three-incision techniques (Fig. 78-2). The specific incisional approach that is used generally determines how much esophagus is removed and where the esophageal anastomosis will be located (see Fig. 78-1). In the past, various surgeons have argued in support of their preferred techniques, giving the impression that all of these approaches were uniquely different procedures. It is now appreciated, however, that all of these incisional techniques use partial esophagogastrectomy (except segmental esophagectomy with free jejunal grafting, which is discussed separately), and the patient outcome results that have been reported are similar in terms of surgical morbidity and mortality. Long-term disease-specific survival after esophagectomy is related to pathologic tumor stage. Prospective studies do not demonstrate a survival advantage related to the surgical esophagectomy technique.[101,102] The data continue to demonstrate no difference in morbidity, mortality, or survival between transthoracic and transhiatal esophagectomy approaches.[103] The main variables in performing a partial esophagogastrectomy are which incision(s) to use, the length of esophagus to resect, what to use to replace the esophagus, and which route through the chest this conduit will take.

Transhiatal Approach

The transhiatal esophagectomy (THE) is a frequently used approach, "rediscovered" in 1976 by Dr. Mark Orringer, in which the intrathoracic esophagus is mobilized distally through the esophageal hiatus and proximally through a cervical incision. The increased prevalence of adenocarcinoma of the distal esophagus and GE junction has largely been responsible for the widespread popularity among surgeons of the transhiatal approach. Because of their distal esophageal location, these tumors are invariably near the esophagogastric junction and readily accessible for direct-vision dissection through the hiatus. Moreover, the regional lymph nodes for these distal tumors are in the parahiatal and proximal lesser curvature regions, both accessible via laparotomy. The resected esophagus is then reconstructed by using stomach or long-segment colon, which are passed up into the neck as vascularized grafts to be anastomosed to the proximal cervical esophagus.[99,104–106] Although reports exist on the use of jejunum for long-segment esophageal replacement, small bowel is generally not an option for esophageal replacement because of its mesenteric vascular anatomy unless specialized techniques with vascular augmentation are used.[107] The esophageal replacement conduit is passed through the chest into the neck by one of three routes: subcutaneous, substernal, or posterior mediastinum. The posterior mediastinum is the preferred route when possible. The advantages of the THE include avoiding post-thoracotomy discomfort, wide proximal esophageal margins to ensure complete resection of tumor and Barrett's mucosa, cervical anastomosis in which the consequences of anastomotic leak are minimized, and an esophageal reconstruction that results in an excellent quality of swallowing. It is well documented that the approach is acceptable for both benign and malignant esophageal disease.[108,109] The disadvantages include inability to visualize middle or proximal third tumors, inability to perform extensive intrathoracic regional lymphadenectomy, potential for injury to intrathoracic structures, and the need for long-segment esophageal replacement. The technique is safe, well tolerated, and associated with infrequent major complications in experienced hands.[110] In large series, late functional results have been good or excellent in 73% of surgeries, and mortality rates as low as none to 3% have been reported.[106,110,111] Recently, Orringer and colleagues reported a series of over 2000 patients who underwent a THE with a mortality rate of only 1% in the patients who underwent surgery since 1998, an anastomotic leak rate of 9%, and 2% pulmonary complications.[110]

Ivor-Lewis Approach

Partial esophagogastrectomy with an abdominal and right thoracotomy approach, also known as the Ivor-Lewis approach, was designed to optimize exposure of the intrathoracic esophagus, which passes through the upper two thirds of the chest along the right posterior mediastinum.[111] Once the involved intrathoracic esophagus is mobilized, a partial esophagogastrectomy is performed, and the esophagus is replaced by stomach, colon, or (less frequently) jejunum, which is passed into the chest along the esophageal bed and anastomosed to the proximal esophagus, usually at or above the level of the azygos arch. The advantages of the technique are the excellent exposure of the middle to upper intrathoracic esophagus, and the disadvantages are related to the use of a thoracotomy, with limits on the proximal resection margin and the potential for an intrathoracic esophageal anastomotic leak, which is a more difficult management problem than a cervical anastomotic leak. Reported complications include respiratory problems in 11% to 20%, anastomotic leak in 3% to 7%, and wound infection in 5%. Operative mortality ranges from none to 4%.[95,98,112,113]

Left Thoracoabdominal Approach

The left thoracoabdominal approach uses a single incision extending from the left chest onto the abdomen; it provides excellent exposure of the lower third of the esophagus and left upper quadrant of the abdomen.[114] This technique is ideal for patients with tumors near the GE junction, especially when the extent of gastric invasion is unclear, because it yields superb exposure and maximizes reconstructive options of the lower third of the esophagus. Respiratory

complications are the most common with this approach. At least some degree of atelectasis, usually involving the left lower lung, occurs in most patients. Pneumonia is reported to occur in up to 24% of cases. Anastomotic leaks occur in as many as 12% (mean: 3.7%) of cases. Other complications include atrial fibrillation in 10%, wound infection in 1.5% to 5.2%, and, infrequently, empyema and subphrenic abscess. The reported operative mortality is none to 6.2%.[115,116]

Multiple Incisions

Multiple-incision surgical approaches combine the incisional strategies of the standard techniques. Of these, the three-incision approach using a cervical incision (right or left), right thoracotomy, and midline laparotomy, as described by McKeown,[117] is the most common and is also referred to as the three-incision, three-hole, total esophagectomy or modified McKeown approach. It combines the exposure of the thoracotomy approach for esophageal mobilization or nodal dissection with the advantages of a cervical esophageal anastomosis. Patient outcome results with this technique are similar to those of other approaches, with reported mortality rates of 3% to 4% and esophageal anastomotic leak rates of 5% or less.[118–120]

Radical Resections

The majority of patients with esophageal cancer are first seen with locally advanced (stage II and III) disease. In these patients, survival results are poor with surgery alone. Two approaches attempt to improve survival in these patients. One involves the use of combination therapies, such as preoperative chemoradiation followed by surgery (to be discussed later); the second involves adding an en bloc, wide-field lymphadenectomy to the standard esophagectomy technique. The esophagus has an extensive regional lymphatic drainage. Arbitrarily, the lymphatic drainage has been divided into three zones or fields: cervical, intrathoracic, and abdominal. Standard esophagectomy techniques involve regional, or one-field, lymphadenectomy. Radical approaches advocate two- or three-field lymphadenectomy in conjunction with esophageal resection and replacement. Hagen and colleagues[121] believe that proximal hemigastrectomy should also be included as part of an en bloc approach, using colon to replace the resected esophagus. Radical esophagectomy is more complex surgery than standard techniques. This is reflected in morbidity rates as high as 58%.[122] Nonetheless, 30-day mortality rates as low as 1.6% to 4.3% have been reported.[121–124] Survival data using radical esophagectomy techniques are conflicting; therefore, it is unknown whether there is sufficient benefit to outweigh the increased operative morbidity. Hagen and associates[121] reported an improved survival in early-stage tumors using en bloc esophagectomy compared with a standard transhiatal technique. Although prospective, their trial was not randomized. Also, earlier-stage patients were selected for the en bloc approach and therefore biased the results and conclusions. A more recent update of their results continues to suggest excellent local tumor control and improved survival.[125]

In another nonrandomized series, Altorki and coworkers[124] reported improved survival in patients with stage III disease with radical esophagectomy compared with standard surgical techniques. Nishimaki and colleagues[122] reported an overall 5-year survival rate of 41% with extended radical esophagectomy for thoracic esophageal cancer. Their results are supported by more recent publications.[126,127] In contrast, Bumm and coworkers[123] demonstrated no difference in overall survival between standard transhiatal and radical THE in which two-field lymphadenectomy is added. Despite the wide surgical dissection with radical techniques, Bhansali and colleagues[128] still documented a 21% locoregional cancer recurrence rate. The determination of which cell type and tumor stage, if any, will benefit from radical surgical techniques has yet to be made.

Free Jejunal Interposition

Free jejunal interposition permits proximal segmental esophageal resection and replacement without the need to resect distal esophagus. For technical reasons related to the microvascular anastomosis that is necessary to support the jejunal interposition, this technique has been limited to replacement of the cervical esophagus for either esophageal, laryngeal, or hypopharyngeal cancers or benign strictures (e.g., lye, radiation). Contraindications include factors that would jeopardize the proposed blood supply to the free intestinal segment, such as advanced age, previous carotid surgery, and cervical radiation, or factors that would interfere with the ability to harvest a suitable jejunal segment, such as peritoneal adhesions or inflammatory bowel disease. In resection of the cervical esophageal segment, the branches of the external carotid artery and external jugular veins are preserved as potential host vessels. A segment of jejunum is selected at least 15 to 20 cm distal to the ligament of Treitz. The specific jejunal segment that is chosen should have a mesenteric arcade supplied by an adequate size artery and vein. Approximately 20 to 25 cm of jejunum can be resected, although 10 to 15 cm is usually sufficient. The free jejunal segment is then transferred to the neck, where in an isoperistaltic fashion, the proximal esophageal anastomosis is performed, the arterial and venous microvascular anastomosis is carried out to the selected host vessels, and then the distal anastomosis is completed.

With this technique, the reported graft survival rate is 85% to 95%, and the operative mortality rate is 5%. For patients with successful grafting, 90% are reported to have an adequate swallowing quality. If graft failure occurs, a second attempt will be successful in 50% to 75% of cases.[129–131]

Minimally Invasive Esophagectomy

With the advent of minimally invasive surgical techniques, an interest has been shown in applying thoracoscopic and laparoscopic techniques to esophagectomy.[132] Certainly, the techniques of gastric and esophageal mobilization have been well established for other complex minimally invasive surgeries. Minimally invasive esophagectomy required that these individual techniques be "spliced" together. Approaches that have been used have included laparoscopic transhiatal resection, combined laparoscopic-thoroscopic procedures, and laparoscopic creation of gastric tube with thoracotomy and other combinations. The need to convert to an open surgery has been uncommon. The number of lymph nodes that are removed also appears similar to that achieved with open surgery.[133]

A steep learning curve exists for these surgeries. The total length of hospitalization may be shortened somewhat. However, equipment costs and length of operative procedure can negate cost savings with this approach. Mortality rates of 40% to 70% in experienced hands are extensively reported.[133–135]

Survival with Surgery Alone

Survival after surgical resection is discussed separately from the description of individual techniques to emphasize the fact that postesophagectomy survival is a function of stage and not of surgical approach. Several points concerning postesophagectomy survival have now become quite clear. The first is that regardless of whether a thoracotomy or nonthoracotomy technique is used, cumulative postoperative survival is the same, approximately 20% to 25%. This has been underscored most graphically by Muller and associates,[136] who reviewed the world literature to compare overall postesophagectomy survival by technique and showed no significant difference. Hulscher and coworkers[137] performed a meta-analysis of the English language literature of transthoracic and transhiatal resection of esophageal cancer and found a higher risk of pulmonary morbidity and mortality with the transthoracic procedure but a similar 5-year survival rate of approximately 20%. These investigators also compared limited transhiatal resection with THE with extended en bloc lymphadenectomy in 220 patients with adenocarcinoma of the esophagus.[137] No significant difference was found in survival or operative mortality. More recent large retrospective series suggest a modest improvement in long-term outlook in recent years, probably the result of lower operative mortality.[138–140] Gockel and colleagues found

that for the periods 1985 to 1995 and 1995 to 2005, the 5-year survival rate increased from 15% to 25%, and the 30-day surgical mortality rate improved from 8.3% to 3.1%.[139] In addition, better patient selection could play an important role in improved outcome. For example, Steyerberg and colleagues have proposed a simple scale based on important comorbidities, age, neoadjuvant therapies, and esophagectomy volume at the treating hospital that divides patients into groups with predicted 30-day mortality of under 4% to approximately 20%.[141] It is also expected that more accurate preoperative staging with PET scanning and esophageal ultrasound could improve surgical outcome by removing some patients who have existing gross metastatic disease.

The second fact is that postoperative survival is stage related. Notably, the majority of patients who are considered for surgery are found to have stage III disease, and the survival rate for these patients, even with surgery, is poor (approximately 10% to 15%). Hofstetter and associates[142] reported results for 1097 consecutive patients undergoing resection and compared outcome by stage from 1970 through 1985, 1986 through 1996, and 1997 through 2001. Although median survival increased from 7 to 34 months, the surgical mortality rate decreased from 12% to 6%, and the R0 resection rate increased from 78% to 94%; no difference was found in survival according to stage. Three-year survival rates through this period were 63%, 52%, and 44% for pathologic stage IIA and 10%, 18%, and 6% for pathologic stage III. Multivariate analysis showed that survival was associated with complete resection and thorough preoperative staging and that preoperative chemotherapy used in the later years was associated with increased complete resection. For T1 N0 M0 adenocarcinoma of the esophagus,[143] survival rates at 5 and 10 years may be closer to 77% and 68% after surgical resection.

New methods of pathologic staging could improve our ability to predict surgical outcome. Immunohistochemical staining may detect lymph node micrometastasis. In one study,[144] 62% of patients (adenocarcinoma and squamous cell carcinoma) with pathologic node-negative stage by conventional criteria had nodal disease, detected by using monoclonal antibody Ber-EP4. This monoclonal antibody binds to certain glycoproteins found on epithelial tissues. The identification of micrometastatic nodal disease had a significant impact on survival. A somewhat lower incidence of micrometastatic disease was found by using anticytokeratin antibodies,[145–148] and there is some suggestion that patients who are upstaged from node-negative disease do have inferior long-term survival.[149,150] These novel techniques require validation in prospective trials and could provide valuable prognostic information as well as allowing optimal selection of patients for adjuvant therapy.

The third point is that postsurgical survival is little influenced by whether the patient's esophageal cancer has a squamous cell carcinoma or adenocarcinoma histology. Holscher and coworkers[151] documented a postresection survival advantage only for patients with stage I adenocarcinoma. Salazar and colleagues[152] reported no difference in cumulative postoperative survival for patients with squamous cell carcinoma and adenocarcinoma. Finally, despite advances in surgical techniques and results, postesophagectomy survival has remained remarkably stable over time. Wilkins[153] made this same point almost a decade ago after reviewing postoperative survival figures for the years 1952 and 1986. On the basis of his review, he queried whether surgery had gone as far as it could go and speculated that further improvement in survival statistics would require combination therapy regimens that included systemic chemotherapy. As new systemic agents are developed, a differential response may be seen in adenocarcinoma and squamous cell carcinoma, which suggests that new agents will need to be evaluated separately in each histologic type.

Optimizing Surgical Outcome

Evidence-based surgery uses the treatment outcomes of cost, morbidity, mortality, and quality of life to help physicians, health care administrators, and hospitals determine the most appropriate setting and specific management of patients. Data consistently show that increased provider experience improves patient outcome, lowers complication rates, and reduces cost for complex surgeries. In terms of technical difficulty, length of stay, morbidity, and mortality, esophageal surgery is classified as a complex GI operation. Gordon and associates[154] reported reduced hospital mortality, length of stay, and cost for a wide range of complex GI procedures, including esophagectomy. The institution of standardized patient care pathways, a product of the evidence-based surgery approach, reduced hospital cost for esophagectomies while keeping surgical mortality low (1.3%).[155] Indeed, the use of clinical protocols for postoperative care has the potential to substantially reduce operative mortality resulting from a variety of surgical approaches, perhaps to 1% or less.[140]

Dimick and colleagues[156,157] documented the importance of surgical volume, hospital experience, and intensive care staffing in optimizing outcome after esophagectomy. These studies underscore the fact that even complex surgical procedures, such as esophagectomy, can be both effective therapy and cost-effective.

In an important multi-institutional analysis[158] of outcome in Medicare patients, a substantial difference in operative mortality was found to exist on the basis of the number of esophagectomies per year at the institution. This varied from 23% for centers doing fewer than 2 of these procedures per year to 8.1% for high-volume centers performing more than 19 per year. The operative mortality rates that were reported in this series are higher than those reported in clinical trials, and this might relate not only to particular expertise of the study centers in esophageal cancer treatment but also to patient selection for clinical research. A subsequent analysis suggested that the variation among hospitals was explained, in part, by lower mortality of individual high volume surgeons with adjusted operative mortality among Medicare patients of 18% for surgeons performing fewer than two esophagectomies per year and 9% for those performing more than six.[159] Other studies have since confirmed this finding.[160,161]

Chemotherapy Followed by Surgery

Promising results for survival improvement that were reported from numerous phase II trials of preoperative chemotherapy regimens tested in newly diagnosed patients[162–173] prompted two large randomized trials with differing results.[66,174] These data are summarized following. Although preoperative chemotherapy can be justified on the basis of an advantage that was demonstrated in the MRC trial, it is considered an investigational approach in the United States. The U.S. Intergroup trial was well conducted and adequately powered. It failed to demonstrate either improved local control or improved survival with preoperative chemotherapy compared to surgery alone. By contrast, there are data indicating survival benefit and improved local control when RT is added to chemotherapy in a concurrent fashion prior to surgery. Hence, trimodality therapy is favored in the United States over the preoperative chemotherapy approach that is preferred in the United Kingdom.

The U.S. G-I Intergroup trial included 467 who were patients randomized to receive either three courses of cisplatin 100 mg/m^2 plus infusional 5-fluorouracil (5-FU) 1000 mg/m^2/day from days 1 to 5 before surgery and two courses after surgery (total: five courses) or immediate surgery.[174] No benefit was demonstrated for the addition of chemotherapy in this trial (see Table 78-3), in which 45% of patients had squamous cell carcinoma and 55% had adenocarcinoma. There were no differences in resectability or median 1-, 2-, or 3-year survival rates between treatment groups and between histologic types. The pathologic complete response (pCR) rate was 2.5%. The median survival and 2-year survival rate were 14.9 months and 35%, respectively, with chemotherapy versus 16.1 months and 37%, respectively, without chemotherapy. In both arms, approximately 60% of enrolled patients underwent a gross total resection (R0), and 17% of those patients had a subsequent local recurrence, for an ultimate 57%

failure to control local disease. There were no differences in surgical morbidity and mortality rates (6% for both arms). Most patients did not receive the planned two cycles of postoperative chemotherapy; 52% received one cycle, and 38% received both cycles. A recent update reported a 32% disease-free 5-year survival rate for patients who had complete resection and negative margins (R0), whereas only 5% of those with a lesser resection (R1 or R2) were alive at 5 years.[67]

The MRC[65] conducted a randomized trial involving 802 patients, testing two cycles of cisplatin 80 mg/m^2 and 5-FU 1000 mg/m^2/day continuous infusion for 4 days given prior to resection of squamous cell carcinoma or adenocarcinoma of the esophagus (see Table 78-3). Patients were required to have resectable tumor, although the staging evaluation was not prescribed by the study. Two thirds of patients had adenocarcinoma. Median survival was significantly improved from 13.3 to 16.8 months, with 2-year survival rates improved from 34% to 43%. No information about patterns of failure was reported, but, similar to the results of the U.S. Intergroup trial, 57% had a complete resection with negative margins (R0). There is no immediate explanation for the difference between the results of this trial and the U.S. Intergroup trial, but these conflicting results may relate to the greater power or the less rigorous staging in the British study, to chance, or to unknown differences between the populations in the two studies. Another trial conducted by the MRC, Adjuvant Gastric Cancer Infusional Chemotherapy, demonstrated a survival benefit for three cycles of preoperative epirubicin, cisplatin, and 5-FU (ECF) and three cycles of postoperative ECF compared with surgery alone. This trial enrolled patients with gastric, GE junction, and distal esophageal adenocarcinoma (26% of patients). Although not powered for subsite analysis, there did not appear to be heterogeneity in treatment effect for distal esophageal lesions or gastric lesions.

A meta-analysis[175] was performed of eight trials of preoperative chemotherapy or chemoradiation compared with immediate surgery to explore the value of chemotherapy. With all-cause mortality as an endpoint, there was not a significant benefit to preoperative chemotherapy alone. When analyzed by histologic type, there was no benefit for squamous cell carcinoma, but the hazard ratio for adenocarcinoma was 0.78 (0.64 to 0.95); however, this estimate was based on only the MRC trial described previously, as outcome by histology was not available from other trials. A greater benefit was seen with preoperative chemoradiation, with a 13% versus 7% absolute 2-year survival benefit for chemotherapy alone.

There has been only one trial directly comparing preoperative chemotherapy and preoperative chemoradiation, and the preliminary results were reported in abstract form. This trial, conducted by investigators in Germany, compared preoperative chemoradiation using cisplatin, folinic acid, and 5-FU to the same chemotherapy without radiation followed by surgery. The trial was closed early because of poor accrual after 126 of 394 planned patients were enrolled. The results favored preoperative chemoradiation but did not reach statistical significance; the pCR rate was 17% versus 2.5%, the complete resection (R0) rate was 85% versus 77%, the 3-year survival rate was 43% versus 27%, and median survival was 33 versus 21 months. These results, albeit limited by inadequate accrual and hence an underpowered study, provide additional support for the concept of preoperative chemoradiation over chemotherapy alone.[67]

Concomitant Chemotherapy and Radiation Therapy Followed by Surgery

The rationale for neoadjuvant chemoradiation or trimodality therapy is the high rate of both local and distant failure that is seen with surgery alone, such that intensified local and systemic therapies are needed to improve survival outcome. For example, data from the surgery-alone control arm of the U.S. Intergroup trial (1990 to 1995) showed a 57% failure to control local disease (including 41% failure to resect all local disease) and 50% distant failure rate in patients who did have complete resection.[174] A single-institution randomized trial that was conducted at the University of Michigan[176] demonstrated similar survival, local control, and distant first failure rates with surgery alone. Another single-institution study of adenocarcinoma of the distal esophagus and GE junction examined patterns of failure after surgery alone. Thirty-four percent of patients had distant failure, 19% had local failure, 14% had locoregional nodal failure, and 6% had peritoneal seeding.[177] These studies show that the rate of complete resection with negative margins and ultimate local control is not improved by the addition of chemotherapy alone prior to surgery. Similarly, the local recurrence rate is high (nearly 50%) after definitive chemoradiation.[178] However, the trimodality approach of chemoradiation followed by surgery results in a significant improvement in local control compared to surgery alone in trials of patients with squamous cell carcinoma and adenocarcinoma.[176,179]

A number of randomized controlled trials of chemoradiation compared to surgery alone have been conducted, with conflicting results. Those that either were limited to adenocarcinoma or included both histologies have been criticized for being underpowered or having a worse than expected outcome for the surgery control arm. However, the combined weight of multiple underpowered or otherwise limited trials supports a local control and survival benefit when compared with the outcome of surgery alone. A number of meta-analyses of randomized controlled trials are now in the literature to evaluate the effect of chemotherapy or chemoradiation prior to surgery.[175,180–183] The most comprehensive analysis was recently reported by Gebski and colleagues.[175] A total of 10 trials and 1209 patients from the period 1983–2006 were identified that compared preoperative chemoradiation with immediate surgery; individual patient data were available for two of the trials. The analysis found a benefit for concomitant chemoradiation followed by surgery compared with surgery alone; the hazard ratio for death by any cause was 0.81 (0.70 to 0.93), which corresponded to a 13% reduction in mortality at 2 years. The benefit was similar for both histologies, but no benefit was identified in trials that gave chemotherapy and radiation sequentially rather than concurrently. Another smaller meta-analysis found improved 3-year survival when the analysis was restricted to trials that used concurrent chemotherapy and radiation (OR: 0.45, 95 % CI: 0.26 to 0.79) but no benefit with sequential regimens.[181] Additionally, patients who received preoperative chemoradiotherapy were more likely to undergo complete resection (R0) (OR: 0.53, 95 % CI: 0.33 to 0.84). In this latter analysis, use of a reduced radiation dose was associated with higher mortality, which might be a design weakness of some of the randomized trials described in the following sections.

A series of randomized trials tested chemoradiation with 5-FU/cisplatin followed by surgery compared with surgery alone. Most of these trials were underpowered, and the results were conflicting. The results of these trials are summarized in Table 78-5. Two trials, those of Nygaard and colleagues[184] and Le Prise and colleagues,[185] utilized a sequential chemotherapy and RT design followed by surgery and failed to demonstrate any significant difference in median, disease-free, or overall survival. These trials will not be further discussed. Notably, the studies published by Walsh and colleagues,[186] Urba and colleagues,[176] and Tepper and colleagues[187] included patients with adenocarcinoma. Those of Bosset and colleagues,[179] Burmeister and colleagues,[188] Walsh and colleagues,[186] Urba and colleagues,[176] and Tepper and colleagues[187] compared concomitant cisplatin-based chemotherapy and RT followed by surgery to immediate surgery. Walsh and colleagues[186] and Tepper and colleagues[187] demonstrated a significant survival benefit, while Urba and colleagues reported a significant improvement in local control, but survival differences were not significant. Bosset and colleagues[179] showed an improvement in disease-free survival and fewer deaths from esophageal cancer but not improvement in overall survival. The trial of Burmeister and colleagues did not demonstrate a survival benefit, but the chemotherapy and RT were suboptimal. All trials (see Table 78-3) reported similar

Table 78-5 Preoperative Chemotherapy and Radiotherapy: Randomized Trials

Author	Treatment Arms	Median (mos.)	Survival Rate (%)		
			1-Year	2-Year	3-Year

5-FU, 5-fluorouracil; S, squamous cell carcinoma; VBL, vinblastine.

3- to 5-year survival rates of 32% to 39% for the investigational combined treatment (trimodality) groups, while the survival rate of patients in the surgery control arms varied from 6% to 16%. This probably reflects differences in the patients who were enrolled in each trial and the rigor of baseline staging. The details of these trials are described following.

The trial reported by Walsh and colleagues[186] was limited to adenocarcinoma of the distal esophagus-GE junction and demonstrated significantly improved survival with concurrent 5-FU 15 mg/kg on days 1 to 5 and days 30 to 35, cisplatin 75 mg/m^2 on days 7 and 37, and RT 40 Gy in 15 fractions on days 1 to 19. The three-year survival rate was 32% versus 6%, and median survival was 16 months versus 11 months ($P = 0.01$). The complete response rate for all patients who were enrolled in the preoperative chemoradiation arm was 22%, and there was evidence of nodal downstaging with 82% node-positive in the surgery arm versus 25% after neoadjuvant therapy ($P < 0.001$). This study has been criticized for the relatively small sample size (it closed when an early stopping rule was met), for unexpectedly poor results in the surgery-alone arm, and for lack of uniform preoperative staging.

The trial reported by Urba and colleagues[176] randomized 100 patients to surgery (transhiatal esophagectomy) with or without preoperative chemoradiation (cisplatin 20 mg/m^2 on days 1 to 5 and days 17 to 21, vinblastine 1 mg/m^2 on days 1 to 4 and days 17 to 20, 5-FU 300 mg/m^2 on days 1 to 21, RT 1.5 Gy twice a day to 45 Gy). Median survival was 17.6 months with neoadjuvant therapy and 16.9 months with surgery alone, and the 3-year survival rate was 30% versus 16%, respectively ($P = 0.18$). Survival of patients in the trimodality arm was consistent with the Walsh study. The gross total resection rate was in excess of 90% in both arms. The pCR rate was 28% and did not differ by histology, but the number of patients was small (75 adenocarcinoma, 25 squamous cell carcinoma). Preoperative therapy reduced the incidence of locoregional failure as the site of first failure from 42% in the surgery control arm to 19% ($P = 0.0002$). Distant failure was not affected; it was approximately 60% in both arms. While the improvement in the overall survival rate from 16% to 30% is in an expected range of 10% to 15%, the study was powered to show a much larger difference on the basis of the results of prior phase II trials from this group.

Bosset and colleagues[179] reported the results of a multicenter trial that was limited to squamous cell carcinoma, stages I and II. These investigators found no difference in overall survival with preoperative therapy, although there was a significant improvement in disease-free survival and local recurrence-free survival. The regimen was cisplatin 80 mg/m^2 given 0 to 2 days prior to each set of RT treatments, and the RT consisted of two 1-week courses of 18.5 Gy in five 3.7-Gy fractions beginning on days 1 and 22. Postoperative mortality was significantly higher, 12% versus 4% in the combined treatment arm. This trial has been criticized because chemotherapy was often not administered on the same day as RT, the chemotherapy was less intensive than that in the other trials, and an unusual hypofractionated and split-course regimen of RT was utilized.

The Trans-Tasman Radiation Oncology Group and the Australasian Gastro-Intestinal Trials Group randomized 256 patients to surgery alone or to one cycle of preoperative cisplatin 80 mg/m^2 on day 1 and 5-FU 800 mg/m^2 on days 1 to 4, with concurrent RT, 35 Gy given in 15 fractions.[188] Sixty-two percent of patients had adenocarcinoma. No survival benefit was identified, but treatment was less intensive with only one cycle of chemotherapy given and a lower radiation dose, although there was a suggestion of benefit for patients with squamous cell carcinoma.

An adequately powered U.S. Intergroup trial was initiated to definitively assess survival outcome with preoperative cisplatin and 5-FU chemotherapy and concurrent radiation in comparison with surgery alone. Unfortunately, this trial was closed early as a result of poor accrual likely because of the existence of a strong bias among physicians about the benefits of preoperative chemoradiation, lack of consensus about an optimal preoperative regimen, and patient resistance to randomization. The long-term outcome for the 56 enrolled patients has been reported in abstract form.[187] The 5-year survival rate was 39% (21%, 57%) versus 16% (5%, 33%; $P = 0.005$). There was no appreciable difference in surgical complications. In that this attempt at a definitive intergroup trial failed to accrue enough patients, it is unlikely that such a trial will be mounted again in the

United States, and treatment guidelines will be formulated on the basis of the aggregated existing data.

On the basis of these data and the results of published series with long-term follow-up (Table 78-6), the use of preoperative chemoradiation is a rational strategy that significantly improves local control and might improve survival. Cisplatin and 5-FU concurrent with standard fractionation RT, total dose 44 to 50 Gy, is most commonly used. Other platinum-based regimens containing paclitaxel, docetaxel, oxaliplatin, or irinotecan have been tested in phase II trials, and pCR rates, preliminary survival outcome, and toxicity do not appear to be improved over those of cisplatin and 5-FU. For example, the Eastern Cooperative Oncology Group conducted trial E1201 to evaluate the potential for improved outcome with two alternative regimens in a randomized phase II design.[189] The pCR rate was the primary endpoint. The regimens that were tested were cisplatin 30 mg/m^2 and irinotecan 50 mg/m^2 on days 1, 8, 22, and 29 of 45 Gy RT/5 weeks and cisplatin 30 mg/m^2 and paclitaxel 50 mg/m^2 1-hour infusion on days 1, 8, 15, 22, and 29 with RT. The trial was limited to patients with resectable adenocarcinoma of the distal esophagus, GE junction, and cardia (stages II, III and IVA); the staging evaluation included esophageal endoscopic ultrasound. Of all eligible randomized patients, 83% (38 of 46) and 70% (31 of 44) had a complete resection with negative margins, and 6 of 46 (15%) (95% CI: 5%, 26%) and 7 of 44 (16%) (95% CI: 7%, 30%) had pCR with preoperative cisplatin, irinotecan CI + RT and cisplatin, paclitaxel + RT, respectively. These pCR rates were lower than those observed with standard 5-FU and cisplatin in other multicenter trials, but survival and pattern of failure are not yet available.

The results of phase II and III preoperative chemoradiation trials demonstrate that pathologic stage based on the resected esophageal specimen and nodes is an important predictor of survival. Patients who are found to have no residual tumor in the resected esophagus and nodes or minimal residual tumor (stage I) have the best prognosis with overall survival rates of 60% to 70% at 5 years. This ability to downstage patients with locally advanced disease and improve survival is a powerful rationale for utilizing preoperative chemoradiation and a reason that it has become common practice. Surgical stage may also be useful in selecting patients for trials of novel adjuvant therapies, given that the rate of distant metastases is high and that they are the predominant cause of death from disease.

Safety of Esophagectomy after Chemoradiation

The question of whether preoperative chemoradiation increases surgical morbidity and mortality is an area of controversy but appears to be less relevant in the modern era. The majority of randomized trials discussed previously reported no significant increase in surgical mortality when trimodality therapy was compared to surgery alone. The results of 120 patients who were treated at Johns Hopkins with preoperative chemoradiation were analyzed for surgical morbidity and mortality to evaluate the overall complication rate.[190] The surgical mortality rate was 1%. The complication rate was 59% for squamous cell carcinoma and 31.6% for adenocarcinoma. The higher complication rate that was observed for squamous cell carcinoma, relative to patients with adenocarcinoma, was attributed to an increased risk of pulmonary complications due to the more proximal location of the primary and potential increased prevalence of chronic lung disease in this population. These results are comparable to the mortality rate (2.2% to 9.0%) and morbidity rate (22% to 74%) that were reported after surgery alone and suggest that with careful technique and attention to postoperative management, preoperative therapy does decrease surgical morbidity. The operative mortality rate when transhiatal esophagectomy was performed was 4% with surgery alone and 2% after preoperative therapy. Similar mortality rates have been reported from recent multicenter trials of patients with adenocarcinoma only or including both histologies.[187,189] A retrospective comparison of squamous cell carcinoma patients who had neoadjuvant chemoradiation or surgery alone demonstrated an operative mortality rate of 6.3% versus 9% and a morbidity rate of 40.3% and 41%, respectively.[191] In contrast, the trial reported by Bosset and colleagues including only patients with squamous cell histology had an operative mortality rate of 12% operative after chemoradiation and 4% after surgery alone.[179]

Assessment of Response to Preoperative Therapy May Predict Outcome

Radiographic and endoscopic assessment of response has not proven accurate enough after chemoradiation to serve as a selection criterion for proceeding to surgery, to guide changing unsuccessful neoadjuvant therapy, or to select patients for more aggressive postoperative therapy. Post-treatment inflammatory changes and thickening are difficult to distinguish from tumor and limit the utility of both CT scanning and endoscopy, even with ultrasound.[190,192,193] The lack of predictability is exemplified by one report[194] of seven patients with no residual tumor in the resected esophagus (pCR) whose staging with endoscopy and EUS immediately prior to resection indicated persistent advanced disease (T4 N1 (one patient), T3 N1 (three patients), T2 N1 (two patients), and T3 N0 (one patient). By contrast, retrospective and prospective[195–197] studies suggest that [^{18}F] FDG-PET imaging that is performed early in treatment may predict outcome and potentially create an opportunity to modify therapy. In a 39-patient prospective study at Memorial Sloan-Kettering Cancer Center,[198] a decrease in the standardized uptake value of more than 60% compared to baseline was associated with a better 2-year disease-free survival rate (67% versus 38%, P = NS). In a 40-patient trial of preoperative chemotherapy,[197] a 35% reduction in standardized uptake value on repeat PET after 2 weeks of neoadjuvant chemotherapy was associated with histologic complete tumor response rate (53% versus 5%, $P < 0.001$), median time to progression (16 months versus 9 months, $P = 0.01$), and overall survival (19 months versus 13 months, $P = 0.04$). An expanded study from these same investigators performing FDG-PET imaging 2 weeks after the start of preoperative chemotherapy found that a more than 35% reduction in metabolic activity was associated with a 70% 3-year survival rate and a 44% pCR rate, while with a lesser reduction in metabolic activity, the median survival was 24 months, and the complete histologic response rate was 5%.[199] Similarly, the preliminary results of a prospective CALGB trial support a possible value of PET imaging.[200] Patients were treated with irinotecan and cisplatin (CI) in weeks 1, 2, 4, 5, and then with concurrent CI in weeks 7, 8, 10, and 11 and RT. Repeat PET imaging was performed after week 5, prior to beginning RT. A decline in standardized uptake value of more than 22% was associated with a median time to progression of 18.5 months versus 5.5 months. It should be emphasized that these prospective studies assessed the prognostic value of repeat PET after chemotherapy alone, in which case the local inflammatory effects from chemoradiation may be substantial and confounding.[201] To date, no prospective study has yet assessed the value of altering therapy on the basis of PET response.

Pathologic stage at the time of surgery is an important predictor of survival outcome that can be used to advise patients and potentially to select high-risk patients for trials of novel adjuvant therapies. In a prospective trial performed at Johns Hopkins and Yale, patients with a pCR had a 67% survival rate at 5 years (median not reached), whereas the remainder of the patients had a 5-year survival rate of 27% (median: 21 months; $P < 0.001$).[202] Patients with pathological stage I tumor at the time of surgery had survival times that were similar to those of patients with a complete response to preoperative therapy. Median survival times for patients with pathologic stage IIA, IIB, III, and IV disease at the time of surgery were 22, 13.5, 18, and 4.9 months, respectively. A review of 276 patients who were assessed after preoperative chemoradiation suggested that the presence of only limited residual nodal disease, even without a complete response of

the primary tumor, could be used as an important prognostic factor. The 3-year survival rate was 70% for T0 to T1 with up to one positive node, 52% for T2 to T4 node negative, for T2 to T4 with one positive node, and 26% for more than two nodes regardless of T stage. Patients with metastatic disease had worse outcomes.[203] These issues may be considered in future modifications of the staging system.

Postoperative Therapy

Several randomized trials have failed to demonstrate a benefit of postoperative RT,[204,205] although postoperative chemotherapy and chemoradiation remain areas of active investigation, with some limited data to support their use under select circumstances. As was discussed in the preceding sections, adjuvant chemotherapy is poorly tolerated following combined modality therapy that includes chemotherapy. Only 54% completed the planned adjuvant chemotherapy after definitive cisplatin and 5-FU and radiation in RTOG 8501,[178] 58% received planned adjuvant taxol/cisplatin chemotherapy[202] after neoadjuvant cisplatin and 5-FU chemoradiation, and 38% received it after neoadjuvant cisplatin and 5-FU chemotherapy.[174] This lack of feasibility limits the usefulness of this strategy in spite of the concern for distant metastases. Several retrospective studies have suggested a benefit for postoperative chemoradiation after surgery alone. The only prospective data to support chemoradiation following surgery are from the randomized GI Intergroup trial for gastric adenocarcinoma or GE junction that compared postoperative 5-FU, leucovorin, and RT with observation.[206] There is a significant survival benefit when 5-FU, leucovorin, and RT are administered after resection of adenocarcinoma of the stomach or GE junction. In that trial, approximately 20% of the patients had tumor of the GE junction, and the remainder had gastric tumors. Therefore, determining the applicability of the finding to patients with tumor primarily involving the GE junction will require further study. Nevertheless, median survival for the entire population in the study was improved from 27 months to 36 months ($P = 0.005$). The 3-year survival rate was 50% versus 41%, and the 3-year relapse-free survival rate was improved from 36% to 47%.

On the basis of these limited data, it is reasonable to consider postoperative chemoradiation for patients after complete resection of stage II or III adenocarcinoma of the GE junction, but the issue is likely to remain controversial until more data that are applicable to this particular subset of patients are obtained. When there is incomplete resection, definitive chemoradiation or palliative single-modality chemotherapy or RT may be considered, depending on the clinical circumstances. Preoperative chemoradiation has been more rigorously studied and has the potential advantages of increasing long-term survival through downstaging and also that most patients are able to complete the neoadjuvant portion of therapy.

Definitive Chemoradiation

Chemoradiation (without surgery) has been demonstrated for squamous cell carcinoma to confer a statistically significant improvement in survival compared with radiation alone. It is the standard of care for locally advanced, unresectable disease and for patients with inoperable disease due to medical comorbidities. Its use as an alternative to operative management for patients with resectable squamous cell carcinoma is controversial, but the curative potential of this approach has been shown in trials that did not require unresectability as an eligibility criterion. Radiation alone should be used only in potentially curable patients who are not candidates for chemotherapy or surgery owing to medical risks. Acute and late toxicities, such as tracheal-esophageal fistula, are increased in comparison to radiation alone, but long-term survival is possible even for patients with extensive, T4 primary disease.[207] To date, there is insufficient information about this approach in the treatment of adenocarcinoma; therefore, it is recommended only for patients of this histology with medically inoperable or unresectable disease.

The landmark trial, RTOG 8501,[178,208] established the role of concurrent chemoradiation in the therapy of locally advanced squamous cell esophageal cancer (see Table 78-3). One hundred and twenty-three patients were randomized to 64 Gy RT alone or 50 Gy RT with 5-FU 1000 mg/m^2 on days 1 to 4 and cisplatin 75 mg/m^2 on day 1 every 4 weeks during RT and for two cycles every 3 weeks after RT. Eligibility criteria included localized (M0) esophageal cancer as documented with CT scan of chest and abdomen, bone scan, and pan-endoscopy. Eighty-eight percent of patients had squamous cell carcinoma. With the addition of chemotherapy, median survival was improved from 9.3 months to 14.1 months, and the 2-year survival rate was 10% versus 36%. Notably, although there were no 3-year survivors with RT alone, the 5-year survival rate with combined modality therapy was 27%. Longer follow-up demonstrated a 10-year survival rate of 20%, establishing combined chemoradiation as an alternative therapy for locally advanced, nonmetastatic squamous cell esophageal cancer. The rate of isolated locoregional persistent or recurrent disease as the site of first failure was reduced from 53% to 38%, whereas the rate of distant failure was 30% versus 16% when chemotherapy was added.[209] Although patients getting combined-modality therapy had the expected increase in acute mucosal and hematologic toxicities, there was no significant increase in late toxicities.

Randomization to chemoradiation or radiation alone on RTOG 8501 was terminated when a significant survival benefit for the chemoradiation group was demonstrated on interim analysis. A confirmatory nonrandomized group of 69 patients was treated with the experimental combined modality arm. The 5-year survival rate for this group was only 14%. The pattern of failure was similar to that of the randomized group. In the randomized and confirmatory portions of the study, there was no difference in outcome for the 15% of patients who had adenocarcinoma and the remainder with squamous cell carcinoma, although the number of patients with adenocarcinoma was too small for meaningful analysis.

The Eastern Cooperative Oncology Group[210] conducted a trial comparing RT (60 Gy) alone with the same total dose of RT and concurrent mitomycin C 10 mg/m^2 on day 2 and 5-FU 1000 mg/m^2/day for 4 days in patients with squamous cell carcinoma of the esophagus (see Table 78-3). The results of this 135-patient study were confounded by the circumstance that patients could undergo resection after 40 Gy of RT was given. Thirty-eight percent of patients were selected to have surgery. Nevertheless, median survival was improved from 9.2 to 14.8 months with the addition of chemotherapy. Two- and 5-year survival rates were 12% versus 27% and 7% versus 9%, respectively. Of note, there were no 3-year survivors who were treated with radiation alone who did not also have surgery.

Long-term follow-up is available from a phase II trial conducted by the National Cancer Institute of Milan.[211] A total of 106 patients with squamous cell carcinoma of the esophagus were treated with cisplatin 100 mg/m^2 on day 1 and 5-FU 1000 mg/m^2 on days 1 to 4 for two cycles with concurrent RT, with a total dose of 30 Gy in 15 fractions. Twenty-four of these patients also had surgery with complete resection. The overall survival rate was 22% at 5 years and 12% at 10 years, which did not differ whether or not surgery was added. These data confirm the curative potential of combined chemoradiation in squamous cell carcinoma.

A successor trial, Intergroup 0122, tested intensification of both chemotherapy and RT by increasing the dose of each drug and the total number of cycles of chemotherapy and escalating the total dose of radiation. Thirty-eight patients, all with squamous histology, were to receive a total of five cycles of infusional 5-FU and cisplatin, three cycles prior to starting radiation and two cycles concomitant with 6480 cGy of RT. This approach was subsequently abandoned, as many patients failed to complete the entire treatment course owing

to toxicity, including a 9% treatment-related death rate, and there was no suggestion of improved efficacy. However, an ongoing trial of the CALGB is now assessing this approach using irinotecan and cisplatin chemotherapy, with investigation of the predictive value of PET response assessed after neoadjuvant chemotherapy but prior to chemoradiation. A similar regimen was shown to be feasible to deliver in a multicenter phase II trial.[212]

A phase III randomized controlled trial, RTOG 94-05 (Intergroup 0123), was then pursued, addressing only intensification of the radiation dose: 64.8 Gy compared to 50.4 Gy, both combined with the identical chemotherapy of two cycles of cisplatin 75 mg/m^2 on day 1 and 5-FU 1000 mg/m^2/day for 4 days during radiation and two adjuvant cycles.[213] Of note, as in the prior two studies, RTOG 94-05 enrolled few patients with adenocarcinoma histology. Surprisingly, not only was there no improvement in median survival (13.0 versus 18.1 months) or in the 2-year survival rate (31% versus 40%) for the comparisons of the high-dose RT regimen versus the standard 50.4-Gy dose, respectively, but there was also no beneficial effect on locoregional control (44% versus 48%). The reason why higher-dose RT did not affect local control is unclear. Thus, the standard of care for definitive chemoradiation remains essentially the treatment program that was published in 1992 from RTOG 85-06: 50 to 50.4 Gy RT by once-daily fractionation (1.8 to 2.0 Gy) with four courses of cisplatin/5-FU.

While randomized trials have clearly demonstrated that chemoradiation is a curative approach for squamous cell carcinoma, this has not been established for adenocarcinoma. Prospective trials evaluating chemoradiation, including RTOG 8501, included few if any patients with adenocarcinoma, such that conclusions about survival benefit for this histology cannot be made, although the data are often extrapolated to justify this approach for unresectable or inoperable adenocarcinoma. For example, only 23 patients with adenocarcinoma were enrolled in RTOG 85-01, with a 5-year survival rate of 13% but a 95% CI of 0% to 27%.[209] The retrospective data related to chemoradiation alone for adenocarcinoma are similarly limited, suggesting poor outcome, and are subject to substantial selection bias.

The Radiation Therapy Oncology Group is planning a phase III U.S. Intergroup trial of nonoperative management that will include paclitaxel, cisplatin, and radiation with randomization to receive or not receive cetuximab. This trial will include stratification for squamous cell carcinoma and adenocarcinoma histology. In addition to determining the benefit of cetuximab in patients who are managed nonoperatively, this trial will provide important prospective information about the use of nonoperative therapy in patients with adenocarcinoma.

It is also important to note that there has not been a definitive randomized comparison of chemoradiation versus surgery alone in squamous cell carcinoma to ascertain the advantages of the two approaches in differing patient populations. Given the potential bias in the selection of patients for treatment with a nonoperative versus a surgical approach, the relative benefits of these two approaches under various clinical scenarios is unknown. However, as is discussed later, surgery might have a substantial local control benefit that can affect quality of life.

Two randomized trials of patients with resectable squamous cell carcinoma have addressed the benefit of surgery added to 5-FU and platinum-based chemoradiation regimens (Table 78-7).[214,215] To date, a survival benefit has not been demonstrated. These particular trials were associated with significant postoperative mortality, which might have diminished the possibility of detecting a therapeutic benefit. However, these trials clearly demonstrate that with the addition of surgical resection, there is substantial improvement in local control and decreased need for stent placement, which could have important quality of life benefits. These trials do not appear to have the statistical power to rule out a small long-term survival benefit, especially as immediate operative mortality is reduced over time. In addition, these trials have not included informative numbers of patients with adenocarcinoma.

A multi-institutional Fondation Française de Cancérologie Digestive trial enrolled 444 patients to receive 5-FU and cisplatin with concurrent continuous course RT 45 Gy in 4.5 weeks or split-course RT 15 Gy on days 1 to 5 and days 22 to 26. Only the 230 responding patients (88% squamous cell carcinoma) were randomized to surgery or three additional cycles of chemotherapy with additional RT, either 20 Gy with conventional fractionation or 15 Gy over 5 days. Each chemotherapy cycle was 5-FU 800 mg/m²/day continuous infusion and cisplatin 15 mg/m² 1-hour infusion on days 1 to 5. Response was assessed by esophagram and clinical improvement. Results for chemoradiation and trimodality therapy were a median survival of 17.7 versus 19.3 months, a 2-year survival rate of 34% versus 40% and a 2-year local control of 66% versus 57%. Interestingly, stents were required in 5% of surgery patients but in 32% of chemoradiation patients even though the population was preselected for positive response. The 3-month mortality rate was 9.3% with surgery versus 0.8% with combined modality therapy. Patients who were judged as nonresponders on the basis of the limited evaluation were excluded, and it is unclear whether such a population would be more likely to benefit from surgical resection of resistant tumor.

The second trial, reported by Stahl, looked at 172 patients with squamous cell carcinoma and had a median follow-up of 6 years. Patients were randomized to either three cycles of induction chemotherapy with bolus 5-FU, leucovorin, and etoposide followed by one additional cycle of chemotherapy with 40 Gy RT followed by surgery or to the same induction chemotherapy followed by chemoradiation with at least 65 Gy of RT. Overall survival was equivalent for surgical and nonsurgical treatment, while the 2-year local progression-free survival rate was significantly improved with surgery: 64% versus 41% ($P = 0.003$). The limitation of this trial was the small sample size. The survival curves began to separate after 3 years, which, along with improved local control, suggests that survival benefit from the addition of surgery might be demonstrable in a larger study. Given the limitations of both trials, chemoradiation followed by surgery remains the standard of care recommendation for patients with good performance status.

Salvage Therapy after Local Failure

The results of surgery for recurrence after definitive chemoradiation for esophageal cancer have been described for small selected groups of patients.[216–218] This intervention is associated with an increase in operative complications and mortality but also may result in long-term survival. Given the risks, only highly selected patients should be considered candidates for this approach.[219,220] Reserving surgery for patients who have clinical evidence of residual disease after chemoradiation requires prospective evaluation. A significant barrier to the success of this approach is the difficulty of assessing response to chemoradiation with noninvasive techniques, as described elsewhere in this chapter. Nevertheless, there is great interest in testing a therapeutic approach in which patients who have an apparent complete response would have close follow-up with surgical salvage if needed rather than immediate surgery.

Similarly, there is only limited information about the results of RT for isolated local failure after surgical resection.[218,221] Because combined chemoradiation is beneficial in gross disease when there is newly diagnosed esophageal cancer, we advocate this approach for the rare patient with isolated locoregional failure after full restaging evaluation. The RT dose may be limited to 45 Gy by the presence of a gastric pull-up in the treatment field.

Radiation Therapy for Management of Tracheoesophageal Fistula

The use of definitive or palliative RT in the setting of a tracheoesophageal fistula has been controversial. Although tracheoesophageal

Table 78-7 Randomized Trials Assessing Benefit of Planned Surgery After Chemoradiation

*Patient had either adenocarcinoma or squamous cell carcinoma.

fistula has historically been considered a contraindication to RT for fear that RT will worsen the fistula, there are data supporting its use and palliative benefit. In a report from the Mayo Clinic,[222] lysis of tumor by RT could not be shown to be an important cause of tracheoesophageal fistula. In 22 patients who developed fistula after prior RT, recurrent tumor was the cause in all cases. For 10 patients who were irradiated with known tracheoesophageal fistula, the fistula did not worsen in any patient, and 6 of 10 had local disease controlled until the time of death from metastatic esophageal cancer.[223] Combined chemotherapy and RT has also been demonstrated to close fistula in four of five responders in one series.[224,225] Additionally, stent placement with or without subsequent radiation can provide successful palliation.[226]

Cervical Esophageal Cancer

Cervical esophageal cancer is a particular treatment challenge. Surgery is extensive, requiring a total laryngopharyngoesophagectomy, an operation associated with significant dysfunction and morbidity. Frequently, postoperative RT is needed for positive margins or nodal disease, unless the primary tumor is found quite early. This has led to the use of chemoradiation as an alternative.

Extrapolating from the results of RTOG 85-01 using chemoradiation for curative treatment of thoracic esophageal carcinoma and the experience with larynx preservation for head and neck cancer, concurrent chemoradiation is used as an alternative. Definitive RT is fraught with technical difficulty in achieving adequate dose, given the complexity of treating a structure in close proximity to the spinal cord, the varying shape of the thorax and upper neck, and the bilateral lymph nodes at risk. The optimal dose is unknown, with many clinicians advocating the higher dose (70 Gy) used for treatment of head and neck squamous cell carcinomas in or bordering the cervical esophagus. Radiation techniques have included raising the arms next to the head and filling the gap between the arms and neck with tissue-equivalent material to create a simpler box shape and use of complex treatment planning with three-dimensional planning and/or intensity-modulated radiation. Burmeister and colleagues reviewed their experience treating 34 patients with cisplatin and 5-FU chemotherapy and RT 61.2.[227] The local control rate was 88%, and the 5-year estimated survival rate was 55%. Acute toxicity was acceptable, although two patients died from complications of strictures. Investigators at M.D. Anderson Cancer Center used intensity-modulated radiation with concurrent 5-FU/platinum chemotherapy to enable excellent radiation coverage of tumor plus 2 to 5 cm superiorly, 4 to 5 cm inferiorly, and 2 cm radially with coverage of nodal areas when involved. All six evaluable patients had a complete response with doses that were generally higher than those typically used in thoracic cancer: 59.4 to 66 Gy to the primary tumor.[228] Other small series have reported success with similar chemoradiation approaches.[229,230]

Nonsurgical Management of Early-Stage (Tis, IA) Esophageal Cancer

RT alone may be an alternative for some cases of early esophageal cancer. Hishikawa reported 68 patients treated with RT alone, dose 60 to 72 Gy with external beam radiation or 55 to 60 Gy plus a brachytherapy boost.[231] The 5-year cause-specific survival and locoregional control rates were 79% and 82%, respectively. Because the locoregional control rate was only 58% for tumors longer than 5 cm long, it was recommended that those patients be treated with combined chemoradiation. Modern staging with esophageal endoscopic ultrasound (not performed in this series) is essential to assess depth of invasion and stage accurately.

Endoscopic techniques may be useful for lesions that are limited to the mucosa. RT can successfully treat a bulky lesion, but the effectiveness of PDT is limited to a depth of 4 to 6 mm, and the penetration of laser or thermal energy is 6 mm or less. These techniques might be sufficient for the treatment of BE and selected patients with high-grade dysplasia but are not considered curative therapy for invasive disease. Submucosal invasion increases the risk of lymph node involvement, which cannot be addressed by these therapies. In one series, the rate of local recurrence was 29% in patients who were treated for mucosal confined adenocarcinoma at a median follow-up of 36 months.[232] In another, Tis/T1 lesions had a 44% complete response rate to PDT, and T2 lesions had a 28% complete response rate to PDT alone, with control maintained in approximately half of complete responders.[233] Although these techniques can be effective for very superficial lesions, esophagectomy is still considered the standard of care, with RT an accepted alternative for patients who are unable to undergo surgery. Endoscopic procedures for high-grade dysplasia, in situ carcinoma, or T1a (carcinoma limited to mucosa) are experimental.

Radiation Therapy Dose Selection and Outcomes

The RT dose required depends on the clinical circumstances. When RT alone is used as definitive treatment in patients who are not appropriate chemotherapy candidates, a dose of 60 to 64 Gy should generally be used. This dose is limited by esophageal tolerance, as well as the need to limit RT dose to the lung. The incidence of both early and late complications varies with total dose, administration of systemic chemotherapy, and volume of esophagus irradiated. Emami and colleagues[234] estimated the radiation dose (with conventional fractionation) that would lead to a 5% rate of clinical stricture or perforation within 5 years to be 60 Gy when one third of the esophagus is treated, 58 Gy if two thirds are treated, and 55 Gy for all of the esophagus.

Dose escalation, when RT is used as a single modality, has been safely carried out by the addition of brachytherapy, although there has been no clearly demonstrated benefit in survival or local control. Nevertheless, it is reasonable to add brachytherapy in patients treated with RT alone when the entirety of the residual disease can be encompassed in the treated volume. The American Brachytherapy Society Clinical Research Committee has published guidelines suggesting that a good candidate for brachytherapy has tumor that is no longer than 10 cm, confined to the thoracic esophagus, and without regional nodes. When brachytherapy is used, the external beam dose should be limited to 45 to 50 Gy in 1.8- to 2.0-Gy fractions, followed by a high-dose-rate boost with two to three treatments of 5 Gy or followed by one low-dose-rate brachytherapy application of 20 Gy over 24 to 48 hours. The dose is prescribed to 1 cm from the midpoint of the treatment catheter.

Given that local control is still not optimal with existing definitive chemoradiation regimens, there has been interest in intensifying the RT dose (above 50.4 Gy) used in this combined-modality approach. This question was addressed in the previously described Intergroup trial 0123 that randomized patients to a dose of 50.4 or 64.8 Gy with concurrent cisplatin and 5-FU.[213] The high-dose regimen did not improve any outcome when compared to the standard of 50.4 Gy in median survival (13.0 versus 18.1 months), 2-year survival (31% versus 40%), or control of local disease (44% versus 48%). There were 11 deaths during treatment in the high-dose arm but only 2 in the lower-dose arm. However, 7 of the deaths in the high-dose arm occurred before the dose of 50.4 Gy was reached; therefore, the dose escalation was not considered to play a role in this imbalance. Otherwise, there was no significant difference in toxicity. A separate analysis excluding the early deaths did not demonstrate any potential benefit for the higher dose. Use of intensified chemotherapy regimens or new agents that are under investigation might ultimately improve outcome but can also lead to substantially increased toxicity. For these reasons, 50.4 Gy is considered the standard dose when radiation is combined with chemotherapy.

The addition of surgery following chemoradiation can be viewed as another means of intensifying local treatment. When surgery is planned, the radiation dose should not exceed 44 to 50.4 Gy with conventional fractionation followed by a 4- to 6-week interval before

surgery. With trimodality therapy, the isolated local failure rate is low, 0% to 15%; therefore, escalating the dose of RT or further intensifying the local is not indicated or recommended. Doses greater than 50 Gy are associated with increased surgical mortality, while lower doses may be associated with increased local failure. We do not favor preoperative chemotherapy without RT, as the initial isolated local failure rate is higher.

When postoperative RT is given with or without chemotherapy, the dose should be limited to approximately 45 Gy to avoid injury to the gastric pull-up or interposed bowel.

Radiation Therapy Techniques

The treatment fields should extend a minimum of 5 cm above and below the radiographically identifiable lesion to account for microscopic or submucosal tumor extension. If definitive RT is used to doses above 50 Gy, a cone down to a margin of 2 cm above and 2 cm below the tumor should be considered. A radial margin of 1.5 to 2.5 cm to the block edge should be used, but this may be limited posteriorly as needed to keep the spinal cord dose within tolerance. In a series of patients with pathologic specimens that were analyzed after surgery alone, Gao and colleagues[235] reported that for squamous cell carcinoma, the median proximal spread and distal spread beyond gross tumor were 10.5 ± 13.5 mm and 10.6 ± 8.5 mm, respectively, with 94% of patients having all tumor contained within a 30-mm margin. For adenocarcinoma, the figures were 10.3 ± 7.2 mm proximally and 18.3 ± 16.3 mm distally, with a distal margin of 30 mm encompassing all tumor in 27 of 32 cases and a margin of 50 mm required to encompass all tumor in 94% of cases. Lymph nodes, which may be identified on CT scan, in EUS, or in PET scanning may extend beyond these margins.

Defining the extent of the tumor requires integration of data obtained from a variety of radiologic studies and procedures. Modern treatment techniques for planning esophageal RT involve the use of CT scans that depict the radial extension of the primary disease that cannot be visualized on barium studies. In addition, because barium can also underestimate the longitudinal extent of disease, all available data from endoscopy and ultrasound should be integrated into the planning process. The extent of nodal disease should be evaluated by CT scan and endoscopy with ultrasound. When appropriate, pathologic assessment of nodal disease can be obtained by ultrasound-guided needle biopsy and/or laparoscopy. PET imaging can also provide important information. Whether there is a benefit to elective treatment of clinically uninvolved supraclavicular nodes for proximal lesions is unknown. Oral contrast administration at the time of simulation and/or CT simulation enhances visualization of the tumor and adds to the precision of treatment planning. This enhances the ability to deliver an adequate dose to the target while limiting dose to the spinal cord. Consideration should be given to using immobilization devices to aid in ensuring uniform day-to-day patient positioning.

The standard approach of a three-field or four-field beam arrangement using an anterior and two posterior oblique off-cord fields with or without the addition of a fourth posterior field has become relatively standard in the treatment of esophageal cancer and allows high doses to be delivered to the tumor while limiting the radiation dose delivered to the spinal cord and lung. The dose that is delivered by the treatment fields should be weighted such that the maximal possible dose (that which delivers up to 45 Gy to the spinal cord) is delivered by the anterior and/or posterior fields, while only the remainder of the dose is delivered by the off-cord oblique fields to minimize the dose delivered to the lung tissue. However, in distal lesions, the need to limit treatment of the heart might require that more of the dose be given through the oblique fields.

This beam arrangement can also be used for treatment of upper esophageal tumors, as none of the beams enter laterally through the arms and shoulders. All fields can be treated from the first day of treatment, which has the advantage of delivering a lower fractional daily dose to uninvolved structures such as the lung, or treatment can begin with anteroposterior/posteroanterior fields only, which may allow a quicker start to treatment while a formal plan is developed, allow more margin for error in daily patient setup, and decrease daily treatment time. Under the latter circumstance, the multifield plan is generally implemented at a dose of no more than 30 to 36 Gy, as a significant daily dose to spinal cord will continue to be delivered even after the initial anteroposterior/posteroanterior treatment has been completed. When preoperative RT is given to the limited dose of 44 to 45 Gy, we generally use anteroposterior/posteroanterior fields to a total dose of 36 to 40 Gy, the remainder of the dose being given by opposed lateral off-cord fields. With this approach, the spinal cord dose is kept below tolerance levels to allow an additional 16 Gy of RT to be given by off-cord oblique fields postoperatively if there is a positive margin. In all cases, care must be taken through careful dosimetry to keep the spinal cord dose within safe limits and to take account of varying thickness of the chest longitudinally. Wedges and compensators should be used as needed to maintain homogeneity of the RT dose distribution. The spinal cord should be limited to 45 Gy, and the dose to lung tissue should be minimized. Care must also be taken to avoid an excess risk of cardiac toxicity when distal lesions are treated, which could necessitate giving a larger proportion of the radiation dose through oblique or lateral fields rather than through anteroposterior/posteroanterior portals, which generally treat more of the heart.

More recently, advanced radiation techniques such as three-dimensional planning or intensity-modulated RT are frequently used. The greater confidence in dosimetry may allow tighter margins with greater shielding of normal tissues while still ensuring more reliable coverage of the targeted volume. These techniques, while they may decrease normal tissue toxicity, are unlikely to improve outcome substantially, as marginal miss of the tumor has not been implicated as an important cause of treatment failure, dose escalation has not improved outcome, and the esophagus itself, rather than potentially shielded nearby normal structures, is generally the dose-limiting structure. It does, however, remain possible that local control was not improved with higher radiation doses in trial[213] because of an underdose of some tumor-bearing areas that can occur in using the standard radiation techniques.

We suggest that target volumes when advanced planning techniques are utilized include a clinical target volume that is 4 cm proximal and distal to the esophageal gross target volume, with caution utilized not to treat an excessive portion of the stomach. A radial margin of 1 to 1.5 cm is suggested as is a similar margin around all involved lymph nodes. For the planning target volume, an additional 0.5 to 1 cm appears prudent. Imaging to assess motion may prove to be helpful in guiding creation of a planning target volume. Although it is controversial, elective treatment of the celiac nodes may be considered for lesions in the distal third, and supraclavicular nodal treatment may be considered for lesions with significant extension above the carina. As always, patient condition and normal tissues might require limitation of margins.

There is also interest in evaluating the potential role of radiation technique for reducing the risk of postoperative pulmonary complications. Limiting the lung dose may be important, and intensity-modulated radiation therapy can be useful for achieving that goal. Interestingly, there is evidence that the volume of esophagus that is exposed to a low dose of radiation as well as the more limited volume that is exposed to a high dose, the lung effective dose, and absolute volume that is shielded from more than 5 Gy all correlate with outcome. This is possibly because these parameters are not independent and are all correlated with each other.[236] It will be important to explore this issue further, as depending on the optimization algorithm, intensity-modulated RT inverse planning systems may use a large number of beam angles to reduce the high-dose volumes, thereby exposing a higher volume of lung to radiation through these weak beams.[237] Better understanding of lung toxicity from studies of

esophageal cancer and lung cancer will allow optimal integration of this new technology. A rough guideline for lung dose in preoperative therapy based on current knowledge is to limit the total lung receiving 20 Gy or more to 20% to 30% and that receiving 10 Gy or more to 40% to 50%, although these guidelines may be exceeded as needed to achieve other important planning goals.

With improvement in survival time, there might also be a need to reevaluate treatment planning techniques to limit injury to other organs such as the heart. Some series with long-term follow-up have raised concerns about cardiac complication such as myocardial infarction or pericardial effusions. Cominos has suggested attention to techniques, such as the use of a four-field rather than a three-field technique. With a targeted dose of 54 Gy, 65% of the heart received more than 45 Gy with two fields, 57% using three fields, and 26% using four fields. Intensity-modulated RT may be useful in reducing the risk of late cardiac toxicity. Suggested dose limits include limiting the whole heart to 30 Gy and less than two thirds of the heart receiving approximately 45 Gy or more, but as long-term survivorship increases, these guidelines could require modification.

Toxicities of Radiation Therapy

Patients will experience a marked esophagitis during radiation treatment, which clears within several weeks of the conclusion of therapy. Topical anesthetics, narcotics, and H_2 blockers are used to minimize discomfort during eating. Oral nutritional supplements should be used to maintain nutritional state. Feeding tubes can be placed prior to therapy if necessary. Other grade III or greater early effects are uncommon but can include skin reactions, laryngeal toxicity (if in treatment field), and pneumonitis. In RTOG 8501, toxicity with both radiation alone and combined chemoradiation were prospectively collected.[178] Five percent of patients who were treated with 60 Gy RT alone developed grade III or greater esophagitis, whereas 20% of those who were treated with concurrent chemoradiotherapy (50 Gy) developed these symptoms. Late esophageal toxicity was observed in 10 of 53 patients versus 11 of 51 patients. Benign stricture is the most common serious late complication, reported to occur in 12% to 30%[238–240] of curatively treated patients, and can be treated with dilation, although experience shows that most long-term strictures are associated with recurrent tumor rather than with the radiation. Decreased esophageal motility, delayed emptying, and reflux may occur. With increased long-term survival, the issue of radiation-induced cardiac and lung injury may be more important to consider in radiation technique.

The toxicities with brachytherapy have not been well quantified. One series of 148 patients who were treated with external beam RT 60 Gy over 6 weeks followed a week later by 12-Gy high-dose-rate brachytherapy in two fractions reported a 28% rate of ulceration, a 10% rate of stricture, and a 6% rate of fistula. Except for fistula formation, which was generally fatal, the complications were rarely severe.[231] In RTOG 9207,[241] the concept of adding brachytherapy, 5 Gy three high-dose-rate treatments, to chemoradiotherapy (as in RTOG 8501) was tested, but the incidence of fistula was excessive (6 of 35 patients), and this approach is not recommended.

Swallowing Function and Palliative Radiation Therapy

Esophageal obstruction due to malignancy can lead to dysphagia that can be painful, associated weight loss, malnutrition, fatigue, and a loss in the enjoyment of eating. Since these signs and symptoms reduce the quality of life of esophageal cancer patients, the restoration of the ability to swallow is a key objective of both curative and palliative treatments. The management of malignant esophageal obstruction should not compromise or interfere with curative therapy. Placement of a percutaneous gastric or jejunostomy feeding tube and esophageal stents may be useful in temporizing symptoms, improving quality of life, and optimizing the patient's nutritional status while curative therapy is initiated. Other endoluminal treatments such as laser, PDT, or brachytherapy are generally not appropriate in situations in which curative treatment is the goal. For patients who are not candidates for curative therapy, the palliative treatment that is selected often depends on the likelihood of success given the length and location of the lesion, life expectancy, and the expertise of the treating team.

Radiation alone improves dysphagia in approximately 70% of patients, and chemoradiotherapy improves dysphagia in 88%.[242–244] Relief is not immediate but is reasonably rapid, with a median time to maximal improvement of 4 weeks (range: 2 to 21 weeks). High doses of RT are generally required for effective palliation and should be used whenever life expectancy is greater than 3 months and Karnofsky performance status is 60 or greater. The addition of chemotherapy should be considered for appropriate patients because of the potential for enhanced response and local control. Relief of dysphagia for the remaining lifetime occurs in approximately half to two thirds of patients who are treated with such aggressive palliative regimens.

A recent review of 106 patients with malignant esophageal obstruction who were treated palliatively with radiation and 5-FU chemotherapy demonstrated that 49% of patients had complete resolution of dysphagia and 78% had improvement of their dysphagia. Over half maintained their improved swallowing function until death or last follow-up with a median survival of 7 months.[245] In considering this option, it should be noted that the toxicity of therapy may transiently worsen swallowing prior to improvement. Therefore, this option, which provides more durable long-term control, is best utilized in patients who have an estimated survival time that justifies the treatment time, toxicity, and recovery period associated with this approach.

Palliative RT with or without chemotherapy can be used to prevent recurrence of swallowing difficulty after stent placement or laser therapy.

Brachytherapy, a procedure that uses endoscopically delivered radiation, is useful in selected cases for palliative treatment of esophageal cancer and can be used in patients who were previously treated with external beam RT.[246] A catheter with a width of 0.6 to 1 cm is inserted, and the lesion is treated with a 1- to 2-cm margin. The dose is generally prescribed at a distance of 1 cm from the radioactive sources, and dose falloff beyond this range is rapid. Therefore, only patients with symptoms resulting from tumor that is confined primarily to the esophageal wall and lumen itself can be effectively and durably palliated. High-dose-rate brachytherapy uses short applications of several minutes each, which are more convenient for the patient and do not require inpatient care. However, several applications are usually required, as fractionated treatment is thought to be safer. With low-dose-rate RT, in which treatment is given at 0.4 to 1.0 Gy/hr, treatment is given with one or two insertions of the applicator but over 24 to 48 hours. Although this approach does require overnight admission and prolonged esophageal intubation, fewer applications are needed, and the technology is more widely available.

The American Brachytherapy Society Consensus Guidelines panel has recommended several palliative regimens as being appropriate.[246] Palliation occurs in 50% to 90% of cases.[247–251] In previously untreated patients, a limited dose of external beam RT (i.e., 30 Gy) can be followed by high-dose-rate brachytherapy (10 to 14 Gy in one or two fractions) or low-dose-rate brachytherapy (20 to 25 Gy in a single application over 1 to 2 days). Dysphagia was palliated by external beam RT followed by brachytherapy in 90%[252] in one series, but the relative benefits of this approach compared with higher doses of external beam RT alone are unknown.

These brachytherapy regimens are generally considered safe, although the rate of complications, including acute esophagitis, ulceration, and stricture, are not well quantified in patients treated for palliation. Brachytherapy along with chemotherapy or immediately following concurrent conventional chemoradiation can result in an unacceptable rate of fistula formation. Brachytherapy can be safely

given several weeks after laser therapy and may increase the dysphagia-free interval,[253–255] while its role along with PDT is uncertain.

Chemotherapy alone may also be considered for palliation of dysphagia, but there are few data evaluating this endpoint. It has been found that 20% to 30% of patients generally respond to chemotherapy used for palliation, and an equivalent proportion would be expected to experience transient improvement in dysphagia symptoms. Depending on the clinical situation, a trial of chemotherapy could be reasonable before endoscopic therapies are considered.

Endoscopic Palliation

Endoscopic techniques to restore esophageal luminal patency are usually palliative procedures that are reserved for patients who are not candidates for curative therapy. However, endoscopic therapy can also be quite useful to provide symptom improvement prior to curative therapy in patients with total or near total malignant obstruction prior to initiation of curative therapy. This can result in increased patient tolerance of subsequent therapy.

The available endoscopic options for management of malignant dysphagia have shifted from using rigid funnel-shaped tubes to the use of expandable stents, laser fulguration, and PDT. Since there are no studies directly comparing the efficacy of the available endoscopic treatment modalities, the treatment modality that is chosen for each patient depends on the length, location, and angulation of the stricture; the patient's overall health status; the cost of the technique; the experience of the endoscopist; and the presence or absence of an esophagorespiratory fistula.

Owing to the relatively high incidence of complications, rigid funnel tubes have been replaced by self-expanding metallic stents (SEMS) and self-expanding plastic stents (SEPS), which are compressible, are easier to place, and have fewer complications. The first-generation SEMS were uncovered and were associated with rapid tumor ingrowth that resulted in stent obstruction. Up to 78% of patients who survived at least 4 months required repeat endoscopic intervention for palliation from tumor ingrowth. Newer SEMS are covered with polyethylene, polyurethane, or silicone sheaths to delay or prevent in growth of tumor, substantially reducing the need for repeat endoscopic procedures. SEMS require less tumor dilatation for insertion and expand to greater luminal diameter than rigid stents and have thinner walls to minimize erosion and hemorrhage. SEMS may be "stacked" on top of another to manage tumor growth over the top of a previously placed expandable stent. Successful insertion of SEMS is reported to occur in over 90% of patients. Initial complications are less frequent and less morbid than those reported with the use of rigid tubes.

A series of 127 stent placements in 100 patients reported no fatal complications; 1.6% of patients suffered severe pain necessitating removal, 3.1% of patients had inadequate deployment, 0.8% of patients suffered perforation, 7.9% of patients had a food impaction, 11% of patients reported severe reflux, and 8.7% of patients suffered stent migration requiring removal. Two of sixteen patients who underwent subsequent chemotherapy after stent placement suffered stent erosion through the esophageal wall. Studies suggest an increased rate of stent-related complications in patients who have undergone prior chemoradiation.[256] Patients will suffer from severe reflux when the esophageal stent traverses the GE junction, and this could result in life-threatening aspiration. There is a SEMS with an antireflux valve that might reduce risk of reflux; however, its success in clinical practice is limited, and widespread use of the antireflux stent is not practiced. Stents that are placed distally into the gastric lumen may be prone to migration and/or the distal end can cause gastric mucosal ulceration, resulting in hemorrhage. This can often be managed endoscopically. SEMS cannot be placed within 2 cm of the cricopharyngeal muscle, as patients cannot tolerate the SEMS owing to severe pain and the sensation of a foreign body in the upper esophagus. There is no difference in efficacy or complication rates among any of the currently available SEMS. SEPS are also available and are indicated for malignant dysphagia, but there have been no comparative studies between SEPS and SEMS. SEPS can be better tolerated if they are placed near the cricopharyngeal muscle and are removable. However, the migration rate might be increased in comparison to SEMS. Despite these complications, placement of esophageal stents for malignant dysphagia does improve swallowing in 88% to 100% of patients.

A clear indication for placement of a SEMS is the presence of a esophagorespiratory fistula. In comparison to other endoscopic options, placement of a SEMS is often a successful palliative measure. In small series, SEMS were found to be effective in sealing esophagorespiratory fistulas with low complication rates.[257] Consideration should be given to placing a respiratory stent as well. A retrospective comparison of self-expandable stent placement and palliative esophagectomy demonstrated palliation with stents that was as least as good as that of surgery over the limited follow-up period with less risk when compared to esophagectomy.

Other endoscopic options for palliation of malignant dysphagia include neodymium : yttrium- aluminum-garnet laser, electrofulguration with a monopolar or bipolar (BICAP) coagulation, and PDT. Short, circumferential, and nonangulated strictures are ideal for laser or electrocoagulation techniques. The mean number of endoscopic sessions that are required to achieve adequate luminal patency is three to four, and there does exist a risk of perforation. After initial success in achieving adequate palliation, repeat endoscopic treatments are usually required to maintain esophageal luminal patency. Successful improvements in swallowing symptoms have been reported in 64% to 100% of patients.

