In people with diabetes, the beneficial effects of exercise are accompanied by an increased risk of hypoglycemia. Although muscle uptake of glucose increases significantly, the ability to maintain blood glucose levels is hampered by failure to suppress the absorption of injected insulin and activate the counterregulatory mechanisms that maintain blood glucose. Not only is there an inability to suppress insulin levels, but also insulin absorption may increase. This increased absorption is more pronounced when insulin is injected into the subcutaneous tissue of the exercised muscle, but it occurs even when insulin is injected into other body areas. Even after exercise ceases, insulin's lowering effect on blood glucose continues. In some people with type 1 diabetes, the symptoms of hypoglycemia occur several hours after cessation of exercise, perhaps because subsequent insulin doses (in people using multiple daily insulin injections) are not adjusted to accommodate the exercise-induced decrease in blood glucose. The cause of hypoglycemia in people who do not administer a subsequent insulin dose is unclear. It may be related to the fact that the liver and skeletal muscles increase their uptake of glucose after exercise as a means of replenishing their glycogen stores, or that the liver and skeletal muscles are more sensitive to insulin during this time. People with diabetes should be aware that delayed hypoglycemia can occur after exercise and that they may need to alter their diabetes medication dose, their carbohydrate intake, or both.

Although of benefit to people with diabetes, exercise must be weighed on the risk–benefit scale. Before beginning an exercise program, persons with diabetes should undergo an appropriate evaluation for macrovascular and microvascular disease.[30] The goal of exercise is safe participation in activities consistent with an individual's lifestyle. As with nutrition guidelines, exercise recommendations need to be individualized. Considerations include the potential for hypoglycemia, hyperglycemia, ketosis, cardiovascular ischemia and arrhythmias (particularly silent ischemic heart disease), exacerbation of proliferative retinopathy, and lower extremity injury. For those with chronic diabetes, the complications of vigorous exercise can be harmful and cause eye hemorrhage and other problems. For people with type 1 diabetes who exercise during periods of poor control (i.e., when blood glucose is elevated, exogenous insulin levels are low, and ketonemia exists), blood glucose and ketones rise to even higher levels because the stress of exercise is superimposed on preexisting insulin deficiency and increased counterregulatory hormone activity.

Oral and Injectable Antidiabetic Agents

Historically, two categories of antidiabetic agents existed: insulin injections and oral medications. However, this classification has become somewhat blurred owing to the introduction of new injectable antidiabetic agents (e.g., glucagon-like peptide-1 and amylin analogs). Because people with type 1 diabetes are deficient in insulin, they are in need of exogenous insulin replacement therapy from the start. People with type 2 diabetes can have increased hepatic glucose production; decreased peripheral utilization of glucose; decreased utilization of ingested carbohydrates; and, over time, impaired insulin secretion and excessive glucagon secretion from the pancreas (Fig. 33-8). The antidiabetic agents used in the treatment of type 2 diabetes (insulin secretagogues, biguanides, α-glucosidase inhibitors, thiazolidinediones, and incretin-based agents) attack each one of these areas and sometimes all.[31,32] If good glycemic control cannot be achieved with one or a combination of antidiabetic agents, insulin can be added or used by itself.

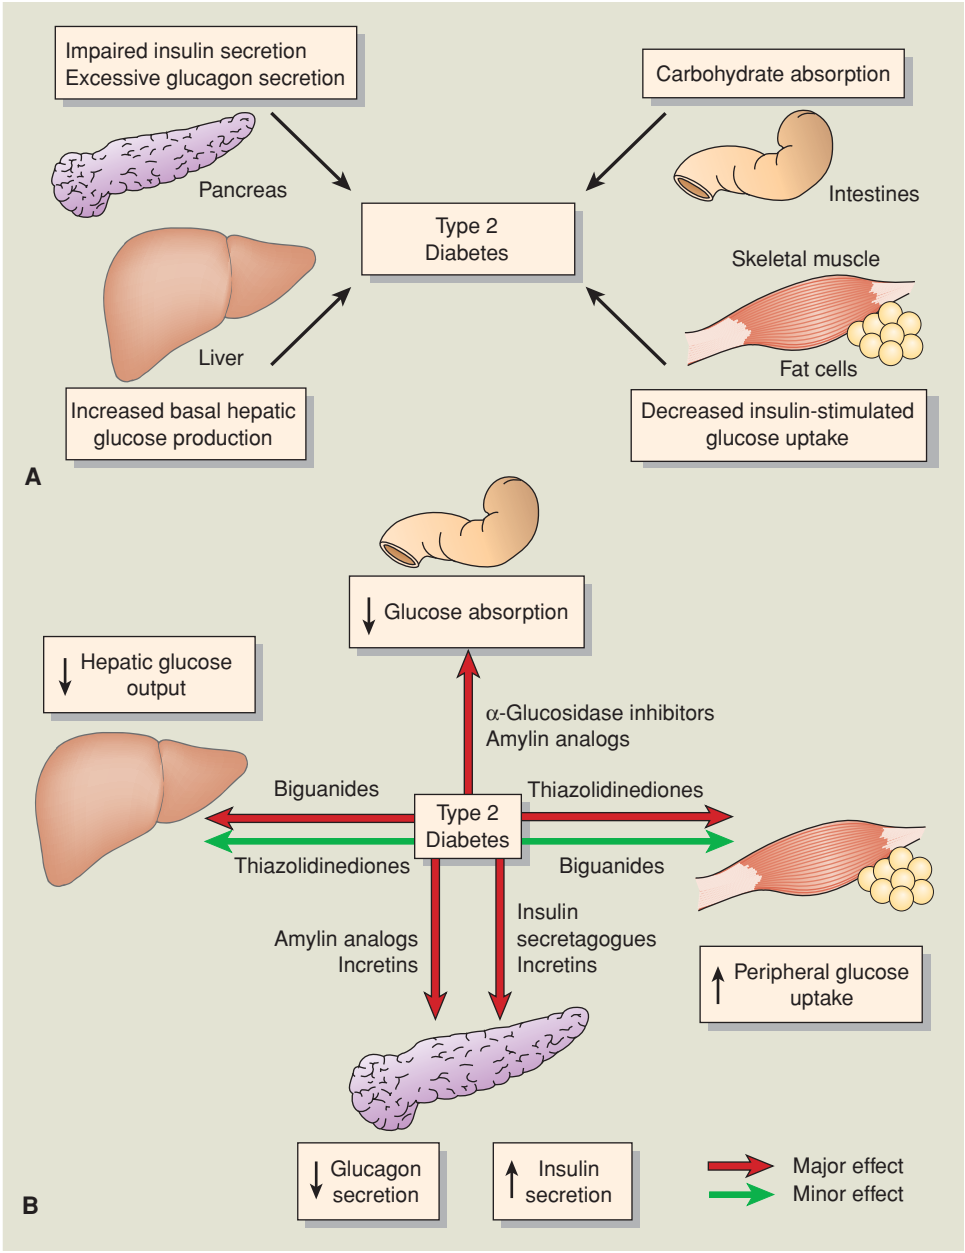

FIGURE 33-8. **(A)** Mechanisms of elevated blood glucose in type 2 diabetes mellitus. **(B)** Action sites of hypoglycemic agents and mechanisms of lowering blood glucose in type 2 diabetes. The incretins are the dipeptidyl peptidase-4 (DPP-4) inhibitors and glucagon-like peptide-1 (GLP-1) agonists.

Insulin Secretagogues. The insulin secretagogues act at the level of the pancreatic beta cells to stimulate insulin secretion. There are two general classes of insulin secretagogues: sulfonylureas and meglitinides and related drugs.[32] Both types of secretagogues require the presence of functioning beta cells, are used only in the treatment of type 2 diabetes, and have the potential for producing hypoglycemia.

The control of insulin release from the pancreatic beta cells by glucose or the sulfonylurea drugs requires the generation of adenosine triphosphate (ATP), closing of an ATP-gated potassium channel, and opening of a transmembrane calcium channel.[32] The sulfonylureas (e.g., chlorpropamide, glipizide, glyburide, glimepiride) act by binding to a high-affinity sulfonylurea receptor on the beta cell that is linked to an ATP-sensitive potassium channel (Fig. 33-9). Binding of a sulfonylurea closes the channel, resulting in a coupled reaction that leads to an influx of calcium ions and insulin secretion. Because the sulfonylureas increase insulin levels and the rate at which glucose is removed from the blood, it is important to recognize that they can cause hypoglycemic reactions. This problem is more common in elderly people with impaired hepatic and renal function who are taking the longer-acting sulfonylureas.

The meglitinides (repaglinide) and related drugs (nateglinide) are relatively new insulin secretagogues that require the presence of glucose for their main action. These agents exert their action by closing the ATP-dependent potassium channel in the beta cells (see Fig. 33-9). Insulin

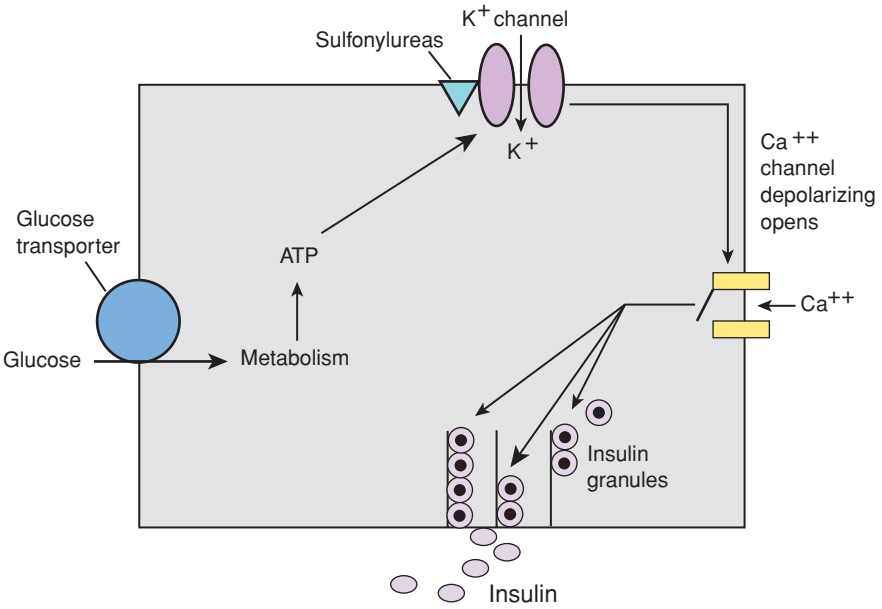

FIGURE 33-9. One model of control of release of insulin by the pancreatic beta cells and the action of the sulfonylurea agents. In the resting beta cell with low adenosine triphosphate (ATP) levels, potassium diffuses through the ATP-gated channels, maintaining the resting membrane potential. As blood glucose rises and is transported into the beta cell by the glucose transporter, ATP rises, causing the potassium channels to close and depolarization to occur. Depolarization results in opening of the voltage-gated calcium channels, which results in insulin secretion. (Modified from Karam J.H. [1992]. Type II diabetes and syndrome X. *Endocrinology and Metabolism Clinics of North America* 21, 339.)

release is glucose dependent and diminishes at low glucose levels. These agents, which are rapidly absorbed from the gastrointestinal tract, are taken shortly before meals (repaglinide 15 to 30 minutes and nateglinide 1 to 30 minutes). Both repaglinide and nateglinide can produce hypoglycemia; thus, proper timing of meals in relation to drug administration is essential.

Biguanides. *Metformin,* the only currently available biguanide, inhibits hepatic glucose production and increases the sensitivity of peripheral tissues to the actions of insulin. Secondary benefits of metformin therapy include weight loss and improved lipid profiles. Unlike the insulin secretagogues, whose primary action is to increase insulin secretion, metformin exerts its beneficial effects on glycemic control through decreased hepatic glucose production (main effect) and increased peripheral use of glucose. This medication does not stimulate insulin secretion; therefore, it does not produce hypoglycemia. Because of the risk for lactic acidosis, metformin is contraindicated in people with elevated serum creatinine levels, clinical and laboratory evidence of liver disease, or conditions associated with hypoxemia or dehydration.[32]

α-Glucosidase Inhibitors. The α-glucosidase inhibitors (acarbose, miglitol) block the action of intestinal brush border enzymes that break down complex carbohydrates.[32] In persons with type 2 diabetes, sulfonylureas, biguanides, or both may have beneficial effects on FPG levels. However, postprandial hyperglycemia persists in many persons and probably accounts for sustained increases in A1C levels. By delaying the breakdown of complex carbohydrates, the α-glucosidase inhibitors delay the absorption of carbohydrates from the gut and blunt the postprandial increase in plasma glucose and insulin levels. Although not a problem with monotherapy or combination therapy with a biguanide, hypoglycemia may occur with concurrent sulfonylurea treatment. If hypoglycemia does occur, it should be treated with glucose (dextrose) and not sucrose (table sugar), whose breakdown may be blocked by the action of the α-glucosidase inhibitors.

Thiazolidinediones. The thiazolidinediones (TZDs) or glitazones (e.g., pioglitazone, rosiglitazone) are the only class of drugs that directly target insulin resistance, a fundamental defect in the pathophysiology of type 2 diabetes. The TZDs improve glycemic control by increasing insulin sensitivity in the insulin-responsive tissues—liver, skeletal muscle, and fat—allowing the tissues to respond to endogenous insulin more efficiently without increased output from already dysfunctional beta cells.[3,32] Pioglitazone and rosiglitazone are both approved for use as monotherapy and in combination therapy. Because of the previous problem with liver toxicity in this class of drugs, liver enzymes should be monitored according to guidelines. Both agents can cause fluid accumulation and are therefore contraindicated in patients with New York Heart Association stage III and IV heart failure[33] (see Chapter 20, Table 20-1). In addition, there is increased risk of bone fractures with both compounds.[34]

The mechanism of action of the TZDs is complex and not fully understood. The action of the TZDs is associated with binding to PPAR-γ[32] (Fig. 33-10). Binding of the TZDs to PPAR-γ begins a cascade of events leading to regulation of genes involved in lipid and glucose metabolism. They result in an increase in the number of GLUT-4 transporters and increased insulin-mediated uptake of glucose in the peripheral tissues. *Adiponectin* is produced by adipocytes and directly sensitizes the body to the actions of insulin, and may be a part of the missing link in explaining insulin resistance in persons with type 2 diabetes.[32] The TZDs are thought to decrease insulin resistance, at least in part by increasing adipocyte production

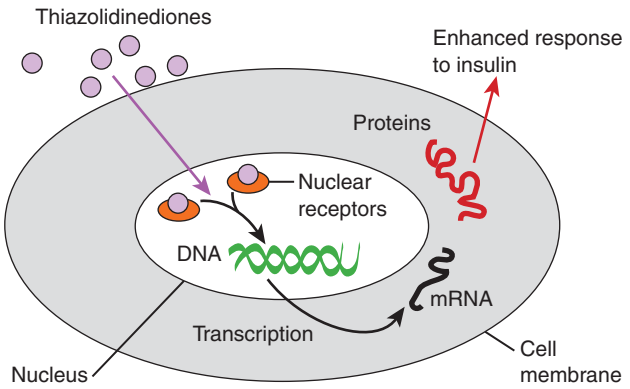

FIGURE 33-10. Action of the thiazolidinediones on activation of the nuclear peroxisome proliferator–activated receptor γ (PPAR-γ) that regulates gene transcription of proteins that regulate glucose uptake and reduce fatty acid release. mRNA, messenger ribonucleic acid.

of adiponectin. Additional effects of TZDs are numerous and include correction of many of the abnormal metabolic features associated with type 2 diabetes. This includes a decrease in FFA and triglycerides, microalbuminuria, blood pressure, inflammatory mediators (e.g., fibrinogen and CRP), and procoagulation factors.[35]

Incretin-Based Agents. Incretins are hormones released into the circulation by the gastrointestinal tract after a meal, especially one high in carbohydrates, that amplify the glucose-induced release of insulin (see Chapter 28).[3,6] The main incretins secreted are glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP).[3,36] Both GLP-1 and GIP are rapidly degraded by the enzyme dipeptidyl peptidase-4 (DPP-4). DPP-4 enzyme inhibitors work by inhibiting the DPP-4 enzyme and increasing GLP-1 and GIP levels, which then increase insulin release. GLP-1 also helps to suppress glucagon release.

Exenatide is a synthetic analog of GLP-1 that is resistant to DPP-4 degradation. Approved in 2005, exenatide was the first type of incretin to become available for treatment of diabetes.[36] Exenatide is approved as an injectable adjunctive therapy for people with type 2 diabetes treated with metformin or sulfonylureas who still have suboptimal glycemic control. The drug has been shown to have multiple actions such as potentiation of glucose-mediated insulin release, slowed gastric emptying, and a central loss of appetite. Exenatide is injected subcutaneously 60 minutes before a meal. When added to preexisting sulfonylurea therapy, the oral hypoglycemic dosage may need to be lowered to prevent hypoglycemia. The major side effects are nausea and weight loss.[36] Although exenatide was the first GLP-1 agonist to be developed and approved, other agents and formulations are in development.

Sitagliptin, approved in 2006, is an oral DPP-4 inhibitor indicated for adjunctive therapy for persons with type 2 diabetes.[36] The drug is given once daily, and may be given in combination with metformin or a thiazolidinedione. Another DPP-4 inhibitor, saxagliptin, was approved in 2009 for treatment of persons with type 2 diabetes either as monotherapy or in combination with metformin, a sulfonylurea, or a thiazolidinedione.[36]

Insulin

Type 1 diabetes mellitus always requires treatment with insulin, and many people with type 2 diabetes eventually require insulin therapy. Insulin is destroyed in the gastrointestinal tract and must be administered by injection or inhalation. An inhaled form of insulin (Exubera) was on the market for a short time in the United States but was withdrawn for commercial reasons. Other inhaled insulin formulations are in clinical development.

During the past several decades, many pharmaceutical companies have entered the insulin manufacturing market. After much research, human insulin has become widely available, providing an alternative to previous forms of insulin that were obtained from bovine and porcine sources. The manufacture of human insulin uses recombinant deoxyribonucleic acid (DNA) technology. More recently, insulin analogs have become available that offer even better and more reproducible release characteristics.[37] In these agents, the human insulin sequence has been modified to improve their pharmacologic properties.

Insulin types are classified by length and peaking of action.[32,37] There are four principal types of insulin: short acting, rapid acting, intermediate acting, and long acting. *Short-acting insulin* (regular) is a soluble crystalline insulin whose effects begin within 30 minutes after subcutaneous injection and generally last for 5 to 8 hours. The *rapid-acting insulins* (lispro, aspart, and glulisine) are produced by recombinant technology with an amino acid substitution. These insulins have a more rapid onset, peak, and duration of action than short-acting regular insulin. The rapid-acting insulins, which are used in combination with intermediate or long-acting insulins, are usually administered immediately before a meal. *Intermediate- to long-acting insulins* include NPH, glargine, and detemir. These insulins have slower onsets and a longer duration of action. They require several hours to reach therapeutic levels, so their use in type 1 diabetes requires supplementation with rapid- or short-acting insulin. *Glargine* and *detemir* have a slower, more prolonged absorption than NPH insulin and provide a relatively constant concentration over 12 to 24 hours. All forms of insulin have the potential to produce hypoglycemia or "insulin reaction" as a side effect (to be discussed).

Two intensive treatment regimens—multiple daily injections and continuous subcutaneous infusion of insulin—closely simulate the normal pattern of insulin secretion by the body. With each method, a basal insulin level is maintained, and bolus doses of short- or rapid-acting insulin are delivered before meals. The choice of management is determined by the person with diabetes in collaboration with the health care team.

With *multiple daily injections* (MDIs), the basal insulin requirements are met by an intermediate- or long-acting insulin administered once or twice daily. Boluses of rapid- or short-acting insulin are used before meals. The development of convenient injection devices (e.g.,

pen injectors) has made it easier for people with diabetes to comply with algorithms for these insulins that are administered before meals.

The *continuous subcutaneous insulin infusion* (CSII) method uses an insulin pump. With this method, the basal insulin requirements are met by continuous infusion of subcutaneous insulin, the rate of which can be varied to accommodate diurnal variations.[38] The CSII technique involves the insertion of a small needle or plastic catheter into the subcutaneous tissue of the abdomen. Tubing from the catheter is connected to a syringe set into a small infusion pump worn on a belt or in a jacket pocket. The computer-operated pump then delivers one or more set basal amounts of insulin. In addition to the basal amount delivered by the pump, a bolus amount of insulin may be delivered when needed (e.g., before a meal) by pushing a button. Although the pump's safety has been proven, strict attention must be paid to signs of hypoglycemia. Self-monitoring of blood glucose levels is a necessity when using the CSII method of management. Hyperglycemia and ketotic episodes caused by pump failure, catheter clogging, and infections at the needle site also are possible complications. Candidate selection is crucial to the successful use of the insulin pump. Only people who are highly motivated to do frequent blood glucose tests and make daily insulin adjustments are candidates for this method of treatment.[38]

Pancreas or Islet Cell Transplantation

Pancreas or islet cell transplantation is not a lifesaving procedure. It does, however, afford the potential for significantly improving the quality of life. The most serious problems are the requirement for immunosuppression and the need for diagnosis and treatment of rejection. Investigators are looking for methods of transplanting islet cells and protecting the cells from destruction without the use of immunosuppressive drugs.[39]

Management of Diabetes in Children

Children with diabetes differ from adults in many respects, including changes in insulin sensitivity related to sexual maturity and physical growth, their ability to provide self-care and need for supervision in child care and school, and vulnerability to hypoglycemia and diabetic ketoacidosis.[11] While current standards of care for diabetes management reflect the need to maintain glucose levels as near normal as possible, glycemic goals need to take into account that children younger than 6 to 7 years of age have a form of "hypoglycemic unawareness."[11] Their counterregulatory mechanisms are immature and they lack the cognitive capacity to recognize and respond to hypoglycemic symptoms, placing them at greater risk for hypoglycemia and its sequelae. Also, unlike adults, young children under 5 years of age are at risk for permanent cognitive impairment after episodes of severe hypoglycemia.[11] Thus, the glycemic goals for children must consider the benefits of long-term health outcomes against the risks of hypoglycemia and the difficulties in achieving normoglycemia in children.

Acute Complications

The three major acute complications of impaired blood glucose regulation are diabetic ketoacidosis, hyperosmolar hyperglycemic state, and hypoglycemia. All are life-threatening conditions that demand immediate recognition and treatment. The Somogyi effect and dawn phenomenon, which result from the mobilization of counterregulatory hormones, contribute to difficulties with diabetic control.

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA), characterized by hyperglycemia, ketosis, and metabolic acidosis, is an acute life-threatening complication of uncontrolled diabetes.[40–42] DKA primarily affects persons with type 1 diabetes, but may also occur in persons with type 2 diabetes when severe stress such as sepsis or trauma is present. It may be an initial manifestation of previously undiagnosed type 1 diabetes or may result from increased insulin requirements in type 1 diabetes during stress situations such as infection or trauma that increase the release of stress hormones. For example, a mother may bring a child into the clinic or emergency department with reports of lethargy, vomiting, and abdominal pain, unaware that the child has diabetes. In clinical practice, ketoacidosis also occurs with the omission or inadequate use of insulin.

Ketoacidosis reflects the effect of insulin deficiency at multiple sites (Fig. 33-11). Insulin lack results in the rapid breakdown of energy stores from muscle and fat depots, leading to increased movement of amino acids to the liver for conversion to glucose and of fatty acids for conversion to ketones. In the presence of ketosis, the levels of glucagon and counterregulatory hormones (i.e., corticosteroids, epinephrine, and growth hormone) are consistently increased. Furthermore, in the absence of insulin, peripheral utilization of glucose and ketones is reduced. Metabolic acidosis is caused by the excess ketoacids that require buffering by bicarbonate ions; this leads to a marked decrease in serum bicarbonate levels.

The definitive diagnosis of DKA consists of *hyperglycemia* (blood glucose levels >250 mg/dL [13.8 mmol/L]), low serum bicarbonate, low arterial pH, and positive urine and serum ketones. It can be further subdivided into *mild DKA* (serum bicarbonate of 15 to 18 mEq/dL [15 to 18 mmol/L], pH 7.25 to 7.30); *moderate DKA* (serum bicarbonate 10 to <15 mEq/dL [10 to <15 mmol/L], pH 7.00 to 7.24): and *severe DKA* (serum bicarbonate <10 mEq/dL [<10 mmol/L], pH <7.00).[40,41] Hyperglycemia leads to osmotic diuresis, dehydration, and a critical loss of electrolytes. Hyperosmolality of extracellular fluids from hyperglycemia leads to a shift of water and potassium from the intracellular to the extracellular compartment. Extracellular sodium concentration frequently is low or normal despite enteric water losses because of an intracellular–extracellular fluid shift. This dilutional effect is referred to as *pseudohyponatremia*. Serum potassium levels may also be normal or elevated, despite total potassium depletion resulting from protracted polyuria and vomiting.

The development of DKA is commonly preceded by a day or more of polyuria, polydipsia, nausea, vomiting,

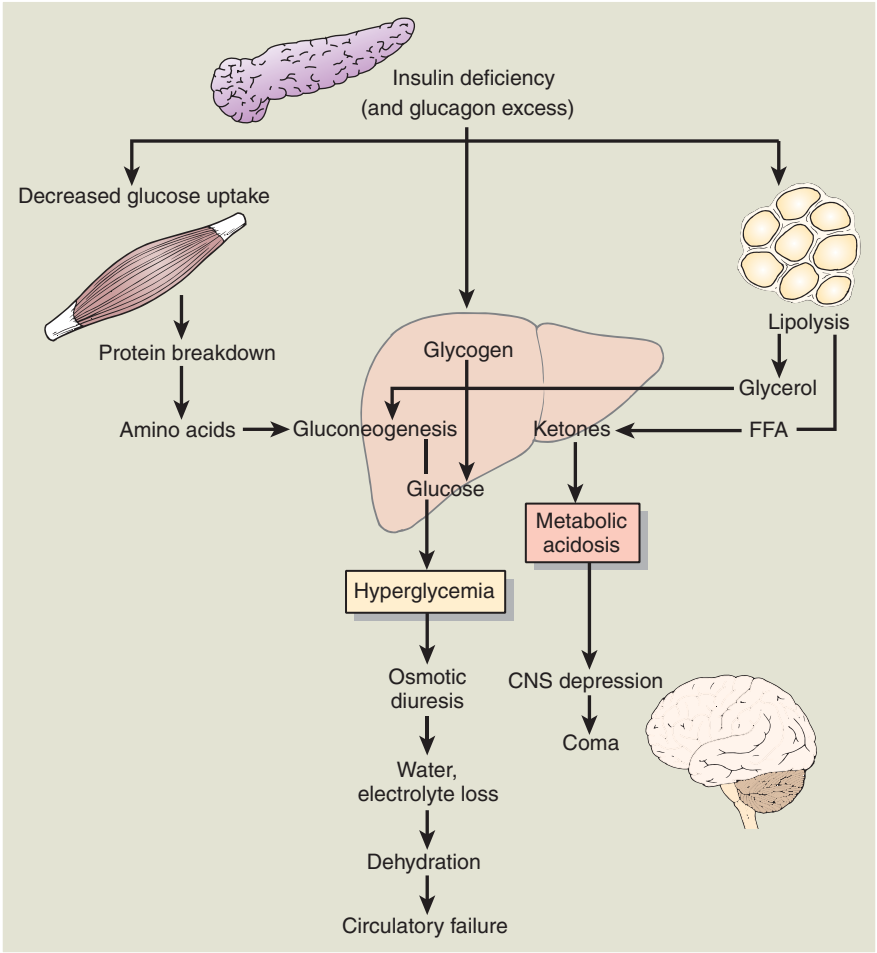

FIGURE 33-11. Mechanisms of diabetic ketoacidosis. Diabetic ketoacidosis is associated with very low insulin levels and extremely high levels of glucagon, catecholamines, and other counterregulatory hormones. Increased levels of glucagon and the catecholamines lead to mobilization of substrates for gluconeogenesis and ketogenesis by the liver. Gluconeogenesis in excess of that needed to supply glucose for the brain and other glucose-dependent tissues produces a rise in blood glucose levels. Mobilization of free fatty acids (FFAs) from triglyceride stores in adipose tissue leads to accelerated ketone production and ketosis. CNS, central nervous system.

and marked fatigue, with eventual stupor that can progress to coma. Abdominal pain and tenderness may be experienced without abdominal disease. The breath has a characteristic fruity smell because of the presence of the volatile ketoacids. Hypotension and tachycardia may be present because of a decrease in blood volume. A number of the signs and symptoms that occur in DKA are related to compensatory mechanisms. The heart rate increases as the body compensates for a decrease in blood volume, and the rate and depth of respiration increase (i.e., Kussmaul respiration) as the body attempts to prevent further decreases in pH. Metabolic acidosis is discussed further in Chapter 8.

The goals in treating DKA are to improve circulatory volume and tissue perfusion, decrease blood glucose, and correct the acidosis and electrolyte imbalances. These objectives usually are accomplished through the administration of insulin and intravenous fluid and electrolyte replacement solutions. Because insulin resistance accompanies severe acidosis, low-dose insulin therapy is used. An initial loading dose of regular insulin often is given intravenously, followed by continuous low-dose infusion. Frequent laboratory tests are used to monitor blood glucose and serum electrolyte levels and to guide fluid and electrolyte replacement. It is important to replace fluid and electrolytes and correct pH while bringing the blood glucose concentration to a normal level. Too rapid a drop in blood glucose may cause hypoglycemia. A sudden change in the osmolality of extracellular fluid can also occur when blood glucose levels are lowered too rapidly, and this can cause cerebral edema. Cerebral and other autoregulatory mechanisms may not be as well developed in younger children, placing them at particular risk for development of cerebral edema.[42] Serum potassium levels often fall as acidosis is corrected and potassium moves from the extracellular into the intracellular compartment. Thus, it may be necessary to add potassium to the intravenous infusion. Identification and treatment of the underlying cause, such as infection, also are important.

Hyperosmolar Hyperglycemic State

The hyperosmolar hyperglycemic state (HHS) is characterized by hyperglycemia (blood glucose >600 mg/dL [33.3 mmol/L]), hyperosmolarity (plasma osmolarity >320 mOsm/L) and dehydration, the absence of ketoacidosis, and depression of the sensorium.[40] HHS may occur in various conditions, including type 2 diabetes, acute pancreatitis, severe infection, myocardial infarction, and treatment with oral or parenteral nutrition solutions. It is seen most frequently in people with type 2 diabetes.

A partial or relative insulin deficiency may initiate the syndrome by reducing glucose utilization while inducing hyperglucagonemia and increasing hepatic glucose output. With massive glycosuria, obligatory water loss occurs. If the person is unable to maintain adequate fluid intake because of associated acute or chronic illness or has excessive fluid loss, dehydration develops. As the plasma volume contracts, renal insufficiency develops and the resultant limitation of renal glucose losses leads to increasingly higher blood glucose levels and severity of the hyperosmolar state.

In hyperosmolar states, the increased serum osmolarity has the effect of pulling water out of body cells, including brain cells. The condition may be complicated by thromboembolic events arising because of the high serum osmolality. The most prominent manifestations are weakness, dehydration, polyuria, neurologic signs and symptoms, and excessive thirst. The neurologic signs include hemiparesis, Babinski reflexes, aphasia, muscle fasciculations, hyperthermia, hemianopia, nystagmus, visual hallucinations, seizures, and coma. The onset of HHS often is insidious, and because it occurs most frequently in older people, it may be mistaken for a stroke.

The treatment of HHS requires judicious medical observation and care as water moves back into brain cells, posing a threat of cerebral edema. Extensive potassium losses that also have occurred during the diuretic phase of the disorder require correction. Because of the problems encountered in the treatment and the serious nature of the disease conditions that cause HHS, the prognosis for this disorder is less favorable than that for ketoacidosis.

Hypoglycemia

Hypoglycemia, or an insulin reaction, occurs from a relative excess of insulin in the blood and is characterized by below-normal blood glucose levels.[43,44] It occurs most commonly in people treated with insulin injections, but prolonged hypoglycemia also can result from some oral hypoglycemic agents. There are many factors that can precipitate an insulin reaction in a person with type 1 diabetes, including error in insulin dose, failure to eat, increased exercise, decreased insulin need after removal of a stress situation, medication changes, and a change in insulin injection site. Alcohol decreases liver gluconeogenesis, and people with diabetes need to be cautioned about its potential for causing hypoglycemia, especially if it is consumed in large amounts or on an empty stomach.

Hypoglycemia usually has a rapid onset and progression of symptoms. The signs and symptoms of hypoglycemia can be divided into two categories: (1) those caused by altered cerebral function and (2) those related to activation of the autonomic nervous system. Because the brain relies on blood glucose as its main energy source, hypoglycemia produces behaviors related to altered cerebral function. Headache, difficulty in problem solving, disturbed or altered behavior, coma, and seizures may occur. At the onset of the hypoglycemic episode, activation of the parasympathetic nervous system often causes hunger. The initial parasympathetic response is followed by activation of the sympathetic nervous system; this causes anxiety, tachycardia, sweating, and constriction of the skin vessels (i.e., the skin is cool and clammy).

The signs and symptoms of hypoglycemia are highly variable, and not everyone manifests all or even most of the symptoms. The manifestations are particularly variable in children and in elderly people. Elderly people may not display the typical autonomic responses associated with hypoglycemia but frequently develop signs of impaired function of the central nervous system, including mental confusion. Some people develop hypoglycemic unawareness. Unawareness of hypoglycemia should be suspected in people who do not report symptoms when their blood glucose concentrations are less than 50 to 60 mg/dL (2.8 to 3.3 mmol/L). This occurs most commonly in people who have a longer duration of diabetes and A1C levels within the normal range.[43] Some medications, such as β-adrenergic blocking drugs, interfere with the sympathetic response normally seen in hypoglycemia. If hypoglycemia occurs with α-glucosidase inhibitors, it should be treated with glucose (dextrose) and not sucrose (table sugar), whose breakdown may be blocked by the action of the α-glucosidase inhibitors.

The most effective treatment of an insulin reaction is the immediate administration of 15 to 20 g of glucose in a concentrated carbohydrate source, which can be repeated as necessary. Monosaccharides such as glucose, which can be absorbed directly into the bloodstream, work best. Complex carbohydrates can be administered after the acute reaction has been controlled to sustain blood glucose levels. It is important not to overtreat hypoglycemia and cause hyperglycemia. Alternative methods for increasing blood glucose may be required when the person having the reaction is unconscious or unable to swallow. Glucagon may be given intramuscularly or subcutaneously. Glucagon acts by hepatic glycogenolysis to raise blood glucose. Because the liver contains only a limited amount of glycogen (approximately 75 g), glucagon is ineffective in people whose glycogen stores have been depleted. In situations of severe or life-threatening hypoglycemia, it may be necessary to administer glucose (20 to 50 mL of a 50% solution) intravenously.

The Somogyi Effect and Dawn Phenomenon

The *Somogyi effect* describes a cycle of insulin-induced posthypoglycemic episodes. In 1924, Joslin and associates noticed that hypoglycemia was associated with alternate episodes of hyperglycemia. It was not until 1959 that Somogyi presented the results of his 20 years of studies, which confirmed the observation that "hypoglycemia begets hyperglycemia."[45] In people with diabetes, insulin-induced hypoglycemia produces a compensatory increase in blood levels of catecholamines, glucagon, cortisol, and growth hormone. These counterregulatory hormones cause blood glucose to become elevated and produce some degree of insulin resistance. The cycle begins when the increase in blood glucose and insulin resistance is treated with larger insulin doses. The hypoglycemic

episode often occurs during the night or at a time when it is not recognized, rendering the diagnosis of the phenomenon more difficult.

Research suggests that even rather mild insulin-associated hypoglycemia, which may be asymptomatic, can cause hyperglycemia in people with type 1 diabetes through the recruitment of counterregulatory mechanisms, although the insulin action does not wane. A waning of insulin's effects when it occurs (i.e., end of the duration of action) causes an exacerbation of the posthypoglycemic hyperglycemia that occurs and accelerates its development. These findings may explain the labile nature of the disease in some people with diabetes. Measures to prevent hypoglycemia and the subsequent activation of counterregulatory mechanisms include a redistribution of dietary carbohydrates and an alteration in insulin dose or time of administration.[46]

The *dawn phenomenon* is characterized by increased levels of fasting blood glucose or insulin requirements, or both, between 5 and 9 AM without antecedent hypoglycemia. It occurs in people with type 1 or type 2 diabetes. It has been suggested that a change in the normal circadian rhythm for glucose tolerance, which usually is higher during the later part of the morning, is altered in people with diabetes.[47] Growth hormone has been suggested as a possible factor. When the dawn phenomenon occurs alone, it may produce only mild hyperglycemia, but when it is combined with the Somogyi effect, it may produce profound hyperglycemia.

Chronic Complications

The chronic complications of diabetes include disorders of the microvasculature (i.e., neuropathies, nephropathies, and retinopathies), macrovascular complications (i.e., coronary artery, cerebral vascular, and peripheral vascular disease), and foot ulcers (Fig. 33-12). The level of chronic hyperglycemia is the best-established concomitant factor associated with diabetic complications.[48,49] The Diabetes Control and Complications Trial (DCCT), which was conducted with 1441 patients with type 1 diabetes, demonstrated that the incidence of retinopathy, nephropathy, and neuropathy can be reduced by intensive diabetic treatment.[49] Similar results have been demonstrated by the United Kingdom Prospective Diabetes Study (UKPDS) in 5000 patients with type 2 diabetes.[50]

Theories of Pathogenesis

The interest among researchers in explaining the causes and development of chronic lesions in a person with diabetes has led to a number of theories. At least three distinct metabolic pathways have been implicated in long-term complications of diabetes: intracellular hyperglycemia and disturbance in polyol pathways, formation of advanced glycation end products, and activation of protein kinase C.[3,48,51]

Polyol Pathway. A polyol is an organic compound that contains three or more hydroxyl (OH) groups. The polyol pathway refers to the intracellular mechanisms responsible for changing the number of hydroxyl units on a glucose molecule. In the sorbitol pathway, glucose is transformed first to sorbitol and then to fructose. This process is activated by the enzyme aldose reductase. Although glucose is converted readily to sorbitol, the rate at which sorbitol can be converted to fructose and then metabolized is limited. Sorbitol is osmotically active, and it has been hypothesized that the presence of excess intracellular amounts may alter cell function in those tissues that use this pathway (e.g., lens, kidneys, nerves, blood vessels). In the lens, for example, the osmotic effects of sorbitol cause swelling and opacity. Increased sorbitol also is associated with a decrease in myoinositol and reduced adenosine triphosphatase activity. The reduction of these compounds may contribute to the pathogenesis

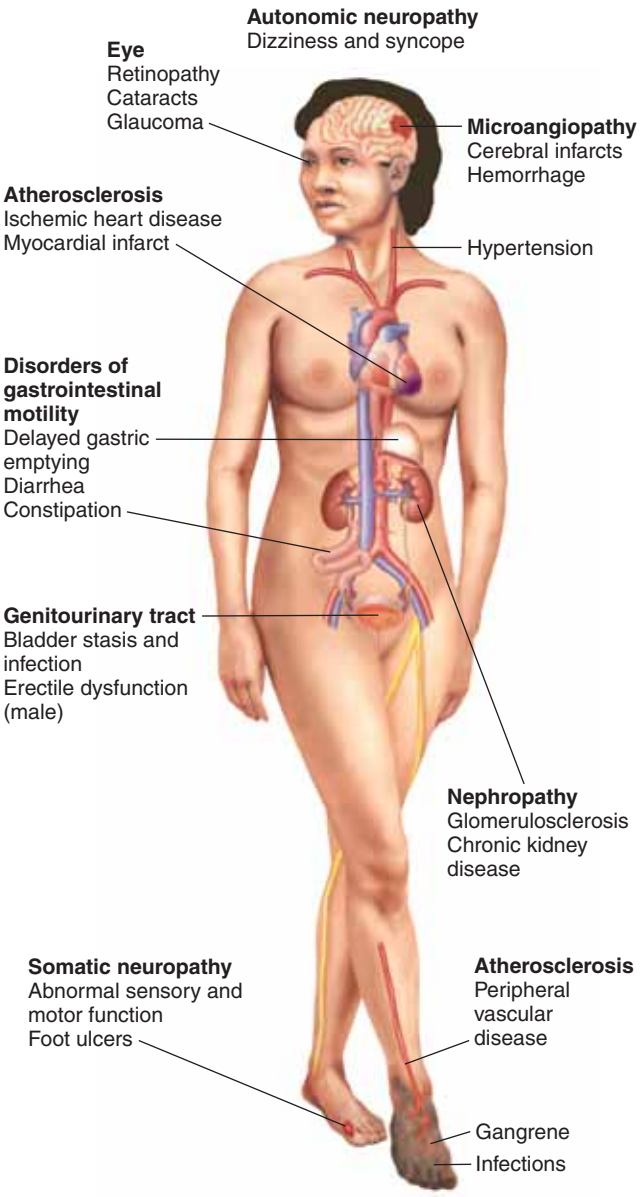

FIGURE 33-12. Long-term complications of diabetes mellitus.