Endoscopic laser therapy is not recommended in the setting of an esophagorespiratory fistula, which is best managed with placement of a SEMS. Complications include fevers, perforation, aspiration pneumonia, and later stricture formation. The reported procedural mortality rate ranges from 0% to 5%. Siegel and colleagues[258] have reported improved survival in patients with squamous cell esophageal tumors who are treated with endoscopic laser therapy when compared with clinical stage-matched controls. The authors speculate that the survival advantage in the treated group might be due to tumor debulking, improved nutritional status, decrease in aspiration pneumonia, enhanced sense of well-being, and patient motivation. A randomized trial has demonstrated that palliative RT reduces the need for repeat procedures for recurrent obstruction and might be warranted in patients with good performance status and limited disease who are likely survive for a long period,[259] a concept that also might apply when other means of endoscopic palliation are utilized.

Electrofulguration techniques use either a monopolar probe or a BICAP. The monopolar probe directly coagulates the obstructing endoluminal tumor under endoscopic control. The BICAP tumor probe is passed through the narrowed esophageal lumen over a guide wire. The mechanism of action of the BICAP includes dilation of the narrowed lumen, tumor coagulation, hyperthermia, and tissue necrosis with delayed sloughing. Because the BICAP probe coagulates blindly and circumferentially, it is not recommended for noncircumferential lesions, since injury to the normal esophageal mucosa may result in perforation. Comparisons of electrocoagulation (monopolar or bipolar) with neodymium : yttrium-aluminum-garnet laser techniques have shown comparable results in terms of morbidity, mortality, and relief of dysphagia. Electrocoagulation is generally less costly than laser.

PDT is a technology that has generated a great deal of interest in the lay and scientific literature. This technique involves the administration of a chemical sensitizer, usually hematoporphyrin derivative or dihematoporphyrin ethers, that accumulates preferentially in the target tumor. The tumor is then exposed to a specific-wavelength low-power laser light that activates the accumulated sensitizing chemical, resulting in tumor necrosis mediated by production of singlet

oxygen radicals. Tumor cell death results from a photochemical and not a thermal effect as with laser techniques. The clinical feasibility of using PDT to manage early or unresectable esophageal cancer is well documented. PDT can be repeated to maintain tumor control. Since the light penetrates only several millimeters, this therapy is most useful for palliative benefit, as only superficial tumors would be treated in their entirety. One series with long-term follow-up demonstrated that 6 of 7 patients maintained controlled disease with an estimated 5-year survival rate of 62%. In another series with median follow-up of 19 months, superficial adenocarcinoma was ablated in 9 of 12 patients.[260]

For more advanced tumors that are thicker or where lymph nodes are involved, PDT is not a potentially curative therapy and is used for palliation. There are studies that document that PDT is at least as effective as laser therapy in palliation for patients with esophageal cancer and is associated with a lower incidence of perforation.[261,262] In a series of 215 patients undergoing palliative PDT, the mean dysphagia-free interval was 66 days. Complications included perforation (2% of treatment courses), stricture (2%), Candida esophagitis (2%), pleural effusions (4%), and sunburn (6%). The procedure-related mortality rate was 1.8%, and median survival was 4.8 months in this population.[263] Disadvantages of PDT relative to other methods of endoscopic palliation include a prolonged period of photosensitivity that may seriously affect quality of life, the risk of post-treatment esophageal strictures, and significant cost (for both the laser and the chemical agents). The potential role of PDT in the therapy of BE is discussed in the section related to therapy of that condition. Newer agents for PDT may be developed that absorb wavelengths of light that will penetrate more deeply into tissue.

Chemotherapy for Advanced Disease

In general, patients with metastatic or recurrent carcinoma of the esophagus have a large tumor burden, their response to chemotherapy is brief (several months), and systemic therapies have limited impact on survival. Clinical trials of new agents are appropriate for this patient population. Palliation of symptoms and improvement in quality of life should be the major goals, but these endpoints are rarely measured. Many of the published trials of the regimens that are most commonly used consist of small numbers of patients and both histologic types; response rates are quite variable, often influenced by the extent of prior treatment and patient performance status, and the 95% confidence intervals for response are often wide. It is not known whether giving chemotherapy prolongs survival over best supportive care and whether treatment with single-agent chemotherapy confers any benefit over combination chemotherapy. In general, combination chemotherapy regimens have greater efficacy than do single agents on the basis of response rates that vary from approximately 30% to 50%. The evaluation of biologics in esophageal cancer, as single agents or added to standard chemotherapy, is just beginning and consists of very limited preliminary data that have mainly been reported in abstract form. There is a rationale for and interest in targeting the epidermal growth factor receptor and vascular endothelial growth factor receptors, in particular as discussed in recent reviews.[264,265] Trials are in progress, and as yet, no biologics have been approved for treatment of esophageal squamous cell carcinoma or adenocarcinoma.

Single agents with reported activity include bleomycin, 5-FU, mitomycin-C, doxorubicin, methotrexate, cisplatin, venorelbine, paclitaxel, and docetaxel. The major response rate to these single agents is in the range of 15% to 30%. Only a few drugs have been adequately tested in patients with esophageal adenocarcinoma. A 31% response rate was observed in a phase II trial of paclitaxel tested in a total of 51 chemonaive patients with esophageal squamous cell carcinoma or adenocarcinoma that was recurrent or metastatic. The dose of paclitaxel was 250 mg/m^2 infused over 24 hours, repeated every 3 weeks.[266] Thirty-three patients had adenocarcinoma, and 11 patients responded. For all patients, the median duration of response was 17 weeks, and the median survival time was 10.2 months. Two other schedules of paclitaxel have been tested. A weekly 1-hour infusion of 80 mg/m^2 was inactive (5% response rate) in patients with prior chemotherapy; in those without prior chemotherapy, a 16% (8 of 50) response rate was reported for adenocarcinoma and a 13% (2 of 15) response rate for squamous cell carcinoma.[267] In contrast, no responses were observed in a small trial of 14 patients who were treated with a 96-hour infusion schedule of paclitaxel 140 mg/m^2 every 21 days.[268] It is noteworthy that the commonly used dose of 175 to 225 mg/m^2 by 3-hour infusion every 21 days has not been evaluated. Also noteworthy is the lack of efficacy of carboplatin that was observed in three well-conducted phase II trials from the 1980s and 1990s in patients with chemonaive recurrent or metastatic adenocarcinoma. Docetaxel has been studied less in esophageal carcinoma. Two phase II trials have been reported; one tested 75 mg/m^2 every 21 days in a total of 22 patients with recurrent esophageal adenocarcinoma and reported an 18% (95% CI: 2.3 to 52) response rate in chemonaive patients and no responders in those who had previously been treated for recurrence.[269] The second trial evaluated docetaxel 100 mg/m^2 every 3 weeks in patients with adenocarcinoma of the upper GI tract origin and reported a 17% (95% CI: 8 to 30) response rate in 41 patients.[270] Cytotoxics that have not been tested as single agents in esophageal cancer, although frequently used in combination regimens because of their activity in other adenocarcinomas of the GI tract, include irinotecan, oxaliplatin, and gemcitabine.

The combination regimens that are most frequently used in the current management of patients with recurrent or metastatic esophageal cancer are shown in Table 78-8. Response rates vary from series to series, with many trials enrolling small numbers of patients and a mix of patients with esophageal squamous cell carcinoma and adenocarcinoma. Response rates are generally in the range of 30% to 50%, with response duration of 3 to 6 months and median survival time of 6 to 8 months. Studies reporting longer median survival rates may reflect variation in patient characteristics, such as better performance status, fewer comorbidities, and limited prior treatment, rather than reflecting more effective therapy. Cisplatin plus 5-FU has been used in patients with both adenocarcinoma and squamous histologic types with similar response rates, in the 30% range.[271] Irinotecan, paclitaxel, docetaxel, and gemcitabine have been studied in various two-drug combinations, most often paired with cisplatin. Whether these regimens improve on the outcome of standard 5-FU/cisplatin has not been assessed, nor is it clear whether any of these regimens improve survival compared to best supportive care.

The combination of cisplatin 30 mg/m^2 and irinotecan 65 mg/m^2 has been evaluated by using a weekly schedule for 4 weeks recycled every 6 weeks or a two-out-of-three-week schedule (days 1 and 8 every 21 days). The results of three trials that included patients with both histologic types demonstrated a major response rate ranging from 36% to 58%.[272–274] Because of toxicity concerns (neutropenia and diarrhea) with the 4-weekly dose regimen, the days 1 and 8 schedule is preferred and appears to be equally effective. A multicenter trial of irinotecan + cisplatin (days 1 and 8 schedule) plus bevacizumab is noteworthy for impressive response rates albeit in a small number of patients with GE junction adenocarcinoma.[275] A 65% (95% CI: 46 to 80%) major response rate was reported in 47 previously untreated patients with either metastatic or unresectable gastric (24 patients) or GE junction (23 patients) adenocarcinoma. The median time to progression was 8.3 months, and median survival was 12.3 months. These encouraging results require confirmation in a larger study limited to adenocarcinoma of the distal esophagus/GE junction.

Paclitaxel has been combined with cisplatin with reported response rates of 41% to 44%. A response rate of 41% was reported in a trial of 32 patients using a biweekly regimen of paclitaxel 90 mg/m^2 infused over 3 hours and cisplatin 50 mg/m^2 repeated every 14

Table 78-8 Activity of Combination Chemotherapy in Recurrent and Metastatic Disease

Chemotherapy	Histology	No. of Trials	Response Rate (%)	Reference
Cisplatin + 5-FU	S	1	34	271
Cisplatin + irinotecan	S + A	3	36–58	272, 273, 274
Paclitaxel + cisplatin	S + A	2	41–44	276, 277
Docetaxel + irinotecan	S + A	2	30–33	278, 279
Docetaxel + venorelbine	S	1	60	280
Gemcitabine + cisplatin	S + A	2	41	281, 282
Gemcitabine + 5-FU + leucovorin	S + A	1	31	285
Oxaliplatin + 5-FU + leucovorin	S + A	1	41	284
Paclitaxel + cisplatin + 5-FU	S + A	1	48	286

days.[276] In an earlier phase II trial, paclitaxel 200 to 250 mg/m^2 as a 24-hour infusion on day 1 followed by cisplatin 75 mg/m^2 on day 2 produced a response rate of 44% (46% for adenocarcinoma and 25% for squamous cell carcinoma) with a median response duration of 3.9 months.[277] However, toxicity was unacceptable with the 24-hour infusion schedule of paclitaxel (grade IV neutropenia occurred in 47% of patients, 50% required hospitalization, and 11% died of therapy-related complications). The most commonly used dosing schedule of this regimen is paclitaxel 175 mg/m^2 infused over 3 hours followed by cisplatin 75 mg/m^2, repeated every 21 days, which, as used in other solid tumor malignancies, is well tolerated. This particular regimen has not been formally tested in recurrent/metastatic esophageal cancer. Docetaxel has also been combined with irinotecan and tested in patients with metastatic disease including both histologies.[278] A 30% response rate was observed in 15 patients treated with irinotecan 160 mg/m^2 followed by docetaxel 60 mg/m^2 every 21 days. However, a 71% incidence of grade IV neutropenia and a 43% incidence of febrile neutropenia was unacceptable, and the regimen was abandoned. By contrast, an alternative low-dose weekly scheduling of these two agents (docetaxel 35 mg/m^2 and irinotecan 50 mg/m^2, days 1 and 8 every 21 days) has been evaluated in esophageal cancer[279] and other GI malignancies with acceptable toxicity. A 33% response rate was reported in previously untreated patients with metastatic adenocarcinoma and squamous cell carcinoma histologies. The combination of docetaxel and venorelbine has activity in recurrent squamous cell esophageal carcinoma according to a small phase II trial in 20 patients that reported a 60% response rate and median overall survival of 10.5 months, although this combination is also associated with substantial myelotoxicity.[280]

Gemcitabine-based doublets have also been studied. The Southwest Oncology Group tested gemcitabine 1000 mg/m^2 on days 1, 8, and 15 and cisplatin 100 mg/m^2 on day 15 repeated every 28 days in patients with recurrent or metastatic esophageal carcinoma.[281] Survival was the primary endpoint of this trial, which enrolled 64 patients and found a median survival of 7.3 months and a 1-year survival rate of 20%. Another group evaluated cisplatin 50 mg/m^2 on days 1 and 8 followed by gemcitabine 800 mg/m^2 on days 2, 9, and 16 in chemonaive patients with unresectable or metastatic squamous cell carcinoma (12 patients) or adenocarcinoma (24 patients) and reported a 41% (14/34) response rate and a median survival of 9.8 months.[282] Cumulative myelosuppression was the major toxicity. The Southwest Oncology Group also evaluated the combination of gemcitabine 1000 mg/m^2 and irinotecan 100 mg/m^2, both drugs given on days 1 and 8 based on preclinical data suggesting dose-dependent synergy.[283] The primary endpoint of this trial, which enrolled 57 patients with recurrent/metastatic squamous cell carcinoma or adenocarcinoma, was 6-month survival. Although the predetermined statistical endpoint was reached with a 56% 6-month survival rate, toxicity was substantial, and the median survival of only 6.3 months was not better than that expected with other doublets.

Two small (35-patient) single-institution phase II studies that included both histologies evaluated the combination of oxaliplatin, 5-FU, and leucovorin[284] and the combination of gemcitabine, 5-FU, and leucovorin.[285] Response rates of 41% and 31.4%, respectively, and median survivals of 7.1 months and 9.8 months, respectively, were reported. Finally, two trials added a taxane to the cisplatin/5-FU base regimen. One tested paclitaxel, cisplatin, and 5-FU in 60 chemonaive patients with unresectable or metastatic esophageal cancer, including both histologic types. A 48% response rate (46% adenocarcinoma, 50% squamous cell carcinoma) and median survival of 10.8 months were reported.[286] The other trial was a phase III multicenter comparison of docetaxel, cisplatin, and 5-FU (DCF) versus cisplatin and 5-FU (CF) as first-line therapy for recurrent or metastatic gastric cancer.[287] A total of 445 patients were enrolled, 22% of whom had a primary tumor in the GE junction. While benefit cannot be determined for GE junction cancers separate from distal gastric adenocarcinoma, nor can it be assumed owing to the differing natural history and pattern of failure for these cancers, the results are noteworthy given the dearth of comparative trial data for esophageal carcinoma of either histologic type. Response, overall survival, and time to progression endpoints were all significantly improved with the three-drug regimen; the median time to progression was 5.6 months for DCF versus 3.7 months for CF (HR: 1.47, 95% CI: 1.19 to 1.82, $P < 0.001$), and the median overall survival was 9.2 months for DCF versus 8.6 months for CF (HR: 1.29, 95% CI: 1.0 to 1.6, $P = 0.02$). These results, however, must be balanced against the significantly increased incidence of severe and life-threatening toxicity (neutropenia, febrile neutropenia, infection, and diarrhea) with DCF compared to CF in this population of untreated patients with good performance status.[288]

In summary, there are now a number of chemotherapy options for treating metastatic or recurrent esophageal squamous cell carcinoma and adenocarcinoma in addition to cisplatin and 5-FU. Whether any one regimen is superior to another in terms of response, survival, or palliation of symptoms is unknown, owing to a lack of comparative trial data. All regimens are associated with substantial toxicity. A recent Cochrane database review attempted to sort out these issues.[289] Randomized controlled trials comparing chemotherapy to best supportive care or comparing two chemotherapy regimens in patients with metastatic squamous cell carcinoma of the esophagus or adenocarcinoma of the esophagus and GE junction were included. Two randomized trials with best supportive care as the control arm were found, but the total number of patients was only 42; five trials compared different regimens (with a total of 1242 patients), but the patient populations and chemotherapy regimens were so varied that a formal pooled analysis could not be performed. The authors rightly

concluded that there is a need for well-designed, adequately powered controlled trials and assessments of quality of life for esophageal cancer patients.

BARRETT'S ESOPHAGUS WITH HIGH-GRADE DYSPLASIA

BE is a premalignant condition for esophageal and GE junction carcinomas and is characterized by intestinal metaplastic changes in the esophageal epithelium as confirmed by biopsy. Because of its premalignant nature, it is recommended that patients with BE undergo regular endoscopic surveillance, primarily to assess for dysplasia. The consensus statement from the American College of Gastroenterology recommends annual surveillance endoscopy for patients with low-grade dysplasia and more aggressive intervention in patients with high-grade dysplasia, since this can be associated with adenocarcinoma. Patients with high-grade dysplasia should undergo a second endoscopic biopsy surveillance procedure to increase the chance of detecting a concomitant early cancer. If no cancer is detected, then patients have several options, including remaining in an endoscopic biopsy surveillance program every 2 to 3 months, esophagectomy, or endoscopic ablative therapy with continued surveillance.[25,290]

The care of patients with high-grade dysplasia is controversial, and treatment should be individualized, taking into account the patient's desires, medical fitness to undergo esophagectomy, and willingness to return for frequent endoscopies. Any patient who will not return at the recommended endoscopic intervals and who has a diagnosis of high-grade dysplasia, confirmed by an expert GI pathologist and a repeat endoscopic biopsy surveillance procedure, should undergo esophagectomy performed by an experienced esophageal surgeon. Esophagectomy is the only treatment option that allows a patient to safely stop periodic endoscopic biopsy surveillance.[24] Even the patient who chooses endoscopic ablative therapy must be willing to undergo endoscopic biopsy surveillance indefinitely. A recent randomized controlled trial of photodynamic therapy of patients who had high-grade dysplasia reported that although numbers of cancers were cut in half compared to numbers in patients who did not have ablation, it did not completely eliminate the risk of malignancy.[291]

Dysplasia in Barrett's mucosa refers to cytologic and histologic epithelial changes that are considered neoplastic. It does not refer to reactive or inflammatory epithelial changes, which are most commonly seen with esophagitis. Historically, it was thought that a minimum of 3 cm of columnar lined epithelium was required for the diagnosis of BE. These shorter lengths of columnar lined epithelium were considered to be normal variants and exempt from the complications of BE. Currently, it is accepted that no length of columnar lined epithelium is normal and that these short segments of BE are susceptible to all of the potential complications of BE, including the development of dysplasia and adenocarcinoma.

On the basis of mucosal architecture, epithelial morphology, and cytologic findings, dysplasia is classified as low, intermediate, and high grade. It is generally accepted that dysplasia in BE precedes the development of invasive adenocarcinoma. Tytgat and Hameeteman[292] illustrated that dysplasia is a prerequisite of adenocarcinoma, that low-grade dysplasia is potentially reversible and that once the threshold of high-grade dysplasia is reached, the patient is at risk for progression to adenocarcinoma. It is unclear which factors influence the time of progression from high-grade dysplasia to adenocarcinoma. As was discussed in the earlier section on pathogenesis of adenocarcinoma, evidence exists that an accumulation of mutations or epigenetically mediated changes in expression of key genes may play an important role.

The diagnosis of Barrett's mucosa with dysplasia is made histologically via endoscopic biopsies. Because of the significance of high-grade dysplasia in terms of patient management, it is important that the diagnosis be confirmed by a pathologist who is experienced in this area, and second opinions obtained as needed.[293–295]

As was noted earlier, three options are available to manage patients with high-grade dysplasia. Heitmiller and colleagues[296] advocated prophylactic esophagectomy for patients with high-grade dysplasia, citing data showing that high-grade dysplasia is a premalignant condition in which no regression has been documented and that occult invasive adenocarcinoma is found in 45% to 50% of patients who undergo esophagectomy with the diagnosis of high-grade dysplasia alone. In their series, operative mortality was 3.3%, occult invasive adenocarcinoma was found in 43% of patients, and the tumor was locally advanced in five of these patients. The authors emphasized that this aggressive surgical therapy is recommended only for patients who are suitable surgical candidates. This is the current standard of care, although it is controversial.

The data to settle the controversy about optimal approach to high-grade dysplasia are not yet available. The existing data suggest a high enough risk that esophagectomy should be strongly considered. Levine and associates[297] reported an endoscopic biopsy protocol that they believe can accurately differentiate high-grade dysplasia from adenocarcinoma. Four-quadrant jumbo forceps biopsies were performed at 2-cm intervals, with additional specimens from any areas of known dysplasia. On the basis of their series of seven patients in whom follow-up surgery confirmed the absence of invasive cancer, the authors advocate endoscopic follow-up for patients with high-grade dysplasia alone. In their series of 22 patients who were followed up in such a fashion for an average of 32 months (range: 4 to 67 months), in none has a known invasive adenocarcinoma developed. However, another group[298] used similar biopsy procedures before esophagectomy, and 10 of 38 were found to have unsuspected invasive adenocarcinoma in the surgical specimen. When high-grade dysplasia is followed up rather than treated, varying risk has been found in several recent large series. This incidence of adenocarcinoma has been reported to be 59% (5-year cumulative),[299] 32% (8-year follow-up),[300] and 16% over a period of 7.3 years.[301] The reason for the varying risks identified is unclear, although in the series with the smallest incidence, no confirmation of diagnosis of high-grade dysplasia was made by a central pathologist. Therefore, although intensive endoscopic surveillance might be a reasonable approach, a substantial portion of patients may have existing adenocarcinoma that was not detected on biopsy, or adenocarcinoma will develop over several years of follow-up. Novel endoscopic imaging techniques and equipment are being developed to improve detection of dysplastic BE.[302–304]

A third option is endoscopic ablative therapy for high-grade dysplasia, although long-term data are only beginning to be assessed. Recent data show resolution of high-grade dysplasia in 78% of patients who were treated with PDT, over a 5-year follow-up.[305] This is an extension of prior data, which showed that patients who were treated with PDT demonstrated 88% resolution of high-grade dysplasia and 78% resolution of low-grade dysplasia.[260] Berenson and coworkers[306] recently reported that endoscopic argon laser photoablation of Barrett's mucosa, in conjunction with antacid therapy with omeprazole, resulted in squamous epithelial reepithelialization. More advanced techniques include endoscopic mucosal resection (which can be combined with PDT) and cryotherapy. Ablation rates are comparable, but long-term data are lacking.[307–309] Such ablative techniques are intriguing; however, further investigation is required to determine whether they reduce the risk of adenocarcinoma.

79 Cancer of the Stomach

Leonard L. Gunderson, John H. Donohue, and Steven R. Alberts

SUMMARY OF KEY POINTS

Epidemiology and Pathology
- For stomach cancer in the United States the expected incidence in 2007 was 21,260 cases and 11,210 deaths.
- These cancers are usually adenocarcinomas.
- In the United States the site of origin is shifting as more proximal lesions are diagnosed.

Biologic Characteristics
- Prognostic factors relate to tumor extent and include nodal involvement and extension beyond the gastric wall.
- Ploidy may be an independent prognostic factor.

Staging Evaluation
- Staging should always include history and physical examination, complete blood cell count, liver chemistries, chest film, endoscopy with biopsy, ultrasonography (determine degree of direct tumor extensions), and computed tomography (CT) of the abdomen (define extragastric disease).
- Additional studies that may help define extragastric extent of disease include upper gastrointestinal imaging, CT of the chest (for gastroesophageal junction lesions), and laparoscopy (rule out peritoneal seeding or early liver metastases).

Primary Therapy
- Surgical resection is the primary therapy of resectable gastric cancers.
- Cure rates of 80% or higher are achieved only with early lesions (nodes negative, confined to mucosa or submucosa), which are uncommon in the United States.
- Role for extended node dissection has not been found in randomized trials.

Adjuvant Therapy
- Adjuvant therapy (chemotherapy, irradiation) is indicated on the basis of patterns of relapse and survival results with surgery alone (high incidence of local-regional relapse and distant metastases).
- Most Western chemotherapy trials are negative for both single and multiple drugs.
- Irradiation alone reduced local-regional relapse and improved overall survival in a Beijing trial of 370 patients testing preoperative irradiation versus surgery alone (5-year survival rate 30% vs. 20%, $P = 0.009$).
- U.S. intergroup phase III trial of 556 patients found a survival benefit for combined-modality postoperative irradiation plus chemotherapy versus surgery alone (3-year relapse-free survival [RFS] 48% vs. 31%, $P = 0.001$; 3-year overall survival [OS] 50% vs. 41%, $P = 0.005$).
- A British phase III trial of 503 patients demonstrated a survival advantage for perioperative ECF chemotherapy (epirubicin, cisplatin, 5-fluorouracil [5-FU]) when compared with surgery alone (5-year OS 36% vs. 23%, $P = 0.009$).

Locally Advanced Disease
- Combined external beam irradiation (EBRT) plus chemotherapy or intraoperative irradiation (IORT) produced long-term survival in 10% to 20% of patients in most randomized and nonrandomized trials.
- Neoadjuvant chemotherapy studies reveal possible increase in resection rates but high incidence of local-regional relapse (consider addition of IORT alone or with EBRT and concurrent chemotherapy to neoadjuvant chemotherapy regimens).

Palliation
- Palliative resection of gastric component of disease may be indicated.
- Multiple-drug chemotherapy regimens have response rates of 30% to 50%, but most regimens do not affect survival. The ECF regimen had improved response rates and survival when compared with FAMTX (5-FU, doxorubicin, high-dose methotrexate) in a British Phase III trial. European phase III trials demonstrate improved quality and duration of life with palliative chemotherapy versus supportive care.

INTRODUCTION

At the time of diagnosis, gastric cancers are localized and surgically resectable in approximately 50% of patients; however, regional nodal metastases or direct invasion of surrounding organs or structures are frequently encountered and preclude cure by surgery alone in many patients. Analyses of patterns of relapse after complete surgical resection demonstrate that subsequent relapse of cancer is common in both the tumor bed and nodal regions as well as systemically.

The standard of care for resectable gastric cancer for patients who can tolerate a surgical procedure is surgical resection. For patients with lower risk lesions (confined to gastric wall, nodes negative; T1–2N0M0 [see Table 79-2]) adjuvant treatment is usually not recommended except in select instances. Because both local and systemic relapses are common after resection of high-risk gastric cancers (beyond wall, nodes positive, or both; T3–4N0, TanyN+), adjuvant treatment is indicated for these patients. The results of phase III trials that demonstrate a survival benefit for preoperative

irradiation, postoperative chemoradiation, or perioperative chemotherapy with epirubicin, cisplatin, and continuous-infusion 5-FU (ECF) versus surgery alone will be summarized and future trial designs will be discussed.

For patients with locally advanced disease that seems unresectable for cure, several treatment options seem to have a favorable impact on disease control and survival. These options include primary external beam irradiation (EBRT) plus concomitant chemotherapy, maximal resection plus intraoperative irradiation (IORT), and preoperative chemotherapy or chemoradiation before resection. Results of these approaches will be summarized and future trial design will be discussed.

In the setting of metastatic disease, many active chemotherapy agents can produce meaningful response alone or in combination with other agents, but the duration of response is often limited. Trials now exist that demonstrate both a survival and quality-of-life benefit for multidrug chemotherapy versus best supportive care for individuals with metastatic cancers.

EPIDEMIOLOGY AND ETIOLOGY

In 2007, cancer of the stomach had an expected incidence in the United States of 21,260 cases and an expected number of 11,210 deaths.[1] Despite these impressive figures, age-adjusted gastric cancer death rates have decreased markedly in the United States since 1930 from approximately 28 to 2.3 in 100,000 females and from 38 to 5.2 in 100,000 males (Fig. 79-1). Of the 45 countries in which age-adjusted death rates for gastric cancer were compared for 2000 (Fig. 79-2), the United States ranked forty-fifth for both males and females.[2] Kyrgyzstan ranked first for both males (47.0 in 100,000) and females (18.9 in 100,000).

The causes of the decline in the U.S. rates are incompletely understood, but environmental factors, chiefly dietary, are suspected. Within the United States the lowest incidence is in whites, Chinese, and Filipinos, with a higher incidence in U.S. Japanese. However, epidemiologists have noted a significant decrease in incidence among migrants from high-incidence countries (such as Japan and Chile) to low-incidence countries. Although there is an overall reduction in gastric cancer incidence, there has been a steady rapid increase in the incidence of gastroesophageal junction and proximal gastric cancers.

Factors that have been associated with a higher incidence of gastric cancer include smoked or salted foods, foods contaminated with aflatoxin, low intake of fruits and vegetables, low socioeconomic status, and possibly a decreased use of refrigeration.[3,4] Possible occupational relationships include coal mining and rubber or asbestos workers. Precursor pathologic conditions include pernicious anemia, achlorhydria atrophic gastritis, gastric ulcers, and adenomatous polyps. Between 5% and 10% of individuals with pernicious anemia subsequently develop malignancy. Prior partial gastrectomy for benign gastric or duodenal ulcer disease produces an increased risk of subsequent malignancy in the gastric remnant with latency periods of 20 years or more.[5,6]

Several studies have shown a three- to sixfold increased risk of gastric cancer in individuals with *Helicobacter pylori* infection versus those with no infection, but the precise role of this bacterium in the etiology of gastric cancer remains unknown.[7–9] A variety of bacterial, patient, and environment factors most likely act in combination to affect the development of gastric carcinoma. The increased association of *H. pylori* with gastric cancer seems to be mainly with distal gastric cancers and intestinal-type malignancy. Only a minority of *H. pylori*-infected individuals develop gastric cancer, and data do not yet exist on the effect of treatment of the *H. pylori* infection on subsequent malignancy.

PREVENTION AND EARLY DETECTION

Early detection would markedly improve the prognosis of gastric cancer in the United States, because surgical resection has a high cure rate with lesions limited to the mucosa or submucosa. However, the incidence of such early gastric cancers is less than 5% in most U.S. series. In Japan the incidence of carcinomas confined to the mucosa or submucosa was only 3.8% in the 1955 to 1956 period. However, by 1966 the incidence of early lesions had increased to 34.5% because of vigorous screening procedures, leading to 5-year survival rates of 90.9% in this cohort of patients.[10] Although mass screening has been useful in Japan to detect early cancers, defined high-risk populations have not existed in the United States in the past to justify the expense of widespread screening endeavors. Whether screening of individuals with *H. pylori* infection would be of value is not yet known. Individual practitioners should use upper gastrointestinal (GI) series or preferably endoscopy to screen patients who have occupational or precursor risk factors or individuals with persistent dyspepsia or gastroesophageal symptoms.

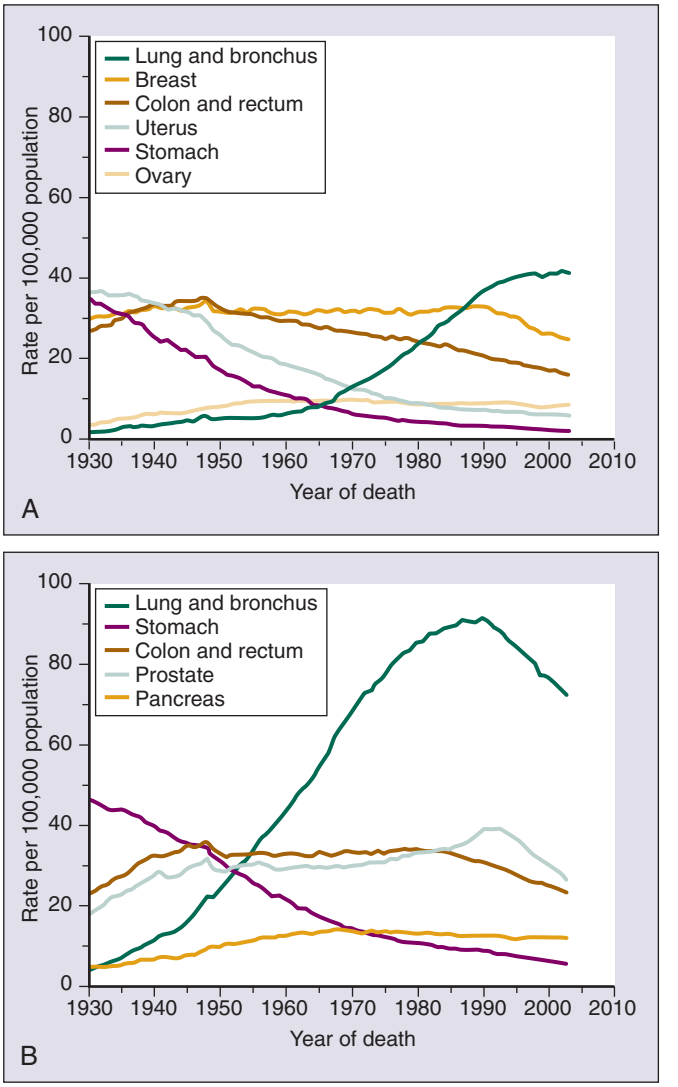

Figure 79-1 • Age-adjusted (to U.S. 1970 standard population) cancer death rates in the United States from 1930 to 2003 in selected sites for females (**A**) and males (**B**). Females have a steady decrease in death rates for stomach, breast, and colorectal cancers. From 1960 to 1998, a continual increase in death rates occurred for lung cancer in females. For males, a similar decrease in death rates occurred with gastric cancer. An increase in death rates for lung cancer existed in males from 1930 to 1990 with a continual decrease during the 1990s. (Data from Jemal A, Siegal R, Ward E, et al: Cancer statistics, 2007. CA Cancer J Clin 2007;57:43–66.)

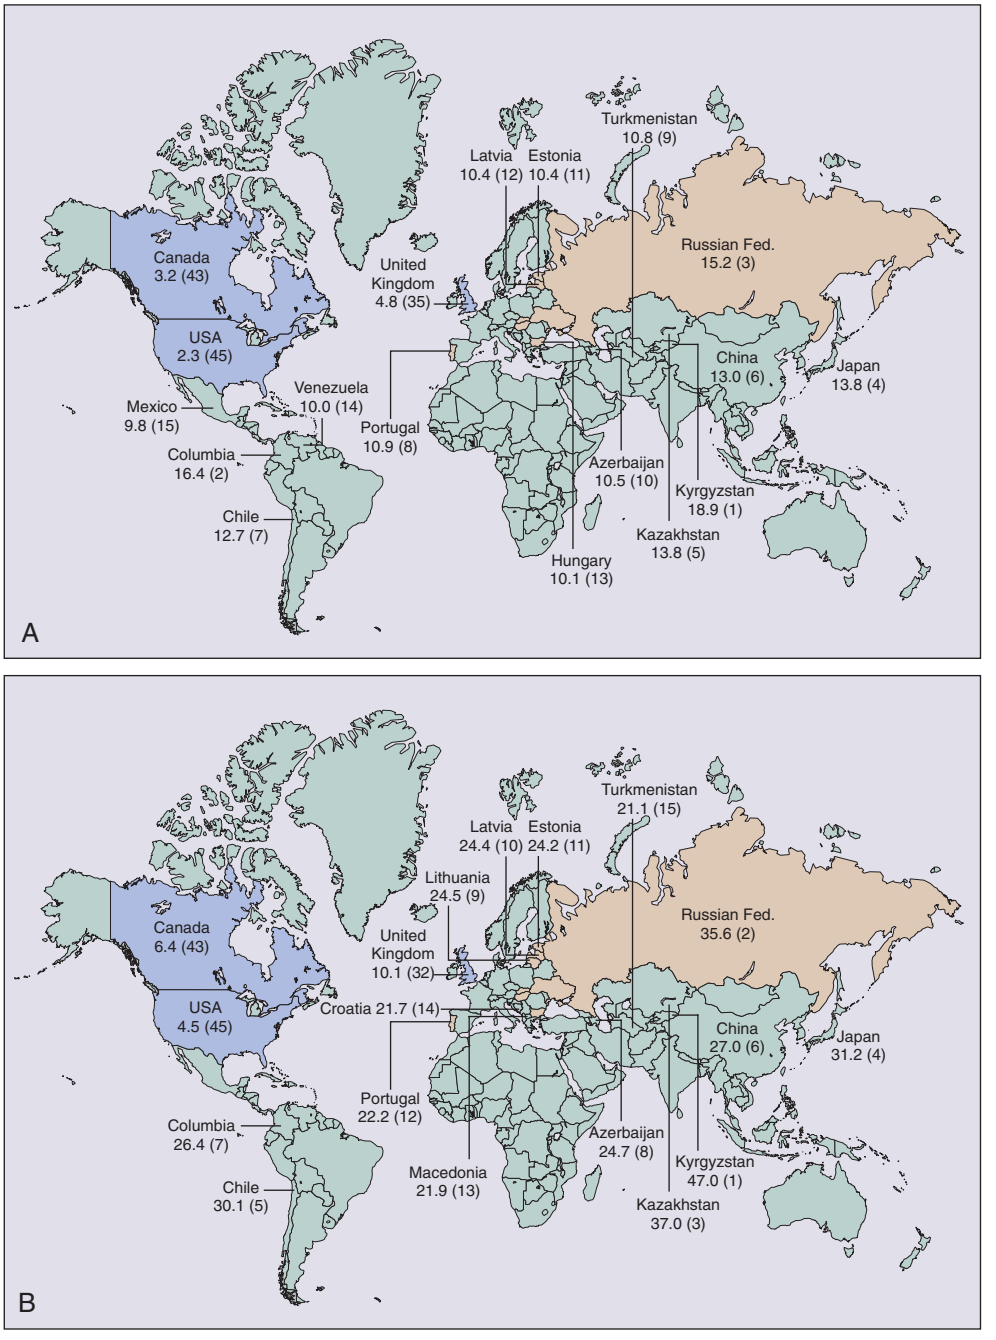

Figure 79-2 • Age-adjusted (to World Health Organization world standard population) death rates for gastric cancer from 2000 in 45 countries for females (**A**) and males (**B**). Rates in the United States, Canada, and United Kingdom are compared with selected countries, including the 15 countries with the highest death rates. (Data from Jemal A, Thomas A, Murray T, et al: Cancer statistics, 2002. CA Cancer J Clin 2002;52:23–47.)

Germline mutations in the *CDH1* gene, which encodes the E-cadherin protein, have recently been recognized in families with hereditary diffuse gastric adenocarcinoma. Carriers of these mutations have a 70% lifetime risk of developing gastric cancer. Several reports of prophylactic gastrectomy[11–13] have demonstrated the routine presence of microscopic intraepithelial carcinomas in patients having regular endoscopic surveillance that includes multiple random biopsies. Early total gastrectomy has been recommended for this small patient population because of the lack of effective early tumor detection by less aggressive techniques. Microscopic evaluation of the proximal and distal resection margins for complete removal of the gastric mucosa is necessary, because residual gastric mucosa can degenerate and result in a gastric cancer.[13]

PATHOLOGY

The terms gastric cancer and stomach cancer usually refer to adenocarcinoma, which accounts for 90% to 95% of all gastric malignancies. Other histologic types include lymphoma (usually intermediate- or high-grade histologic types), leiomyosarcoma, carcinoid, adenoacanthoma, and squamous cell carcinomas. The site of origin within the stomach has changed in frequency in the United States over recent decades, with more proximal lesions now being diagnosed and treated. The largest percentage of gastric cancers still arises within the antrum or distal stomach (around 40%), are least common in the body of the stomach (around 25%), and are of intermediate frequency in the fundus and esophagogastric junction (around 35%).[14]

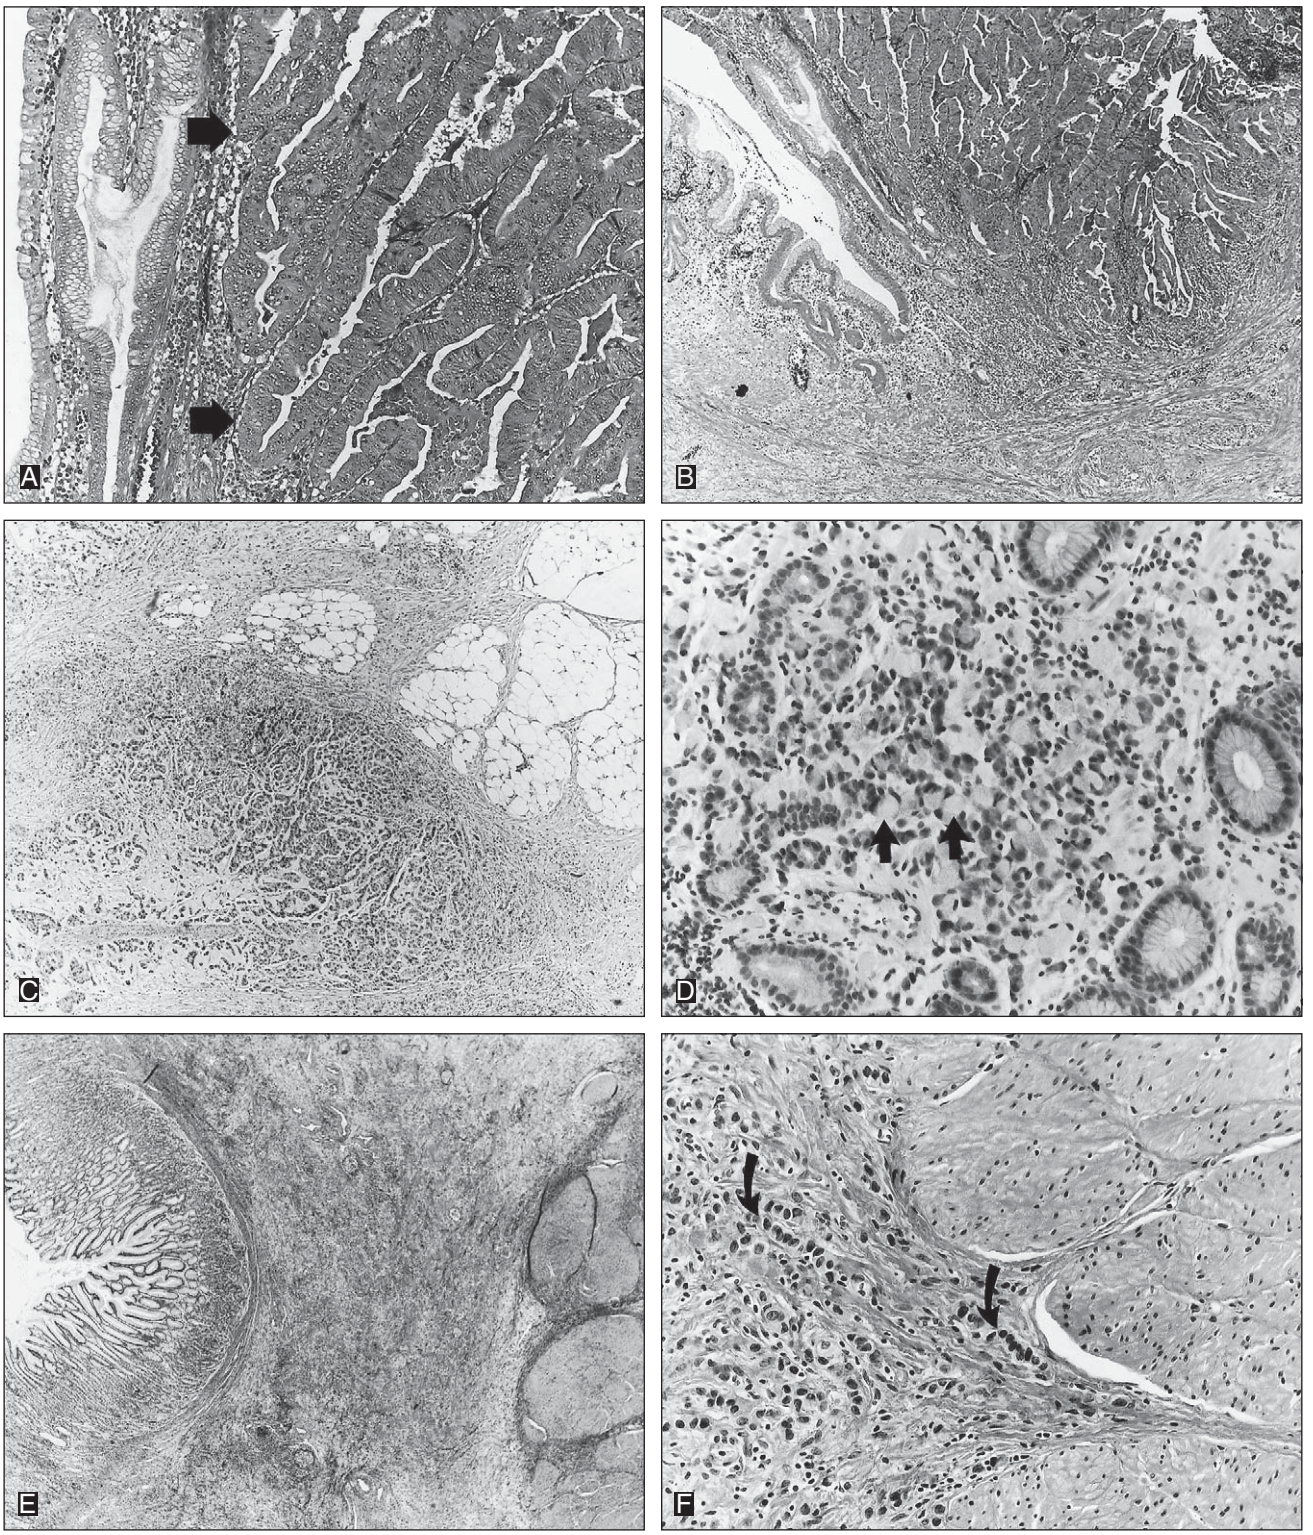

Figure 79-3 • Photomicrographs demonstrating histopathologic features of gastric cancer. **A–C,** Gastric adenocarcinoma, intestinal type. **A,** The neoplasm shows complex gland formation (*arrows*). This type would be regarded as moderately differentiated or grade 2 in a four-grade system. (×125.) **B,** This tumor infiltrates the superficial portion of the submucosa. Typical of intestinal-type adenocarcinoma, the pre-existing gastric epithelium is obliterated. (×42.5.) **C,** This tumor extends into perigastric serosa and, in view of the more irregular gland formation, would be graded with grade 3 of 4. (×42.5.) **D–F,** Diffuse-type gastric adenocarcinoma. **D,** Diffuse-type adenocarcinomas often contain signet cells (*arrows*). (×225.) **E,** Linitis plastica. Note how the underlying mucosa, submucosa, and muscularis propria appear thickened but are otherwise intact, in contrast to intestinal-type adenocarcinomas (**B**). (×22.5.) **F,** Linitis plastica at high power. Neoplastic cells may be very subtle (*arrows*). This tumor extended to the peritoneal surface and had metastasized. (×125.) (Courtesy of K. Batts, MD, Department of Pathology, Mayo Clinic, Rochester, MN.)

Gastric carcinomas have been categorized by using both microscopic (Fig. 79-3) and gross pathologic features. The Lauren classification system includes an intestinal type with improved prognosis that predominates in regions with high prevalence of gastric cancer, as well as a diffuse histologic type, with poor prognosis, which occurs more commonly in countries with low prevalence of stomach cancer.[15] Grossly, gastric cancers can be categorized according to Borrmann's[16] five types: I, polypoid or fungating; II, ulcerating lesions surrounded by elevated borders; III, ulceration with invasion of the gastric wall; IV, diffusely infiltrating (linitis plastica); and V, unclassifiable. The Japanese Research Society for Gastric Cancer has a classification system that divides lesions into protruded (I); superficial (II) with elevated (IIa), flat (IIb), and depressed (IIc) subtypes; and excavated (III) types.[17]

Pathways of Tumor Spread

Direct Extension

The stomach is surrounded by a number of organs and structures that can be involved by direct extension once a lesion has extended beyond the gastric wall. These structures include the omenta, pancreas, diaphragm, transverse colon or mesocolon, duodenum, jejunum, spleen, liver, superior mesenteric and celiac vessels, abdominal wall, left adrenal gland, and kidney. Adherence from inflammatory conditions can mimic direct extension of tumor, but all adhesions between a gastric carcinoma and adjacent structures must be regarded as malignant.

Lymphatics

Abundant lymphatic channels are present within the submucosal and subserosal layers of the gastric wall. Microscopic or subclinical spread well beyond the visible gross lesion (intramural spread) occurs via these lymphatic channels. Accordingly, frozen sections of the gastric resection margins should be obtained intraoperatively to ensure that margins of resection are uninvolved microscopically. The submucosal lymphatic plexus is also prominent in the esophagus and the subserosal plexus in the duodenum, allowing both proximal and distal intramural tumor spread.

Because of the numerous pathways of lymphatic drainage from the stomach, it is difficult to perform a complete nodal dissection (Fig. 79-4). Although initial drainage is usually to lymph nodes along the lesser and greater curvatures (perigastric or N1 nodes using the Japanese Research Society for Gastric Cancer designation), primary node drainage includes nodes along all three branches of the celiac axis (common hepatic, splenic, left gastric) and the celiac artery itself (Japanese N2 nodes).[14] Node groups that are more distal include hepatoduodenal, peripancreatic, root of mesentery (N3), periaortic, and middle colic (N4). When proximal gastric lesions extend into distal esophagus, the paraesophageal nodal system is at risk for involvement.

Hematogenous Spread

For malignancies confined to the stomach, venous drainage is primarily to the liver via the portal system. At initial exploration, liver involvement is found in up to 30% of patients, predominantly as a result of hematogenous metastases but sometimes because of direct tumor extension. For lesions that extend proximally to involve the esophagus or posteriorly, the lung may be at risk for distant metastases.

Peritoneal Involvement

Because the stomach is an intraperitoneal organ, peritoneal dissemination is possible once a lesion extends beyond the gastric wall to a free peritoneal (serosal) surface. Peritoneal spread may initially be a localized process limited by surrounding organs and ligaments (gastrohepatic, gastrosplenic, and gastrocolic).

BIOLOGIC CHARACTERISTICS

Prognostic Factors

The most meaningful prognostic indicators relate to extent of tumor. With either hematogenous metastasis or peritoneal seeding, prognosis is almost uniformly fatal. Recent immunohistochemical analysis of bone marrow aspirates has shown the presence of tumor cells to be an independent predictor of adverse outcome; however, confirmatory studies have yet to be published.[18,19] Survival decreases with progressive direct tumor extension both within and beyond the gastric wall.[20,21] Lymph node involvement, per se, is not as important as the number and location of nodes.[22–24] Minimal lymph node involvement adjacent to the primary lesion results in the most favorable prognosis in node-positive patients, but even micrometastases in regional nodes may adversely impact survival.[25] The solitary finding of either involved lymph nodes or complete penetration of the gastric wall is usually not as ominous as the presence of both[20,23] (Table 79-1).

The tumor grade and the gross and histologic pathologic appearance of the primary malignancy seem to provide some prognostic information, but none of these factors is a prognostic variable independent of the tumor stage. Prognosis is generally worse with higher grade and diffuse-type carcinomas, which usually present with higher pathologic stages of disease (see Fig. 79-3). Borrmann types I and II carcinomas have a relatively favorable 5-year survival rate, but patients with type IV tumors (linitis plastica) fare very poorly.[26,27]

Some investigators have suggested that tumors of the gastric cardia may have epidemiologic factors different from cancers of the distal stomach[28,29] and may exhibit different tumor biology.[30] The prognosis is worse for cardia lesions,[31,32] and flow cytometry reveals a greater incidence of aneuploidy when compared with tumors of the antrum and body.[33]

Flow cytometry provides valuable prognostic information for gastric cancer and may be an independent prognostic factor.[33,34] As noted previously, aneuploidy is associated with unfavorable tumor location such as the cardia[33,35] but is also associated with lymph node metastasis[34,35] and direct tumor extension.[34] Unfavorable DNA flow cytometry characteristics seem to relate closely to an unfavorable prognosis.[33,34] In one series in which multivariate analysis of DNA ploidy was analyzed with other known prognostic factors such as stage, age, and sex, DNA ploidy carried statistically significant independent prognostic information.[34]

The presence of several peptides including estrogen receptor,[36] epidermal growth factor receptor,[37] the e-erb-b2 protein,[38] and plasminogen activator inhibitor type 1[19] seems to affect prognosis adversely. The expression of epidermal growth factor receptor and high levels of epidermal growth factor correlate with a higher incidence of primary tumor infiltration, poor histologic differentiation, and linitis plastica. The pathophysiologic relationship between these peptide receptors and poor patient prognosis is not clear. Gastric cancers with class II major histocompatibility complex antigen expression (human leukocyte antigen [HLA]-DR) have a better prognosis, but the loss of expression is not an independent prognostic factor.[39]

CLINICAL MANIFESTATIONS, PATIENT EVALUATION, STAGING

Neither patient symptoms nor routine physical examination will lead to an early diagnosis of gastric cancer. The most common presenting symptoms and signs are loss of appetite, abdominal discomfort, weight loss, weakness (due to anemia), nausea and vomiting, and melena. The duration of symptoms is less than 3 months in nearly 40% of patients and longer than 1 year in only 20%.

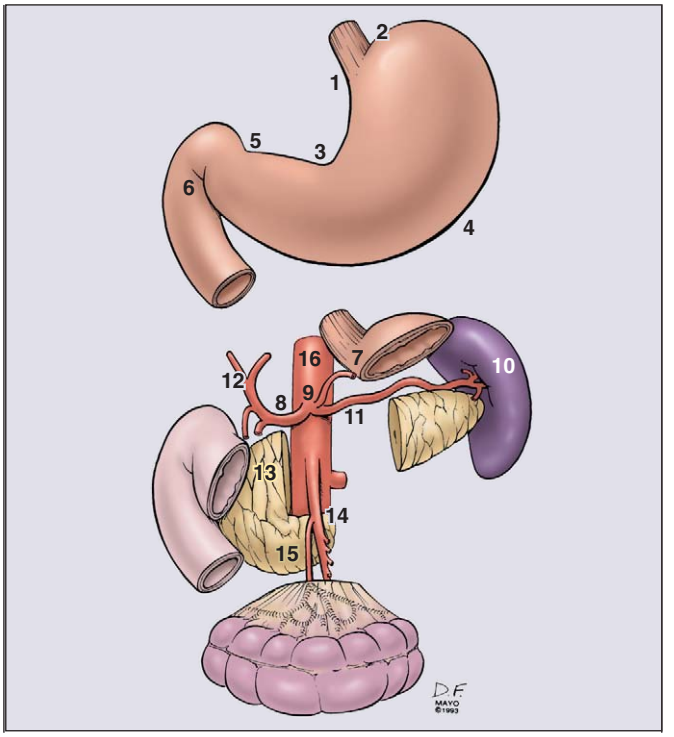

Figure 79-4 • Classification and anatomic location of lymph node groups. Involvement of nodes along the lesser or greater curvature (groups 1–6) constitutes N1 disease, and the celiac axis and its three branches are N2 (7–11), N3 (12–14), and N4 (15, 16). N1: 1, right paracardial; 2, left paracardial; 3, lesser curvature; 4, greater curvature; 5, suprapyloric; 6, infrapyloric. N2: 7, left gastric artery; 8, common hepatic artery; 9, celiac artery; 10, splenic hilus; 11, splenic artery. N3: 12, hepatic pedicle; 13, retropancreatic; 14, mesenteric root. N4: 15, middle colic artery; 16, para-aortic. (Reprinted by permission of the Mayo Foundation.)

Evaluation of the Patient

Positive findings on physical examination are those of advanced disease. Findings may include an abdominal mass (representing the primary tumor, hepatic metastasis, or ovarian metastasis [Krukenberg's tumor]), remote node metastasis (left supraclavicular [Virchow's node]; periumbilical [Sister Mary Joseph node]; or left axillary [Irish's node]), ascites, or a rectal shelf (peritoneal seeding).

The diagnosis of gastric cancer is usually confirmed by upper GI endoscopy, or radiographs. Double-contrast radiographs may reveal small lesions limited to the superficial (inner) layers of the gastric wall. Endoscopy is now the preferred initial diagnostic test, because it allows direct tumor visualization, cytologic testing, and histologic biopsy that yield the diagnosis in 90% or more of patients with exophytic lesions. Ulcerated cancers and linitis plastica lesions may be harder to diagnose endoscopically, but multiple biopsies and washings enhance the probability of accurate diagnosis. Endoscopic ultrasonography (EUS) has a high degree of accuracy in determining depth of tumor invasion (i.e., does the lesion extend beyond the muscularis propria?) but is less accurate in detecting regional nodal metastasis.[40–42] Ultrasound-guided fine-needle aspiration for cytologic test allows the assessment of regional lymph nodes and some distant metastatic sites (e.g., liver), further enhancing the ability of EUS to determine tumor stage and resectability.

The extent of disease at exploration or laparoscopy is usually more extensive than is suggested on upper GI radiography or endoscopy. Abdominal CT scan is valuable in determining the abdominal extent of disease with regard to larger liver metastasis (1 cm or greater), involvement of celiac or periaortic nodes, or extragastric extension (may help determine which lesions extend to surgically unresectable structures). CT scan is of little value, however, in ruling out peritoneal metastases or small hepatic metastasis. Diagnostic laparoscopy allows visualization of small serosal or liver metastases and may give added information with regard to the amount of direct extension of the primary tumor. Distant (hematogenous) metastases should be ruled out with a chest radiograph, serum liver chemistries, and abdominal CT scan, or liver ultrasonography (we prefer CT scan to ultrasonography because of the additional information concerning regional nodal status, extragastric extent of disease, and extension within the distal esophagus). CT scans also provide valuable tumor

Table 79-1 Extent of Initial Disease versus Survival Rates in Stomach Cancer*

	1–3	3	0
	Any	Any	0

TIS, carcinoma in situ; intraepithelial tumor without invasion of the lamina propria; T1, tumor invades lamina propria or submucosa; T2, tumor invades the muscularis propria (T2a) or the subserosa (T2b); T3, tumor penetrates the serosa (visceral peritoneum) without invasion of adjacent structures; T4, tumor invades adjacent structures; N0, no regional lymph node metastasis; N1, metastasis in 1–6 regional nodes; N2, metastasis in 7–15 regional nodes; N3, metastasis in more than 15 regional nodes; M0, no distant metastasis; M1, distant metastasis.

*Metastases to other intra-abdominal lymph nodes such as hepatoduodenal, retropancreatic, mesenteric, or para-aortic are considered distant metastases within this system but are N3 or N4 in the Japanese Research Society Classification.

localization information should irradiation be indicated. If a proximal gastric tumor extends to involve the esophagus, CT scan of the chest is useful in determining mediastinal node involvement or parenchymal lung metastases.

Staging

With the development of laparoscopic general surgery, diagnostic laparoscopy is commonly used to assess for distant metastasis or unresectable locally advanced abdominal cancers. Several groups[43,44] have reported the use of laparoscopy in stomach cancer patients. Metastatic disease was documented laparoscopically in 35% to 40% of patients.[43–45] The sensitivity for metastases was 85% or greater[44,45] and this technique was particularly sensitive in detecting liver and peritoneal disease. Laparoscopy is more sensitive and accurate in staging patients with regard to intra-abdominal metastases than either ultrasound or CT scan.[45,46] Many surgeons now routinely perform laparoscopy in all gastric cancer patients who do not require palliation, to avoid nontherapeutic laparotomy.

The current TNM (tumor, lymph node, metastasis) staging system is depicted in Table 79-2 and is acknowledged as the standard system for reporting outcomes in stomach cancer.[47] Several comparison studies, including some from Japan,[48,49] have shown better prediction of prognosis using the AJCC TNM system compared with other staging systems, including that of the Japanese Research Society for Gastric Cancer.

PRIMARY THERAPY AND RESULTS

Surgical Method

Surgical excision of the gastric and nodal components of disease remains the primary therapy for all potentially curable gastric carcinomas. Based on pathologic findings, the Japanese Research Society for Gastric Cancer has defined four categories of surgical resection: (1) absolute curative (no peritoneal or hepatic metastases, no serosal involvement, and a level of lymph nodes removed beyond those involved); (2) relative curative (same as 1 but nodal involvement to the level excised); (3) relative noncurative (complete gross tumor excision but curative criteria not met); and (4) absolute noncurative (residual cancer).[17] Most curable tumors can be removed with adequate margins by subtotal gastrectomy; total gastrectomy is used when mandated by proximal cancer location or disease extent. Routine total gastrectomy does not improve survival by providing wider margins and eliminating multicentric disease but may increase the rates of patient morbidity and mortality. A randomized study[50] showed similar survival rates with subtotal and total gastrectomy. Surgical resection alone, including endoscopic mucosal resection in selected patients[51], is an excellent treatment for gastric carcinomas limited to the mucosa or submucosa without nodal involvement (TIS or T1N0M0). These early gastric cancers now occur with an incidence of over 30% in Japan but still less than 5% in the United States and other Western countries. At least one Japanese report showed similar excellent results for T2 cancers if lymph nodes were uninvolved.[52] For the more invasive gastric carcinomas, curative or palliative resection is indicated for 50% to 60% of patients at the time of disease presentation, but only 25% to 40% of these patients will have potentially curative surgical procedures. Increasingly subtotal[53] and total[54] laparoscopic gastrectomies are being performed safely and without apparent compromise of patient outcome.

Only one prospective randomized trial[50] exists with regard to the extent of gastric resection, but extensive experience exists with various different surgical procedures, and appropriate generalizations can be made. The preferred treatment for lesions arising in the body or antrum of the stomach is a radical distal subtotal resection (Fig. 79-5). This removes approximately 80% of the stomach along with the first portion of the duodenum, the gastrohepatic and gastrocolic omenta, and the nodal tissue adjacent to the three branches of the celiac axis. Extensive or proximal cancers will require a total gastrectomy to achieve an adequate proximal gastric margin (Fig. 79-6). Total gastrectomy provides no advantage when subtotal gastrectomy will provide a 5-cm clearance of the gross tumor.[50] The propensity for gastric carcinoma to spread via submucosal and subserosal lymphatics dictates the need for a 5-cm surgical resection margin of normal stomach beyond the visible tumor. It may be necessary to extend the resection to include some (or additional) esophagus or duodenum if frozen-section pathologic evaluation of the surgical margins fails to confirm the adequacy of proximal and distal resection margins. If total gastrectomy is necessary, a splenectomy is sometimes performed, particularly in gastric cancers of the proximal third of the stomach, and tumors of the body near the greater curvature. These cancers are more apt to metastasize to lymph nodes in the splenic hilum that cannot be completely excised without a splenectomy. The value of routine splenectomy has been addressed in a prospective randomized trial. No benefit of splenectomy was apparent in this trial.[55]

Direct spread beyond the gastric wall should be treated with en bloc extended resection to achieve negative margins of resection, if a curative resection is contemplated.[56,57] These extended resections are potentially curative but increase perioperative morbidity and mortality. Common examples of local tumor extension include involvement of the body or tail of the pancreas (treated by distal pancreatectomy and splenectomy), invasion of the transverse mesocolon (often requires transverse colectomy), and involvement of the spleen (splenectomy) or left lobe of the liver (usually requires wedge resection with a 1-cm or wider clearance).

The optimal extent of lymph node dissection for gastric cancer remains controversial. The presence and extent of lymph node metastasis correlate with the depth of primary tumor invasion.[58] Japanese surgeons universally advocate regional lymph node removal for all

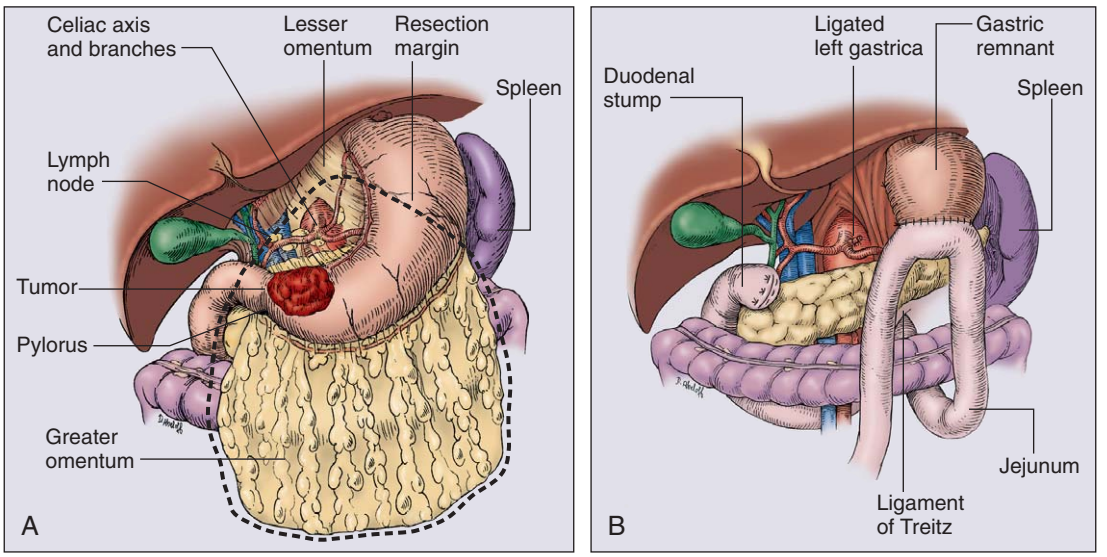

Figure 79-5 • **A,** Radical subtotal gastrectomy. The extent of resection for this tumor of the antrum includes the distal 80% of the stomach, the lesser and greater omenta, the perigastric lymph nodes (Japan N1), and lymph nodes along the left gastric, celiac, and common hepatic arteries (Japan N2). **B,** Radical subtotal gastrectomy reconstruction. After closure of the duodenal stump and lesser curvature of the stomach, the gastric remnant and proximal jejunum are anastomosed end to side in an antecolic position. The spleen and distal pancreas have been left in situ.

but in situ or intestinal mucosal tumors as a means to improve both local control and survival.[59] Because more distal nodes can be involved with metastasis in 11% of patients with negative perigastric nodes, a wider regional nodal dissection is deemed necessary for cure.[58] A recent study of sentinel lymph node biopsies in gastric cancer patients in Japan[60] demonstrated that 37% of tumors drained to N2 nodes, either in combination with N1 sentinel nodes (32%) or as the sole site of lymphatic drainage (5%). When performing a radical subtotal gastrectomy and omentectomy, all N1 and N2 nodes should be removed (D2 dissection; see Fig.79-4) (N1, perigastric nodes; N2, nodes along the left gastric, common hepatic, celiac, and splenic arteries). Some surgeons in Japan routinely remove N3 lymph nodes (D3 dissection, usually portal and retropancreatic). A recently completed prospective trial of D2 versus D3 dissections determined that the more extensive lymphadenectomy did not increase complication rates, but no long-term survival outcomes are available for this study.[61]

Thus far, randomized trials[62,63] have not demonstrated either disease-free or overall survival advantage for extended lymphadenectomy (D2 dissection). A large multicenter phase III study that accrued 711 curable gastric cancer patients in the Netherlands[62] noted significantly higher morbidity and mortality rates with the more exten-

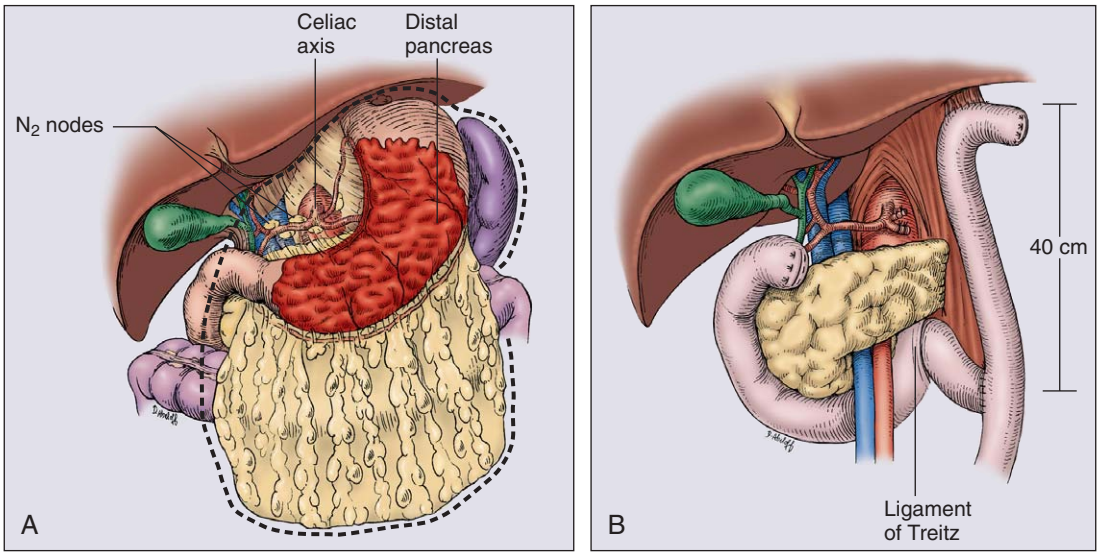

Figure 79-6 • **A,** Radical total gastrectomy. A total gastrectomy is indicated for this extensive tumor of the stomach. Both omenta, the spleen, distal pancreas, and Japan N2 lymph nodes are to be included with the operative specimen. **B,** Radical total gastrectomy reconstruction. Although a variety of anastomoses and jejunal pouches have been described, no benefit seems to accrue from any approach, except to keep the biliary and pancreatic secretions away from the esophageal mucosa. The Cohn end-to-side Roux-en-Y esophagojejunostomy with a 40-cm limb is depicted.

Table 79-3 Extent of Surgery: Randomized Trials of D1 versus D2 Dissection

Series	No. of Patients	5-YR SURVIVAL (%)		OPERATIVE MORTALITY (%)		
		D1	D2	D1	D2	*P* Value
Dutch[62]	711	45	47	4	10	<0.05
MRC[63]*	400	35	33	6.5	13	<0.05

Both trials showed significantly increased morbidity and mortality with more extensive dissections.
*Defined D1 dissection as resection of AJCC nodes (those within 3 cm of primary tumor).

sive nodal dissection (Table 79-3). A randomized study from the United Kingdom that included 400 patients with gastric adenocarcinoma also demonstrated higher morbidity and mortality rates in the extended lymphadenectomy cohort (see Table 79-3).[63] Neither the Dutch[62] nor the British trial[63] demonstrated any improvement in overall or disease-free survival (see Table 79-3). In the Dutch study,[62] patients who did not undergo a splenectomy or distal pancreatectomy had an improvement in relapse-free survival ([RFS] 71% vs. 59% at 5 years, $P = 0.02$). Splenectomy and pancreatectomy had significant adverse impact on survival in both trials.[62,63] Preliminary data from a Japanese trial comparing D2 and D3 resections[61] and an Italian study comparing D1 and D2 resections[64] did not show increased morbidity with extended lymphadenectomy. Results for disease-free and long-term overall survival are not yet available from either study.

Any potential survival benefit seen with the extended node dissection performed in Japan may be due to the phenomenon of a stage migration rather than superior surgical therapy.[65] In Japan and the United States gastric resection specimens are handled quite differently.[66] Japanese pathologists evaluated an average of 62 nodes in subtotal gastrectomy specimens and as many as 100 in total gastrectomy cases, including lymph nodes less than 3 mm in diameter.[67] This number compares with an average of 12 and 13 nodes examined after subtotal and total gastrectomy, respectively, at Memorial Sloan-Kettering.[68] Patient survival after a curative operation significantly improves when more than 15 lymph nodes are pathologically examined.[69,70] Failure to evaluate an adequate number of regional lymph nodes probably results in the understaging of many gastric cancer patients. N2 nodes cannot be defined as positive if they are not resected and examined; involvement of resected N1 nodes cannot be assessed if the specimen is not thoroughly evaluated by the pathologist. Most patients with more than six lymph node metastases or with lymph node metastasis not adjacent to the primary tumor still have a very poor outcome.[24] Extended lymph node dissection seems reasonable for experienced surgeons who can perform this procedure without significantly increased surgical morbidity or mortality, because it improves pathologic staging.[61,64,71]

Endoscopic laser surgery has been used in selected individuals with early gastric cancer.[72] Small lesions (≤3 cm) that are not ulcerated, do not involve the submucosa, and are well differentiated infrequently have lymph node metastasis (<5%). As many as 75% of these select tumors can be completely removed endoscopically. Although early gastric cancer may have a long natural history before progression, standard surgical resection rather than endoscopic removal is still preferable for most Western patients.

Survival after Surgery Alone

Overall survival results with surgery alone remain poor, despite improved perioperative treatment, which has resulted in a substantial decline in postoperative mortality rate (median of 4.6% in the 1980s).[73] A large review from Europe reported excellent 5-year survival rate for early gastric cancer patients (83%) but a marked diminution in survival for more invasive cancers.[74] Excellent survival in excess of 90% has been achieved throughout the world with surgical resection of lesions confined to the mucosa or submucosa[52,75,76] (Table 79-4). In contrast, for gastric cancers with deeper invasion or nodal involvement, survival decreases proportionally to the degree of invasion or involvement (see Table 79-4). When N1 or N2 nodes are involved, Western reports continue to show 5-year survival rates of 10% to 30%,[77] whereas Japanese authors report 5-year surgical cure rates of 25% to 60% (vs. <10% with N3 or N4)[78,79] (see Table 79-4). Although pathologic staging differences, different tumor biology, and more radical surgical extirpation have been proposed as explanations, the cause of the difference in U.S. and Japanese results with N1 or N2 disease remains uncertain. Even in the Orient half of all individuals with more invasive gastric cancer die of their disease, a fact that underlies the need for new nonsurgical therapies.

Relapse Patterns after "Curative Resection"

Local regrowth or failure in the tumor bed and regional lymph nodes, or distant failures via hematogenous or peritoneal routes are all common mechanisms of failure after "curative resection" in clinical,[80,81] reoperative,[21] and autopsy[82–85] series. For lesions of the esophagogastric junction, both the liver and lungs are common sites of hematogenous spread. With gastric lesions that do not extend to the esophagus, the initial site of hematogenous spread is usually the liver, and many relapses could be prevented if an effective "abdominal" therapy could be combined with treatment of the primary tumor and regional lymph nodes.

Local-regional failures occur commonly within the region of the gastric bed and nearby lymph nodes (Table 79-5). Tumor relapse in anastomoses, the gastric remnant, or the duodenal stump is also frequently seen. In a University of Minnesota reoperative analysis,[21] local-regional failure occurred as the only evidence of relapse in 29% of the 86 patients with relapse (23% of the 105 evaluable patients at risk) and as any component of failure in 88%. More extensive

operative procedures including routine splenectomy, omentectomy, and radical lymph node dissection neither improved survival[86] nor decreased the incidence of local or regional regrowth[21] in the reoperative analysis. Subsequent relapse within the scope of the initial node dissection occurred in a high percentage of the patients even when radical node dissections were performed (removal of N1, N2, and sometimes N3 nodes; Table 79-6).[87] This indicates the difficulty of obtaining a complete lymph node excision encompassing this anatomic location.

Patterns of failure by stage were analyzed in detail in a series of 130 patients who underwent resection performed with curative intent at the Massachusetts General Hospital (MGH).[80] Local-regional failure occurred as any component of failure in 49 patients (38%) and as the sole failure in 21 (16% of 130 patients at risk and 24% of the 88 patients with disease progression). The incidence of local-regional failure by stage was in excess of 35% for T3N0, T4N0, T3N1–3, and T4N1–3 lesions. The sites at highest risk for local-regional failure included the gastric bed (27 of 130 patients, 21%) and the anastomosis or gastric remnant (33 of 130 patients, 25%). The true incidence of gastric bed, regional lymph node, and peritoneal failures may be higher, because this was neither a reoperative nor an autopsy series (see comparative findings in Tables 79-5 and 79-6). In a more recent clinical analysis of patterns of relapse, D'Angelica and colleagues found that 50% of patients with relapse had a local-regional component.[81] Some additional information on patterns of relapse by stage exist in both the University of Minnesota reoperation analysis[21] and the University of Washington autopsy analysis.[84] Although patterns of failure data are more accurate in such analyses, patient selection is biased.

All these data suggest that the development of an effective therapy for local-regional disease as an adjuvant to surgery could potentially benefit at least 20% of patients. However, effective systemic therapy is also essential to improve the outcome for resected high-risk gastric cancer patients.

ADJUVANT TREATMENT AFTER COMPLETE RESECTION—RESULTS

Adjuvant Systemic Chemotherapy

The results of surgery alone for resectable gastric cancer have already been presented and justify the evaluation of adjuvant chemotherapy with regard to an attempt to reduce systemic risks of relapse and thereby improve survival. Although many active single agents exist and several drug combinations have been associated with response rates of 40% or more, randomized North American and European (Western) trials have generally failed to show positive survival findings for adjuvant chemotherapy. Differences in outcome have been noted between Western and Asian studies.

Initial trials to assess the benefit of adjuvant chemotherapy in the United States were conducted by the Veterans Administration in 1957 testing *single agents*. Survival was not improved with the adju-

vant use of either single-agent 5-fluorodeoxyuridine (FUDR) or triethylenethiophosphoramide (thiotepa) when compared with surgery alone.[88,89]

In subsequent North American and European trials, the potential benefit of *multidrug regimens* that had shown benefit in the metastatic setting were evaluated in the adjuvant setting. These regimens included: (1) a combination of 5-fluorouracil (5-FU) and methyl-CCNU (MeCCNU); (2) FAM, a combination of 5-FU, doxorubicin (adriamycin), and mitomycin C; and (3) FAMTX, a combination of 5-FU, doxorubicin, and methotrexate. Although a trial from the Gastrointestinal Tumor Study Group (GITSG) demonstrated a survival advantage for the 71 patients assigned to combination chemotherapy with 5-FU and MeCCNU when compared with an equal number of control patients assigned to surgery alone ($P < 0.03$)[90], subsequent studies performed by the Eastern Cooperative Oncology Group (ECOG), and the Veterans Administration could not confirm a survival advantage for patients treated with the same adjuvant chemotherapy.[91,92] Phase III trials testing the use of either FAM or FAMTX in an adjuvant setting also failed to demonstrate a survival advantage when compared with a surgery-alone control arm.[91–99]

Mixed results have been seen in trials performed in Asia. Nakajima and colleagues have performed a series of adjuvant studies in individuals with resected gastric cancer.[100–103] In their first study, mitomycin C was given on a twice-a-week schedule for 5 weeks, but no survival benefit was seen for the whole cohort of patients.[100] In a subsequent three-arm adjuvant trial, patients were randomized to surgery alone, mitomycin C alone, or the combination of twice-weekly MFC (mitomycin C, 5-FU, and cytosine arabinoside).[101] Forty-two patients were entered in each arm of the study. At 5 years a survival benefit for MFC-treated patients was seen when compared with surgical control subjects. No significant benefit was seen for the mitomycin C arm. These same investigators studied the regimen of MFC followed by either long-term oral 5-FU or ftorafur compared to surgery alone.[102] A significant survival benefit was seen for individuals with stages I to III disease treated with MFC and oral 5-FU. In a fourth study the role of adjuvant mitomycin C and 5-FU followed by oral uracil and tegafur was evaluated in patients undergoing complete resection for early-stage gastric cancer.[103] When compared to a control group, adjuvant therapy for this group of patients showed no benefit over surgery alone.

Many of the trials reported from North America, Europe, and Asia were underpowered to adequately assess any potential differences between the control and treatment arms in regard to overall survival. Accordingly, a clinically meaningful result may have been missed. In an attempt to better determine the benefit of adjuvant therapy after potentially curative surgery for stomach cancer, several *meta-analyses* have been performed.

The two most recent meta-analyses both showed a significant survival advantage to the use of chemotherapy following surgical resection of gastric cancer.[104,105] In one of the meta-analyses, 21 randomized clinical trials before 2000 were summarized.[104] This analysis included 3658 patients enrolled in trials from Europe and North America. Whereas a variety of individual trials had failed to show benefit to adjuvant therapy, the meta-analysis indicated that adjuvant chemotherapy reduces the risk of death by 18% (hazard ratio [HR] 0.82, 95% CI 0.75–0.89, $P < 0.001$). An expanded meta-analysis that included Asian trials showed similar results.[105]

Six subsequent phase III trials of adjuvant postoperative chemotherapy have been performed with a surgery-alone control arm,[106–111] but only two demonstrated a survival benefit from the adjuvant chemotherapy (Table 79-7). Neri and associates treated surgically resected node-positive patients with the addition of adjuvant epirubicin, 5-FU, and leucovorin (68 patients) and compared them to 69 surgery-alone control patients.[106] A significant improvement in 5-year survival was noted in patients receiving the adjuvant chemotherapy (30% vs. 13%, $P < 0.01$). In the large Japanese trial by Sasako and coworkers, 1059 patients with stomach cancer were randomized to either surgery alone or to surgery followed by 1 year of treatment with the oral fluoropyrimidine S-1.[111] Although this trial has been published only in abstract form, a hazard ratio in favor of decreased deaths at 3-years was noted (HR 0.68, 95% CI 0.52–0.87).

Summary—Adjuvant Systemic Chemotherapy

The role of chemotherapy in the adjuvant postoperative treatment of resected high-risk stomach cancer remains uncertain. Except for the recent Japanese trial with S-1, individual trials have generally not shown clinically meaningful benefit. Future trial design must include adequate statistical power to detect meaningful differences in outcome. Surgery-alone control arms will probably not be feasible in

future trials in view of survival benefit achieved with either perioperative chemotherapy or adjuvant combined-modality chemotherapy–radiation therapy when compared with a surgery-alone control arm (see subsequent sections).

Intraperitoneal Therapy

The use of postoperative intraperitoneal chemotherapy has been evaluated based on the pharmacokinetic advantage of intraperitoneal chemotherapy and the finding that many patients relapse in the peritoneum after surgical resection. A variety of phase II and III trials have been performed.

Building on early promising results from phase II trials, several phase III studies have evaluated the role of intraoperative or postoperative intraperitoneal therapy in patients undergoing potentially curative surgery. In an early study by Dixon and colleagues patients were randomized to surgery alone or to surgery followed by intraperitoneal thiotepa.[88] No significant difference in survival was seen between the two groups. In a more recent study Sautner and associates examined the use of postoperative intraperitoneal cisplatin compared with surgery alone in a group of 67 patients.[112] Although the primary lesion was resected in each case, 21% of the individuals had localized peritoneal carcinomatosis. No survival benefit was seen for the treated patients.

In a phase III trial from Japan, 113 patients were randomized to surgery alone or intraoperative mitomycin C at the time of surgery.[113] For patients who underwent curative surgery, intraperitoneal therapy led to a significant improvement in 2- and 3-year overall survival. No difference in survival was seen for patients with macroscopic peritoneal carcinomatosis.

In a single-institution phase III trial from Korea, 248 patients with clinical stage II or III gastric cancer were randomized to surgery alone or to receive intraperitoneal mitomycin C on day 1 and intraperitoneal 5-FU on days 2 to 5.[114] Overall, 110 of the 248 patients had either stage I or stage IV disease. When 5-year survival was calculated for the entire group, benefit to adjuvant therapy was seen ($P = 0.0278$). In a subset analysis, however, the benefit was limited to patients with stage III or IV disease.

The use of intraperitoneal therapy in the adjuvant setting remains investigational and requires further evaluation. Until further studies show clear benefit to this approach, the use of intraperitoneal therapy should be restricted to controlled clinical trials.

Adjuvant Irradiation

Postoperative Irradiation

Irradiation has only been minimally evaluated as the sole adjuvant treatment following complete surgical resection in randomized phase III trials (Table 79-8). Adjuvant EBRT reduced local-regional failures when compared with the surgery-alone control arm in a British adjuvant trial, but no survival benefits were found.[115] Although phase III trials from Japan[116] and China[117] suggest some survival benefit for IORT versus a surgery-alone control arm, the advantage was found only in subset analyses. At the National Cancer Institute, Sindelar and coworkers[118] performed a small randomized trial of IORT versus EBRT following complete surgical resection; this trial demonstrated improved local control with IORT but no survival benefit.[118] A surgery-alone control arm did not exist in the National Cancer Institute trial. Phase II studies combining EBRT and IORT have been conducted in Pamplona (Spain) and the United States (by the Radiation Therapy Oncology Group [RTOG]) and are still under way in Lyon (France).

The British Stomach Cancer Group completed a prospectively randomized trial of surgery only versus postoperative FAM or EBRT (45 Gy in 25 fractions ± 5-Gy boost).[115] A total of 436 patients were randomized and followed for a minimum of 12 months; arms were well balanced with regard to prognostic factors. No patient survival differences by treatment arm were seen (median, 15 months). However, local-regional failure was documented in only 15 of 153 (10%) in the EBRT arm versus 39 of 145 (27%) in the surgery-alone arm, and 26 of 138 (19%) in the FAM group. Interpretation of the results is complicated by the inclusion of 93 patients (21%) with resection but gross residual disease (British Stomach Cancer Group stage IVAi) and 78 (18%) with gross total resection but microscopically positive resection margins. Neither group of patients would be candidates for current gastric surgical adjuvant trials in the United States. In addition, nearly one third of patients randomized to receive adjuvant treatment did not receive the assigned therapy. Of 153 patients randomized to the EBRT arm, only 104 (68%) received a dose of 40.5 Gy or more, and 36 (24%) received none. Only 62% of patients received six or more cycles of chemotherapy. The results in this study are similar to results seen in the adjuvant treatment of rectal cancer, in which adjuvant pre- and postoperative irradiation as a single adjuvant modality improve local control but do not increase patient survival in most trials, unless combined with chemotherapy.

Takahashi and Abe[116] reported results from a large Japanese trial in which 211 patients were randomized on the basis of day of hospital admission to receive either surgery only or surgery plus IORT (28–35 Gy). Five-year survival rates for Japanese stages II to IV were improved approximately 15% to 25% in the IORT group versus those treated with surgery alone (stage II, 84% vs. 62%; stage III, 62% vs. 37%; stage IV, 15% vs. 0%). This magnitude of survival improvement correlates nicely with the approximately 20% of patients who fail only local-regionally after complete surgical resection. Although the data are intriguing, this method of randomization is susceptible to bias in treatment selection, and the trial failed to stratify for important prognostic factors.

In an analysis from Beijing, individuals with stage III (serosal involvement or node-positive tumors) or stage IV (unresectable metastasis or adjacent organ involvement) disease were randomized to surgery alone or IORT (single dose, 25–40 Gy).[117] In their most recent report of 200 patients, a survival advantage with IORT was demonstrated for only stage III patients (65% vs. 30% 5-year survival; 52% vs. 22% 8-year survival; $P < 0.01$).

Preoperative Irradiation

Randomized trials testing preoperative irradiation have been performed in both Russia and China. All have reported a positive survival benefit when compared with surgery-alone control arms.

Three prospective randomized Russian trials have evaluated preoperative irradiation in potentially resectable gastric cancer.[119–121] The first trial randomly assigned 293 patients to receive either surgery alone, surgery after preoperative EBRT (20 Gy in four fractions), or surgery after the same EBRT plus daily hyperthermia. The survival rates at 3 and 5 years were improved in both irradiation arms compared with surgery alone, and the improvement with combined EBRT and hyperthermia was statistically significant at both 3 and 5 years.[119] The second trial compared preoperative EBRT (20 Gy) with surgery alone in 279 patients. Both 3- and 5-year survival rates were increased, and no increase in operative morbidity was observed.[120] The third trial compared surgery alone to preoperative EBRT (32 Gy with concomitant inhalation of 8% oxygen) plus surgery. A survival advantage was observed with preoperative treatment, and the resection rate was increased by 17%.[121] There are some methodologic uncertainties with all three of these trials, and their applicability to Western gastric carcinoma is not clear.

A double-blind randomized trial from Beijing, conducted from 1978 to 1989, compared a surgery-alone control arm ($N = 199$) with preoperative EBRT plus surgery ($N = 171$) for individuals with adenocarcinoma of the gastric cardia.[122] Irradiation was given with 8-MV photons or cobalt with anteroposterior-posteroanterior (AP-PA) fields to a dose of 40 Gy in 20 fractions of 2 Gy over 4 weeks. Surgery was performed 2 to 4 weeks after completion of irradiation. Both downstaging of disease and improvements in radical resection

§Three-year survival estimated from published survival curves.

rates were found with the addition of preoperative EBRT (radical resection rates of 80% vs. 62% with preoperative EBRT vs. surgery alone).

Survival and local-regional disease control were improved in the patients assigned to preoperative EBRT versus surgery alone (see Table 79-8). The 5- and 10-year survival rates were 30% versus 20% and 20% versus 13%, respectively ($P = 0.009$ Kaplan-Meier log rank). The divergence in survival curves began in the first year of follow-up and persisted through 9 years. Local and regional disease control were also improved with combined-modality treatment with local relapse rates of 39% versus 52% ($P < 0.025$) and regional node relapse rates of 39% versus 54% ($P < 0.05$). The rates of distant metastases were the same at 24% versus 25%. The improvements in survival and disease control (local-regional) were accomplished with no increase in treatment-related morbidity or mortality rates (operative mortality 0.6% vs. 2.5% with or without preoperative EBRT; intrathoracic leak rates were 1.8% and 4.2%, respectively).

In view of the survival advantage with or without disease control and radical resection rates demonstrated for preoperative EBRT in four published trials from Russia and China, such approaches need to be evaluated further in U.S. and European study groups. As suggested by the authors from the Beijing trial, factors to be evaluated include radiation dose escalation to 45 to 50 Gy (1.8- to 2.0-Gy fractions) and the addition of chemotherapy (maintenance, concurrent with EBRT).

Adjuvant Irradiation Plus Chemotherapy

Postoperative External-Beam Irradiation Therapy Plus Chemotherapy

Phase II single-institution gastric cancer trials that showed promise for combination postoperative adjuvant therapy were reported from MGH,[123] Israel (Hadassah),[124] Thomas Jefferson University Hospital,[125] the University of Pennsylvania,[126] and the Mayo Clinic.[127] Gunderson and associates,[123] from the MGH, reported a median survival time of 24 months and 4-year survival rate of 43% in 14 patients who had complete resection of tumors with extension beyond the wall, nodal involvement, or both. Patients received postoperative irradiation (45–52 Gy, 1.8 Gy/day) plus concomitant 5-FU-based chemotherapy. Subsequent local-regional relapse was documented in only 2 of the 14 (14%), in contrast to a 42% incidence in similar high-risk patients treated with surgery alone at MGH.[80]

A prospective randomized trial conducted at the Mayo Clinic included 62 patients with poor-prognosis completely resected gastric cancers who were randomized to either surgery alone or surgery followed by irradiation (37.5 Gy in 24 fractions over 4–5 weeks) plus concomitant 5-FU (15 mg/kg, days 1–3 by IV bolus).[128] A nonstratified, prerandomization scheme was used with a 2 : 3 ratio favoring treatment. Informed consent was requested only of the 39 patients randomized to treatment. Of the 39 patients, 10 refused further therapy and were observed. When analyzed by intent to treat, the adjuvant arm had statistically significant improvement in both relapse-free and overall survival (5-year OS 23% vs. 4%; $P < 0.05$; Tables 79-8 and 79-9). When patient outcome was compared by actual treatment received (29 adjuvant treatment, 33 surgery alone), 5-year survival rate still favored the adjuvant group (20% vs. 12%), but the differences were not statistically significant in view of small patient numbers. As seen in Table 79-9, the 10 patients who refused assignment to adjuvant treatment had more favorable prognostic findings than the other two groups of patients. When the two groups with equally poor prognostic factors were compared, the 5-year OS rate was 20% versus 4%, with an advantage to those receiving adjuvant treatment.[128] When analyzed by treatment delivered, local-regional relapse was decreased with adjuvant treatment (54% incidence with surgery alone vs. 39% with irradiation plus 5-FU).

Because of conflicting results in earlier small phase III studies, a confirmatory U.S. GI trial (INT 0116) was initiated to evaluate postoperative combined 5-FU-based chemotherapy and irradiation to the gastric bed and regional nodes versus surgery only in completely resected but high-risk gastric cancer patients.[129] Eligibility included patients with stages IB, II, IIIA, IIIB, and IV nonmetastatic adenocarcinoma of the stomach or gastroesophageal junction (extension beyond muscularis propria [T2–4N0] or involved nodes [T1–2N1–3]). After an en bloc resection, 556 patients were randomized to either surgery alone or postoperative combined-modality therapy

Table 79-9 Randomized Gastric Adjuvant Trial at the Mayo Clinic (Surgery ± Irradiation + 5-FU)

EBRT, external-beam irradiation; 5-FU, 5-fluorouracil.

Modified from Moertel CG, Child DS Jr, O'Fallon JR, et al: Combined 5-fluorouracil and radiation therapy as a surgical adjuvant for poor prognosis gastric carcinoma. J Clin Oncol 1984;2:1249.

consisting of one 5-day cycle of 5-FU plus leucovorin followed by concurrent chemoradiation (45 Gy in 25 fractions plus concurrent 5-FU and leucovorin, 4-day cycle on week 1, 3-day cycle on week 5) and subsequently by two additional 5-day cycles of 5-FU and leucovorin given at 1-month intervals. Nodal metastases were present in 85% of patients. With median follow-up period of 5 years, RFS at 3 years is 48% for adjuvant treatment and 31% for observation ($P = 0.001$); 3-year OS rate is 50% for treatment and 41% for observation ($P = 0.005$; see Table 79-8). The median OS in the surgery-only group was 27 months, as compared with 36 months in the chemoradiation therapy (CRT) group. The median duration of RFS was 30 months in the CRT group and 19 months in the surgery-only group. Patterns of relapse were based on the site of first relapse only and were categorized as local, regional, or distant. Local recurrence occurred in 29% of the patients who relapsed in the surgery-only group and 19% of those who relapsed in the CRT group. Regional relapse—typically abdominal carcinomatosis—was reported in 72% of those who relapsed in the surgery-only group and 65% of those who relapsed in the CRT group. Extra-abdominal distant metastasis was diagnosed in 18% of those who relapsed in the surgery-only patients and 33% of those who relapsed in the CRT group. Treatment was tolerable, with 3 (1%) toxic deaths. Grade 3 and 4 toxicity occurred in 41% and 32% of cases, respectively.

The results of the large randomized phase III U.S. GI trial (INT 0116) demonstrate a clear survival advantage to the use of postoperative CRT in resected high-risk patients.[129] Furthermore, the results strongly support the integration of postoperative CRT into the routine care of individuals with curatively resected high-risk carcinoma of the stomach and gastroesophageal junction. This approach is now viewed by many as the standard of care in the United States.

Quality control of irradiation field design in INT 0116 was conducted during the cycle of chemotherapy given before the start of concurrent CRT.[130] The initial quality control provided the mechanism to correct most of the major or minor deviations (35% incidence) in irradiation field design before the start of treatment, and resulted in only a 6.5% final major deviation rate. Use of initial quality control may have been a key factor in achieving a positive survival advantage for adjuvant CRT.

Postoperative Chemoradiation Plus D2 Resection

Because extended node dissections were not commonly performed as a component of surgery in the U.S. GI trial INT 0116, some have questioned whether postoperative CRT would give added benefit following a D2 nodal resection. Although this is unlikely to be tested in a phase III trial, a recent South Korea analysis evaluated the potential role of postoperative CRT in a series of 990 patients with D2 resection who were at high risk for relapse.[131] Disease and patient characteristics and the method of chemoradiation treatment paralelled the U.S. GI INT 0116 trial. Both disease control and survival were improved in the 544 patients who received postoperative CRT when compared with the 446 patients treated with surgery alone (5-year OS, 57% vs. 51%, $P = 0.02$; 5-year RFS, 54.5% vs. 47.9%, $P = 0.016$; local-regional relapse, 14.9% vs. 21%, $P = 0.005$; Tables 79-8 and 79-10).

Preoperative External Beam Irradiation Therapy Plus Chemotherapy

Randomized trials testing preoperative EBRT plus chemotherapy for gastric cancer alone have not yet been published, but the Walsh and colleagues trial for adenocarcinoma of the esophagus and gastric cardia certainly has relevance.[132] Patients were randomized to either immediate surgery (control arm) versus preoperative EBRT (40 Gy in 15 fractions), 5-FU (15 mg/kg/day continuous infusion [this is approximately equivalent to 600 mg/m^2] for 5 days, weeks 1 and 6), and cisplatin (75 mg/m^2 on the first day of each 5-FU infusion), followed by surgical resection 8 weeks after completion of EBRT plus chemotherapy. A highly significant difference in survival was observed with combined-modality therapy (intent to treat median survival time, 16 vs. 11 months, 3-year survival rate, 32% vs. 6%; $P = 0.01$; actual treatment median survival time, 32 vs. 11 months; $P = 0.001$; 3-year survival rate, 37% vs. 7%; $P = 0.006$). Survival rates for the control group of patients were inferior to other historical data.

A confirmatory intergroup trial was attempted in North America for patients with either esophagus or esophagogastric junction cancers (squamous or adenocarcinoma) but was stopped because of poor accrual. Despite the low accrual, patients randomized to trimodality treatment had a survival benefit when compared with patients randomized to surgery alone (median survival 54 vs. 21.6 months; 5-year OS, 39% vs. 16%, $P = 0.008$.[133]

Summary—Adjuvant Irradiation Alone or Plus Chemotherapy

In summary, both preoperative irradiation[122] and postoperative CRT[129,130] have been demonstrated to be superior to surgery alone for resectable gastric and gastroesophageal cancers in randomized phase III trials. Future preoperative irradiation trials should evaluate the addition of concurrent and maintenance chemotherapy. Postoperative CRT trials are evaluating more aggressive chemotherapy both as concurrent and maintenance components of treatment.

Irradiation Techniques

The irradiation field should include unresected or residual tumor or the tumor bed plus major nodal regions. The pattern of tumor bed and nodal failures in the reoperative series from the University of Minnesota is demonstrated in Figure 79-7A in conjunction with an idealized, shaped AP-PA irradiation portal that incorporates the areas

Table 79-10 Surgery (D2 resection) ± Postoperative Chemoradiation for Gastric Cancer, South Korea Series

	5-Year Overall Survival			5-Year Relapse-Free Survival		
Stage	**Surgery Alone**	**Postop CRT**	***P* Value**	**Surgery Alone**	**Postop CRT**	***P* Value**

Postop CRT, postoperative chemoradiation therapy.

Modified from Kim S, Lim DH, Lee J, et al: An observational study suggesting clinical benefit for adjuvant postoperative chemoradiation in a population of over 500 cases after gastric resection with D2 nodal dissection for adenocarcinoma of the stomach. Int J Radiat Oncol Biol Phys 2005;63:1279.

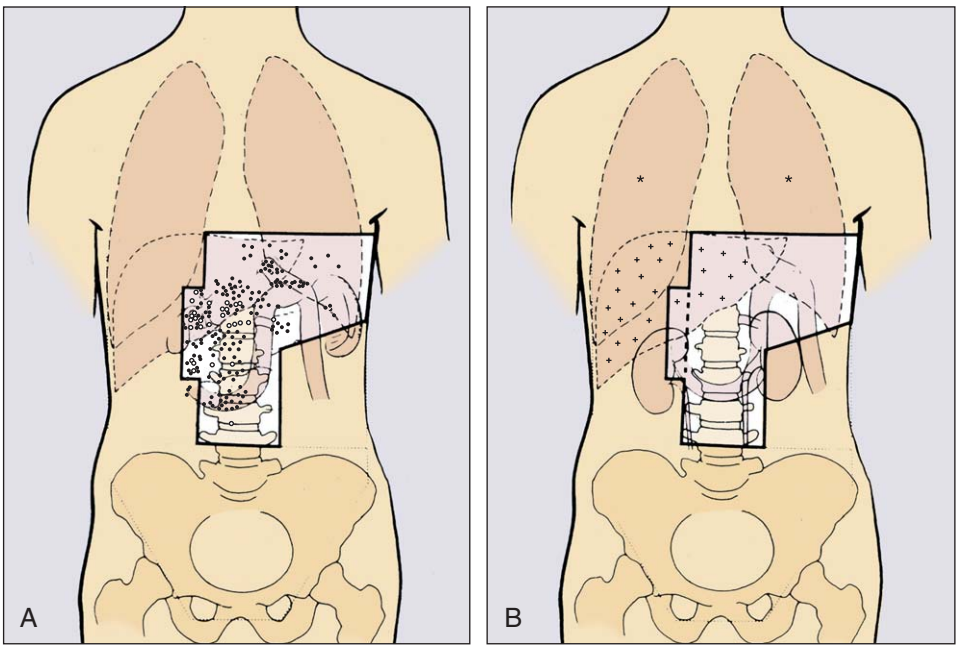

Figure 79-7 • **A** and **B,** Patterns of failure in the University of Minnesota gastric cancer reoperative series with superimposed idealized irradiation fields, and relationship to dose-limiting organs or structures (**A**). •, local failures in surrounding organs or tissues; ○, lymph node failures; *, lung metastases; +, liver metastases.

of local-regional relapse.[21,82] The tumor bed and nodal volumes are reconstructed with the aid of preoperative and postoperative imaging studies and surgical clip placement. In Figure 79-7B the idealized AP-PA field is superimposed on the organs and structures that define irradiation tolerance.

Dose-limiting organs and structures in the upper abdomen are numerous (stomach, small intestine, liver, kidneys, and spinal cord). With properly shaped fields, doses of 45 to 50.4 Gy in 1.8- to 2.0-Gy fractions can be delivered to stomach and small intestine with a 5% or less risk of severe toxicity.[134] In most patients a portion of both kidneys will be within the AP-PA treatment field, but at least two thirds to three fourths of one kidney should be excluded (can include entirety of both kidneys to the level of 20 Gy if necessary). For patients with gastroesophageal junction or proximal to mid-gastric cancers (Figs.79-8 and 79-9), one half to two thirds of the left kidney can often be spared as a result of accurate field definition, which is aided by pre- and postoperative imaging studies and clip placement. The pancreaticoduodenal nodes can be included, if indicated, while sparing 75% to 90% of the right kidney. However, for distal gastric lesions with narrow or positive duodenal resection margins, the duodenal circumference may need to be included as target volume (Fig. 79-10). In such instances 50% or more of the right kidney is within the field, and two thirds to three fourths of the left kidney should be spared. Chronic renal problems are infrequent when these techniques are utilized.[123,135–137]

With preoperative or primary CRT for individuals with gastroesophageal junction or proximal gastric lesions, a 3- to 5-cm margin of distal esophagus should be within the irradiation field (see Fig. 79-9). If the lesion extends beyond the gastric wall with proximal lesions, a major portion of the left hemidiaphragm should be included. In either instance, Cerrobend blocks or multi-leaf collimators should be used to decrease the volume of irradiated heart (see Figs. 79-8 through 79-10) and lung when technically feasible. For patients with gastroesophageal junction cancers, preoperative EBRT fields can usually be much more conservative than postoperative fields with regard to both heart and lung volumes, and are preferred, if preoperative imaging and EUS demonstrate indications for preoperative adjuvant treatment (see Fig. 79-9). Lateral or oblique fields can be used as a component of treatment to decrease the volume of heart within the irradiation field (see Fig. 79-9).

More routine use of multiple field techniques should be considered when preoperative imaging exists to allow accurate reconstruction of target volumes (see Figs. 79-8 through 79-10).[137] Single-institution data suggest that multiple field arrangements may produce less toxicity.[127] When patients are treated preoperatively, paired lateral fields are usually combined with AP-PA fields to achieve improve dose homogeneity (see Fig. 79-9). Dependent on the posterior extent of the gastric fundus, either oblique or more routine lateral portals can be used to deliver a 10- to 20-Gy component of irradiation to spare spinal cord or kidney. When lateral fields are used, liver and kidney tolerance limits the use of lateral fields to 20 Gy or less for patients with gastric cancer; for patients with gastroesophageal junction cancers the contribution from lateral fields would preferably be limited to 10 to 15 Gy because of lung tolerance. With the wide availability of three-dimensional treatment-planning systems, it may be possible to target more accurately the high-risk volume and to use unconventional field arrangements and/or intensity-modulated radiation therapy[138,139] to produce superior dose distributions. To accomplish this without marginal misses it will be necessary to both carefully define and encompass the various target volumes, because use of oblique or noncoplanar beams could exclude target volumes that would be included in AP-PA fields or nonoblique four-field techniques (AP-PA and lateral).

In individual patients the idealized field must be modified depending on the surgical/pathologic extent of disease and site of the primary tumor.[136,137] The relative risk of nodal metastases at a specific nodal location is dependent on both the site of origin of the primary tumor and other factors including width and depth of invasion of the gastric wall. Tumors that originate in the proximal portion of the stomach and the gastroesophageal junction have a higher propensity of spread to nodes in the mediastinum and pericardial region but a lower likelihood of involvement of nodes in the region of the gastric antrum, periduodenal area, and porta hepatis. Tumors that originate in the body of the stomach can spread to all nodal sites, but have the highest likelihood of spreading to nodes along the greater and lesser curvature, near the location of the primary tumor mass. Tumors that originate in the distal stomach have a high likelihood of spread to the periduodenal, peripancreatic, and porta hepatis nodes, but they have a lower likelihood of spread to the nodes near the cardia of the stomach, the periesophageal and mediastinal nodes, or to the splenic hilar nodes (see Fig. 79-10). Any tumor originating in the stomach

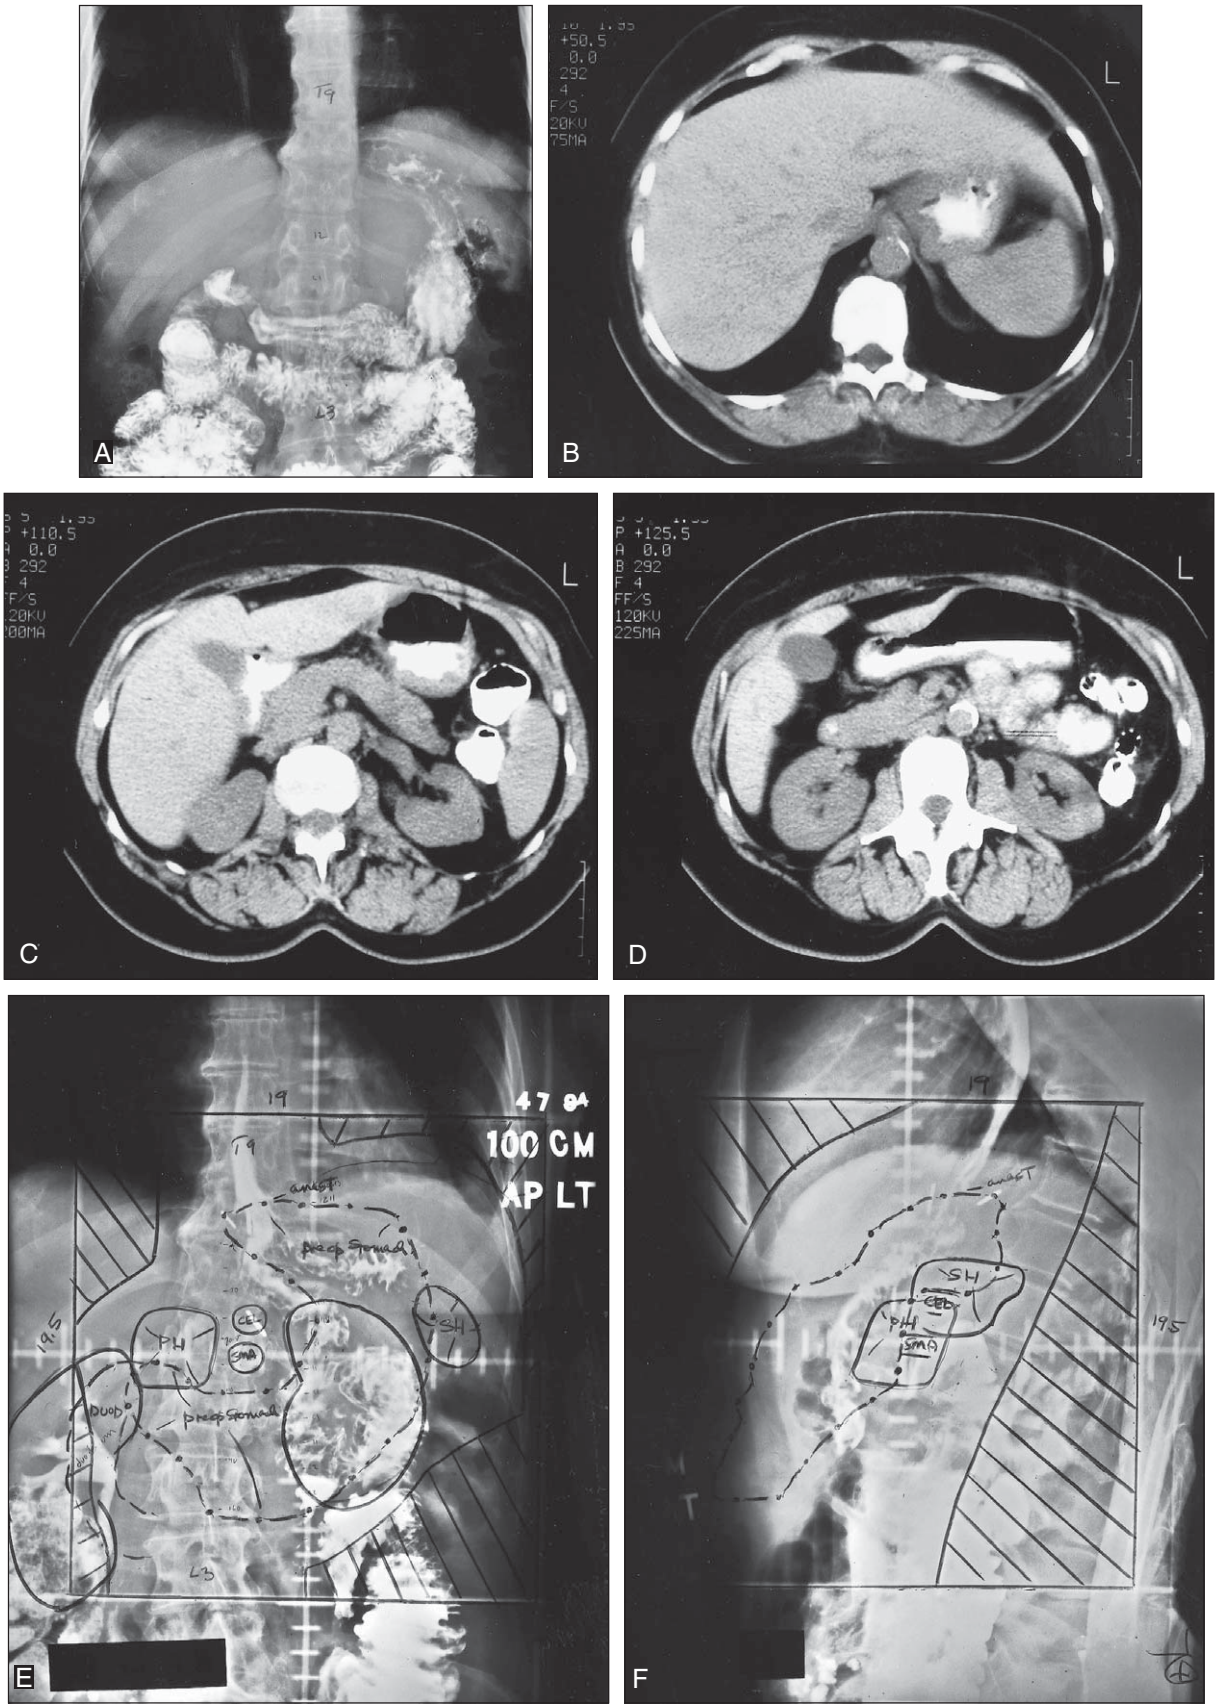

Figure 79-8 • Postoperative irradiation fields based on preoperative radiographs following complete resection of a proximal gastric cancer (T3N2M0); patient was randomized to the irradiation chemotherapy arm on the intergroup gastric adjuvant study. **A–D,** Reconstruction of tumor bed/target volumes with preoperative upper gastrointestinal radiograph (**A**) and CT scans (**B** and **D**). CT cuts demonstrated thickened gastric wall proximally (**B** and **C**) and normal thickness distally (**D**), as well as relationship of the stomach to surrounding organs including liver and spleen (**B**), liver, body and tail of pancreas, and splenic flexure (**C**), and head of pancreas (**D**). **E** and **F,** AP-PA irradiation field (**E**) with cross-hatched blocks encompasses all the left kidney but less than 20% of the right. Nodal groups at risk and preoperative gastric duodenal locations (-•-•) are demonstrated on the AP-PA and lateral (**F**) simulation fields. CEL, celiac; PH, porta hepatis; SH, splenic hilum; SMA, superior mesenteric artery.

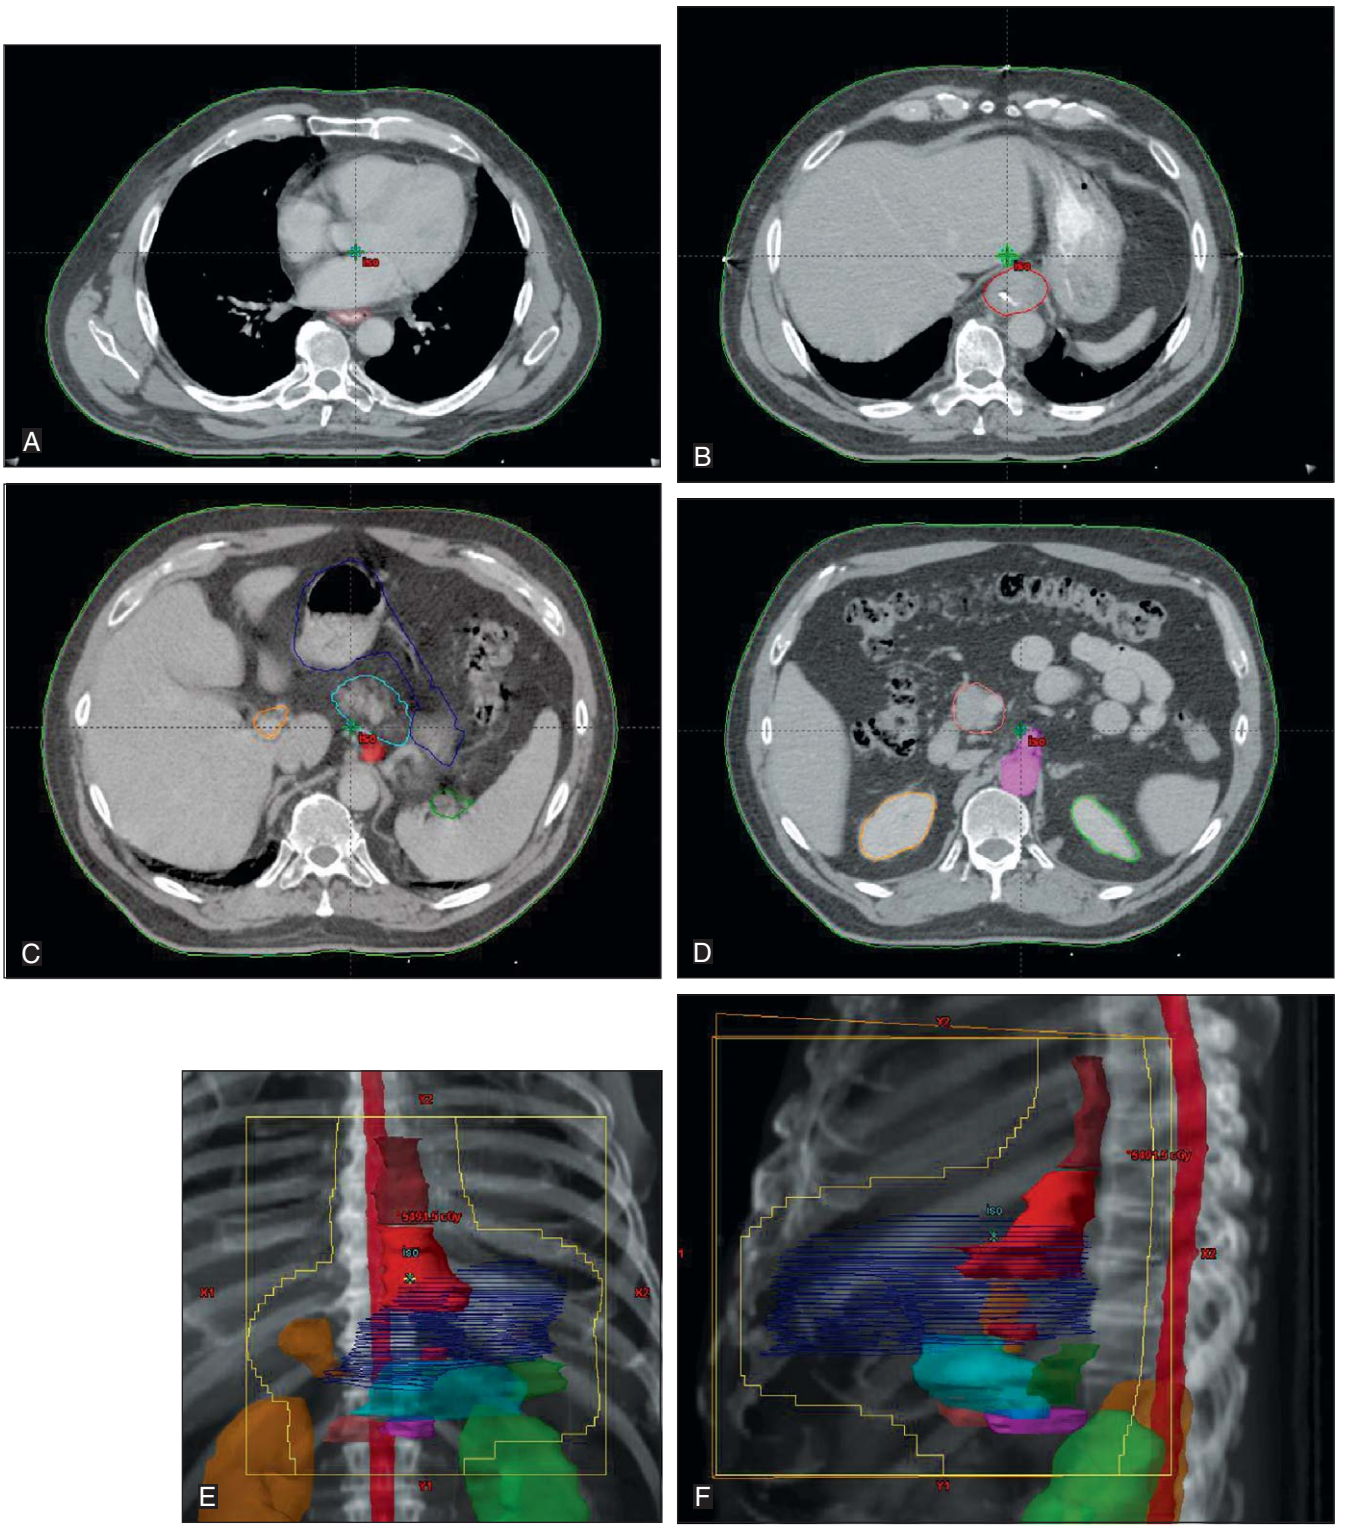

Figure 79-9 • Patient is a 54-year-old male with a T3N1 adenocarcinoma of the distal esophagus extending into the proximal stomach who was treated with preoperative concurrent CRT at Mayo Clinic in Arizona (45 Gy in 25 fractions over 5 weeks to extended field and 50.4 Gy in 28 fractions within boost field). CT simulation was performed with intravenous and oral contrast, and structures of interest were delineated (**A–D**). The normal thickness of the more proximal esophageal wall (**A**) contrasts with the markedly thickened distal esophagus wall seen at the level of the adenocarcinoma (**B**). An enlarged gastrohepatic node (**C**) was biopsy positive for adenocarcinoma at the time of pretreatment EUS. Other delineated organs/structures were celiac artery, body and head of pancreas, porta hepatis, and splenic hilum (**B–D**). Three-dimensional conformal irradiation fields (**E** and **F**) were designed to include the primary tumor (red) with at least 5-cm margins of esophagus proximally and stomach distally (to include potential submucosal tumor spread) plus nodal volumes (periesophageal and celiac, as per Table 79-12; decision was made to also include porta hepatis, suprapancreatic and splenic hilar nodes in view of the documented gastrohepatic nodal disease [also shown in red]). Lateral fields (**F**) were used as a component of treatment for purpose of sparing heart and spinal cord. The patient subsequently had a laparoscopic esophagogastrectomy, mediastinal and celiac node dissection, pyloroplasty, and neck anastamosis (esophagogastrostomy) at Mayo Clinic Hospital in Arizona. Pathologic examination revealed a 3.5 × 2.5 × 1.0 cm ulcerated mass at the esophagogastric junction that microscopically consisted of paucicellular and acellular mucin and rare tumor cells floating in mucin with 0/20 positive nodes.

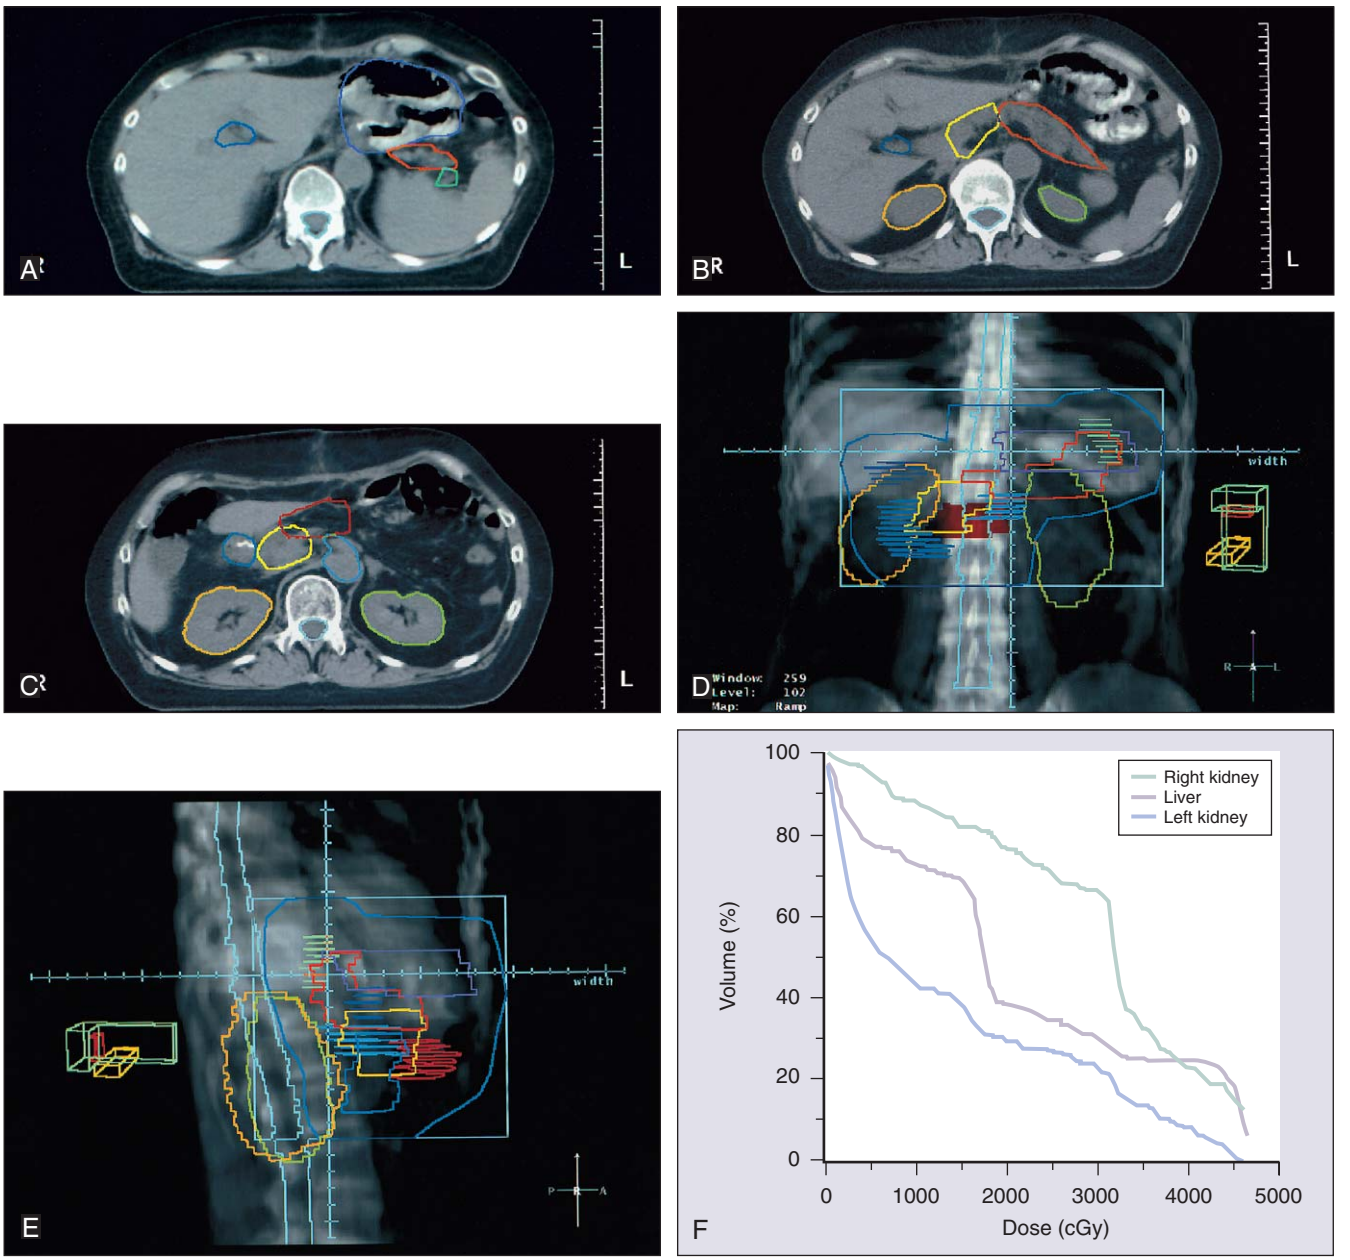

Figure 79-10 • Optimized postoperative irradiation fields for patient with T3N2 antral primary tumor (see Table 79-13). **A–C,** Structures of interest were delineated at time of CT simulation. **D** and **E,** Irradiation fields were designed with the aid of digitally reconstructed radiographs. A dose volume histogram was performed to be certain that appropriate volumes of liver and at least one kidney were excluded beyond certain dose levels. **A,** Gastric remnant (lavender) is demonstrated along with the body/tail of pancreas (red-orange), splenic hilum (light green), and porta hepatis (dark blue). **B,** Head of pancreas (yellow) and kidneys (*left*, yellow green; *right*, yellow orange) are delineated in addition to the body/tail of the pancreas. **C,** The celiac artery (light blue), antral tumor bed (red), and duodenum (medium blue) are shown together with the head of pancreas and kidneys. A four-field technique of AP (**D**), PA, and paired lateral fields (**E**) was designed. The fields included the gastric remnant (lavender), tumor bed (red), head of pancreas (yellow), first and second part of the duodenum (medium blue, cross-hatched), pertinent nodal volumes (perigastric, pancreaticoduodenal, porta hepatis [dark blue cross-hatched], suprapancreatic), and the optional nodal volume of splenic hilum (light green cross-hatched). **D,** AP field (field margins as shown in medium blue exclude approximately two thirds of the left kidney while including approximately 90% of the right kidney). Exclusion of the optional splenic hilar nodes would not have allowed any additional sparing of the left kidney in view of the adjacency of the gastric remnant and the splenic hilum. **E,** Right lateral field demonstrated exclusion of the spinal cord (turquoise) along with substantial portions of both kidneys. **F,** The dose volume histogram, combining dose from all four fields, demonstrated that the dose volume of 20 Gy included about 30% of the left kidney versus approximately 75% of the right kidney. With regard to the liver, about 30% receives a dose of 30 Gy and about 25% receives a dose of 35 Gy and 40 Gy.

Table 79-11 General Guidelines of Impact of T and N Categories on Inclusion of Remaining Stomach, Tumor Bed, Nodal Sites within Irradiation Fields

TN Stage	Remaining Stomach*	Tumor Bed	Nodes
T1–2 (not into subserosa) N0	N	N	N
T2N0–into subserosa†	Variable	Y	N
T3N0	Variable	Y	N
T4N0	Variable	Y	Variable
T1–2N+	Y	N	Y
T3–4N+	Y	Y	Y

*Inclusion of the remaining stomach is preferable in most patients if two thirds of one kidney can be excluded. This is dependent on the extent of surgical resection and uninvolved margins (in cm).

†Posterior wall T2N0 lesions, or those that extend beyond muscularis propria, especially tumors located in the proximal or distal stomach, are at risk for local relapse. In addition, patients with low-stage disease with close or positive surgical margins should be considered for treatment to the tumor bed.

From Tepper JE, Gunderson LL: Radiation treatment parameters in the adjuvant postoperative therapy of gastric cancer. Semin Radiat Oncol 2002;12:187.

has a high propensity of spread to nodes along the greater and lesser curvature, although they are most likely to spread to those sites in close anatomic proximity to the primary tumor mass.

Recently, guidelines for defining the clinical target volume for postoperative radiation fields have been developed based on location and extent of the primary tumor (T category) and location and extent of known nodal involvement (N category).[136,137] Table 79-11 presents general guidelines on the impact of T and N categories on inclusion of the remaining stomach (gastric remnant), tumor bed and nodal sites, and Tables 79-12 and 79-13 present treatment guidelines based on TN stage for two of the four primary sites (esophagogastric junction, proximal, mid-, and distal stomach). In general, for individuals with node-positive disease there should be wide coverage of tumor bed, remaining stomach, resection margins, and nodal drainage regions. For node-negative disease, if there is a good surgical resection with pathologic evaluation of at least 10 to 15 nodes, and there are wide surgical margins on the primary tumor (at least 5 cm), treatment of the nodal beds is optional. Treatment of the remaining stomach should depend on a balance of the probable normal tissue morbidity and the perceived risk of local relapse in the residual stomach.

LOCALLY ADVANCED DISEASE (BORDERLINE RESECTABLE, UNRESECTABLE, AND RESIDUAL)—TREATMENT AND RESULTS

The term locally advanced disease has different interpretations depending on the author and institution. In our institution and for the purposes of this chapter, this term refers to primary cancers that the surgeon would not expect to resect with negative pathologic margins (i.e., locally unresectable for cure as determined at surgical exploration or as defined preoperatively with CT scan, EUS, laparoscopy, or other studies; locally recurrent cancers with no evidence of metastasis). Other authors use the term also to include lesions that are completely resected but have high-risk factors for local recurrence or distant metastasis (nodal involvement, extension beyond gastric wall, or both).

Surgical Aspects

The extent of the surgical procedure must be tempered by the knowledge that cure is at best improbable. Patients with symptomatic obstruction, hemorrhage, and ulceration, and the rare patient with perforation can be successfully relieved of symptoms by even a limited gastric resection. Radical subtotal or total gastrectomy may be indicated in some patients whose cancers cannot be completely resected with negative pathologic margins for symptomatic palliation. Our own results with total gastrectomy in advanced gastric cancer showed good quality of life when this procedure was indicated for bulky or proximal malignancies, but symptom relief was less likely for patients

Table 79-12 Impact of Site of Primary Lesion and TN Category on Irradiation Treatment Volumes for the Gastroesophageal Junction: General Guidelines

Site or Primary and TN Category	Remaining Stomach	Tumor Bed Volumes*	Nodal Volumes	Tolerance Organs or Structures
GE junction	If allows exclusion of 2/3 R kidney	T-category dependent	N-category dependent	Heart, lung, spinal cord, kidneys, liver
T2N0 with invasion of subserosa	Variable dependent on surgical pathologic findings†	Medial left hemidiaphragm; adjacent body of pancreas	None or perigastric, periesophageal‡	
T3N0	Variable dependent on surgical pathologic findings†	Medial left hemidiaphragm; adjacent body of pancreas	None or perigastric, periesophageal, mediastinal, celiac‡	
T4N0	Preferable but dependent on surgical pathologic findings†	As for T3N0 plus site(s) of adherence with 3- to 5-cm margin	Nodes related to site of adherence, ± perigastric, periesophageal, mediastinal, celiac	
T1–2N+	Preferable	Not indicated for T1, as above for T2 into subserosa	Periesophageal, mediastinal, proximal perigastric, celiac	
T3–4N+	Preferable	As for T3, T4N0	As for T1–2N+ and T4N0	

*Use preoperative imaging (CT, barium swallow), surgical clips, and postoperative imaging (CT, barium swallow).

†For tumors with wide (>5 cm) surgical margins confirmed pathologically, treatment of residual stomach is optional, especially if this would result in substantial increase in normal tissue morbidity.

‡Optional node inclusion for T2–3N0 lesions if adequate surgical node dissection (D2 dissection) and at least 10–15 nodes examined pathologically.

From Tepper JE, Gunderson LL: Radiation treatment parameters in the adjuvant postoperative therapy of gastric cancer. Semin Radiat Oncol 2002;12:187.

Table 79-13 Impact of Site of Primary Gastric Lesion and TN Stage on Irradiation Treatment Volumes—Antrum/Pylorus/Distal Third of Stomach: General Guidelines

Site or Primary TN Category	Remaining Stomach	Tumor Bed Volumes*	Nodal Volumes	Tolerance Organs or Structures
Pylorus/distal third stomach	Yes but spare 2/3 of one kidney, usually left	T-category dependent	N-category dependent	Kidneys, liver, spinal cord
T2N0 with invasion of subserosa	Variable dependent on surgical pathologic findings†	Head of pancreas (± body), 1st and 2nd duodenum	None or perigastric; optional pancreaticoduodenal, porta hepatis, celiac, suprapancreatic‡	
T3N0	Variable dependent on surgical pathologic findings†	Head of pancreas (± body), 1st and 2nd duodenum	None or perigastric; optional pancreaticoduodenal, porta hepatis, celiac, suprapancreatic‡	
T4N0	Preferable but dependent on surgical pathologic findings†	As for T3N0 plus site(s) of adherence with 3- to 5-cm margin	Nodes related to site(s) of adherence ± perigastric, pancreaticoduodenal, porta hepatis, celiac, suprapancreatic	
T1–2N+	Preferable	Not indicated for T1	Perigastric, pancreaticoduodenal, porta hepatis, celiac, suprapancreatic; optional, splenic hilum	
T3–4N+	Preferable	As for T3, T4N0	As for T1–2N+ and T4N0	

*Use preoperative imaging (CT, barium swallow), surgical clips, and postoperative imaging (CT, barium swallow).

†For tumors with wide (>5 cm) surgical margins confirmed pathologically, treatment of residual stomach is optional if this would result in substantial increased normal tissue morbidity.

‡Optional node inclusion for T2–3N0 lesions if adequate surgical node dissection (D2 dissection) and at least 10–15 nodes examined pathologically.

Tepper JE, Gunderson LL: Radiation treatment parameters in the adjuvant postoperative therapy of gastric cancer. Semin Radiat Oncol 2002;12:187.

with linitis plastica.[140] Although resection of adjacent organs should be undertaken if all the gross tumor can be removed, it is rarely justified if residual tumor would remain.[56,57] If sites of residual disease or adherence are judiciously marked with clips, postoperative irradiation plus chemotherapy can be delivered with greater accuracy.

Primary Irradiation or Chemoradiation

Although some patients with no resection have long-term survival using irradiation alone or plus chemotherapy, this approach is not a viable alternative to surgical resection plus adjuvant therapy as indicated, because the initial bulk of disease and the limited tolerance of the stomach and surrounding organs prevent a suitable therapeutic ratio between cure and complications. When locally advanced disease is diagnosed before surgical exploration, preoperative radiation would preferably be used in combination with chemotherapy (concomitant and maintenance), followed by restaging and an attempted resection of all gross primary and lymph node disease.

Irradiation Alone

The available literature suggests that adenocarcinoma of the stomach is radiation responsive. Wieland and Hymmen[141] used 60 Gy when feasible (1.5 to 2.0 Gy daily) with 11% (9 of 82) 3-year and 7% (5 of 72) 5-year survival rates. Takahashi[142] compared historical control subjects with patients who were unresectable or who had palliative procedures and received postoperative radiation therapy (unknown if chemotherapy also used). The average survival time for the irradiated group was 9 to 10 months longer, with 74% 1-year (32 of 43) and 27% 2.5-year survival rates (12 of 43). Takahashi and Abe[116] reported 15% 5-year survival rate with a single dose of IORT (28–35 Gy) in a group of 27 patients with stage IV disease. Three of the four long-term survivors had residual disease after resection. In the same study, 18 stage IV patients were randomized to a surgery-alone control arm; the 5-year survival rate was 0%.

Irradiation Plus Chemotherapy

Most early reports of combined irradiation and chemotherapy for gastric cancer involved patients with residual or unresectable primary disease, and most phase III trials in this setting show an advantage for combined-modality treatment over single-modality treatment. In a randomized series from the Mayo Clinic,[143] 5-FU was used during the first 3 days of irradiation in one half of the patients (irradiation, 35–37.5 Gy in 4 to 5 weeks; 5-FU, 15 mg/kg for 3 days, week 1 of irradiation). For the combined-treatment group, mean and overall survival was improved (13 months vs. 5.9 months and 3 of 25 patients or 12% vs. 0 of 23 patients surviving over 5 years; Table 79-14). In a randomized study by the GITSG,[144,145] the combination of irradiation and 5-FU followed by maintenance 5-FU plus MeCCNU resulted in statistically superior long-term survival when compared with 5-FU plus MeCCNU alone (3- and 4-year survival rates of 18% vs. 6% to 7%; $P < 0.05$). GITSG performed a second trial in which combined irradiation plus chemotherapy did not produce a survival advantage when compared with chemotherapy alone.[146] Because 46% of patients on the combined arm either did not receive full-course irradiation or had a major deviation in the delivery of the irradiation, the results are difficult to interpret. In a randomized European Organization for Research and Treatment of Cancer (EORTC) trial of external irradiation with or without 5-FU, residual disease after resection was identified in 22 patients.[147] The three long-term survivors (14%) received both irradiation and 5-FU.

Data from nonrandomized single-institution or group analyses also suggest that the combination of external irradiation and chemotherapy may have an impact on disease control and survival. In published series from the Mayo Clinic[148] and MGH,[123] long-term survival of 10% or more was demonstrated in patients who received external irradiation plus chemotherapy following subtotal surgical resection with residual disease (MGH) or with unresectable lesions. In a University of Pennsylvania analysis[126] of individuals with unresected adenocarcinoma of the esophagogastric junction or esophagus,

Table 79-14 Unresectable or Residual Gastric Cancer: Treatment Results

Group or Institution	Treatment Arms	EBRT Dose/ Schedule (Gy)	Chemotherapy	No. of Patients	Results (Failure Patterns and Survival)
RANDOMIZED					
Mayo Clinic[143]	EBRT ± 5-FU	35–40 Gy; 9–12 Gy/wk	5-FU 15 mg/kg, d 1–3, wk 1 EBRT	48	Increased SR for EBRT + 5-FU with mean SR 13 vs. 5.9 mo and 3/25 (12%) vs. 0/23 5-yr SR

For other abbreviations, see footnotes to Table 79-7 and 79-8.

*Treatment method based on date of hospitalization.

local control was better with combined- versus single-modality treatment (irradiation, 1 of 23 or 4%; chemotherapy, 0 of 8; irradiation plus chemotherapy, 11 of 21 or 52%). Median survival time with the combined-modality treatment was 10 months compared with 5 months for irradiation alone. In a Mayo Clinic North Central Cancer Treatment Group (NCCTG) dose escalation pilot study, external irradiation was combined with 5-FU plus low-dose leucovorin (400 mg/m^2 and 20 mg/m^2, respectively, for 3–4 days, weeks 1 or 1 plus 5 of irradiation).[149] Two of six patients with locally advanced gastric cancer were alive and free of disease beyond 3 years.

Published analyses from both GITSG and MGH suggest an improvement in survival if partial resection with gross residual disease or gross total resection with microscopic residual can be accomplished. In the GITSG series 3-year survival rate was about 25% as compared with 10% in partially resected versus unresected patients.[144,145] In the MGH analysis, median survival with irradiation plus chemotherapy was 24 months for microscopic residual, 15 months with gross residual, and 14 months in unresected patients.[123] Four-year survival rate was 0% in unresected patients as compared with 10% in those with residual disease after maximal resection.

In the most recent Mayo Clinic analysis of irradiation alone or plus chemotherapy for gastric or esophagogastric cancers, an improvement in median survival was also suggested for patients with gross total resection but microscopic residual disease when compared with higher risk subsets of patients.[150] In this analysis, the results of irradiation or chemoirradiation therapy were evaluated in 87 patients with either locally advanced primary or locally recurrent adenocarcinoma of the stomach or gastroesophageal junction treated from July 1980 through January 1996 at the Mayo Clinic. Of those with primary lesions, 28 had unresectable disease, and 39 had resection but residual disease (microscopic, 28; gross, 10). An additional 21 presented with a local or regional relapse with no evidence of abdominal (liver, peritoneal) or extra-abdominal metastasis (lung, other). Chemotherapy with 5-FU (alone or plus leucovorin) was given during or following EBRT in 75% of the individuals with microscopic residual disease and 92% of the other subgroups (concomitant with EBRT in 84%). An intraoperative electron radiation therapy (IOERT) supplement to EBRT was given in 13 patients. Median survival time in primary cancer patients with microscopic residual was 16.7 months compared with 9.2 months in patients with subtotal resection and gross residual or 12 months in those with unresectable disease. Patients who presented with local or regional relapse had a median survival of 10 months.

Prognostic factor analyses showed that long-term survival seemed slightly poorer in patients who had resection before irradiation or CRT in the latest Mayo Clinic analysis. Actuarial 4-year survival rate was 0% versus 9% in individuals with gross residual disease after partial resection (1 of 11 patients alive with no evidence of disease 2 years after treatment), 9% in those with microscopic residual after gross total resection, and 18% in patients with unresectable primary or locally recurrent cancers. The survival trends may be a reflection of both treatment sequence and higher irradiation dose; 12 of 13 patients with EBRT plus IOERT had unresectable primary or locally recurrent cancers. In the 21 patients with locally or regionally recurrent cancers, irradiation dose greater than 54 Gy had a trend for improved survival (median survival, 25.6 vs. 5.5 months; $P = 0.06$). If patients with microscopic residual disease are excluded, an increase in the number of cycles of chemotherapy seemed to correlate with an improvement in median survival (median survival 5.2 months with less than two cycles, 11.5 months with two or three cycles, and 14.5 months with four or more cycles; $P = 0.014$).

Although problems with excess toxicity from combined CRT were encountered in the GITSG study,[144] such problems were minimal or nonexistent in the MGH series of 46 patients.[123] In the latter series, 43 of 46 patients received both irradiation and chemotherapy, but shaped radiation portals and single-fraction size of 1.8 Gy or less were used.

Neoadjuvant and Perioperative Chemotherapy

The use of adjuvant preoperative (neoadjuvant) chemotherapy has been less well studied than has adjuvant postoperative therapy. Due to the frequent inability of adjuvant postoperative systemic therapy to prolong survival in surgically managed gastric cancer, several investigators have pursued the approach of neoadjuvant (preoperative) chemotherapy in an attempt to increase resectability and improve survival. These studies involve a mix of patients including those determined surgically or clinically unresectable for cure, those with "locally advanced" disease (as defined by the study authors), and those with clinically operable lesions. Some patients were staged clinically by a variety of methods, making it difficult to know which patients were truly resectable before neoadjuvant treatment.

Unresectable Disease

Seven different trials have assessed the potential benefit of preoperative chemotherapy for patients with initially "unresectable" stomach cancer.[151–158] Each of the trials was small in size. The seven trials combined included 155 patients and demonstrated that preoperative chemotherapy in this subset of patients was feasible and resulted in clinical response rates of 30% to 68%. Curative resections were possible in as few as 8% or as many as 73% of patients. This wide range of resectability probably reflects patient selection rather than superiority of any one regimen. Unfortunately, pathologic complete responses (CRs) were uncommon except for the Wilke trial (pathologic CR in 5 of 34 patients or 15%).[151]

Borderline Resectable and Locally Advanced Disease

Three phase II studies have tested the use of preoperative systemic treatment in individuals defined by the study authors as having "locally advanced" stomach cancer.[159–161] Presumably this represents a mix of clinically resectable and unresectable or borderline resectable patients. Resectability rates ranged from 60% to 77%, which seems to be higher than for patients with unresectable cancers. It is likely that more patients in these trials were potentially (borderline) resectable before neoadjuvant chemotherapy.

Kang and associates have presented an updated report of the only phase III trial of neoadjuvant chemotherapy in locally advanced or borderline resectable gastric cancer.[162] In the trial, 107 patients were randomized to receive two to three cycles of etoposide, 5-FU, and cisplatin followed by surgery versus surgery alone. Of the 53 patients randomized to preoperative treatment, 47 (89%) were explored and 37 (70%) were resected for cure. A 7% complete pathologic response rate was noted. In the control group of 54 patients, 100% were explored and 61% curatively resected. Median survival was 43 versus 30 months in favor of neoadjuvant treatment, but this difference did not reach statistical significance ($P = 0.114$).

Resectable Disease

Several investigators have examined the role of neoadjuvant chemotherapy in patients with clinically resectable disease. Ajani and colleagues have performed two phase II studies of preoperative chemotherapy in this setting.[163,164] In their first study, 25 patients were treated with two cycles of etoposide, 5-FU, and cisplatin preoperatively.[163] Three cycles were administered postoperatively if a positive response to neoadjuvant treatment could be detected endoscopically or radiographically. All 25 patients underwent surgery, and 72% were resected for cure. No pathologic complete responses were seen, and the median survival was 15 months overall. Following the report of Wilke and coworkers of pathologic complete response to chemotherapy with epirubicin, doxorubicin, and cisplatin (EAP),[151] Ajani and associates treated 48 potentially curable patients with three cycles of preoperative EAP and two cycles following surgery if a response to preoperative treatment was observed.[164] Of the 85% of patients who underwent exploration, 77% were resectable. Although 12% of patients achieved a complete clinical response, no pathologic complete responders were seen. The overall median survival was 15.5 months. Unfortunately, in this group of resectable patients with potentially smaller tumor burdens, the impressive results obtained with neoadjuvant EAP in Wilke's study could not be reproduced.

One of the few randomized trials to assess the potential benefit of preoperative chemotherapy to surgery alone in potentially resectable patients failed to show any benefit in outcomes.[165,166] In this Dutch trial, 59 patients were randomized to either FAMTX followed by surgery ($N = 29$) or surgery alone (30). Patients with T1 tumors, tumors arising from the gastric cardia, or evidence of distant metastases were excluded from participation. The study was closed early as a result of poor accrual. No benefit was seen with the addition of FAMTX before surgery (Table 79-15).

Preoperative Systemic and Postoperative Intraperitoneal Chemotherapy

Recently, other investigators have examined the usefulness of combining preoperative chemotherapy and postoperative treatment with intraperitoneal chemotherapy in view of the high peritoneal failure rate following resection of gastric cancer. Initial attempts to use intraperitoneal chemotherapy alone in the adjuvant setting did not show benefit.[112,113,167–171]

Kelsen and associates studied 56 patients with high-risk (clinical stage T3–4) gastric cancer as determined by EUS.[169] Patients received

three cycles of neoadjuvant FAMTX. Following surgery, patients were treated with intraperitoneal 5-FU and cisplatin along with infusional 5-FU for three cycles. Fifty (89%) patients were explored and 34 (61%) resected for cure. When the initial EUS result was compared to the final pathologic staging, 51% of these patients were downstaged. No complete pathologic responses were observed, and the median survival was 15.3 months.

Crookes and colleagues updated their promising results with a somewhat similar trial design.[170] Fifty-nine potentially resectable patients received two cycles of 5-FU, leucovorin, and cisplatin preoperatively, and two cycles of intraperitoneal 5-FUDR and cisplatin were given postoperatively to resected patients. Ninety-five percent of the patients underwent exploration, and 68% had a curative resection. The rate of pathologic CR was only 9%, but the median survival is estimated to be an impressive 52 months.

In a more recent phase II trial, 32 evaluable patients with locally advanced but potentially resectable stomach cancer received two cycles of systemic cisplatin and irinotecan.[171] Twenty-nine patients were able to undergo surgery, and 25 had an R0 resection. Patients with resection subsequently received two cycles of intraperitoneal FUDR and cisplatin. Preoperative chemotherapy led to downstaging in 50% of the patients. With a median follow-up of 28 months, 10 (31%) were alive without relapse, 4 (13%) were alive with relapse, and the remainder had died from either disease (41%) or other causes (16%). Of the 25 patients with an R0 resection, none had a local relapse. A phase III trial of this approach has not yet been reported.

Summary

Preoperative systemic treatment may have certain advantages, such as the potential of reducing tumor bulk and increasing resectability. Micrometastatic disease may also be addressed earlier using this approach. Potential negatives to preoperative treatment include toxicity, delay in definitive therapy, and possibly increased surgical morbidity and mortality rates.

The high response rates achieved with neoadjuvant chemotherapy are of interest, and this form of treatment will undoubtedly be the subject of further investigation as new and more active systemic therapies are developed. Thus far, however, no survival advantage has been demonstrated in phase III trials, and neoadjuvant chemotherapy should be considered investigational. Resectability rates in neoadjuvantly treated patients seem higher than the median rate of 40% from several surgical studies, but the patients in these studies are highly selected. Except for the trials in which some patients were unresectable on the basis of prior exploration, the successful operations in these reports may not have been influenced by neoadjuvant chemotherapy. In general, pathologic CR rates are low (≤15%), and no proof exists that clinically staged patients are made more resectable by such treatment. The impact of preoperative systemic treatment on survival is even less clear. The one randomized trial that has been reported shows a nonsignificant improvement in survival for neoadjuvant treatment in borderline resectable/locally advanced disease.[163] Newer technologies such as EUS may identify patients who will do poorly with standard therapy alone and would be reasonable candidates for future neoadjuvant studies. The reports of combined systemic and intraperitoneal approaches are provocative and may warrant future phase III trials, because only through such studies will any impact on survival be determined.