Chronic Complications of Diabetes

- The chronic complications of diabetes result from elevated blood glucose levels and associated impairment of lipid and other metabolic pathways.
- Diabetic nephropathy, which is a leading cause of chronic kidney disease, is associated with the increased work demands and microalbuminuria imposed by poorly controlled blood glucose levels.
- Diabetic retinopathy, which is a leading cause of blindness, is closely linked to elevations in blood glucose and hyperlipidemia seen in persons with uncontrolled diabetes.
- Diabetic neuropathies, which can affect the somatic and autonomic nervous systems, result from the demyelinating effect of long-term uncontrolled diabetes.
- Macrovascular disorders such as coronary heart disease, stroke, and peripheral vascular disease reflect the combined effects of unregulated blood glucose levels, elevated blood pressure, and hyperlipidemia.
- The chronic complications of diabetes are best prevented by measures aimed at tight control of blood glucose levels, maintenance of normal lipid levels, and control of hypertension.

of neuropathies caused by Schwann cell damage. Aldose reductase inhibitors are in development with the aim of reducing complications resulting from this pathway; however, to date none of them has been successful for a variety of reasons.

Formation of Advanced Glycation End Products. Glycoproteins, or what could be called *glucose proteins*, are normal components of the basement membrane in smaller blood vessels and capillaries. These glycoproteins are also termed *advanced glycation end products* (AGEs). It has been suggested that the increased intracellular concentration of glucose associated with uncontrolled blood glucose levels in diabetes favors the formation of AGEs. These abnormal glycoproteins are thought to produce structural defects in the basement membrane of the microcirculation and to contribute to eye, kidney, and vascular complications. Some of the altered cellular functions resulting from AGEs are due to binding to specific receptors for AGEs (RAGEs).

Protein Kinase C. Diacylglycerol (DAG) and protein kinase C (PKC) are critical intracellular signaling molecules that can regulate many vascular functions, including permeability, vasodilator release, endothelial activation, and growth factor signaling. Levels of DAG and PKC are elevated in diabetes. Activation of PKC in blood vessels of the retina, kidney, and nerves can produce vascular damage. A PKC inhibitor is currently in clinical trials for diabetic retinopathy and neuropathy, but has shown variable results.[3]

Neuropathies

Although the incidence of neuropathies is high among people with diabetes, it is difficult to document exactly how many people are affected by these disorders because of the diversity in clinical manifestations and because the condition often is far advanced before it is recognized. Results of the DCCT study showed that intensive diabetic therapy can reduce the incidence of clinical neuropathy by 60% compared with conventional therapy.[52]

Two types of pathologic changes have been observed in connection with diabetic neuropathies. The first is a thickening of the walls of the nutrient vessels that supply the nerve, leading to the assumption that vessel ischemia plays a major role in the development of these neural changes. The second finding is a segmental demyelinization process that affects the Schwann cell. This demyelinization process is accompanied by a slowing of nerve conduction.

Although there are several methods for classifying the diabetic peripheral neuropathies, a simplified system divides them into the somatic and autonomic nervous system neuropathies (Chart 33-2).

Somatic Neuropathy. A distal symmetric polyneuropathy, in which loss of function occurs in a stocking–glove pattern, is the most common form of peripheral neuropathy. Somatic sensory involvement usually occurs first and usually is bilateral and symmetric, and associated with diminished perception of vibration, pain, and temperature, particularly in the lower extremities.[53] In addition to the discomforts associated with the loss of sensory or motor function, lesions in the peripheral nervous system predispose a person with diabetes to other complications. The loss of feeling, touch, and position sense increases the risk of falling. Impairment of temperature and pain sensation increases the risk of serious burns and injuries to the feet. Denervation of the small muscles of the foot result in clawing of the toes and displacement of the submetatarsal fat pad anteriorly. These changes, together with joint and connective tissue changes, alter the biomechanics of the foot, increasing plantar pressure and predisposing to development of foot trauma and ulcers.[53]

Painful diabetic neuropathy involves the somatosensory neurons that carry pain impulses. This disorder, which causes hypersensitivity to light touch and occasionally severe "burning pain," particularly at night, can become physically and emotionally disabling.[53]

Autonomic Neuropathy. The autonomic neuropathies involve disorders of sympathetic and parasympathetic nervous system function. There may be disorders of vasomotor function, decreased cardiac responses, inability to

CHART 33-2 Classification of Diabetic Neuropathies

Somatic

Polyneuropathies (bilateral sensory)
- Paresthesias, including numbness and tingling
- Impaired pain, temperature, light touch, two-point discrimination, and vibratory sensation
- Decreased ankle and knee-jerk reflexes

Mononeuropathies
- Involvement of a mixed nerve trunk that includes loss of sensation, pain, and motor weakness

Amyotrophy
- Associated with muscle weakness, wasting, and severe pain of muscles in the pelvic girdle and thigh

Autonomic

Impaired vasomotor function
- Postural hypotension

Impaired gastrointestinal function
- Gastric atony
- Diarrhea, often postprandial and nocturnal

Impaired genitourinary function
- Paralytic bladder
- Incomplete voiding
- Erectile dysfunction
- Retrograde ejaculation

Cranial nerve involvement
- Extraocular nerve paralysis
- Impaired pupillary responses
- Impaired special senses

empty the bladder, gastrointestinal motility problems, and sexual dysfunction.[54] Defects in vasomotor reflexes can lead to dizziness and syncope due to postural hypotension when the person moves from the supine to the standing position (see Chapter 18). Incomplete emptying of the bladder predisposes to urinary stasis and bladder infection and increases the risk of renal complications.

Gastrointestinal motility disorders are common in persons with long-standing diabetes. The symptoms vary in severity and include gastroparesis, constipation, diarrhea, and fecal incontinence. Gastroparesis (delayed emptying of stomach) is commonly seen in persons with diabetes.[55] The disorder is characterized by complaints of epigastric discomfort, nausea, postprandial vomiting, bloating, and early satiety. Abnormal gastric emptying also jeopardizes the regulation of the blood glucose level. Diarrhea is another common symptom seen mostly in persons with poorly controlled type 1 diabetes and autonomic neuropathy.[56] The pathogenesis is thought to be multifactorial. Diabetic diarrhea is typically intermittent, watery, painless, and nocturnal and may be associated with fecal incontinence.

In the male, disruption of sensory and autonomic nervous system function may cause sexual dysfunction (see Chapter 39). Diabetes is the leading physiologic cause of erectile dysfunction, and it occurs in both type 1 and type 2 diabetes. Of the 7.8 million men with diabetes in the United States, 30% to 60% have erectile dysfunction.[54]

Nephropathies

Diabetic nephropathy, a term used to describe the combination of lesions that occur concurrently in the diabetic kidney, is the leading cause of chronic kidney disease in persons starting renal replacement therapy (see Chapter 26).[57] Not all people with diabetes develop clinically significant nephropathy; for this reason, attention is focusing on risk factors for the development of this complication. Among the suggested risk factors are genetic and familial predisposition, elevated blood pressure, poor glycemic control, smoking, hyperlipidemia, and microalbumuria.[11,58] Diabetic nephropathy occurs in family clusters, suggesting a familial predisposition, although this does not exclude the possibility of environmental factors shared by siblings. The risk for development of kidney disease is greater among Native Americans, Hispanic Americans (especially Mexican Americans), and African Americans.[11,58]

The most common kidney lesions in people with diabetes are those that affect the glomeruli. Various glomerular changes may occur in people with diabetic nephropathy, including capillary basement membrane thickening, diffuse glomerular sclerosis, and nodular glomerulosclerosis (see Chapter 25). Nodular glomerulosclerosis, also called *intercapillary glomerulosclerosis* or *Kimmelstiel-Wilson syndrome*, is a form of glomerulosclerosis that involves the development of nodular lesions in the glomerular capillaries of the kidneys, causing impaired blood flow with progressive loss of kidney function and, eventually, renal failure. Nodular glomerulosclerosis is thought to occur only in people with diabetes. Changes in the basement membrane in diffuse nodular glomerulosclerosis allow plasma proteins to escape in the urine, causing albuminuria, hypoalbuminemia, edema, and other signs of impaired kidney function.

Kidney enlargement, nephron hypertrophy, and hyperfiltration are early accompaniments of diabetes, reflecting the increased work performed by the kidneys in reabsorbing excessive amounts of glucose. One of the first manifestations of diabetic nephropathy is an increase in urinary albumin excretion (i.e., microalbuminuria), which is easily assessed by laboratory methods. Microalbuminuria is defined as a urine protein loss between 30 and 300 mg/day or an albumin-to-creatinine ratio (A/C ratio) between 30 and 300 μg/mg (normal <30 μg/mg) from a spot urine collection.[58] It is recommended that the A/C ratio be the preferred screen for microalbuminuria. Both systolic and diastolic forms of hypertension accelerate the progression of diabetic nephropathy. Even moderate lowering of blood pressure can decrease the risk of chronic kidney disease.[11]

Measures to prevent diabetic nephropathy or its progression in persons with diabetes include achievement of glycemic control, maintenance of blood pressure control (<130/80 mm Hg), prevention or reduction in the level of proteinuria (using angiotensin-converting enzyme

inhibitors or angiotensin receptor blockers, or protein restriction in selected patients), treatment of hyperlipidemia, and smoking cessation in people who smoke.[11,57] Smoking increases the risk of chronic kidney disease in both persons with and without diabetes. People with type 2 diabetes who smoke have a greater risk of microalbuminuria, and their rate of progression to chronic kidney disease is approximately twice as rapid as in those who do not smoke.[11]

Retinopathies

Diabetes is the leading cause of acquired blindness in the United States.[58,59] Although people with diabetes are at increased risk for development of cataracts and glaucoma, retinopathy is the most common pattern of eye disease. Diabetic retinopathy is estimated to be the most frequent cause of newly diagnosed blindness among Americans between the ages of 20 and 74 years.[59]

Diabetic retinopathy is characterized by abnormal retinal vascular permeability, microaneurysm formation, neovascularization and associated hemorrhage, scarring, and retinal detachment[59] (see Chapter 38). Twenty years after the onset of diabetes, nearly all people with type 1 diabetes and more than 60% of people with type 2 diabetes have some degree of retinopathy. Pregnancy, puberty, and cataract surgery can accelerate these changes.[59] Although there has been no extensive research on risk factors associated with diabetic retinopathy, they appear to be similar to those for other complications. Among the suggested risk factors associated with diabetic retinopathy are poor glycemic control, elevated blood pressure, and hyperlipidemia. The strongest case for control of blood glucose comes from the DCCT and UKPDS studies, which demonstrated a reduction in retinopathy with improved glucose control.[49,50]

Because of the risk of retinopathy, it is important that people with diabetes have regular dilated eye examinations. The recommendation for follow-up examinations is based on the type of examination that was done and the findings of that examination. People with persistently elevated glucose levels or proteinuria should be examined yearly.[59] Women who are planning a pregnancy should be counseled on the risk of development or progression of diabetic retinopathy. Women with diabetes who become pregnant should be followed closely throughout pregnancy. This does not apply to women in whom GDM develops because such women are not at risk for development of diabetic retinopathy.

People with macular edema, moderate to severe nonproliferative retinopathy, or any proliferative retinopathy should receive the care of an ophthalmologist who is knowledgeable and experienced in the management and treatment of diabetic retinopathy. Methods used in the treatment of diabetic retinopathy include the destruction and scarring of the proliferative lesions with laser photocoagulation. The use of antagonists to growth factors (e.g., vascular endothelial growth factor) may also play a role in management.

Macrovascular Complications

Diabetes mellitus is a major risk factor for atherosclerotic coronary artery disease, cerebrovascular disease, and peripheral vascular disease. The prevalence of these macrovascular complications is increased twofold to fourfold in people with diabetes.

Multiple risk factors for macrovascular disease, including obesity, hypertension, hyperglycemia, hyperinsulinemia, hyperlipidemia, altered platelet function, endothelial dysfunction, systemic inflammation (as evidenced by increased CRP), and elevated fibrinogen levels, frequently are found in people with diabetes. There appear to be differences between type 1 and type 2 diabetes in terms of duration of disease and development of macrovascular disease. In people with type 2 diabetes, macrovascular disease may be present at the time of diagnosis. Indeed, approximately 50% of people with type 2 diabetes have some form of complication at presentation (either microvascular or macrovascular). The reason for these discrepancies has been attributed to the associated cardiovascular risk factors that are part of the metabolic syndrome.[19,20]

Aggressive management of cardiovascular risk factors should include smoking cessation, hypertension, lipid lowering, diabetes control, and antiplatelet agents (aspirin or clopidogrel) if not contraindicated[11,19] (see Chapter 18). If treatment is warranted for peripheral vascular disease, the peroneal arteries between the knees and ankles commonly are involved in diabetes, making revascularization difficult.

Diabetic Foot Ulcers

Foot problems are common among people with diabetes and may become severe enough to cause ulceration, infection, and, eventually, the need for amputation.[60,61] Foot problems have been reported as the most common complication leading to hospitalization among people with diabetes. In people with diabetes, lesions of the feet represent the effects of neuropathy and vascular insufficiency. Approximately 60% to 70% of people with diabetic foot ulcers have neuropathy without vascular disease, 15% to 20% have vascular disease, and 15% to 20% have neuropathy and vascular disease.[60]

Distal symmetric neuropathy is a major risk factor for foot ulcers. People with sensory neuropathies have impaired pain sensation and often are unaware of the constant trauma to the feet caused by poorly fitting shoes, improper weight bearing, hard objects or pebbles in the shoes, or infections such as athlete's foot. Neuropathy prevents people from detecting pain; they are unable to adjust their gait to avoid walking on an area of the foot where pressure is causing trauma and necrosis. Motor neuropathy with weakness of the intrinsic muscles of the foot may result in foot deformities, which lead to focal areas of high pressure. When the abnormal focus of pressure is coupled with loss of sensation, a foot ulcer can occur. Common sites of trauma are the back of the heel, the plantar metatarsal area, or the great toe, where weight is borne during walking (Fig. 33-13).

All persons with diabetes should receive a full foot examination at least once a year. This examination

FIGURE 33-13. Neuropathic ulcers occur on pressure points in areas with diminished sensation in diabetic polyneuropathy. Pain is absent (and therefore the ulcer may go unnoticed). (From Bates B.B. [1995]. *A guide to physical examination and history taking* [6th ed.]. Philadelphia: J.B. Lippincott.)

should include assessment of protective sensation, foot structure and biomechanics, vascular status, and skin integrity.[3,61] Evaluation of neurologic function should include a somatosensory test using either the Semmes-Weinstein monofilament or vibratory sensation. The Semmes-Weinstein monofilament is a simple, inexpensive device for testing sensory status (Fig. 33-14). The monofilament is held in the hand or attached to a handle at one end. When the unattached or unsupported end of the monofilament is pressed against the skin until it buckles or bends slightly, it delivers 10 g of pressure at the point of contact.[61] The test consists of having the person being tested report at which of two moments he or she is being touched by the monofilament. For example, the examiner will call out "one" and then "two" and briefly touch the monofilament to the site at one of the two test times. Between 4 and 10 sites per foot are touched. An incorrect response at even one site indicates increased risk of neuropathy and foot complications.

Because of the constant risk of foot problems, it is important that people with diabetes wear shoes that have been fitted correctly and inspect their feet daily, looking for blisters, open sores, and fungal infection (e.g., athlete's foot) between the toes. If their eyesight is poor, a family member should do this for them. In the event a lesion is detected, prompt medical attention is needed to prevent serious complications. Specially designed shoes have been demonstrated to be effective in preventing relapses in people with previous ulcerations.[61] Smoking should be avoided because it causes vasoconstriction and contributes to vascular disease. Because cold produces vasoconstriction, appropriate foot coverings should be used to keep the feet warm and dry. Toenails should be cut straight across to prevent ingrown toenails. The toenails often are thickened and deformed, requiring the services of a podiatrist.

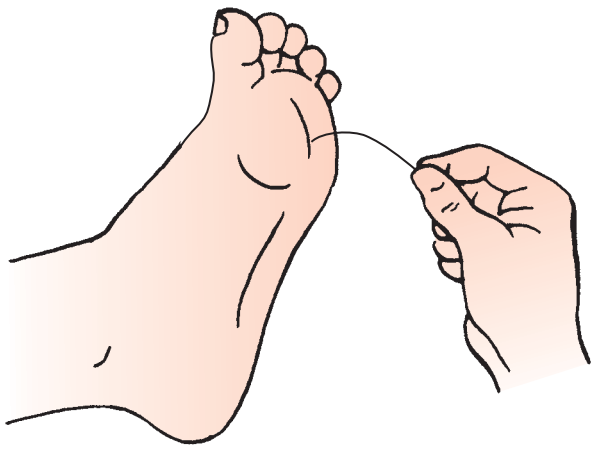

FIGURE 33-14. Use of a monofilament in testing for impaired sensation in the foot of a person with diabetes.

Persons with diabetes mellitus develop more extensive and rapidly progressive peripheral vascular disease than do individuals without diabetes. Cardiovascular risk factors should be addressed in patients with diabetic ulcers and peripheral vascular disease. Ulcers that are resistant to standard therapy may respond to application of growth factors. Growth factors provide a means by which cells communicate with each other and can have profound effects on cell proliferation, migration, and extracellular matrix synthesis. Becaplermin, a topical preparation of recombinant human platelet-derived growth factor (PDGF), is used in the treatment of neuropathic lower extremity ulcers.

Infections

Although not specifically an acute or a chronic complication, infections are a common concern of people with diabetes. Certain types of infections occur with increased frequency in people with diabetes: soft tissue infections of the extremities, osteomyelitis, urinary tract infections and pyelonephritis, candidal infections of the skin and mucous surfaces, dental caries and periodontal disease, and tuberculosis.[62,63] Controversy as to whether infections are more common in people with diabetes or whether infections seem more prevalent because they often are more serious in people with diabetes.

Suboptimal response to infection in a person with diabetes is caused by the presence of chronic complications, such as vascular disease and neuropathies, and by the presence of hyperglycemia and altered neutrophil function. Sensory deficits may cause a person with diabetes to ignore minor trauma and infection, and vascular disease may impair circulation and delivery of blood cells and other substances needed to produce an adequate inflammatory response and effect healing. Pyelonephritis and urinary tract infections are relatively common in persons with diabetes, and it has been suggested that these infections may bear some relation to the presence of a neurogenic bladder or nephrosclerotic changes in the kidneys. Hyperglycemia and glycosuria may influence the growth of microorganisms and increase the severity of the infection. Diabetes and elevated blood glucose levels also may impair host defenses such as the function of neutrophils and immune cells. Polymorphonuclear leukocyte function, particularly adherence, chemotaxis, and phagocytosis, is depressed in persons with diabetes, particularly those with poor glycemic control.

In summary, diabetes mellitus is a disorder of carbohydrate, protein, and fat metabolism resulting from an imbalance between insulin availability and insulin need. The disease can be classified as type 1 diabetes, in which there is destruction of beta cells and an absolute insulin deficiency, or type 2 diabetes, in which there is a lack of insulin availability or effectiveness. Type 1 diabetes can be further subdivided into type 1A immune-mediated diabetes, which is thought to be caused by autoimmune mechanisms, and type 1B idiopathic diabetes, for which the cause is unknown. Other specific types of diabetes include secondary forms of carbohydrate intolerance, which occur secondary to some other condition that destroys beta cells (e.g., pancreatic disorders) or endocrine diseases that cause increased production of glucose by the liver and decreased use of glucose by the tissues (e.g., Cushing syndrome). Gestational diabetes develops during pregnancy, and although glucose tolerance often returns to normal after childbirth, it indicates an increased risk for the development of diabetes. The metabolic syndrome represents a constellation of metabolic abnormalities characterized by obesity, insulin resistance, high triglyceride levels and low HDL levels, hypertension, cardiovascular disease, and increased risk for development of type 2 diabetes.

The most commonly identified symptoms of type 1 diabetes are polyuria, polydipsia, polyphagia, and weight loss despite normal or increased appetite. Although persons with type 2 diabetes may present with one or more of these symptoms, they are often asymptomatic initially. The diagnosis of diabetes mellitus is based on clinical signs of the disease, fasting blood glucose levels, random plasma glucose measurements, and results of the glucose tolerance test. Glycosylation involves the irreversible attachment of glucose to the hemoglobin molecule; the measurement of glycosylated hemoglobin (A1C) provides an index of blood glucose levels over several months. Self-monitoring provides a means of maintaining near-normal blood glucose levels through frequent testing of blood glucose and adjustment of insulin dosage.

Dietary management focuses on maintaining a well-balanced diet, controlling calories to achieve and maintain an optimum weight, and regulating the distribution of carbohydrates, proteins, and fats. Two types of antidiabetic agents are used in the management of diabetes: injectable insulin (and newer injectable agents including amylin and GLP-1 analogs) and oral diabetic drugs. Type 1 diabetes, and sometimes type 2, requires treatment with injectable insulin. Oral antidiabetic drugs include the insulin secretagogues, biguanides, α-glucosidase inhibitors, thiazolidinediones, and DPP-4 enzyme inhibitors. These drugs require a functioning pancreas and may be used in the treatment of type 2 diabetes.

The metabolic disturbances associated with diabetes affect almost every body system. The acute complications of diabetes include diabetic ketoacidosis, hyperglycemic hyperosmolar state, and hypoglycemia in people with insulin-treated diabetes. The chronic complications of diabetes affect the microvascular system (including the retina, kidneys, and peripheral nervous system) and the macrovascular system (coronary, cerebrovascular, and peripheral arteries). The diabetic foot is usually a combination of both microvascular and macrovascular dysfunction. Infection is also a frequent cofactor in the diabetic foot.

REVIEW EXERCISES

1. A 6-year-old boy is admitted to the emergency department with nausea, vomiting, and abdominal pain. He is very lethargic; his skin is warm, dry, and flushed; his pulse is rapid; and he has a sweet smell to his breath. His parents relate that he has been very thirsty during the past several weeks, his appetite has been poor, and he has been urinating frequently. His initial plasma glucose is 420 mg/dL (23.1 mmol/L), and a urine test for ketones is strongly positive.

A. What is the most likely cause of this boy's elevated blood glucose and ketonuria?
B. Explain his presenting signs and symptoms in terms of the elevated blood glucose and metabolic acidosis.
C. What type of treatment will this boy require?

2. A 53-year-old accountant presents for his routine yearly examination. His history indicates that he was found to have a fasting glucose of 120 mg/dL (6.7 mmol/L) on two prior occasions. Currently, he is asymptomatic. He has no other medical problems and does not use any medications. He neither smokes nor drinks alcohol. His father had type 2 diabetes at age 60 years. His physical examination reveals a blood pressure of 125/80 mm Hg, BMI of 32 kg/m^2, and waist circumference of 45 in (114 cm). Laboratory study results are as follows: complete blood count (CBC), thyroid-stimulating hormone (TSH), and alanine aminotransferase (ALT) are within normal limits. The lipid panel shows that his HDL cholesterol (30 mg/dL [0.8 mmol/L]) and LDL cholesterol (136 mg/dL [3.5 mmol/L]) are within the normal range, and triglycerides are elevated (290 mg/dL [2.3 mmol/L]; normal is <165 mg/dL [1.9 mmol/L]).

A. What is this man's probable diagnosis?
B. Based on this man's blood glucose level and the ADA diabetes classification system, what diabetic status would you place this man in? Does he need a 75-g OGTT for further assessment of his IFG?
C. His OGTT test result reveals a 2-hour glucose value of 175 mg/dL (9.63 mmol/L). What is the diagnosis? What type of treatment would be appropriate for this man?

Chapter 34

Organization and Control of Neural Function

The nervous system, in coordination with the endocrine system, provides the means by which cell and tissue functions are integrated into a solitary, surviving organism. It controls skeletal muscle movement and helps to regulate cardiac and visceral smooth muscle activity. The nervous system enables the reception, integration, and perception of sensory information; it provides the substratum necessary for intelligence, anticipation, and judgment; and it facilitates adjustment to an ever-changing external environment.

Nervous Tissue Cells

The nervous system can be divided into two basic components: the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of the brain and spinal cord, which is protected by the skull and vertebral column, whereas the PNS is found outside these structures. Inherent in the basic design of the nervous system is the provision for the concentration of computational and control functions in the CNS, with the PNS relaying somatic and visceral sensory (afferent) input to the CNS for processing and transmitting efferent or motor output from the CNS to effector organs throughout the body (Fig. 34-1). Functionally, the nervous system is divided into the somatic and visceral or autonomic nervous systems. The somatic (Greek *soma*, "body") nervous system provides sensory and motor innervation for all parts of the CNS and PNS except viscera, smooth muscle, and glands. The autonomic nervous system

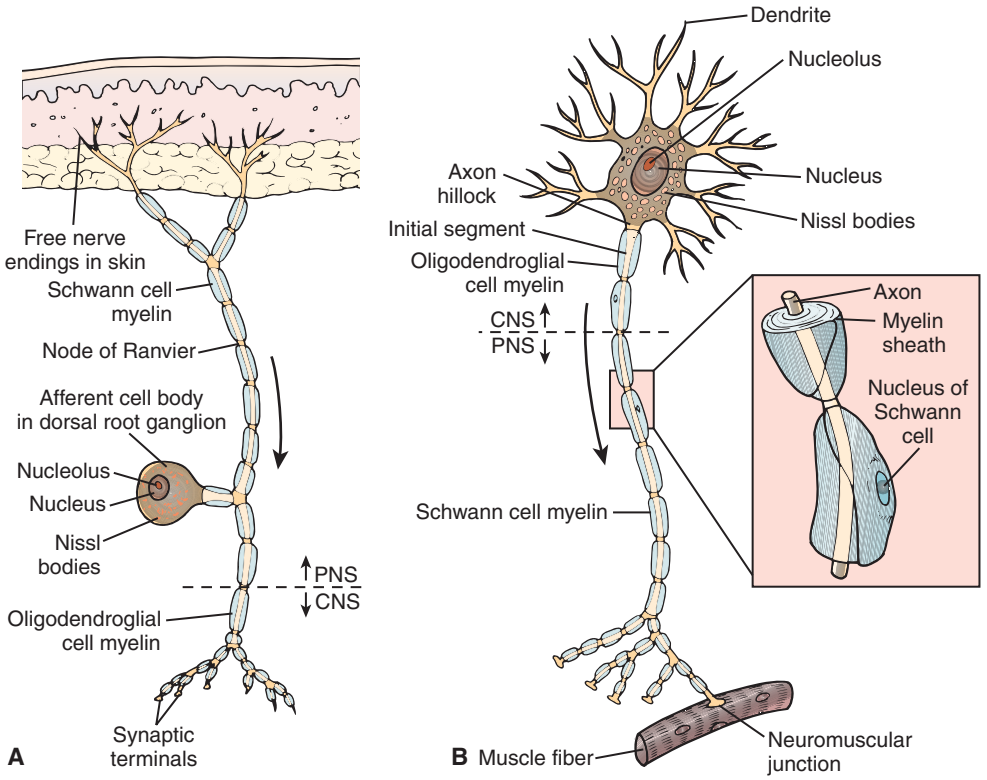

FIGURE 34-1. Afferent **(A)** and efferent neurons **(B),** showing the soma or cell body, dendrites, and axon. *Arrows* indicate the direction for conduction of action potentials.

(ANS) provides efferent motor innervation to smooth muscle, the conducting system of the heart, and glands. The ANS is further divided into a sympathetic division and a parasympathetic division.

Nervous tissue consists of two principal types of cells, neurons and supporting cells. The neurons are the functional cells of the nervous system. They exhibit membrane excitability and conductivity and secrete neurotransmitters and hormones, such as epinephrine and antidiuretic hormone. The supporting cells, such as the Schwann cells in the PNS and the glial cells in the CNS, protect the nervous system and provide metabolic support for the neurons.

Neurons

Neurons, which are the functioning cells of the nervous system, have three distinct parts: the cell body and its cytoplasm-filled processes, the dendrites and axons (Fig. 34-1). The axonal and dendritic processes form the functional connections, or synapses, with other nerve cells, receptor cells, or effector cells. Afferent, or sensory, neurons of the PNS transmit information to the CNS (see Fig. 34-1A), whereas efferent, or motor, neurons carry information away from the CNS (see Fig. 34-1B). Interspersed between the afferent and efferent neurons is a network of interconnecting neurons (also called *interneurons* or *internuncial* neurons) that modulate and control the body's response to changes in the internal and external environments.

The *cell body* of a neuron, also known as the *soma*, contains a large vesicular nucleus with one or more distinct nucleoli and a well-developed rough endoplasmic reticulum. A neuron's nucleus has the same deoxyribonucleic acid (DNA) and genetic code content that is present in other cells of the body, and its nucleolus, which is composed of portions of several chromosomes, produces ribonucleic acid (RNA) associated with protein synthesis. The cytoplasm contains large masses of ribosomes that are

The Structural Organization of the Nervous System

- The nervous system is divided into two parts: the central nervous system (CNS), consisting of the brain and spinal cord, which are located in the skull and spinal column, and the peripheral nervous system (PNS), which is located outside these structures.
- The nervous system contains two major types of cells: neurons, which are functioning cells of the nervous system, and supporting cells, which protect the nervous system and supply metabolic support.
- There are two types of neurons: afferent neurons or sensory neurons, which carry information to the CNS, and efferent neurons or motoneurons, which carry information from the CNS to the effector organs.

prominent in most neurons. These acidic RNA masses, which are involved in protein synthesis, stain as dark Nissl bodies with basic histologic stains (see Fig. 34-1B). The Nissl bodies and free ribosomes extend into the dendrites, but not into the axon. This area of the cell body, called the *axon hillock,* is free of large cytoplasmic organelles and serves as a landmark to distinguish between axons and dendrites in microscopic preparations.

The *dendrites* (from the Greek *dendron,* "tree") are multiple, branched extensions of the nerve cell body; they conduct information toward the cell body and are the main source of information for the neuron. The dendrites and cell body are studded with synaptic terminals that communicate with axons and dendrites of other neurons.

Axons are long efferent processes that project from the cell body and carry impulses away from the cell. Most neurons have only one axon; however, axons may exhibit multiple branching that results in many axonal terminals. The cytoplasm of the cell body extends to fill the dendrites and the axon. The proteins and other materials used by the axon are synthesized in the cell body and then flow down the axon through its cytoplasm.

The cell body of the neuron is equipped for a high level of metabolic activity. This is necessary because the cell body must synthesize the cytoplasmic and membrane constituents required to maintain the function of the axon and its terminals. Some of these axons extend for a distance of 1 to 1.5 m and have a volume that is 200 to 500 times greater than the cell body itself. Two axonal transport systems, one slow and one rapid, move molecules from the cell body through the cytoplasm of the axon to its terminals. Replacement proteins and nutrients slowly diffuse from the cell body, where they are transported, down the axon, moving at the rate of approximately 1 mm/day. Other molecules, such as some neurosecretory granules (e.g., neurotransmitters, neuromodulators, and neurohormones) or their precursors, are conveyed by a rapid, energy-dependent active transport system, moving at the rate of approximately 400 mm/day. For example, antidiuretic hormone and oxytocin, which are synthesized by neurons in the hypothalamus, are carried by rapid axonal transport to the posterior pituitary, where the hormones are released into the blood. A reverse rapid (i.e., retrograde) axonal transport system moves materials, including target cell messenger molecules, from axonal terminals back to the cell body.

Supporting Cells

The supporting cells of the nervous system, the Schwann cells of the PNS and the several types of glial cells of the CNS, give the neurons protection and metabolic support. The supporting cells segregate the neurons into isolated metabolic compartments, which are required for normal neural function.

The many-layered wrappings of the Schwann cells of the PNS and the oligodendroglia of the CNS produce myelin sheaths that serve to increase the velocity of nerve impulse conduction in axons. Myelin has a high lipid content, which gives it a whitish color, and hence the name *white matter* is given to the masses of myelinated fibers of the spinal cord and brain. Besides its role in increasing conduction velocity, the myelin sheath is essential for the survival of larger neuronal processes, perhaps by the secretion of neurotrophic compounds.

In some pathologic conditions, such as multiple sclerosis in the CNS and Guillain-Barré syndrome in the PNS, the myelin may degenerate or be destroyed, leaving a section of the axonal process without myelin while leaving the nearby Schwann or oligodendroglial cells intact. Unless remyelination takes place, the axon eventually dies.

Supporting Cells of the Peripheral Nervous System

Schwann cells are the supporting cells in the PNS. They produce the myelin sheath that isolates axons of neurons in the PNS from the surrounding extracellular compartment, ensure rapid conduction of nerve impulses, and aid in cleaning up PNS debris and guide the regrowth of PNS axons. During the process of myelination, the Schwann cell wraps around each nerve process several times in a "jelly roll" fashion (Fig. 34-2). Schwann cells line up along the neuronal process, and each of these cells forms its own discrete myelin segment. Successive Schwann cells are separated by short extracellular fluid gaps, called the *nodes of Ranvier,* where the myelin is missing and voltage-gated sodium channels are concentrated. The nodes of Ranvier increase nerve conduction by allowing the impulse to jump from node to node through the extracellular fluid in a process called *saltatory conduction* (from the Latin *saltare,* "to jump"). In this way, the impulse can travel more rapidly than it could if it were required to move systematically along the entire nerve process. This increased conduction velocity greatly reduces reaction time, or time between the application of a stimulus and the subsequent motor response. The short reaction time is especially important in peripheral nerves with long distances (sometimes 1 to 1.5 m) for conduction between the CNS and distal effector organs.

Each of the Schwann cells along a peripheral nerve is encased in a continuous tube of basement membrane, which in turn is surrounded by a multilayered sheath of loose connective tissue known as the *endoneurium* (see Fig. 34-2). The endoneurial sheath, which is essential to the regeneration of peripheral nerves, provides a collagenous tube through which a regenerating axon can again reach its former target. The endoneurial sheath does not penetrate the CNS. The absence of the endoneurial sheaths is thought to be a major factor in the limited axonal regeneration of CNS nerves compared with those of the PNS.

The endoneurial sheaths are bundled with blood vessels into small clusters of nerves called *fascicles*. In the nerve, the fascicles consisting of bundles of nerve fibers are surrounded by another protective covering called the *perineurium*. Usually, several fascicles are further surrounded by the heavy, protective *epineurial sheath* of the peripheral nerve. The protective layers that surround the peripheral nerve processes are continuous with the connective tissue capsule of the sensory nerve endings and the connective tissue that surrounds the effector structures, such as the skeletal muscle cell. Centrally, the connective tissue

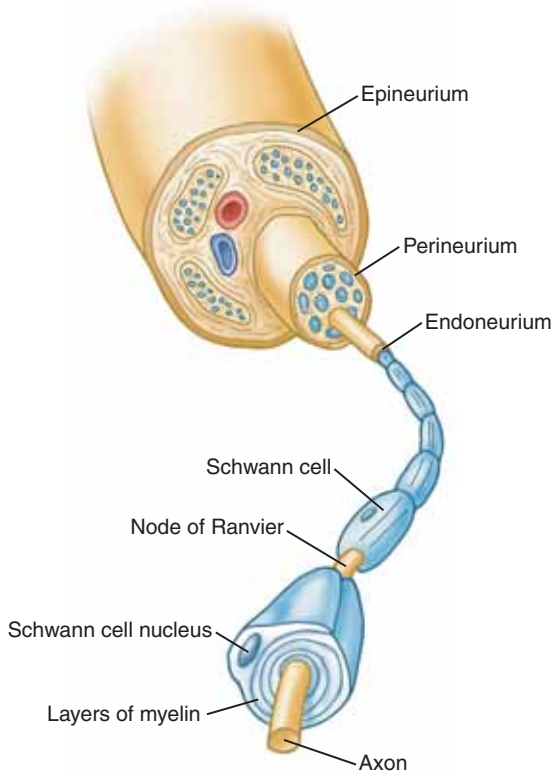

FIGURE 34-2. Section of a peripheral nerve containing both afferent (sensory) and efferent (motor) neurons. Schwann cells form a myelin sheath around the larger nerve fibers in the peripheral nervous system. Successive Schwann cells are separated by short extracellular fluid gaps called the *nodes of Ranvier,* where the myelin is missing and the voltage-gated sodium channels are concentrated.

layers continue along the dorsal and ventral roots of the nerve and fuse with the meninges that surround the spinal cord and brain.

Supporting Cells of the Central Nervous System

Supporting cells of the CNS consist of the oligodendrocytes, astrocytes, microglia, and ependymal cells (Fig. 34-3). The *oligodendrocytes* form the myelin in the CNS. Instead of forming a myelin covering for a single axon, these cells reach out with several processes, each wrapping around and forming a multilayered myelin segment around several different axons. As with peripheral myelinated fibers, the covering of axons in the CNS increases the velocity of nerve conduction.

Astrocytes are the largest and most numerous of neuroglial cells and are particularly prominent in the gray matter of the CNS. They form a network within the CNS and communicate with neurons to support and modulate their activities. Astrocytes have many processes, some stretching their processes from blood vessels to neurons and others filling most of the intercellular space within the CNS. It is now thought that astrocytes play an important role in the movement of metabolites and wastes to and from neurons and regulate ionic concentrations in the intercellular compartment. In addition, astrocytes take up neurotransmitters from synaptic zones after their release and thereby help regulate synaptic activity. They also have a role in maintaining the tight junctions of capillaries that form the blood-brain barrier. Astrocytes are also the principal cells responsible for repair and scar formation in the brain. They can fill their

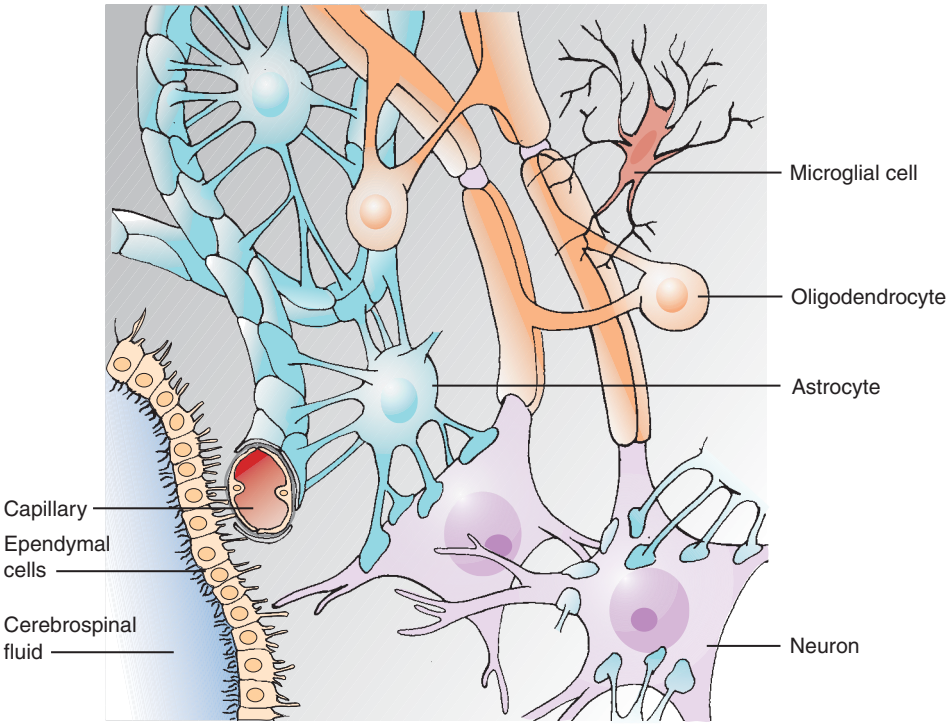

FIGURE 34-3. The supporting cells of the central nervous system (CNS). Diagrammatic view of relationships between the glial elements (astrocyte, oligodendrocyte, microglial cell, and the ependymal cells), the capillaries, the cerebrospinal fluid, and the cell bodies of CNS neurons.

cytoplasm with microfibrils (i.e., fibrous astrocytes), and masses of these cells form the special type of scar tissue that develops in the CNS when tissue is destroyed, a process called *gliosis*.