Perioperative Chemotherapy

The use of perioperative chemotherapy was recently addressed in a phase III trial referred to as the MAGIC (Medical Research Council Adjuvant Gastric Infusional Chemotherapy) trial.[172] A total of 503 patients with resectable adenocarcinoma of the stomach (372 patients), gastroesophageal junction (58 patients), or lower esophagus (73 patients) were randomized to either surgery alone or to perioperative chemotherapy with three cycles of epirubicin, cisplatin, and continuous-infusion 5-FU (ECF) before surgery and three cycles of ECF after surgery. With a median follow-up of 4 years, patients randomized to receive perioperative chemotherapy had significantly improved OS when compared with patients randomized to receive surgery alone (5-year OS 36% vs. 23%; HR for death 0.75; 95% CI 0.60–0.93; $P = 0.009$).

In general the use of ECF was well tolerated in the preoperative setting. The incidence of overall postoperative complications was similar (45.7% vs. 45.3%) as well as 30-day mortality rates (5.6% vs. 5.9%). Of the 237 patients who started chemotherapy, 215 completed the planned three cycles of preoperative therapy. Of the 209 patients who went to surgery, 137 started postoperative chemotherapy. The most common reasons for not starting chemotherapy included disease progression, early death, postoperative complications, and patient choice. Overall 103 patients completed all six cycles of chemotherapy.

Preoperative Chemoradiation

Several series of neoadjuvant chemotherapy for initially unresectable have demonstrated high rates of local-regional relapse in patients who were resected after the neoadjuvant chemotherapy. In the neoadjuvant EAP phase II trial reported by Wilke and associates, 15 of the 34 initially unresectable patients (44%) could subsequently be resected, and 5 of 15 were pathologic complete responders (15% of the original 34).[151] Median survival was 18 months for the entire study group. In an update of these data at an international gastrointestinal cancer symposium in Germany, results were reported in a series of 21 patients who had total resection after EAP chemotherapy for locally unresectable disease.[173] Of 21 patients 14 had relapsed, and 11 of 14 had a local-regional component of disease (79% of relapses, 52% of group at risk). Plukker and coworkers studied 20 patients with unresectable gastric cancer.[153] Seventeen of the patients had undergone laparotomy, and three patients were deemed unresectable on the basis of CT imaging. After receiving up to four courses of sequential 5-FU and high-dose methotrexate, 14 patients (70%) underwent attempted resection. Eight of 20 patients (40%) were found to be resectable for cure, but subsequent local relapse occurred in five of eight.

In view of the high incidence of local-regional relapse in several series of patients resected after neoadjuvant chemotherapy for initially unresectable lesions, irradiation would be logical to incorporate into the study design of trials for patients with borderline or unresectable cancers. As previously noted, the phase III study by Walsh and colleagues compared preoperative 5-FU and cisplatin plus radiation therapy followed by surgery ($N = 58$) versus surgery alone ($N = 55$) in individuals with esophageal and gastric cardia adenocarcinoma.[132] Pathologic CR was found in 13 of 52 patients (25%) who had surgery after preoperative CRT. Both median and long-term survival were improved with the preoperative treatment ($P = 0.01$). Thirty-five percent of the patients had lesions of the gastric cardia; however, there were more of these patients in the control group (42% vs. 28%). The positive esophagus/gastric cardia trial by Walsh and associates and high pathologic CRs in similar pilot studies with gastric cancer[132,174,175] led to a U.S. GI Intergroup confirmatory trial of neoadjuvant combined-modality therapy in carcinoma of the esophagus and gastroesophageal junction. Although this study was stopped because of inadequate accrual, a survival advantage was demonstrated for trimodality treatment versus the surgery-alone control arm ($P = 0.008$).[133]

PALLIATION OF THE INCURABLE PATIENT

This section is limited to discussion of patients with documented hematogenous or peritoneal metastasis. Patients with locally unresected disease are occasionally cured and were discussed in the previous section (5-year survival rate of 5% to 20%).

Surgery

Surgical intervention in the patient with metastatic gastric cancer requires sound judgment. The underlying health and function (performance status) of the patient, the estimated duration of patient survival, and the nature of the symptoms must all be taken into account before deciding to proceed with an operation. Resection for palliation is generally better than bypass or intubation in appropriate selected patients, leading to better symptomatic relief and often longer survival.[176] Laparoscopic procedures, including subtotal and total gastrectomy, are feasible and are becoming increasingly popular. Obstructing lesions may be resected with excellent palliation, but endoluminal stents, endoscopic laser treatments, or gastrostomy tube placement should be considered for poor operative candidates. Although significant hemorrhage from an ulcerating or necrotic polyploid tumor may be temporarily controlled by endoscopic techniques, stabilization and urgent surgical intervention should be undertaken when appropriate. A perforated gastric cancer usually presents as an emergency and may be unrecognized preoperatively. Aggressive treatment with gastric resection should be carried out in the fit patient, but pain control and hydration alone are preferable for the moribund or unfit patient.

Irradiation Alone or Plus Chemotherapy

If palliative resection is not indicated in symptomatic patients with metastases, a shortened course of irradiation alone or plus concurrent 5-FU-based chemotherapy could be used (37.5 Gy in 15 fractions over 3 weeks), to be followed by systemic treatment. Patients who have proximal lesions with esophageal obstruction may be candidates for laser ablation instead of irradiation. If laser is successful in overcoming obstruction, patients could proceed directly to treatment with chemotherapy.

Chemotherapy

Overview

Several clinical trials assessing the benefit of chemotherapy have been performed, including several that compared *chemotherapy* to *best supportive care*. Six trials assessed the potential benefit of early forms of chemotherapy for advanced gastric cancer compared to an untreated control group.[177–182] In the largest of these trials 193 patients were randomized to either 5-FU + MeCCNU or to no treatment.[178] The median survival time was 22 weeks for control subjects and 25 weeks for those who received at least one 6-week course of chemotherapy. Patients who died in the first 2 months were excluded from these figures. Median survival, estimated from survival curves, was in the 8- to 10-week range for all the patients, with no apparent difference between the two groups. It is of interest that a quality-of-life analysis was done in this trial and that it was published in 1978. Pain, well-being, and performance status were assessed at 8 and 16 weeks. Results of this quality-of-life analysis slightly favored the patients treated with chemotherapy, but few patient results were available for the 16-week time point. Subsequent trials with chemotherapy versus best supportive care have in general demonstrated a trend toward improved survival and quality of life with the use of chemotherapy.[179–182]

The initial trials with chemotherapy reported response rates of 10% or higher and included agents such as 5-FU, mitomycin C, doxorubicin, epirubicin, cisplatin, BCNU (carmustine), methotrexate, etoposide, chlorambucil, and hydroxyurea. More recently a variety of new chemotherapy drugs have become available. Some have shown promising response rates in advanced gastric cancer, as discussed in the following sections, including docetaxel, irinotecan, and oxaliplatin. Multiple phase II trials of combination chemotherapy have built upon the promising activity seen with a variety of single agents. Many of the combinations have shown promising activity based on initial results, only to be shown to be less active and more toxic in subsequent phase II and III trials. It has therefore been important to interpret the results of initial phase II trials with caution. With some of the more recent combinations showing promise, using drugs such as docetaxel or oxaliplatin, older regimens such as FAM, FAMTX, and the combination of etoposide, leucovorin, and 5-FU are now less commonly used.

Fluoropyrimidines

A number of trials with 5-FU have been performed over the last several decades culminating in a recent series of phase III trials (Table 79-16).[183–185] In a trial that mixed 254 patients with either adenocarcinoma, squamous cell carcinoma, or undifferentiated carcinoma of the esophagus or stomach, patients were randomized to either protracted-infusion 5-FU or protracted-infusion 5-FU with mitomycin C.[183] The overall response rates were 16% and 19%, respectively, with median survivals of 6.3 and 5.3 months ($P = 1.0$), respectively. In a phase III trial performed in Japan, 280 patients with advanced stomach cancer were randomized to receive one of three protocols: protracted-infusion 5-FU, continuous-infusion 5-FU combined with cisplatin, or the oral fluoropyrimidine UFT combined with mitomycin C.[184] This trial also showed no advantage of the two combinations over the benefits obtained with 5-FU alone. In a third phase III trial the potentially promising combinations of etoposide + leucovorin + 5-FU, infusional 5-FU + cisplatin, and FAMTX were compared.[185] A total of 399 patients with advanced carcinoma of the stomach were randomized. All three regimens showed modest activity with no significant difference in the primary outcome measures.

While these 5-FU-based phase III trials were under way a variety of phase II trials and several additional phase III trials were performed evaluating potentially more promising agents or combinations.

Taxanes

Taxanes have been evaluated in a variety of phase II trials. Two North American trials of single-agent paclitaxel have been reported. Paclitaxel (210 mg/m^2 over 3 hours every 3 weeks) as a single agent in previously untreated patients with metastatic gastric cancer provided a response rate of 11% and a median survival of 5.8 months.[186] In a separate trial, assessing two different infusion schedules (200 mg/m^2 over 3 hours vs. 24 hours every 3 weeks), an overall response rate of 17% was seen with a higher rate occurring in those receiving a 24-hour infusion. The median survival in this trial was 8 months.[187] In several trials performed in Japan, using paclitaxel (210 mg/m^2 over 3 hours every 3 weeks) as a single agent in the treatment of previously untreated patients with advanced gastric cancer, response rates of 23% and 28% were reported with a median survival of 7.7 and 11.2 months.[188–190] Subsequent trials have assessed paclitaxel in combination with other chemotherapy agents. Phase II trials assessing paclitaxel in combination with cisplatin have given response rates of 33% to 46%, with median survivals of 8.9 to 13.8 months.[191,192] The use of low-dose paclitaxel in combination with cisplatin did not seem to alter outcome, with a response rate of 44% and overall survival of 12.1 months in a phase II trial performed in Korea.[193]A response rate of 33% and a median survival of 7.5 months have been reported in a small phase II trial with paclitaxel and carboplatin.[194] Paclitaxel in combination with 5-FU and leucovorin has been assessed in several phase II trials. In two trials using a 24-hour infusion of 5-FU response rates of 46% to 48% and median survivals of 11 months were reported.[195,196]

Docetaxel as a single agent has been evaluated in several phase II trials. In several single-institution trials of docetaxel 100 mg/m^2 every 3 weeks, a response rate of 17% and 24% was reported along with a median survival of 7.8 months in one of the trials.[197,198] Other trials assessed lower doses of docetaxel (60 mg/m^2 or 75 mg/m^2) and have reported similar results with response rates of 18% to 24% and a median survival of 11 months with the 75-mg/m^2 dose.[199–201]

Subsequent trials have evaluated docetaxel in combination with several other chemotherapy agents. The combination of docetaxel,

5-FU, and leucovorin has been evaluated in several phase II trials from Europe and Korea. This combination led to a response rate of 26% to 28% and a median survival of 7.7 to 9.7 months.[202–204] In a randomized phase II trial the combination of docetaxel and 5-FU was compared to paclitaxel and 5-FU.[205] Similar response (33% and 42%) and median survival (9.3 and 9.9 months) rates were reported for the two regimens. Several trials have assessed the combination of capecitabine and either weekly or every-3-week docetaxel and reported response rates of 39% to 60% and median survivals of 9.4 to 12 months.[206–208]

The combination of docetaxel and cisplatin has been evaluated in several clinical trials as either the two-drug combination or in combination with other chemotherapy agents. With the two-drug combination in phase II trials the reported response rate was 28% to 46% and median survival of 10.4 to 11.5 months.[209–212] Given the apparent promising activity of this combination, other trials explored the added benefit of 5-FU and reported response rates of 40% to 43% and median survivals of 9.0 to 9.7 months.[213,214] A multicenter randomized phase II trial, involving 158 patients, assessed docetaxel and cisplatin with or without 5-FU as potential support for a phase III trial.[215] In this trial the combination of docetaxel and cisplatin gave a response rate of 26% and a median survival of 10.5 months. The addition of 5-FU increased the response rate to 43%; however, the median survival was only 9.6 months.

In a subsequent phase III trial (see Table 79-16) the combination of docetaxel, cisplatin, and 5-FU was compared to cisplatin and 5-FU.[216] Overall survival was significantly longer with docetaxel, cisplatin, and 5-FU ($P = 0.02$). The response rate was also higher with this combination (69% vs. 59%, $P = 0.01$). However, the combination of docetaxel, cisplatin, and 5-FU was also more toxic, with 69% of patients developing treatment-related grade 3 or 4 adverse events compared with 59% of patients receiving cisplatin and 5-FU. Neutropenia and neutropenic fever were both significantly higher with the three-drug combination.

Platinums

Platinum-containing regimens have been the focus of many different trials. Many of the trials conducted in the past focused on the use of cisplatin, whereas more recent trials have begun to evaluate the potential use of oxaliplatin. The combination of 5-FU and cisplatin has been evaluated in several trials and provided a response rate of 41% to 45% and a median survival of 7 to 11 months.[217–221] Given the apparent activity of this combination, a variety of phase III trials have compared 5-FU and cisplatin to other regimens (see Table 79-16). The response rates in these larger trials were 20% to 51%, whereas the median survival was 7.2 to 8.6 months.[216,222–224]

Building on this two-drug combination a variety of trials have assessed the combination of either 5-FU, cisplatin, and doxorubicin (FAP) or EAP. The FAP combination resulted in response rates of 31% to 50% and median survivals of 9 to 12 months in phase II trials.[225–228] A phase III study, however, could not show an advantage for FAP over 5-FU alone.[229] Less favorable outcomes were noted for the combination of EAP in phase II trials.[230,231] This combination also caused significant toxicity, with a toxic death rate averaging 12%. The combination of cisplatin, epirubicin, leucovorin, and 5-FU (PELF) was compared to FAMTX in a randomized phase III trial. Although both the overall and CR rates with PELF were significantly higher (overall, 39% vs. 22%; CR, 13% vs. 2%), only a nonsignificant improvement in overall survival was seen with PELF (see Table 79-16).[232]

The ECF combination has been recognized as a potentially more promising cisplatin-containing regimen. Based on the results of phase II trials, this regimen showed activity at least comparable to other platinum regimens, but with less toxicity.[233–236] A subsequent phase III trial of patients with previously untreated locally advanced or metastatic gastroesophageal cancer compared ECF to the combination of FAMTX.[237] The overall response rate (45% vs. 21%; $P = 0.0002$) and median survival (8.9 vs. 5.7 months; $P = 0.0009$) were

both significantly higher with ECF. The global quality-of-life scores were also better in patients receiving ECF.

Both carboplatin and oxaliplatin have been evaluated as potential alternatives to cisplatin. Only limited trial data are available for carboplatin. Carboplatin as a single agent has minimal activity.[238,239] However, the combination of carboplatin and paclitaxel has a reported response rate of 33% and median survival of 7.5 months with only moderate toxicity.[194]

Oxaliplatin was initially developed for colorectal cancer but has been evaluated as a potential treatment option for gastric cancer when used in combination with 5-FU and other chemotherapy agents. Although the use of 5-FU and leucovorin alone result in response rates of 5% to 12% with short median survivals,[240,241] the addition of oxaliplatin seems to significantly improve response and overall survival. A variety of schedules using the combination of 5-FU, oxaliplatin, and leucovorin have been evaluated in phase II trials, including FUFOX, FOLFOX, and XELOX. These regimens have generally shown similar results with response rates of 38% to 65% and median overall survivals of 8.6 to 11.5 months.[22,242–247] No phase III trials have yet been reported using one of these combinations.

Given the potentially promising activity of ECF, as described previously, a recent phase III trial for gastroesophageal cancer was conducted to assess the potential benefit of replacing cisplatin with oxaliplatin and infusional 5-FU with capecitabine using a 2 × 2 design (see Table 79-16).[248] This trial enrolled 1002 patients from 61 centers, and the results have been presented in a meeting abstract. Using a noninferiority statistical design for the trial, the combination of epirubicin, oxaliplatin, and capecitabine (EOX) was shown to be the most active of the four regimens evaluated. Compared with ECF, patients receiving EOX had both an improved 1-year survival (46.8% vs. 37.7%) and a statistically improved median survival (11.2 months versus 9.9 months; HR, 0.80, 95% CI, 0.65–0.97).[249]

Oral Fluoropyrimidines

The recent use of oral fluoropyrimidines in gastric cancer has focused on capecitabine and S-1. As a single agent in previously untreated patients capecitabine provided an overall response rate of 23% using a 3-week treatment schedule in a trial performed in Japan.[250] OS was 10 months. Various combinations of capecitabine and other chemotherapy drugs, such as cisplatin or docetaxel, have been evaluated.[206,251–253] The majority of recent trials, including a phase III trial as described previously, have evaluated capecitabine as a potential replacement for 5-FU.

The drug S-1 is an oral fluoropyrimidine in which the 5-FU prodrug tegafur is combined with two 5-FU-modulating substances, 5-chloro-2,4-dihydroxypyridine (gimeracil), and potassium oxonate (oteracil), at a molar ratio of 1 : 0.4 : 1. The dose-limiting side effects of S-1 are primarily nonhematologic and mainly diarrhea, nausea, and vomiting. There is also a difference in metabolism of the tegafur component of S-1 in Asians and whites related to polymorphic differences in the *CYP2A6* gene.[254] This has led to different tolerable doses of S-1 in studies conducted in Asia compared with those conducted in Western populations. A variety of trials using S-1, alone or in combination with other chemotherapy drugs, have been performed in Asia, Europe, and North America. S-1 as a single agent has a reported response rate of 26% to 32%.[255] Based on the early evidence of activity, S-1 has been evaluated in combination with cisplatin in several phase II trials. In these trials a response rate of 49% to 55% and OS of approximately 11 months were reported.[256–258]

Irinotecan

The topoisomerase-I inhibitor irinotecan (CPT-11) has activity in gastric cancer, though limited as a single agent. In a phase II trial it provided a median survival of 6.4 months with a 14% response rate.[259] CPT-11 has been evaluated in combination with other potentially active chemotherapy drugs. In combination with docetaxel a response rate of 46% and OS of 8.2 months has been reported.[260] Similar response rates and OS have been reported for CPT-11 and cisplatin, CPT-11 and capecitabine, CPT-11 and mitomycin C, and CPT-11 and oxaliplatin.[261–264] The addition of the antiangiogenic agent bevacizumab to the combination of CPT-11 and cisplatin in a phase II trial did increase the response rate to 65% and the OS to 12.3 months.[265] The combination of CPT-11 with leucovorin and infusional 5-FU (FOLFIRI) in a randomized phase II trial also showed promising results, with a response rate of 40% and overall survival of 11.3 months.[266] Phase III trials with these combinations have not been reported.

Summary

In summary, it is clear that chemotherapy may result in response rates of up to 50% or more in selected groups of patients with advanced gastric cancer. There is now growing evidence from both recent phase II and III trials indicating that chemotherapy seems to prolong survival over what would be expected with best supportive care. In recent trials median survival times have begun to clearly increase, with subsequent improvement in outcome measures including overall survival for treated patients compared to what had been observed in the prior several decades of clinical trials. However, it is not clear that there yet exists a standard treatment for advanced gastric cancer. Investigation of new agents and combinations must continue, and any "new standards" should be tested in controlled clinical trials looking at survival, quality of life, and cost analysis endpoints.

THE FUTURE

Completely Resected Lesions

Many patients with gross complete resection of their gastric cancer are not cured with surgery alone. The final results of the British and Dutch multicenter trials evaluating the value of extended lymphadenectomy demonstrated that the procedure produced greater morbidity with no impact on survival. Because experienced surgeons have performed extended node dissection without significant increases in surgical morbidity or mortality rates,[61,64] use of the procedure is still reasonable in node-positive patients. Such patients will still be at high risk for local-regional and systemic relapse, however, and should receive postoperative CRT (Table 79-17). This philosophy is supported by the nonrandomized South Korea analysis by Kim and associates, which appeared to demonstrate an advantage in disease control and survival in 544 patients who received postoperative CRT following D2 resection versus the 446 surgery-alone patients (5-year OS, 57% vs. 51%, $P = 0.02$; 5-year RFS, 54.5% vs. 47.9%, $P = 0.016$).[163]

With regard to replacement postoperative CRT trials, the U.S. GI Intergroup replacement phase III randomized trial was designed to build on the positive results of INT 0116[129,130] by testing 5-FU infusion versus bolus 5-FU + leucovorin as the concurrent chemotherapy during EBRT, and ECF chemotherapy versus 5-FU + leucovorin as the maintenance component of chemotherapy. A phase II trial tested the tolerance of the more aggressive infusional 5-FU and ECF regimen in a multicenter trial involving CALGB institutions together with the Mayo Clinic.[267] The irradiation treatment fields in both the phase II and successor phase III trials are based on idealized field design related to site of the primary lesion and TN stage of disease.[136,137]

On the basis of encouraging results with preoperative chemotherapy and CRT for locally advanced or borderline resectable disease and the survival advantage for perioperative ECF chemotherapy versus surgery alone for resectable gastroesophageal cancers in the British phase III MAGIC trial,[173] future phase III studies should evaluate preoperative chemotherapy (alone or followed by postoperative CRT) and preoperative CRT in combination with resection for patients with potentially resectable lesions. Although some inves-

Table 79-17 Treatment Algorithm for Gastric or Gastroesophageal Junction Cancer, Mayo Clinic Cancer Center

TNM Extent*	Surgery	Irradiation (Alone or with Chemo)	Chemotherapy
T1–2N0M0	Radical subtotal gastrectomy and regional nodes	Not routinely recommended, except posterior wall T2N0M0	NR
T1–2N1–3M0; T3N0–3M0	Radical subtotal and regional nodes	Postop EBRT-Chemo, 45–50 Gy; evaluate preop EBRT-Chemo, gastric; prefer preop EBRT-Chemo, GE junction†	5-FU + leucovorin bolus wk 1,5—CCRT and maint; evaluate maint ECF in current U.S. GI Intergroup phase III
T4N0–3M0	Radical subtotal and regional nodes; attempt en bloc resection, involved organ(s)	Preop EBRT-Chemo, 45–50 Gy; attempt resection and IOERT	5-FU + leucovorin, bolus wk 1, 5; evaluate alternate CCRT including infusion; 5-FU; evaluate other maint chemo (ECF, other)
$T_{any}N_{any}M1$	Palliative if feasible	Palliative CCRT if indicated	MACT; ICT phase I, II, or III

CCRT, concurrent chemoradiotherapy; EBRT, external beam irradiation; EBRT-Chemo, external beam irradiation + chemotherapy; eval, evaluate; ICT, investigational chemotherapy clinical trials; IOERT, intraoperative electron irradiation; MACT, multiagent chemotherapy; maint, maintenance; NR, not recommended; postop, postoperative; preop, preoperative;

*For TNM definitions, see Table 79-2.

†We prefer preop CRT for gastroesophageal (GE) junction cancer found to be T1–2N1–3M0 or T3N0–3M0 on endoscopic ultrasonography, because one can usually design safer EBRT fields with preop CRT rather than postop CRT. If transhiatal resection is performed, keeping the reconstructed stomach in the mediastinal midline, postop CRT can be given more safely than if Ivor-Lewis resection is performed.

tigators and institutions may prefer to simply replace postoperative adjuvant CRT with perioperative ECF chemotherapy, it would seem advantageous to attempt to combine the advances in disease control and survival found with both approaches, in that neither approach by itself resulted in optimal outcomes. This philosophy is being tested in part in the current U.S. GI INT trial by the comparison of ECF versus 5-FU + leucovorin as the maintenance component of chemotherapy. A randomized phase II study was conducted by RTOG to evaluate several combinations of preoperative CRT, and results are awaited. Because some of the newer chemotherapy drug combinations have CR rates of about 20%, the hope is that these regimens will lower systemic relapse rates more than previous combinations. This change has not yet been demonstrated in phase III trials.

Locally Advanced Disease (Unresectable for Cure)

For patients with locally advanced disease that appears unresectable for cure, it seems reasonable to build on existing positive segments of treatment data (EBRT plus chemotherapy, IORT, preoperative chemotherapy, preoperative chemoradiation) plus patterns of relapse information. External irradiation plus chemotherapy or IORT alone or added to EBRT has controlled disease and produced long-term survival in 10% to 20% of patients in most single-institution analyses and randomized trials in patients with residual disease after resection. Neoadjuvant chemotherapy for unresectable disease has resulted in subsequent total resection of disease in 20% to 73% of patients in several European trials with EAP, FAMTX, or other regimens. However, the incidence of subsequent local-regional relapse is significant, even after total resection. It would be of interest to merge these components of treatment.

Following preoperative chemotherapy, patients with marginal gross total or subtotal resection with residual disease or resection but high-risk factors for relapse (beyond the gastric wall, nodes positive, or both) should be placed on studies that evaluate IORT, postoperative EBRT, or both in conjunction with concurrent and maintenance chemotherapy. For patients who are unresectable after preoperative (neoadjuvant) chemotherapy but still have localized tumor on the basis of preoperative staging (including laparoscopy) or exploratory laparotomy, EBRT plus concurrent chemotherapy should be given. Decisions regarding attempts at later resection alone or plus IORT could be individualized by institution.

An alternate approach is to initiate treatment with preoperative CRT followed by restaging, resection (alone or plus IORT), and postoperative maintenance chemotherapy. Questions to be addressed with this approach include whether to give several cycles of multiagent chemotherapy before initiating concomitant CRT or whether to start with concomitant CRT, how many cycles of chemotherapy to deliver, and which agents to give both with irradiation and as the systemic component of treatment.

Metastatic Disease

Recent trials with newer chemotherapy agents in combinations such as EOX and docetaxel, cisplatin and 5-FU (DCF) are beginning to show meaningful increases in overall survival.[216,248] However, it is unlikely that significant advances will be made through the addition of other new chemotherapy drugs to those already available. Advances will more likely occur through the use of targeted therapies. Trials with targeted therapy used alone or in combination with chemotherapy are under way. Ultimately the goal must focus on improvements in both overall survival and response rate, while continually focusing on quality of life. Adequately powered trials in both the phase II and phase III settings will be important in providing meaningful answers.

Treatment Algorithm by Tumor, Lymph Node, and Metastasis Disease Extent

The contents of this section are supported by Table 79-17 and Figures 79-11 and 79-12.

T1–2N0M0

Total surgical resection of the adenocarcinoma with a radical subtotal gastrectomy and reconstruction with gastrojejunostomy is recommended as standard treatment. Patients with posterior-wall T2N0M0 lesions should be evaluated for postoperative adjuvant CRT (see next discussion).

T1–2N1–3M0; T3N0–3M0

Postoperative CRT is the preferred standard of treatment in the United States based on demonstrated improvement in survival (disease-free and overall) when compared with a surgery-alone control arm in the phase III U.S GI trial (INT 0116).[180,181]

Our institutions prefer the use of preoperative CRT for patients who have T1–2N1–3M0 or T3N0–3M0 gastroesophageal junction cancers at the time of EUS, because we can usually design safer EBRT fields for preoperative CRT rather than postoperative CRT. If transhiatal resection is performed, keeping the reconstructed stomach in

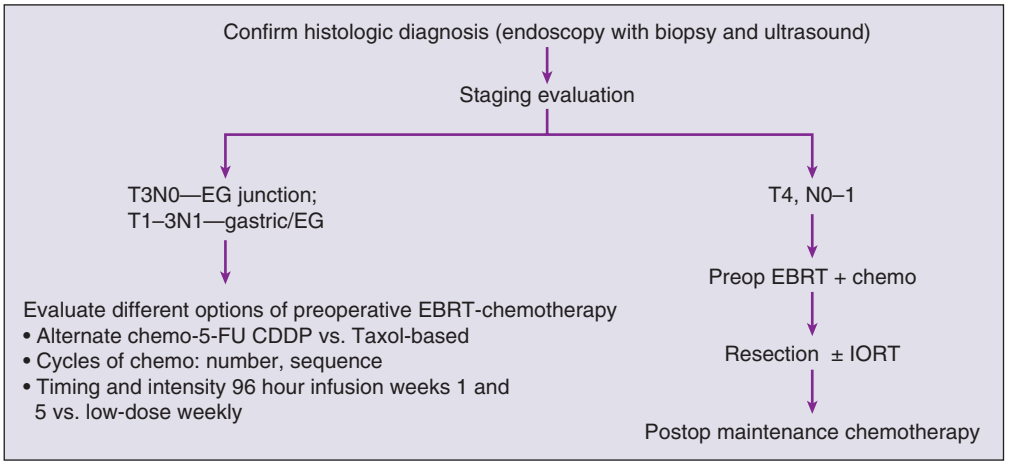

Figure 79-11 • Treatment algorithm: newly diagnosed gastric cancer adjuvant therapy precedes surgery.

the mediastinal midline, postoperative CRT can be given more safely than if Ivor-Lewis resection is performed.

T4N0–3M0

Preoperative CRT followed by restaging, gross total resection (may include en bloc resection of adjacent organs), and IOERT is recommended for potentially resectable T4N0–3 lesions in institutions with IOERT capability. Postoperative CRT has also been used for completely resected lesions.

For patients with locally unresectable T4N0–3M0 gastric cancers, preoperative or primary CRT or multiple-drug chemotherapy can be used, preferably in the setting of controlled prospective clinical trials. For patients with good performance status, the treatment approach would preferably involve preoperative CRT, restaging, and surgical resection with an attempt at marginal gross total resection and IOERT.

TanyNanyM1

Multidrug chemotherapy combinations are the preferred treatment for patients with metastatic cancers. Patients should be placed on controlled trials if available. Palliative irradiation can be used for painful metastatic lesions but is otherwise not indicated. Palliative resection may be indicated for patients with obstruction or bleeding, if total gastrectomy can be avoided.

Nutritional Support during Chemoradiation Therapy

Many patients who receive preoperative CRT (with plans to proceed to surgical resection) or primary CRT may require parenteral or enteral hyperalimentation during treatment. This feeding may also be necessary in subsets of patients with borderline performance status who are candidates for postoperative CRT. Improvement in nutritional status may require stent placement during endoscopy, feeding jejunostomy, or percutaneous endoscopic gastrostomy tube placement. Feeding jejunostomy may be preferable to percutaneous endoscopic gastrostomy tube placement for patients receiving preoperative CRT, so as to preserve later use of the stomach for reconstruction.

CONCLUSIONS

In summary, gastric malignancies present a variety of challenges. Innovative combined-modality approaches will be required to improve survival with acceptable morbidity. This treatment may include combinations of EBRT plus chemotherapy, IORT, and resection for the local component of disease, systemic or intraperitoneal chemotherapy for the abdominal component, and systemic treatment (chemotherapy, other) for the extra-abdominal risks of relapse. For patients with metastatic disease, the availability of growth factors may allow more aggressive multidrug approaches.

80 Cancer of the Small Bowel

Alessandro Fichera, Ronald P. DeMatteo, and Fabrizio Michelassi

SUMMARY OF KEY POINTS

Incidence
- Cancers of the small bowel are rare.
- These cancers account for less than 10% of all gastrointestinal tumors and less than 1% of all malignancies; approximately 5600 new cases are diagnosed each year, with 1100 cancer-related deaths.

Etiology and Epidemiology
- Several factors explain the rarity of these tumors: rapid transit time of carcinogens; carcinogens diluted by gastric, biliary, and pancreatic secretions; small bowel flora being less metabolically active; detoxifying enzymes; immunosurveillance.
- Dietary risk factors for small bowel adenocarcinoma are similar to those for colorectal cancers.
- Increased incidence is seen in Crohn's disease, familial adenomatous polyposis, and hereditary nonpolyposis colorectal cancer, as well as in individuals with a history of irradiation to the abdomen.

Pathology and Biology
- About one third of all small bowel tumors are benign.
- Of the malignant lesions 45% are adenocarcinomas, 30% are carcinoids, 15% are lymphomas, and 10% are sarcomas and gastrointestinal stromal tumors (GISTs).
- The majority of malignant lesions are located in the duodenum (50% to 60%), followed by the jejunum and ileum.
- Molecular markers for adenocarcinomas include: K-ras, p53, c-erbB-2, Ki-67, tenascin, CEA, and CA 19-9.
- KIT immunostaining has greatly facilitated the diagnosis of GIST, because nearly all GISTs are KIT-positive.

Clinical Findings
- Symptoms, when they do occur, tend to be vague and nonspecific and are determined by the tumor's location, growth rate, and size.

Staging
- Small bowel tumors are staged by the tumor-node-metastasis (TNM) staging system published by the American Joint Committee on Cancer (AJCC).
- Small bowel lymphomas are staged by the Ann Arbor system based on lymphatic and extralymphatic involvement on either side of the diaphragm.

Primary Therapy
- The treatment for localized resectable small bowel tumors is surgical excision with negative margins.
- Depending on the location of the tumor, specifically tailored surgical options are available.
- For primary small bowel lymphoma, para-aortic and mesenteric lymph node sampling, liver biopsy, and bone marrow biopsy should be performed upon surgical exploration.

Prognosis
- Factors associated with poor prognosis for small bowel adenocarcinomas are advanced stage, poor tumor differentiation, extramural venous spread, and positive margins.
- Previously, the 5 year survival after resection of a primary GIST was 50% to 75%, and once metastasis occurred patients lived a median of 10 to 20 additional months. Since the introduction of the tyrosine kinase inhibitors imatinib mesylate (Gleevec; Novartis) and sunitinib (Sutent; Pfizer), the median survival in metastatic GIST is now 58 months.

INCIDENCE

Although the small bowel accounts for 75% of the gastrointestinal length and 90% of its absorptive surface, neoplasms of this organ, both benign and malignant, are relatively rare. These tumors represent less than 10% of all gastrointestinal tumors, 1% to 3% of gastrointestinal malignancies, and 0.4% of all malignancies.[1,2] The annual incidence of small bowel cancer is about 5640 cases, with 1090 deaths related to small bowel cancer per year in the United States.[1] Malignant lesions have a slight male predominance[3]; benign tumors occur with roughly equal gender incidence.

Over the last decade, the incidence of two small bowel tumors, lymphomas and GISTs, has increased substantially. In the case of primary small bowel lymphomas, incidence in the United States has nearly doubled in the last 2 decades, as a result of the increased numbers of immunocompromised patients (i.e., those with acquired immunodeficiency syndrome [AIDS] or rheumatoid arthritis, transplant recipients with immune disorders, or individuals with congenital immunodeficiency syndromes) and immigrants from third-world countries.[4] In the case of GISTs, the application of KIT protein (CD117) immunohistochemistry has changed the way spindle cell tumors of the gastrointestinal tract are classified. Previously most intestinal sarcomas were considered to be leiomyosarcomas, but now it is clear that they are in fact GISTs. Because of this increased awareness and recognition, the annual incidence of new cases of GIST in the United States has greatly increased and is estimated to be as high as 4000. The stomach is the most frequent (60%) site of GIST, whereas approximately 30% occur in the small intestine.

EPIDEMIOLOGY

The first reports of duodenal adenocarcinoma and small bowel sarcoma were published in the eighteenth and nineteenth centuries.[5] Since then many reports and reviews have been published based on autopsy data or single-center series. The significance and relevance of these data are limited by the retrospective nature of these studies.

The National Cancer Data Base, a joint project of the American College of Surgeons Commission on Cancer and the American Cancer Society, maintains data on as many as 60% of all cancer cases in the United States. It is the main source of epidemiologic data for all cancers, and it represents a particularly useful resource for rare neoplasms, such as small bowel malignancies. Howe and colleagues reviewed the database for nonampullary small bowel cancers and found 4995 cases for the period between 1985 and 1995.[6] The mean age at presentation was 65 years, with equal incidence in both genders. On presentation, 32% had evidence of metastatic disease and 26% were locally advanced.[6]

Epidemiologic studies have identified several predisposing conditions associated with small bowel malignancies. Crohn's disease is associated with a 40- to 100-fold increase in relative risk.[7–14] Patients with familial adenomatous polyposis have a 50- to 300-fold increase in relative risk of developing proximal small bowel malignancy, specifically duodenal adenocarcinomas.[15,16] In a recent series 57% of hereditary nonpolyposis colorectal cancer patients developed small bowel adenocarcinomas as the presenting neoplasm.[17] Other conditions such as blind loop syndrome,[18,19] Peutz-Jeghers syndrome,[20] celiac sprue,[21] neurofibromatosis, and IgA deficiency[18,19] have been associated with an increased risk of small bowel malignancy.

ETIOLOGY AND PATHOGENESIS

The disproportion between the rarity of malignant tumors of the small bowel in comparison with the size of its surface area suggests a significant sparing from or resistance to the development of malignancy. Indeed, several hypotheses, based on experimental animal models,[18,19] have postulated that carcinogens in the enteric content may be in contact with small bowel mucosa over a limited time due to the relatively rapid transit time or may be in a diluted and less carcinogenic form. The preponderance of small bowel adenocarcinomas in the duodenum suggests a role for bile or pancreatic secretions either as primary small bowel carcinogens or even as simple vectors for unknown carcinogens.[22] The fact that biliary diversion decreases the incidence of chemically induced small bowel malignancy in animal models supports a role for bile in small bowel carcinogenesis.[23]

Other specific characteristics of the small bowel microscopic and chemical environment might be responsible for the observed cancer resistance. The limited and metabolically inactive bacterial flora of the small bowel is probably unable to transform procarcinogens into their active metabolites,[24] especially in an alkaline milieu. In addition, the proximal small bowel secretes several enzyme systems (e.g., benzopyrene hydroxylase)[25,26] that detoxify carcinogens.

Finally, the presence of a high concentration of B cells and lymphocytes and high amounts of secretory immunoglobulin A in the distal small bowel might constitute an effective local immunosurveillance system that prevents carcinogenesis and explains the rarity of distal small bowel neoplasms. This theory seems to be supported by the observation that immunocompromised patients (i.e., those with AIDS or rheumatoid arthritis, transplant recipients with immune disorders, or individuals with congenital immunodeficiency syndromes) have an increased incidence of lymphoma and Kaposi's sarcoma of the distal small bowel.

Dietary risk factors that have been involved in colorectal carcinogenesis have been looked at in patients with malignancies of the small bowel. High-caloric dietary intake in general and more specifically consumption of red meat, fat, and salt-cured smoked foods have been shown to increase the incidence of small bowel carcinoma in large population studies.[27–29] This similarity in risk factors explains the relatively high risk of synchronous or metachronous colorectal cancer in patients with a known small bowel malignancy.[30–33]

PATHOLOGY

Approximately one third of primary small bowel neoplasms are benign and two thirds are malignant. The most common benign tumors are leiomyomas and adenomas; less common lesions include inflammatory polyps, hemangiomas, lipomas, hamartomas (Peutz-Jeghers syndrome), and fibromas (Fig. 80-1).[19,20] These tumors can occur throughout the small bowel but tend to increase in frequency from proximal to distal, with the exception of adenomas, which occur with the highest frequency in the duodenum.

Leiomyomas arise from smooth muscle and can grow both intra- and extraluminally. They can often become very large before causing symptoms. On gross inspection it is sometimes difficult to distinguish these lesions from their malignant counterparts. This distinction is made histologically with standard criteria including nuclear pleomorphism, increased mitosis, and the presence of necrosis, although even histologic examination may occasionally fail to unequivocally distinguish between benign and malignant lesions.

Adenomas are the next most common benign tumors of the small intestine. The duodenum is the most common site of involvement, and the lesion most commonly noted is the villous adenoma. These lesions tend to involve the region of the ampulla of Vater. They may present with obstructive jaundice and are easily diagnosed by upper endoscopy and biopsy. Up to 30% of these tumors may have a malignant degeneration. The risk of malignant degeneration in a significant proportion of patients poses challenges to treatment planning.

Malignant tumors tend to increase in frequency from proximal to distal, again with the exception of adenocarcinomas, which are most frequent in the duodenum.[2,6,18,19,34,35] Adenocarcinoma is the most common histologic type (45%), followed by carcinoids (30%), lymphomas (15%), and sarcomas and GISTs (10%).[18,36,37] Pathologic

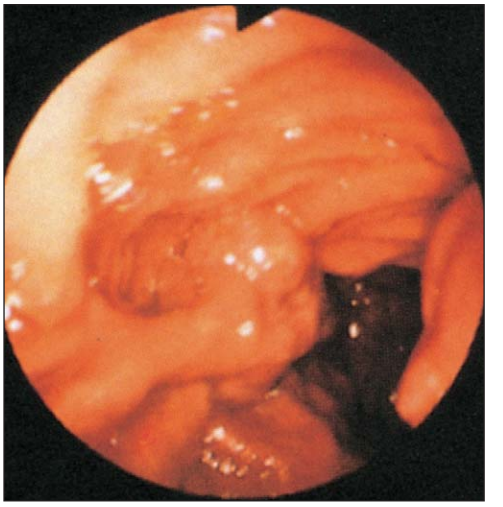

Figure 80-1 • Hamartomatous polyp in Peutz-Jeghers syndrome. Endoscopic view shows a broad-based polyp in the duodenum in a patient with Peutz-Jeghers syndrome. These small intestinal polyps only rarely become malignant. This syndrome is an autosomal dominant condition that is also marked by deposits of melanin on the buccal mucosa, lips, and digits. Ovarian neoplasms arise in almost 5% of women with this syndrome. (Kulke H, Turner J, Skarin A: Cancer of the gastrointestinal tract. In Skarin A [ed]: Atlas of Diagnostic Oncology, 3rd ed. St. Louis, Mosby, 2003, p 113.)

staging is performed according to the American Joint Committee on Cancer (AJCC) tumor-node-metastasis (TNM) system.[38]

Most small bowel adenocarcinomas are solitary, sessile lesions, often appearing in association with adenomas. They are usually moderately to well differentiated and almost always positive for acid mucin. Most arise in the duodenum. Within the duodenum 15% of these tumors are located in the first portion, 40% are in the second portion, and 45% are in the distal duodenum.[39,40] Most of these tumors are sporadic, with the exception of the ones originating in the context of familial adenomatous polyposis. Presenting symptoms include epigastric and abdominal pain or discomfort, and possibly jaundice and gastric outlet obstruction, depending on the location of the tumor (Fig. 80-2). These symptoms and the accessibility of the duodenum and proximal small bowel to endoscopic modalities allow a relatively high rate of diagnosis and resectability.[41]

Carcinoid tumors (Fig. 80-3A and B) are the most common endocrine tumors of the gastrointestinal system and the second most common malignancy involving the small bowel.[2,18,19,42,43] In the small bowel itself carcinoids are the most common distal small bowel neoplasm. These neoplasms arise from enterochromaffin cells and are characterized by the ability to secrete many biologically active substances, including serotonin, bradykinin, dopamine, histamine, and 5-hydroxyindoleacetic acid. They tend to be small (<2 cm) and submucosal in location, with a propensity for multicentricity. The most common classification for these tumors is based on embryologic derivation: foregut (stomach and pancreas), midgut (small bowel), and hindgut (colon and rectum). Their presentation depends largely on the hormones elaborated and on the site of origin.[42,43] The majority of these tumors (90% or more) are midgut primary cancers. Up to 40% of small bowel carcinoids are associated with a second gastrointestinal malignancy, and 30% are multicentric. A full evaluation of the small and large intestine is therefore warranted.[42,43]

The gastrointestinal tract is the most frequent site of extranodal lymphoma: within the gastrointestinal tract the stomach is the most common site, followed by the small bowel and the colon, respectively; within the small bowel lymphomas parallel the distribution of lymphoid follicles, resulting in the ileum being the most common site of involvement.[2,18,19,36,44,45] These tumors may be primary or secondary as a manifestation of generalized involvement of systemic lymphoma. For the diagnosis of primary small bowel lymphomas there must be no peripheral or mediastinal lymphadenopathy, with a normal white blood cell count and differential, and the tumor must be predominantly in the gastrointestinal tract. When primary they may be multifocal in as many as 15% of cases. Predisposing conditions include immunodeficiency conditions (i.e., AIDS, rheumatoid arthritis, and immune disorders in transplant recipients), Crohn's disease, and celiac disease.[14,18,19,21]

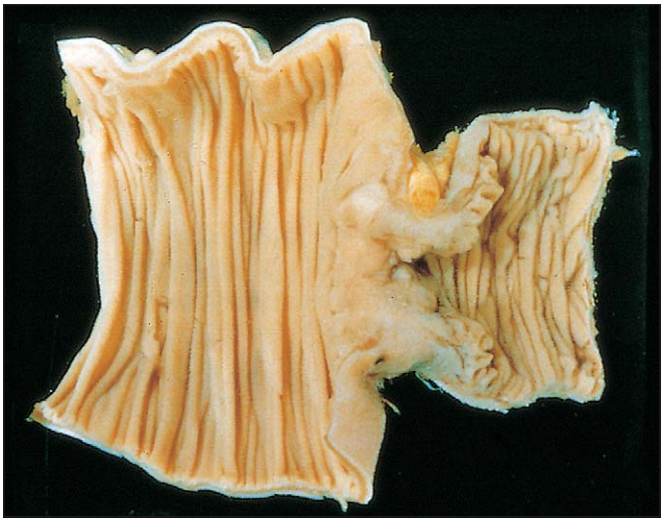

Figure 80-2 • Adenocarcinoma of the jejunum causing annular constriction. (Kulke H, Turner J, Skarin A: Cancer of the gastrointestinal tract. In Skarin A [ed]: Atlas of Diagnostic Oncology, 3rd ed. St. Louis, Mosby, 2003, p 142.)

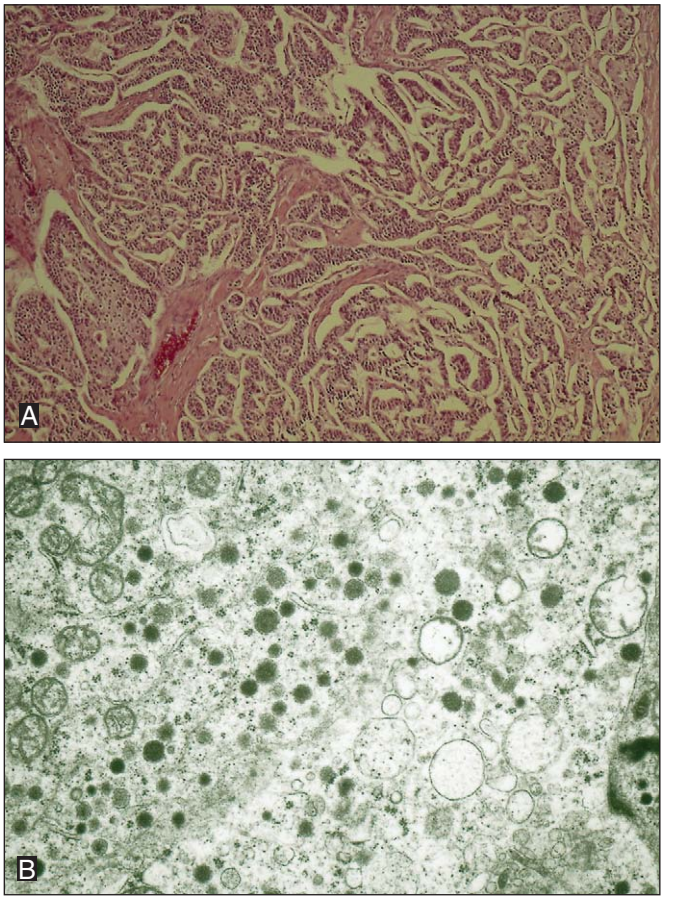

Figure 80-3 • Neuroendocrine tumor of the small intestine (carcinoid tumor). **A,** Small uniform round cells with very infrequent mitoses show a trabecular growth pattern. **B,** An electron microscopic image of the cell cytoplasm reveals the numerous dense core neuroendocrine granules typical of this tumor type.

The five distinct clinical pathologic subtypes of primary small intestinal lymphoma are the adult Western type, the pediatric type, the immunoproliferative or Mediterranean type, enteropathy-associated (celiac sprue) T-cell lymphoma, and Hodgkin's lymphoma.[4] The most common is the adult Western type, occurring in the sixth and seventh decades of life with a male predominance.[45]

Sarcomas make up only 10% of small bowel malignancies.[2,18,19,27,34] Overall, these tumors are located in the jejunum and ileum, are relatively slow growing, and are locally invasive. Their growth pattern is most commonly extramural; therefore, they rarely result in obstruction, but sometimes they present with free intra-abdominal bleeding from central tumor necrosis and peritoneal rupture. As a result of their insidious nature and growth pattern, more than three fourths of these tumors exceed 5 cm in diameter at the time of diagnosis. The most common histologic subtypes (in descending order of frequency) are GISTs (Fig. 80-4), leiomyosarcomas, fibrosarcomas, liposarcomas, and malignant schwannomas and angiosarcomas. Similar to sarcomas from other anatomic regions, small bowel sarcomas rarely metastasize to regional lymph nodes. The initial sites of metastasis include the liver and peritoneum, whereas other sites,

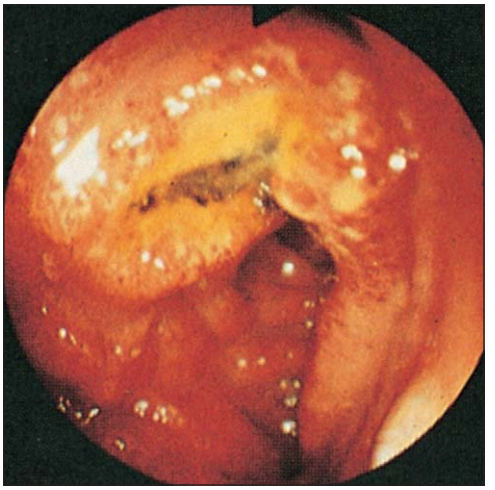

Figure 80-4 • An endoscopic view of a GIST of the duodenum. (Kulke H, Turner J, Skarin A: Cancer of the gastrointestinal tract. In Skarin A [ed]: Atlas of Diagnostic Oncology, 3rd ed. St. Louis, Mosby, 2003, p 142.)

such as lung and bone, might become involved late in the course of disease.

Mazur and Clark introduced the term GIST in 1983 to describe gastrointestinal nonepithelial stromal tumors that lack the immunohistochemical features of Schwann cells and do not have the characteristics of smooth muscle cells.[46] GIST is now considered the most common sarcoma of the gastrointestinal tract and accounts for about 5% of all small bowel malignancies.[47] Clinical, histopathologic, ultrastructural, and molecular biologic findings have clearly shown that GIST is a completely separate entity from leiomyoma and leiomyosarcoma. It is currently thought that GISTs originate from stem cells that differentiate toward the interstitial cells of Cajal (ICCs). ICCs arise from precursor mesenchymal cells and are the pacemaker cells of the gastrointestinal tract.[48] They intercalate between nerve fibers and muscle cells and can be seen in the adult intestine in and around the myenteric plexus.[49] Both ICCs and GISTs express KIT protein, have similar ultrastructural features, and express the embryonic form of the heavy chain of smooth muscle myosin.[50,51] All these features support a common origin, and the term gastrointestinal pacemaker cell tumor has been used to describe these lesions.[51]

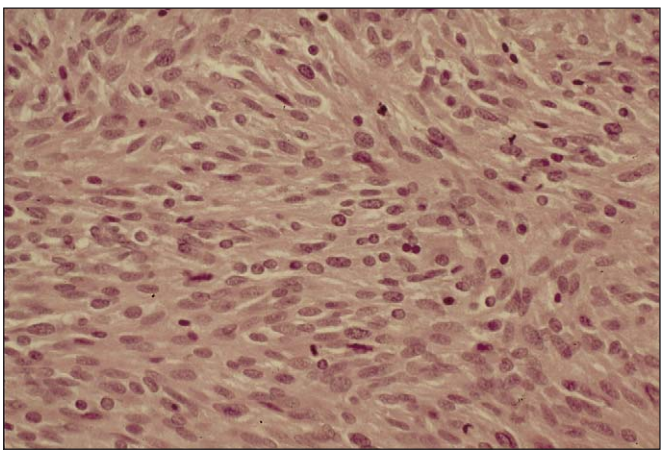

Figure 80-5 • High-grade gastrointestinal stromal tumor. Plump spindle cells with pale eosinophilic cytoplasm with a storiform pattern of growth show a high mitotic rate (20×).

Nearly all GISTs overexpress KIT protein. Consequently, the gold standard for diagnosing GIST has become KIT immunostaining in conjunction with an assessment of tumor morphology on hematoxylin and eosin staining. A small percentage of GISTs lack KIT staining, in which case the diagnosis relies on morphology (Fig. 80-5) and molecular analysis for either a KIT or platelet-derived growth factor receptor-α (PDGFRα) gene mutation.[52] Small intestine GISTs generally contain either a KIT exon 9 or 11 mutation or have no identifiable mutation. In contrast, PDGFRα mutations are basically restricted to gastric GISTs. Approximately 85% of GISTs have a mutation in the KIT proto-oncogene, whereas another 5% contain a PDGFRα gene mutation. Thus, about 10% of GISTs do not have an identifiable mutation, but KIT is nonetheless strongly activated. Such GISTs might contain KIT mutations that are not readily detected by conventional screening methods, or alternately, KIT might be activated by nonmutational mechanisms. Most GISTs have noncomplex cytogenetic profiles, often featuring deletions of chromosomes 14 and 22. Additional chromosomal aberrations are acquired as GISTs progress to higher histologic grade. These cytogenetic aberrations are undoubtedly important in GIST pathogenesis, but currently they do not play a key role as diagnostic adjuncts.[53]

To better characterize GISTs, other markers have been studied: About 60% to 70% show immunopositivity for CD34, 30% to 40% for smooth muscle actin, and around 5% for S-100 protein. None of these antigens are therefore specific for GIST but can help in the differential diagnosis in KIT-negative tumors. Desmin positivity in true KIT-positive GISTs is extremely uncommon (1% to 2% of cases) and is invariably focal, with positivity in only a small number of tumor cells.[52] The immunophenotype of true KIT-positive GISTs varies to some degree by location, with CD34 positivity seen most consistently in colorectal and esophageal lesions and smooth muscle actin positivity seen most often in small bowel tumors.[54]

BIOLOGY

There are similarities in the genetic makeup of small bowel and large bowel adenocarcinomas. K-ras mutations at codon 12 have been noted in duodenal adenocarcinomas, suggesting a possible pathogenetic role similar to that seen in pancreatic and colorectal cancer.[55] As shown in colorectal and other malignancies, overexpression of p53 in de novo small bowel adenocarcinomas has been associated with a worse prognosis.[56] Increased expression of c-erbB-2, Ki-67, and tenascin was associated with poorer survival rate in a small group of patients with duodenal adenocarcinomas.[57] Strong cytoplasmic carcinoembryonic antigen (CEA) staining has been described in small bowel adenocarcinomas.[58] Immunohistochemical staining for CEA, and to a lesser extent CA 19-9, is positive in the majority of ampullary and about half of nonampullary duodenal small bowel adenocarcinomas.[59] However, their independent prognostic value has not been established. The rarity of small bowel adenocarcinomas makes it difficult to carry out meaningful, large, prospective studies to assess the prognostic and clinical significance of these markers.

A recent major advance has been achieved by the recognition of the central role of activating KIT mutations in the pathogenesis of GISTs,[60–62] leading to expression of the KIT protein, a new and reliable phenotypic marker for these neoplasms.[51,63] Constitutive activation of the KIT receptor tyrosine kinase is a central pathogenetic event in most GISTs and generally results from point mutations or deletions, which involve either extracellular or cytoplasmic domains of the receptor. These mutations permit the KIT receptor to phosphorylate various substrate proteins in the absence of the natural ligand to KIT, which is called KIT ligand or stem cell factor. The result is activation of signal transduction cascades, which regulate cell proliferation, apoptosis, chemotaxis, and adhesion. KIT mutations can be broadly assigned to two groups, those that involve the "regulatory" regions responsible for modulating KIT enzymatic activity, and those that involve the enzymatic region itself.[53]

Figure 80-6 • The small bowel is a frequent site for melanoma metastases. This resected jejunum contains multiple pigmented nodules, some with ulceration. (Kulke H, Turner J, Skarin A: Cancer of the gastrointestinal tract. In Skarin A [ed]: Atlas of Diagnostic Oncology, 3rd ed. St. Louis, Mosby, 2003, p 146.)

CLINICAL PRESENTATION

The vast majority of patients with benign small intestine neoplasms are asymptomatic, whereas the vast majority of those with malignancies are symptomatic before diagnosis (Fig. 80-6). The most common presentation of benign tumors is intermittent episodes of acute crampy abdominal pain associated with intussusception, followed by chronic bleeding with iron deficiency anemia in up to 50% of patients.

Malignant lesions are generally associated with weight loss due to delay in the establishment of a diagnosis. Symptoms, when they occur, tend to be vague and nonspecific. In general most symptoms can be attributed to the location of the tumor, its rate of growth, and its size.[2,18,19,34,35] For example, tumors in the duodenum tend to be symptomatic at an earlier stage, presenting with pain, gastric outlet obstruction, or obstructive jaundice, whereas those in the jejunum or ileum may present at a later stage with obstructive symptoms. Obstruction in this setting tends to be progressive, compared with benign lesions, whose obstructive symptoms tend to be intermittent as they relate to episodes of intussusception. Bleeding and perforation (in up to 10%) may also occur, predominantly in lymphomatous lesions, but they can also be features of any malignant tumor because of ulceration or necrosis. GIST may be associated with acute hemorrhage as well.

Carcinoid tumors produce symptoms secondary to hormone production, including hot flashes, bronchospasms, and arrhythmias. This constellation of symptoms, called carcinoid syndrome, occurs when the liver is not able to metabolize the active substances produced by the carcinoid tumor. This problem usually results when tumors are either bulky or metastatic, or when their venous drainage bypasses the liver.

LABORATORY AND IMAGING STUDIES

A high index of suspicion is required because of the nonspecificity of the signs and symptoms of small intestine tumors. A correct preoperative diagnosis is made in only 50% of patients. Biochemical and hematologic studies are often not helpful. Iron deficiency anemia may be detected with chronic blood loss; elevated liver enzymes may be noted with periampullary lesions or hepatic metastases; elevated 24-hour urinary 5-hydroxyindoleacetic acid can be detected in more than 50% of patients with carcinoid tumors.

Radiographic contrast imaging modalities tend to be the most useful in the establishment of the diagnosis (Fig. 80-7). Plain films of the abdomen are generally not helpful and at best may demonstrate nonspecific signs of obstruction or a mass effect. Except for the duodenum and the very proximal jejunum, which can often be evaluated by endoscopy, the diagnosis of small intestinal neoplasms depends on contrast studies such as a small bowel follow-through or preferably enteroclysis. Small bowel follow-through is still the most commonly used method in most institutions in the evaluation of small bowel disease, although enteroclysis may be a superior imaging modality. In a recent study comparing the sensitivity and tumor detection rate of small bowel follow-through and enteroclysis, the sensitivity rates were 61% and 95%, respectively. The actual tumor

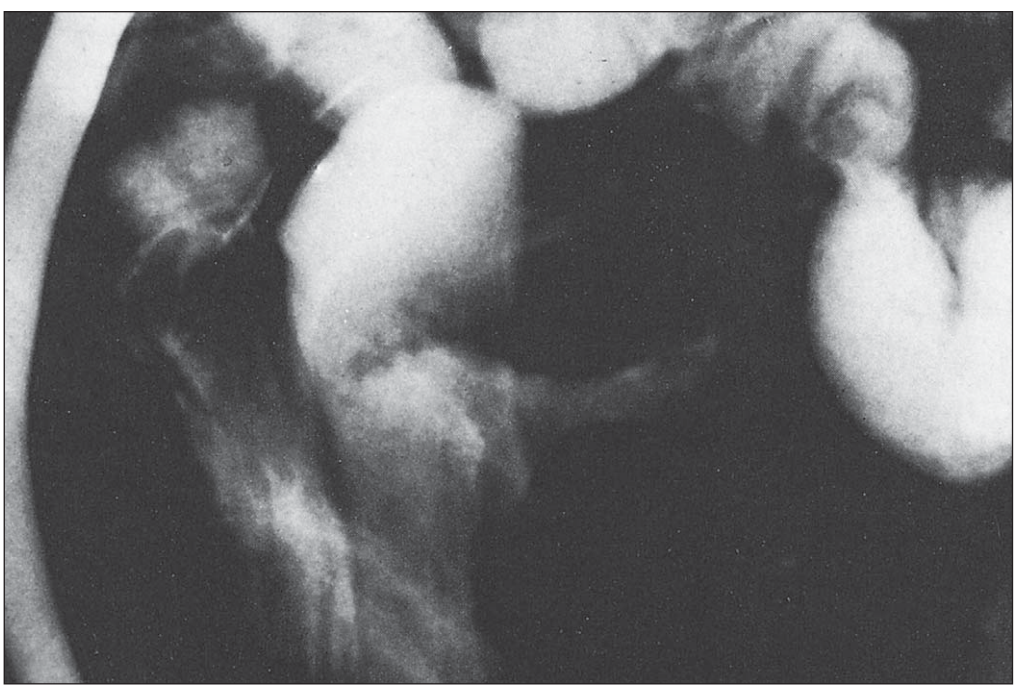

Figure 80-7 • A barium contrast study of the small intestine demonstrating an annular constricting lesion that proved to be an adenocarcinoma of the ileum. (Kulke H, Turner J, Skarin A: Cancer of the gastrointestinal tract. In Skarin A [ed]: Atlas of Diagnostic Oncology, 3rd ed. St. Louis, Mosby, 2003, p 142.)

detection rate was 33% for small bowel follow-through and 90% for enteroclysis.[64]

Computed tomography (CT), ultrasonography, and magnetic resonance imaging (MRI) are complementary to barium studies in the detection of small bowel neoplasms. Abdominal CT has a sensitivity of 50% to 80% in detecting the primary small bowel tumors and occasionally plays an important role in differentiating benign from malignant tumors. Additionally, CT is valuable in staging malignant tumors (presence or absence of hepatic metastases) and in providing important information related to local extent (presence or absence of local invasion, mesenteric implants, and metastatic lymph nodes). Contrast-enhanced abdominal CT examination and enteroclysis are truly complementary to each other. Enteroclysis provides optimal wall distension and displays mucosal pattern well; CT demonstrates the extraluminal component of the tumor and aids in the staging process.

Angiography, though helpful in diagnosing and localizing neoplasms of vascular origin, is rarely helpful in establishing or refining a diagnosis of small bowel malignancy. In rare cases angiographic demonstration of tumor neovascularity without contrast agent extravasation may be of diagnostic importance in patients with chronic occult bleeding when other diagnostic studies such as endoscopy and barium contrast have been negative.[65] By contrast, angiography is rarely beneficial in localizing bleeding tumors, because the vast majority of such tumors bleed at a rate considerably below the limit of detection with this technique. Scintigraphy with technetium-labeled red blood cells may identify bleeding sites with blood loss rates as low as 0.1 mL per minute.

Sonde enteroscopy, by now only of historical interest,[66] involved intubation of the small bowel with a thin endoscope equipped with a balloon tip, inserted transnasally, and moved distally by way of peristalsis. Evaluation of the bowel occurred as the scope was withdrawn. This scope did not allow for biopsy or therapeutic intervention, the entire bowel lumen often was not visualized, and the duration of the procedure was on the order of 6 hours. This modality was used in the diagnostic workup of individuals who had had nondiagnostic contrast studies and upper and lower endoscopies.[67]

Enteroscopy is now available in a fiberoptic form, using conventional endoscopes or in a wireless form. Fiberoptic small bowel enteroscopy, or push enteroscopy, initially made use of a pediatric or adult colonoscope that was advanced orally.[68] Specialized scopes that can be used to visualize jejunum 100 cm or farther from the ligament of Treitz are now available. The bowel is evaluated as the endoscope is both advanced and withdrawn, and biopsy or cauterization can be done concomitantly through an accessory channel.

Wireless capsule endoscopy is a new technique that uses a miniature camera that is swallowed by the patient and records images as it progresses down the gastrointestinal tract. It offers the potential to examine the whole small intestine combined with the advantage of being painless. Using a miniature camera and a lens with a short focal length, images are obtained as the capsule progresses though the entire length of the intestine, without requiring air inflation. The capsule endoscope is propelled by peristalsis through the gastrointestinal tract. The video images are transmitted using radiotelemetry and are stored on a small portable recorder carried on a belt and subsequently downloaded for analysis. The system allows more than 7 hours of continuous recording of images of the gastrointestinal tract. The patients are free to continue their daily routine during the examination.[69] Animal studies using this modality have shown that capsule enteroscopy was as effective as enteroscopy in detecting beads in canine small intestine.[70] Recently, several human studies, usually looking at patients with occult gastrointestinal bleeding, have indicated that capsule endoscopy seems to be significantly superior to push enteroscopy in this group of patients,[71–74] and it is invariably preferred by patients undergoing both procedures.[69] A study by Costamagna and associates[75] found wireless capsule endoscopy significantly superior to small bowel follow-through studies, if small bowel disease was suspected.

Fluorodeoxyglucose (labeled with fluorine-18) positron emission tomography (FDG-PET) has been shown to be highly sensitive to assess disease status in patients with GISTs. FDG-PET is sometimes used for preoperative staging, but more important, it can be used to assess response to therapy. Glucose uptake of GIST decreases within a few hours to a few days after the start of treatment with the targeted agent imatinib mesylate, which can be verified by FDG-PET.[76] Furthermore, in case of disease progression, increased areas of FDG uptake are observed by PET.[77] Overall, though, PET is mostly used as a research tool in GIST and contrast CT is the gold standard. It is now understood that a decrease in contrast uptake or decrease in density of a GIST indicates response to treatment. Meanwhile, standard criteria of response based on tumor size are inaccurate, in that GISTs often remain the same size, or even swell, initially during a response.

Limited information is available regarding the efficacy of diagnostic laparoscopy in the diagnosis and workup of small bowel neoplasms. At present its usefulness may reside in obtaining staging information and determining resectability before formal laparotomy in the case of tumors of the duodenum, and in obtaining images and potentially in making tissue diagnoses when other imaging studies have failed to suggest an etiology. It is clear, however, that despite the currently available technology, the diagnosis of these tumors is difficult to establish preoperatively in a significant group of individuals. Laparotomy is often required for definitive diagnosis.

STAGING CLASSIFICATION

Radiologic staging is based mainly on the use of CT and MRI. Intraoperative assessment plays a role in clinical staging, especially when tumor cannot be resected. Metastatic involvement of the liver may be further evaluated by intraoperative ultrasonography. With regard to pathologic staging, the TNM staging system has been recently revised by the AJCC,[38] but no major changes have been implemented for small bowel neoplasms. The primary tumor is staged according to its depth of penetration and the involvement of adjacent structures or distant sites. There is no subdivision within the N category based on the number of nodes involved with tumor. Discontinuous hematogenous metastases or peritoneal metastases are coded as M1. Involvement of the celiac nodes is considered M1 disease (Tables 80-1 and 80-2). Cancers of the small intestine can metastasize to most organs, especially the liver, or to the peritoneal surfaces. For small bowel lymphoma the most commonly used staging system is the Ann Arbor system, based on lymphatic and extralymphatic involvement on either side of the diaphragm (Table 80-3).

PROGNOSIS

Prognosis for small bowel adenocarcinoma is based on similar variables as for colorectal cancer, including stage, perineural and vascular invasion, grade, resectability, and surgical margins.[35,78–80] The majority of tumors have regional spread at time of diagnosis, and up to one fourth of patients have distant organ disease. Overall, the 5-year survival rate is 20% to 30% in most series. For resectable disease of the duodenum the 5-year survival rate approaches 50%.[2,6,35,78–81]

It has been frequently postulated that a small bowel adenocarcinoma carries a worse prognosis in patients with Crohn's disease in comparison with the general population. Recent studies have demonstrated that, in these patients, survival correlates purely with stage of tumor at resection. In our series no patient with regional or distant metastasis survived 5 years, in comparison with an 83% 5-year actuarial survival rate of patients with tumor confined to the intestinal wall. Mean survival time was 6 months for Crohn's disease patients with small bowel cancer in comparison with 65 months for Crohn's

Table 80-1 Definition of TNM Stages

Stage	Definition
PRIMARY TUMOR (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
TIS	Carcinoma in situ
T1	Tumor invades lamina propria or submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades through the muscularis propria into the subserosa or into the nonperitonealized perimuscular tissue (mesentery or retroperitoneum) with extension 2 cm or less
T4	Tumor perforates the visceral peritoneum or directly invades other organs or structures (includes other loops of small intestine, mesentery, or retroperitoneum more than 2 cm, and abdominal wall by way of serosa; for duodenum only, invasion of pancreas)
REGIONAL LYMPH NODES (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
DISTANT METASTASIS (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

Table 80-2 Stage Grouping

Stage	T	N	M
0	TIS	N0	M0
I	T1	N0	M0
	T2	N0	M0
II	T3	N0	M0
	T4	N0	M0
III	Any T	N1	M0
IV	Any T	Any N	M1

Table 80-3 Ann Arbor Staging System for Small Bowel Lymphoma

Stage	Criteria
I	Involvement of a single nodal group (I) or a single extralymphatic organ or site (IE)
II	Involvement of more than one nodal group on the same side of the diaphragm (II) or a single extralymphatic site with one or more nodal groups on the same side of the diaphragm (IIE)
III	Involvement of nodes on both sides of the diaphragm (III) with or without involvement of extralymphatic sites (IIIE), spleen (IIIS), or both (IIIES)
IV	Diffuse involvement of viscera or bone marrow

disease patients with large bowel cancer, reflecting a tendency toward more advanced lesions in the small bowel.[13]

The prognosis for carcinoid tumors with localized disease is excellent, with 5-year survival rates approaching 100% after resection. More than 90% of the symptomatic patients have metastatic disease at the time of surgical exploration. The likelihood of distant disease correlates closely with both the size of the primary lesion and the depth of invasion. For tumors smaller than 1 cm, the risk of lymph node metastases is on the order of 2%; for 1- to 2-cm lesions, the incidence of lymph node involvement is approximately 50%; and 80% of tumors larger than 2 cm have positive nodes. Survival rates of up to 68% at 5 years have been reported when all gross metastatic disease, including hepatic metastases, is resected. For those unfortunate individuals with extensive unresectable disease, debulking has proved to be of some benefit in terms of symptomatic palliation. It is notable that the 5-year survival rate for unresectable disease is approximately 35% to 40%, reflecting the relatively indolent growth of these tumors.

Prognostic factors for primary small bowel lymphomas include higher grade, greater depth of tumor penetration, lymph node involvement, peritoneal disease, and distant metastases.[35,44,45] Overall 5-year survival rates range from 20% to 40% for all stages. Five-year survival rates of up to 60% have been reported for patients with resected localized low-grade tumors.[18]

Sarcomas tend to have an insidious growth pattern; more than three fourths of these tumors are larger than 5 cm at the time of diagnosis, and up to 50% of them are not resectable for cure when the diagnosis is established. Prognosis correlates most closely with grade, followed by stage.[82] Five-year survival rate after curative resection ranges from 60% to 80% for low-grade tumors and is no more than 20% for high-grade lesions.

Assessment of the risk of recurrence after resection of a primary GIST is difficult. In general, patients with small intestine GIST have a higher chance of developing recurrent disease than those with gastric GIST. Historically, size has been used to assess tumor behavior. All GISTs, except very small (<1 cm) tumors, should be considered as having the potential for metastasis. Although tumors larger than 5 cm carry a higher risk of recurrence, no cutoff diameter predicts subsequent metastasis with certainty.[83]

In addition to size, mitotic rate has been used to predict tumor behavior. Tumors with more than five mitoses per 50 high-power fields (HPFs) have a much higher risk of metastasis, and those with more than 20 to 50 mitoses per 50 HPFs are virtually guaranteed to recur.[49,84] Nevertheless, a low mitotic count does not exclude the possibility of metastasis.[85] Other factors that have shown prognostic value include presence of tumor necrosis, high cellularity, and pronounced pleomorphism; a high S-phase fraction and DNA aneuploidy in flow cytometry or image cytometry; a high Ki-67 score; proliferating cell nuclear antigen expression; presence of telomerase activity[37]; incomplete surgical resection; tumor rupture at surgery[86]; and invasion of adjacent structures.

Whether the presence of a KIT mutation is an independent prognostic factor for individuals with a primary GIST is unclear. Before the era of imatinib, Taniguchi and coworkers[87] suggested that GISTs should be divided into mutation-positive and -negative subtypes, the prognosis being worse in patients with mutation-positive GISTs. More recent data have not substantiated their findings. What is clear is that the response of metastatic GIST to imatinib depends on mutation subtype. Tumors with KIT exon 11 mutation have a greater likelihood of responding than those with KIT exon 9 mutations. Meanwhile, GISTs with no mutation have the least chance of responding to imatinib.

Precise data on long-term survival for patients with GISTs are difficult to provide because of the recent introduction of tyrosine kinase inhibitor therapy (imatinib mesylate and more recently sunitinib) in clinical practice and the recognition of the KIT protein (CD117), which has changed the way spindle cell tumors of the

gastrointestinal tract are classified. Before the introduction of imatinib mesylate, the available chemotherapeutic protocols were not effective against GISTs and the outcome for these patients was bleak.[88] Furthermore, until recently studies on GISTs included tumors that are not presently classified as GISTs. It is nevertheless believed that the overall or disease-specific 5-year survival rate is 28% to 60% among patients with GIST; the median disease-specific survival time is about 5 years for primary disease, and 10 to 20 months in recurrent or metastatic disease.[47,89] Most recurrences take place within 5 years of the primary diagnosis.[85] Remarkably, with the application of the tyrosine kinase inhibitors imatinib and sunitinib, the median survival in metastatic GIST is now 58 months.

The outcome for patients with metastatic malignancies to the small intestine (more commonly ovarian, colon, and lung cancers, renal cell carcinoma, and melanoma) is dismal despite palliative therapeutic intervention.

PRIMARY TREATMENT

Treatment of adenocarcinoma of the small intestine with localized disease is based on oncologic and anatomic principles. For duodenal lesions the availability of endoscopic ultrasound has allowed better preoperative staging,[90,91] and the availability of endoscopic resection techniques[92] has offered additional therapeutic options. Ultrasound-localized and biopsy-proven benign duodenal or ampullary adenomas can be resected endoscopically with excellent results. If these benign lesions are associated with familial polyposis, chemoprevention with sulindac or cyclo-oxygenase-2 inhibitors may be beneficial.[93]

Invasive lesions of the first and second portion of the duodenum without major vessel involvement and distant spread are best treated by a pancreaticoduodenectomy (Whipple procedure). For tumors in the third or fourth portion of the duodenum, segmental resection with regional lymphadenectomy is indicated.[18,19,79–81] Debate persists about the optimal surgical management of early duodenal cancer. Although early reports suggest that an endoscopic approach could be justified in early favorable lesions, long-term follow-up is still lacking,[94] and surgical resection is preferred in the good-risk patients. Palliative options for unresectable or metastatic duodenal carcinoma include gastrojejunostomy or biliary enteric bypass or endoscopic/interventional placement of stents to relieve the intestinal or biliary obstruction.

Adenocarcinoma of the jejunum and ileum is treated by wide excision, including areas of contiguous spread and the associated mesentery, with negative surgical margins. Although only small series have been published, these tumors do not seem to respond to the conventional 5-fluorouracil-based chemotherapy regimens, and there is a radiation dose limitation due to small bowel toxicity. However, for palliation of chronic blood loss in patients with locally advanced unresectable duodenal carcinomas, radiation therapy may provide short-term benefit.