A third type of neuroglial cell, the *microglia,* is a small phagocytic cell that is available for cleaning up debris after cellular damage, infection, or cell death. The fourth type of cell, the *ependymal cell,* forms the lining of the neural tube cavity, the ventricular system. In some areas, these cells combine with a rich vascular network to form the *choroid plexus,* where production of the cerebrospinal fluid (CSF) takes place.

Metabolic Requirements of Nervous Tissue

Nervous tissue has a high rate of metabolism. Although the brain makes up only 2% of the body's weight, it receives approximately 15% of the resting cardiac output and consumes 20% of its oxygen. Despite its substantial energy requirements, the brain can neither store oxygen nor engage in anaerobic metabolism. An interruption in the blood or oxygen supply to the brain rapidly leads to clinically observable signs and symptoms. Without oxygen, brain cells continue to function for approximately 10 seconds. Unconsciousness occurs almost simultaneously with cardiac arrest, and the death of brain cells begins within 4 to 6 minutes. Interruption of blood flow also leads to the accumulation of metabolic by-products that are toxic to neural tissue.

Glucose is the major fuel source for the nervous system. Unlike muscle cells, neurons have no glycogen stores and must rely on glucose from the blood or the glycogen stores of supporting glial cells to meet their energy needs. Persons receiving insulin for diabetes may experience signs of neural dysfunction and unconsciousness (i.e., insulin reaction or shock) when blood glucose drops because of insulin excess (see Chapter 33).

In summary, the nervous system can be divided into two basic components: the CNS or brain and spinal cord, which are located within the skull and vertebral column, and the PNS, which is located outside these structures. Inherent in the basic design of the nervous system is the provision for the concentration of computational and control functions in the CNS, with the PNS relaying input to the CNS for processing and transmitting output from the CNS to effector organs throughout the body.

Nervous tissue consists of two types of cells: neurons and supporting cells. Neurons, which are the functional components of the nervous system, are composed of three parts: a cell body, which controls cell activity; the dendrites, which conduct information toward the cell body; and the axon, which carries impulses from the cell body. The supporting cells consist of Schwann cells of the PNS and the oligodendrocytes, astrocytes, microglial cells, and ependymal cells of the CNS. The supporting cells protect and provide metabolic support for the neurons and aid in segregating them into isolated compartments, which is necessary for normal neuronal function. The Schwann cells of the PNS and the oligodendroglial cells of the CNS form the myelin sheath that allows for rapid conduction of impulses.

The nervous system has a high level of metabolic activity, requiring a continuous supply of oxygen and glucose. Although the brain makes up only 2% of the body's weight, it receives approximately 15% of the resting cardiac output and consumes 20% of its oxygen.

Nerve Cell Communication

Neurons are characterized by the ability to communicate with other neurons and body cells through electrical impulses or action potentials, which are abrupt, pulsatile changes in the membrane potential that last a few ten thousandths to a few thousandths of a second. The frequency and pattern of action potentials constitute the code used by neurons to transfer information from one location to another.

Action Potentials

The cell membranes of excitable tissue, including those of nerve and muscle cells, contain ion channels that are responsible for generating action potentials (see Chapter 1, Fig. 1-13). These ion channels are guarded by voltage-dependent gates that open and close with changes in the membrane potential. Separate voltage-gated channels exist for the sodium, potassium, and calcium ions. Each type of ion channel has a characteristic membrane potential that opens and closes its channels. Also present are ligand-gated channels that respond to chemical messengers such as neurotransmitters, mechanically gated channels that respond to physical changes in the cell membrane, and light-gated channels that respond to fluctuations in light levels.

Action potentials can be divided into three phases: the resting or polarized state, depolarization, and repolarization (Fig. 34-4). The *resting membrane potential* (approximately −90 mV for large nerve fibers) is the undisturbed period of the action potential during which the nerve is not transmitting impulses (discussed in Chapter 1). During this period, the membrane is said to be *polarized* because of the large separation of charge (i.e., positive on the outside and negative on the inside). The resting phase of the membrane potential continues until some event causes the membrane to increase its permeability to sodium. A *threshold potential* (approximately −60 mV in large nerve fibers) represents the membrane potential at which neurons or other excitable tissues are stimulated to fire. When the threshold potential is reached, the gate-like structures in the ion channels open. Below the threshold potential, these gates remain tightly closed. The gates function on an all-or-none basis; they are either

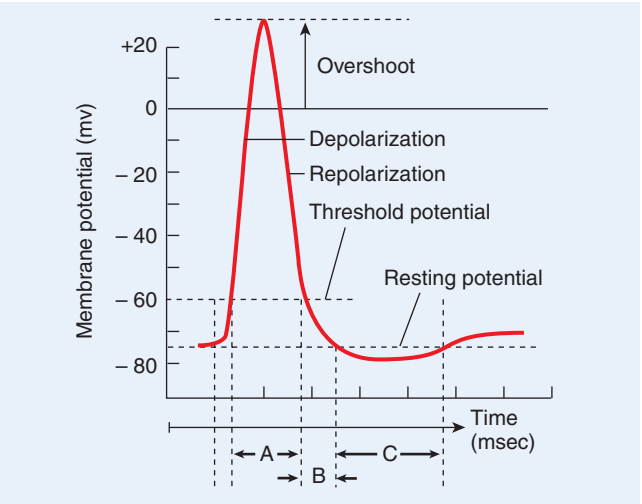

FIGURE 34-4. Time course of the action potential recorded at one point of an axon with one electrode inside and one outside the plasma membrane. The rising part of the action potential is called the *spike.* The rising phase plus approximately the first half of the repolarization phase is the absolute refractory period **(A)**. The portion of the repolarization phase that extends from the threshold to the resting membrane potential represents the relative refractory period **(B)**. The remaining portion of the repolarization phase to the resting membrane potential is the negative afterpotential **(C)**.

fully open or fully closed. Under ordinary circumstances, the threshold stimulus is sufficient to open many ion channels, triggering massive depolarization of the membrane (the action potential).

Depolarization is characterized by the flow of electrically charged ions. During the depolarization phase, the membrane suddenly becomes permeable to sodium ions; the rapid inflow of sodium ions produces local currents that travel through the adjacent cell membrane, causing the sodium channels in this part of the membrane to open. In neurons, sodium ion gates remain open for approximately a quarter of a millisecond. During this phase of the action potential, the inner face of the membrane becomes positive (approximately +30 to +45 mV).

Repolarization is the phase during which the polarity of the resting membrane potential is reestablished. This is accomplished with closure of the sodium channels and opening of the potassium channels. The outflow of positively charged potassium ions across the cell membrane returns the membrane potential to negativity. The sodium/potassium–adenosine triphosphatase (Na^+/K^+-ATPase) pump gradually reestablishes the resting ionic concentrations on each side of the membrane. Membranes of excitable cells must be sufficiently repolarized before they can be reexcited. During repolarization, the membrane remains refractory (i.e., does not fire) until repolarization is approximately one-third complete. This period, which lasts approximately one half of a millisecond, is called the *absolute refractory period.* During one portion of the recovery period, the membrane can be excited, although only by a stronger-than-normal stimulus. This period is called the *relative refractory period.*

The excitability of neurons can be affected by conditions that alter the resting membrane potential, moving it either closer to or farther from the threshold potential. *Hypopolarization* increases the excitability of the postsynaptic neuron by bringing the membrane potential closer to the threshold potential so that a smaller subsequent stimulus is needed to cause the neuron to fire. *Hyperpolarization* brings the membrane potential further from the threshold and has the opposite, inhibitory effect, decreasing the likelihood that an action potential will be generated.

Synaptic Transmission

Neurons communicate with each other through structures known as *synapses.* Two types of synapses are found in the nervous system: electrical and chemical. *Electrical synapses* permit the passage of current-carrying ions through small openings called *gap junctions* that penetrate the cell junction of adjoining cells and allow current to travel in either direction. The gap junctions allow an action potential to pass directly and quickly from one neuron to another and often serve to link neurons having close functional relationships into circuits.

The most common type of synapse is the *chemical synapse.* Chemical synapses involve special presynaptic and postsynaptic membrane structures, separated by a synaptic cleft. The presynaptic terminal secretes one and often several chemical transmitter molecules (i.e., neurotransmitters or neuromodulators). The secreted neurotransmitters diffuse into the synaptic cleft and bind to receptors on the postsynaptic membrane. In contrast to an electrical synapse, a chemical synapse serves as a rectifier, permitting only one-way communication. Chemical synapses are divided into two types: excitatory and inhibitory. In excitatory synapses, binding of the neurotransmitter to the receptor produces depolarization of the postsynaptic membrane. Binding of the neurotransmitter to the receptor in an inhibitory synapse reduces the postsynaptic neuron's ability to generate an action potential.

A neuron's cell body and dendrites are covered by thousands of synapses, any or many of which can be active at any moment. Because of the interaction of this rich synaptic input, each neuron resembles a little integrator, in which circuits of many neurons interact with one another. It is the complexity of these interactions and the subtle integrations involved in producing behavioral responses that give rise to the nervous system's intelligence.

Chemical Synaptic Transmitters

The function of the nervous system relies on chemical substances that function as synaptic transmitters. These messengers include the neurotransmitters, neuromodulators, and neurotrophic or nerve growth factors.

Neurotransmitters. Neurotransmitters are small molecules that incorporate a positively charged nitrogen atom; they include several amino acids, peptides, and

monoamines. The amino acids glutamine, glycine, and γ-aminobutyric acid (GABA) serve as neurotransmitters at most CNS synapses. GABA mediates most synaptic inhibition in the CNS. Drugs such as the benzodiazepines (e.g., the tranquilizer diazepam) and the barbiturates exert their action by binding to their own distinct receptor on a GABA-operated ion channel. The drugs by themselves do not open the channel, but they change the effect that GABA has when it binds to the channel at the same time as the drug. *Peptides* are low–molecular-weight molecules that are made up of two or more amino acids. They include substance P and the endorphins and enkephalins, which are involved in pain sensation and perception (see Chapter 35). A *monoamine* is an amine molecule containing one amino group (NH_2). Serotonin, dopamine, norepinephrine, and epinephrine are monoamines synthesized from amino acids.

The process of neurotransmission involves the synthesis, storage, and release of a neurotransmitter; the reaction of the neurotransmitter with a receptor; and termination of the receptor action. Neurotransmitters are synthesized in the cytoplasm of the axon terminal. The synthesis of transmitters may require one or more enzyme-catalyzed steps (e.g., one for acetylcholine and three for norepinephrine). Neurons are limited as to the type of transmitter they can synthesize by their enzyme systems. After synthesis, the neurotransmitter molecules are stored in the axon terminal in tiny, membrane-bound sacs called *synaptic vesicles*. These vesicles protect the neurotransmitters from enzyme destruction in the nerve terminal. There may be thousands of vesicles in a single terminal, each containing 10,000 to 100,000 transmitter molecules. The arrival of an impulse at a nerve terminal causes the vesicles to move to the cell membrane and release their transmitter molecules into the synaptic space.

Neurotransmitters exert their actions through specific proteins, called *receptors,* embedded in the postsynaptic membrane. These receptors are tailored precisely to match the size and shape of the transmitter. In each case, the interaction between a transmitter and receptor results in a specific physiologic response. The action of a transmitter is determined by the type of receptor (excitatory or inhibitory) to which it binds. For example, acetylcholine is excitatory when it is released at a myoneural junction, and it is inhibitory when it is released at the sinoatrial node in the heart. Receptors are named according to the type of neurotransmitter with which they interact. For example, a *cholinergic receptor* is a receptor that binds acetylcholine.

Rapid removal of a transmitter, once it has exerted its effects on the postsynaptic membrane, is necessary to maintain precise control of neural transmission. A released transmitter can undergo one of three fates: (1) it can be broken down into inactive substances by enzymes, (2) it can be taken back up into the presynaptic neuron in a process called *reuptake,* or (3) it can diffuse away into the intercellular fluid until its concentration is too low to influence postsynaptic excitability. For example, acetylcholine is rapidly broken down by acetylcholinesterase into acetic acid and choline, with the choline being taken back into the presynaptic neuron for reuse in acetylcholine synthesis. The catecholamines are largely taken back into the neuron in an unchanged form for reuse. Catecholamines also can be degraded by enzymes in the synaptic space or in the nerve terminals.

Neuromodulators. Other classes of messenger molecules, known as *neuromodulators,* also may be released from axon terminals. Neuromodulator molecules react with presynaptic or postsynaptic receptors to alter the release of or response to neurotransmitters. Neuromodulators may act on postsynaptic receptors to produce slower and longer-lasting changes in membrane excitability. This alters the action of the faster-acting neurotransmitter molecules by enhancing or decreasing their effectiveness. By combining with autoreceptors on its own presynaptic membrane, a transmitter can act as a neuromodulator to augment or inhibit further nerve activity. In some nerves, such as the peripheral sympathetic nerves, a messenger molecule can have both transmitter and modulator functions. For example, norepinephrine can activate an α_1-adrenergic postsynaptic receptor to produce vasoconstriction or stimulate an α_2-adrenergic presynaptic receptor to inhibit further norepinephrine release.

Neurotrophic Factors. Neurotrophic or nerve growth factors are required to maintain the long-term survival of the postsynaptic cell and are secreted by axon terminals independent of action potentials. Examples include neuron-to-neuron trophic factors in the sequential synapses of CNS sensory neurons. Trophic factors from target cells that enter the axon and are necessary for the long-term survival of presynaptic neurons also have been demonstrated. Target cell–to–neuron trophic factors probably have great significance in establishing specific neural connections during normal embryonic development.

In summary, neurons communicate with other neurons and body cells through pulsed electrical signals called *action potentials.* The cell membranes of neurons contain ion channels that are responsible for generating action potentials. Action potentials are divided into three parts: the resting membrane potential, during which the membrane is polarized but no electrical activity occurs; the depolarization phase, during which sodium channels open, allowing rapid inflow of the sodium ions that generate the electrical impulse; and the repolarization phase, during which the membrane is permeable to the potassium ion, allowing for the efflux of potassium ions and return to the resting membrane potential.

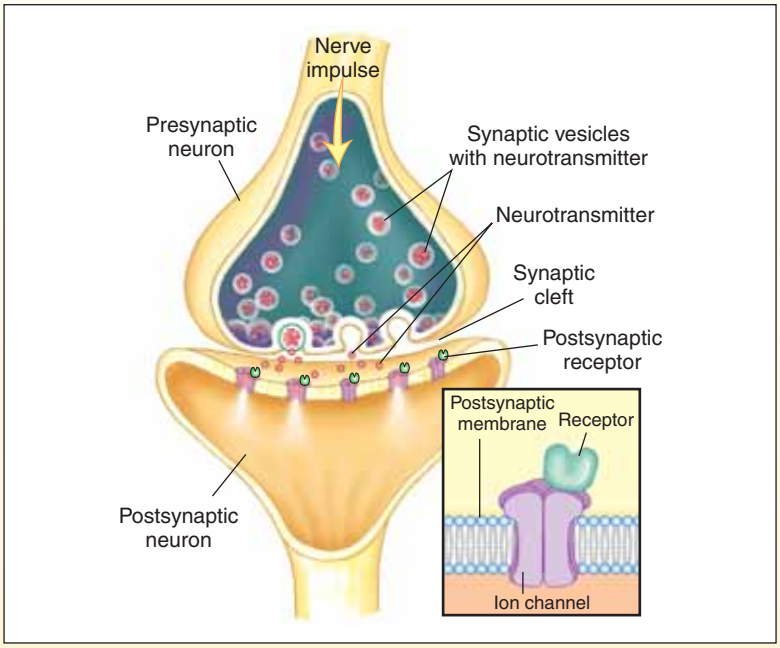
Synapses are structures that permit communication between neurons. Two types of synapses have been identified: electrical and chemical. Electrical synapses consist of gap junctions between adjacent cells that allow action potentials to move rapidly from one cell to another. Chemical synapses involve special presynaptic and postsynaptic structures, separated by a synaptic cleft. They rely on chemical messengers, released from the presynaptic neuron, that cross the synaptic cleft and then interact with receptors on the postsynaptic neuron.

UNDERSTANDING → Synaptic Transmission

Neurons communicate with each other through chemical synapses and the use of neurotransmitters. Chemical synapses consist of a presynaptic neuron, a synaptic cleft, and a postsynaptic neuron. The communication process relies on (1) synthesis and release of the neurotransmitter from a presynaptic neuron, (2) binding of the neurotransmitter to receptors in the postsynaptic neuron, and (3) removal of the neurotransmitter from the receptor site.

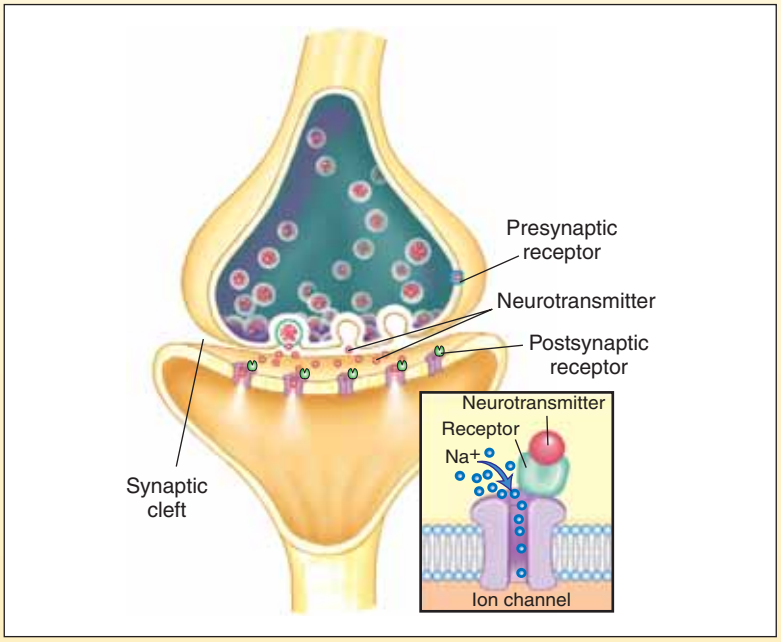
1

Neurotransmitter Synthesis and Release. Neurotransmitters are synthesized in the presynaptic neuron, and then stored in synaptic vesicles. Communication between the two neurons begins with a nerve impulse that stimulates the presynaptic neuron, followed by movement of the synaptic vesicles to the cell membrane and release of neurotransmitter into the synaptic cleft.

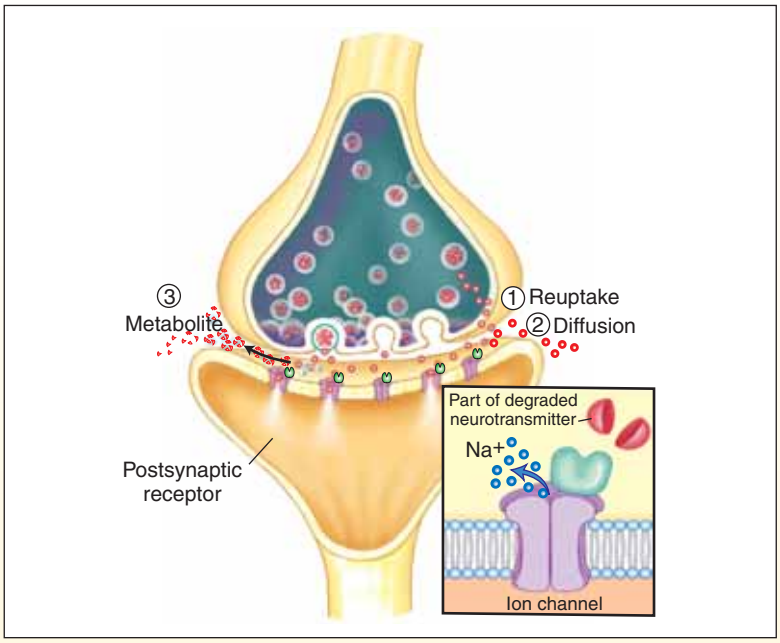


2

Receptor Binding. Once released from the presynaptic neuron, the neurotransmitter moves across the synaptic cleft and binds to receptors on the postsynaptic neuron. The action of a neurotransmitter is determined by the type of receptor (excitatory or inhibitory) to which it binds. Binding of a neurotransmitter to a receptor with an excitatory function often results in the opening of an ion channel, such as the sodium channel. Many presynaptic neurons also have receptors to which a neurotransmitter binds. The presynaptic receptors function in a negative feedback manner to inhibit further release of the neurotransmitter.



3 **Neurotransmitter Removal.** Precise control of synaptic function relies on the rapid removal of the neurotransmitter from the receptor site. A released neurotransmitter can (1) be taken back up into the neuron in a process called reuptake, (2) diffuse out of the synaptic cleft, or (3) be broken down by enzymes into inactive substances or metabolites. The action of norepinephrine is largely terminated by the reuptake process, in which the neurotransmitter is taken back into the neuron in an unchanged form and reused. It can also be broken down by enzymes in the synaptic cleft or in the nerve terminals. The neurotransmitter acetylcholine is rapidly broken down by the enzyme acetylcholinesterase.



Neurotransmitters are chemical messengers that control neural function; they selectively cause excitation or inhibition of action potentials. Three major types of neurotransmitters are known: amino acids such as glutamic acid and GABA, peptides such as the endorphins and enkephalins, and monoamines such as epinephrine and norepinephrine. Neurotransmitters interact with cell membrane receptors to produce either excitatory or inhibitory actions. Neuromodulators are chemical messengers that react with membrane receptors to produce slower and longer-acting changes in membrane permeability. Neurotrophic or growth factors, also released from presynaptic terminals, are required to maintain the long-term survival of postsynaptic neurons.

Developmental Organization of the Nervous System

The organization of the nervous system can be described in terms of its embryonic development, in which newer functions and greater complexity result from the modification and enlargement of earlier developed structures. Thus, the rostral or front end of the CNS, which is the last to develop, is more specialized in its functions than the brain stem and spinal cord, which are the first to develop. The dominance of the front end of the CNS is reflected in what has been termed a *hierarchy of control*, with the forebrain having control over the brain stem and the brain stem having control over the spinal cord. In the developmental process, newer functions were added to the surface of earlier developed systems. As newer functions became concentrated at the rostral end of the nervous system, they also became more vulnerable to injury. Nothing exemplifies this principle better than the persistent vegetative state (discussed in Chapter 37) that occurs when severe brain injury causes irreversible damage to higher cortical centers, while lower stem centers such as those that control breathing remain functional.

Embryonic Development

The nervous system appears very early in embryonic development (22 to 23 days). This early development is essential because it influences the development and organization of many other body systems, including the axial skeleton, skeletal muscles, and sensory organs such as the eyes and ears. Throughout life, the organization of the nervous system retains many patterns that were established during embryonic life. It is this early pattern of segmental development in the embryo that is presented as a framework for understanding the nervous system.

During the second week of development, embryonic tissue consists of two layers, the endoderm and the ectoderm.

The Developmental Organization of the Nervous System

- Embryologically, the nervous system begins its development as a hollow tube, the cephalic portion of which becomes the brain and the more caudal part the spinal cord.
- In the process of development, the basic organizational pattern is that of a longitudinal series of segments, each repeating the same basic fundamental organizational pattern: a body wall or soma containing the axial skeleton and a neural tube, which develops into the nervous system.
- On cross-section, the embryonic neural tube develops into a central canal surrounded by gray matter or cellular portion (cell columns) and the white matter, or tract system of the central nervous system (CNS).
- As the nervous system develops, it becomes segmented, with a repeating pattern of afferent neuron axons forming the dorsal roots of each succeeding segmental nerve, and the exiting efferent neurons forming the ventral roots of each succeeding segmental nerve.
- The nerve cells in the gray matter are arranged longitudinally in cell columns, with afferent sensory neurons located in the dorsal columns and efferent motor neurons located in the ventral columns.
- The axons of the cell column neurons project out into the white matter of the CNS, forming the longitudinal tract systems.

At the beginning of week 3, the ectoderm begins to invaginate and migrates between the two layers, forming a third layer called the *mesoderm* (Fig. 34-5). Mesoderm along the entire midline of the embryo forms a specialized rod of embryonic tissue called the *notochord*. The notochord and adjacent mesoderm provide the necessary induction signal for the overlying ectoderm to differentiate and form a thickened structure called the *neural plate*, the primordium of the nervous system. Within the neural plate an axial groove (i.e., neural groove) develops and sinks into the underlying mesoderm, allowing its walls to fuse across the top and form an ectodermal tube called the *neural tube*. This process, called *closure*, occurs during the later third and fourth weeks of gestation and is vital to the survival of the embryo.

During embryonic development, the neural tube develops into the CNS, while the notochord becomes the foundation around which the vertebral column ultimately develops. The surface ectoderm separates from the neural tube and fuses over the top to become the outer layer of skin. Initial closure of the neural tube begins at the cervical and high thoracic levels and zippers rostrally toward the cephalic end of the embryo and caudally toward the sacrum. Complete closure occurs at the rostral-most end of the brain (i.e., anterior neuropore) around day 25 and at about day 27 in the lumbosacral region (i.e., posterior neuropore).

As the neural tube closes, ectodermal cells called *neural crest cells* migrate away from the dorsal surface of the neural tube to become the progenitors of the neurons and supporting cells of the PNS. During this period of embryonic development, neural cell adhesive molecules (N-CAMs) are produced to decrease migration of neural crest cells. In addition, fibronectin molecules are produced to increase the formation of pathways that guide the neural crest cells during their migration. Some of these cells gather into clusters to form the *dorsal root ganglia* at the sides of each spinal cord segment and the *cranial ganglia* that are present in most brain segments. Neurons of these ganglia become the afferent or sensory neurons of the PNS. Other neural crest cells become the pigment cells of the skin or contribute to the formation of the meninges, many structures of the face, and the peripheral ganglion cells of the autonomic nervous system, including those of the adrenal cortex.

During development, the more rostral portions of the embryonic neural tube—approximately 10 segments—undergo extensive modification and enlargement to form the brain (Fig. 34-6). In the early embryo, 3 swellings, or primary vesicles, develop, subdividing these 10 segments into the prosencephalon, or forebrain, containing the first 2 segments; the mesencephalon, or midbrain, which develops from segment 3; and the rhombencephalon, or hindbrain, which develops from segments 4 to 10. In the prosencephalon or forebrain, two pairs of lateral outpouchings develop: the optic cup, which becomes the optic nerve and retina, and the telencephalic vesicles, which become the cerebral hemispheres. Within the prosencephalon, the hollow central canal expands to become enlarged CSF-filled cavities, the first and second (lateral) ventricles. The remaining diencephalic portion of the neural tube develops into the thalamus and hypothalamus. The neurohypophysis (posterior pituitary) grows as a midline ventral outgrowth at the junctions of segments 1 and 2. A dorsal outgrowth, the pineal body, develops between segments 2 and 3.

Neural Tube Defects

The major morphogenic defects of the spine and spinal cord are due to the abnormal formation or closure of the neural tube and surrounding tissues. These neural tube defects can involve neural tissue, the meninges that cover the spinal cord, muscle tissue, skin, and the vertebral column. Severe neural tube defects occur in approximately 1 in 1000 births. These defects range from spina bifida occulta to spina bifida with myeloschisis. In spina bifida occulta, the lamina (neural arches) of lumbar (L) 5 and/or sacral (S) 1 fail to develop and spinal cord and surrounding meninges lie within the incomplete vertebral column. The defect is concealed by the overlying skin, but its location is often marked by a patch of hair in the lumbar region. Most people with spina bifida occulta have no back problems. In severe types of spina bifida,

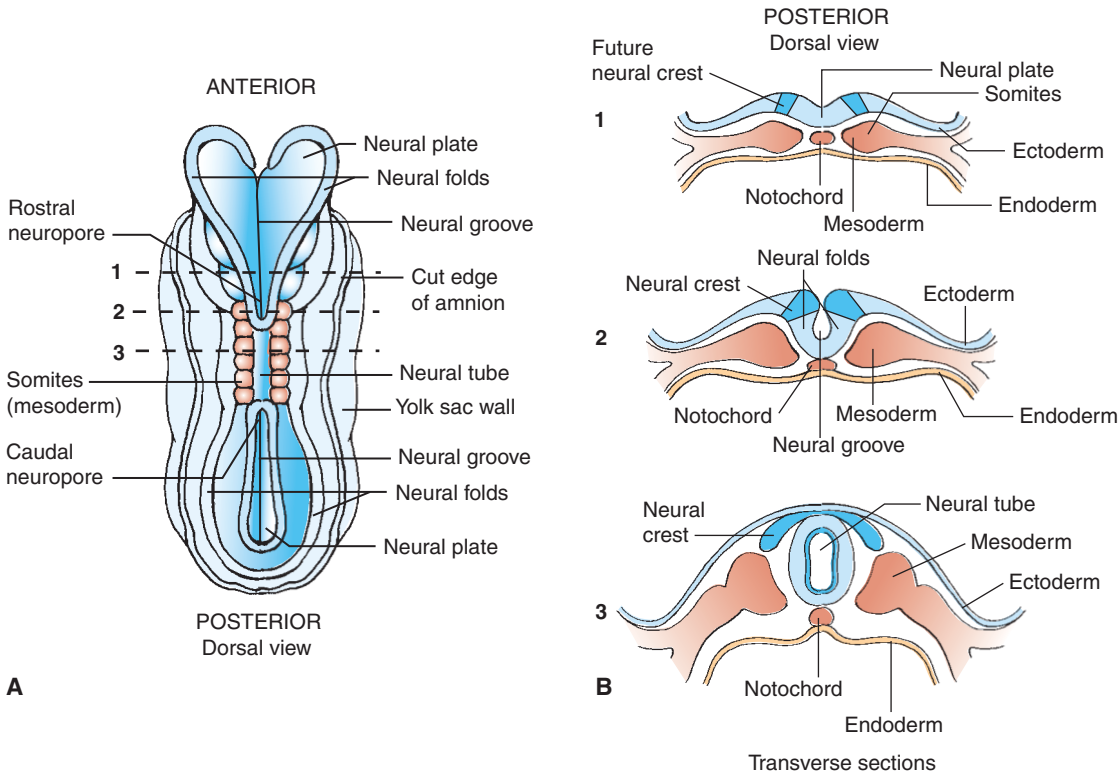


FIGURE 34-5. Folding of the neural tube. **(A)** Dorsal view of a six-somite embryo (22 to 23 days) showing the neural folds, neural groove, and fused neural tube. The anterior neuropore closes at about day 25 and the posterior neuropore at about day 27. **(B)** Three cross-sections taken at the levels indicated in A. The sections indicate where the neural tube is just beginning to form.

one or more of the vertebral arches may fail to develop completely. In spina bifida cystica, there is herniation of the meninges (meningocele, a spina bifida associated with a meningeal cyst) and/or the spinal cord (meningomyelocele) (Fig. 34-7).

Clinical neurologic dysfunction is related to abnormalities in the cord itself and to superimposed infections that extend from the thin overlying skin. Meningomyeloceles occur most commonly in the lumbosacral region and produce clinical deficits referable to motor and sensory function in the lower extremities as well as disturbances in bowel and bladder control. The etiology of neural tube defects is unknown. Folate deficiency during the initial weeks of gestation has been implicated as a risk factor, possibly interacting with host and environmental factors. Antenatal diagnosis has been facilitated by ultrasonographic imaging and maternal blood sampling for elevated α-fetoprotein (see Chapter 6).

Segmental Organization

Developmentally, the basic organizational pattern of the body is that of a longitudinal series of segments, each repeating the same fundamental pattern. Although the early muscular, skeletal, vascular, and excretory systems and the nerves that supply the somatic and visceral structures have the same segmental pattern, it is the nervous system that most clearly retains this organization in postnatal life. The CNS and its associated peripheral nerves consist of approximately 43 segments, 33 of which form the spinal cord and spinal nerves, and 10 of which form the brain and its cranial nerves.

The basic pattern of the CNS is that seen in the spinal cord—a central cavity surrounded by an inner core of gray matter and a superficial layer of white matter (Fig. 34-8). The brain retains this organization, but it also contains additional regions of gray matter that are not evident in the spinal cord. The gray matter is functionally divided into longitudinal columns of nerve cell bodies called the *cell columns*. The superficial white matter region contains the longitudinal tract systems of the CNS. The dorsal half or dorsal horn of the gray matter contains afferent neurons. The ventral portion, or *ventral horn,* contains efferent neurons that communicate by way of the ventral roots with effector cells of the body segment. Many CNS neurons develop axons that grow longitudinally as tract systems that communicate between neighboring and distal segments of the neural tube.

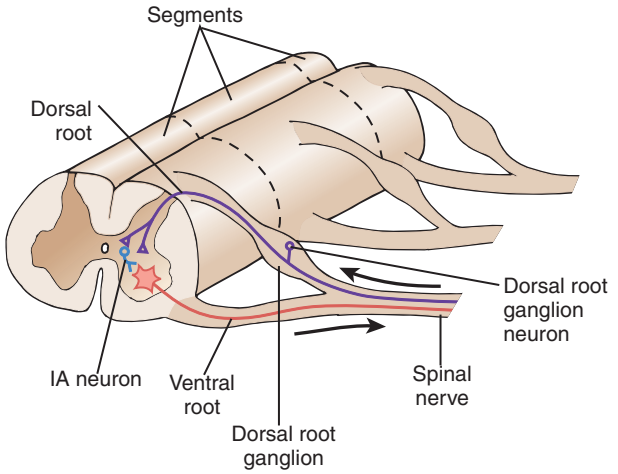

FIGURE 34-8. In this diagram of three segments of the spinal cord, three dorsal roots enter the dorsal lateral surface of the cord, and three ventral roots exit. The dorsal root ganglion contains dorsal root ganglion cells, whose axons bifurcate: one process enters the spinal cord in the dorsal root, and the other extends peripherally to supply the skin and muscle of the body. The ventral root is formed by axons from motoneurons in the spinal cord. IA, input association.

Each segment of the CNS is accompanied by bilateral pairs of bundled nerve fibers, or roots, a dorsal pair and a ventral pair. The paired dorsal roots connect a pair of dorsal root ganglia and their corresponding CNS segment. The dorsal root ganglia contain many afferent nerve cell bodies, each having two axonlike processes—one that ends in a peripheral receptor and the other that enters the dorsal horn of its respective CNS segment. The paired ventral roots of each segment contain fibers supplying skeletal muscles and visceral structures of the body segment.

All brain segments, except segment 2, retain some portion of the basic segmental organization of the nervous system in which each segment has multiple paired branches containing a grouping of component axons. The classic pattern of spinal nerve organization, which consists of a pair of dorsal and a pair of ventral roots, is a later development that has not occurred in the cranial nerves. Consequently, the cranial nerves, which are arbitrarily numbered 1 through 12, retain the early pattern of development, with more than one cranial nerve branching from a single segment. The truly segmental nerve pattern of the cranial nerves is altered because all branches from segment 2 and most of the branches from segment 1 are missing. Cranial nerve 2, also called the *optic nerve,* is not a segmental nerve. It is a brain tract connecting the retina (modified brain) with the first forebrain segment from which it developed.

Cell Columns

The body is organized into soma (e.g., skin, muscles, and skeletal structures of the body wall) and viscera (e.g., internal organs and blood vessels). The organizational structure of the nervous system can be best explained and simplified as a pattern in which functionally specific PNS and CNS afferent and efferent somatic and visceral neurons are repeated as parallel cell columns running lengthwise along the nervous system. In this organizational pattern, afferent neurons, dorsal horn cells, and ventral horn cells are organized as a bilateral series of 11 cell columns.

The cell columns on each side can be further grouped according to their location in the PNS: four in the dorsal root ganglia that contain sensory neurons, four in the dorsal horn containing sensory input association neurons, and three in the ventral horn that contain motor neurons (Fig. 34-9). The axonlike process that enters the dorsal horn communicates with a neuron called an *input association (IA) neuron.* The IA neurons distribute afferent information to local reflex circuitry and to more rostral segments of the CNS. The ventral horns contain *output association* (OA) neurons and lower motor neurons,

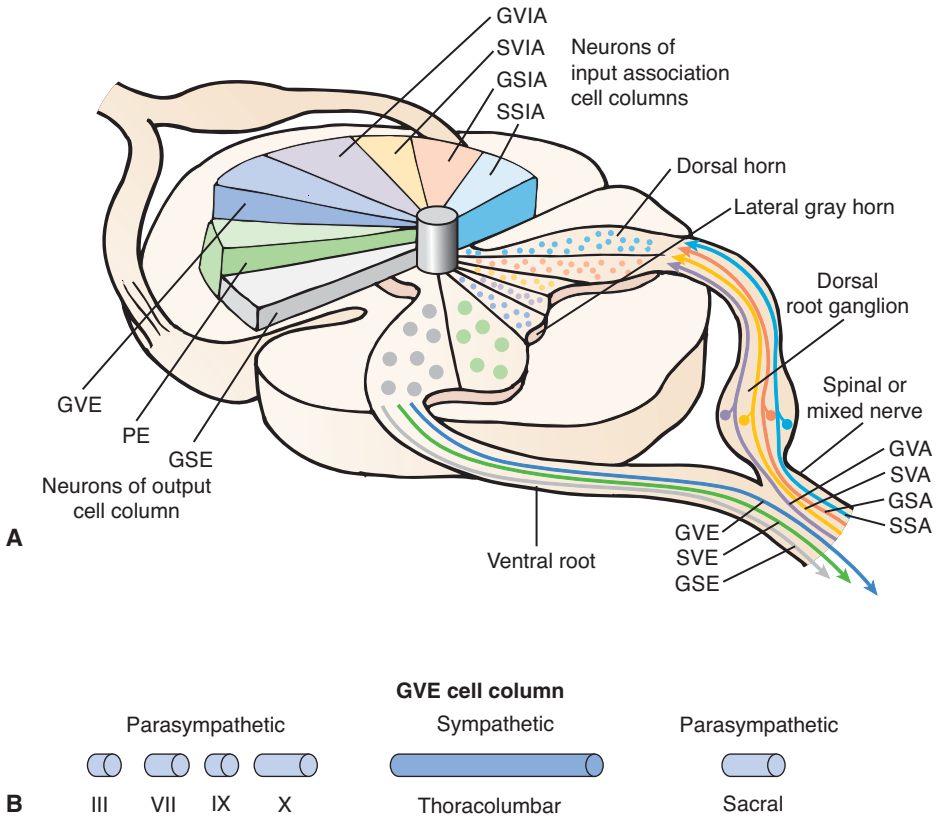

FIGURE 34-9. **(A)** Cell columns of the central nervous system. The cell columns in the dorsal horn contain input association (IA) neurons for the general visceral afferent (GVA), special visceral afferent (SVA), special sensory afferent (SSA), and general somatic afferent (GSA) neurons with cell bodies in the dorsal root ganglion. The cell columns in the ventral horn contain the general visceral efferent (GVE), pharyngeal efferent (PE), and general somite efferent (GSE) neurons and their output association (OA) neurons. **(B)** Schematic of the GVE cell column showing both parasympathetic and sympathetic components. The column is not continuous but is interrupted in the brain stem because only the nuclei of cranial nerves III, VII, IX, and X contain preganglionic parasympathetic neurons. The column again is interrupted until levels T1 to L1 or L2, where the preganglionic neurons of the sympathetic portion are found in the lateral horn of the spinal cord. Another gap is evident until the sacral portion of the parasympathetic nervous system.

which project to the effector muscles. The afferent and efferent cell columns of the PNS and CNS, their projections, and the type of information they transmit are summarized in Table 34-1.

Between the IA neurons and the OA neurons are networks of small internuncial neurons arranged in complex circuits. Internuncial neurons provide the discreteness, appropriateness, and intelligence of responses to stimuli. Most of the billions of CNS cells in the spinal cord and brain gray matter are internuncial neurons.

Dorsal Horn Cell Columns. Four columns of afferent (sensory) neurons in the dorsal root ganglia directly innervate four corresponding columns of IA neurons in the dorsal horn (see Fig. 34-9). These columns are categorized as special (special somatic and special visceral) and general (general somatic and general visceral) afferent neurons.