The mainstay of therapy for carcinoid tumors is radical surgical excision. In preparation for surgery a complete assessment of the entire gastrointestinal tract is warranted, because up to 40% of midgut carcinoids are associated with a second gastrointestinal malignancy and 30% may be multicentric.[42,43] In addition, pre-emptive treatment with octreotide is indicated to prevent carcinoid crisis at the time of surgery. At surgery, wide en bloc resection including the draining mesentery is the standard approach,[18,19,42,43] particularly for small bowel carcinoid, because these lesions have the propensity to metastasize even when very small. Large lesions near the ampulla may require a pancreaticoduodenectomy for cure, and smaller lesions may be treated with either local excision or endoscopic resection with close endoscopic follow-up. Likewise, lesions of the terminal ileum or carcinoid tumors of the appendix larger than 2 cm require a formal right hemicolectomy for oncologic clearance of disease.

Treatment for advanced locoregional and distant disease includes both medical and surgical modalities. In one published study, after complete resection of all known disease a 73% actuarial 5-year survival rate was obtained, compared with 29% in patients who were deemed unresectable.[95] Therefore, surgery should be indicated in persons with resectable metastatic disease for potential cure or at least meaningful palliation. Orthotopic liver transplantation has been used in the treatment of metastatic neuroendocrine tumors to the liver.[96–99] In a recent report all patients had complete symptomatic response initially, but tumor recurrence was noted in 6 of 11 cases at a median of 11 months, with a mortality rate of 45%.[98] These discouraging results have limited the use of orthotopic liver transplantation for metastatic carcinoid tumors.

The role of multimodality therapy, including α2b interferon and octreotide, for metastatic carcinoid remains limited.[100–102] Interferon seems to provide symptomatic control in up to 70% of patients with carcinoid syndrome[101] and to increase 5-year survival rates to 71% in patients who continued treatment for 1 year as compared with 37% of those who stopped the treatment.[100] The addition of liver chemoembolization has not been shown to have a significant effect on survival in patients with metastatic disease to the liver[100,101] but may have a role in controlling or decreasing the symptoms associated with carcinoid crisis. Octreotide has been effective in the treatment of individuals with carcinoid syndrome by improving diarrhea in up to 83% of the patients and abolishing flushing and wheezing, but has no effect on survival.[102–104] In consideration of the slow growth rate of many carcinoid tumors, individuals with distant metastatic disease can also undergo resection for debulking and palliation of symptoms.[95,105–107] For those unfortunate individuals with extensive unresectable disease, the indications for surgical intervention are limited to the occurrence of obstruction, perforation, and bleeding. Radiation therapy has not been proved to be effective in either the adjuvant or palliative setting.

Treatment of small bowel lymphoma requires conservative resections with para-aortic and mesenteric lymph node sampling, liver biopsy, and bone marrow biopsy performed for staging. Low-grade localized lesions are treated with resection alone, and for intermediate- and high-grade lesions resection and chemotherapy are recommended. Radiation is used only for palliation in poor-performance patients.[45] This modality is associated with significant side effects, such as bowel necrosis, bleeding, and perforation, and is offered for palliation only to patients unfit for surgery or chemotherapy.

Surgical treatment for small bowel sarcomas consists of an en bloc resection with tumor-free margins. There is no role for extended lymphadenectomy in these tumors.[18,19,82] In the presence of metastatic disease, local excision or palliative bypass procedure might be indicated to prevent or ameliorate bleeding and obstruction. Furthermore, there is no clear benefit from chemoradiation therapy in the adjuvant setting, because radiation doses are limited because of small bowel toxicity. In the presence of recurrent or metastatic disease partial response rates after palliative chemotherapy and radiation therapy have been reported in the 10% to 20% range, with minimal improvement in survival at best.

Despite advances in molecular therapy, the treatment of primary, localized GISTs remains surgical resection. Usually a true tumor capsule does not exist, like in other soft tissue sarcomas, and the tumor should be removed en bloc with its pseudocapsule and margins of normal soft tissue or bowel.[108] In the presence of large lesions involving other organs, where an en bloc resection may be associated with significant morbidity, preoperative neoadjuvant use of imatinib mesylate may be entertained,[37] although at present data to support this practice are still lacking, pending results of the Radiation Therapy Oncology Group/American College of Radiology Imaging Network phase II study of imatinib mesylate in the neoadjuvant setting followed by surgery after 2 months of treatment.

At surgery an effort should be made to obtain tumor-free margins; several studies have shown better overall survival in patients who have undergone margin-negative resections,[82,86,109] and this practice helps

to avoid tumor violation or rupture, which is associated with increased risk of peritoneal implants.[82] Regional lymph node dissection is not recommended unless suspicious nodes are present, because GIST rarely metastasizes to nodes.[108]

A significant breakthrough in the management of small bowel tumors and specifically GISTs has come from understanding the molecular and genetic makeup of these lesions. After the discovery that GISTs characteristically express the KIT protein, a transmembrane tyrosine kinase receptor for a stem cell factor, a specific tyrosine kinase inhibitor, imatinib mesylate, has been introduced in clinical practice with partial response or stable disease occurring in approximately 80% of patients with advanced GIST.[110] Studies are under way examining the potential benefit of giving adjuvant imatinib after resection of primary GIST. The American College of Surgeons Oncology Group is leading two intergroup North American studies. The first is a phase II study for high-risk resected GIST; the second is a phase III study examining GISTs larger than 3 cm and randomizes patients to placebo or imatinib mesylate at 400 mg/day. In each study the treatment is given for 1 year.

The role of surgery for recurrent or metastatic disease has been questioned since the introduction of imatinib mesylate.[111] Currently the standard of care for metastatic GIST is imatinib mesylate at a dose of 400 mg/day. Because few complete responses to imatinib mesylate have been observed and resistance to the drug eventually develops in most patients, investigators at several centers have undertaken removing residual metastatic GIST after initial response to imatinib.[112,113] The idea is to delay or prevent the development of resistance. However, a randomized trial will be necessary to prove the benefit of surgery in metastatic GIST that is stable on tyrosine kinase therapy. Before the advent of imatinib there were data suggesting that resection of metastasis may improve survival in selected patients with well- to moderately differentiated GIST with isolated resectable metastasis and a disease-free interval of more than 12 months.[114,115] Surgery should also be considered in patients with bleeding or obstructive disease and after partial response to imatinib mesylate if the residual disease is deemed to be resectable.

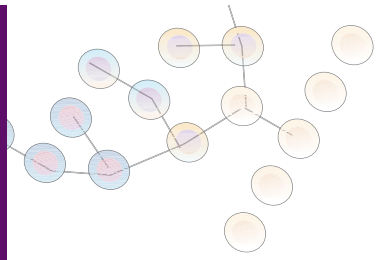
Occasionally patients may appear to develop new metastatic disease, especially in the liver, while receiving imatinib mesylate. However, these lesions often represent occult disease not detected on the initial CT scan that becomes evident as the tumor mass necroses or changes density with decreased perfusion. Obviously, in these cases it is important to continue treatment with imatinib mesylate. On the other hand, acquired clinical resistance to imatinib mesylate has been reported in chronic myeloid leukemia[116] and more recently in GISTs.[77] In chronic myeloid leukemia, resistance to imatinib mesylate treatment is primarily associated with reactivation of BCR-ABL signal transduction.[114,115] This reactivation is caused by several different molecular mechanisms, including BCR-ABL gene amplification and single-amino acid substitution.[114,117] In GIST the median time of resistance to imatinib is 2 years from starting therapy. The mechanism of resistance in half of patients is the development of an additional KIT mutation.[118,119] Once patients become resistant to imatinib, sunitinib is generally used as a second-line agent. Like imatinib, sunitinib inhibits KIT and PDGFRα but also inhibits vascular endothelial growth factor receptor.

Because imatinib mesylate is used more and more often in the treatment of GISTs, it is important to briefly review side effects and complications associated with its use. The recommended starting dose for imatinib is 400 mg/day, and tolerability has been reported for daily doses up to 800 mg or more. Most side effects are mild to moderate and include periorbital and lower extremity edema, nausea, muscle cramps, diarrhea, headache, dermatitis, fatigue, anemia, and neutropenia.[77] Grades 3 and 4 toxic effects occur in less than 30% of patients at a dose of 400 to 600 mg/day.[77,120] Dramatic response to imatinib mesylate may be complicated by intratumoral bleeding in less than 5% of patients, sometimes resulting in free intraperitoneal or intraluminal bleeding requiring surgical exploration. Minor side effects usually resolve after cessation of treatment.[37] Drug interactions with warfarin and paracetamol have been reported, and these combinations should be avoided.

FOLLOW-UP

In general, routine follow-up for small bowel cancers is accomplished with endoscopy and radiologic imaging. In GIST, because highly effective therapies are now available, it seems reasonable, though unproven, to follow patients closely after resection of a primary GIST. Contrast CT scans are recommended every 3 to 6 months for 5 years. For patients with metastatic or unresectable primary GIST who are being treated with a tyrosine kinase inhibitor, CT scans should be performed every 3 to 4 months to survey for the development of drug resistance.

CONCLUSIONS



Despite the remarkable advances in the imaging, classification, and treatment of small bowel cancer, much is still to be achieved. Capsule endoscopy, enteroclysis, endoscopic ultrasound, and PET scan have all improved our diagnostic ability, but differentiating diagnostic tools for earlier diagnosis of these rare malignancies are needed. Imatinib mesylate represents an innovative therapy, one of the first successful pharmacologic manipulations of the product of a constitutively activating mutation that drives pathogenesis of a solid tumor. As such, imatinib mesylate has an impact on the actual mechanism of cancer development and progression. However, many questions remain unanswered with this new drug: optimal duration of therapy, its role in the neoadjuvant or adjuvant setting, its role in combination therapy, and the overall long-term results. More important, the mechanisms behind acquired resistance to imatinib mesylate have to be further elucidated. Finally, combination therapy with conventional chemotherapy and other signal transduction inhibitors must be further investigated.

81 Colon Cancer

Carolyn Compton, Ernie Hawk, Louise Grochow, Fred Lee, Jr., Mark Ritter, and John E. Niederhuber

SUMMARY OF KEY POINTS

Epidemiology

- Colorectal cancer (CRC) is the fourth most common cancer in the United States, with about 153,760 new cases expected in 2007. With 52,180 deaths expected in 2007, it is the second leading cause of U.S. cancer mortality.
- Worldwide, with 1,023,152 new cases and 528,978 deaths estimated for 2002, CRC is the third most commonly diagnosed malignancy and the fourth leading cause of cancer-related death.
- There is a 5.5% lifetime risk of developing CRC in the United States.
- The overall 5-year survival in the United States improved greatly in past the decades and is now approximately 65%, with variations across racial and ethnic subgroups.
- African Americans have the highest age-adjusted CRC incidence and mortality rates in the United States.
- Ninety percent of U.S. cases occur after 50 years of age.
- U.S. incidence and mortality rates are higher in men than in women.
- Worldwide, there is a 25-fold variation in incidence, developed areas having the highest rates.

Etiology

- Initiation begins as a clonal proliferation within an aberrant crypt focus with progression to adenoma and on to invasive carcinoma.
- The APC tumor suppressor gene is defective in more than 80% of adenomatous polyps and colon cancers.
- Defective DNA mismatch repair is believed to be responsible for 15% to 20% of CRC.
- Inherited genetic variation increases risk in concert with dietary and environmental exposures.
- A high body mass index is associated with a twofold excess risk of CRC, relating to the concept of energy balance.
- Hereditary syndromes account for fewer than 10% of cases.

Screening for Colon Cancer

- Colonoscopy is the mainstay of screening as well as a useful tool in diagnosis.
- Other acceptable screening tools are fetal occult blood tests, flexible sigmoidoscopy, and double-contrast barium enema. Virtual colonography is being developed as a potential screening tool.
- Screening is based on risk categories that take into account age; race; personal history of inflammatory bowel disease, polyps, or cancer; family history of colon cancer; and presence of familial syndromes.

Prevention of Colon Cancer

- Calcium/vitamin D and selenium supplementation might have preventive benefits.
- Chemopreventive drugs such as cyclooxygenase-2 inhibitors may prevent polyps in high-risk patients.
- Hormone replacement therapy reduces the incidence of colon cancer but increases the risk of breast cancer and cardiovascular complications.
- Ursodexycholic acid has been shown to reduce incidence of high grade adenomas.
- There have been mixed results in studies of the effect of statins on colon cancer risk.

Diagnosis and Staging

- Colorectal cancer is often insidious in development, underlying the importance of screening.
- Fatigue, anemia, altered bowel function, and weight loss are frequent symptoms.
- Obstruction is the most common acute surgical problem (about 30% of left-sided lesions present with an obstruction).
- About 5% of people with CRC will have synchronous cancer. About 20% to 40% will have synchronous polyps with cancer primary.
- Imaging used in staging includes computed tomography, magnetic resonance imaging, and positron emission tomography.
- Intraoperative ultrasound is the most sensitive way to evaluate the liver.
- The liver is the most common site for synchronous metastases.
- Tumor size is not as critical as are depth of invasion and nodal status in determining prognosis.
- High histologic grade, lymphatic invasion, venous invasion, and involvement of surgical resection margins are independent adverse prognostic factors

Surgical Treatment

- Treatment may consist of en bloc resection of anatomically defined portions of colon with in-continuity draining nodes to the root of the mesocolon.
- Laparoscopic-assisted surgery is investigational; sentinel node mapping remains to be studied.
- Careful preparation of the bowel prior to surgery minimizes the risk of morbidity and mortality.
- Experienced surgeons and the use of high-volume hospitals improve the chance of good surgical outcome.

Surveillance

- 80% to 90% of recurrence after curative resection occurs within the first 2 or 3 years. Fewer than 5% of recurrences occur after 5 years.
- Recurrent disease is frequently isolated and surgically resectable; 35% of surgically managed metastatic disease results in a cure. A high percentage of first failures occur in the liver and are asymptomatic. Of those patients who

are followed closely for evidence of recurrence, about 20% are candidates for surgery to clear metastases. They have a 5-year disease-free survival rate of 18.6% compared to only a 5.6% 5-year disease-free survival rate when metastatic disease is diagnosed because it has become symptomatic (patients who are not undergoing surveillance).
- Suggested surveillance
  - Physician exam every 3 months for first 2 years and then every 6 months
  - Carcinoembryonic antigen level monitoring every 3 months
  - Colonoscopy 1 year postsurgery and then every 3 to 5 years
  - In patients with nonmetastatic disease, annual CT scan for 3 years in patients who are at high risk of recurrence
  - In patients with metastatic disease, CT scan every 3 to 6 months for 2 years, then every 6 to 12 months in years three to five.

Adjuvant Therapy
- Fifty to sixty percent of patients who undergo successful surgery for colon carcinoma have residual micrometastatic disease.
- Systemic chemotherapy is given in an effort to clear micrometastatic disease and is routine for patients with nodal disease (stage III). Adjuvant therapy is also used for higher-risk stage II patients.
- Recommended therapy is 6 months of oxaliplatin with 5-fluorouracil (5-FU) and leucovorin.
- Adjuvant radiation therapy has no standardized role but may be considered for cases in which resection of T3 and T4 lesions leaves potentially positive circumferential resection margins.

Management of Metastatic Disease
- Patients with metastatic disease, particularly liver metastases, should be evaluated to determine whether curative resection is possible.
- Chemotherapy with infusional 5-FU and leucovorin regimens (or capecitabine) in combination with irinotecan or oxaliplatin and bevacizumab has prolonged median survival to more than 20 months.
- Additional trials have demonstrated advantages for both FOLFOX and IFL-bevacizumab compared with IFL.
- Cetuximab and panitumumab, as well as agents that are still being investigated, provide a variety of available treatments that can be tailored to meet an individual patient's situation.

INTRODUCTION

Adenocarcinoma of the colon and rectum is one of the most common human malignancies. It is a major public health issue in developing and underdeveloped countries. In developed countries, thanks to screening, removal of neoplastic polyps, and advances in surgery, radiation, and chemotherapy, there has been a small but persistent improvement in survival over the past two decades, improvements that have not yet been seen in the rest of the world. This chapter reviews progress in understanding the biology of colon cancer, the epidemiology and prevention of colon cancer, and its diagnosis and treatment. The chapter has been divided into eight sections pertaining to the following topics:

- Epidemiology and etiology of colon cancer
- Screening for colon cancer
- Prevention of colon cancer
- Anatomy and physiology of the colon
- Diagnosis and staging of colon cancer
- Surgical treatment
- Outcomes of surgical treatment and the role of adjuvant therapy
- Medical oncology management of metastatic disease

EPIDEMIOLOGY OF COLORECTAL CANCER

Colorectal Cancer in the United States

Colorectal cancer (CRC) is the fourth most commonly diagnosed cancer and second most common cause of cancer-related mortality in the United States, with 153,760 new cases and 52,180 CRC-related deaths anticipated in 2007.[1] These statistics are sobering given that CRC should be one of the most preventable cancers through well-established screening and surgical techniques, if not molecularly-targeted approaches that are increasingly available. Nevertheless, the incidence and mortality of CRC have declined fairly consistently over the last 25 years, with well-documented 20% to 25% reductions in CRC mortality rates from 1990 to 2003 (Fig. 81-1). The lifetime risk of developing CRC is approximately 5.5%. This risk can be effectively reduced by any of several screening techniques, and a few primary prevention approaches seem promising. In addition, new targeted therapeutics are making important contributions to early-stage disease management, but advanced CRC remains largely refractory to available therapeutics. Five-year survival is highly dependent on the stage at diagnosis, with localized, regional, and distant presentations resulting in estimated survival rates of 90%, 68%, and 10%, respectively. Overall 5-year survival rates in the United States have improved significantly over the last 30 years, most recent estimates averaging 65%.

Substantial variations in CRC rates across various sectors of the U.S. population suggest the etiologic importance of aging and

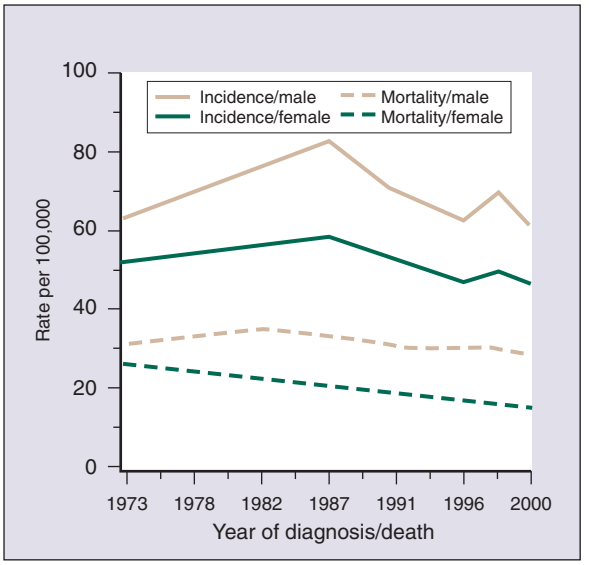

Figure 81-1 • Decline in incidence and mortality of colorectal cancer in the United States from 1973 to 2000. The decline of new cases per year began in the mid-1980s first for women and then for men. The decline occurred in each stage with a recent increase in localized disease. The decline in mortality began for women before 1973 and for men in the mid-1980s.

environmental influences and highlight disparities in CRC screening and care. As with many other cancers, CRC risk rises strongly with age, more than 90% of CRCs occurring in people older than 50 years of age. SEER data from 2000–2003 demonstrate a dramatic fourfold rise in age-specific CRC incidence rates from 52.1 cases per 100,000 in those 50 to 54 years of age, to 415.9 cases per 100,000 in those 85+ years of age.[2] CRC's strong association with aging reinforces the notion of adenomatous polyps as precursor lesions of most sporadic CRC as well, because the age-stratified prevalence of adenomas among residents of developed countries is striking: 30% at 50 years, 40% to 50% at 60 years, and 50% to 65% at 70 years.[3] CRC subsite distributions also vary by age, as is demonstrated by several recent analyses in which proximal cancers appear to be more common in elderly patients.[4] This shift is hypothesized to result from the greater likelihood of prior polypectomy in the distal colorectum.

CRC is a significant health issue for aging Americans of both genders, but there are some differences between CRC rates in men and women. Age-adjusted CRC incidence and mortality rates based on SEER data between 2000 and 2003 were higher for men (61.7 and 24.0 per 100,000, respectively) than for women (45.3 and 16.9 per 100,000, respectively).[2] Five-year survival rates from the same period were more similar at 65.0% for men and 63.2% for women. Finally, incidence trends were falling for both men and women between 1994 and 2003; however, the annual percent change was a bit greater in men (−1.3% per year in men, −0.8% per year in women). Gender differences in CRC rates are largely unexplained but might relate to differences in sex hormones, since estrogens could protect against microsatellite instability-positive cancers in particular.[5]

SEER estimates of age-adjusted CRC incidence, mortality, and survival rates from 2000–2003 differ substantially across racial and ethnic subgroups, based on five subgroups: blacks, whites, Asian/Pacific Islanders, American Indians/Alaskan Natives, and Hispanics. Blacks have the highest age-adjusted rates of CRC incidence (62.8 cases per 100,000) and mortality (27.3 deaths per 100,000), followed by whites at 52.0 cases per 100,000 and 19.3 deaths per 100,000, respectively.[2] Among these groups, Hispanics have the lowest rate of CRC incidence (39.0 cases per 100,000), and the next to the lowest mortality rate (13.8 deaths per 100,000). Five-year survival rates are better for whites than for blacks regardless of the stage of disease at diagnosis, by as much as 17%, but survival has improved for both subgroups between 1975 and 2002, albeit with more dramatic improvements for whites than for blacks.[1,2] One explanation for these disparities lies in the fact that blacks present more often with distant disease (i.e., 24% of CRC in blacks versus 19% of CRC in whites). Other arguments that have been advanced to explain black-white disparities in CRC outcomes include racial dissimilarities in age at diagnosis, anatomic subsite distribution, histopathologic characteristics, screening utilization, medical oncology referral patterns, comorbidities, social support, and medical treatment.

Socioeconomic status has been inconsistently associated with variations in CRC rates, but geographic differences seem robust in both resident and migrant populations. Typically, variations in incidence between countries are much more dramatic than variations within each country, but in high-risk countries, notable differences can still be seen. A study of the geographic distribution of the predicted incidence and observed mortality rates for CRC using 1999 data noted the highest rates in the northeastern and upper Midwest regions of the United States and the lowest rates in the West.[6] In some instances, detailed assessments of geographic variations seem to correlate with lifestyle practices.[7]

Colorectal Cancer in the World

The International Agency for Research on Cancer prepares periodic estimates of the global cancer burden in terms of age-adjusted incidence, mortality, survival, and prevalence, stratified by sex and geographic region. The most recent analysis estimated that there would be 1,023,152 new CRC cases (550,465 in males, 472,687 in females) and 528,978 CRC-related deaths (278,446 in males, 250,532 in females) in 2002, making CRC the third most common malignancy and the fourth most common cause of cancer-related death.[8] There is at least a 25-fold variation in the occurrence of CRC across various regions of the world, developed areas—particularly Australia, Western Europe, Japan (in males), and North America—having the highest incidence rates. Estimated 5-year survival rates also vary widely by region, from 30% in India to 65% in North America. The large differences in incidence are probably due to environmental factors, which are believed to play a very important role in CRC etiology. For more than 30 years, epidemiologists have described strong international correlations between CRC and various dietary constituents, including the consumption of fiber, animal fats, and meat; recent evidence seems to suggest that red meat consumption and physical inactivity are likely to play the largest role.[9] Incidence trends suggest that risks are rising in previously low-risk regions (e.g., Asia) but are either stable or falling in many previously high-risk regions (e.g., North America). The substantial differences in survival probably arise from variations in screening, early diagnosis, and therapeutic services.

The study of migrant populations has provided important insights into CRC development, and highlighted the importance of environmental factors. Overall, migrant groups tend to assume the CRC risks of their adopted country, typically within one or two generations. For example, studies of Japanese and Chinese immigrants to the United States demonstrated clear increases in risk, perhaps owing to changes in dietary habits, available food sources, or physical activity.[10,11] The converse is also true; resettlement from a high-risk region to a low-risk region can reduce a population's CRC risks. For example, Italian immigrants to South America assumed the risks of their adopted homes, with CRC rates falling among those settling in low-risk Sao Paulo but increasing in migrants to high-risk Argentina.[12]

ETIOLOGY OF COLORECTAL CANCER

Molecular Pathogenesis

The development of cancer appears to result from the accumulation of genetic and epigenetic alterations that affect at least six essential cellular and tissue-level functions.[13] An important multistep model outlining key pathogenic changes in oncogenes and tumor suppressor genes was first hypothesized for CRC development by Vogelstein and colleagues in 1988.[14] Since publication of this model, other work has provided consistent support for the Vogelstein model of the adenoma-to-carcinoma sequence (Fig. 81-2), but additional alternative mechanisms have been described as well. Potter recently summarized these data by describing three genetic pathways to CRC.[15]

APC-β-Catenin-Tcf-MYC Pathway

The initial mutation probably occurs at the tumor suppressor gene APC, which is on chromosome 5q. The APC tumor suppressor gene is defective in more than 80% of adenomas and colon cancers. It is the most common defect and the one that appears earliest in the sequence of accumulated genetic alterations. In CRC, the majority of mutations in the APC gene cause a truncation of the APC protein and therefore a loss of its normal function to degrade cytoplasmic β-catenin. This degradation occurs when β-catenin is bound to the APC/AXIN/GSK-3β complex. GSK-3β acts to phosphorylate β-catenin, leading to its conjugation to the ubiquitin protein and degradation. β-Catenin stability is regulated by diacylglycerol-independent protein kinase C-like kinase activity, which is required for β-catenin ubiquitination[16] (Fig. 81-3). The absence of a functioning APC protein leads to the accumulation of β-catenin in the cytoplasm and its translocation to the nucleus. β-Catenin plays an important role in cell-cell adhesion by linking cadherin receptors to the actin

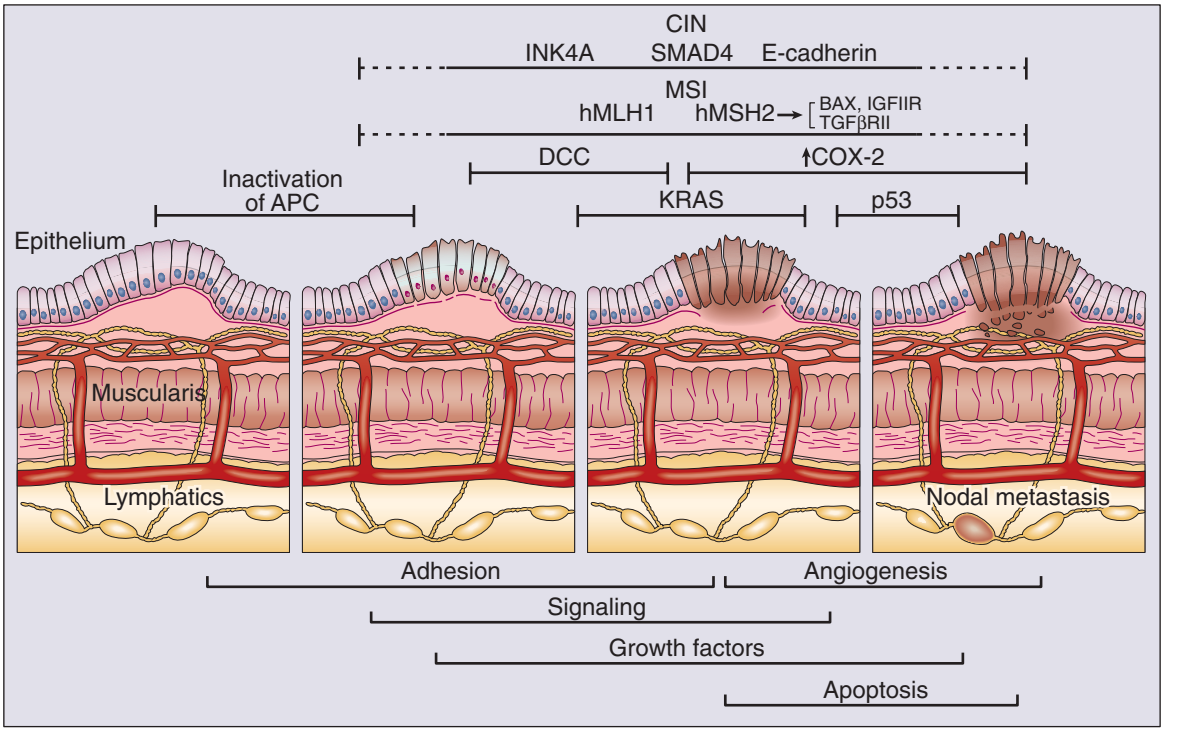

Figure 81-2 • Adenoma-to-carcinoma sequence and the associated molecular alterations involved in colon cancer development.

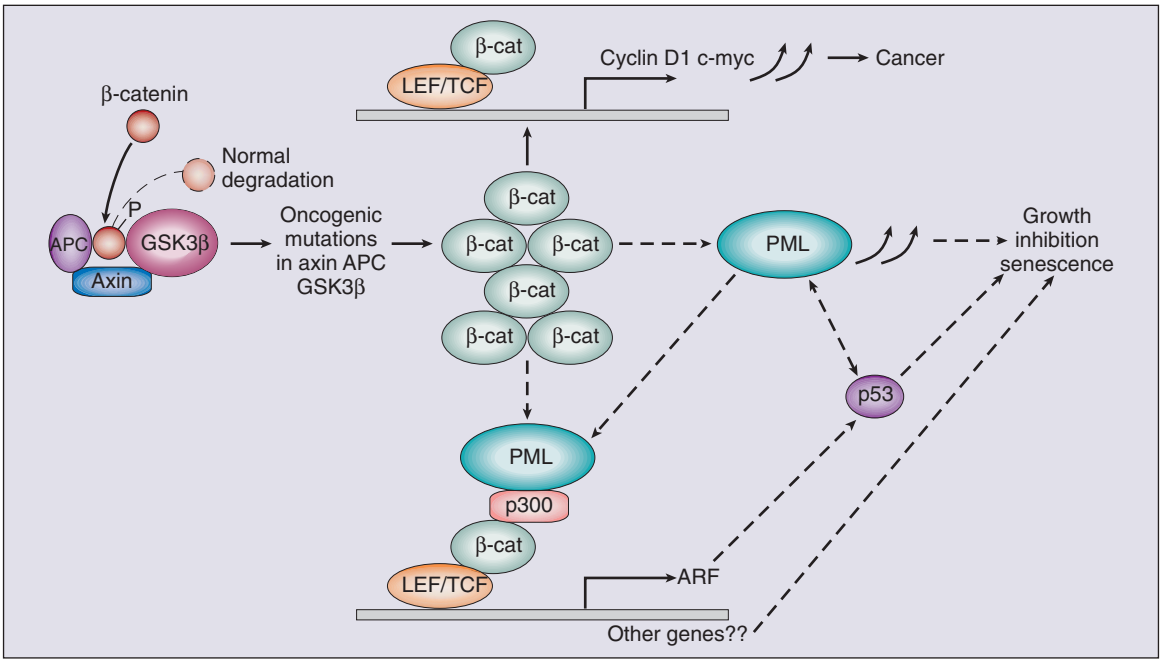

Figure 81-3 • Molecular pathway for the oncogenic and tumor-suppressive effects caused by the activation of β-catenin (overexpression). In the normal colonic epithelial cell, β-catenin is phosphorylated by GSK-β after it is bound to the APC-Axin-GSK-3β complex. This leads to normal degradation of β-catenin. Oncogenic mutation of APC leads to failure to bind, phosphorylate, and degrade β-catenin. The result is increasing cytoplasmic concentrations of β-catenin which translocates to the nucleus and activates the LEF-TCF complex, in turn activating a number of target genes promoting cell proliferation. β-Catenin induces expression of the PML gene and other pathways. (Adapted from Shtutman M, Zlurinsky J, Oren M, et al: PML is a target gene of β-catenin and plakoglobin, and coactivates β-catenin-mediated transcription. Cancer Res 2002;62:5947–5954, fig. 6.)

cytoskeleton. β-Catenin is also related to the Wnt-signaling pathway that determines cell fate, specifically during development. If Wnt signaling is activated and in turn activates the Wnt receptor, phosphorylation and inactivation of GSK-3β occur, which then prevent GSK-3β from phosphorylating β-catenin.[17] The nuclear accumulation of β-catenin causes it to complex with Tcf/LEF (T-cell factor/lymphocyte enhancer factor). The β-catenin LEF protein complex can activate genes with Tcf/LEF promoter recognition sites, including c-Myc, cyclinD1, PPARS, matrilysn, Fra-1, UPAR, c-Jun, PML, and gastrin. These changes, in turn, stimulate cell proliferation and inhibit apoptosis.[18]

In this model of CRC development, progression from adenoma to carcinoma is dependent on the accumulation of other genetic and epigenetic aberrations as well. Another important alteration includes point mutation of the K-ras proto-oncogene. Additionally, hypomethylation of DNA leading to gene activation seems to play a role. Deletions of 18q21 have also been described, and DCC, a tumor suppressor gene, was identified at this chromosomal location.[19] In addition, SMAD2 and SMAD4, two other genes that are involved in CRC, have been identified at 18q21.[20,21] SMAD2 is a receptor-regulated gene and is activated by transforming growth factor-β and activin signaling. Its role in colon cancer appears to be a late event, acting to accelerate progression in the later stages of invasive carcinogenesis.[22] Finally, allelic loss or mutation at chromosome 17p, which has been associated with the p53 tumor suppressor gene, appears to play a late role in CRC by stimulating invasion. It is generally assumed that it is the accumulation of lesions, rather than their precise order, that is critical to progression.

Defective Mismatch Repair Pathway

Some 15% to 20% of CRCs are believed to develop through a different pathway in which there is a defective DNA mismatch repair system. This pathway is characterized by instability of short, repetitive DNA sequences (i.e., DNA microsatellites). Several mismatch repair genes—hMLH1, hMSH2, hPMS1, hPMS2, and hMSH6—are involved in identifying and correcting errors in these sequences.[23] In most sporadic CRCs that are associated with microsatellite instability, hypermethylation of the promoter region of the hMLH1 gene has been found.[24] Most familial cases, identified as hereditary nonpolyposis colorectal cancers (HNPCC), have been associated with mutations in the hMLH1 or hMSH2 genes. Importantly, tumors that develop from defective mismatch repair can also acquire additional somatic frameshift mutations of coding repeats within other important genes. For example, a frameshift mutation of the BAX gene,[25] a gene that promotes apoptosis, and mutations of the transforming growth factor-β type II receptor gene,[26] and a tumor suppressor gene have been described.

Ulcerative Colitis Dysplasia and Carcinoma Pathway

Patients with chonic ulcerative colitis are at an approximately 20-fold increased risk of CRC.[27] The development of CRC in these patients appears to have several unique features that distinguish it from the pathways outlined previously. First, rapid cell turnover and oxidative injury are commonly observed in inflammatory conditions. These conditions lead to accelerated telomere shortening, increased chromosomal fusing, damage, and instability.[28] In addition, p53 mutations appear to occur earlier than in most sporadic CRC.[29]

Other Molecular Pathways and Lesions

Although investigations have focused on identifying the genetic alterations that are present in the adenoma to carcinoma model of CRC, recent work has suggested another alternative, but probably minor, path for CRC development. The term *serrated adenoma* has been used for hyperplastic polyps with serrated morphology that demonstrate dysplasia throughout the lesion. This alternative molecular route evolves from hyperplastic polyps through serrated adenomas and is characterized by mutations in the BRAF kinase gene and hypermethylation of CpG islands.[30] Studies suggest that BRAF mutations are rare in traditional adenomas (i.e., 3% to 10%) but common in serrated adenomas.[31]

What is becoming clear is that CRC is a heterogeneous disease made up of several genetically discrete subsets, each of which evolves through quite separate pathways of genetic alterations.[32] Each of these subsets will require considerable study before a final understanding of CRC as a disease can be reached. This will be essential to the future of designing rational molecularly targeted approaches to prevention and therapy.

Environmental Influences

The importance of environmental factors in CRC is underscored by migrant studies that suggest that changes in lifestyle can affect a population's cancer rates within a single generation and the 25-fold variation in international CRC incidence rates. Determining which environmental risk factors account for these observations and translating them into specific public health recommendations that can be offered to reduce CRC risks remains an active area of research.

Nutrition

Support for the role of dietary factors in CRC development comes from six lines of evidence: geographic observations,[33] chronologic observations,[34] migration studies,[10,11] mechanistic inquiries, animal models, and human trials. Intuitively, the relationship between ingested substances (or their metabolites) and CRC makes sense because they have direct, topical contact with the colorectum, thereby potentiating any inherent procarcinogenic or anticarcinogenic effects.

High fiber intake has been proposed as a CRC protective factor for more than 40 years, since Burkitt originally suggested that high-fiber diets and low rates of CRC in Africa were correlated.[35] Subsequent case-control and cohort studies have examined the relationship between fiber, as well as fruits and vegetables in general, and CRC risk. Taken together, more than 10 case-control studies generally showed a 40% to 50% protective association between vegetable intake and CRC risk.[36,37] However, subsequent cohort studies involving tens of thousands of participants have shown much weaker, if any, protective effects of fiber, fruit, or vegetable intake on CRC risk.[38–40] The situation is made more complex by a recent report from the European Prospective Investigation into Cancer and Nutrition cohort study involving 10 countries and more than 500,000 people that reported a 40% reduction in CRC incidence between those consuming the highest versus lowest levels of fiber.[41] On the basis of observational studies alone, the association between dietary fiber, fruits, and vegetables and lowering CRC risk seems inconsistent and modest at best; however, diets that are high in these components may have many other health benefits, such as reducing the risk of symptomatic colonic diverticuli, coronary artery disease, hypertension, and diabetes.[42]

Dietary fat has been proposed as a CRC risk factor for decades; however, the association has been inconsistent across studies. Although multiple retrospective studies described positive associations between total fat intake and CRC risk,[43] a meta-analysis of 13 case-control studies found that overall dietary fat consumption was not associated with CRC risk.[37] One reason for the inconsistent observations might be that only specific sources or subtypes of fat are linked to CRC; another reason might be that risk is related more to excess energy intake than to fat intake per se. Red meats have been reported to increase the risk of CRC across multiple studies, perhaps owing to their fat content.[38,39,44] Two recent meta-analyses related to processed meats in particular suggested strong risks for CRC.[45,46] The reasons underlying red meats' association with CRC are unclear, but hypotheses related to their total fat content, saturated fat content, or carcinogens derived from their cooking have been advanced. Mutagenic heterocyclic amines can be generated during cooking, and the

CRC risk of meat eaters who prefer heavily browned surfaces or who cook meat at high temperatures is often elevated.[47] Select gene polymorphisms might potentiate the risks of ingesting charred red meats by differentially metabolizing cooking-related carcinogens.[48]

Folate and methionine are dietary methyl donors that support critical cellular functions such as nucleotide synthesis and gene regulation. Therefore, diets that are deficient in these substances might contribute to CRC by altering the capacity for DNA synthesis, repair, or transcriptional control. Observational studies have generally supported the notion of an inverse association between folate and methionine intake and CRC risk,[49–51] risk estimates suggesting reductions on the order of 25% to 50%. A recent pooled analysis based on more than 500,000 participants followed for up to 13 years identified a 21% lower risk of CRC among those with the highest intake of folate, regardless of whether it was received as a part of the diet or through supplements.[52] Once again, polymorphisms in key genes associated with the metabolism of folate to methionine or thymidylate synthesis, involving the methylenetetrahydrofolate reductase enzyme, may play an important role.[53] Given that alcohol is a potent antagonist of folate metabolism, the role of these variants in CRC might be most relevant in alcohol users. Overall, a twofold to fivefold increase in risk has been described in people with high-alcohol, low-folate diets.[50] These risks might be particularly important for individuals with the methylenetetrahydrofolate reductase TT genotype, who are at relatively low risk if they have a good diet but have an elevated risk if they have a diet that is low in folates and high in alcohol.[54,55] More recently, a meta-analysis of 18 studies involving Japanese populations has reported a consistently increased risk associated with alcohol intake, even among those with moderate levels of use.[56]

Calcium intake has been hypothesized to reduce the risk of CRC owing to its ability to bind ionized fatty acids and secondary bile acids to reduce their mucosal toxicity and/or directly reduce intestinal proliferation.[57,58] A meta-analysis of 16 case-control and 8 cohort studies reported a statistically significant 14% risk reduction among subjects in the highest versus lowest categories of intake.[59] More recent large prospective studies have typically reported a modest inverse association but without a clear dose-response relationship.[60] In addition, some studies suggest that the maximum benefit can be achieved with intakes of 700 to 800 mg/day, and effects are most striking for distal, rather than proximal, CRC.[61] Recent randomized controlled trials confirm calcium's protective effects (see later in the chapter). Vitamin D has also been proposed as a potent CRC preventive agent on the basis of its ability to suppress proliferation and to induce differentiation and apoptosis in certain preclinical settings.[62] While the proposal has intuitive appeal, definitive results are lacking, and it remains a topic of intense research.

Several other dietary constituents have been investigated for their possible association with CRC risk. Antioxidant micronutrients, including retinoids, carotenoids, ascorbic acid, α-tocopherol, and selenium, have been considered in both retrospective and prospective studies but without a clear conclusion regarding their role in CRC etiology.[63] Alcohol's role in CRC etiology has been debated for decades; recent analyses suggest a modest but significant increase in CRC risk among those who drink more than two drinks per day.[64] For example, the Pooling Project of Prospective Studies recently reported a 24% increase in CRC risk in those who consume at least 30 grams per day.[65] The mechanisms underlying alcohol's effects on CRC might involve its ability to induce cellular proliferation, block methyl group donation, and inhibit DNA repair. Deleterious effects of alcohol could be particularly important for individuals with marginal dietary intakes of folate and methionine (see the earlier discussion).

Energy Balance

Accurate measurements of energy balance can be difficult in an epidemiologic context because of the inherent complexity of the various factors involved—dietary intake, individual metabolic rates, and physical activity—as well as their variation over time. Therefore, a variety of surrogate measures have been employed to investigate the role of energy balance in CRC etiology. A high body mass index has been reliably associated with at least a twofold excess CRC risk across multiple epidemiologic studies,[66,67] and some studies suggest increased risks with central adiposity even independently of body mass index, particularly in men.[68]

Moderate levels of physical activity have also been consistently associated with a reduced risk of colorectal neoplasia, regardless of gender. Colditz and colleagues summarized 23 case-control and 18 cohort studies and reported a 40% to 50% reduction in CRC risk among subjects reporting high versus low levels of physical activity.[69] The effects may be most striking for distal CRC, but even moderate levels of activity (such as walking 3 to 4 hours per week) may be effective. More recently, the European Prospective Investigation into Cancer and Nutrition study reported a 22% reduction in the hazard ratio for CRC among the most active participants compared with the inactive ones, with a dose-response trend.[70]

Finally, there are strong similarities between risk factors for CRC and non-insulin-dependent diabetes mellitus, which include excess caloric intake, physical inactivity, and central adiposity; suggesting a possible link between these diseases. Although the pathogenic details remain to be elucidated, non-insulin-dependent diabetes mellitus has consistently been associated with a 30% to 40% increased risk of CRC in retrospective and prospective studies.[71,72]

Environmental Exposures

At least three environmental exposures have been evaluated for their roles in CRC etiology. Tobacco use has been consistently associated with a twofold to threefold risk of colorectal adenomas and recently also with an increased risk of CRC.[73] Interestingly tobacco appears to act early in CRC development, so its effects on CRC incidence might take 30 to 40 years to manifest themselves. Tobacco cessation might reduce risks, but it is likely that some level of excess risk persists indefinitely. Sporadic reports suggest that pelvic irradiation for gynecologic malignancies can increase the risk of rectal cancers by twofold to threefold; newer, more focused treatment modalities should minimize these risks.[74] Finally, asbestos has been reported in some studies to increase CRC risks by up to 40%,[75] but this association is considered controversial.[76]

Host Influences

Hereditary Factors

Several genetic susceptibility syndromes have been described that place individuals who harbor characteristic mutations at increased risk for CRC. Although the associated CRC risks are dramatically elevated in these groups, the proportion of CRC that is attributable to these syndromes is small (probably less than 10% in total) because of the rarity of the syndromes.

Familial adenomatous polyposis (FAP) is a rare autosomal dominant disorder that is characterized by the occurrence of hundreds to thousands of colorectal adenomas by 20 to 30 years of age[77] (Fig. 81-4). In general, the disorder is the result of an inherited defect in one allele of the APC gene, which acts as a tumor suppressor gene (see earlier in the chapter); however, up to 20% of cases could represent de novo mutations without an apparent family history. When the second allele is inactivated through mutation early in childhood, the colonic epithelium begins a process of uncontrolled hyperplasia and polyposis. The lifetime risk of CRC is nearly 100% and appears to be correlated with the number of adenomas,[78] but given the rarity of the disorder, it accounts for only 1% to 2% of all incident CRC. In addition to the risk of CRC, other phenotypic manifestations of the disorder can include tumors of the central nervous system (also known as Turcot's syndrome),[79] epidermal cysts, osteomas, dental abnormalities, mesenteric or abdominal wall desmoid tumors (also known as Gardner's syndrome),[80] congenital hypertrophy of the

Figure 81-4 • A segment of a large intestine covered with adenomatous polyps in a patient with familial adenomatous polyposis. The entire colon is covered with hundreds of polyps. (From Skarin AT, Shaffer K, Wieczorek T [eds]: Atlas of Diagnostic Oncology, 3rd ed. St. Louis, Mosby, 2003, p 153.)

retinal pigmented epithelium, and upper gastrointestinal tumors, especially periampullary duodenal carcinoma. Several of these phenotypic features have been correlated with specific mutation sites.[81] The most common genetic abnormality results in a stop codon, leading to the production of a truncated and nonfunctional APC protein. The in vitro production of this abnormal protein now serves as a genetic screening procedure for the disease following appropriate genetic counseling. In the absence of preventive measures, invasive CRC occurs in FAP patients at an average age of 42 years. This provides a compelling rationale for a variety of preventive interventions, including early endoscopic screening, proctocolectomy, colectomy with ileorectal anastomosis, lifelong upper and lower intestinal surveillance, and participation in clinical trials evaluating the potential benefits and risks of chemopreventive options. An attenuated form of FAP has been described in some individuals who harbor mutations at the extreme 3′ or 5′ end of the APC gene. In these individuals, disease onset is typically delayed by 20 years; polyposis is not nearly as dramatic, with 100 or fewer colorectal adenomas; and polyps are more common in the proximal colon. Although the lifetime penetrance of CRC appears to be high in this variant, extracolonic features are less common.[82]

Hereditary nonpolyposis colorectal cancer (HNPCC) is an autosomal dominant disorder involving one of several genes involved in the mismatch repair system, including hMSH2, hMLH1, hPMS1, PMS2, or hMSH6. Defects in one or more of these proteins result in microsatellite instability and characteristic clinical phenotypic features that include early-onset CRC (often by 50 years of age) typically in the proximal colon; the occurrence of rare, villous, high-grade adenomas; and a variety of extracolonic tumors involving the endometrium, ovary, upper GI tract, pancreas, ureter, or renal pelvis.[83] Penetrance of the disorder has been estimated to be approximately 80% to 85%, and the syndrome is believed to account for 4% to 6% of all incident CRC.

In addition to high-penetrance genes such as those described earlier in the chapter, a variety of low-penetrance, polymorphic genes have been investigated for their potential to influence CRC risks, particularly when considered in the context of concomitant dietary or environmental exposures.[84] Most of these analyses involve genes that play a role in metabolizing various carcinogenic compounds, including heterocyclic amines or polycyclic aromatic hydrocarbons (e.g., N-acetyl transferase, cytochrome P450s, glutathione-S-transferase enzymes), catabolizing alcohol (e.g., aldehyde dehydrogenase), and maintaining methyl donor activity (e.g., methylenetetrahydrofolate reductase) or directly affect carcinogenesis through their activity as oncogenes (e.g., HRAS1) or tumor suppressors (e.g., p53). De Jong and colleagues recently performed a pooled analysis of 30 polymorphisms in 20 genes and identified 7 polymorphic genes that were significantly associated with CRC risk in more than one study.[84] Specifically, polymorphisms associated with an increased risk of CRC included the NAT2 fast phenotype (70% increased risk); the GSTfi1 null genotype (40% increased risk); one or two mutant alleles of ALDH2; any of four rare variants of the proto-oncogene HRAS1; and the a2, a5, and a13 alleles of TNFa. The pooled analysis also revealed reductions in CRC risk for the following polymorphisms: homozygous carriers of the C677T variant allele of methylenetetrahydrofolate reductase (20% to 30% reduced risk) and heterozygous or homozygous carriers of an intron 3 polymorphism of the p53 gene. Not included in De Jong and colleagues' analysis are whole-genome scanning techniques that have also recently identified single-nucleotide polymorphisms at the 8q24 locus as associated with increased risk of CRC.[85,86]

Inflammatory bowel disease (IBD) is described in two clinical forms: ulcerative colitis and Crohn's disease.[87] Both forms of IBD appear to result from a polygenic disorder with a strong familial component. For example, in a patient with IBD, the lifetime risk that a first-degree relative will be affected averages 10%. In addition, monozygotic twins are much more likely than are dizygotic twins to be affected. CRC risk in chronic ulcerative colitis increases with the duration and extent of disease. Estimates of CRC risk rise 0.5% to 1.0%, on average, per year after 10 years of chronic inflammation, making colonoscopic surveillance mandatory, although improvements in medical management seem to be reducing risks in some individuals. IBD-associated CRC has several unique features that distinguish it from sporadic CRC.[88] Specifically in IBD, CRCs occur about 20 to 30 years earlier, are more often mucinous or anaplastic in nature, arise from either flat or dysplasia-associated lesions versus adenomas, and occur in a multiple, synchronous manner in up to 12% of individuals; also, in contrast to sporadic CRC, p53 mutations occur earlier in the disease course, while APC mutations occur much later.

Familial clustering of CRC is common even in those without a definable genetic predisposition. For example, twin studies suggest that heritable factors are important in CRC development, even in the absence of known genetic predispositions.[89] Two recent meta-analyses of observational studies demonstrated an approximate relative risk of 2.25 in individuals with a single first-degree relative affected by CRC and a 4 to 4.25 relative risk in those with more than one affected relative or with a family member who developed CRC before 45 years of age.[90,91] Risks were slightly higher for colon cancer than for rectal cancer. Population lifetime CRC risk estimates for a 50-year-old increased from 1.8% to 3.4% with one affected relative and to 6.9% with two or more affected relatives. Risks were also elevated approximately twofold for individuals with first-degree relatives who harbored colorectal adenomas, lending support to the notion that colorectal adenomas and carcinomas are linked.

Somatic Factors

Nearly all CRCs are believed to arise from prior adenomas, but fewer than 10% of adenomas progress to become CRCs.[92] Nevertheless individuals with a prior history of colorectal neoplasia (either adenomas or carcinomas) are at increased risk for developing metachronous or recurrent CRC. Important features of adenomas that increase the individual's subsequent risk of CRC include their size, villous histopathology, and multiplicity. In a cohort study of more than 800 patients with adenomas, the relative risk estimate for CRC after 13 years of follow-up was 3.6; the relative risk rose to 6.6 among patients with more than one adenoma at baseline.[93] Risks for CRC are similarly elevated among patients with prior resected CRC.

Prior cholecystectomy has been suggested as a risk factor for CRC owing to the resulting continuous excretion of bile acids, which, when metabolized by intestinal bacteria, can be mutagenic.

Two meta-analyses of retrospective studies found modestly increased risks for proximal CRC, but the potential for confounding by other related factors tempers the implications of the association.[94,95] At present, prior cholecystectomy does not affect any of the prominent GI screening or surveillance guidelines.

A variety of other uncommon conditions have been associated with an increase in CRC risk. For example, there are several reports of colon carcinoma occurring years after ureterosigmoidostomy for congenital extrophy of the bladder.[96] Risk estimates suggest that the incidence of CRC in this setting may be as high as 5% to 10% after 20 to 30 years of follow-up. *Streptococcus bovis* bacteremia or endocarditis has also been noted in many case series as a warning sign of latent colorectal neoplasia.[97] Acromegaly is a endocrinologic disorder that is characterized by excessive circulating levels of growth hormone and its tissue mediator, insulin-like growth factor-1, and up to a 13-fold higher prevalence of colorectal neoplasia compared to population controls.[98] More recent studies have found twofold to ninefold increased relative risks for colorectal adenomas and cancer among acromegalics and identified a correlation between serum concentrations of growth hormone and CR neoplasia.[99,100] Serum levels of insulin-like growth factor-1 during childhood and adolescence influence linear growth and correlate with height.[101] Interestingly, observational studies have commonly reported positive associations between height and colon cancer risk as well, although risk estimates have been modest.[102,103]

SCREENING FOR COLON CANCER

Screening the General Population at Low to Average Risk

The American Gastroenterological Association and other groups recommend that "men/women at average risk should be offered options for screening for colorectal cancer and polyps beginning at age 50 years." African Americans are considered to be at above-average risk, according to the American College of Gastroenterology, and will be discussed later in the chapter.[104] Screening options for average-risk patients should be offered, with information about the advantages and disadvantages associated with each approach. If the result of a screening test is abnormal, physicians should recommend a complete structural examination of the colon and rectum by colonoscopy (or flexible sigmoidoscopy and double-contrast barium enema if colonoscopy is not available).[105]

Fecal occult blood testing (FOBT) should be offered annually, using a guaiac-based test with dietary restriction or a fecal immunochemical test (FIT) without dietary restriction. Two samples from each of three consecutive stools should be examined without rehydration. Patients with a positive test on any specimen should be followed up with colonoscopy.[105] The sensitivity of a single FOBT is low, detecting only about 26% to 69% of cancers. A single FIT performs better, with a sensitivity of 66% to 90% and specificity over 90%.[106] In the case of either test, its success as a screening tool is not evaluated on a one-time basis. A program of repeated testing can detect the majority of cancers and result in an 18% to 21% reduction in colon cancer mortality, according to strong evidence from randomized prospective clinical trials.[107–109]

Flexible sigmoidoscopy should be offered every 5 years, on the basis of evidence of reduced mortality from four case-control studies and two randomized controlled trials.[110–115] When combined with FOBT or FIT, the fecal test should be done first; if it is positive, a complete colon exam would be indicated.[116–118] The combination of flexible sigmoidoscopy and FOBT or FIT is preferred to either one alone.[119,120]

Colonoscopy should be offered every 10 years. The interval of 10 years is based on the typical rate of progression from adenoma to cancer.[121] Although there are no studies evaluating whether screening colonoscopy alone reduces the incidence or mortality from colorectal cancer in people who are at average risk, several lines of evidence support the effectiveness of screening colonoscopy.[105] Colonoscopy has not only diagnostic but also therapeutic benefits, as it allows removal of adenomas and reduces the incidence of colorectal cancer, as was demonstrated in two cohort studies of people with adenomatous polyps.[122] Colonoscopy examines more of the colon than sigmoidoscopy, and as expected, it has been proven to detect twice as many significant adenomas and cancers as sigmoidoscopy in two large prospective studies in which half of all patients with advanced proximal neoplasms had no distal colonic findings on sigmoidoscopy that would have prompted referral for a complete colon exam.[123,124]

Both the American Cancer Society[119] and the National Comprehensive Cancer Network (NCCN) list double-contrast barium enema as a screening option to be offered every 5 years.[120] No trials have been done to evaluate the effect of double-contrast barium enema screening on CRC incidence or mortality; however, in studies of patients with known disease, double-contrast barium enema was shown to have a sensitivity level ranging from 80% to 90% for colorectal cancer.[125] Although these numbers cannot be directly applied to general screening, the efficacy of double-contrast barium enema in detecting adenoma and early cancers has made it an attractive screening option.[126]

Virtual colonography (VC), though not listed among any current screening guidelines, is a screening technology that is likely to be adopted in the near future.[126] VC, also referred to as CT colonography, is a noninvasive radiologic study for the detection of colonic polyps and masses (Fig. 81-5). VC was introduced in 1994 and uses two-dimensional and three-dimensional reconstruction of conventional CT data sets to examine the luminal surface of the prepped and insufflated colon. Early reports in polyp-rich patient cohorts were highly encouraging, but these results could not be duplicated in initial studies of low-prevalence cohorts.[127–129] Improved techniques, including stool tagging and the use of a primary three-dimensional approach that mimics the endoluminal display of conventional colonoscopy, have dramatically improved the detection of polyps with diameters of 6 mm and greater.[130,131] Of the three multicenter trials that have been performed to date, only the largest trial (the sole trial to use three-dimensional techniques and stool tagging) showed performance comparable with that of optical colonoscopy for detection of relevant lesions.[130]

Several challenges remain prior to the widespread implementation of screening with VC, despite encouraging results at some centers

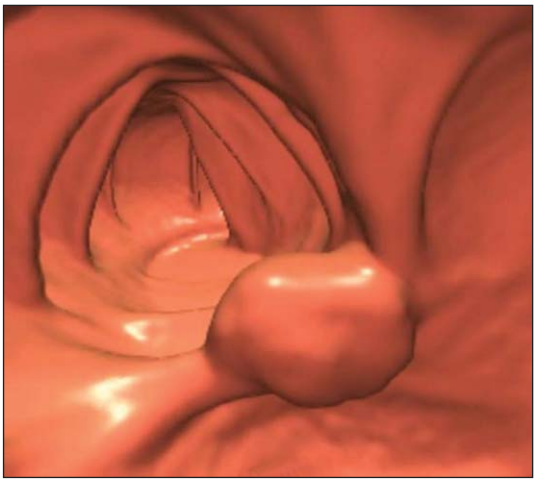

Figure 81-5 • Three-dimensional endoluminal image from screening CT colonography in an asymptomatic average-risk 62-year-old man shows a large 17-mm polyp in the transverse colon, which proved to be a well-differentiated invasive adenocarcinoma after removal at same-day colonoscopy. The patient underwent subsequent extended right hemicolectomy without complication.

and a patient preference for VC versus optical colonoscopy or barium enema.[132] Differences in software, technical parameters, and viewing techniques clearly affect results, and many of the systems and techniques that are in clinical use have not been adequately validated or have fallen short when measured against optical colonoscopy. The lack of widespread reimbursement for the procedure is another limitation, but the single center that has third-party reimbursement has successfully screened over 4000 patients in the 3 years since coverage was secured.[131] The inability to remove polyps at the time of detection is a further limitation that requires the availability of a same-day colonoscopy service if the patient is to avoid a second bowel preparation for polyp removal. Despite these limitations, the use of VC is likely to increase substantially as the results of large state-of-the-art single-center and multicenter trials that are currently in progress become available.

Screening Individuals with Moderately Increased Risk

Surveillance colonoscopy should be performed earlier and at more frequent intervals for patients who are at increased risk because they are African American,[104] have been treated for colorectal cancer, have had an adenomatous polyp diagnosed, have a disease that predisposes them to colorectal cancer (e.g., IBD), or have a family history of colon polyps or cancer.[119] NCCN adds to this list individuals with a history of endometrial or ovarian cancer before age 60.[120]

Individuals with a first-degree relative affected with colon cancer, an adenoma before age 60 years, or two or more first-degree relatives affected by colon cancer at any age should have colonoscopy every five years beginning at age 40 or 10 years younger than the earliest diagnosis in the family, whichever comes first.[119] Those with a personal history of IBD should begin colonoscopy screening with biopsies 8 to 10 years after onset of symptoms. Screening should be repeated every 1 to 2 years.[120] African Americans should begin screening at age 45 rather than 50 and, because of the prevalence of proximal bowel lesions in this population, should undergo colonoscopy.

Screening Individuals with High-Risk Familial Syndromes

Patients with more severe family history or syndromes, including FAP and HNPCC, require more frequent colon exams beginning at younger ages because of the earlier onset and higher frequency of cancers and polyps in individuals with an inherited or germline mutation.

Hereditary Nonpolyposis Colorectal Cancer

Colonoscopy exams for patients with HNPCC and their at-risk relatives has been proven an effective method for reducing the incidence and mortality of colorectal cancer.[133] The incidence of cancer is reduced by more than half, presumably owing to the removal of precursor polyps, when complete colonoscopy is begun at an early age and repeated at regular intervals.[134] Colonoscopy in HNPCC families generally should begin at least 5 to 10 years before the youngest age at cancer diagnosis in an affected family member or no later than age 21 years. No guidelines or authorities recommend intervals longer than 3 years in HNPCC. The American Cancer Society guidelines recommend that colonoscopy for HNPCC screening be repeated every 2 years until age 40 and then annually.[119] Once a polyp or cancer has been detected, more frequent screening should be considered, perhaps every 6 to 12 months.

Familial Adenomatous Polyposis

Screening is a well-established method of cancer prevention in FAP because polyposis can be diagnosed and colectomy completed long before cancer develops.[135] Screening for FAP should be done by videoendoscopic rather than radiologic methods because of the usual small polyp size and because of the requirement of histology to confirm the diagnosis of adenomas. Full colonoscopy should be done in anyone with polyposis that is already well developed at the time of initial diagnosis, because in such cases, larger polyps and malignancy could be present in the proximal colon. Flexible sigmoidoscopy is considered sufficient for scheduled screening of any descendants of a person with FAP, because those with the classic severe phenotype will develop numerous polyps throughout the colon. Annual examinations with flexible sigmoidoscopy or colonoscopy should begin by 10 to 15 years of age in anyone with a known deleterious mutation of the APC gene and in those for whom genetic testing has not been done or is uninformative or not definitively negative. In patients without adequate genetic testing, screening intervals can be increased to every 2 years at age 25, every 3 years at age 35, and every 5 years from age 45 on. Full colonoscopy should be considered to screen patients every 5 years starting at age 20, even in the absence of polyposis, on the chance that the patient has attenuated FAP.[120]

PREVENTION OF COLORECTAL CANCER

The term *prevention* refers to an intentional intervention that is taken or recommended to reduce the development or risk of colorectal neoplasia from its earliest clinical manifestation—typically, a preinvasive neoplastic lesion, such as an adenoma, through its downstream clinicopathologic manifestations (e.g., cancer, cancer-related morbidity or mortality). Drawing on this concept, the most solid recommendations related to CRC prevention are derived from adequately powered, well-controlled trials that focus on reductions in important clinical endpoints. The selection of appropriate endpoints for clinical trials in colorectal cancer prevention is an area of controversy. Clearly, the most compelling endpoint for trials is overall mortality, followed in turn by CRC-associated mortality, CRC incidence, and adenoma incidence. Trials that intend to change current standards of practice (i.e., phase III trials) have typically used the latter two endpoints, but the choice of endpoints is a contentious issue. While all investigators seek to reduce these parameters in a consonant manner and thus improve the clinical status of participants across time, experts disagree about the importance of treatment-related reductions in anything less than CRC-associated mortality, which could take thousands of participants and/or decades of time to demonstrate even with an effective agent, particularly if the control arm includes polypectomy.

In recognition of the infeasibility of this approach for all agents and trials and because adenomas are already a meaningful focus of clinical practice, most contemporary trials of investigational preventive agents use colorectal neoplasia—inclusive of measurable adenomas, "advanced" adenomas, and colorectal cancers—as their primary efficacy endpoint.[63] Biomarker-based trials that focus on earlier or lower-level histopathologic, cellular, or molecular endpoints can provide important supportive and/or mechanistic data but are not reasonably validated to serve as primary measures of efficacy at this time.

CRC prevention trials have typically focused on patient groups that are at greater than average risk owing to germline mutations (e.g., FAP or HNPCC patients) or prior colorectal adenomas or carcinomas.[63] This approach has been taken because these patients are both the most likely to benefit from prevention efforts (at least in the near term) and the most likely to tolerate some degree of toxicity. In addition, this approach is appealing because of its practical implications; that is, trials in these high-risk cohorts can typically be conducted more effectively and more efficiently in terms of the numbers of patients, time, and resources required to demonstrate significant effects.

Agents that were initially considered for clinical testing were identified because of their association with reduced CRC risks based on epidemiologic studies (e.g., low-fat/high-fiber diets, calcium supplements) and/or preclinical/mechanistic studies (e.g., cyclooxygenase-2 inhibitors). As our molecular insights into colorectal carcinogenesis

have grown and the correlation between human cancer and animal models of carcinogenesis has improved, the selection of candidate agents has become more rigorous. Currently, candidates are prioritized by their in vitro activity against mechanistic targets, their efficacy and lack of apparent toxicity in animal models, and (when available) epidemiologic evidence of efficacy and apparent safety.

Surgical Prevention

Surgical prevention by the identification and removal of endoscopic polyps (and, in particular, adenomas) is an effective means of CRC risk reduction with an estimated efficacy of up to 75% based on comparisons of surveillance colonoscopy with polypectomy compared to data from three historical controls.[136] This approach has become the current standard of care; therefore, randomized, controlled trials evaluating polypectomy versus observation are felt to be infeasible in the United States.

Molecular Prevention (Chemoprevention)

Molecular or medical prevention by lifestyle alterations or putative chemopreventive strategies have been investigated for the last 15 to 20 years (Table 81-1). Early trials that focused on dietary modifications (e.g., fiber supplements, fat reductions, increases in fruits and vegetables) or nutritional supplements (e.g., wheat bran fiber, antioxidants) largely failed to identify significant reductions in risk.[63,137–141]

Dietary Modification

Several trials have evaluated the efficacy of dietary modifications—including adjustments in total fat, fiber, and/or fruit and vegetable intake—in reducing colorectal neoplasia. A randomized trial of wheat bran fiber in 1429 subjects with prior adenomas showed no significant reduction in colorectal adenomas associated with high-fiber cereal supplements over a 3-year period.[140] Another phase III trial involving 665 participants found that fiber supplementation increased participants' risk for recurrent adenomas by 67%.[137] By contrast, a large international observational study, the European Prospective Investigation into Cancer and Nutrition study, found a statistically significant 25% reduction in CRC risk between individuals who consumed the highest versus lowest quintiles of dietary fiber.[41] Another trial that assessed the efficacy of a diet that was low in fat (<20% of total calories), and high in fiber (18 g of dietary fiber/1000 kcal) and fruits and vegetables (3.5 servings/1000 kcal) also reported null results with regard to recurrent adenomas over a 3-year period.[141]

Finally, the Women's Health Initiative involving 48,835 postmenopausal women aged 50 to 79 years has contributed information about the effect of diet on CRC risk.[142] In one component of the trial, participants were randomized to a modified diet of 20% total fat intake and increased daily vegetables, fruits, and grains. As a result, the participants on the experimental arm achieved a 10% reduction in fat intake over 8.1 years of follow-up. However, invasive colorectal cancers were not reduced by the modification (hazard ratio: 1.08; 95% CI: 0.90 to 1.29). Similarly, the modified diet did not yield significant reductions in cardiovascular disease, cancer mortality, or overall mortality.[143] These mixed results suggest that trials using different types of fiber or dietary modifications, different schedules (i.e., earlier, later, or in a manner not yet determined), and/or different biologic endpoints (i.e., CRC incidence [in some], overall cancer incidence, and/or cancer-associated mortality) in different cohorts (i.e., younger people or those without prior adenomas) might help to determine whether dietary modifications can protect against colorectal carcinogenesis.[63] At least two ongoing placebo-controlled international trials are evaluating the efficacy of resistant starch and/or aspirin in patients who are at increased risk for CRC due to hereditary mutations associated with FAP or HNPCC.[144,145]

Calcium and Vitamin D Supplementation

Mechanistic, preclinical, and observational data have largely supported the notion that calcium supplementation could reduce colorectal neoplasia, although threshold effects have been suggested.[61] In a randomized, controlled trial of calcium carbonate supplementation at 1200 mg elemental calcium per day in 913 patients with prior adenomas, approximately 20% reductions in recurrent adenomas were reported after 3 years, with initial effects within 1 year.[146] A recent update suggests that these preventive benefits may extend to 5 years.[147] Similarly, a 34% reduction (albeit not statistically significant) in adenoma recurrence was observed in a European trial involving 655 patients who were randomized to 2 grams of elemental calcium versus placebo per day over 36 months.[137] At a minimum, these results suggest that calcium supplementation is well-tolerated and achieves modest reductions in recurrent adenomas.

More recently, the Women's Health Initiative randomizing more than 36,000 postmenopausal women to calcium and vitamin D versus placebo (among other agents) did not identify a reduction in invasive CRC although the short duration of follow-up (approximately 7 years) relative to the endpoint of invasive CRC may account for this.[148] Limited data suggest that vitamin D supplementation alone might be associated with up to a 50% reduction in colorectal cancer risk, but definitive data from ongoing randomized controlled trials are not yet available.[149,150]

Vitamin, Antioxidant, or Selenium Supplementation

Several lines of evidence, observational and experimental, suggest that folic acid might reduce the risk of colorectal neoplasia, although the findings are not entirely consistent, and they do not generally account for the current situation in which the U.S. food supply is already being broadly fortified.[151] Observational studies that have been published after the U.S. government's implementation of folate fortification in 1998 continue to suggest that higher folate levels might reduce the risk of recurrent adenomas, but only in individuals with lower baseline intakes and/or high homocysteine levels.[152] Several ongoing randomized, placebo-controlled trials are evaluating the efficacy of supplemental folate, with or without other chemopreventive agents such as aspirin, in reducing colorectal adenomas.[153]

In theory, antioxidant vitamins (e.g., α-tocopherol, ascorbic acid, β-carotene) could prevent carcinogen formation and blunt genotoxicity, thereby offering an appealing chemopreventive strategy. Epidemiologic associations have been inconsistent and difficult to interpret because of the many strong correlations between antioxidants and other putative chemopreventive components of healthy diets. Therefore, randomized, controlled trials have been helpful in sorting out their effects.[63] Thus far, efficacy with these agents has not been convincing. For example, the Alpha-Tocopherol Beta Carotene Trial randomized 15,538 male smokers to α-tocopherol, β-carotene, both, or neither and reported a statistically significant 66% increase in colorectal adenomas with α-tocopherol but a discordant, nonsignificant 16% reduction in CRC incidence.[154,155] Explanations for these findings include a slightly higher rate of gastrointestinal symptoms among subjects who were on α-tocopherol, which might have led to more endoscopies. Long-term follow-up will be essential to confirm the effects of α-tocopherol on colorectal cancer (if any).

Other prevention trials investigating antioxidants have used vitamin C or vitamin E or both, most often in combination with other micronutrients.[63] Although two trials described protective effects against mucosal hyperproliferation or adenoma recurrence,[156,157] a larger, longer-term trial failed to demonstrate significant protective effects against recurrent adenomas.[138] Finally, a large trial, evaluating the incidence of all cancers in 13,017 people taking a combination of antioxidant agents, did not identify significant reductions in overall cancer incidence, cardiovascular disease, or overall mortality, although secondary analyses suggest possible benefits in

Table 81-1 Randomized, Controlled Colorectal Neoplasia Prevention Trials

Cohort	Sample Size	Intervention	Outcome(s)	Reference
AVERAGE RISK				
U.S. male physicians	22,071	Aspirin 325 mg QOD vs. placebo × 5 years	Primary CRC incidence RR = 1.15 (95% CI = 0.80–1.65) In situ cancer/polyp incidence RR = 0.86 (95% CI = 0.68–1.10)	Gann et al.[167]
Male cigarette smokers 50–69 years old	29,133	α-Tocopherol 50 mg every day vs. β-carotene 20 mg vs. both every day vs. placebo every day × 5–8 years	Primary CRC incidence • α-Tocopherol RR = 0.78 (95% CI = 0.55–1.09) • β-Carotene RR = 1.05 (95% CI = 0.75–1.47) Adenoma incidence (analytic cohort = 13,017) • AT RR = 1.66* (95% CI = 1.19–2.32) • BC RR = 0.98 (95% CI = 0.71–1.35)	Albanes et al.,[155] Malila et al.[154]
Postmenopausal women aged 50–79 years	48,835	Dietary modification targeting reductions in dietary fat and increases in fruits, vegetables, and grains × 8.1 years average follow-up	Primary CRC incidence HR = 1.08 (95% CI = 0.90–1.29)	Beresford et al.[142]
Postmenopausal women aged 50–79 years	36,282	Calcium carbonate 500 mg (elemental) + vitamin D3 200 IU BID vs. placebo × 7.0 years	Primary CRC incidence HR = 1.08 (95% CI = 0.86–1.34)	Wactawski-Wende et al.[148]
Postmenopausal women aged 50–79 years with an intact uterus	16,608	Conjugated equine estrogens 0.625 mg + medroxyprogesterone acetate 2.5 mg every day vs. placebo × 5.6 years average follow-up	CRC incidence HR = 0.56* (95% CI = 0.38–0.81) • Greater number of positive lymph nodes (mean = 3.2 vs. 0.8, $P = 0.002$) • More advanced stage = 76.2% vs. 48.5% $P = 0.004$	Chlebowski et al.[179]
French adults (7876 women aged 35–60 years and 5141 men aged 45–60 years	13,017	Ascorbic acid 120 mg + vitamin E 30 mg + β-carotene 6 mg + selenium 100 mcg + zinc 20 mg every day vs. placebo × 7.5 years	Cancer incidence • RR for men = 0.69* (95% CI = 0.53–0.91) • RR for women = 1.04 (95% CI = 0.85–1.29) All-cause mortality: • RR for men = 0.63* (95% CI = 0.42–0.93) • RR for women = 1.03 (95% CI = 0.64–1.63)	Hercberg et al.[158]
Patients 18–80 years of age with a history of basal or squamous cell skin carcinoma	1.312	Selenium 200 mcg every day vs. placebo × 4.5 years	Primary CRC incidence RR = 0.42 (95% CI = 0.18–0.95)	Clark et al.[160]
MODERATELY ELEVATED RISK				
Recent resected adenoma	864	β-carotene 25 mg every day vs. vitamin C 1 g + vitamin E 400 mg every day vs. both vs. placebo × 4 years	Adenoma recurrence • β-Carotene RR = 1.01 (95% CI = 0.85–1.20); • Vitamin C + vitamin E RR = 1.08 (95% CI = 0.91–1.29)	Greenberg et al.[138]
Prior resected adenoma	255	Vitamin A 30,000 IU + vitamin C 1 g + vitamin E 70 mg every day vs. lactulose 20 g every day vs. no treatment × 18 months	Adenoma recurrence significantly different by Kaplan-Meier log rank comparison ($P < 0.0001$) • Vitamins = 5.7%* • Lactulose = 14.7%* • Untreated = 35.9%	Roncucci et al.[157]
Recent resected adenoma	424	Low dietary fat (25% of calories) vs. wheat bran 25 g every day vs. β-carotene 20 mg every day vs. combinations vs. placebo × 4 years	Adenoma recurrence: No significant effect with any of the interventions; Secondary analysis of large adenoma recurrence: low fat + wheat bran combination reduced recurrence,* $P = 0.03$	MacLennan et al. (1995)†
Recent resected adenoma	1429	Wheat bran fiber 13.5 g every day vs. 2 g every day × 5 yrs	Adenoma recurrence adj. OR = 0.88* (95% CI = 0.70–1.11)	Alberts et al.[140]
Recent resected adenoma	2079	Intensive low fat, high fiber, high fruits and vegetable diet vs. no intervention × 4 years	Adenoma recurrence RR = 1.00 (95% CI = 0.90–1.12)	Schatzkin et al.[141]
Recent resected adenoma	665	Calcium gluconolactate/carbonate 2 g every day vs. ispaghula husk 3.5 g every day vs. placebo × 3 years	Adenoma recurrence • Calcium adj. OR = 0.66 (95% CI = 0.38–1.17) • Fiber adj. OR = 1.67* (95% CI = 1.01–2.76)	Bonithon-Kopp et al.[137]

men and in healthy individuals with low antioxidant levels at baseline.[158,159]

Selenium has been reported to reduce CRC incidence by as much as 58% in a phase III trial that enrolled 1312 persons with a history of skin cancer randomized to selenium versus placebo.[160] After an average of 6.4 years follow-up and on the basis of a total of 27 cases, the effect on colorectal cancer was reported, albeit as a secondary endpoint, suggesting only that additional investigation is probably warranted.