The special somatic afferent (SSA) fibers are concerned with internal sensory information such as joint and tendon sensation (i.e., proprioception). Neurons in the special sensory IA cell columns relay their information to local reflexes concerned with posture and movement. These neurons also relay information to the cerebellum, contributing to coordination of movement, and to the forebrain, contributing to experience. Afferents innervating the vestibular system of the inner ear also belong to the special somatic afferent category. *Special visceral afferent* (SVA) neurons innervate specialized gut-related visceral receptors, such as the taste buds and receptors of the olfactory mucosa. Their central processes communicate with special visceral IA column neurons that project to reflex circuits producing salivation, chewing, swallowing, and other responses. Forebrain projection fibers from these association cells provide sensations of taste (i.e., gustation) and smell (i.e., olfaction).

General somatic afferent (GSA) neurons innervate the skin and other somatic structures, responding to stimuli such as those that produce pressure or pain. General sensory IA column neurons relay information to protective and other local reflex circuits and project the information to the forebrain, where it is perceived as painful, warm, cold, and the like. *General visceral afferent* (GVA) neurons innervate visceral structures such as the gastrointestinal tract, urinary bladder, and heart and great vessels; they project to the general visceral IA column, which relays information to vital reflex circuits and sends information to the forebrain regarding visceral sensations such as stomach fullness and bladder pressure.

Ventral Horn Cell Columns. The ventral horn contains three longitudinal cell columns: the general visceral efferent, pharyngeal efferent, and general somatic efferent (see Fig. 34-9). The efferent neurons for the OA in the ventral horn originate in brain centers (motor cortex and ANS centers) that control skeletal muscle and visceral function. Each of these cell columns contains OA and efferent neurons. The OA neurons coordinate and integrate the function of the efferent motor neurons of its column.

The *general visceral efferent* (GVE) neurons transmit the efferent output of the ANS and are called *preganglionic neurons*. These neurons are structurally and

TABLE 34-1 The Segmental Nerves and Their Components

Segment and Nerve	Component	Innervation	Function
1. Forebrain			
I. Olfactory	SVA	Receptors in olfactory mucosa	Reflexes, olfaction (smell)
2. II. Optic nerve		Optic nerve and retina (part of brain system, not a peripheral nerve)	
3. Midbrain			
V. Trigeminal (V_1) ophthalmic division	SSA	Muscles: upper face: forehead, upper lid	Facial expression, proprioception
	GSA	Skin, subcutaneous tissue; conjunctiva; frontal/ethmoid sinuses	Somesthesia Reflexes (blink)
III. Oculomotor	GVE	Iris sphincter	Pupillary constriction
		Ciliary muscle	Accommodation
	GSE	Extrinsic eye muscles	Eye movement, lid movement
4. Pons			
V. Trigeminal (V_2) maxillary division	SSA	Muscles: facial expression	Proprioception Reflexes (sneeze), somesthesia
	GSA	Skin, oral mucosa, upper teeth, hard palate, maxillary sinus	
V. Trigeminal (V_3) mandibular division	SSA	Lower jaw, muscles: mastication	Proprioception, jaw jerk
	GSA	Skin, mucosa, teeth, anterior ⅔ of tongue	Reflexes, somesthesia
	PE	Muscles: mastication tensor tympani tensor veli palatini	Mastication: speech Protects ear from loud sounds Tenses soft palate
IV. Trochlear	GSE	Extrinsic eye muscle	Moves eye down and in
5. Caudal Pons			
VIII. Vestibular, cochlear (vestibulocochlear)	SSA	Vestibular end organs	Reflexes, sense of head position
		Organ of Corti	Reflexes, hearing
VII. Facial nerve, intermedius portion	GSA	External auditory meatus	Somesthesia
	GVA	Nasopharynx	Gag reflex: sensation
	SVA	Taste buds of anterior ⅔ of tongue	Reflexes: gustation (taste)
	GVE	Nasopharynx	Mucus secretion, reflexes
		Lacrimal, sublingual, submandibular glands	Lacrimation, salivation
Facial nerve	PE	Muscles: facial expression, stapedius	Facial expression Protects ear from loud sounds
VI. Abducens	GSE	Extrinsic eye muscle	Lateral eye deviation
6. Middle Medulla			
IX. Glossopharyngeal	SSA	Stylopharyngeus muscle	Proprioception
	GSA	Posterior external ear	Somesthesia
	SVA	Taste buds of posterior ⅓ of tongue	Gustation (taste)
	GVA	Oral pharynx	Gag reflex: sensation
	GVE	Parotid gland; pharyngeal mucosa	Salivary reflex: mucus secretion
	PE	Stylopharyngeus muscle	Assists swallowing
7,8,9,10. Caudal Medulla			
X. Vagus	SSA	Muscles: pharynx, larynx	Proprioception
	GSA	Posterior external ear	Somesthesia
	SVA	Taste buds, pharynx, larynx	Reflexes, gustation
	GVA	Visceral organs (esophagus to midtransverse colon, liver, pancreas, heart, lungs)	Reflexes, sensation
	GVE	Visceral organs as above	Parasympathetic efferent
	PE	Muscles: pharynx, larynx	Swallowing, phonation, emesis
XII. Hypoglossal	GSE	Muscles of tongue	Tongue movement, reflexes
Spinal Segments			
C1–C4 Upper Cervical	PE	Muscles: sternocleidomastoid, trapezius	Head, shoulder movement
XI. Spinal accessory nerve			
Spinal nerves	SSA	Muscles of neck	Proprioception, DTRs
	GSA	Neck, back of head	Somesthesia
	GSE	Neck muscles	Head, shoulder movement
C5–C8 Lower Cervical	SSA	Upper limb muscles	Proprioception, DTRs
	GSA	Upper limbs	Reflexes, somesthesia
	GSE	Upper limb muscles	Movement, posture

Segment and Nerve	Component	Innervation	Function
Spinal Segments *(continued)*			
T1–L2 Thoracic, Upper Lumbar	SSA	Muscles: trunk, abdominal wall	Proprioception
	GSA	Trunk, abdominal wall	Reflexes, somesthesia
	GVA	All of viscera	Reflexes and sensation
	GVE	All of viscera	Sympathetic reflexes, vasomotor control, sweating, piloerection
	GSE	Muscles: trunk, abdominal wall, back	Movement, posture, respiration
L2–S1 Lower Lumbar, Upper Sacral	SSA	Lower limb muscles	Proprioception, DTRs
	GSA	Lower trunk, limbs, back	Reflexes, somesthesia
	GSE	Muscles: trunk, lower limbs, back	Movement, posture
S2–S4 Lower Sacral	SSA	Muscles: pelvis, perineum	Proprioception
	GSA	Pelvis, genitalia	Reflexes, somesthesia
	GVA	Hindgut, bladder, uterus	Reflexes, sensation
	GVE	Hindgut, visceral organs	Visceral reflexes, defecation, urination, erection
S5–Co2 Lower Sacral, Coccygeal	SSA	Perineal muscles	Proprioception
	GSA	Lower sacrum, anus	Reflexes, somesthesia
	GSE	Perineal muscles	Reflexes, posture

Afferent (sensory) components: SSA, special somatic afferent; GSA, general somatic afferent; SVA, special visceral afferent; GVA, general visceral afferent.

Efferent (motor) components: GVE, general visceral efferent (autonomic nervous system); PE, pharyngeal efferent; GSE, general somatic efferent; DTRs, deep tendon reflexes.

functionally divided between either the sympathetic or the parasympathetic nervous systems (discussed later in this chapter). Their axons project through the segmental ventral roots to innervate smooth and cardiac muscle and glandular cells of the body, most of which are in the viscera. In the viscera, three additional cell columns are present on each side of the body. These become the postganglionic neurons of the ANS. In the sympathetic nervous system, the columns are represented by the paravertebral or sympathetic chain ganglia and the prevertebral series of ganglia (e.g., celiac ganglia) associated with the dorsal aorta. For the parasympathetic nervous system, these become the enteric plexus in the wall of the gut-derived organs and a series of ganglia in the head.

The *pharyngeal efferent* (PE) neurons innervate the muscles of mastication and facial expression, as well as the muscles of the pharynx and larynx. PE neurons also innervate the muscles responsible for moving the head. The *general somatic efferent* (GSE) neurons supply skeletal muscles of the body and head, including those of the trunk, limbs, and tongue and the extrinsic eye muscles. These efferent neurons of the PNS transmit the commands of the CNS to peripheral effectors, the skeletal muscles. They are the "final common pathway neurons" in the sequence leading to motor activity. They often are called *lower motor neurons* (LMNs) because they are under the control of *upper motor neurons* (UMNs) that have their origin in the CNS.

Longitudinal Tracts

The gray matter of the cell columns in the CNS is surrounded by bundles of myelinated axons (i.e., white matter) and unmyelinated axons that travel longitudinally along the length of the neural axis. This white matter can be divided into three layers: an inner, middle, and outer layer (Fig. 34-10). The inner layer contains short fibers that project for a maximum of approximately five segments before reentering the gray matter. The middle layer projects to six or more segments. The inner and middle layer fibers have many branches, or collaterals, that enter the gray matter of intervening segments. The outer layer contains large-diameter axons that can travel the entire length of the nervous system (Table 34-2). *Suprasegmental* is a term that refers to higher levels of the CNS, such as the brain stem and cerebrum and structures above a given CNS segment. The middle and outer layer fibers have suprasegmental projections.

The longitudinal layers are arranged in bundles, or fiber tracts, that contain axons that have either the same destination, origin, or function (Fig. 34-11). These longitudinal

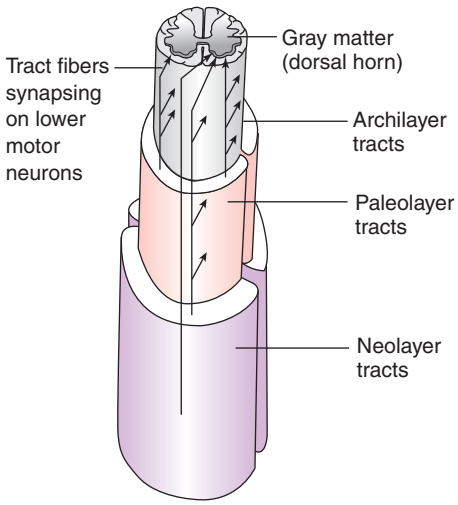

FIGURE 34-10. The three concentric subdivisions of the tract systems of the white matter. Migration of neurons into the archilayer converts it into the reticular formation of the white matter.

TABLE 34-2 Characteristics of the Concentric Subdivisions of the Longitudinal Tracts in the White Matter of the Central Nervous System

Characteristics	Archilayer Tracts	Paleolayer Tracts	Neolayer Tracts
Segmental span	Intersegmental (<5 segments)	Suprasegmental (≥5 segments)	Suprasegmental
Number of synapses	Multisynaptic	Multisynaptic but fewer than archilayer tracts	Monosynaptic with target structures
Conduction velocity	Very slow	Fast	Fastest
Examples of functional systems	Flexor withdrawal reflex circuitry	Spinothalamic tracts	Corticospinal tracts

tracts are named systematically to reflect their origin and destination; the origin is named first, and the destination is named second. For example, the spinothalamic tract originates in the spinal cord and terminates in the thalamus. The corticospinal tract originates in the cerebral cortex and ends in the spinal cord.

The Inner Layer. The inner layer of white matter contains the axons of neurons that connect neighboring segments of the nervous system. Axons of this layer permit the pool of motor neurons of several segments to work together as a functional unit. They also allow the afferent neurons of one segment to trigger reflexes that activate motor units in neighboring and in the same segments. It is the most primitive of the three layers, and it is sometimes called the *archilayer.* It is the first of the longitudinal layers to become functional, and its circuitry may be limited to reflex types of movements, including reflex movements of the fetus (i.e., quickening) that begin during the fifth month of intrauterine life.

The inner layer of the white matter differs from the other two layers in one important aspect. Many neurons in the embryonic gray matter migrate out into this layer, resulting in a rich mixture of neurons and local fibers called the *reticular formation.* The circuitry of most reflexes is contained in the reticular formation. In the brain stem, the reticular formation becomes quite large and contains major portions of vital reflexes, such as those controlling respiration, cardiovascular function, swallowing, and vomiting. A functional system called the *reticular activating system* (RAS) operates in the lateral portions of the reticular formation of the medulla, pons, and especially the midbrain. Information converging from all sensory modalities, including those of the somesthetic, auditory, visual, and visceral afferent nerves, bombards the neurons of this system.

The RAS has descending and ascending portions. The descending portion communicates with all spinal segmental levels through middle-layer reticulospinal tracts and serves to facilitate many cord-level reflexes. For example, it speeds reaction time and stabilizes postural reflexes. The ascending portion accelerates brain activity, particularly thalamic and cortical activity. This is reflected by the appearance of awake brain-wave patterns. Sudden stimuli result in protective and attentive postures and cause increased awareness.

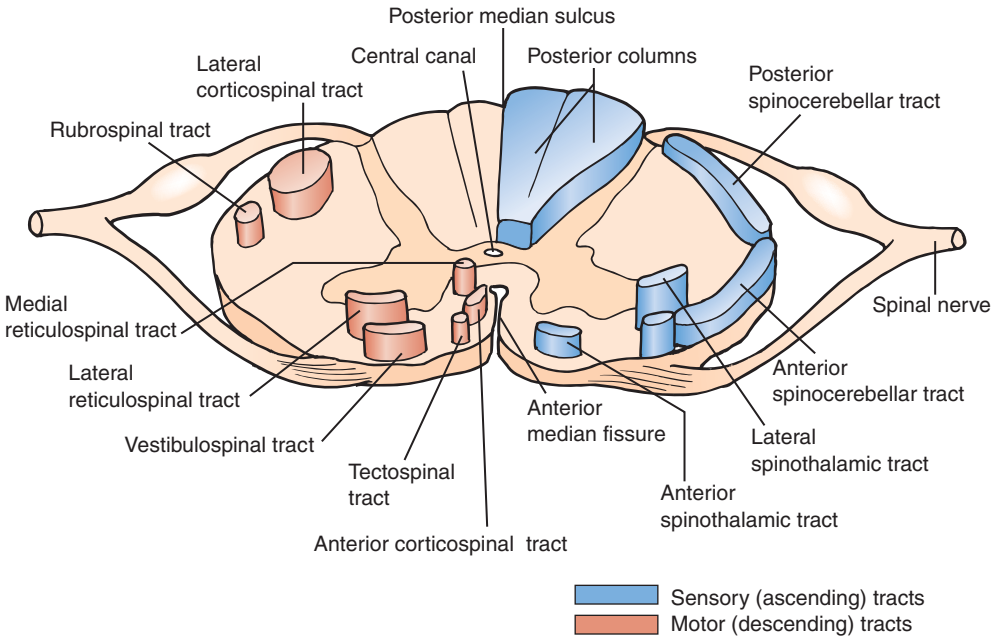

FIGURE 34-11. Transverse section of the spinal cord showing selected sensory and motor tracts. The tracts are bilateral but are indicated only on one half of the cord.

The Middle Layer. The middle layer of the white matter, sometimes called the *paleolayer,* contains most of the major fiber tract systems required for sensation and movement. It contains the ascending spinoreticular and spinothalamic tracts. This layer consists of larger-diameter and longer suprasegmental fibers, which ascend to the brain stem and are largely functional at birth. It facilitates many primitive functions, such as the auditory startle reflex, which occurs in response to loud noises. This reflex consists of turning the head and body toward the sound, dilating the pupils of the eyes, catching of the breath, and quickening of the pulse.

The Outer Layer. The outer layer of the tract systems is the newest of the three layers with respect to development, and it is sometimes called the *neolayer.* This pathway, which becomes functional at about 2 years of age, contains the pathways needed for bladder training. Myelination of these suprasegmental tracts, which include many pathways required for delicate and highly coordinated skills, is not complete until approximately the fifth year of life. This includes the development of tracts needed for fine manipulative skills, such as the finger–thumb coordination required for using tools and the toe movements needed for acrobatics. Being the last to be most developed and more superficial, the neolayer tracts are the most vulnerable to injury.

Collateral Communication Pathways. Axons in the archilayer and paleolayer characteristically possess many collateral branches that move into the gray cell columns or synapse with fibers of the reticular formation as the axon passes each succeeding CNS segment. Should a major axon be destroyed at some point along its course, these collaterals provide multisynaptic alternative pathways that bypass the local damage. Damage usually is followed by slow return of function, presumably through the collateral connections.

Neolayer tracts do not possess these collaterals but instead project mainly to the target neurons with which they communicate. When neolayer tracts are damaged, the paleolayer and archilayer tracts often remain functional, and rehabilitation methods can result in effective use of the older systems. Delicacy and refinement may be lost, but basic function remains. For example, when the corticospinal system, an important neolayer system that permits the fine manipulative control required for writing, is damaged, the remaining paleolayer systems, if intact, permit the grasping and holding of objects. The hand can still be used to perform its basic function, but the individual manipulation of the fingers is permanently lost.

In summary, the organization of the nervous system retains many early patterns of segmental development that were established during early embryonic life. Developmentally, the basic organizational pattern of the body is that of a longitudinal series of segments, each repeating the same fundamental pattern—a central cavity surrounded by an inner core of gray matter made up of nerve cells and a superficial layer of white matter containing axons of the longitudinal tract systems.

The 43 or more body segments are connected to their corresponding CNS or neural tube segments by segmental afferent and efferent PNS neurons. Afferent neuronal processes that carry sensory information enter the CNS through the dorsal root ganglia and are of four types: general somatic, special sensory, general visceral, and special visceral. Each of these afferent neurons synapses with its appropriate input association neurons in the cell columns of the dorsal horn. There are three cells columns of output association neurons in the ventral horn that synapse with lower motor neurons that exit the CNS in the ventral roots: general somatic efferent neurons that innervate skeletal muscles, pharyngeal efferent neurons that innervate pharyngeal muscles, and general visceral neurons that innervate visceral structures.

Longitudinal communication between CNS segments is provided by tracts that are arranged in three layers: an inner, a middle, and an outer layer. The inner layer of white matter contains the axons of neurons that connect neighboring segments of the nervous system. It contains a mixture of nerve cells and axons called the *reticular formation* and is the site of many important spinal cord and brain stem reflex circuits. The middle layer tracts provide the longitudinal communication between more distant segments of the nervous system; it contains most of the major fiber tract systems required for sensation and movement. The outer or neolayer systems, which become functional during infancy and childhood, provide the means for very delicate and discriminative function.

Spinal Cord and Brain

The Spinal Cord

In the adult, the spinal cord is found in the upper two thirds of the spinal canal of the vertebral column (Fig. 34-12A). It extends from the foramen magnum at the base of the skull to a cone-shaped termination, the conus medullaris, usually at the level of the first or second lumbar vertebra (L1 or L2) in the adult. The dorsal and ventral roots of the more caudal portions of the cord elongate during development and angle downward from the cord, forming what is called the *cauda equina* (from the Latin for "horse's tail"). The filum terminale, which is composed of nonneural tissues and the pia mater, continues caudally and attaches to the second sacral vertebra (S2).