Cyclooxygenase Inhibitors (Nonsteroidal Anti-Inflammatory Drugs)

Nonsteroidal anti-inflammatory drugs (NSAIDs) have been investigated for their chemopreventive effects in animals for more than 25 years on the basis of the promotional effects of prostaglandins on carcinogenesis. More than 40 retrospective and prospective observational studies have consistently shown that NSAID use (especially aspirin, based merely on the frequency of its use in the population) is associated with approximately 50% reductions in colorectal adenoma incidence, CRC incidence, and CRC-associated mortality as compared with nonuse.[161] The mechanisms underlying the efficacy of NSAIDs are probably numerous. Cyclooxygenase (COX) exists as two isoforms, COX-1 and COX-2, which transform arachidonic acid into a variety of bioactive prostanoids. COX-1 plays a housekeeping role in a variety of tissues, but COX-2 is induced in response to a variety of stimuli and is commonly found overexpressed in a wide variety of tumors. In neoplastic tissues, COX-2 activity induces cellular proliferation and neoangiogenesis and blocks apoptosis and immune responses, thus promoting neoplastic progression. By blocking COX activity and possibly by a variety of non-COX effects as well, NSAIDs and COX-2 selective inhibitors inhibit colorectal carcinogenesis. For example, COX-2 is overexpressed in nearly 50% of colorectal adenomas and 80% to 85% of adenocarcinomas, whereas it is rarely expressed in normal colorectal epithelium.[162] COX-2 overexpression appears to be functionally important for neoplastic progression, as suggested by the lower incidence of intestinal polyps in mice lacking a functional COX-2 gene.[163]

In terms of randomized, controlled trials, sulindac treatment resulted in a significant reduction in adenoma prevalence after 6 months of administration in patients with FAP, although long-term efficacy is more limited.[164,165] Initial suppression of adenomas with sulindac in prephenotypic FAP patients has not proven successful.[166]

The only randomized evaluation of NSAIDs against CRC incidence comes from a secondary analysis of the Physicians' Health Study, which randomized 22,071 U.S. male physicians to aspirin 325 mg every other day versus placebo for an average of 5 years.[167] Somewhat surprisingly, aspirin did not reduce CRC or in situ colorectal cancers significantly. This null effect has been attributed variously to the cohort (i.e., average risk male physicians), the lack of uniform colorectal surveillance guidelines, the limited dose and duration of aspirin, and, most important, the limited duration of follow-up relative to the long natural history of colorectal carcinogenesis. Subsequently, the same or higher doses of aspirin were evaluated in three placebo-controlled trials in patients with prior colorectal adenomas or carcinoma, and statistically significant reductions in recurrent adenomas were reported after 1 or more years.[168–170] Sandler and colleagues randomized 635 CRC survivors to aspirin (325 mg/day) versus placebo and reported a significant reduction in patients with incident adenomas and a delay in the time to a first adenoma.[169] Baron and colleagues randomized 1121 patients with prior colorectal adenomas to aspirin (81 or 325 mg/day) versus placebo and reported a 4% to 19% reduction in the number of people with a recurrent adenoma and a 17% to 41% reduction in advanced adenomas.[168] Finally, interim results from Benamouzig and colleagues' trial involving 272 patients with prior adenomas noted a significant reduction in recurrent adenomas as well.[170] Recent data suggest that aspirin might be most effective in individuals with a high body mass index.[171] Although these efficacy results are consistent and compelling, aspirin use is associated with significant risks of gastrointestinal ulceration and hemorrhagic stroke; therefore, the U.S. Preventive Services Task Force does not currently recommend it as a strategy for CRC risk reduction in average-risk individuals.[172]

In an effort to improve the therapeutic index of COX inhibitors for CRC risk reduction, COX-2-selective inhibitors (e.g., celecoxib, rofecoxib) have been evaluated for their efficacy and safety in a variety of clinical settings. Celecoxib administered for 6 months to 83 individuals with FAP produced significant reductions in colorectal adenoma number and size, with a side effect profile comparable to that of placebo.[173] These data prompted the U.S. Food and Drug Administration (FDA) in 2000 to approve celecoxib to complement the standard care (i.e., surveillance and prophylactic surgery) of patients with FAP. In patients with prior sporadic adenomas, celecoxib was associated with an approximate 40% and 66% reduction in recurrent colorectal adenomas and advanced adenomas, respectively, in two recent placebo-controlled trials of 3 years' duration.[174,175] Despite this profound efficacy, celecoxib use was also associated with an elevated risk for serious cardiovascular events in these trials (i.e., twofold to threefold higher rates of CV-associated death, myocardial infarctions, unstable angina, heart failure, or stroke).[176] A placebo-controlled trial of rofecoxib 25 mg/day in 2587 patients with prior colorectal adenomas reported a significant 24% reduction in recurrent adenomas and greater efficacy against advanced adenomas but an increased risk of serious cardiovascular events, leading to its eventual withdrawal from the marketplace.[177] Therefore, additional work to verify these data and to understand the mechanisms underlying the efficacy and safety of COX-2-selective inhibitors are needed before this strategy can be pursued further for average-risk individuals.

Postmenopausal Hormone Replacement

A meta-analysis of 18 observational studies suggested that the use of hormone replacement therapy in postmenopausal women reduced the development of colon cancer by approximately 20%.[178] Subsequently, a large randomized controlled trial of estrogen + progesterone in postmenopausal women participating in the Women's Health Initiative demonstrated a 44% reduction in colorectal cancer incidence[179]; however, incident cancers in those using hormone replacement therapy were more advanced, with more nodal involvement. In addition, women who were treated with estrogen alone did not experience a similar reduction in incidence. Furthermore, the Women's Health Initiative identified several safety concerns associated with estrogen and progesterone therapy, including a 26% increase in invasive breast cancer, a 29% increase in cardiac events, a 41% increase in strokes, and a twofold increase in thromboembolic events.[180]

Ursodeoxycholic Acid

Unconjugated fecal bile acids are mutagenic and cytotoxic to the colorectal epithelium, possibly promoting the transformation of adenomatous lesions to invasive carcinoma.[181] Deoxycholic acid, a secondary bile acid, stimulates colorectal epithelial proliferation in animal models and serum levels correlate with rectal mucosal proliferation in humans.[182] Interestingly, other reports suggest that ursodeoxycholic acid, a noncytotoxic, hydrophilic epimer of chenodeoxycholate, reduces the mucosal concentrations of phospholipase A2 at the messenger RNA and protein levels, and thereby, the concentrations of mucosal prostaglandin E_2 and 6-keto prostaglandin $F_{1\alpha}$, as well as the incidence of aberrant crypt foci in azoxymethane-exposed rats.[183] Thereafter, ursodeoxycholic acid reduced carcinogen-induced colorectal adenomas and carcinomas in a rat model[184] and was subsequently tested in a phase III, placebo-controlled, randomized clinical trial involving 1285 individuals with a past adenoma.[185]

After 3 years of treatment, ursodeoxycholic acid resulted in a statistically insignificant 12% reduction in recurrent adenomas and a statistically significant 39% reduction in adenomas with high-grade dysplasia.

Statins

3-Hydroxy-3-methyl-glutaryl-CoA reductase inhibitors (or statins) have been associated with a significant 50% reduction in colorectal cancer risk in a well-conducted, population-based case-control study,[186] but other studies, including a meta-analysis of placebo-controlled trials evaluating statins for their potential to reduce cardiovascular risks, have not reported any significant effects—positive or negative—of statins on CRC risk.[187]

Future Directions

There are many promising preventive interventions based on preclinical mechanistic screens, animal models of colorectal carcinogenesis, and/or observational studies. Examples include NSAID derivatives (e.g., nitric oxide-donating NSAIDs); selected dietary components such as omega-3 fatty acids, curcumin, and quercetin; peroxisome proliferator-activated receptor agonists; physical activity; and possibly targeted therapeutics with infrequent or minimal toxicities. For instance, in a small, uncontrolled trial involving five FAP patients, a combination of curcumin and quercetin given over 6 months was recently reported to reduce both polyp number and size by 50% to 60%.[188] Ongoing placebo-controlled trials are evaluating the effects of folate, vitamin D, and various NSAID-based combinations. Trials evaluating combinations of chemopreventive agents in particular hold great promise based on the inherent molecular complexity of colorectal carcinogenesis and preclinical data suggesting synergistic efficacy.[189–191] Preliminary clinical studies of complex combinations have recently been reported.[192]

DIAGNOSIS AND STAGING OF COLON CANCER

Colon cancer is usually quite insidious in its development. Asymptomatic patients are suspected of having colon cancer because of anemia or a positive fecal occult blood test that is found during routine physical exam. With increasing awareness of the benefits of screening colonoscopy, cancer could be discovered at the time of this examination. Symptomatic patients might relate episodes of bleeding per rectum (hematochesia) or increased frequency of bowel dysfunction—constipation or diarrhea and/or vague abdominal discomfort. Weight loss is less common unless disease is advanced, but fatigue is frequent. On occasion, the degree of anemia can be severe enough to produce cardiac ischemic symptoms in patients with occult coronary artery disease and syncope, which leads to the finding of anemia and evidence of bleeding from the colon tumor. On occasion, patients present with hypokalemia secondary to diarrhea from large villous tumors producing excess mucous.

Fatigue and anemia are symptoms that are associated with right-sided lesions. Gross bright red blood per rectum, increasing constipation, and cramping abdominal pain are symptoms that suggest a left-sided lesion. Advanced tumors can present with symptoms that are indicative of extension to other organs, such as the bladder (pneumaturia). A perforated colon cancer must always be considered when the patient presents emergently with abdominal free air and diffuse peritonitis. At times, the emergent status presents the surgeon with the difficult task of differentiating between an inflammatory mass secondary to a perforated colon cancer of the sigmoid colon or upper rectum and a perforated diverticulitis. Obstruction, however, is the most common acute problem requiring emergency surgery for colon cancer (with an incidence of approximately 30%). Although obstruction almost always occurs secondary to the tumor that is obstructing the lumen, the tumor can cause intussusception in the adult.

The diagnosis of colon cancer is best established by colonoscopy. Colonoscopy provides direct visualization, a fairly accurate determination of location, and the opportunity to obtain tumor tissue for histologic evaluation. There are two issues to keep in mind during the course of evaluating the patient with suspected colon cancer. The first is the possibility of a second occult primary cancer (approximately 5%); the second is the presence of additional polyps (approximately 20% to 40% probability), which must be cleared or tattooed so that they can be dealt with at the time of surgery. When it is not possible to complete colonoscopy to the ileocecal valve, air-contrast barium enema and virtual colonoscopy are options for completing the evaluation of the colon.

Laboratory Evaluation

The goal in preoperative evaluation of the patient who is newly diagnosed with colon cancer is to determine whether comorbid conditions exist that could affect perioperative morbidity and mortality. The standard laboratory evaluation includes a hemogram, evaluation of clotting capacity, liver injury and renal function tests, fasting blood sugar, electrolytes, a urinalysis, and measurement of carcinoembryonic antigen (CEA) level. Other laboratory studies are determined by a careful history of past medical problems and a thorough system review.

Imaging Modalities for Staging of Colon Cancer

The use of imaging for the staging of colon cancer can be divided into two broad categories: (1) detection and staging of the primary tumor and (2) determination of the extent of metastatic disease. For the detection of the primary cancer and of polyps greater than 1.0 cm in diameter, conventional single- and double-contrast barium enema has been used for many years. With the advent of helical computed tomography (CT) scanning, CT colonography has been used for screening for polyps and other masses (Figs. 81-6 and 81-7), and more recently, some investigators are examining techniques for magnetic resonance imaging (MRI) colonography. For the staging of potential extracolonic metastatic disease, ultrasound, CT, MRI, and positron emission tomography (PET) have been used with varying levels of success.[193,194]

Barium Enema

Until the advent of modern colonoscopy, barium enema was considered the mainstay for detection of large colonic polyps and colon

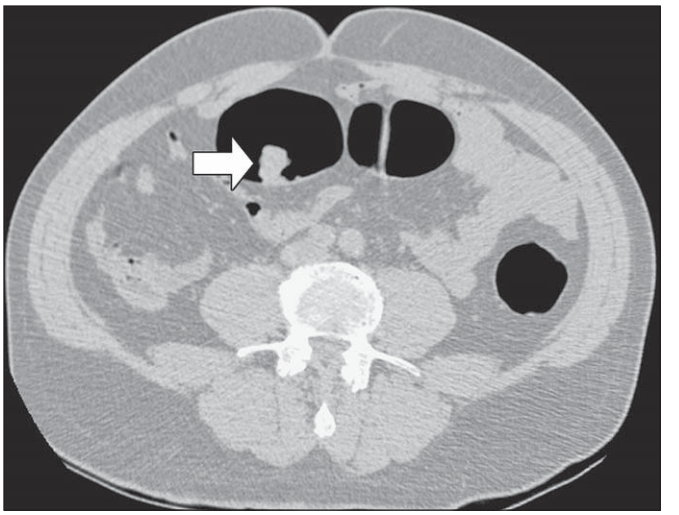

Figure 81-6 • Nonenhanced CT image (source data for a virtual colon examination) demonstrates a large pedunculated polyp in the transverse colon (*arrow*). This was later proven to contain colon carcinoma.

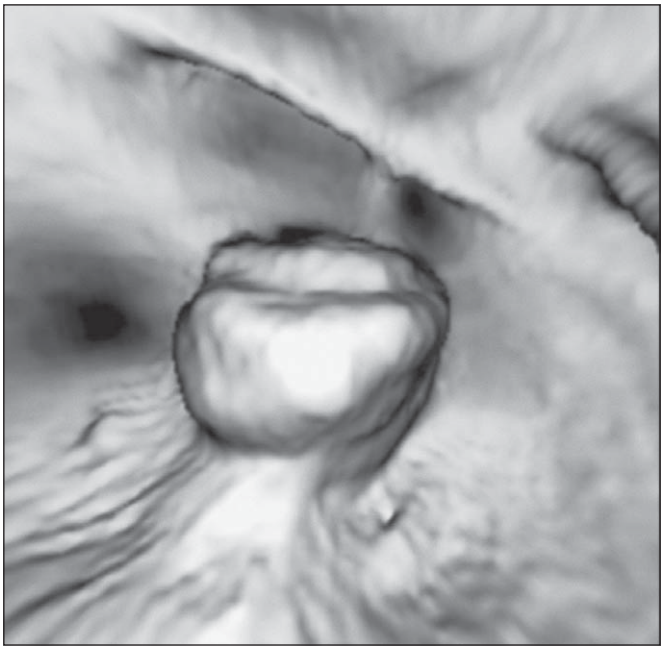

Figure 81-7 • Surface-rendered three-dimensional reconstruction of the polyp seen in Figure 81-6. Primary three-dimensional image interpretation is now available. When combined with an appropriate software platform, "fly-through" examinations that mimic the views obtained by conventional video-assisted colonoscopy are now possible.

cancer (Fig. 81-8). Single-contrast barium enema uses a continuous column of barium injected in a retrograde fashion, and double-contrast barium enema uses a thicker barium mixture that adheres to the colonic mucosa, resulting in a mucosal relief image. For small polyps, double-contrast studies are generally considered to have a higher sensitivity than single-contrast enemas. Regardless of the technique, barium enema is not as sensitive or specific as colonoscopy for colonic pathology and should be chosen as the initial screening test only for patients in whom colonoscopy has failed, who are at high risk for complications from colonoscopy, or for whom colonoscopy is not available.[195] Barium enema has no role in determining the extent of colonic wall invasion by colon cancer, lymph node involvement, or distant disease in patients who are at high risk for metastases.

Ultrasound

Conventional transcutaneous ultrasound plays no role in the detection of primary colonic tumors. Because the liver can be imaged by transcutaneous ultrasound with varying degrees of success, ultrasound has been used to screen the liver for signs of metastatic disease in patients with known colon cancer. In addition, liver metastases often are found incidentally when sonography is used in patients who present with vague gastrointestinal symptoms or for other reasons. In studies performed on North American patients, the sensitivity of hepatic ultrasound is not sufficient for it to be used as a sole modality for screening or as a preoperative evaluation in patients who are to undergo primary tumor resection or hepatic metastasectomy.[196] The sensitivity for detection of liver metastases appears to improve substantially when contrast-enhanced ultrasound techniques are used. In one multicenter study, the sensitivity improved from 71% to 87% with the addition of contrast material.[197] However, ultrasound contrast agents are not available for routine clinical use in the United States, although they are available and widely used in Europe. Ultrasound is the modality of choice for liver biopsy for most hepatic masses (Fig. 81-9) owing to its low cost, real-time imaging, and excellent needle-guidance systems.[198,199]

Intraoperative Ultrasound (Open and Laparoscopic)

Intraoperative ultrasound is considered the most sensitive and specific imaging test for detection of hepatic metastases from colon cancer (Fig. 81-10). It is far more sensitive for the detection of metastatic lesions than are inspection and palpation of the liver by the surgeon, particularly for deep tumors.[200,201] Liver metastases as small as 3.0 mm can be detected routinely by intraoperative ultrasound.[202] Additional advantages of intraoperative ultrasound are its ability to guide biopsies of suspicious hepatic lesions and its use as an aid in both liver resection planning and guiding tumor ablation (e.g., cryoablation or radiofrequency ablation; Fig. 81-11). Intraoperative ultrasound has a very limited role in the evaluation of extrahepatic metastases from colon cancer because of the highly targeted nature of the examination. Occasionally, retroperitoneal lymph nodes and other metastatic deposits can be imaged if specific abnormalities are noted on preoperative imaging or if an abnormality is noted during inspection and palpation of the abdomen.

Laparoscopic ultrasound can be used for the same purposes as open intraoperative ultrasound of the liver. Owing to lack of access to some areas of the liver, the sensitivity of laparoscopic ultrasound appears to be slightly less than that of open intraoperative ultrasound, but laparoscopic ultrasound has the advantage of being a less invasive approach.[203] This is particularly useful in patients who have a high likelihood of unresectable liver disease or peritoneal disease or in patients who are to undergo another minimally invasive treatment for known liver metastases, such as tumor ablation.

Computed Tomography

Contrast-enhanced helical CT is considered the mainstay of preoperative imaging of colon cancer patients. CT combines a high

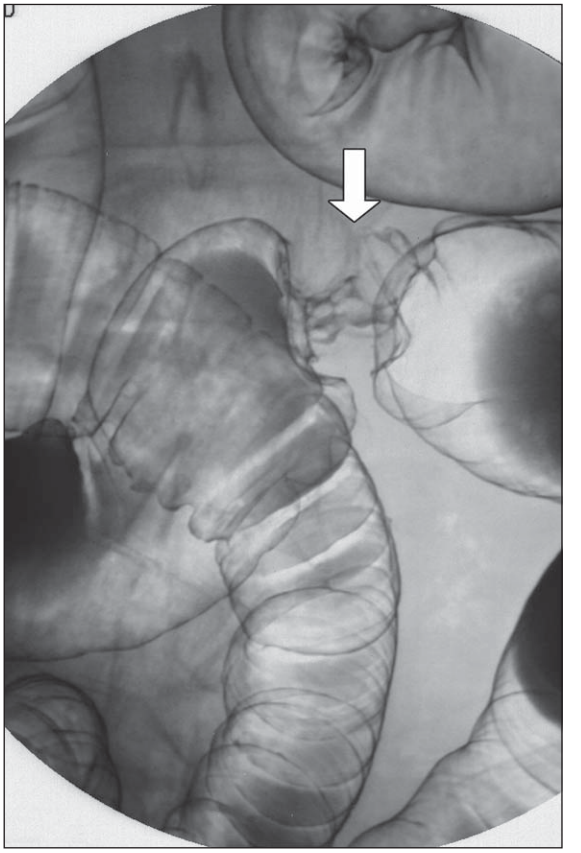

Figure 81-8 • Double-contrast barium enema demonstrates circumferential luminal narrowing with mucosal destruction (*arrow*) due to colon carcinoma, the so-called apple core lesion.

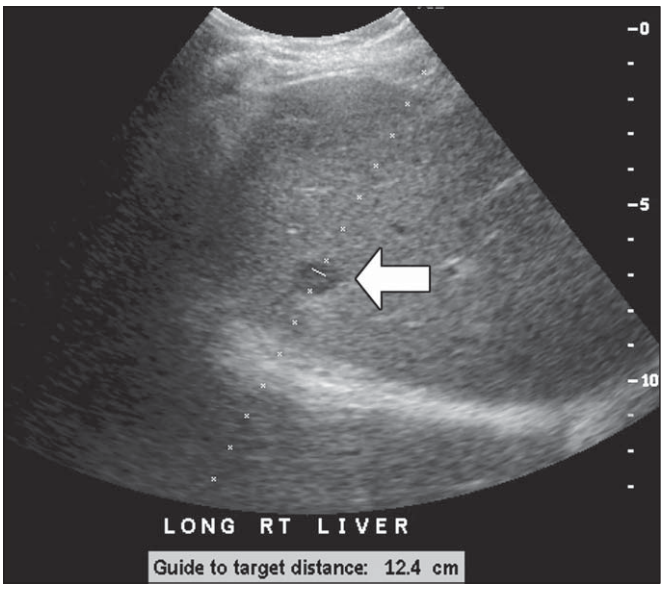

Figure 81-9 • Ultrasound-guided biopsy of the liver lesion with small right lobe metastatic tumor (*arrow*) from a primary colon carcinoma. Note the needle guidance software that predicts the path of the biopsy needle before its deployment through a fixed guide. This procedure can also be performed freehand without the use of a guide. Ultrasound-guided biopsy has been found to be both efficient and cost-effective in comparison with other modalities owing to the real-time capability and low cost of ultrasound.

sensitivity for the detection of lung and liver metastases with availability, safety, and the ability to aid in the detection of peritoneal disease and metastatic lymph nodes. The sensitivity of CT is low, however, for abnormalities that adhere to peritoneal and visceral surfaces, such as peritoneal carcinomatosis. An added advantage of CT as a preoperative imaging modality for hepatic surgery is that CT

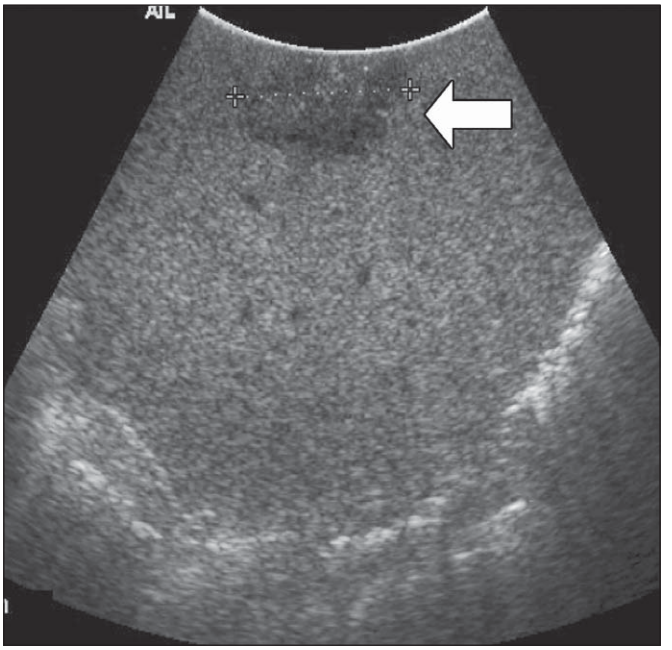

Figure 81-10 • Intraoperative ultrasound of right lobe liver metastasis in a patient with known colon cancer. Note the high-quality ultrasound images that are possible with intraoperative ultrasound (*arrow*). Tumors as small as 3.0 mm are detected routinely with this technique.

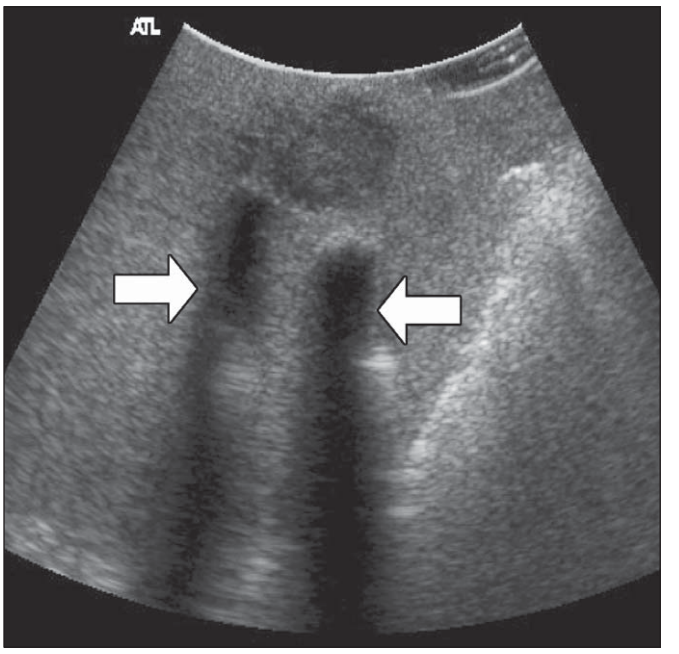

Figure 81-11 • Intraoperative ultrasound of the liver during cryoablation. The right lobe hepatic metastasis in Figure 81-10 has undergone cryoablation with formation of an iceball superimposed over the tumor. Ice does not conduct sound, hence the lack of information from within the iceball and the posterior acoustic shadowing. Two cryoablation probes are also visible (*arrows*) with acoustic shadows.

angiography can be obtained at the same time as a conventional diagnostic CT (Figs. 81-12 through 81-15). This can be important in screening for hepatic arterial and venous anomalies prior to hepatic resection or if the surgeon is considering inserting a hepatic artery infusion pump. CT angiography is an excellent modality for determining the hepatic arterial, portal venous, and hepatic venous anatomy and for assessing variants of these vessels.[204]

CT technology recently has undergone major changes due to the introduction of multidetector row helical CT scanners. Currently, 64-channel scanners are becoming increasingly available. These

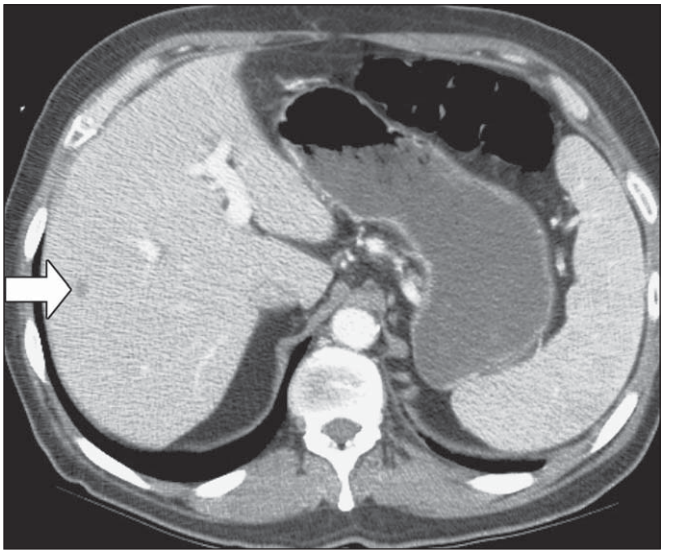

Figure 81-12 • Helical CT image of the liver after intravenous contrast injection demonstrates a liver lesion (*arrow*) in Figure 81-9.

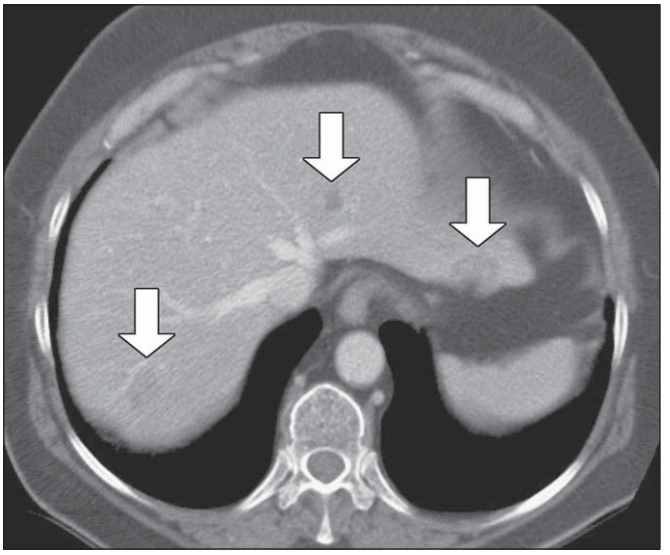

Figure 81-13 • Helical CT image of the liver after intravenous contrast in patient shown in Figure 82-10. Three low-attenuation hepatic metastases are visible (*arrows*).

scanners can reconstruct image data with thicknesses as low as 0.5 mm. Unfortunately, although the thin slices that are possible with multidetector row CT are likely to increase sensitivity for the detection of hepatic metastases, there is a paucity of data comparing single-detector row to multidetector row helical CT or comparing multidetector row scanners that have fewer detector rows (4 to 32) to 64 row scanners. Recent data for detection of colon cancer metastases using single-detector row CT demonstrate sensitivities on the order of 85% and specificities approaching 96%, but this sensitivity greatly decreases for metastases smaller than 1.0 cm.[205,206] A recent meta-analysis of 15 studies using helical CT of various detector row configurations yielded an overall sensitivity of 64.7%.[207]

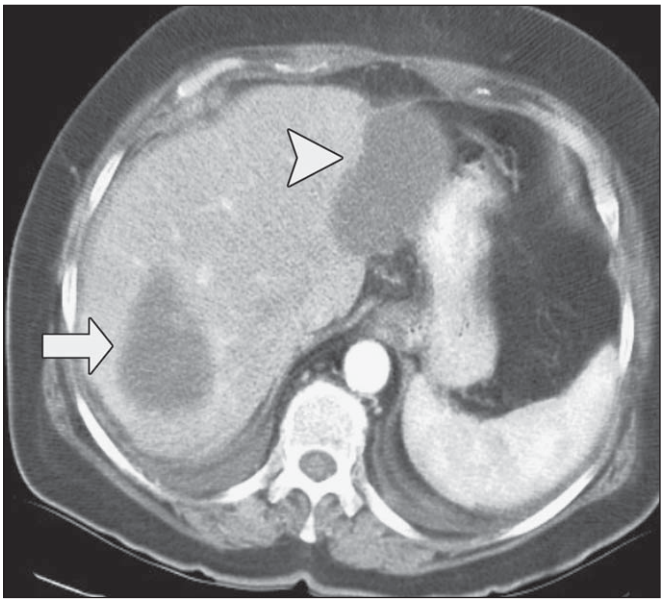

Figure 81-14 • Helical CT image of the liver after intravenous contrast in the same patient shown in Figure 81-10. This postoperative image demonstrates a small hematoma after a left lobe hepatic resection (*arrowhead*) and typical postcryoablation changes of the right hepatic lobe tumor (*arrow*).

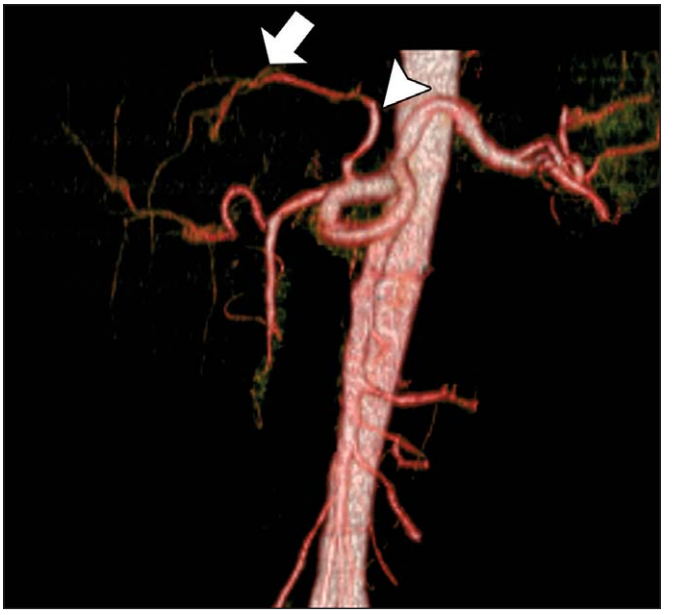

Figure 81-15 • CT angiogram of the abdominal vasculature shows a replaced left hepatic artery (*arrow*) arising from the left gastric artery (*arrowhead*). CT angiogram can be a valuable preoperative screening tool to evaluate hepatic arterial, portal venous, and hepatic venous anatomy.

Magnetic Resonance Imaging

Compared with CT, MRI is probably slightly more sensitive and specific for detection and characterization of colon cancer metastases in the liver.[207–209] On the other hand, the long scan times, the relatively high degree of image artifacts, the lack of availability of MRI scanners and scan time, questions about the ability of MRI to detect bowel abnormalities and other evidence of extraperitoneal disease, and the increased expense of MRI combine to limit the use of MRI for the routine preoperative staging of colon cancer. Indications for preoperative MRI (rather than or in addition to CT) for colon cancer include an inability to tolerate conventional iodinated contrast materials (renal insufficiency or allergies) and further clarification of abnormalities that were detected at CT. Recently, gadolinium-enhanced fat saturation MRI, particularly when combined with delayed imaging, has shown promise in identifying even very thin, "sheetlike" peritoneal tumor involvement.[210] MRI is specifically indicated in evaluating patients with central nervous system symptoms to determine the presence of metastases and in evaluating difficult to image pelvic wall recurrences.

Most colon cancer metastases show high signal intensity on T_2-weighted images compared with background liver (Fig. 81-16) and low signal intensity on T_1-weighted images. Rapid gradient-echo pulse sequences are now available that allow imaging of the entire liver in a single breath-hold. When combined with a bolus injection of gadolinium-based contrast agents, information similar to that derived from contrast-enhanced CT scanning can be obtained, which aids in lesion characterization. New liver-specific contrast materials have recently become available for clinical use. These agents are based on targeting of either hepatocytes (gadobenate dimeglumine, gadoxetic acid, mangafodipir trisodium) or the reticuloendothelial cell system (superparamagnetic iron oxides).[211] Several studies have demonstrated increased sensitivities for the detection of liver metastases for MRI enhanced with these targeted agents, but their increased expense, the complicated delivery methods, and lack of availability of MRI time have hampered the routine use of these compounds.[209,210]

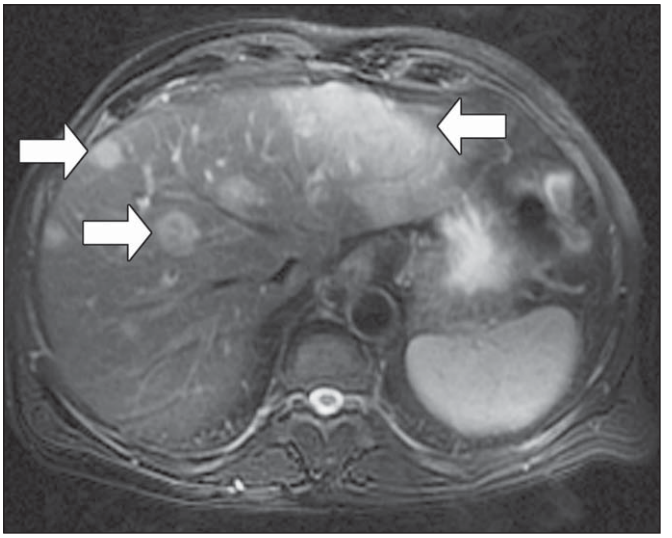

Figure 81-16 • Axial MRI (T_2 with fat suppression) demonstrating rounded high-intensity metastatic lesions (*arrows*) throughout the liver in a patient with known colon cancer primary.

Fluorodeoxyglucose Positron Emission Tomography

The advent of fluorodeoxyglucose positron emission tomography (FDG-PET) imaging has been a huge advance in triaging patients who are potential candidates for surgery. The main value of PET imaging has been in the detection of small-volume, extrahepatic metastatic disease. Compared with CT imaging, PET has a lower sensitivity for the detection of hepatic metastases but a higher sensitivity for extrahepatic metastases.[212] Therefore, many centers now use a combination of CT and PET scanning to stage patients prior to potential hepatic resection. This can be accomplished with dedicated PET/CT machines that decrease misregistration artifacts and allow precise localization of areas of increased glucose metabolism or with CT and PET performed at different settings (Figs. 81-17 and 81-18).[213] The use of a dedicated PET/CT strategy increased the accuracy of staging from 78% to 89% on a patient-by-patient basis.[214] Overall, the sensitivity of PET for detecting recurrent tumor throughout the body is in the range of 92% to 95%.[207,215]

Table 81-2 Sensitivity of Imaging for Detection of Hepatic Metastases

Modality	Detection Rate for Individual Metastases (%)
Transabdominal sonography	40–70
Noncontrast CT	50
Nonspiral contrast-enhanced CT	60–75
Spiral contrast CT (single detector)	90–92
MRI	80–90
CT arterial portography	85–95
Intraoperative ultrasound	90–96

Adapted from Paulson EK: Evaluation of the liver for metastatic disease. Sem Liver Dis 2001;21:225–236.

In detection of extrahepatic disease, the increased sensitivity of PET compared with CT often has changed patient management (29% to 40% of cases).[216,217] Patients who might otherwise be considered candidates for potentially curative resection but who have retroperitoneal metastases identified by FDG-PET may be referred for systemic chemotherapy and spared the complications and risks of surgical procedures that will not be curative. The uptake of FDG in colorectal cancers could also hold prognostic significance. In one study, patients with low FDG uptake in metastases of colorectal cancer (standardized uptake values < 4.26) had longer median survivals (32 months) than did patients with high FDG uptake (19 months).[218] Table 81-2 compares the various methods of imaging and their relative sensitivities with regard to the detection of hepatic metastases.[219]

Staging

The anatomic extent of disease at presentation (stage) is the strongest predictor of survival for patients with colorectal cancer and forms the basis of appropriate patient management. The Tumor, Node, Metastasis (TNM) staging system of the American Joint Committee on Cancer (AJCC)[220] and the International Union Against Cancer[221] is considered the international standard for colorectal cancer staging.[222] In contrast to other staging systems for colorectal cancer, the TNM

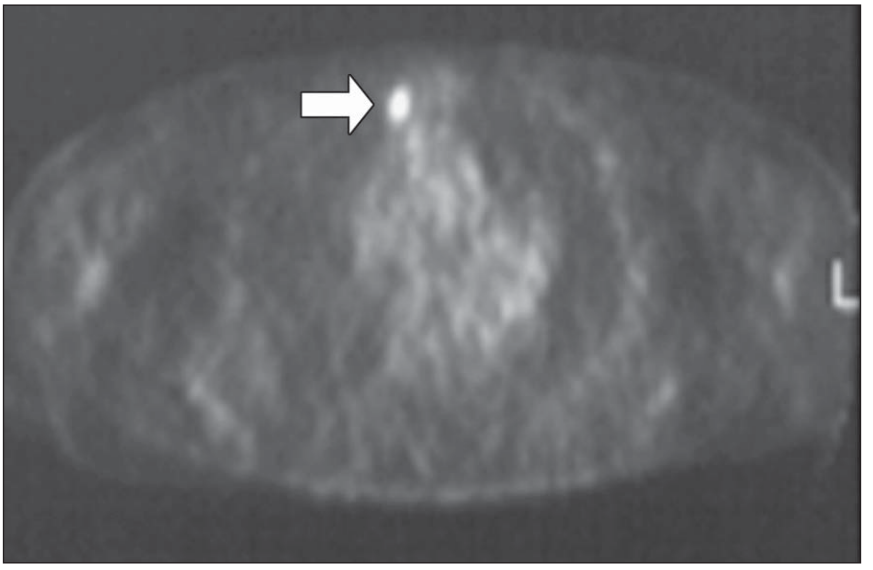

Figure 81-17 • PET image of the chest in a patient with colon carcinoma. The patient was being evaluated for a hepatic resection. PET imaging unexpectedly showed a lesion in the chest wall (*arrow*), which changed management from hepatic metastectomy to systemic chemotherapy.

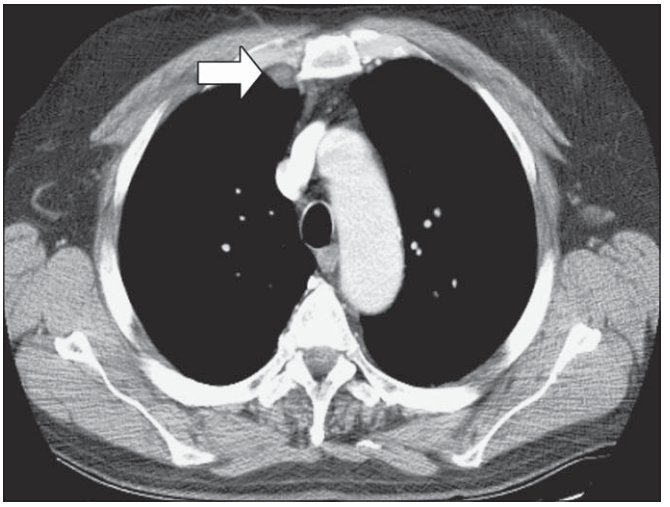

Figure 81-18 • Helical CT image of the chest (same patient as in Fig. 81-17) demonstrates the small chest wall metastasis (*arrow*).

system is continuously updated on the basis of existing data, multidisciplinary in design, allowing for the incorporation of all technologic approaches to staging, and has a comprehensive set of rules of application that ensure uniform use. The predictive accuracy of TNM staging can be increased through incorporation of validated prognostic features, such as lymphatic or venous invasion, into the overall assessment process. (Table 81-3; Fig. 81-19).

In the TNM system, the designation "T" refers to the local extent of the untreated primary tumor, "N" to the status of the regional lymph nodes, and "M" to distant metastatic disease at the time of diagnosis and initial workup. The prefix "p" is used to denote the pathologic determination of a staging parameter (i.e., T, N, or M), as contrasted with the clinical determination, which is designated by "c." By convention, pathologically assigned T and N parameters are considered more accurate than clinically assigned parameters but require a resection of the primary tumor or biopsy that is adequate to evaluate the highest pT category and nodes that are adequate to validate lymph node metastasis, respectively. Assignment of M0, signifying a global determination of the absence of distant metastasis anywhere in the body, is impossible by pathologic means. Therefore, pM0 is not part of the TNM staging system. A pM1 designation, however, is assigned when any distant metastasis is confirmed by tissue or cytologic examination. Clinical classification (cTNM) is based on evidence acquired through a variety of techniques that include but are not limited to physical examination, radiologic imaging, endoscopic examination, biopsy, and surgical exploration. Clinical staging is carried out during initial evaluation of the patient before any cancer-directed therapy is initiated and, once assigned, is not changed in the medical record on the basis of subsequent information, remaining as documentation of the basis for treatment planning. It may be revised only if more accurate clinical information becomes available (e.g., higher-resolution imaging studies) before initiation of treatment or before making the decision not to treat the patient. Stage evaluation continues through the first course of surgery or 4 months following presentation, whichever is longer. Staging ends at the time of diagnostic workup if a decision is made not to treat the patient or if pathologic classification is not possible. When pathologic staging information becomes available following surgical resection, a combined pathologic and clinical stage (typically pT, pN, cM) can be constructed.

The definitions of the individual TNM categories and stage groupings and stage-related survival are shown in Figure 81-19, and comparisons of the TNM system to other historical staging systems are shown in Table 81-3.

All tumors should be verified microscopically as carcinomas to confirm the appropriateness of TNM staging, which applies only to

Figure 81-19 • **A,** Modified Duke's staging classification of colon cancer. Stages B3 and C3 (not shown) signify perforation or invasion of contiguous organs or structures (T4; see also Table 81-3). **B,** The TNM classification provides a more accurate staging system. (Adapted from Skarin AT, Shaffer K, Wieczorek T [eds]: Atlas of Diagnostic Oncology, 3rd ed. St. Louis, Mosby, 2003, pp 155–156.)

primary colorectal carcinomas, and to plan appropriate treatment. Other tumor types that may resemble colorectal carcinoma clinically include colorectal lymphomas, carcinoid tumors, gastrointestinal stromal tumors, metastatic tumors that exhibit tropism for the gastrointestinal tract (e.g., melanoma), malignancies of adjacent organs that directly invade the colorectum (e.g., cancers of the ovary, endometrium, bladder, or prostate), or appendiceal tumors. Benign lesions that may mimic colorectal cancer include adenomas, hamartomas, solitary rectal ulcers, stercoral ulcers, endometriomas, and Crohn's disease or diverticular disease producing mural strictures.

Because the colorectal mucosa is architecturally unique and lacks stromal lymphatics, tumor invasion of the lamina propria has no associated risk of regional nodal metastasis and is included in the definition of pTis. To be classified as pT1, tumor must invade through the muscularis mucosae into the submucosa. T2 connotes invasion of the muscularis propria, and the T3 category refers to all transmurally invasive tumors that are confined to the perimuscular soft tissue (i.e., that have neither violated the serosal surface nor infiltrated an adjacent structure). Extramural extension of the tumor within lymphatics or veins does not count as local spread of tumor as defined by T3 but is instead denoted as L1 or V1 disease, respectively, in the L or V classification schema of the TNM system. In contrast, discrete smooth-contoured extramural tumor nodules of any size are classified as replaced lymph nodes, and each is counted separately in the N category on the basis of evidence that the number of pericolonic tumor-involved nodes correlates inversely with disease-free survival.[223]

The highest category of local extent is pT4, which includes either extension into adjacent organs or structures or penetration of the parietal peritoneum with or without gross perforation of the wall or involvement of an adjacent structure. Among the features that define T4 tumors, serosal penetration is the direst.[224] It is also possible to classify a tumor as pT4 on the basis of positive cytologic specimens of touch preparations from the serosa overlying the primary tumor. Direct invasion of adjacent organs or structures or other segments of the colorectum by way of the serosa or mesocolon (e.g., invasion of the sigmoid colon by carcinoma of the cecum) all should be classified as pT4. In contrast, intramural (longitudinal) extension of tumor from one subsite (segment) of the large intestine into an adjacent subsite or into the ileum (e.g., for a cecal carcinoma) or anal canal (e.g., for a rectal carcinoma) does not affect the pT classification.

Stage-related outcome data are based on pN assignment by conventional histologic staining of lymph nodes that are identified on routine macroscopic examination. Because many nodal metastases in colorectal cancer are found in small lymph nodes (<5 mm in diameter),[225] diligent search for lymph nodes in resection specimens is essential. The number of lymph nodes that are recovered from resection specimens varies widely and depends on several factors: patient factors such as age and anatomic variation; surgical resection technique; and diligence of the pathologist in harvesting all existing nodes. It has been shown that a minimum of 12 to 18 lymph nodes must be examined to accurately predict regional node negativity in colorectal cancer.[226] For this reason, it has been suggested that 12 lymph nodes be considered the minimum acceptable harvest from a careful specimen dissection. If fewer than 12 nodes are found after careful gross examination, additional techniques (i.e., visual enhancement techniques such as fat clearing) may be considered. It has been further recommended that all grossly negative or equivocal lymph nodes be submitted entirely for microscopic examination and that involvement of grossly positive lymph nodes be confirmed by either complete or partial microscopic examination.

To be included in the N category, a lymph node must be within the regional lymphatic drainage area of the primary tumor. Metastasis in other lymph nodes is classified as M1. Occasionally, however, a colorectal cancer may involve more than one site or subsite by continuous longitudinal extension. For example, a cecal carcinoma might extend across the ileocecal valve into the ileum. In these cases, the regional lymph nodes are defined as those of all involved sites and subsites. In rare cases, the regional nodes of the primary tumor site are free of malignancy but the nodes in the drainage area of an organ directly invaded by the primary tumor contain metastases. In this circumstance, the lymph nodes of the invaded site are considered as those of the primary site and are classified in the N category.

Increasingly, attention is being focused on alternative methods of detection of very small amounts of metastatic tumor in draining lymph nodes, but the impact on outcome of single or minute clusters of tumor cells in such nodes has not yet been definitively demonstrated. To ensure uniform pathologic assessment and data collection on this issue, small numbers of tumor cells that are detected only by special techniques or that are seen histologically but measure 0.2 mm or less in diameter are defined as "isolated tumor cells" (ITCs). According to current American Joint Committee on Cancer/International Union Against Cancer recommendations, ITCs are classified as N0 or M0, as appropriate. In contrast, small amounts of metastatic tumor that measure greater than 0.2 mm but less than 2.0 mm are defined as "micrometastases" and classified as N1 or M1. The number of lymph nodes that are involved by micrometastases or ITCs should be stated in the pathology report. To date, the data on the prognostic impact of ITCs in colorectal cancer are conflicting.[227–229] Therefore, changes in routine methodologies for lymph node evaluation currently are not recommended. Pending definitive demonstration of the biologic impact of ITCs and the clinical utility of more sensitive methods of lymph node analysis, neither routine examination of multiple tissue levels of paraffin blocks nor use of special or ancillary techniques such as immunohistochemistry or polymerase chain reaction techniques to enhance tumor cell detection are considered standard of care.

Positive peritoneal fluid cytology or tumor that is present (only) in lymphatic vessels of a distant site is considered pM1 disease. Excluded from pM1 designation are ITCs that are found in the bone marrow and tumor foci in the mucosa or submucosa of adjacent bowel, also known as satellite lesions or skip metastases. However, the latter must be distinguished from synchronous primary tumors.

For tumors that are treated prior to staging, stage-related prognosis is altered in comparison to tumors that are staged prior to treatment. This is especially relevant to rectal cancers that are treated with neoadjuvant radiation. However, the rules of application of TNM allow for description of the extent of post-treatment disease using the same TNM parameters modified by the prefix "y." The classification of residual disease also may be a strong predictor of post-treatment outcome, and the ypTNM classification provides a standardized framework for the collection of data that are needed to accurately evaluate new therapies.

Stage-related prognosis is also modified by the presence of residual tumor in the patient after primary surgical resection. Stage-related prognosis in disease with no (or limited hepatic) distant metastasis at presentation is predicated on complete eradication of all detectable tumor with cancer-directed surgery. The postoperative residual disease status of the patient, reflecting the efficacy of primary treatment, is categorized by a system known as the R classification, as follows:[220]

RX Presence of residual tumor cannot be assessed
R0 No residual tumor
R1 Microscopic residual tumor
R2 Macroscopic residual tumor

The R classification has stage-independent prognostic significance in that R1 and R2 are adverse prognostic factors compared to R0 status at any stage of disease. The relevance of the R classification to the pathologist is primarily related to resection margin evaluation. By convention, tumor that is present microscopically or macroscopically at a resection margin corresponds to R1 or R2, respectively. However, R0 status cannot necessarily be assigned to a case with negative resection margins because R0 refers to absence of residual tumor anywhere in the patient, including distant metastatic sites.

The pertinent margins of a colorectal cancer resection specimen include the proximal and distal transverse margins, the mesenteric margin, and, when appropriate, the circumferential (radial) margin. The circumferential resection margin (CRM) represents the retroperitoneal or perineal adventitial soft tissue margin of the excised bowel. For all segments of the large intestine that are either incompletely encased (ascending colon, descending colon, upper rectum) or not encased (lower rectum) by peritoneum, the CRM is created

by surgical dissection of the retroperitoneal or subperitoneal aspect, respectively, at operation.

When the distance between the tumor and the nearest transverse margin is 5 cm or more, anastomotic recurrences are very rare. Therefore, histologic examination of the proximal and/or distal margin might not be necessary if these margins are 5 cm or more from the tumor. By extension, the donuts from stapling devices, which are the true margins of resection, need not be examined histologically if the tumor is greater than 3 cm from the cut end of the main specimen.[230] In low anterior rectal resection specimens of rectal cancers, however, wide distal cuffs of normal mucosa can be hard to achieve, owing to anatomic constraints. In this circumstance, a margin of 2 cm is accepted as adequate, and in many cases, distal margins of 1 cm or less also prove sufficient, especially for T1 and T2 tumors.

In rectal carcinoma, the CRM has been demonstrated to be the margin of greatest importance in predicting risk of local recurrence, which is itself a strong predictor of survival.[231,232] In fact, multivariate analyses have suggested that tumor involvement of the CRM is the single most critical factor in predicting local recurrence in rectal cancer.[231] Emerging data on CRM involvement in the ascending or descending colon suggest a similar relationship to risk of local recurrence.[233] Therefore, routine assessment of the CRM is recommended in all applicable colorectal cancers, and measurement of the distance from the tumor to the nearest CRM, representing the "surgical clearance" around the tumor, is suggested.[232] On the basis of published data from clinical trials, the risk of local recurrence is strongly increased if tumor is present 1 mm or less from the nonperitonealized surface of the specimen.[234] By convention, therefore, the AJCC and VICC now define a positive CRM as one that is 1 mm or less from the closest approach of tumor. Some data have suggested that the risk of local recurrence also is significantly increased with clearances of 2 mm or less.[235] In contrast, the risk of recurrence is very low with clearance of more than 2 mm and can be considered "negative."

For segments of the colon that are completely encased by a peritonealized (serosal) surface (e.g., cecum, transverse, and sigmoid colon), the mesenteric resection margin may be a relevant "radial" margin, since tumors may extend to this margin with (pT4) or without (pT3) penetrating the serosal surface. It should be examined when the point of deepest penetration of the tumor is on the mesenteric aspect of the colon, especially when the mesentery has been trimmed close to the colonic wall. For tumors that are limited to an antimesenteric peritonealized aspect of the bowel, the mesenteric margin usually is not relevant.

Histopathology

The internationally accepted histologic classification of colorectal carcinomas proposed by the World Health Organization (Table 81-4) is recommended by the College of American Pathologists (CAP). According to this classification, the majority of colorectal cancers are adenocarcinomas of no special type. Aside from a few notable exceptions, histologic type has no stage-independent prognostic significance. The exceptions include the non-gland-forming tumor types such as signet-ring cell carcinoma, small cell carcinoma, and undifferentiated carcinoma, which are prognostically unfavorable, and medullary carcinoma, which is relatively favorable compared to other non-gland-forming tumor types. By convention, histopathologic types that do not form glands are always considered to be high-grade, except for medullary carcinoma, which is not graded. High tumor grade is itself an adverse prognostic factor (see later in the chapter). Medullary carcinoma was added to the revised World Health Organization classification in 2000.[236] It has a distinctive morphology composed of large polygonal tumor cells and abundant tumor-infiltrating lymphocytes (Fig. 81-20). The importance of this rare and unique histologic type is its strong association with defective DNA replication fidelity and high microsatellite instability, molecular features that are, in turn, associated with a more favorable stage distribution and prognosis compared to microsatellite stable tumors.[237] Most tumors of this type occur in the proximal colon in association with the hereditary nonpolyposis colon cancer syndrome.

Table 81-4 World Health Organization Classification of Colorectal Carcinoma*

Adenocarcinoma
Mucinous (colloid) adenocarcinoma (>50% mucinous)
Signet-ring cell carcinoma (>50% signet-ring cells)
Squamous cell (epidermoid) carcinoma
Adenosquamous carcinoma
Small cell (oat cell) carcinoma
Medullary carcinoma
Undifferentiated carcinoma
Other (e.g., papillary carcinoma)

*The term *carcinoma, NOS* (not otherwise specified) is not part of the WHO classification.

The grading of colorectal carcinoma, overall, is based on both architectural features and cytologic features (e.g., pleomorphism, hyperchromatism, and mucin production), but the degree of gland formation is widely regarded as the most important feature in grading. For adenocarcinoma, however, the estimation of grade is largely subjective. The lack of uniformity in histopathologic grading is further complicated by the existence in the literature of a number of different grading schemas without widespread acceptance and uniform use of any single system by practicing pathologists. Furthermore, the published systems have varied markedly as to the number, type, and relative importance of the specific features used to distinguish different grades. Irrespective of the type or complexity of the criteria, however, most systems stratify tumors into three or four grades as follows:

Grade 1: Well differentiated
Grade 2: Moderately differentiated
Grade 3: Poorly differentiated
(Grade 4: Undifferentiated)

Despite the lack of standardization and the existent interobserver variation in assessment, histologic grade repeatedly has been shown by multivariate analyses to be a stage-independent prognostic factor.[238–240] More specifically, high tumor grade has been shown to

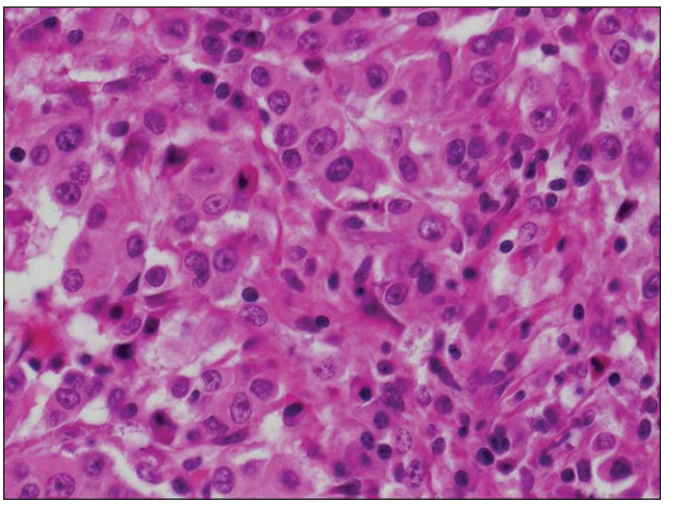

Figure 81-20 • Medullary carcinoma of the colon.

be an adverse prognostic factor. In almost all studies documenting the prognostic power of tumor grade, three- or four-tiered grading schemas have been collapsed for data analysis as follows:

Low-grade = grades 1 and 2
High-grade = grades 3 and 4

On the basis of these data, a two-tiered grading system for colorectal carcinoma (i.e., low-grade and high-grade) has been recommended by a multidisciplinary colorectal working group of a consensus conference sponsored by the CAP.[241]

There are no special histopathologic studies, such as histochemical or immunohistochemical assays, that are performed routinely for colon cancer. In some cases, immunostaining may be electively performed for MLH1 and MSH2, the two DNA repair genes that are most often found to be silenced in sporadic microsatellite unstable colon cancer. Immunostaining for cytokeratin also may be performed in special circumstances. For example, colon adenocarcinoma is characteristically positive for keratin 20 and negative for keratin 7, and although it is not pathognomonic, this feature can be helpful in distinguishing a metastatic lesion in the lung from a primary lung adenocarcinoma. Another example of the elective use of cytokeratin immunohistochemical staining is the examination of the advancing edge of the tumor for a phenomenon known as budding or dedifferentiation. This phenomenon is an adverse prognostic factor and is associated with a high risk of recurrence after curative surgery. It is characterized by small clusters or single infiltrating carcinoma cells (<5) at the invasive edge. The finding correlates with loss of adhesion molecules expression and increased metalloprotease expression[242] corresponding to a more aggressive tumor phenotype on a molecular level.[243] Because these cells may be quite small and neither form glands nor make mucin, they may require immunostains for identification, especially when accompanied by an inflammatory reaction that obscures their presence on routine histologic stains. The survival rate for stage II patients with tumor budding might not be significantly different from the survival rate for all stage III patients.[244–246]

ANATOMY AND PHYSIOLOGY OF THE COLON

For the purposes of this chapter on colon cancer, a discussion of the anatomy of the colon and its physiology will address aspects that are important to the spread of colon cancer and its surgical management. Anatomically, the colon is divided into the ascending or right colon, the transverse colon, the left or descending colon, and the sigmoid colon. The right colon is derived embryologically from the midgut, whereas the left colon is derived from the hindgut. Colon length varies not only according to body size but also among normal individuals of the same size and is estimated to range from 91 to 125 cm. The luminal diameter varies from its greatest width at the cecum (approximately 8.5 cm) to its narrowest at the distal sigmoid (approximately 2.5 cm). This change in diameter and the consistency of formed fecal content in the descending and sigmoid colon account for the frequent presentation of obstructive symptoms among patients with annular cancers in these colonic segments. The merging of the three taenia coli (from the Latin word for "tape") or longitudinal muscle bands into a continuous (encompassing) longitudinal muscle layer for the rectum at the pelvic peritoneal reflection marks the junction between the sigmoid colon and rectum.

Three segments of the colon—the cecum, transverse colon, and sigmoid colon—are intraperitoneal. The ascending colon, hepatic flexure, splenic flexure, and descending colon and the beginning and end of the sigmoid colon are retroperitoneal structures. As a result, the surgical resection and the patterns of recurrence are greatly influenced by the location of the tumor within the colon and, for the segments that are retroperitoneal, by its position within the bowel at the primary site (e.g., primarily posterior in location versus on the anterior wall of the colon). Although the beginning of the colon (cecum) and its appendix are largely intraperitoneal, the ascending colon and its mesocolon are fused to the posterior abdominal wall in a retroperitoneal position. It should be noted that the ileocecal valve at the junction of the ileum to the colon is actually formed by two reflected folds of the mucosal wall of the cecum. These folds unite and project further around the cecum as the frenulum. The opening of the appendix into the cecum is near the ileocecal valve.

Examination of the inner surface of the colon reveals the semilunar folds, the sacculations that are termed *haustrae*, and the longitudinal muscle bands, or taenia. Lymphoid follicles are also visible on the luminal surface. As was noted previously, the taenia start at the base of the appendix and continue throughout the colon.

The hepatic flexure lies just below the right lobe of the liver and the gallbladder and overlies the lower pole of the right kidney. The transverse colon extends across the abdomen and can be of variable length. It is intraperitoneal and is attached to the transverse mesocolon along the taenia mesocolica. The greater omentum attaches to the transverse colon along the taenia omentalis. The taenia libera is free of any attachments. Along the intraperitoneal transverse colon and sigmoid colon, one sees numerous fatty appendages hanging from the serosa. These are called *appendices epiploicae*. They are small, saclike structures containing fat and have no known function.

The splenic flexure lies, as its name suggests, in close proximity to the hilum of the spleen and the tail of the pancreas. This is an important relationship when the transverse or descending colon is being surgically mobilized. Attachments between the splenic flexure and the lower pole of the spleen must be divided carefully to avoid injury to the spleen. The descending colon, like the ascending colon, is fused to the posterior abdominal wall and lies in the retroperitoneum. The sigmoid colon begins the intraperitoneal distal portion of the colon and is of variable length. Its lumen is the narrowest diameter of the entire colon. The sigmoid colon terminates at the upper rectum in the general area of the sacral prominence (Fig. 81-21).

Vascular Supply to the Colon

The superior mesenteric vessels supply the cecum, the ascending colon, and a good portion of the transverse colon. The major branches of the superior mesenteric artery (SMA) are the ileocolic artery supplying the ileocecal region, the right colic artery in support of the ascending colon, and the middle colic branch to the hepatic flexure and transverse colon. These vessels have extensive branching near the colon and contribute to the formation of the important marginal artery (marginal artery of Drummond). The veins that accompany these arteries drain back to the superior mesenteric vein and thence to the portal vein. It is this unique venous drainage to the liver that is believed to account for the high incidence (approximately 80%) of first-site metastatic failure in the liver for colon and upper/middle third rectal cancers.

The inferior mesenteric artery (IMA) arises from the aorta and supplies the descending colon via the left colic artery. The marginal artery acts as a collateral vessel to link the branches of the superior mesenteric artery to the right colon with the arterial flow from the inferior mesenteric artery and its left colic artery (see Fig. 81-21A). Distally, the inferior mesenteric artery gives rise to several sigmoid arteries and the superior rectal artery. Veins draining the left side accompany these arteries and drain via the inferior mesenteric vein to the splenic vein and thence to the portal vein. A patent, healthy marginal artery provides a measure of safety in performing resections of the colon by providing collateral arterial flow. These arteries and veins lie within the "leaves" of the mesocolon.

Lymphatics of the Colon

Lymphatics and nerves to the colon also lie within the mesocolon and follow the course of the arteries. The lymphatic channels originate in the lower lamina propria and muscularis mucosae at the base of the colonic mucosa. These channels drain into the extramural lymphatics. Cancer that is growing superficial to the level of the

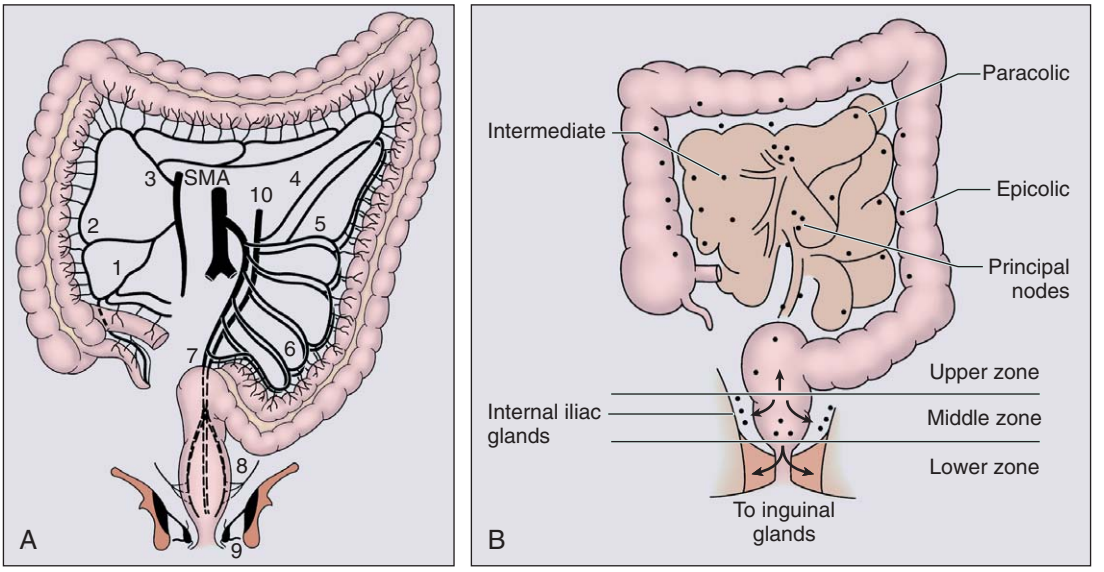

Figure 81-21 • **A,** Arterial and venous supply of the colon. Branches of the superior mesenteric artery: (1) ileocolic, (2) right colic, (3) middle colic. Branches of the inferior mesenteric artery: (4) ascending left colic, (5) left colic, (6) sigmoid branches, (7) superior rectal artery, (8) middle rectal artery, (9) inferior rectal artery, (10) inferior mesenteric vein. **B,** Principal nodal drainage sites of the colon.

muscularis mucosae has not been shown to have access to the lymphatic channels and therefore has not been found to have metastatic potential. The lymph nodes lie roughly along the vessels and are grouped as epicolic; paracolic (located along the marginal artery); intermediate (located along mesenteric vessels); and principal or central nodes at the junction with the superior mesenteric artery or, in the case of the inferior mesenteric artery, with the aorta (see Fig. 81-21B).

All collecting lymph channels from the abdominal viscera, the abdominal wall, and the lower extremities converge in an elongated sac (approximately 5 cm) known as the cisterna chyli. The cisterna chyli lies along the aorta, and a large afferent lymph channel proceeds from the cisterna superiorly through the aortic opening in the diaphragm along the right diaphragmatic crus. There are numerous communicating lymphatics between the larger channels, which could account for the observed "skipping" of metastases and multiple "sentinel" nodes for a given tumor site. Malignant cells might also pass through initial nodes before being trapped in more distant nodes. Lymph nodes also have an arterial supply and a venous drainage feature, which could play a role in metastatic spread to nodes as hematogenous metastases and account for unusual sites of node involvement that appear completely unrelated to direct drainage of lymph fluid from the original tumor.

Autonomic Innervation

The autonomic nervous system mediates control of colonic motor and secretory function and primary visceral sensation. The autonomic innervation includes both sympathetic and parasympathetic components. The preganglionic parasympathetic nerve fibers are quite long, extending from the brain stem to the colon wall, where they terminate within the mesenteric and submucosal plexuses. In contrast, the first synapse of the sympathetic fibers can occur within the paravertebral ganglia, but most pass through the ganglion without synapsing. The sympathetic fibers are gathered into bundles know as the greater (fourth to tenth thoracic), the lesser (ninth to eleventh thoracic), the least (eleventh thoracic to the first lumbar), and the lumbar (second and third lumbar) splanchnic nerves. The splanchnic nerves (preganglonic fibers) pass to the preaortic ganglia, so named for the adjacent arterial trunks such as celiac and superior mesenteric ganglia and plexus. These preganglonic sympathetic fibers synapse within the preaortic ganglia. The postganglionic adrenergic fibers follow arteries to their effector organs in the wall of the colon.

An extensive network of fibers and ganglia cells lies within the submucosa and muscular walls of the colon. The intact mucosa of the colon is insensitive to direct stimuli. Sensory receptors in the colon wall react to stretching (as with gas) and to muscular spasm. The mesentery is sensitive to tugging or stretching. Impulses arising from these stimuli are sent over the autonomic (mainly sympathetic) afferent fibers.

Visceral pain derived from distension of the bowel or traction on the mesentery of the cecum, the ascending colon, and the majority of the transverse colon (structures of midgut origin) initially presents as periumbilical pain. If there is inflammation, ischemia, or direct tumor infiltration of the abdominal wall, the pain is somatic and located at the site of involvement. Referred pain is rare. Pathology of the distal transverse colon, splenic flexure, and descending and sigmoid colon (structures of hindgut origin) produces visceral pain, initially along the midline below the umbilicus. Somatic pain from the left colon may occur with tumors, causing inflammation or invasion into the abdominal wall.

The pain that is associated with an obstructing colon tumor is initially experienced as cramping waves of pain located below the umbilicus. In the beginning, these spasms last for minutes, but they gradually increase in intensity and duration. Over 24 to 48 hours of obstruction, the pain becomes constant and more diffuse throughout the abdomen.

Embryology

By the 6-week embryo stage, the midgut has formed and exists as a long intestinal loop in an elongated celomic cavity within the umbilical cord. At the beginning of the third month, the intestinal loop residing in the umbilical cord begins to rotate counterclockwise around the axis of the superior mesenteric artery. In doing so, the distal limb of the intestinal loop, consisting of the future cecum, terminal ileum, and ascending colon, passes over and to the right of the future jejunum and ileum. With this twist, the superior mesenteric artery comes to cross in front of the duodenum. As the intestinal loop withdraws from the umbilical cord, the proximal limb leads

the way and, as a result, pushes the distal colon to the left side of the abdomen. The cecum and terminal ileum migrate downward and to the right lower quadrant of the abdomen.

From this brief discussion, it is obvious that any interruption of this rotation can alter the position of certain segments of the colon. The most common is a high position of the cecum beneath the liver in the right upper abdomen. Earlier interruptions of rotation could find the colon remaining on the left side.

When the rotation process proceeds normally, the entire mesentery to the cecum and ascending colon becomes fused to the right posterior abdominal wall as a triangle with the apex at the base of the mesentery just above the emergence of the superior mesenteric artery. The upper section of this mesenteric triangle covers the second and third segments of the duodenum, which sweeps from right to left behind the superior mesenteric artery.

The mesentery of the transverse colon is retained, and the transverse colon develops an attachment horizontally with the greater omentum. Similar to the ascending colon, when the descending colon becomes fixed to the left posterior abdominal wall, its mesentery becomes part of the posterior wall. The sigmoid colon retains its redundancy and therefore a mesentery.

A thorough knowledge of the embryonic development of the colon is important to the surgeon and to the safe mobilization and resection of various colonic segments.

Microscopic Anatomy of the Normal Colon

A single layer of columnar epithelium covers the colonic mucosa, overlying the internal surface and lining the crypts along the lamina propria (Fig. 81-22). The single layer of colonic epithelium consists of columnar or cuboidal cells and serves as a protective barrier against the luminal content. At the level of bases of the glands, there is a thin, continuous muscle layer termed the *muscularis mucosae* that separates the lamina propria from the submucosa.

The epithelial layer has two additional functions. One is to facilitate the process of water absorption, and specific cells are responsible for colonic ion and water transport. These cells do not contain mucin and have an eosinophilic cytoplasm. The second function of the epithelium is to synthesize, store, and secrete mucous granules; this is accomplished by goblet cells in the colonic epithelial layer. The colonic epithelium is supported by a thin basement membrane that anchors the epithelial cells. The basement membrane consists of collagen and other proteins and is permeable to absorbed or secreted ions, water, and proteins. One of the unique characteristics of the colon mucosa is the presence of straight-sided crypts, which have a somewhat heterogeneous population of epithelial cells. At the base of each crypt are undifferentiated stem or precursor cells. These cells are continually dividing (see Fig. 81-22). Daughter cells migrate toward the surface epithelial layer to renew the surface epithelium, which is constantly being shed into the lumen or undergoing apoptotic death. As the daughter cells move from the base of the crypt toward the lumen of the colon, they lose their ability to divide but continue to differentiate to become functionally mature. The upper 25% of the crypt represents such mature cells. Neuroendocrine cells and Paneth cells are found in the bases of the crypts, but Paneth cells are found only in the mucosa of the cecum and proximal right colon.

The lamina propria extends from the basement membrane to the muscularis mucosae. It is composed of loose strands of collagen, and B lymphoid cells are abundant and may occur in small aggregates between crypts. These B cells produce immunoglobulins, mostly of IgA class. T lymphocytes and macrophages are also found in the lamina propria, as are fibroblasts.

The muscularis mucosae is a thin layer of muscle that separates the superficial layers of epithelium and lamina propria from the deeper submucosa. Between the muscularis mucosae and the submucosa are found the neural plexus of Meissner and the deep submucosal neural plexus of Henle. The muscular layers of the colon include a circular inner layer of smooth muscle fibers and an outer longitudinal layer. Auerbach's neural plexus lies between the circular and longitudinal muscle layers. These muscle layers are covered by a thin layer of connective tissue (the subserosa) and a layer of mesothelial cells (the serosa or visceral peritoneum), except at the points of attachment of the ascending and descending colon to the abdominal sidewall where the visceral peritoneum is discontinuous.

Figure 81-22 • Normal colonic basal crypt epithelium. Among the absorptive cells and goblet cells are a mitotic figure and endocrine cells with basally oriented secretory granules (red stained). (From Sternberg SS: Histology for Pathologists. New York, Raven Press, 1992.)

Physiology of the Colon

The colon functions to prepare the normal waste products left after digestion and absorption of nutrient food products for elimination in a controlled manner. Water is withdrawn through the colonic mucosa from the fluid stool entering the cecum and ascending colon. Both water and salt are absorbed as the right colon acts to reduce the daily liter of ileal liquid chyme to approximately 200 g of formed fecal matter. The left colon is responsible for storage and eventual expulsion. The movement of fecal matter through the colon is regulated hormonally and neurally.

The mucosal lining of the colon keeps its surface coated with mucous to protect the epithelial cells from injury and to act as a lubricant. Mucus is produced by the tubular glands, which contain many goblet cells, and mucous production is controlled primarily by parasympathetic nerve fibers.

The colon has abundant bacterial flora, including *Escherichia coli*, *Aerobacter aerogenes*, *Clostridium welchii*, various lactobacilli, cocci, and yeast organisms. The flora is somewhat influenced by diet, being more gram-negative when the diet is primarily protein in nature and more gram-positive if the diet is mainly carbohydrates and green vegetables. Some of the colonic organisms synthesize vitamins of the B complex and vitamin K.

Carbohydrate-consuming bacteria within the lumen work on undigested carbohydrates and dietary fiber, producing short-chain fatty acids, flatus, and water. These short-chain fatty acids can be absorbed by colonic mucosal epithelial cells and can be a source of dietary calories. Although these various bacteria reside in relative balance, the normal equilibrium of bacteria can be altered significantly by antibiotics, giving rise to an overgrowth of harmful bacteria such as *Clostridium difficile*.

Antibiotic-associated diarrhea occurs in an estimated 1% to 15% of individuals who are given broad-spectrum antimicrobic therapy. It is caused by an overgrowth of *C. difficile* when the normal bacterial flora of the colonic mucosa is suppressed. *C. difficile* colonic infection generally causes cramping and mild diarrhea, but it can result in a more life-threatening pseudomembranous colitis. Patients with colon cancer or those who are receiving treatment for recurrent disease are frequently at risk for developing antibiotic-associated diarrhea. In such cases, the antibiotic should be stopped and the patient should be given vancomycin (250 mg every 6 hours orally for 7 days) or metronidazole (500 mg every 8 hours for 7 days). Treatment should be started when the diagnosis is suspected, before the results of a stool assay for *C. difficile* toxins are available.

SURGICAL TREATMENT

Radical resection of the tumor-bearing segment of colon, with wide margins and removal of the lymphatic drainage of the tumor, is the standard for curative therapy. The extent of resection is determined by tumor size, location, histologic grade, and tumor extension into the colon wall and into adjacent tissue or organs. Historically, resections of the colon for cancer have been quite radical with respect to the removal of the mesocolon-bearing draining lymphatics at risk for tumor spread. Studies, however, indicate that there is no major survival advantage by extended lymph node dissection. Even so, limited segmental resections are indicated primarily when the surgery is deemed palliative.

Preoperative preparation of the colon to clear the colon of fecal matter and to reduce the quantity of bacteria within the colon is important to ensure a safe operation with minimal morbidity (Box 81-1 summarizes this preparation). For elective surgery, patients are placed on a liquid diet starting 3 days before scheduled surgery. For the last 24 hours of diet preparation, they are urged to take only clear liquids. The night prior to surgery, patients have an active mechanical bowel preparation to ensure optimal cleansing of the colon. Before surgery, they are given parenteral antibiotics. Patients should be given intravenous hydration before surgery, preferably during the night of their mechanical bowel preparation. It might be necessary to modify the preparation of the colon if the tumor is large enough to cause partial obstruction.

It is important to use a suitable regimen to minimize the risk of deep venous thrombosis and thereby to reduce the likelihood of pulmonary embolism. Routine use of low-molecular-weight heparin and intermittent compression leggings during the perioperative period may be appropriate. Early ambulation is an important adjunct to heparin and compression.

The choice of placement of the incision is dependent on the location of the tumor and the surgeon's preference. A midline or Para median incision is favorable for two reasons. First, it allows better access to the liver in case unexpected synchronous liver metastases are discovered; second, it is not uncommon to reoperate such patients for recurrent tumor. A midline approach, in contrast to a transverse approach (incision), allows the surgeon to move up or down within the abdomen for future surgical therapy.

Once the abdomen has been entered, the surgeon performs a thorough exploration of the abdomen to assess the extent of the tumor and to search for metastatic disease. The liver deserves special attention because it is most commonly the site of first failure, and approximately 10% to 15% of patients will have synchronous metastatic involvement of the liver. Intraoperative evaluation of the liver is generally accomplished by visual inspection and palpation. If there is any suspicion of liver metastasis based on preoperative CT scan, intraoperative ultrasound of the liver is performed and increases the frequency of detecting occult metastases.[200–202,247,248] Particular attention should be paid to nodes in the porta hepatis, and if unusually large or suspicious nodes are found, they should be sampled.

The four classic resections for colon cancer are depicted in Figs. 81-23 through 81-26. A right hemicolectomy (see Fig. 81-23) is the standard approach for tumors involving the cecum and right colon. The mesocolon and its vascular structures are transected at the base of the mesocolon along the superior mesenteric artery. The ileocolic and right colic arteries are the branches of the superior mesenteric artery that are ligated, along with branches of the middle colic artery. The middle colic artery is usually preserved unless the tumor is located in the hepatic flexure of the colon. In this situation, the resection is extended to include the middle colic artery. For a right

Box 81-1. PREPARATION OF BOWEL FOR ELECTIVE RESECTION

- Begin diet restriction to full liquids 3 days before scheduled surgery.
- Limit diet to clear liquids for 24 hours preceding surgery.
- Admit patient to hospital 1 day before surgery for intravenous hydration.
- Administer metoclopramide, 10 mg intramuscularly or orally, 30 minutes before beginning mechanical bowel preparation.
- Administer D5/0.5 saline solution with 40 mg KCl intravenously at 100 mL/hr beginning at 11:00 P.M. on the evening before surgery.
- Administer 1.5 L GI lavage solution four times hourly by mouth until stool is clear. Begin lavage at approximately 4:00 P.M. on the afternoon before surgery.
- Administer neomycin base orally 1 and 2 hours after completion of GI lavage (approximately 10:00 P.M.)
- Administer erythromycin base orally 1 and 2 hours after completion of GI lavage.
- Check serum potassium 2 hours after completion of GI lavage and at 6:00 A.M. preoperatively.
- Ensure that intravenous Cefotetan is available on call to the operating room.

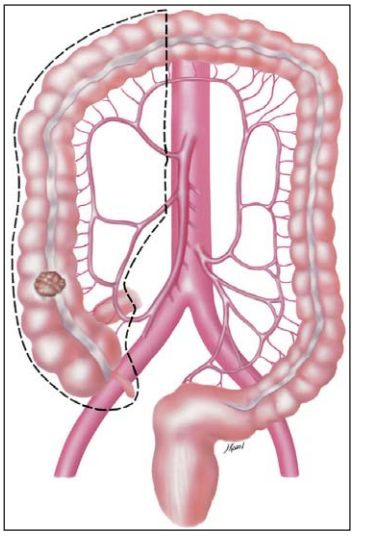

Figure 81-23 • Right hemicolectomy resection margins for right colon carcinoma.

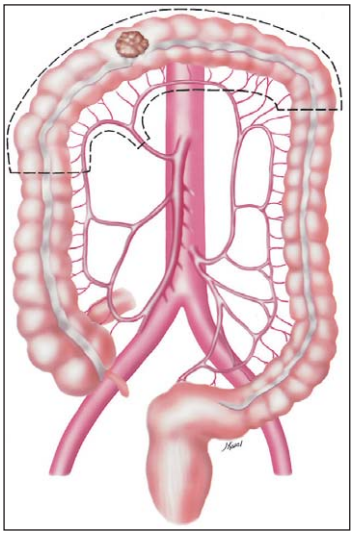

Figure 81-24 • Transverse colon resection margins for transverse colon carcinoma.

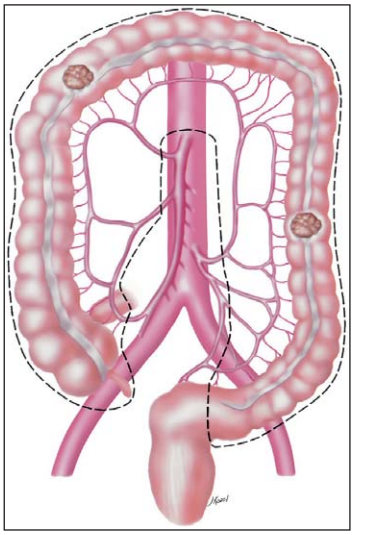

Figure 81-26 • Resection margins for synchronous right colon and left colon carcinomas with reconstruction via ileorectostomy.

hemicolectomy, the ileum is divided approximately 10 cm from the ileocecal valve. Continuity of the bowel is reestablished by anastomosis of the terminal ileum to the transverse colon. Although the greater omentum is often removed in part or completely to facilitate resections of the right and transverse colon, there is no evidence that this measure improves survival.

Cancer involving the transverse colon requires mobilization of both the hepatic and splenic flexures. The middle colic artery is transected at the superior mesenteric artery (see Fig. 81-24). When the tumor is located in the splenic flexure region, the surgeon must be more concerned about adequate collateral blood supply through the marginal artery. This concern is increased in elderly patients who have a history of significant vascular disease.

Tumors that are located in the left colon are managed by a left hemicolectomy. The inferior mesenteric artery is ligated near its origin on the aorta. The more distal the location of the cancer, the more mobilization of the upper rectum will be needed. It is almost always necessary to mobilize the splenic flexure. Cancers that involve the sigmoid portion of the colon are resected by what is commonly termed an anterior sigmoid colon resection or a low anterior sigmoid resection. The more distal sigmoid tumors require resection of the upper rectum to achieve an adequate distal margin. It is always more difficult, in cases of left colon and sigmoid colon cancers, to determine an appropriate amount of colon and mesentery for resection. It is helpful to map the vascular structures draining the area of the tumor visually. There is increasing evidence that aggressive radical resections of the left colon provide no additional survival benefit.

As has been noted, in colon surgery it is the arterial blood supply that usually dictates the extent of resection. The rule is to provide a minimum of a 5- to 6-cm margin of colon in the resection. Evidence suggests, however, that it is rare to find colon cancer spread beyond 1.2 cm from the gross margin of the tumor. Figure 81-26 illustrates a subtotal colectomy and ileorectostomy. A subtotal colectomy might be required in patients who harbor synchronous cancer in the right and left colon and patients presenting with colon cancer at a young age. Other indications for subtotal colectomy could include obstructing cancer, extensive diverticular disease, and a right colon lesion with extension into the sigmoid colon or, similarly, a cancer of a redundant sigmoid colon that invades into the right colon.

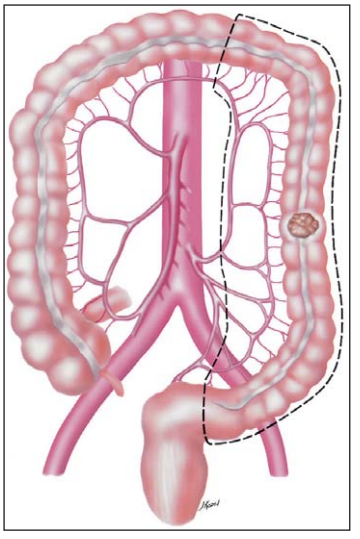

Figure 81-25 • Left colon resection margins for left colon carcinoma.

Restoring Continuity

The restoration of bowel continuity is an important step in the procedure. Use of appropriate techniques for accomplishing the anastomosis minimizes the risks of abscess, sepsis, and the significant morbidity associated with a leak postoperatively. The anastomosis is performed either hand-sewn or by using a stapling technique. There is little if any evidence that one technique is superior to the other. It is important to use surgical packs to isolate the anastomosis procedure from the rest of the abdomen until it has been completed.

Using a separate set of instruments once the bowel is opened and discarding these when the closure of the anastomosis is completed is considered prudent. Schwab and colleagues[249] reported the results of an in vitro study comparing initial bursting strength for three different anastomosis techniques. These authors performed 10 hand-sutured anastomoses, 10 biofragmentable ring anastomosis, and 10 stapled anastomoses of fresh human colon that was harvested at time of colon cancer surgery. They measured the pressure that was required to burst the anastomosis and found no significant difference. They concluded that because there were no differences, hand-sutured anastomoses were certainly the least expensive and should remain the standard.

In prior years, some surgeons advocated a "no-touch technique" in removing colon cancer. This was based on the concern that manipulation of the tumor-bearing tissue before high ligation of the draining veins and lymphatics might increase the risk of metastasis. A study by Sales and coworkers[250] failed to show a survival benefit for rigorous application of the "no-touch" high ligation of vessel technique.

Occasionally, surgeons either use povidone-iodine to irrigate a segment of colon during preparation for anastomosis or inflate the distal rectum and sigmoid colon to kill shed tumor cells within the lumen. Concern had existed regarding mucosal injury and absorption of iodine. Studies have shown that the elevated serum iodine levels that can occur with irrigation do not cause thyroid or bowel injury, and such irrigations can be performed with negligible risk.[251]

Surgical Management of Lymph Nodes in Colon Cancer

Lymph node metastasis is the most important prognostic factor in locoregional colon cancer. As was described previously in this chapter, colon resection has classically involved taking the mesocolon of the resected bowel at the origin of the vessels supplying the segment of colon to be removed. This ensures removal of the first level of lymph nodes (often called the epicolic and pericolic nodes) and the intermediate or second level of nodes in the resection when the vascular branches supplying the segment are taken at the SMA and IMA. The rationale for these more or less standard resections is based on the assumption that lymphatic tumor dissemination follows an orderly, sequential route of first-order nodes, second-order nodes, and so forth.

It is known, however, that metastases can be found in distant node groups—para-aortic, celiac, and porta hepatis—even when regional nodes appear to be normal. Supporting this observation is a report of administering 25-mci ^{99m}Tc-tagged fab-fragment-antibody to carcino-embryonic antigen (CEA) before the patients underwent colon resection. Intraoperatively, a hand-held scintillation probe was used, and surgeons removed all nodes that were identified as suspicious. Seven of 20 patients were upstaged, and metastatic spread was found at distant sites of retroperitoneum and renal hilum.[252]

The accuracy of regional node analysis and its prognostic value are directly proportional to the thoroughness of the surgical technique in removing all regional nodes and the pathologic examination of the resection specimen in identifying and harvesting all regional lymph nodes for microscopic assessment (see section on staging). The AJCC and the CAP have recommended examination of at least 12 lymph nodes to assign stage II.[253] It has been shown that a minimum of 12 to 18 lymph nodes must be examined to accurately predict regional node negativity in colorectal cancer.[223,225,254–260] For this reason, it has been suggested that 12 lymph nodes be considered the minimal acceptable harvest from a careful specimen dissection, and the National Quality Forum has accepted this recommendation as a quality indicator.[261]

Increasingly, however, the evidence indicates that the greater the number of nodes that are examined, the greater is the likelihood that metastasis will be found. In one study of T3 tumors, for example, nodal metastases were found in 22% of cases if fewer than 15 lymph nodes were harvested from the specimen, whereas 85% of cases with 15 or greater recovered nodes showed metastasis.[254] In a study of more than 2400 pT3 colorectal cancers that were resected at a single institution over 45 years, Goldstein and colleagues showed by mathematical analysis that the predictive probability of identifying a single positive node increased in a continuous manner as the number of recovered lymph nodes increased, suggesting that there is no minimum number of nodes that accurately or reliably stages all patients.[254]

More important, it has been shown that clinical outcome is linked to the lymph node harvest. Numerous studies have shown that conventional pathologic examination of increased numbers of lymph nodes is itself associated with an increased survival advantage in stage II disease,[255–259,262,263] indicting a positive effect of optimal mesenteric resection by the surgeon, optimal lymph node harvest from the resection specimen by the pathologist, or both. Similarly, a large study based on Intergroup Trial INT-0089, which included 3759 patients with stage III or high-risk stage II disease, showed that overall survival and cause-specific survival both increased as more lymph nodes were examined, suggesting that the number of lymph nodes that are analyzed is itself an independent prognostic variable in colorectal cancer.[255] In contrast, survival is significantly worse for patients with stage II colon cancer, roughly equivalent to stage III disease, in cases with fewer than 7 to 9 lymph nodes harvested from the resection specimen, suggesting clinically significant understaging when too few nodes are sampled.[264–266]

Despite the strength of the data demonstrating the critical nature of adequate lymph node assessment in colorectal cancer, significant variation in lymph node recovery from resection specimens exists within and among medical centers.[267–270] In addition, the average number of lymph nodes examined per specimen is often found to be lower than the minimal recommended number, suggesting that a large number of patients with colorectal cancer are staged inadequately.[271] The number of lymph nodes that are recovered from resection specimens is dependent on several factors. Surgical technique, surgery volume, and patient factors such as age and anatomic variation alter the actual number of nodes in a resection specimen, but the diligence and skill level of the pathology examination in identifying and harvesting lymph nodes in the resection specimen also are major factors.[270] Since it has been shown that many nodal metastases in colorectal cancer are found in small lymph nodes (<5 mm in diameter),[225] diligent search for lymph nodes is required on gross examination of resection specimens.

Lymphatic mapping and sentinel lymph node (SLN) identification can help surgeons and pathologists to identify lymphatic drainage routes and apply ultrastaging techniques to the first draining lymph nodes. While some studies have suggested that this is a useful procedure for micrometastasis detection,[272–276] other studies have highlighted the lack of established techniques and high false-negative rates.[277] The overall usefulness of SLN analysis in colorectal cancer is questionable, since fewer than 20% of cases are SLN-only positive.[278] The high rate of non-SLN metastases, with or without SLN metastases, may be attributed to the rich anastomotic relationship of lymphatics in colonic mesentery. For micrometastasis/ITC detection, greater accuracy is achieved by applying the special techniques to all lymph node blocks. Overall, the data are still insufficient to support routine use of specialized techniques for lymph node mapping or SLN analysis. As was discussed earlier in the chapter (in the section on Staging), the prognostic significance of the finding of ITCs remains to be definitively demonstrated, so the value of ultrastaging techniques might be moot.

Surgical Management of Obstructing Colon Cancer

In a large population of 4583 patients in the United Kingdom, obstruction was noted in 16%.[279,280] The obstructing tumor, as expected, occurred more frequently on the left side, the splenic flexure being the most common site (49%). Twenty-three percent of obstructions occurred in the descending colon, and 23% occurred in the right colon. Serpell and associates[281] reported a similar incidence of 16%, with 30% demonstrating symptoms and evidence of partial obstruction.

Malignant obstruction can present as a progression of symptoms associated with colon function, such as increasing frequency and severity of episodes of cramping abdominal pain or decreasing frequency of bowel evacuation leading to constipation and abdominal distention. It is not uncommon to have the patient present in the emergency room with the acute onset of symptoms. Diagnosis is confirmed by abdominal x-rays and CT scan. Carefully conducted

colonoscopy to avoid dangerous distention of colon by air insufflation and barium contrast study could prove useful in localizing the tumor and clearing the colon of other polyps or synchronous cancer.[282]

There are several options for managing obstructing tumors, depending on their location. These include the following:

- Resection with proximal temporary colostomy and Hartmann's procedure (closed distal stump)
- Intraoperative lavage of colon, systemic antibiotics, and primary anastomosis
- Subtotal colectomy with primary anastomosis

A temporary colostomy and Hartmann's procedure require a second operation for colostomy takedown and restoration of bowel continuity. Although this is a safe approach, with approximately 10% morbidity, subsequent colostomy closure might not be feasible or advisable in the poor-risk patient and itself carries an additional risk of complications of 40%.[280]

The second approach, intraoperative colon lavage, is accomplished by placing a Foley catheter through the appendiceal stump and irrigating the preserved colon until it is mechanically clean. Although this procedure is time consuming, the overall morbidity is approximately 10%, and the rate of anastomotic leak is quite low.[283]

The third approach, subtotal colectomy, has become more acceptable. It can be accomplished quickly, does not require a temporary colostomy, and has the advantage of removing any proximal synchronous lesions.[284–286] Wong and colleagues,[285] in an analysis of 35 patients undergoing subtotal colectomy for an obstructing cancer, found a significant incidence of proximal synchronous tumors in 32% of patients. Thus, patients with complete obstruction of their colon and dilated proximal colon might best be served by undergoing a subtotal colectomy. In general, fewer than 50% of obstructing lesions can be resected for cure, and a review of 12 reports by Sugarbaker and coworkers[286] found a 5-year survival rate of only 40% for those patients who were resected for cure.

Surgical Management with Involvement of Adjacent Organs

When a cancer of the colon is adherent to the peritoneal surface of the abdominal wall, the area of contact should not be divided, even if it is suspected to be an adhesion. In more than 50% of patients, what appears to be an adhesion will involve direct invasion of the tumor into the peritoneum.[287] Surgically disrupting these sites of adherence could result in a spill of cancer cells within the peritoneal cavity, leading to an increase in intra-abdominal recurrence and a decrease in survival. Adjacent organs are usually partially resected or totally resected in continuity with the colon tumor. When the tumor involves the abdominal wall, a portion of the peritoneum and underlying muscle are resected by developing a 2- to 3-cm margin around the site of adherence. Such carefully performed resections can lead to a good outcome in 20% to 50% of patients.[287] The redundant nature of the sigmoid colon frequently is responsible for involvement of the bladder by a sigmoid tumor. Fujisawa and colleagues[288] reported an analysis of 35 patients requiring some aspect of urologic surgery to accomplish a removal of their cancers. This group included 19 sigmoid cancers that involved 15 patients undergoing bladder-sparing partial cystectomy. An ileal conduit and ileal neobladder were needed in two patients.

Surgical Management of Perforated Colon Cancer

The frequency of colon cancer presenting as isolated acute perforation with peritonitis is low. But perforation combined with fistulation into an adjacent organ or into the retroperitoneum with the development of an abscess is estimated to occur in 6% to 8% of patients with colon cancer.[289] When the presentation is acute, with free air and diffuse peritonitis, an emergent surgery is required, and prognosis for long-term survival is poor. Sugarbaker and coworkers[286] found a 5-year survival rate of 7.3% for free perforation and 41% for contained perforations. The risk of peritoneal seeding and the future development of carcinomatosis is reported to be approximately 20% for patients with perforation.[290]

Surgical Management of the Malignant Colon Polyp

"Malignant polyps" are adenomas that contain any amount of invasive carcinoma, which is defined as tumor that penetrates through the muscularis mucosae into the submucosa. They also include polypoid carcinomas, in which the entire polyp head is replaced by carcinoma. By definition, malignant polyps exclude adenomas that contain intraepithelial carcinoma or intramucosal carcinoma because these polyps possess no biologic potential for metastasis. Polyps that contain invasive carcinoma represent about 5% of all endoscopically resected adenomas.[291] Malignant polyps often constitute a form of early carcinoma (pT1) that may be cured by endoscopic polypectomy alone. However, the incidence of an unfavorable outcome (i.e., lymph node metastasis or local recurrence from residual malignancy) for malignant polyps that are treated by polypectomy alone varies from about 10% to 20%.[292] Pathologic features that are associated with a significantly increased risk of residual or recurrent disease include (1) high tumor grade, (2) tumor at or less than 1 mm from the polyp resection margin, and lymphatic vessel involvement.[293] One or more of these features increases the risk of regional nodal metastasis or local recurrence following polypectomy by about 10% to 25%.[294] Therefore, if one or more of these high-risk features are found on pathologic examination, further therapy is usually indicated.

Sessile polyps containing cancer are more problematic. They have a higher incidence of lymph node involvement: approximately 10% to 25%, compared with 3% for pedunculated polyps.[295] Unless there are significant comorbid conditions that preclude resection, it is safest to resect the segment of the colon in which a cancerous sessile polyp has been found.[295] Extension of cancer to "Haggitt" level 3 in a pedunculated polyp is a good indicator for performing colon resection (Fig. 81-27).[296]

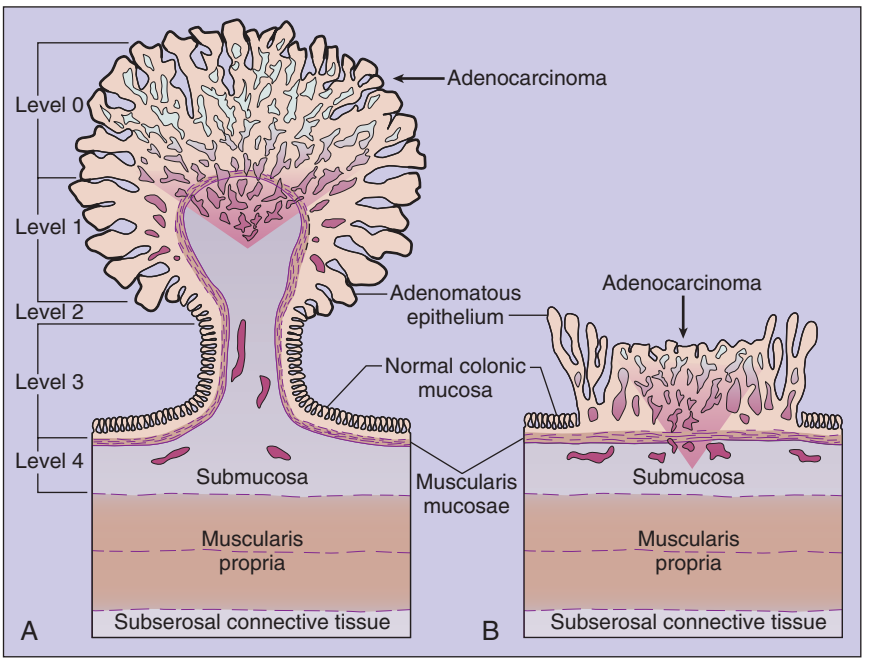
In dealing with malignant polyps, it is best to err on the side of overtreatment. Any polyp for which there is a question of adequate margin or angiolymphalic invasion should have a resection of the involved colon if the histology is grade 3. Identifying the correct segment to resect can be difficult at the time of surgery. Identification of the polyp site is facilitated by the endoscopist tattooing the site or by placing small metal chips at the polypectomy site. The histology of benign and malignant polyps is illustrated in Figure 81-28.

A reasonable approach is a limited segmental resection measuring 6 to 10 cm in either direction and including enough mesentery to provide assessment of the first level of draining lymph nodes. Often, this type of segmental resection can be accomplished by laparoscopic or laparoscopic assisted approaches.

Surgical Management of Synchronous Metastatic Disease

Synchronous metastatic disease is present in 10% to 15% of patients with a newly diagnosed colon cancer. The vast majority of such patients present with synchronous involvement of the liver. It is rare for patients to present with extensive peritoneal metastases or visceral metastases other than in the liver. When the latter, more extensive disease is found, the surgeon is faced with determining whether surgery is indicated. Organs other than the liver that are most commonly involved are kidney, duodenum, pancreas, and pelvic organs such as the bladder.

As a rule, patients with synchronous metastases should be managed aggressively. Surgical resection of the primary tumor and of those



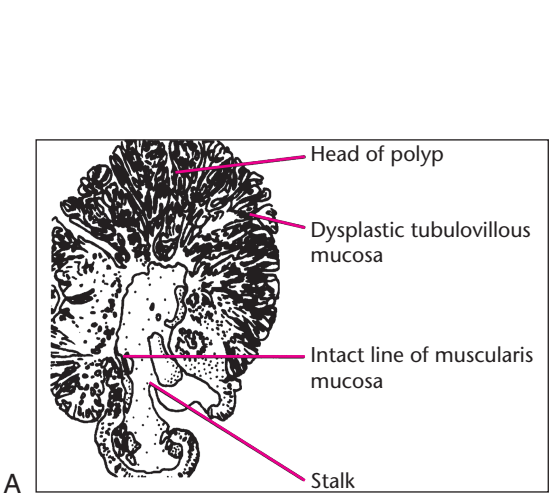


Figure 81-27 • **A,** Pedunculated polyp showing the layers through which the invasion in a pedunculated polyp would need to travel in the stalk before reaching the submucosa of the bowel wall. **B,** Sessile polyp; contrasted with pedunculated polyp. (From Haggitt RC, Glotzbach RE, Soffer EE, Wruble LD: Prognostic factors in colorectal carcinomas arising in adenomas: implications for lesions removed by endoscopic polypectomy. Gastroenterology 1985;82:328–336.)

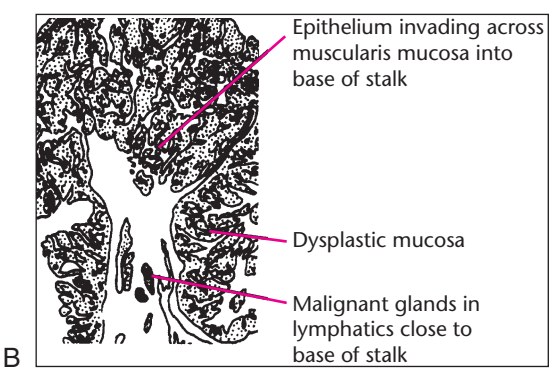

Figure 81-28 • Adenomatous lesions of colon. **A,** In the premalignant neoplastic lesion, the muscularis mucosa is intact. **B,** In the malignant lesion, the muscularis is obviously invaded by malignant epithelium. Malignant glands in the lymphatics are seen close to the base of the stalk. (From Skarin AT, Shaffer K, Wieczorek T [eds]: Atlas of Diagnostic Oncology, 3rd ed. St. Louis, Mosby, 2003, p 149.)

metastases that are appropriately resectable is the accepted approach for surgical management. As was stated previously, the synchronous disease usually involves the liver. Surgical resection combined with either cryogenic or radiofrequency ablation of liver metastases has greatly extended the operative management of such patients.

Patients who present with a metastatic burden that is clearly unresectable could require a palliative operation. For example, a patient with extensive peritoneal involvement could require palliative resection of the primary colon cancer to control bleeding (chronic anemia), obstructive symptoms, or perforation. Quality of life could be improved in an obstructed patient by ileostomy, colostomy, or intestinal bypass procedures. When patients are deemed to be truly advanced and asymptomatic with regard to their primary tumors, they can be safely treated nonoperatively. In one study, only 8.7% required subsequent surgery, and none of these was for perforation or bleeding.[297] Endoscopic fulguration using electrocautery or laser is occasionally used for rectal lesions but is generally too risky for colonic tumors because of the danger of perforation.

Patients who have resectable, synchronous liver metastases generally received adjuvant therapy. Therapy with five-times-daily 5-fluorouracil (5-FU) and LV after liver resection had improved 5-year disease-free survival (DFS) rates (33.5% versus 26.7%, $P = 0.028$), with a trend toward improved overall survival (OS) (51.1% versus 41.1%, $P = 0.13$).[298] The European Organisation for Research and Treatment of Cancer has completed accrual (364 patients) of a trial comparing 12 weeks of preoperative and 12 weeks of postoperative FOLFOX 4 and surgery only for patients with up to four potentially resectable liver metastases; 3-year progression-free survival (PFS) results were presented at the meeting of the American Society of Clinical Oncology (ASCO) in 2007.[299] Only 303 patients, evenly balanced between the two arms, actually underwent resection, and 115 of 151 in the chemotherapy arm received postoperative chemotherapy. The 3-year PFS rate was 28.1% in the surgery-only arm versus 35.4% for the patients who were randomized to combined therapy ($P = 0.058$ for ITT analysis). Excluding the 6% ineligible patients, the PFS rate was 28.1% versus 36.2%, and for those who actually underwent resection, the 3-year PFS rate was 33.2% versus 42.4%. Although the usual adverse events related to FOLFOX chemotherapy occurred, there was also an increased rate of postoperative complications (25.3% versus 15.9%), including biliary fistula, liver failure, intra-abdominal infection, and repeat surgery.

Patients who present with synchronous, unresectable metastatic disease should be evaluated by a multidisciplinary team to establish the need for surgery, radiation, and/or chemotherapy; to ensure that a curative approach is not feasible; and to select appropriate palliative therapy. Patients who present with metastatic disease and who do not require resection of the primary colon cancer to address acute or subacute problems such as significant bleeding, impending obstruction, or perforation and abscess may receive chemotherapy as their initial treatment. A review of 82 patients who were treated without prior resection compared with 280 concurrent patients who did undergo resection showed no increased incidence of peritonitis, fistula formation, or intestinal hemorrhage, occurring in 2.4%, 3.7%, and 3.7% of unresected patients, respectively. Nor was there an increased incidence of obstruction, which occurred in 13.4% of the unresected patients and 13.2% of the resected patients.[300]

Endoscopically placed self-expanding stents have been shown to have a palliative role for the obstructed patient who is not a candidate for surgery, as well as a role in acting as a bridge to surgery. In a systematic review of 598 patients,[301] the stents were successfully placed and deployed in 92% of cases. In the 336 patients for whom the stents were palliative, 90% achieved colonic decompression within 96 hours without reintervention, complications, or reobstruction. In the 262 patients for whom the stents were a bridge to surgery, 80% were associated with a one-stage colonic resection.

Surgical Management of the Ovaries

The ovaries have been known as a site of both synchronous metastases and metachronous involvement. As a result, prophylactic oophorectomy at the time of initial colon resection has been advocated in the past to improve survival. The synchronous involvement of the ovaries as the sole site of disease, however, occurs in fewer than 5% of newly diagnosed colon cancer patients, and about the same percentage of patients will develop isolated ovarian metastases at a later time.

Sielezneff and colleagues[302] studied prophylactic oophorectomy in postmenopausal women and found an incidence of only 2.4% having ovarian metastases, with no difference in 5-year survival.

The Mayo Clinic found no gross or microscopic ovarian involvement in 77 women who were randomized to prophylactic oophorectomy. There was no evidence of a survival benefit in the oophorectomy arm.[303] As a result, there is no evidence to support prophylactic oophorectomy, even in the postmenopausal patient.

Occasionally, the surgeon and pathologist will be confronted with a Krukenberg's tumor of the ovary that presents the dilemma of whether the cancer is primary ovarian with direct extension or metastasis to the colon or a colonic cancer extending to the ovary. Because very different chemotherapy regimens are used to treat these two primary cancers, it is important to diagnose them accurately. Serum markers CEA and CA125 are not very helpful in this situation, and careful histologic examination, including immunohistochemistry by an experienced pathologist, is essential.

Minimally Invasive Laparoscopic Colon Cancer Resection

Laparoscopically assisted colon resection was first described in 1991. Its advantages, as with any minimally invasive procedure, are reduced pain, reduced impact on pulmonary function, more rapid return of bowel function, and less fatigue.[304]

The surgical approach is either completely laparoscopic or laparoscopically assisted colon resection with intraperitoneal gas insufflation or mechanical abdominal wall lift. The anastomosis can be performed intraperitoneally by using a double-staple technique or extraperitoneally through a small (7- to 8-cm) incision to permit stapling or hand sewing the anastomosis.

The learning curve for laparoscopic colorectal surgery has been estimated to range from 20 to 70 cases. This presents a significant hurdle for the average general surgeon in this country, who performs only six to seven open colorectal resections annually.[305,306]

One of the concerns that hampered widespread acceptance of laparoscopic surgery for cancer was the reported incidence of port site recurrences. However, a meta-analysis[307] of four randomized control trials with follow-up to 4.4 years showed an incidence of only 0.5% port site recurrence in laparoscopic surgery as compared with 0.2% wound recurrence in open procedures. The incidence of port site recurrence appears to be related to operator experience. Schneider and associates[308] reported a study of port site recurrences using a porcine model. The authors created a pneumoperitoneum and injected 107 human HeLa cells, creating a xenogeneic tumor. The pigs were subjected to a laparoscopic sigmoid colon resection in which four trocars were used. Schneider and associates tested preventive measures in nine animals, including trocar fixation, prevention of gas leaks, rinsing of instruments with povidone-iodine, rinsing of trocars before removal, peritoneal closure, and irrigation of port wounds with povidone-iodine. Tumor was found in 23 of 36 port sites in control animals and in only 5 of 36 port sites of animals in the prevention group. These results strongly supported the importance of high-quality technique in minimizing the risk of port site recurrence.

Advantages of Laparoscopically Assisted Colon Resection

Short Term

- Earlier return of bowel function (2 days versus 4.5 to 5.0 days)
- Shorter hospital stay (an estimated 40% reduction in length of stay)
- Fewer days of parenteral and oral analgesics
- Earlier recovery
- Fewer infections and wound complications

Long Term

- None yet apparent

Several prospective randomized trials have been designed and implemented to test the hypothesis that DFS and OS are equivalent for laparoscopic-assisted colectomy and standard open colectomy. A meta-analysis of 1536 patients[309] (796 patients in the laparoscopic arm and 740 patients in the open surgery arm) enrolled in four of these trials: Barcelona, Clinical Outcomes of Surgical Therapy (COST), Colon Cancer Laparoscopic or Open Resection (COLOR), and Conventional versus Laparoscopic-Assisted Surgery in Patients with Colorectal Cancer (CLASSIC) with endpoints measuring 3-year DFS and OS has shown no difference in the two approaches. While laparoscopic surgery in colon cancer is concluded to be oncologically safe, it appears that the principal advantage of the minimally invasive procedure is in the short term. Further enhancement of laparoscopic surgery through the use of surgical robots has been attempted in one study[310]; however, only short-term outcomes (estimated blood loss, length of operation, length of hospital stay, and complications) and cost variables were evaluated. There are no current data that clinical outcome, measured by survival, mortality, and recurrence, favors robotic colectomy over traditional laparoscopic surgery much less open colectomy in colon cancer. The cost-benefit analysis of laparoscopic versus open surgery favors the latter.[311] Though the greater expense of laparoscopic surgery can be nearly offset by shorter hospital stays, it has been suggested that the use of enhanced protocols during postoperative recovery would eliminate differences in recovery time between the two types of surgery.[307]

Age as a Factor in Surgery of Colon Cancer

Although colon cancer is a major cause of morbidity and mortality in elderly people, it does occur in patients younger than 40 years of age. Although younger patients present with the same symptoms (abdominal pain, rectal bleeding, weight loss, changes in bowel habits), they are more likely to experience a delay in diagnosis and to present with stage III or IV disease. Survival by stage is comparable for the younger patients and those older than 40 years.[312] Some reports suggest that the younger population is less responsive to chemotherapy.[313]

Older patients are more likely to present with right-sided cancers and to have disease detected when it is less invasive than the younger than 40 years age group.[314] Elderly patients, as expected, are more likely to have comorbid conditions that increase their risk for surgery. Simmonds and coworkers[315] reported the results of a systematic review of published and aggregated data examining the outcomes of colorectal surgery in elderly patients. They grouped patients aged 65 to 74 years, 75 to 84 years, and older than 85 years and compared these groups to those younger than 65 years. They analyzed 28 studies that included 34,194 patients. Their review found that elderly patients had an increased risk of comorbid diseases, presented with later-stage disease, had a higher incidence of emergent surgery, and were at greater risk for having noncurative surgery when compared with the age group younger than 65 years.

As expected, postoperative morbidity and mortality increase with advancing age. Differences in cancer-specific survival, however, are much less dependent on increasing age. Thus, careful preoperative evaluation to diagnose comorbid conditions, so that these can be appropriately managed during surgery and the period of postoperative recovery, is important to providing a successful outcome. Elderly patients (older than 85 years of age) can anticipate a good survival and should be managed similarly to younger people when at all possible.

Managing Complications of Colon Cancer Surgery

The most common postoperative morbidity associated with colon cancer surgery is prolonged ileus. With open resection of the colon, the majority of patients have return of bowel function as manifested by the presence of bowel sounds on abdominal auscultation and the passage of flatus by $4^1/_2$ to 5 days following surgery. For the majority of patients, postresection nasogastric decompression is not required. An exception is the patient who presents with significant obstruction or perforation. If the delay in return of function exceeds 7 to 10 days, there must be concern for an underlying cause. The surgeon must look for electrolyte imbalance, evaluate the level of narcotic use (ruling out excessive use), and search for evidence of intra-abdominal abscess or mechanical obstruction. Instituting nasogastric decompression is often generally indicated.

Anastomotic leaks are reported to be between 4% and 18%, but subclinical leaks could occur much more frequently.[316] More severe leaks with abscess can be managed by percutaneous drainage using CT or ultrasound guidance to place the drain tube. Larger leaks with anastomotic dehiscence and peritonitis require operative intervention, with closure of the anastomosis or resection of the anastomosis and proximal diverting colostomy or ileostomy. A long-term complication of anastomotic leaks that do not require emergency surgery may be stricture formation.

Wound infections are dependent on preoperative preparation of the bowel for surgery, decreasing skin bacteria, and operative technique, all of which measures are designed to minimize bacterial contamination of the wound. The risk of wound infection after colon surgery is 3% to 16% for all presentations. For elective colon cancer resection performed under ideal circumstances and optimal bowel preparation (which accounts for the majority of cases), the risk of wound infection is less than 5%. When an infection occurs, the portion of the wound involved is opened to allow irrigation and twice-daily packing. Wound dehiscence is uncommon and should raise suspicion of anastomotic leak and peritonitis. As might be expected, such dehiscence is significantly increased for patients who are undergoing emergency surgery for colon cancer.[317]

As with other major cancer operations, there has been interest in whether a surgeon's training, experience, and operative volume are important to patient outcome in patients undergoing colon resection for cancer. One such report involved a retrospective analysis of 15,427 admissions in northern Illinois undergoing segmental colon resection between 1994 and 1997. These surgeries were performed at 76 nonfederal hospitals and involved 514 surgeons. The authors determined inpatient mortality, complications of surgery, and hospital length of stay. They found that American Board of Surgery certification and increasing years of experience were associated with reduced mortality. Added colorectal certification and site of training did not factor significantly into the outcomes.[318] Other studies suggest that high-volume colonic surgery performance by the surgeon and having the procedure at a high-volume hospital are important predictors of in-hospital outcome.[319]

Managing Uncommon Tumors of the Colon

More than 98% of the tumors of the large intestine are adenocarcinomas. The remaining 2% of colon tumors are lymphomas, leiomyosarcomas (including gastrointestinal stromal tumors), carcinoids, and (rarely) nonpulmonary small cell cancer. Gastrointestinal stromal

tumors are tumors that arise from the "pacemaker" cells located in the muscularis propria. These tumors tend to present as large masses within the colon but can extend to other organs.[320,321]

The peak incidence of stromal tumors of colon is in the fifth decade, slightly more males than females being diagnosed. Pain is the most frequent presenting symptom.[322]

Gastrointestinal stromal tumors are managed by resection, and recurrences may be found in the peritoneal cavity and liver. The introduction of imatinib mesylate (STI-571, Gleevec), an inhibitor of tyrosine kinase activity of the c-kit proto-oncogene, has provided the first significant opportunity to treat this malignancy by means other than surgery.

Carcinoid tumors (well-differentiated endocrine neoplasms) of the colon account for an estimated 6% of all gastrointestinal carcinoids, more than half originating in the cecum. They almost never present as classic carcinoid syndrome but tend to be advanced, with abdominal pain and weight loss in most patients, nodal involvement in 60%, and liver metastases in 40% of patients. Carcinoid tumors tend to be indolent in their course, and although patients generally live more than 5 years (often with known disease), the OS rate is probably only 25% to 35% with standard treatment.[323]

Lymphomas are known to arise in the gastrointestinal tract, and the colon is the site of origin for approximately 15% of gastrointestinal lymphoma cases. They are extremely rare, accounting for fewer than 1% of colon malignancies. For the colon to be accepted as the primary site, there must be no clinically detected peripheral adenopathy and no imaging evidence of disease in the chest, the peripheral blood smear and bone marrow analysis must be negative, and there must be no evidence of liver or spleen involvement. Malignant lymphoma of the colon has been found as a complication of ulcerative colitis. Both Hodgkin's and non-Hodgkin's lymphoma have been diagnosed.[324] The majority of colon lymphomas are B-cell type and of intermediate- to high-grade histology. Treatment is often surgical resection, but systemic chemotherapy is the mainstay of long-term survival, and surgery might be better used for chemotherapy failures. The overall 5-year survival rate is usually cited to be approximately 50%. There have been a few case reports of multiple mucosal lymphomatous polyps affecting various lengths of colon that appear to be similar to the mucosa-associated lymphoid tissue lymphoma that is seen in the stomach; treatment is 3 months of combination chemotherapy.[325] There are rare reports of mast cell sarcoma and clear cell sarcoma arising in the colon.[326,327]

Surgical Management of Tumors of the Appendix

An estimated 1% (0.9% to 1.4%) of all appendectomy specimens contain a neoplasm. The majority of appendiceal tumors are carcinoids, while the remaining 10% to 20% are mucinous cyst adenocarcinoma, adenocarcinoma, lymphosarcoma, paraganglioma, and granular cell tumors.[328] As expected, most present as acute appendicitis, and in some 40% of cases, the diagnosis is made after appendectomy.

If a mass in the appendix is encountered incidentally during the course of abdominal surgery, an appendectomy is performed with frozen-section analysis of the mass. Most masses prove to be benign mucoceles or very small carcinoids. When carcinoid tumors of the appendix are small (<1 cm in diameter), they may be treated adequately by standard appendectomy. If they are greater than 2 cm in diameter, the patient should have a right hemicolectomy.

Treatment of appendiceal adenocarcinoma is a right hemicolectomy. Mucinous cystadenocarcinoma can be very difficult to manage. Treatment should be a right hemicolectomy and debulking of peritoneal implants.

Currently, the best results in treating mucinous cystadenocarcinoma appear to be obtained with an aggressive combination of cytoreductive surgery, perioperative intraperitoneal chemohyperthermia, and early postoperative intraperitoneal chemotherapy.[329] These measures could provide 5-year and 10-year survival rates as high as 80% and 60%, respectively. If debulking is incomplete, the survival rates are markedly reduced to only 20% and 0%, respectively, and long-term survival cannot be achieved. This tumor can be indolent in its course, and patients commonly have multiple debulking surgeries before ultimately succumbing to their disease.

Managing Colon Cancer in the Pregnant Patient

The incidence of diagnosing a cancer of the colon during pregnancy is estimated to be less than 0.1%. It is interesting that pregnant women have a much higher incidence of rectal cancer (83%), compared with colon sites (17%). This is in contrast to nonpregnant women younger than 40 years of age, among whom the site distribution is 68% colon and 32% rectum.[330]

Certainly, any pregnant patient who reports rectal bleeding or has hemoccult positive stool on examination deserves careful evaluation to rule out cancer.

OUTCOMES OF SURGICAL TREATMENT AND ROLE OF ADJUVANT THERAPY

Optimal Surveillance after Curative Resection

The natural history of colon cancer has several aspects that influence the approach to follow-up. For example, it is well recognized that 80% to 90% of recurrences after curative resection are discovered within the first 2 to 3 years.[331] Fewer than 5% of all recurrences occur after 5 years. Furthermore, these recurrences are often isolated, and when resected completely, they provide about 35% of patients with a cure of their disease.[332,333] This is somewhat distinctive to colon cancer and clearly influences the frequency and method of postsurgical evaluation. It is also recognized that a high percentage of first failures occur in the liver and lung, which could therefore be asymptomatic at the time when they are detected by imaging.

In theory, early detection of recurrent disease can alter the long-term prognosis for an individual patient if the disease that is found is resectable (e.g., isolated liver or lung metastases) or if prompt treatment can alter the long-term prognosis. Patients who can undergo salvage surgery—approximately 20% of patients who are followed closely for recurrence—have an 18.6% 5-year DFS compared with only 5.6% of patients whose recurrences are identified by new symptoms.[334]

Surveillance strategies and inadequately powered trials of surveillance have been reviewed recently.[335] NCCN practice guidelines recommendations for follow-up, using evidence-based medicine approaches, suggest the following measures:

- Physician visits every 3 to 6 months for the first 2 years, then at 6-month intervals until 5 years
- CEA testing at 3- to 6-month intervals for 2 years, then every 6 months until 5 years for T2 or greater lesions
- Consider chest/abdominal/pelvic CT for 3 years in high-risk nonmetastatic disease, that is, with lymphatic or venous invasion or poorly differentiated tumors
- CT scan every 3 to 6 months for 2 years, then every 6 to 12 months in years three to five in patients with metastatic disease
- Colonoscopy 1 year postoperatively, another 3 years later and then every 5 years[336]

Current recommendations are available at www.nccn.org.

For these reasons, patients are initially seen every 3 to 4 months for examination and review of symptoms. In addition, liver injury tests and serum CEA are obtained. Patients with suspicious symptoms, whether focal or constitutional, should undergo evaluation at the time they present. Constitutional symptoms include fatigue, decreased appetite, night sweats, and fever. Suspicious focal

symptoms include early satiety, right-upper-quadrant or right shoulder pain, and crampy abdominal pain.

If complete colonoscopy was not achieved at the time of diagnosis, the first postoperative colonoscopy for the detection of synchronous disease and elimination of any additional polyps should be performed 6 months after surgery to permit complete healing of the anastomosis. Otherwise, colonoscopy is usually performed at yearly intervals for the first 2 years, then every third year, unless additional adenomatous polyps are identified or the patient is in a group that is genetically at high risk for rapid development of invasive malignancy (as discussed previously).

There is a school of thought that the expense of CT imaging as well as the low prevalence of colon cancer recurrences amenable to surgical intervention argues against its routine use as a postoperative surveillance tool.[337–340] However, a number of analyses of prospective randomized trials have offered different conclusions.[334] A review of 1247 patients with resected stage II or III colon carcinoma who were followed in cooperative group trials identified recurrences in 548 patients,[334] of whom 109 underwent a second surgical procedure with curative intent. Of the patients who went to surgery, 77 recurrences were identified by CEA or CT scan. The 5-year DFS rate for all patients undergoing surgery with curative intent was 23%. A second review from the University of Barcelona looked at the outcomes for 199 patients who were followed at 3-month intervals.[338] Of the 140 patients who underwent regular surveillance, 18 of the 56 patients with recurrence were operable, compared with only 3 of 28 patients with symptomatic recurrence. This difference also resulted in differences in long-term cancer-related deaths, 51% of the nonscreened patients dying of cancer within 5 years of their original surgery, compared with 31% of the patients who underwent close follow-up. Obrand and Gordon[339] reported that 24% of their 146 patients with recurrence underwent attempts at reresection, with a 47% 80-month survival rate (i.e., 17 of 146 patients with recurrence were reresectable with long-term survival).

Finally, the evaluation of a multicenter prospective randomized study comparing efficacy of two adjuvant therapy regimens in 530 patients with colorectal cancer that included follow-up surveillance by clinic visit, CEA measurement and thoracic, abdominal, and pelvic CT has shown value in the use of CT scans.[340] The median time to recurrence was 20.6 months in patients whose symptoms led to discovery of new lesion, 14.5 months for CEA, and 13.2 months for CT. Eligible patients underwent reresection. Although there was no significant difference in overall survival from time of randomization among the groups, 5-year survival rates from time of relapse were 0%, 18.6%, and 25.9%, respectively, for symptomatic, CEA, and CT groups. Lead time (7.4 months) bias alone could not explain the difference, as there was a 13.8-month median survival advantage between the symptomatic and CT groups.

For patients with hereditary colon cancer syndromes who develop cancer, postoperative recommendations do not differ from those already described for screening these patients. For all other patients, recommendations for follow-up are described in the NCCN practice guidelines and in the 2000 update of guidelines agreed to by the ASCO.[336,341]

Carcinoembryonic Antigen in the Management of Patients with Colorectal Cancer

CEA is an oncofetal antigen that was first described by Gold and Freedman[342] in 1965. Although CEA is the most commonly used serum marker for malignancies of the gastrointestinal tract, it has never proved useful as a screening test for early cancers. Primary colorectal cancers are commonly CEA negative, even though 90% of tumors can be shown to produce CEA.[343] An explanation for this can be found in the fact that CEA that is produced by colorectal cancer (except for the very low rectal cancers) enters the portal venous circulation and is extracted on the first pass through the liver. As a result, CEA is hypothetically a useful marker of systemic recurrence, even for patients who initially at time of diagnosis presented with normal levels (<5 μg/mL for normal individuals), because the venous drainage from the recurrence is into the systemic circulation. CEA can be modestly elevated in about 19% of smokers who do not have cancer and in 3% of the normal population.[344] These false elevations, however, are almost always less than 10 ng/mL and remain stable during serial testing, in contrast to CEA that is produced by recurrent tumor, for which increasing values are evident over a period of months.[344,345]

When CEA levels are elevated preoperatively for the primary colorectal cancer, they predict a worse prognosis. The sensitivity of CEA as a monitoring test varies from 43% to 89%, with a specificity of 70% to 90%. Elevation of CEA in primary tumors correlates with stage (45% of stage III and 25% of stage II). Even though CEA predicts a worse prognosis, studies have not proved it to be useful in determining the need for adjuvant therapy.[346]

Persistent elevation of CEA 1 month postoperatively suggests the presence of occult metastatic disease and predicts for early development of measurable recurrence. For patients with a normal preoperative CEA and patients whose CEA returns to normal within 4 to 6 weeks of the resection of their primary tumor, a CEA increase is often the first warning of metastatic disease. A significant and progressively increasing CEA is associated with 75% of patients with metastatic colorectal cancer.[347] Monitoring of CEA at intervals of 3 to 6 months is the single most effective method of detecting early failures. The benefit of monitoring, however, decreases after 2 years. Opponents of regular CEA monitoring argue that the gain in lives saved or significantly prolonged is quite small, perhaps only in the 1% to 3% range.[334,339] Patients whose disease is detected by CEA and who have proved to have isolated recurrence (e.g., solitary hepatic metastasis) do achieve significant benefit, however (having an approximately 50% 2-year survival rate).[339,340]

CEA measurements during therapy of metastatic disease are quite helpful. A decrease to normal levels after metastasectomy is a positive finding that predicts a more favorable course. Similarly, during chemotherapy, a substantial fall in CEA occurs in patients who have image-based responses. It is not, however, a substitute for appropriate tumor imaging. The ASCO Tumor Marker Panel recommends monitoring CEA every 2 to 3 months during chemotherapy treatment of metastatic disease if CEA is elevated initially.[341] If CEA increases in two consecutive occasions above baseline or lowest level during therapy, this usually indicates progression of disease; however, patients can develop modest elevations of CEA during adjuvant therapy in association with fatty infiltration of the liver. Intercurrent acute events such as pneumonia, hepatitis, and severe gastroenteritis can also produce modest, reversible elevations of CEA as high as 20 ng/mL.

Metastatic disease patterns for colon cancer include a 15% incidence of local recurrence as the first site of recurrence. Patients have a 36% chance of having liver metastasis as their first site of failure. Reviews of patients in large randomized trials (randomized to the surgery-only arm) confirm these patterns of recurrence.[347] The majority of patients who do recur develop recurrence within the first 3 years, providing a logical basis for less frequent screening visits after that period. Patients with nodal involvement have earlier recurrence than those without nodal involvement.

Evaluation of a Patient with Symptoms

Patients with recurrent cancer can present with very nonspecific symptoms, such as weight loss, malaise, fatigue, or night sweats. They can have focal pain complaints, right upper quadrant or right shoulder pain from liver metastases, or diffuse crampy abdominal pain and abdominal distension from peritoneal carcinomatosis, or pelvic or low back pain from pelvic recurrence. They can develop unilateral pedal edema or pleuritic chest pain from Trousseau's syndrome, with

Box 81-2. SURVEILLANCE GUIDELINES

- Serum CEA performed every 3 months (64% of recurrences are detected first by CEA*)
- Liver injury tests
- Colonoscopy following resection of primary 6 to 12 months after surgery and repeated every 3 years if no polyps are found.
- CT every 3 to 4 months for 2 years, then every 6 months through 5 years. This is controversial absent elevation in CEA (CT scan is first positive test in 11% of patients)

*Castells A, Bessa X, Daniels M, et al: Value of postoperative surveillance after radical surgery for colorectal cancer. Dis Colon Rectum 1998;41:714–724.

deep venous thrombosis or pulmonary emboli. Cough or dyspnea on exertion could indicate pulmonary metastases. Morning headache or focal neurologic complaints (from central nervous system metastases) or focal musculoskeletal pain (from bony metastases), although they are rarely the first signs of metastatic disease in patients with colorectal cancer, could suggest recurrence. New subcutaneous nodules, particularly at pre-existing scar sites, can also be the first presentation of metastatic disease and are a more common physical finding than is new lymphadenopathy in otherwise asymptomatic patients.

Patients with symptoms that are suggestive of recurrent disease should be assessed both with focal radiologic techniques (e.g., CT of the chest, abdomen, and pelvis), clinical chemistries, and serum CEA. The peritoneal surface is notoriously difficult to evaluate, however, and some patients with extensive, symptomatic peritoneal carcinomatosis can have false-negative CT scans because of the difficulty in evaluating this area. For patients with abdominal symptoms, CT scanning, newer MRI techniques, or FDG-PET scanning as discussed earlier for primary staging can suggest the diagnosis and direct further treatment. See Box 81-2 for a summary of surveillance guidelines.

Evaluation of a Patient with Findings on Screening Evaluations

In patients with CEA elevations at the time of initial resection, many clinicians obtain serial CEA measurements to aid in the early detection of potentially resectable recurrence. To trigger further evaluation, CEA not only should be above the normal limit but also should have doubled in value twice. For the majority of patients, history, physical examination, and CT will identify the source of CEA elevation. Up to 10% of patients may have lesions identified that appear to be amenable to curative reresection. When conventional evaluations do not reveal the source of CEA elevation, patients become, understandably, even more distressed than they were when informed that they could have recurrent disease.

Single photon emission computed tomography (SPECT) with radiotagged antibodies has been evaluated for its utility in identifying potentially resectable sites of recurrence. To date, immunoscintigraphy has not been shown to alter clinical outcomes, and its cost effectiveness is unproven.[348] Murine and humanized antibodies directed against tumor-associated antigens have been evaluated for their utility in identifying the site of disease recurrence in these patients.[349] 111In-CYT-103, a murine monoclonal antibody targeting TAG-72, has been shown to be comparable to CT in sensitivity, although it did identify lesions in six patients with negative CT scans.[350] Immunoscintigraphy with ^{99m}Tc anti-CEA showed 20% greater sensitivity for pelvic and retroperitoneal disease.[351] In 173 patients with at least one tumor site that had been identified by CT scan, a totally monoclonal antibody, 88BV59, technetium scan was able to identify only 87% of the lesions (sensitivity 87%) but had a better specificity, with 57% of the lesions identified by SPECT actually representing malignancy at exploration.[352] In 29 patients with rising CEA and no apparent disease, 15 patients (68%) had true positive SPECT findings. Of all 43 lesions that were identified, only 10 were in the liver (where resection of limited disease may be curative), and the number of patients who had disease that was actually resectable for possible cure was not stated. The authors point out, however, that use of CT alone results in an underestimate of disease extent in 41% of patients, compared with 27% underestimation for patients who undergo both procedures.[352] Given the limitations of SPECT scanning, despite the approval of two different preparations for this purpose, its utility at present is limited to identifying disease that is unlikely to be resectable (e.g., inapparent retroperitoneal adenopathy) to avoid futile attempts at surgical ablation of apparently limited metastatic disease.

In patients who have a rising CEA and no apparent disease shown via CT, FDG-PET, or enhanced MRI, surgical exploration failed to find the source of the CEA elevation in 7 of 29 patients (25%) who proceeded to laparotomy.[353] In a series of patients undergoing resection for recurrent disease, however, more than half will actually have resectable disease at exploration.[338]

Patients with Potentially Resectable Recurrent Disease

When a suspicious lesion is identified by CT scan of an asymptomatic patient, further evaluation is directed at ascertaining the feasibility of curative resection. Thus, a solitary lesion in the liver or lung will precipitate spiral CT scan of the remainder of the thorax, abdomen, and pelvis and FDG-PET scan to identify any additional lesions that might preclude resection. In the absence of symptoms or signs of metastatic disease to the bone or brain, these sites are so rarely involved that radiologic evaluation is not undertaken. However, in patients in whom the suspicion of additional metastatic sites is high (i.e., liver metastasis within 1 year of the primary surgery in patient with multiple positive nodes), scanning with radioimmunoglobulin or PET scanning may suggest sites of additional disease that would mandate against an attempt at surgical resection.

In patients who have potentially resectable abnormalities identified by CT and PET scans, 5% to 6% will have benign findings at laparoscopy.[353] PET scanning with FDG could identify the site(s) of disease for 80% to 90% of these patients. Before PET scanning became available, surgical exploration for potentially resectable disease was undertaken in selected patients. At present, if no disease sites are identifiable in an asymptomatic patient, regular reevaluation at 3- to 6-month intervals is appropriate.

Additional imaging could be valuable for patients who appear to have potentially resectable liver metastases to identify the 5% to 10% of patients who have extrahepatic disease and spare them the morbidity and expense of surgery (see Chapter 59). A second group that might benefit from more accurate assessment of the extent of disease consists of patients who will undergo reresection of recurrent rectal carcinoma, identifying those who might have a chance of benefiting from radical surgical resection.

Experienced cancer surgeons regularly evaluate patients with recurrence for their potential resectability. Patients with isolated, solitary metastasis in the liver or lung, in the absence of other life-limiting illnesses, are widely considered to be candidates for resection.

INDICATIONS FOR ADJUVANT THERAPY

Surgical stage remains the most accurate predictor of survival, including the depth of invasion (T1/2 versus T3 versus T4), nodal status, and grade. Table 81-3 shows the 5-year survival rates associated with stage after surgical resection for cure. Patients with five or more positive nodes continue to have a poor prognosis, although they receive comparable benefits from adjuvant therapy. Greene and colleagues reviewed the course of 50,000 patients in the early

1990s, documenting a 5-year survival rate of 22% for surgery alone compared to 33% for adjuvant therapy.[354] Similarly, in a review of 3300 patients in National Surgical Adjuvant Breast and Bowel Project (NSABP) trials, patients with more than five nodes and low grade had 5-year survival rate of 11% to 39% (T4 to T1/2) after surgery, increasing to 27% to 57% with 5-FU-based adjuvant therapy.[355] Another recent study of adjuvant therapy estimated 5-year survival at 82% for N0, 74% for N1, and 54% for N2–3 patients.[356]

Molecular Risk Factors

At present, all molecular risk factors remain in the IIB category, according to the CAP.[241] Unfortunately, despite some studies analyzing data from larger patient populations, markers or combinations of markers that might identify patients who are more (or less) likely to benefit with current adjuvant therapy have not been identified. Many small series have explored additional prognostic factors for patients with colorectal carcinoma, including angiogenic factors such as vascular endothelial grown factor (VEGF) and nitric oxide,[357,358] tumor aggression factors such as microsatel-lite instability or loss of heterozygosity of chromosome 18, proliferation measures such as Ki-67, survival measures such as p53, and factors related to chemotherapy effects such as thymidylate synthase (TS).[359–365]

Mutations in p53, frequently leading to overexpression of nonfunctional protein, have been associated in the laboratory with decreased sensitivity to several classes of chemotherapy, including DNA-damaging agents such as irinotecan and oxaliplatin.[363,364,366] There have been serious limitations in the assessment of p53 status from clinical samples, so direct sequencing is rarely used, and immunohistochemistry results correlate with sequencing results only in the 60% to 80% range.[362] The association of p53 overexpression with poor outcome has not been demonstrated consistently in clinical trials.[359,361]

Several studies have reported that patients with cancer who overexpress TS have a lower response rate to treatment with 5-FU.[360,361,364,365,367,368] Ichikawa and colleagues[369] evaluated both dihydropyrimidine dehydrogenase expression (lower activity would result in decreased catabolism of 5-FU and greater exposure to active drug) and TS, finding that patients with low dihydropyrimidine dehydrogenase and low TS had a median survival time of 16.3 months, compared with 8.4 months for patients with high dihydropyrimidine dehydrogenase and high TS. Johnston and colleagues[370] found that the expression of TS as measured in primary tumors using TS106 antibody did not correlate with 5-FU activity in metastatic sites. Overexpression of TS, however, predicts a poorer survival, regardless of whether patients received adjuvant therapy, and formal tests for interaction with chemotherapy suggest that patients with differing levels of TS expression maintained benefit from adjuvant chemotherapy.[361]

Kidd and coworkers[371] obtained samples for pharmacogenomic analysis from 524 of 795 patients treated for metastatic colorectal carcinoma with IFL, FOLFOX, or IROX (see chemotherapy regimens discussed later in this chapter). They looked at panels relevant to 5-FU metabolism and variations in its targets of thymidylate synthase and methylenetetrahydrofolate reductase, panels relevant to oxaliplatin metabolism, excision repair (ERCC2 and XRCC1), and irinotecan metabolism (14 potential variants in all). Only ERCC2 K751Q (14% frequency) was correlated with response to treatment ($P = 0.0052$), and UGT1A1 7/7 was associated with neutropenia from irinotecan (7% frequency, $P = 0.007$). The only other statistically relevant association with response and time to progression was the thymidylate synthase variant 1494del, with a 47% frequency ($P = 0.02$). The TRAIL receptor, DR5, has been shown to be important for response to 5-FU in xenograft models.[372] High expression of the DR4 receptor for TRAIL has also been identified as a negative prognostic factor for patients receiving adjuvant therapy, with a relative risk of recurrence of 2.19 for the 82% of patients who were high expressors.[373]

Other proposed prognostic markers include the CpG island methylator phenotype (CIMP), a phenotype that has been observed in 20% to 40% of patients with colon cancers, which presumably is associated with transcriptional silencing of tumor suppressor genes.[374] Although CIMP-positive patients have poorer survival if treated with surgery alone, there was a trend for improved survival of CIMP-positive patients who received adjuvant chemotherapy. Van Rijnsoever and colleagues hypothesize that the hypermethylated DNA status in CIMP-positive tumors could be a marker for aberrations in cellular folate and methyl group metabolism, rendering CIMP-positive cancers more sensitive to 5-FU. This proposal needs to be evaluated prospectively in a larger patient population.

History of Development of Adjuvant Treatment and Established Adjuvant Regimens

As many as 50% to 60% of patients who undergo "successful" surgery for colon carcinoma have residual micrometastatic disease, and clinically evident cancer will develop, either locally or at distant sites, within 5 years of surgery. Systemic treatment, known as adjuvant therapy and intended to reduce the risk of recurrence, is now widely recommended for patients with lymph node involvement (stage III), as well as higher-risk patients with T3N0, although the absolute percentage benefit for stage II is quite small. There has been considerable variability regionally in both the United States and elsewhere in the use of adjuvant therapy after curative surgery. In Japan, adjuvant chemotherapy has been used for all patients except those in stage A; in the United States, on the other hand, adjuvant therapy is used for patients with stage B2 rectal carcinoma (see Chapter 82), and is used selectively for patients with higher-risk B2 colon cancer. Adjuvant therapy is generally recommended for patients with lymph node involvement without other significant comorbidities. In Europe, in contrast, even patients with stage C (nodal involvement) did not receive routine adjuvant therapy until 1995.

The original trials of systemic chemotherapy after surgery for colorectal cancer were undertaken more than 40 years ago. Although some clinicians favored adjuvant therapy on the basis of these early experiences, the studies were underpowered to identify the realistic benefits of such treatment. Larger trials with more aggressive drug administration schedules were initiated in the 1970s and showed small but statistically significant benefits for adjuvant therapy. A small positive trial of levamisole, an antihelminthic agent with immunostimulatory properties, led to a series of large confirmatory trials. In contrast to the initial trial, these studies showed no benefit for levamisole as a single agent.[375] Selected recent randomized trials of 5-FU adjuvant regimens versus surgery alone are listed in Table 81-5. Compared with 5-FU modified with folinic acid (leucovorin), however, 5-FU with levamisole was inferior, and it is no longer used in this setting. Subsequently, the addition of oxaliplatin to 5-FU/LV (MOSAIC trial) has set the current standard of care. Additional trials have addressed the duration of therapy (6 months versus 12 months), the use of 5-FU with leucovorin (LV) or oral capecitabine on a variety of schedules and durations, and the addition of irinotecan. Ongoing trials are exploring the use of bevacizumab and cetuximab in the adjuvant setting.

Adjuvant Treatment of Patients with Full-Thickness Bowel Wall Invasion and Negative Lymph Nodes (Stage II, T3 N0 M0, Dukes B2)

The role of adjuvant therapy for node-negative patients with disease extending through the bowel wall has not been established unequivocally, as many underpowered clinical trials have been published. Many current trials accrue these patients to trials of adjuvant therapy but in numbers that are inadequate to establish the expected small

Table 81-5 Selected Early Randomized Trials of Adjuvant 5-FU-Based Chemotherapy versus Observation Following Surgical Resection in Colon Cancer

Study, Time Period, and Country	*N*	Stage	Treatment Regimens	5-Year DFS (%)	*P*-Value	5-Year OS (%)	*P*-Value	Comments	Reference
INT 0035, 1984–1987, United States	929	Stage III	1. Observation 2. Observation 2. 5FU/LV	62 (3-year) 71 (3-year)	<0.0001	68 (3-year) 74 (3-year)	0.018	Long-term follow-up demonstrated a survival benefit for 5-FU/LV for patients with stage III cancer.	International Multicentre Pooled Analysis of Colon Cancer Trials (IMPACT) Investigators,[390] Marsoni[395]

DFS, disease-free survival; 5-FU, 5-fluorouracil; LEV, levamisole; LV, leucovorin; NR, not reported; OS, overall survival.

*The three trials (GMO, NCIC-CTG, FFCD) included in this meta-analysis were those that were stopped prematurely when surgery-alone control arms were no longer thought to be the standard of care in Dukes' C (stage III) disease.

Adapted from Chau I, Cunningham D: Chemotherapy in colorectal cancer: new options and new challenges. Br Med Bull 2002;64:159–180.

fractional benefit definitively. Because surgery alone results in 5-year DFS rates of 75% to 80% for patients with stage II colon carcinoma, 3572 patients must be randomized to show a 4% improvement to 84% with 80% power.[376] The QUASAR study was nearly this size, as 92% of the 3239 patients had stage 2 and were randomized between observation or 5-FU/LV regimens. With a median follow-up of 5.5 years, the 5-year recurrence-free rates were 84% for chemotherapy and 80% for observation, and 5-year survival rates were 85% versus 82%, respectively.[377]

Clinicians and groups vary in their recommendations to patients, most reserving adjuvant therapy for patients who have some adverse prognostic indicator, such as T4 lesions, inadequate node sampling (<13), bowel perforation, or poorly differentiated histology.[378]

The same schedule of 5-FU and levamisole that was used for patients with lymph node involvement (see later discussion) was evaluated in patients with stage II colon cancer.[379] Although the recurrence rate was reduced by 31% in these patients (71% DFS rate for the observation arm versus 79% for patients receiving 5-FU/levamisole), there was no difference in OS rate (72% at 5 years). The lack of survival advantage was attributed in part to the unexplained occurrence of twice the number of noncancer-related deaths in the patients who received adjuvant chemotherapy. It should be noted that these deaths also were not directly associated with treatment. In addition, six of seven patients who had surgically curable recurrences were in the surgery-only group.[379] This result was confirmed in a European study that showed a similar improvement in survival rate from 70% to 78%.[380] An Italian study comparing surgery alone with postoperative 5-FU and LV (370 mg/m^2 plus 200 mg/m^2 daily for 5 days for the first week of each 4-week cycle) for 6 months (six cycles of chemotherapy) showed a 21% reduction in mortality rate (23% to 20%). There was an 8% absolute difference in the DFS rate at 5 years (76% versus 68% alive without recurrence). It should be noted that the 5-year DFS rate in this study was somewhat inferior to that in other trials that were conducted during the same period.[381]

A single trial of autologous tumor cell vaccine augmented with bacille Calmette-Guérin has also shown some DFS benefit for patients with stage II disease, although trials attempting to evoke immune responses to eradicate micrometastatic disease have not yet shown improvement in overall survival (see the following discussion).[382] There is an ongoing Japanese trial evaluating the uracil-tegafur combination, UFT, with krestin, a polysaccharide immune modulator, although it is likely underpowered (340 patients).

A discussion of approaches to meta-analysis of the many inadequately powered trials has been undertaken.[383] Meta-analysis from four large trials conducted by the National Surgical Adjuvant Breast and Bowel Project has assessed the improvements in OS and DFS rates to be comparable for patients with stage II tumors: from 82% to 88% ($P = 0.08$).[384] Another group, however, found a smaller (and also statistically nonsignificant) possible benefit in their meta-analysis, with 5-year OS rates of 80% for untreated patients and 82% for treated patients.[385] The results for the 318 stage II patients in the Intergroup trial of 5-FU plus levamisole versus postoperative observation also favored adjuvant therapy, but again the trial was too small to demonstrate a probability of false positive of less than 5%.[379]

Adjuvant Treatment of Patients with Lymph Node Involvement (Stage III, Dukes C)

Chemotherapy with 6 months of 5-FU and LV after primary surgery was the first established beneficial adjuvant based on trials conducted in the 1980s. Adjuvant therapy is currently recommended for patients with colon carcinoma and nodal involvement to reduce the rate of cancer recurrence and prolong survival; however, the original 5-FU regimens have been supplanted by the combination of fluoropyrimidines with oxaliplatin.[386–388] Although adjuvant therapy does not necessarily alter the recurrence rate for each patient and therefore is not universally useful to patients, an additional 10% to 20% of patients with nodal involvement are cured by postoperative adjuvant chemotherapy, and others have prolongation of disease-free survival, although they eventually relapse. Recently published trials have addressed replacing intravenous 5-FU/LV with capecitabine, the duration of treatment and reduction of adverse events, as well as the use of newer chemotherapy agents such as oxaliplatin and irinotecan and the use of agents with novel targets such as bevacizumab, cetuximab, and panitumumab.

The NSABP C-03 was the first trial to demonstrate the value of 5-FU and LV in the adjuvant setting.[389] Those results were subsequently confirmed in additional large trials.[390–397] Table 81-6 summarizes selected randomized trials comparing various 5-FU-based adjuvant regimens. Early adjuvant trials were not sized adequately to detect survival differences as small as 10% to 15%, and chemotherapy was not widely prescribed postoperatively until 15 years ago. Most of the early trials enrolled only 100 to 200 patients, a sample size that can detect only survival differences greater than 30%. The initial trials of 5-FU and levamisole, using a 5-day bolus "loading dose" followed 1 month later by weekly 5-FU, showed absolute differences of 8%. A large confirmatory trial randomizing 929 patients reduced the recurrence rate by 40% and the death rate by 33%, resulting in 5-year DFS rates of 47% compared with 35% in patients who underwent surgery alone or with levamisole.[375]

Because of the advances that were observed in patients with metastatic disease who were treated with fluorouracil modulated by LV, this regimen has been evaluated widely in the adjuvant setting. The NSABP trial found similar improvements in DFS and OS rates for 1 year of treatment with 5-FU (500 mg/m^2 weekly for 6 out of 8 weeks) and LV (500 mg/m^2).[384,391] Subsequent studies have evaluated the role of LV and the duration of treatment in this setting. Patients undergoing 6 months of treatment with 5-FU (425 mg/m^2 daily for 5 days every fourth week) plus LV (20 mg/m^2 daily for 5 days every fourth week) experienced a 16% absolute difference in 5-year DFS rate compared with patients undergoing surgery only (74% versus 58% DFS at 5 years).[392] The overall 5-year survival rate difference was 11%, improving from 63% to 74% for the patients who received 5-FU plus LV. Six months of treatment with 5-FU and LV produced 5-year survival rates comparable to 12 months of either 5-FU plus LV or 5-FU plus levamisole. Six months of treatment with 5-FU plus levamisole yields results inferior to those of the other regimens.[398]

A three-armed trial of 5-FU plus LV (weekly intravenous bolus) versus 5-FU plus levamisole versus all three agents enrolled 2151 patients with Dukes B or C colon carcinoma. 5-FU with LV, used for 6 months, resulted in a modest increase in the DFS rate at 5 years (65% versus 60%, $P = 0.04$) and in the OS rate (74% versus 70%, $P = 0.07$); levamisole added toxicity and resulted in lower (statistically insignificant) DFS and OS rates.[399]

Adjuvant infusional regimens of 5-FU have been evaluated in European studies and have been demonstrated to have efficacy similar to 5-day intravenous bolus regimens given monthly but with reduced adverse effects.[400,401] An FULV2 regimen (LV 200 mg/m^2 over 2 hours, 5-FU intravenous bolus 400 mg/m^2 followed by 5-FU 600 mg/m^2 over 22 hours on days 1 and 2) was compared with five-times-daily treatment in the first of 4 weeks (LV 200 mg/m^2 intravenous bolus plus 5-FU 400 mg/m^2 intravenous bolus for 5 days in the first week of a 4-week cycle), prescribed for either 24 or 36 weeks in a 2 × 2 factorial design. In this study, 905 patients were followed for a median of 40 months.[400] The 48-hour infusional regimen was less toxic, and no difference in DFS or OS was found between the arms, although the cohort size precludes demonstrating small advantages for one arm. Protracted venous infusion of 5-FU at 300 mg/m^2/day for 12 weeks has been compared with 6 months of 5-FU/LV (5-FU 425 mg/m^2 plus LV 20 mg/m^2 as intravenous bolus on days 1 through 5 repeated every 28 days) in a cohort of 716 patients with stage II or III colon cancer. Although overall survival at 3 years did not differ statistically between the study arms (83.2% versus 87.9%), patients receiving 6 months of bolus therapy had a worse relapse-free survival

Table 81-6 Selected Randomized Trials of Adjuvant Chemotherapy Comparing 5-FU-based Regimens in Colon Cancer

Study, Time Period, Country	Stage	*N*	Regimen	5-Year DFS (%)	5-Year OS (%)	Comment (*P*-values)
NSABP C-03, 1987–1988, United States[389]	Stages II and III	1080	1. 5-FU-HDLV (1 year)	66	76	Both a DFS benefit ($P = 0.0004$) and OS benefit ($P = 0.003$) were noted for 5-FU-LV over the MOF regimen
			2. 5-FU/semustine/vincristine (MOF)	54	66	
INT 0089, 1988, United States[397]	Stage II (high-risk Dukes B2) and stage III	3759	1. 5-FU-LEV (1 year)	56	63	5-FU-LDLV + LEV had improved DFS ($P = 0.014$) and OS ($P = 0.007$) compared to 5-FU-LEV. All other did not demonstrate any differences. 6 months of 5-FU-LV became the standard for adjuvant therapy.
			2. 5-FU-LDLV (6 months)	59	66	
			3. 5-FU-HDLV (6 months)	60	65	
			4. 5-FU-LDLV + LEV (6 months)	60	67	
NSABP C-04, 1989–1990, United States[399]	Stages II and III	2151	1. 5-FU-HDLV (1 year)	65	74	5-FU-HDLV was superior to 5-FU-LEV in DFS ($P = 0.04$) and not significantly better for OS ($P = 0.07$). The addition of LEV to 5-FU-HDLV was not beneficial.
			2. 5-FU-LEV (1 year)	60	70	
			3. 5-FU-HDLV + LEV (1 year)	64	73	
NCCTG 894651 [NCCTG-NCIC], 1996, United States, Canada[398]	Stage II (Dukes B2) and stage III	890	1. 5-FU-LEV (6 months)	57	60	5-FU-LDLV + LEV for 6 months was superior to 5-FU + LEV for 6 months ($P < 0.01$); however, there were no significant difference between 6 and 12 months of treatment with the same regimen
			2. 5-FU-LEV (1 year)	63	68	
			3. 5-FU-LDLV + LEV (6 months)	63	70	
			4. 5-FU-LDLV + LEV (1 year)	57	63	
QUASAR, 1994–1997, United Kingdom*	Stages II and III (2×2 factorial design)	4927	1. 5-FU-LDLV + LEV (6 months)	64 (3-year) HDLV arms	70 (3-year) HDLV arms	No significant difference in DFS and OS between high-dose or low-dose LV and no difference between LEV and placebo
			2. 5-FU-LDLV + placebo (6 months)	64 (3-year) LDLV arms	71 (3-year) LDLV arms	
			3. 5-FU-HDLV + LEV (6 months)	63 (3-year) LEV arms	69 (3-year) LEV arms	
			4. 5-FU-HDLV + placebo (6 months)	65 (3-year) placebo arms	72 (3-year) placebo arms	
French National Study, 1996–1999, France[400]	Stages II and III (2×2 factorial design)	905	1. Infusional LV5FU2 (semimonthly) (24 weeks)	73 (3-year) LV5FU2 arms	86 (3-year) LV5FU2 arms	No significant difference in DFS and CS between treatment arms but small trial size precluded demonstration of small advantages for one arm and LV5FU2 was less toxic
			2. Bolus 5FU/LV (monthly) (24 weeks)	72 (3-year) 5FU/LV arms	88 (3-year) 5-FU/LV arms	
			3. Infusional LV5FU2 (semimonthly) (36 weeks)	73 (3-year) 24-week arms	87 (3-year) 24-week arms	
			4. Bolus 5FU/LV (monthly) (24 weeks)	72 (3-year) 36-week arms	83 (3-year) 36-week arms	
MOSAIC, 1998–2001, Europe[386]	Stages II and III	2246	1. LV5FU2 (de Gramont regimen) (6 months)	73 (3-year)	Results not yet available	3-year DFS benefit ($P < 0.01$)
			2. FOLFOX4 (6 months)	78 (3-year)		
NSABP C-07, 2000–2002[387]	Stage II/III	2407	1. Weekly FU/LV	71.8 (3-year)	Pending	
			2. FLOX (wkly FU/LV with biweekly oxaliplatin)	76.1 (3-year)		
X-ACT, 1998–2001, global[402]	Stage III	1987	1. Capecitabine	64.2 (3-year)	81.3 (3-year)	$P = 0.12$ NS
			2. 5-FU/LV d × 5	60.6	77.6 (3-year)	$P = 0.005$

DFS, disease-free survival; 5-FU, 5-fluorouracil; FOLFOX4, oxaliplatin with infusional 5-fluorouracil (de Gramont regimen); HDLV, high-dose leucovorin; LDLV, low-dose leucovorin; LEV, levamisole; LV5FU2, de Gramont regimen of infusional 5-fluorouracil with leucovorin; OS, overall survival.

*QUASAR Collaborative Group: Comparison of flourouracil with additional levamisole, higher-dose folinic acid, or both, as adjuvant chemotherapy for colorectal cancer: a randomised trial. Lancet 2000;355:1588–1596.

rate (68.6% versus 80%) and greater toxicity, including increased neutropenia, diarrhea, and stomatitis.[401]

Capecitabine, an oral agent that delivers fluorouracil in tumor tissue (see later in the chapter), has been evaluated in a large (1987 patients) randomized adjuvant trial, demonstrating equivalent DFS compared with 5-FU/LV given five times daily every 4 weeks for 24 weeks, with fewer adverse events. The 3-year rates of disease free survival were 64.2% (capecitabine) versus 60.6% ($P = 0.12$) , with 3-year OS rates of 81.3% versus 77.6%.[402] Another large adjuvant trial comparing capecitabine and oxaliplatin (CAPEOX or XELOX) with bolus 5-FU/LV has accrued 1886 patients; safety results from this trial have been reported, confirming the expected increase in emesis, hand-foot syndrome, and neurosensory adverse events; the expected decrease in diarrhea; and a 0.6% treatment related mortality, which is comparable to perioperative mortality. Final results from this study are expected in 2008.[388]

Adjuvant Oxaliplatin Combinations

The value of adding oxaliplatin to fluoropyrimidine regimens in the adjuvant setting was established in 2004 in the first of three large multicenter trials. Andre and colleagues compared patients with stage 2 and 3 colon carcinoma receiving infusional 5-FU and LV (LV5FU2) with or without oxaliplatin for 12 2-week cycles. 1123 patients were assigned to each arm, with a 3-year DFS of 78.2% versus 72.9% ($P = 0.002$) for all eligible patients. The 3-year DFS rate for patients with stage III disease was 72.2 versus 65.3%, and for patients with stage II disease, it was 87.0 versus 84.3 %; stage II patients represented 40% of the study population.[386]

Two phase III trials have compared bolus 5-FU/LV with or without oxaliplatin in the adjuvant setting. NSABP confirmed the benefit of adding oxaliplatin to a weekly bolus 5-FU/LV regimen.[387] In this study, randomizing 2407 patients (29% stage II) to either weekly bolus FU/LV for 6 out of 8 weeks for 6 months with or without oxaliplatin 85 mg/m^2, every other week, the 3-year DFS rates were 76.1% versus 71.8%. Safety data from a third adjuvant trial evaluating adjuvant capecitabine with oxaliplatin versus bolus 5-FU/LV on the five-times-daily (Mayo) regimen was just reviewed.[388]

In contrast to the consistent improvement in DFS for trials of oxaliplatin with 5-FU/LV, the addition of irinotecan to either infusional or bolus regimens did not improve DFS in three separate trials that were presented at ASCO meetings in 2004 and 2005 (but have not yet been published in final form); each trial differed in design from the successful oxaliplatin combination trials in specific ways: The PETACC trial included second noncolorectal carcinomas as an endpoint; T staging was not included as a stratification factor in the ACCORD study, which was also powered to establish an absolute 15% difference in 3-year DFS and therefore was underpowered. However, these unsuccessful trials illustrate the critical importance both of trial design and of not extrapolating activity in patients with advanced disease to the adjuvant setting.

Adjuvant therapy regimens for colon carcinoma are generally well tolerated after individual dose adjustment. Treatment-related mortality has been found to be less than 1% for 5-FU/LV, and only 18 deaths while on chemotherapy occurred among the 2151 patients who were treated in NSABP C-04.[389,399] On regimens using 5-FU at 425 mg/m^2 for 5 days, one third of patients will experience severe (grade III or IV) stomatitis, and one quarter will have severe diarrhea. Grade III leukopenia occurs in 10% to 15% of patients and severe nausea in only 5% to 7%. On a weekly bolus schedule, hematologic toxicity occurs in fewer than 2% of patients, ataxia in 1%, and grade III or IV diarrhea occurs in at least one course for 35% of patients, resulting in dose reductions.[399] About half of patients treated require dose reduction, with a reduction to 75% of baseline as the median adjustment. The percentage of the total prescribed dose that is actually given averages 70%, with 77% of patients completing all courses of therapy (excluding patients who die or have disease recurrence).[389] Dose reduction (either 4 days of treatment or reduced daily doses) usually abrogates the intensity of these side effects in subsequent cycles. When starting at a lower dose (375 mg/m^2), only 5% of patients experience grade III to IV mucositis, while 4.5% experience severe diarrhea and 2.5% experience severe emesis. Transient grade IV neutropenia occurs in 14%. If lower doses are used initially, however, physicians should consider dose escalations for patients who have no side effects in the first cycle of treatment, as dose intensity of 5-FU has been correlated with activity against disease.

The National Cancer Institute-sponsored CALGB trial, which randomized 1263 stage III patients between irinotecan, 5-FU, and LV (IFL) for 30 weeks versus 5-FU/LV weekly, was closed in April 2001 because of concerns about the 60-day all-cause mortality rate of 2.5% in the IFL arm versus 0.7% (see the discussion later in the chapter in the section on Irinotecan).[403] This trial has subsequently not shown an advantage for the addition of irinotecan in the adjuvant setting. Attention to dose-adjustment recommendations and supportive care can minimize the adverse effects of 5-FU/LV on patient well-being. In particular, close nursing observation is critical for the safety of these regimens and ensures that treatment breaks are initiated when patients experience mucositis or diarrhea. Patients who develop oral pain or diarrhea before receiving their fifth of five daily doses should not receive the final scheduled dose(s). It is important to assess any changes in the patient's bowel habits prior to administering weekly doses of 5-FU/LV. Persisting in the administration of a cell cycle-specific antimetabolite after diarrhea or mucositis has developed exposes proliferating crypt cells that have been recruited into S phase to a drug that is specific for cells in S phase and can result in more severe diarrhea and mucositis symptoms that could require hospitalization for management. Symptomatic measures could be helpful; for example, mucositis can be reduced by using oral ice chips for 30 minutes when 5-FU is administered by intravenous bolus.[404] Patients who experience moderate to severe diarrhea usually benefit symptomatically from loperamide administration but still require a treatment break even if their symptoms are subsiding with supportive care. Comparison of FOLFOX and LV5FU2 regimens[386] had the expected differences in adverse event profiles, with a higher frequency of grade III/IV neutropenia (41% versus 5%), neutropenic fever (1.8% versus 0.2%), grade III/IV diarrhea (10.8% versus 6.6%), grade III/IV emesis (5.8% versus 1.6%), allergic reaction (2.9% versus 0.2%), and peripheral neuropathy (92% versus 15%), although only 12.4% had grade III neuropathy, and only 1.1% had persistent grade III neuropathy at 12 months. There was a 0.5% 60-day (treatment-related) mortality rate for each arm and a 1.2% (FOLFOX) versus 1.8% (LV5FU2) rate of thromboembolic events. Toxicity was somewhat more intense with oxaliplatin combined with bolus FU-based regimens[387,388]; The 60-day mortality rate was slightly higher (1% and 1.2%), as was the incidence of grade III/IV diarrhea (38% and 32%), but the rate of grade III neurotoxicity was slightly lower (8.2%). The NSABP investigators carefully described chemotherapy-induced enteropathy, with diarrhea and bowel wall thickening, which occurred in 9.1% of the FLOX arm and 3.9% of the FULV arm.[387] Adjuvant trials that have recently completed accrual or are still in progress for patients with stage III colon cancer are listed in Table 81-7.

Adjuvant Therapy in the Elderly

Older patients who otherwise meet eligibility requirements have been included in recent large randomized trials, albeit at rates that are substantially lower than the incidence of disease (16% of trial patients versus approximately 50% of all patients with colon carcinoma). In older patients without comorbidities that are likely to result in limited survival, the effectiveness of adjuvant regimens is comparable to its utility in younger patients. In a review of the safety of FOLFOX regimens (adjuvant and therapeutic) involving patients older than 70

Table 81-7 Selected Randomized Trials of Adjuvant Chemotherapy in Colon Cancer That Have Closed Recently or Are Still in Progress*

Study, Country	Stage	*N*	Regimens	Status
ECOG 5202, United States	II	3610	FOLFOX ± bevacizumab; stratification by IIa vs IIb, MSI	Open 2005; potential accrual through 2010
NSABP C-08, United States	II/III	2632	FOLFOX ± bevacizumab	closed to accrual
AVANT, Europe	II/III	3450	FOLFOX ± bevacizumab and xelox/bevacizumab (3 arms)	Open Dec 2004

*As of August 2007.

years of age (614 of 3742 total patients), only neutropenia (43% versus 49% incidence of grade > III) and thrombocytopenia (2% versus 5%) were somewhat more frequent in the older patients, and there was a nonsignificant trend to an increased 60-day mortality rate (1.1% versus 2.3%, $P = 0.2$). However, only 15 of the reviewed patients in these four trials were 80 years or older.[405] Sanoff and colleagues have recently reviewed the issues of managing older patients with colorectal carcinoma.[406]

Radiation Therapy

While prospective randomized trials have largely defined the role of adjuvant chemotherapy in patients with high-risk colon cancer, the role of adjuvant radiation therapy remains poorly defined. Adjuvant radiation therapy has not attained common practice, primarily because failure patterns after attempted curative resection tend to favor abdominal rather than local recurrence. However, although the overall incidence of local failure is 20% or less, local failure risk can be significantly higher in certain subsets of patients, implying that a selective application of postoperative radiation therapy could provide benefit. Such subsets might be identifiable from various reports on patterns of failure.[407–410] Analysis of failure patterns in patients undergoing reoperation or autopsy indicates that patients with tumor adherence (T4) and/or lymph node involvement have increased local recurrence risk.[407] Gunderson and colleagues[407] found a 67% incidence of local regional failure in 24 patients with adherence to or invasion of surrounding structures, while Russell and coworkers[409] found a 69% incidence in a similar group of patients and a 30% incidence of local failure in patients with both regional nodal involvement and bowel wall penetration.

In addition to these pathologic factors, anatomic location has also been proposed to influence risk of local recurrence, presumably by compromising radial margins, although there is less consensus over this issue. Gunderson and colleagues[407] have suggested that lesions located in immobile areas such as the ascending and descending colon, particularly when posteriorly located, could have compromised margins of resection, a situation that is not likely to occur in mobile, intraperitoneal structures such as the sigmoid and transverse colon. But whereas Willett and associates[410] also found differences in local recurrence rates by location, the observed patterns differed from the observations that had been made in the previous study. In addition, Minsky and associates[408] found no difference in failure rates between regions of colon that were considered to be mobile or immobile, further calling into question the degree to which location and bowel mobility are predictive of local recurrence risk.

Overall, then, pathology rather than location appears to be the clearest predictor of local recurrence risk, with tumor adherence to abdominal structures and with bowel penetration in combination with nodal involvement predicting local recurrence risks that can be substantial.

Role of Adjuvant Radiation Therapy

Although several randomized clinical trials for rectal cancer have shown postoperative chemoradiotherapy to decrease pelvic recurrence and increases survival in T3 or higher T stage and/or N-positive rectal cancer, there is only a single, underpowered, negative randomized trial for colon cancer.[411] There are, however, several single-institution studies suggesting that postoperative irradiation reduces local failure.[410,412,413]

Willett and colleagues[410] have reported on the largest single-institution experience. In this retrospective trial, 203 patients received postoperative radiation therapy (45 Gy plus a reduced-field boost to 50.4 to 54 Gy) with and without concurrent 5-FU chemotherapy after resection of T3, T4, and T3/4, N-positive colon tumors. Of the 203 patients, 30 (15%) had residual local tumor after resection. The 173 remaining patients treated with adjuvant radiation therapy were compared with a historical control group of 395 patients undergoing surgery only. Improved local control and recurrence-free survival rates were seen for patients with T4 N0 and T4 N+ colon carcinoma treated with postoperative radiation therapy, compared with a similarly staged group of patients undergoing surgery only. In addition, irradiated patients whose tumors had an associated abscess or fistula formation had improved local control and recurrence-free survival rates compared with a similar group of patients undergoing surgery only. Finally, patients with residual local disease after subtotal resection still had a 37% 5-year DFS rate, indicating that a certain proportion of patients with residual disease can be salvaged. Treatment toxicity rates were significant but acceptable, with 4.5% of patients developing bowel conditions requiring surgery. A 10-year update of this series again found increased control for adjuvantly treated T4 N0 and T4 N+ patients.[414] In this study, the nonrandomized addition of 5-FU chemotherapy to radiotherapy did not alter local control, the rate of distant metastasis, or disease-free survival.

Another retrospective study, from the University of Florida,[412] carried out in patients with locally advanced but completely resected colon cancer, found a local control rate of 88% after adjuvant radiotherapy. A dose response was also found, with local control rate of 96% versus only 76% for patients receiving greater than or less than 50 Gy, respectively. An additional retrospective study carried out in 103 patients with locally advanced colon cancer who received postoperative radiation therapy found 5-year actuarial local failure rates of 10%, 54%, and 79% in patients with no residual disease, microscopic disease, or gross residual disease after surgery, respectively.[413] In the 35 patients with gross residual disease, the addition of intraoperative radiotherapy to external beam radiation reduced the local failure rate from 82% to 11%. In a prospective phase II trial, Palermo

and colleagues treated 45 patients between 1984 and 1989 with combined intraperitoneal 5-FU and local plus para-aortic nodal radiation therapy.[415] Six cycles (five times daily) of intraperitoneal 5-FU were given, separated from each other by 4 weeks, with two courses of radiotherapy (22.5 Gy each delivered in 1.5-Gy fractions) given after the first and third chemotherapy cycles. Potential advantages of intraperitoneal 5-FU delivery could include a higher drug concentration for at-risk peritoneal surfaces as well as delivery of 5-FU by the portal circulation to the liver. Only four patients experienced local recurrence, and tolerance was acceptable with four patients experiencing grade III peritonitis. In spite of a lower than expected rate of locoregional recurrences, however, survival rates were similar to those reported by others using systemic chemotherapy and radiation. With a 112-month median follow-up, actuarial DFS and OS rates of 49% ± 8% and 53% ± 7%, respectively, were found.

These retrospective studies, in spite of their inherent limitations, suggest that selected groups of patients with more locally advanced colon carcinoma might benefit from postoperative irradiation. Therefore, it became important to validate these retrospective findings in a prospective randomized trial. Given the proven benefit of adjuvant chemotherapy in node-positive colon cancer and its enhancement of radiation efficacy in rectal cancer, an Intergroup trial (INT 0130) was designed to compare adjuvant chemotherapy alone to chemotherapy plus radiation in a randomized fashion.[411] Patients with tumor adherence or invasion of surrounding structures or T3N1-2 tumors were randomized to 1 year of 5-FU plus levamisole with or without 45 to 50.4 Gy in 25 to 28 fractions. A total of 222 out of an original accrual goal of 700 patients were randomized, and of these, 187 were eligible for analysis.

Five-year DFS and OS rates were 52% and 62% for chemotherapy patients, respectively, and 51% and 58% for chemoradiotherapy patients, respectively (both with $P > 0.50$). Grade III or higher toxicity occurred in 42% of chemotherapy patients and 54% of chemoradiotherapy patients ($P = 0$ .04) with the excess in toxicity in the radiotherapy arm being primarily hematologic in nature. Extent of nodal involvement influenced outcome in both arms while extent of invasion (T4 versus T3) did not. Thus, patients in this trial who received chemotherapy or chemoradiotherapy had similar OS and DFS rates, while toxicity was higher among chemoradiotherapy patients.

As was mentioned, this intergroup study is the only published, randomized trial of adjuvant radiation therapy in colon cancer. As was discussed by the investigators, the low accrual, frequent lack of preoperative imaging, frequent failure to place radiopaque clips to guide treatment fields, and inconsistent pathology detail could have limited the ability of the study to detect a meaningful benefit from adjuvant radiotherapy. Furthermore, the study was somewhat diluted by the approximately 19% of its patients who had T3 tumors and might therefore not have had the highest risk for local failure.

In conclusion, several retrospective trials suggest that a subset of patients with high-risk, resected colon cancer derive benefit from the addition of adjuvant radiation therapy to the resected tumor bed. The one randomized trial that tested adjuvant radiation therapy did not confirm a benefit, but several problems might have limited the study's power. At present, therefore, definitive evidence is lacking to support the universal application of adjuvant radiotherapy in locally advanced colon cancer, whereas adjuvant therapy in selected highest-risk patients may offer benefit. There arguably are clinical situations in which its use is reasonable, including when the risk of local recurrence is high because of known or likely microscopic or gross residual disease, as in patients with positive margins or T4 tumors with invasion of or adherence to unresectable abdominal or pelvic structures. Such a selective application of adjuvant radiotherapy is consistent with current NCCN guidelines.[416] Given the efficacy of concurrent, adjuvant chemotherapy and radiotherapy for rectal cancer, adjuvant radiation therapy, when given for colon cancer, should be combined with systemic chemotherapy. Other options include intraoperative radiotherapy, which allows a more localized delivery of a higher dose and may play a role as well, particularly in subtotally resected tumors. Also, newer chemotherapy agents or targeted agents such as cetuximab or bevacizumab, having proven useful in metastatic and adjuvant settings, might be beneficially combined with radiotherapy.

Hepatic and Whole-Abdominal Irradiation

High rates of hepatic metastasis and peritoneal failure have led to several investigations of adjuvant hepatic or whole-abdominal radiotherapy. A phase III trial exploring the role of adjuvant hepatic irradiation was performed by the Gastrointestinal Tumor Study Group.[417] A total of 300 patients with resected T3, T4, or node-positive colon cancer were randomized to either observation or 21 Gy of hepatic radiation in 1.5-Gy fractions with concomitant 5-FU chemotherapy. Results of the study, however, indicated no therapeutic benefit for either survival or recurrence endpoints, with the liver recurrence rate remaining unchanged by hepatic therapy.

Several small, nonrandomized studies of whole-abdominal irradiation have also been reported.[418–420] The study by Wong and colleagues[420] treated 30 patients who had undergone a complete resection with whole-abdominal irradiation and reported a 5-year actuarial survival rate of 55%. An additional 25 patients who had either gross total residual disease after surgery or peritoneal metastases had very poor outcomes after whole-abdominal irradiation. The largest of these studies, a Southwestern Oncology Group phase I/II trial (SWOG 8572), reported on 41 patients who received 30 Gy whole-abdominal irradiation in 1-Gy fractions (20 Gy maximum to the liver) with an additional 16-Gy tumor bed boost, along with concurrent, continuous infusional 5-FU.[419,421] Five-year DFS and OS estimates were 58% and 67%, respectively, for all T3N1–2 patients. Seventeen percent of patients had severe toxicity, and 7% had life-threatening toxicity of any kind. Although conclusions are difficult in the absence of randomized trials, patients in SWOG 8572 who received whole-abdominal irradiation plus tumor bed irradiation with infusional 5-FU did demonstrate reduced tumor bed, liver, and peritoneal relapse rates when compared with patients who were treated in other studies with either surgery alone or surgery plus chemotherapy. However, on the basis of all studies to date, there is no compelling evidence that whole-abdominal irradiation is superior to locoregional irradiation, particularly when the higher toxicities of whole-abdominal irradiation are accounted for.

In conclusion, adjuvant radiation therapy to the tumor bed can decrease the risk of local recurrence after resection of locally advanced colon cancer and may be useful in patients who are at very high risk for recurrence. Intraoperative radiation therapy to achieve higher, more directed doses could further improve tumor control in patients with incompletely resected disease. In addition, hepatic irradiation and whole-abdominal irradiation have not improved survival and remain highly investigational.

MEDICAL ONCOLOGY MANAGEMENT OF METASTATIC DISEASE

As was noted previously, 45% of the 153,000 patients who are diagnosed with colorectal cancer in the United States each year will either present with or eventually develop disease recurrence.[1] Similar risks apply to the more than 1,023,000 patients who will be diagnosed worldwide, as 529,000 deaths were estimated in 2001.[422] At the time of diagnosis of metastatic disease, the median survival was estimated to be 6 months without additional therapy. Chemotherapy regimens have increased that survival to more than 20 months.[423–432]

Several randomized trials have now reported median survivals over 20 months from the time of diagnosis, including fluoropyrimidine-based regimens combined with chemotherapy (oxaliplatin or irinotecan) and antiangiogenic agents (bevacizumab) particularly when followed by second-line alternate regimens.[428–432]

Assessment of the effect of treatment is a tenet of all medical care. For cancer, this assessment is still made for an individual patient by measuring the diameter of lesions and establishing that no new lesions have developed since treatment was initiated. It is important that the baseline measurements be obtained within a short period before initiation of treatment (i.e., within 1 week and certainly within 1 month), as growth of disease before chemotherapy is initiated could otherwise be misinterpreted as progression. Clinical trials frequently reevaluate for response at 8-week intervals. Response can be assessed by radiologic measurements (e.g., chest x-ray of lung lesions or CT of liver metastases). Other markers have also been used and generally correlate with cell kill and extended survival—50% decline in CEA, for example (see the discussion on carcinoembryonic antigen earlier in this chapter). Improvement in patient well-being can also be an indication that treatment is containing the neoplastic process, although the placebo effect has been implicated in some improvements, particularly in pain assessment. Nonetheless, patients whose performance status improves and who gain weight on treatment in the absence of a change in measurable disease may be clinically benefiting from the treatment. In randomized clinical trials in colorectal carcinoma, measures of population benefit such as PFS or OS are critical to the establishment of evidence-based therapeutics producing clinical benefit.

In evaluating a patient with colon cancer prior to therapy, CT of the chest, abdomen, and pelvis usually suffices to establish measurable disease. Because metastases to the brain and bone are rare (<10%) and tend to occur late in disease progression, only patients with symptoms such as headache and skeletal pain are evaluated with imaging of the brain or bone scan. Assessing hematopoietic function (with blood counts), liver injury, and renal function are included in all protocols before start of treatment.

Historically, alterations in overall survival were difficult to detect owing to study size and the modest effect of single-agent 5-FU therapy. If only 33% of patients have substantial decrease in disease (partial or complete regression) and the responding patients have a true median survival of 18 months compared with 12 months for patients receiving only supportive care, and if the remaining 66% of patients receiving chemotherapy have no change in their 12-month survival, a randomized trial with 100 patients treated and 100 observed would show a 2-month difference in survival, with a *P* value of 0.1. With more effective regimens for patients with metastatic colorectal carcinoma, differences in overall survival produced by initial therapy can be obscured by additional poststudy therapies; this has led to the use of progression-free survival as a primary trial endpoint for first- and second-line therapies.

The quandary of patients who have definite tumor regression (partial regression assessed as greater than 50% decline in the area of lesions) but also a decline in functional status due to treatment-related morbidity is commonly faced in general oncology and has recently become an issue for patients with colon cancer with the addition of more effective but more toxic agents such as irinotecan and oxaliplatin to 5-FU. Patients with specific toxicities, such as oxaliplatin-induced peripheral neuropathy or who have failure to thrive while receiving chemotherapy need to be reassessed carefully regarding the goals of treatment. Patients who are receiving potentially curative adjuvant therapy in a high-risk setting are balancing short-term toxicity against the possibility of a normal life span. In the setting of metastatic disease, in which cure is generally not feasible, both quality and quantity of life—usually assessed as adjusted quality-of-life years—have to be balanced. For many patients with symptomatic disease, even a minimal regression can be associated with improved quality of life (resolution of jaundice, return of appetite, increased performance status, diminished pain, absence of tumor fever, weight gain) at the cost of inconvenience and intermittent mild fatigue, nausea, and loose stools. Patients who are asymptomatic fall somewhere between two opposite ends of a spectrum in their approach to treatment. Some, possibly with unrealistic expectations of cure, want the most aggressive (i.e., toxic and expensive) approach available, hoping to maximize their survival and possibly be one of the few long-term survivors with unresectable metastatic disease. Others are, understandably, reluctant to impair their currently excellent quality of life for the small chance that they might have a modestly longer survival if chemotherapy is initiated at the first evidence of recurrence.

As a tumor marker CEA, though neither sensitive enough nor specific enough to be useful for screening, is helpful in monitoring the course of disease during and after treatment, particularly in patients with metastases that are not easily evaluated by current imaging technology, such as peritoneal carcinomatosis. Evidence of regression in patients with colon carcinoma is generally not rapidly apparent, even in the few patients who eventually have complete regression of measurable disease. Thus, reevaluation after 8 weeks of treatment, in the absence of signs or symptoms that suggest progression in the interval, is generally appropriate. Measurement of CEA earlier than this can result in false impressions of progression, as CEA can be released from dying tumor cells, and with its slow systemic clearance, it could initially be elevated before eventually declining.

For the approximately 50% of patients who have measurable regressions with current chemotherapy regimens, response is durable for the majority, with the median time to progression after first-line therapy at 7 to 11 months (see the later discussion). Even patients with less than 50% regression could have meaningful improvement in duration of survival with minimal symptoms.

Fluorinated Pyrimidines in the Treatment of Metastatic Colorectal Carcinoma

For the past 30 years, 5-FU has been used to treat patients with metastatic colorectal cancer, but improved understanding of its pharmacology has led to steady improvements in the usefulness of treatment. Bolus intravenous administration of 5-FU was the standard of care until 1990. Compared with best supportive care, intravenously administered 5-FU might result in small improvements in survival duration.[433]

Our understanding of the role of inhibition of thymidylate synthase and the cofactor, folinic acid, by the active metabolite of 5-FU, 5-FdUMP, reflects 5-FU's status both as the first "molecularly targeted agent" and as an outstanding example of the potential benefits of careful biochemical pharmacology research. Improved understanding of the biochemistry of 5-FU and its congeners has permitted the development of more effective agents and regimens. To enhance the duration of thymidylate synthase inhibition, 5-FU can be given by 48-hour or continuous infusion and/or in conjunction with LV (also called folinic acid) to improve the response rate.[434–437]

Infusion regimens permit the administration of higher doses of 5-FU while minimizing hematologic toxicity and reducing diarrhea. Meta-analysis of trials that compared infusional regimens (with or without LV) also confirm the increase in response rate (22% versus 14%) and modest increase in survival (12.1 versus 11.3 months) that this approach provides.[438]

The intensity of treatment with fluorouracil has been well correlated with its activity in patients with advanced disease. Patients with a lower 5-FU exposure (measured as the area under the concentration-versus-time curve) were more likely to have disease progression even when treated with the same regimen.[439] In a multivariate analysis in patients with head and neck cancer, the exposure to 5-FU correlated with both response and with survival.[439] A meta-analysis of randomized trials comparing 5-FU alone with 5-FU and LV has confirmed the improved response rates (23%) and median survival (10.5 months) provided by modulating 5-FU with LV.[440]

It is possible to use 5-FU without any side effects, but only at the cost of compromising its activity. On the other hand, patients with intolerable toxicity generally are receiving the highest drug exposures, and their doses can be reduced to produce acceptable quality of life

Table 81-8 Commonly Used 5-FU and LV Regimens

Regimen	Reference
LV 20 mg/m^2 days 1–5, 5-FU 425 mg/m^2, days 1–5, q4–5 weeks (Mayo 5-FU/LV regimen)	Poon et al.[423]
LV infusion 500 mg/m^2 over 2 hours 5-FU IV bolus 600 mg/m^2 weekly × 6, then 2 weeks rest (Roswell-Park regimen)	Petrelli et al.[424]
LV 200 mg/m^2 over 2 hours followed by 5-FU IV bolus 400 mg/m^2 plus 5-FU 600 mg/m^2 over 22 hours, days 1 and 2, every 2 weeks (DeGramont regimen)	de Gramont et al.[435]
LV 500 mg/m^2 over 2 hours followed by 5-FU 2600 mg/m^2 over 24 hours weekly × 6 then 2 weeks rest (AIO regimen)	Kohne et al.[426]
5-FU 3000 mg/m^2 over 48 hours	Diaz-Rubio et al.[425]
5-FU 250–300 mg/m^2/day continuous IV infusion for 6 weeks, then 2 weeks rest (Lokich regimen)	Lokich et al.[434]
Capecitabine 1250 mg/m^2 bid days 1–14/21	Twelves et al.[402]

while still providing enough drug to produce a predictable likelihood of benefit. This information is important to reassure patients who worry that dose reductions mandated by severe toxicity will compromise their chances of cure in the adjuvant setting. The corollary, however, is that patients who have minimal or no side effects when receiving 5-FU could have their doses increased as tolerated in subsequent courses.

Although few of these regimens have been compared directly in randomized trials, regimens that produce similar rates of moderate to severe toxicity produce similar response rates. The various regimens do differ in their dose-limiting toxicities and with respect to the time, cost, and technical demands for their delivery, although all can be provided in the outpatient setting. Regimens that deliver 5 days of treatment every 3 to 4 weeks result in dose-limiting mucositis, diarrhea, and neutropenia. Weekly 5-FU/LV regimens are generally limited by diarrhea. Continuous-infusion regimens are limited by hand-foot syndrome or mucositis and rarely result in severe diarrhea or neutropenia, but they do require placement of vascular access catheters. High-dose regimens delivered over 24 to 48 hours of continuous infusion also can cause altered mental status or angina-like chest pain that is rarely seen in the other regimens, but the de Gramont 48-hour bolus and infusion regimens (Table 81-8) are generally well tolerated, with diarrhea and hand-foot syndrome generally dose limiting. Oral capecitabine (see the section on Orally Available Fluoropyrimidines later in the chapter) requires better patient adherence than do regimens that are delivered in a clinic and has a substantial incidence of hand-foot syndrome and diarrhea.

Randomized Trials of 5-FU Regimens

In patients without prior therapy, 5-FU administered continuously intravenously as 750 mg/m^2/day for 7 out of 21 days was compared to administration of 500 mg/m^2/day via intravenous bolus for 5 days every 28 days (without LV), with response rates of 26% versus 13%, respectively. Diarrhea and stomatitis were more common in the infusion group and would have been less prominent at lower daily doses without interruption.[436] In another four-arm randomized trial (477 patients) comparing a conventional loading dose followed by weekly 5-FU (500 mg/m^2/day for 5 days followed by a 1-week break, then 600 mg/m^2 once a week, compared with infusional 5-FU at 300 mg/m^2/day), responses were seen in 18% of 153 patients versus in 28% of 159 infusion patients.[313] Median time to progression overall was 5.1 months for the group receiving intravenous bolus administration versus 6.2 months for the group receiving continuous intravenous infusion.[313] Survival was 10.4 months for the intravenous bolus group and 13 months for the continuous intravenous infusion group; 6% of the patients were still alive at 3 years. These extended infusion regimens are much less likely to cause neutropenia (24% grade 4 for the intravenous bolus group versus 1% for the continuous intravenous infusion group). Hand-foot syndrome is seen in only 20% of patients, and infusion site infections are seen in 14% of patients; 2% of patients have bacteremia.[435–438]

The de Gramont (LV5FU2) regimen of bolus followed by 48-hour infusions, for total FU doses of 2000 mg/m^2 every 2 weeks, has been evaluated with several modifications. The basic regimen is LV 200 mg/m^2 over 2 hours at 0 and 24 hours, with bolus 5-FU 400 mg/m^2 after the 2 hours, at 2 and 26 hours, and then 600 mg/m^2 over the ensuing 22 hours on both the first and second days. The first phase II trials reported a 38% response rate (2.5% complete remissions) with an overall median survival of 10.3 months and 17 months median survival in patients with a response.[435] More than 60% of patients treated at this dose had either no toxicity or minor side effects, and only 8% experienced grade III or IV toxicity.[435] In a randomized trial that compared this dose with 5-FU 425 mg/m^2 plus LV 20 mg/m^2 daily for 5 days out of 4 weeks (Mayo regimen), response rates were 14.4% (somewhat low for the Mayo regimen) versus 32.6% (GERCOD), with a 5-week improvement in median survival (56.8 weeks versus 62 weeks). The Mayo arm produced grade III to IV toxicities in 24% versus GERCOD reporting 11%, primarily neutropenia, diarrhea, and mucositis (7% grade 4 versus 2% to 3% for de Gramont).[435] Further dose escalation of the GERCOD regimen to 500 mg of LV and 1500 to 2000 mg/m^2/day 5-FU resulted in toxicity equal to that of the Mayo regimen (grade III to IV in 15%, 2% with grade IV neutropenia, 5% with grade III to IV diarrhea, 1% encephalopathy) and produced a similar response rate (34%, 101 patients) but with five complete responses and a median survival of 18 months. The median time to progression was 8 months.[435,441]

Orally Available Fluoropyrimidines

Because extended exposure to short-lived, cell-cycle-specific agents such as 5-FU is desirable, many attempts to provide 5-FU orally have been undertaken to eliminate extended infusion regimens and their requirements for indwelling lines and pump hardware. Efforts to develop oral cytotoxic agents are complicated by patient adherence to oral regimens, an issue that most cancer treatment protocols do not directly address.

Several approaches to overcoming the inconsistent and minimal absorption of oral 5-FU have been undertaken in the past decade, including agents that would inactivate the principal catabolic enzyme, dihydropyrimidine dehydrogenase, such as eniluracil/5-FU or UFT[442–445] and prodrugs such as capecitabine (Xeloda, Roche), tegafur, and S-1.[446–448]

Capecitabine is a fluoropyrimidine carbamate that is adequately absorbed after oral dosing. It is metabolized by carboxyl esterase in the liver to 5′-deoxy-5-fluorocytidine, deaminated via cytidine deaminase in both liver and tumor tissue to 5′-deoxy-5-fluorouridine (5-dFUR), and then further transformed by thymidine phosphorylase in tumors to 5-FU.[449,450] The final steps of anabolism to 5′FdUMP and binding in a ternary complex to TS in the presence of folinic acid are then identical to those of parenterally administered 5-FU. The relative concentration of 5-FU that is generated in tumors is eightfold to 14-fold higher than the plasma concentrations.[449,450] These differentials, though substantial, are not as large as those in murine studies, which reported intracellular levels of 5-FU 16- to

35-fold higher than those produced by administration of 5-FU, with tissue levels 100- to 200-fold higher in tumors than in plasma or muscle, where the final conversion of 5′-dFUrd to 5-FUra does not occur.[450] Two phase III trials of capecitabine (1250 mg/m^2 twice daily for 2 weeks out of 3) in 1207 patients with previously untreated metastatic colon cancer compared the oral regimen to the Mayo regimen (5 days of bolus 5-FU/LV every 28 days).[451–454] The overall response rate was 26% for capecitabine and 17% for 5-FU/LV ($P < 0.002$); the median time to progression was 4.3 to 5.2 months versus 4.3 to 4.7 months; and the OS was 13.2 to 12.5 months versus 12.1 to 13.3 months (combined, 12.9 months versus 12.8 months).[455–457] Neither trial showed a statistically significant difference in any activity parameter except response rate. Adverse effects for capecitabine on this schedule are comparable to those for high-dose, 48-hour infusional 5-FU, with hand-foot syndrome prominent and occurring in 53% of patients (17% grade III) and diarrhea occurring in 48%. Bilirubin elevations to grade III to IV were reported in 28% of patients for capecitabine versus in 6% for 5-FU/LV, but less stomatitis (2% grade III to IV) and neutropenia (2.2% grade III to IV) were seen with capecitabine.[458] Because the Mayo five-times-daily regimen is also more toxic than is continuous infusion or de Gramont 48-hour infusion (LV5FU2), the significance of these toxicity differences is unclear.

Capecitabine adverse effects are comparable to those for infusional 5-FU regimens, although capecitabine is more likely than protracted continuous infusions to produce diarrhea and hand-foot syndrome. Dose-limiting toxicity is gastrointestinal, involving diarrhea, nausea, and vomiting. When capecitabine is used without any break, hand-foot syndrome, fatigue, and dizziness also occur. A variety of small (150 to 160 patients) phase II trials of combinations of capecitabine with oxaliplatin or irinotecan have been completed, with the expected differences in frequencies of adverse events such as diarrhea (greater with irinotecan) or peripheral neuropathy (greater with oxaliplatin).[459,460]

In combinations with oxaliplatin, neurosensory toxicity occurs in 78% (11% grade III/IV), nausea in 66%, diarrhea in 60%, fatigue in 35%, hand-foot syndrome in 29%, and neutropenia in 27% to 50% of patients (9% grade III/IV), and grade 3/4 thrombocytopenia occurs in approximately 5%.[388]

Current Combinations of Fluoropyrimidines with Other Chemotherapy: Oxaliplatin and Irinotecan Combinations

Although LV modulation and infusion of 5-FU have resulted in improved response rates, for decades, colon carcinoma was not treated with combination chemotherapy. Clinical trials showed no advantage for combining either nitrosoureas (principally methyl-CCNU) mitomycin, cisplatin, or interferon with 5-FU. Over the past decade, two new classes of chemotherapy have been introduced into clinical use: the topoisomerase I inhibitor irinotecan (CPT-11, irinotecan, Camptosar-Pfizer) and the platinating agent oxaliplatin (Eloxatin, Sanofi-Synthelabo).

Oxaliplatin

Although prior studies suggested that cisplatin in conjunction with 5-FU would enhance response rate and duration of response by altering DNA repair, clinical trials comparing the addition of cisplatin to 5-FU by continuous intravenous infusion showed insignificant improvement in response at the cost of substantial additional toxicity.[313] Oxaliplatin (trans-l-1,2 diaminocyclohexane oxaloplatinum), a diaminocyclohexane platinum complex, has greater in vitro activity in colon lines than do other platinum analogs.[461,462] Oxaliplatin has not only demonstrated synergistic cytotoxicity in vitro,[461,463–465] it also has clearly improved both progression-free and overall survival compared to IFL427 and was approved by the U.S. FDA in 2002 for patients with colon cancer. Like cisplatin and carboplatin, this compound platinates DNA and forms DNA interstrand links and adducts that block DNA transcription and replication.[464,465]

The single-agent response rate for oxaliplatin is 10% in previously treated patients with colorectal cancer.[466,467] In patients without prior therapy, oxaliplatin as a single agent produces an 18% to 24% partial response rate, with a median time to progression of 6 months and a median survival of 13 to 14 months.[468,469]

Oxaliplatin's role in combination with a fluorinated pyrimidine in patients with disease that is refractory to 5-FU/LV was demonstrated by partial responses in 20 of 97 patients with documented progression on infusional 5-FU/LV who received the same initial regimen with oxaliplatin 85 mg/m^2, a response rate that is approximately double that for oxaliplatin as a single agent in second-line therapy. The median duration of response was 7.5 months.[470] The combination of continuous intravenous infusion 5-FU with oxaliplatin was shown to improve response rates compared with high-dose infusional 5-FU alone in several small trials, with response rates between 29% and 58%.[455,456,471]

Initial treatment for 420 patients with intravenously administered LV5FU2 (de Gramont-5-FU bolus 400 mg/m^2/day for 2 days, followed by 22-hour infusion of 600 mg/m^2/day for 2 days administered every 2 weeks) with oxaliplatin 85 mg/m^2 on day 1 [FOLFOX]) was shown to be superior to LV5FU2 without oxaliplatin, producing an improvement in progression-free survival from 6.2 months to 9 months, and improving the response rate from 22.3% to 50.7%. The study cohort was too small, however, to show an improvement in OS (16.2 months versus 14.7 months, $P = 0.12$).[457]

The combination results in a 42% rate of grade III to IV neutropenia, 12% grade III/IV diarrhea, and 18% grade III neurotoxicity, which is the most common reason for discontinuing therapy.[457] When compared with a 5-day chronomodulated 5-FU infusion (700 mg/m^2/day given for 5 days, with peak dose delivered at 4:00 A.M.) with oxaliplatin, 125 mg/m^2 versus the same 5-FU/LV regimen, there was a difference in response rate (53% for the oxaliplatin/FU/LV versus 16% for the 5-FU/LV) and a trend for progression-free survival (8.7 months versus 6.1 months, $P = 0.48$).[472] This regimen also resulted in a 43% rate of grade III to IV diarrhea, 13% moderate neuropathy, and less than 2% grade IV neutropenia.[472]

The survival benefit that FOLFOX provided was definitively demonstrated in N9741, a National Cancer Institute-sponsored cooperative group trial led by the North Central Cancer Treatment Group, which incorporated six different treatment arms. Time to progression for FOLFOX compared with IFL was 8.7 months versus 6.9 months ($P = 0.0014$), response rates were 45% versus 31% , and the overall survival was 19.5 months versus 15.0 months ($P = 0.0001$), unequivocally demonstrating that FOLFOX can prolong survival as first-line therapy for metastatic colon cancer.[427] A three-arm trial for second-line use of FOLFOX after disease progression on IFL found no response to infusional 5-FU (LV5FU2), a 1.3% response rate for oxaliplatin alone, and a 9% response rate for FOLFOX.[473] Two subsequent trials comparing infusional 5-FU regimens combined with either oxaliplatin or irinotecan (FOLFIRI versus FOLFOX) in first-line metastatic colorectal carcinoma did not demonstrate differences in either progression-free or overall survival.[429,474]

A series of combinations of oxaliplatin on the background of de Gramont bolus and infusions of 5-FU/LV (LV5FU2) have been published, referred to collectively as FOLFOX 1 to 7. Table 81-9 lists selected combination regimens. The FOLFOX 4 regimen is inconvenient for patients and caregivers, requiring a second intravenous 2-hour infusion of LV and 5-FU on the second day. FOLFOX 6 has yielded similar results as second-line therapy, with a response rate of 27% and a median survival of 10.9 months, and it is now commonly used in clinical trials.[475]

Oxaliplatin has also been combined with capecitabine for patients with metastatic disease. Oxaliplatin and capecitabine were given to 43 patients, with a response rate of 44%. Diarrhea was dose limiting, occurring in 28% of the patients.[476] The median OS was 20 months

Table 81-9 Commonly Used 5-FU/LV Chemotherapy Combination Regimens

Regimen	Doses/Schedule	Reference
IFL	Irinotecan 125 mg/m^2 over 90 minutes day 1: LV 20 mg/m^2 IV bolus; 5-FU 500 mg/m^2 IV bolus weekly for 4 weeks followed by 2-week rest in a 6-week cycle	Saltz et al.[492]
FOLFIRI	Irinotecan 180 mg/m^2 in 90-minute infusion day 1; leucovorin 200 mg/m^2 IV over 2 hours after irinotecan administration or concurrently with irinotecan in separate infusion line day 1; 5-FU bolus 400 mg/m^2, followed by 5-FU 22-hour continuous infusion 600 mg/m^2 day 1 and day 2, every 2 weeks	Douillard et al.[493]
FOLFOX 4*	Oxaliplatin 85 mg/m^2 over 120 minutes day 1; LV 200 mg/m^2 2-hour infusion day 1 and day 2; 5-FU 400 mg/m^2 IV bolus plus 5-FU 600 mg/m^2 IV over 22 hours day 1 and day 2, every 2 weeks	Andre et al.[470]
FOLFOX 6	Oxaliplatin 100 mg/m^2 over 120 minutes day 1; LV 400 mg/m^2 2-hour infusion day 1; 5-FU bolus 400 mg/m^2 plus 2400 (to 3000) mg/m^2 46-hour (–48-hour) infusion day 1, every 2 weeks	Maindrault-Goebel et al.[475]
mFOLFOX 6	Oxaliplatin 85 mg/m^2 over 120 minutes day 1; 1-LV 175 mg/m^2—2-hour infusion day 1; 5-FU bolus 400 mg/m^2 plus 2400 (to 2800) mg/m^2 46 hour–48-hour infusion day 1, every 2 weeks	Braun et al.,[480] Cheeseman et al.,[†]
FOLFOX 7	Oxaliplatin 130 mg/m^2 over 120 minutes day 1; LV 400 mg/m^2 2-hour infusion day 1; 5-FU bolus 400 mg/m^2 plus 2400 mg/m^2 46-hour infusion day 1, every 2 weeks	Maindrault-Goebel et al.[481]
FLOX	LV 500 mg/m^2 IV over 2 hours; 5-FU 500 mg/m^2 IV bolus 1 hour after the infusion has begun weekly (days 1, 8, 15, 22, 29, 35) for 6 weeks followed by a rest period; Oxaliplatin 85 mg/m^2 IV over 120 minutes before the 5-FU and LV (days 1, 15, 29). Repeat treatment begins 21 days after last dose previous cycle (1 cycle = 8 weeks) for a total of 3 cycles	Kuebler and de Gramont[482]
CAPOX	Oxaliplatin 120–130 mg/m^2 over 120 minutes day 1; capecitabine 1000–1250 mg/m^2 po bid days 1–14, every 3 weeks	Zeuli et al.,[476] Scheithauer et al.,[477] Sumpter et al.,[478] Borner et al.[479]
IROX	Oxaliplatin 85 mg/m^2 IV over 120 minutes day 1; irinotecan 200 mg/m^2 IV over 30 minutes day 1, every 3 weeks	Goldberg et al.[427]

*The doses of leucovorin used in the FOLFOX4 regimen may vary; some refer to D,L-leucovorin and some to pure L-leucovorin.

[†]Cheeseman SL, Joel SP, Chester JD, et al: A modified de Gramont regimen of fluourouracil alone and with oxaliplatin, for advanced colorectal cancer. Br J Cancer 2002;87:393–399.

in this phase II study. Additional studies have been published, including both formal trials and institutional experiences.[477–479] Oxaliplatin (130 mg/m^2 on day 1) and capecitabine (1250 mg/m^2 twice daily on days 1 to 14 every 3 weeks) produced a partial response rate of 49% in 42 patients without prior therapy and in 15% of 26 patients with prior 5-FU.[479] Borner and colleagues[479] recommend a reduced dose of capecitabine (to 1000 mg/m^2 twice daily) for patients with prior therapy. Two- and three-week courses were also explored in a randomized trial of either

- Oxaliplatin, 130 mg/m^2 on day 1 with capecitabine, 1000 mg/m^2 twice daily for 14 days of a 21-day cycle

or

- Oxaliplatin, 85 mg/m^2 on day 1 with capecitabine, 1750 mg/m^2 twice daily for the first 7 days of a 14-day cycle in 89 patients. The biweekly regimen had a higher response rate (54.5% versus 42.2%) and a longer progression-free survival (10.5 months versus 6 months, $P = 0.013$). Overall survival was not reported because the median had not been reached.[477]

Cumulative delayed neuropathy frequently limits the total dose of oxaliplatin that can be delivered; the median time to development of grade 3 neuropathy is 22 weeks,[430] with approximately 70% of patients stopping treatment without evidence of disease progression. In an effort to delay the onset of cumulative neurotoxicity that would result in discontinuation of treatment, a modified FOLFOX 6 (mFOLFOX 6) regimen appears to maintain efficacy in phase II studies and is being used in several trials.[480–482] An additional approach to circumvent this limitation is the use of interrupted schedules of oxaliplatin (OPTIMOX regimens).[483] The initial study evaluated the use of six 2-week cycles of FOLFOX 7 (with 130 mg/m^2 oxaliplatin), followed by 12 weeks of weekly infusions of 5-FU and LV, followed by a second six 2-week cycles of FOLFOX 7 compared in a randomized trial to FOLFOX 4. Patients receiving FOLFOX 4 (the control arm) had a median time on treatment of 12 cycles (24 weeks), median PFS of 9 months, and OS of 19.3 months with a response rate of 58.5%; patients receiving 6 cycles of FOLFOX 7 followed by maintenance weekly LV5FU2 (the investigational arm) had a median time on treatment of 15 cycles (30 weeks, with the 6 cycles of FOLFOX 7 being the median received), median PFS of 8.7 months and OS of 21.2 months with a response rate of 59.2%. As anticipated, 17.9% of patients receiving FOLFOX 4 had grade III neuropathy; despite the higher biweekly doses of oxaliplatin in patients receiving OPTIMOX the incidence was 13.3% ($P = 0.12$); no patients in either arm had grade IV neuropathy, suggesting that physician and patient decisions to discontinue oxaliplatin (which occurred at a median of 12 cycles in patient receiving FOLFOX 4) might have minimally reduced the number of patients with moderate neuropathy compared to automatically stopping at 6 cycles of FOLFOX 7.

Delayed peripheral neuropathy and acute oral-pharyngeal dysesthesia occur in many patients who are receiving oxaliplatin and are particularly exacerbated by cold exposure.[427,468,484] The acute dysesthesia can be quite disconcerting for patients if they have not been warned in advance. Patients can experience a "TMJ-like syndrome"

when chewing; a sharp pain can occur with the first few bites and then abate quickly as the meal continues. Patients can also experience an acute dysesthesia during or shortly after drug infusion, which produces a sensation that they are not breathing, although their tidal volume and oxygenation remain normal. The sensation subsides quickly and is well addressed by forewarning the patient and providing reassurance. Grade III delayed neurotoxicity can present as a fine movement disturbance, as tingling or numbness in a peripheral sensory neuropathy, or as ataxia at an oxaliplatin median cumulative dose of 900 mg/m^2 (about 10 doses/20 weeks). The incidence increases from 10% of patients at 790 mg/m^2 to 50% at 1170 mg/m^2 to 75% of patients receiving 1560 mg/m^2. The likelihood that neurologic symptoms will regress after treatment is discontinued is inversely related to cumulative dose and severity of the neuropathy. Within 4 to 6 months, grade I to II neuropathy will have improved in 82% of patients and will have resolved entirely in 41% of patients by 6 to 8 months. The neurotoxicity of oxaliplatin has been reviewed recently.[485] Grade III or worse neutropenia occurs in 50% of patients receiving FOLFOX.[427] Other toxicities that are commonly reported are nausea and vomiting (which usually are well controlled with 5-HT3 antagonists), anemia, and infrequent diarrhea.

Irinotecan

Irinotecan is a prodrug that is catabolized to its much more potent, active form, SN-38, which interacts to stabilize topoisomerase I bound to DNA, resulting in DNA strand breaks. It was approved by the U.S. FDA in 1997 for the treatment of patients with refractory colorectal cancer. The response rate for single-agent irinotecan is 32% in patients without prior therapy and 13% in patients with prior 5-FU therapy, with a median duration of response of 9 months.[486–488] The U.S. phase III trials used a schedule of 125 mg/m^2 weekly for 4 out of 6 weeks, and the European trials used 300 mg/m^2 once every 3 weeks. A randomized trial comparing these two schedules for patients with progression on 5-FU/LV confirmed that there was no difference in response rate, survival, or time to progression.[489] The type of serious toxicity differed between the two schedules: Grade III to IV diarrhea was reported in 36% of patients treated weekly and in 19% of patients receiving the therapy every 3 weeks, while grade III to IV neutropenia occurred in 29% of weekly and 34% of triweekly patients. Treatment-related mortality was high in both regimens: 5.3% and 1.3%, respectively. Acute cholinergic symptoms and nausea were more common with the triweekly schedule.[489] Irinotecan alone is somewhat more toxic than 5-FU/LV regimens, producing severe or life-threatening neutropenia and diarrhea in one fourth to one third of patients. Despite the combination of neutropenia and diarrhea, neutropenic fever was unusual (4 of 121 patients, or 3.3%).[486,487] Patients with prior radiation therapy are more likely to develop severe leucopenia. Diarrhea can generally be well controlled with the aggressive use of loperamide. During the infusion, irinotecan can produce nausea, vomiting, and cholinergic symptoms (sweating, cramping, nasal stuffiness, and acute diarrhea). Rougier and Bugat have reviewed clinical experience with irinotecan.[487]

Second-line single agent irinotecan was initially shown to improve survival in patients with disease progression on 5-FU/LV when compared with either best supportive care or infusional 5-FU.[490,491] Rougier and colleagues[490] reported a randomized trial of irinotecan versus fluorouracil by continuous infusion after fluorouracil failure in patients with metastatic colorectal cancer, and Cunningham and coworkers[491] reported a randomized trial of irinotecan plus supportive care versus supportive care alone after fluorouracil failure for patients with metastatic colorectal cancer. The trial comparing infusional therapy and irinotecan (300–350 mg/m^2) given every 3 weeks permitted sites to use their infusional regimen of choice—either the de Gramont bolus/46-hour infusion every 2 weeks, the Lokich continuous infusion, or the AIO 24-hour infusion weekly (see Table 81-8)—and demonstrated better response rates, progression-free survival (5.2 months versus 2.9 months), and 1-year survival rates (54% versus 32%) for the combination with irinotecan. For patients with disease progression after initial 5-FU/LV treatment, median survival was 10.1 months, compared with 8.5 months for patients receiving infusion 5-FU.[490,491]

The overlapping dose-limiting toxicity—diarrhea—initially precluded delivering both 5-FU and irinotecan at full doses at maximal dose intensity.

Two combination regimens have been in widespread use: IFL (and modified IFL) and FOLFIRI.[492] It has also been feasible to combine irinotecan and oxaliplatin with 5-FU in one regimen.[432] IFL in comparison with 5-FU/LV bolus daily for 5 days resulted in significantly longer progression-free survival (median: 7.0 versus 4.3 months; $P = 0.004$), higher response rate (39% versus 21%, $P < 0.001$), and longer OS (median: 14.8 months versus 12.6 months; $P = 0.04$).[492] Combining irinotecan with 48-hour infusional schedules (FOLFIRI) also improved time to progression (median: 6.7 months versus 4.4 months; $P < 0.001$), response rate (35% versus 22%, $P < 0.005$) and OS (median: 17.4 months versus 14.1 months, $P = 0.031$).[493]

A direct comparison of FOLFIRI, modified IFL, and CapeIri has been undertaken in a trial of 430 patients, demonstrating a trend for improved efficacy for FOLFIRI compared with either modified IFL or CapeIri (overall response rate: 47% versus 43% versus 39%, P = NS), improved PFS (7.6 versus 5.9 versus 5.8 months, $P = 0.004$) and OS (23.1 versus 17.6 versus 18.9 months, $P = 0.087$).[494]

Careful screening of patients to ensure that they can tolerate IFL's potential for diarrhea and neutropenia, close monitoring during the first month of therapy, aggressive treatment of diarrhea, attention to symptoms and mandated dose adjustments, and institution of aggressive inpatient support (including antibiotics for patients who have neutropenia, diarrhea, and fever) are critical to minimizing mortality associated with this regimen. The life-threatening toxicity of IFL became evident in randomized trials for patients with both metastatic disease and in the adjuvant setting.[430,493] Early deaths on those trials were threefold higher in comparison with the other arms in the trials (2.5% versus 0.8% and 3.5% versus 1.1%). Although these values appeared higher than the treatment-related death rate in the phase III IFL studies (0.2% to 1.3%), it is consistent with the 60-day "all cause" mortality reported in Saltz's original publication.[440,492,493] The subsequent cohort in N9741 received reduced-dose IFL but still had a 3.3% 60-day mortality rate compared to 2% for patients receiving FOLFOX 4.[430]

For patients without prior therapy for metastatic disease (first-line regimens), direct comparison of IFL with FOLFOX (see earlier in the chapter) in a National Cancer Institute-sponsored randomized trial conducted by the North Central Oncology Group with six initial arms found FOLFOX to produce superior response rates (38% versus 29%, $P = 0.03$), time to progression (8.6 months versus 6.9 months, $P = 0.0009$), OS (18.1 months versus 14.4 months, $P = 0.004$), and adverse event profile.[427]

At the cost of manageable increases in neutropenia and neuropathy, it has been feasible to combine infusional 5-FU with oxaliplatin (85 mg/m^2) and irinotecan (165 mg/m^2) with 5-FU (3200 mg/m^2 over 48 hours) every 14 days.[432] In a first-line randomized trial in 244 patients comparing FOLFIRI with FOLFOXIRI, the PFS was 6.9 months versus 9.8 months ($P = 0.0006$), and the OS was 16.7 months versus 22.6 months ($P = 0.032$). The majority of patients (75% to 75%) in both arms received subsequent chemotherapy, again supporting the importance of delivering oxaliplatin in first-line regimens in relationship to increasing survival. A similar-sized trial (283 patients) that used a bolus dose of 5-FU (400 mg/m^2, followed by 600 mg/m^2/24 hours for 2 days) and lower doses of oxaliplatin (65 mg/m^2) and irinotecan (150 mg/m^2) had the same survival trends, without statistical significance: 21.5 months versus 19.5 months ($P = 0.34$), with a time to progression of 8.4 months versus 6.9 months ($P = 0.17$).[495] Falcone and colleagues[432] recommend that FOLFOXIRI be offered, as they did for entry

into that trial, only for older patients with performance status 0 to 1 and younger patients with performance status 0 to 2. The 60-day mortality rates in the HORG trial's arms were 2.7% and 2.9%, while in the GONO trial, there was no treatment-associated mortality.

Antiangiogenic Approaches

Considerable evidence has been developed regarding the importance of angiogenesis in tumor growth and progression.[496] VEGF is a central regulator of normal and neoplastic angiogenesis. Increased expression of VEGF in patients with colorectal carcinoma has been associated with recurrence and poor prognosis.[497]

Bevacizumab

Bevacizumab (anti-VEGF, Avastin, Genentech) is a human monoclonal antibody directed at VEGF as an antiangiogenic strategy and is now approved for use with 5-FU-containing regimens for patients with metastatic colorectal carcinoma. Several large randomized phase III studies in colon cancer have been published. Bevacizumab (5 mg/kg daily every other week with IFL, which was the "standard" U.S. first-line regimen at the time the study was initiated) was compared with IFL alone in 925 patients receiving initial treatment for metastatic colorectal carcinoma. Median survival was 20.3 versus 15.6 months, the PFS was 10.6 months versus 6.2 months, and the response rate was 45% versus 35%, respectively.[428] In 2004, the U.S. FDA approved bevacizumab in combination with 5-FU-based chemotherapy for first-line treatment. The role of bevacizumab has been evaluated in patients who previously had been given IFL, randomizing 829 patients to second-line treatment FOLFOX plus bevacizumab versus FOLFOX versus bevacizumab alone.[431] The PFS was 7.3 months for the triplet compared with 4.7 months for second-line FOLFOX 4 (hazard ratio: 0.61, $P = 0.0001$) and 2.7 months for bevacizumab as a single agent. Survival was also improved in those receiving the triplet: 12.9 months versus 10.8 months versus 10.2 months (with many patients receiving additional treatment postprotocol).

An intergroup phase III trial led by SWOG compared mFOLFOX 6 to CAPOX with or without bevacizumab in a 2×2 factorial design for patients with metastatic disease who had not previously received chemotherapy, but results are not yet available. A phase II study of two doses of bevacizumab (5 or 10 mg/kg every 2 weeks) with 5-FU and folinic acid (weekly) in patients without prior chemotherapy produced response rates of 40% in the low-dose arm, 24% in the high-dose arm, and 17% in the chemotherapy-alone arm; longer time to progression (9 months versus 7.2 months versus 5.2 months, respectively), and improved survival (21.5 months versus 16.1 months versus 13.8 months, P = NS) were also noted. Only 2 of 22 patients who were treated with bevacizumab as second-line therapy after failure of chemotherapy alone had partial responses, and median time to progression for these patients was only 2 months.[498] The current National Cancer Institute-sponsored first-line trial compares the administration of either FOLFOX or FOLFIRI with cetuximab and/or bevacizumab.[499]

In common with most targeted therapies and in contrast to the unrealistic expectation that such treatments will be as benign as low-dose aspirin, bevacizumab treatment is associated with adverse events, including hypertension (generally responsive to medical management but severe on rare occasions), thrombotic events and bleeding (venous and arterial), bowel perforation, and delayed wound healing. An increased incidence of hypertension was observed on the bevacizumab arm of the IFL bevacizumab study (11% versus 2.3%), as was an increase in bowel perforation, but there was no statistically significant increase in grade III or IV bleeding (2.5% versus 3.1%) or thromboembolic events (16.1% versus 19.3%). If major surgery is required during treatment, wound complications increased from 1 of 29 control patients to 10 of 75 patients receiving bevacizumab.[500,501] In patients with lung cancer, lethal hemoptysis has been reported; an increased rate of perforation and gastrointestinal bleeding can occur in patients with colon cancer; and other serious and life-threatening hemorrhages have been reported. Less serious events include epistaxis (grade I or II), proteinuria with rare nephrotic syndrome, fever, headache, and rash.

Many additional antiangiogenic approaches are currently in clinical development for patients with colon carcinoma, including other agents directed at VEGF itself (VEGF-TRAP) and additional small molecules directed at the VEGF, such as sunitinib, sorafinib, vandetinib, and cediranib. Other elements of angiogenesis have been shown to be upregulated in colorectal carcinoma, such as CXCL1.[502]

New Molecularly Targeted Agent: Epidermal Growth Factor Receptor

Four related receptor tyrosine kinases (ErbB1, ErbB2, ErbB3, ErbB4) are involved as heterodimers in proliferative signaling as both autocrine and paracrine mediators of the RAS/RAF/MAPK and PI3K/AKT pathways, among others. Each protein has extracellular, transmembrane, and intracellular ATP-binding sites that present potential therapeutic targets. Monoclonal antibodies to the extracellular domain are presumed to act by preventing ligand binding and dimerization. Agents that mimic the intracellular ATP-binding site interfere with the tyrosine kinase phosphorylation and downstream activation of proliferative networks. These interactions can produce cell cycle arrest, potentiate apoptosis, and reduce angiogenesis, invasion, and metastases in the laboratory.[503,504]

ErbB1 (EGFR) is overexpressed in 25% to 77%[505] and expressed in 80% to 90% of screened patients[506] with colorectal cancers. Overexpression is associated with poor prognosis.[507] However, there is no evidence that overexpression is required for activity of EGFR-directed therapy. Overexpression of erbB2 (Her-2/neu), the target of trastuzumab (herceptin), is infrequent in colorectal carcinoma, resulting in very limited accrual of patients to a clinical trial of trastuzumab.

Two EGFR-directed antibodies have been approved for the treatment of patients with advanced colorectal carcinoma: cetuximab, a chimeric antibody, and panitumumab, a fully human antibody. Cetuximab (C-225, IMC-C225, Erbitux, Imclone) is a partially humanized (chimeric) IgG1 antibody directed at EGFR. Binding of both natural ligands (EGF and transforming growth factor-α) is blocked, and ligand-induced activation of the tyrosine kinase is inhibited. When used as a single agent in 346 patients with advanced disease that is refractory to irinotecan, oxaliplatin, and fluorinated pyrimidines, the response rate was 11.6%, with a PFS of 1.4 months and an OS of 6.6 months.[506,508]

A randomized phase III trial was performed in Europe, in which a total of 329 patients with metastatic colorectal cancer whose disease had progressed on a previous irinotecan-based therapy were randomized in a 2 : 1 manner to either cetuximab plus irinotecan or cetuximab alone. The response rate (primary endpoint of the study) in patients who received the combination was 23% compared with 11% in those who received cetuximab alone. The median time to progression was 4.1 months in the combination arm compared with 1.5 months in the single-agent arm. There was no difference in OS between the two arms; however, patients were allowed to cross over from the single-agent arm to the combination arm at progression.[508] In 2004, the U.S. FDA approved cetuximab for use in second-line treatment.

Preliminary results of a randomized trial for 1217 patients with metastatic disease treated initially with either FOLFIRI plus cetuximab versus FOLFIRI demonstrated an increase in overall response rate (46.9% versus 38.7%, $P = 0.005$) and median PFS (8.9 months versus 8 months, $P = 0.036$).[509] In a randomized trial in 572 EGFR-expressing patients who had received two prior combination regimens, single-agent cetuximab had a documented benefit in median OS of 6.1 months versus 4.6 months for best supportive care.[510]

Adverse events related to cetuximab include the mechanism-associated acneiform skin rash, which occurs in 75% of patients

but is grade III or IV in only 15%, and allergic infusion reactions, which are reported in 21% of patients, although only 1% to 5% have severe reactions.[505,506,508,510] Patients also can have fatigue, nausea, emesis, and diarrhea; one third of patients have these symptoms, with fewer than 10% at an intensity of grade III or IV.[511] CALBG attempted to compare first-line chemotherapy (FOLFOX or FOLFIRI) with or without cetuximab, but the trial was prematurely terminated with only 238 patients accrued. The response rate was higher for each combination with cetuximab: FOLFIRI: 36%, FOLFIRI plus cetuximab: 44%, FOLFOX: 40%, FOLFOX + cetuximab: 60%, but PFS data might lack statistical significance when available.[512]

Panitumumab is a fully human IgG2 antibody. It was approved by the FDA on the basis of a randomized trial of 6 mg/kg every other week with best supportive care versus best supportive care in 463 third-line patients with EGFR expression out of 1040 screened patients.[505] The partial response rate, 10%, was consistent with prior phase II trials presented at AACR and ASCO meetings. PFS was 49% at 8 weeks for patients receiving panitumumab versus 30% for patients receiving best supportive care alone. The mean PFS was 13.8 versus 8.5 weeks. However, the large randomized phase III trial adding panitumumab to FOLFOX/bevacizumab and FOLFIRI/bevacizumab has not demonstrated benefit in multiagent first-line therapy.[513] Like other antibodies, panitumumab has a long half-life (7 days) and can be administered at doses of 2.5 mg/kg weekly or 6 mg/kg every other week. The EGFR-mediated skin rash occurs in 90% of treated patients, but only 14% have grade III or IV cutaneous toxicity. As a fully human antibody, panitumumab has a slightly lower rate of allergic reactions compared to chimeric antibodies (e.g., 1% for panitumumab and 3% to 5% for cetuximab).[514] Several additional anti-EGFR monoclonal antibody or related compounds (EMD 72000) are also in early clinical development.

Gefinitib (ZD1839, Iressa), erlotinib (OSI-774, Tarceva), PKI-166, and GW2016 are small molecule inhibitors of the phosphorylation of EGFR. These agents are dose limited by both the mechanism-specific acneiform rash and diarrhea. As single agents, they have not produced responses in phase II trials in patients with refractory colorectal carcinoma, although there was evidence that gefitinib inhibited EGFR activity and decreased proliferation in patients.[515,516] The reasons for the difference in activity of the antibodies and small molecules in colon cancer is being explored actively, and combinations of novel agents are being evaluated. For example, a phase III trial of FOLFOX/bevacizumab or CAPEOX/bevacizumab ± erlotinib is accruing 640 patients in Europe, CALGB 80405 was discussed earlier (in the section on Bevacizumab), and SWOG 0600 will accrue 1260 second-line patients to a three-arm trial comparing an irinotecan regimen (either irinotecan or FOLFIRI) with either (1) cetuximab, (2) cetuximab and bevacizumab, or (3) cetixumab and higher-dose bevacizumab.

Immunologic Approaches to the Treatment of Colon Cancer

Attempts to activate lymphocytes and/or antibodies that would eliminate colon cancer have been undertaken for decades. Tumor-associated antigens present targets for these effector arms (which might be activated by enhancing the immunogenicity of the tumor-associated antigens) and by increasing the activity of the immune response. In the third in a series of adjuvant trials in patients with stage II and III disease, comparing vaccination with autologous tumor cells mixed with bacille Calmette-Guérin for three weekly doses postoperatively in 412 patients, no improvement in DFS or OS was evident.[517] In a phase II trial, the autologous tumor cell plus bacille Calmette-Guérin approach was combined with 5-FU/LV to assess alterations in immunity; delayed-type hypersensitivity measured by induration decreased only from 20.3 mm to 18.4 mm.[518] Addition of a fourth vaccination at 6 months, when immunity was waning, was evaluated in a randomized trial involving 254 patients. This study was felt to have better quality control for the vaccine production (one facility was used, and 98% of all vaccines met quality control specifications); 97% of all patients receiving vaccine developed induration greater than 5 mm by the third vaccination, compared with only 88% of the vaccines prepared and only 85% of the patients developing induration in the ECOG trial. Only 101 of 128 vaccination patients received all four vaccinations, however. The four-year DFS rate was 70% versus 59% for those who were observed, but there was no difference in OS.[382]

Another strategy for breaking tolerance to tumor antigens is to use anti-idiotype antibodies that mimic the tumor-associated antigen and permit the immune system to generate anti-anti-idiotype antibodies that also recognize the tumor antigen. CeaVac (3H1 IgG) is an anti-idiotype murine monoclonal antibody to a murine antibody against CEA, and TriAb (11D10 IgG) is a murine anti-idiotype antibody to a murine antibody against HMFG (another tumor-associated antigen).[519] These are being evaluated in patients who have had resection of liver metastases as adjuvant therapy.