The spinal cord is somewhat oval on transverse section, with the gray matter that forms the dorsal and ventral horns having the appearance of a butterfly or the letter "H" (see Fig. 34-12B). The central portion of the cord, which connects the dorsal and ventral horns, is called the *intermediate gray matter.* The intermediate gray matter surrounds the central canal. In the thoracic area, the small,

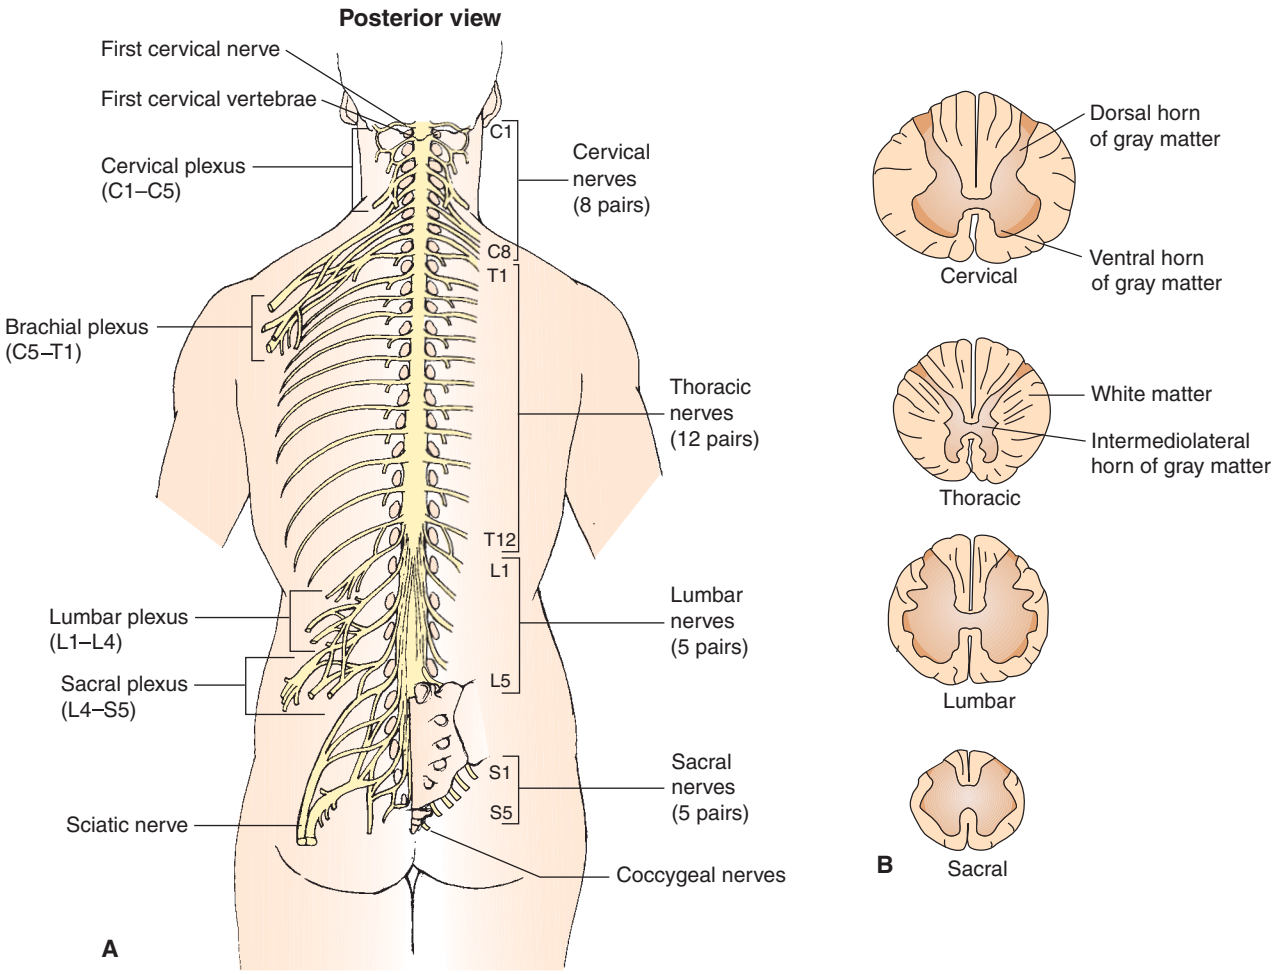

FIGURE 34-12. **(A)** Posterior view of the spinal cord, including portions of the major spinal nerves and some of the components of the major nerve plexuses. **(B)** Cross-sectional views of the spinal cord, showing regional variations in gray matter and increasing white matter as the cord ascends.

slender projections that emerge from the intermediate gray matter are called the *intermediolateral columns* of the horns. These columns contain the visceral OA neurons and the efferent neurons of the sympathetic nervous system.

The gray matter is proportional to the amount of tissue innervated by a given segment of the cord (see Fig. 34-12B). Larger amounts of gray matter are present in the lower lumbar and upper sacral segments, which supply the lower extremities, and in the fifth cervical segment to the first thoracic segment, which supply the upper limbs. The white matter in the spinal cord also increases progressively toward the brain because ever more ascending fibers are added and the number of descending axons is greater.

The spinal cord and the dorsal and ventral roots are covered by a connective tissue sheath, the pia mater, which also contains the blood vessels that supply the white and gray matter of the cord (Fig. 34-13). On the lateral sides of the spinal cord, extensions of the pia mater, the denticulate ligaments, attach the sides of the

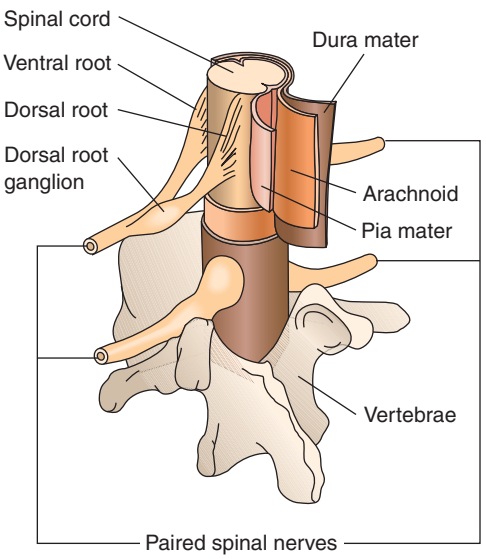

FIGURE 34-13. Spinal cord and meninges.

spinal cord to the bony walls of the spinal canal. Thus, the cord is suspended by both the denticulate ligaments and the segmental nerves. A fat- and vessel-filled epidural space intervenes between the spinal dura mater and the inner wall of the spinal canal.

The spinal cord, spinal nerves, and their supporting structures are protected by the vertebral column. The vertebral body is the anterior, more massive part of the bone that gives strength to the vertebral column and supports body weight. Each vertebral body has two pedicles that extend posteriorly and support the laterally oriented transverse processes of the laminae, which arch medially and fuse to continue as the spinal processes. The vertebral arch and posterior surface of the vertebral body form the wall of the vertebral foramen. The succession of vertebral foramina in the articulated spinal column forms the vertebral canal (spinal canal), which contains the spinal cord, meninges, fat, and spinal nerve roots. The spaces between the vertebral bodies are filled with fibrocartilaginous discs and stabilized with tough ligaments. A gap, the intervertebral foramen, occurs between each two succeeding pedicles, allowing for the exit of the segmental nerves and passage of blood vessels. Supporting structures of the spinal cord are discussed further in Chapter 36.

Early in fetal life, the spinal cord extends the entire length of the vertebral column and the spinal nerves exit through the intervertebral foramina (openings) near their level of origin. Because the vertebral column and spinal dura grow at a faster rate than the spinal cord, a disparity develops between each succeeding cord segment and the exit of its dorsal and ventral nerve roots through the corresponding intervertebral foramina. In the newborn, the cord terminates at the level of L2 or L3. In the adult, the cord usually terminates in the inferior border of L1, and the arachnoid and its enclosed subarachnoid space, which is filled with CSF, do not close down on the filum terminale until they reach the level of S2. This results in the formation of a pocket of CSF, the *dural cisterna spinalis,* which extends from approximately L2 to S2. Because this area contains an abundant supply of CSF and the spinal cord does not extend this far, the area often is used for sampling the CSF. A procedure called a *spinal tap,* or puncture, can be done by inserting a special needle into the dural sac at L3 or L4. The spinal roots, which are covered with pia mater, are in little danger of trauma from the needle used for this purpose.

Spinal Nerves

The peripheral nerves that carry information to and from the spinal cord are called *spinal nerves*. There are 32 or more pairs of spinal nerves (i.e., 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 2 or more coccygeal); each pair is named for the segment of the spinal cord from which it exits. Because the first cervical spinal nerve exits the spinal cord just above the first cervical vertebra (C1), the nerve is given the number of the bony vertebra just below it (see Fig. 34-12A). However, the numbering is changed for all lower levels. An extra cervical nerve, the C8 nerve, exits above the T1 vertebra, and each of the subsequent nerves are numbered for the vertebra just above its point of exit.

Each spinal cord segment communicates with its corresponding body segment through the paired segmental spinal nerves. Each spinal nerve, accompanied by the blood vessels supplying the spinal cord, enters the spinal canal through an intervertebral foramen, where it divides into two branches, or roots. One branch enters the dorsolateral surface of the cord (i.e., dorsal root), carrying the axons of afferent neurons into the CNS. The other branch leaves the ventrolateral surface of the cord (i.e., ventral root), carrying the axons of efferent neurons into the periphery. These two branches or roots fuse at the intervertebral foramen, forming the mixed spinal nerve—"mixed" because it has both afferent and efferent axons.

After emerging from the vertebral column, the spinal nerve divides into two branches or *rami* (singular, *ramus*): a small dorsal primary ramus and a larger ventral primary ramus (Fig. 34-14). The thoracic and upper lumbar spinal nerves also lead to a third branch, the ramus communicans, which contains sympathetic axons supplying the blood vessels, the genitourinary system, and the gastrointestinal system. The dorsal ramus contains sensory fibers from the skin and motor fibers to muscles of the back. The ventral primary ramus contains motor fibers that innervate the skeletal muscles of the anterior body wall and the legs and arms.

Spinal nerves do not go directly to skin and muscle fibers; instead, they form complicated nerve networks called *plexuses* (see Fig. 34-12A). A plexus is a site of intermixing nerve branches. Many spinal nerves enter a plexus and connect with other spinal nerves before exiting from the plexus. Nerves emerging from a plexus form progressively smaller branches that supply the skin and muscles of the various parts of the body. The PNS contains four major plexuses: the cervical plexus, the brachial plexus, the lumbar plexus, and the sacral plexus.

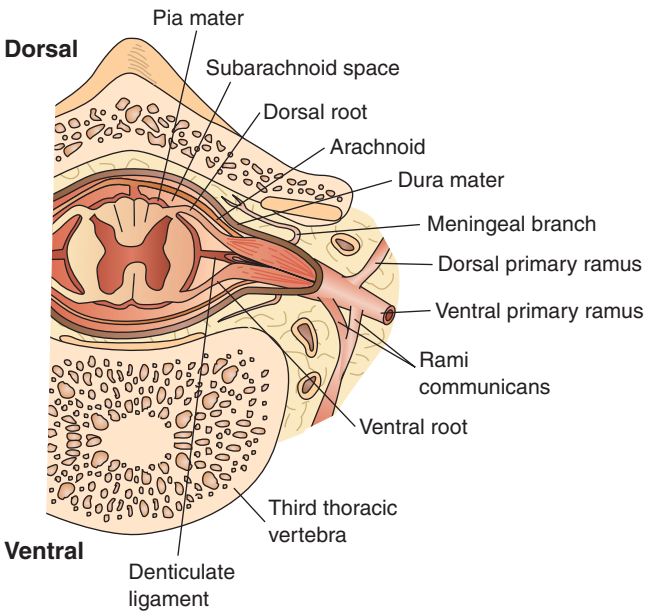

FIGURE 34-14. Cross-section of vertebral column at the level of the third thoracic vertebra, showing the meninges, the spinal cord, and the origin of a spinal nerve and its branches or rami.

Spinal Reflexes

A *reflex* is a highly predictable relationship between a stimulus and an elicited motor response. Its anatomic basis consists of an afferent neuron, the connection or synapse with CNS interneurons that communicate with the effector neuron, and the effector neuron that innervates a muscle or organ. Reflexes are essentially "wired in" to the CNS in that normally they are always ready to function; with training, most reflexes can be modulated to become parts of more complicated movements. A reflex may involve neurons in a single cord segment (i.e., segmental reflexes), several or many segments (i.e., intersegmental reflexes), or structures in the brain (i.e., suprasegmental reflexes). Two important types of spinal motor reflexes are the withdrawal reflex and myotatic reflex.

The *withdrawal reflex* is stimulated by a painful (nociceptive) stimulus and quickly moves the body part away from the offending stimulus, usually by flexing a limb part. The withdrawal reflex is a powerful reflex, taking precedence over other reflexes associated with locomotion. Any of the major joints may be involved, depending on the site of afferent stimulation. All the joints of an extremity (e.g., finger, wrist, elbow, shoulder) typically are involved. This complex, polysynaptic reflex also shifts postural support to the opposite side of the body with a crossed extensor reflex and simultaneously alerts the forebrain to the offending stimulus event. The withdrawal reflex also can produce contraction of muscles other than the extremities. For example, irritation of the abdominal viscera may cause contraction of the abdominal muscles.

The *myotatic* or *stretch reflex* controls muscle tone and helps maintain posture. Specialized sensory nerve terminals in skeletal muscles and tendons relay information on muscle stretch and joint tension to the CNS (see Chapter 36). This information, which drives postural reflex mechanisms, also is relayed to the thalamus and the sensory cortex and is experienced as *proprioception*, the sense of body movement and position.

The Brain

The brain is divided into three regions, the hindbrain, the midbrain, and the forebrain (Fig. 34-15). The hindbrain includes the medulla oblongata, the pons, and its dorsal outgrowth, the cerebellum. Midbrain structures include two pairs of dorsal enlargements, the superior and inferior colliculi. The forebrain, which consists of two hemispheres and is covered by the cerebral cortex, contains central masses of gray matter, the basal ganglia (discussed in Chapter 36), and the rostral end of the neural tube, the diencephalon with its adult derivatives—the thalamus and hypothalamus. With the exception of the olfactory and optic nerves, which are considered part of the forebrain, the motor and sensory nuclei of the 3rd to the 12th cranial nerves are located in the midbrain and hindbrain.

An important concept is that the more rostral, recently developed parts of the neural tube gain dominance or control over regions and functions at lower levels. They do not replace the earlier developed circuitry but merely dominate it. After damage to the more vulnerable parts of the forebrain, as occurs with severe brain injury, a brain stem–controlled organism remains that is capable of breathing and may survive if the environmental temperature is regulated and nutrition and other aspects of care are provided. However, all aspects of intellectual function, experience, perception, and memory usually are permanently lost. The organization of content in this section moves from the less developed circuitry of the hindbrain to the more dominant and recently developed structures of the forebrain.

Hindbrain

During embryonic development, the hindbrain becomes subdivided into the three important structures, the cerebellum, the pons, and the medullar oblongata—also referred to as the medulla. The pons and cerebellum derive from the rostral half of the hindbrain (called the *metencephalon*) and the medulla from the caudal half

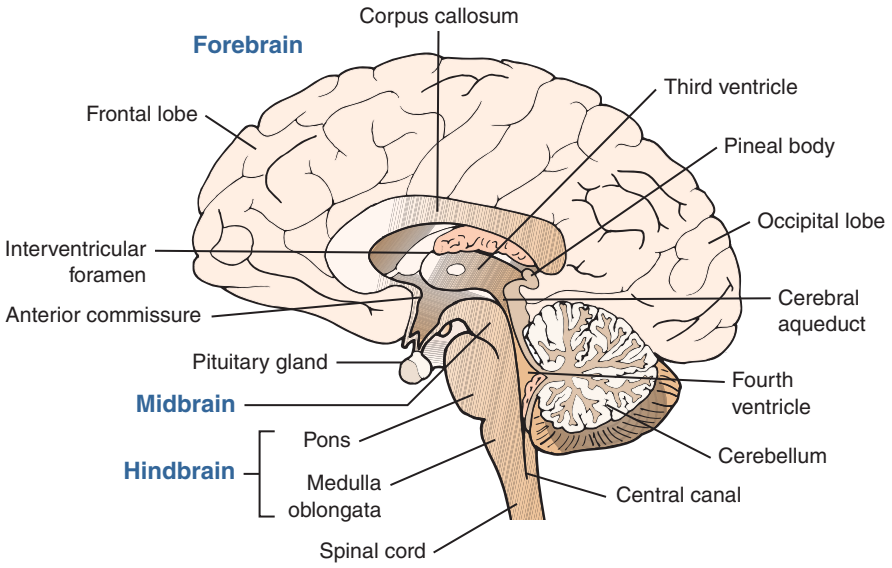

FIGURE 34-15. Midsagittal section showing structures of the hindbrain, midbrain, and forebrain.

(called the *myelencephalon*). The CSF-filled tube becomes the fourth ventricle, which is continuous with the cerebral aqueduct of the midbrain (Fig. 34-15). The cerebellum, the "little brain," is an important movement control center (see Chapter 36). It receives massive axonal inputs from the spinal cord and the pons. The spinal cord provides information about the body's position in space, and the pons relays information from the cerebral cortex specifying the goals of intended movements.

Brain Stem. The term *brain stem* often is used to include the medulla and pons. This area has the organization of spinal cord segments, except that more longitudinal cell columns are present, reflecting the increased complexity of the cranial segmental nerves. In the brain stem, the reticular formation has been greatly expanded. Certain groups of neurons termed *vital centers* are located in the reticular formation of the pons and medulla. These centers include the respiratory, cardiovascular, and vasomotor centers. Still other centers in the brain stem are concerned with swallowing, intestinal movements, control of micturition, and a variety of more specific functions such as salivation and pupillary diameter.

The *medulla* represents the caudal five segments of the brain part of the neural tube; the cranial nerve branches entering and leaving it have functions similar to the spinal segmental nerves. Although the ventral horn areas in the medulla are quite small, the dorsal horn areas are enlarged, processing the large amount of the information pouring through the cranial nerves. Cranial nerves XII (hypoglossal), X (vagus), and IX (glossopharyngeal) have their origin in the medulla (see Table 34-1).

The *pons*, which develops from the fifth neural tube segment, is located between the medulla and the midbrain. Dorsally, it forms part of the anterior wall of the fourth ventricle (see Fig. 34-15). As the name implies (*pons,* Latin for "bridge"), the pons is composed chiefly of conduction fibers. The enlarged area on the ventral surface of the pons contains the pontine nuclei, which receive information from all parts of the cerebral cortex. The axons of these neurons form a massive bundle that swings around the lateral side of the fourth ventricle to enter the cerebellum. In the pons, the reticular formation is large and contains the circuitry for masticating food and manipulating the jaws during speech. Cranial nerves VIII, VII, and VI have their origin in the pons (see Table 34-1).

Midbrain

The midbrain develops from the fourth segment of the neural tube, and its organization is similar to that of a spinal segment. Two prominent bundles of nerve fibers, the *cerebral peduncles,* pass along the ventral surface of the midbrain. These fibers include the corticospinal tracts and are the main motor pathways between the forebrain and the pons. On the dorsal surface, four "little hills," the *superior* and *inferior colliculi,* are areas of cortical formation. The inferior colliculus is involved in directional head turning and, to some extent, in experiencing the direction of sound sources. The superior colliculi are essential to the reflex mechanisms that control conjugate eye movements when the visual environment is surveyed. Two general somatic efferent cranial nerves, the oculomotor nerve, or cranial nerve III, and the trochlear nerve, or cranial nerve IV, exit the midbrain (see Table 34-1).

Forebrain

The most rostral part of the brain, the forebrain consists of the telencephalon, or "end brain," and the diencephalon, or "between brain." The diencephalon forms the core of the forebrain, and the telencephalon forms the cerebral hemispheres.

Diencephalon. Three of the most forward brain segments form an enlarged dorsal horn and ventral horn with a narrow, deep, enlarged central canal—the third ventricle—separating the two sides. This region is called the *diencephalon*. The dorsal horn part of the diencephalon is the thalamus and subthalamus, and the ventral horn part is the hypothalamus (Fig. 34-16). The optic nerve, or cranial nerve II, and retina are outgrowths of the diencephalon.

The thalamus consists of two large, egg-shaped masses, one on either side of the third ventricle. The thalamus is divided into several major parts, and each part is divided into distinct nuclei, which are the major relay stations for information going to and from the cerebral cortex. All sensory pathways have direct projections to thalamic nuclei, which convey the information to restricted areas of the sensory cortex. Coordination and integration of peripheral sensory stimuli occur in the thalamus, along with some crude interpretation of highly emotion-laden auditory experiences that not only occur but can be remembered. For example, a person can recover from a deep coma in which cerebral cortex activity was minimal and remember some of what was said at the bedside.

The thalamus also plays a role in relaying critical information regarding motor activities to and from selected areas of the motor cortex. Two neuronal circuits are significant in this regard. One is the pathway from the cerebral cortex to the pons and cerebellum and then, by way of the thalamus, back to the motor cortex. The second is the feedback circuit that travels from the cortex to the basal ganglia, then to the thalamus, and from the thalamus back to the cortex. The subthalamus also contains movement control systems related to the basal ganglia.

Through its connections with the ascending reticular activating system, the thalamus processes neural influences that are basic to cortical excitatory rhythms (i.e., those recorded on the electroencephalogram), to essential sleep–wake cycles, and to the process of attending to stimuli. Besides their cortical connections, the thalamic nuclei have connections with each other and with neighboring nonthalamic brain structures such as the limbic system. Through their connections with the limbic system, some thalamic nuclei are involved in relating stimuli with the emotional responses they evoke.

The ventral horn portion of the diencephalon is the hypothalamus, which borders the third ventricle and includes a ventral extension, the posterior pituitary gland or neurohypophysis. The hypothalamus is the area of

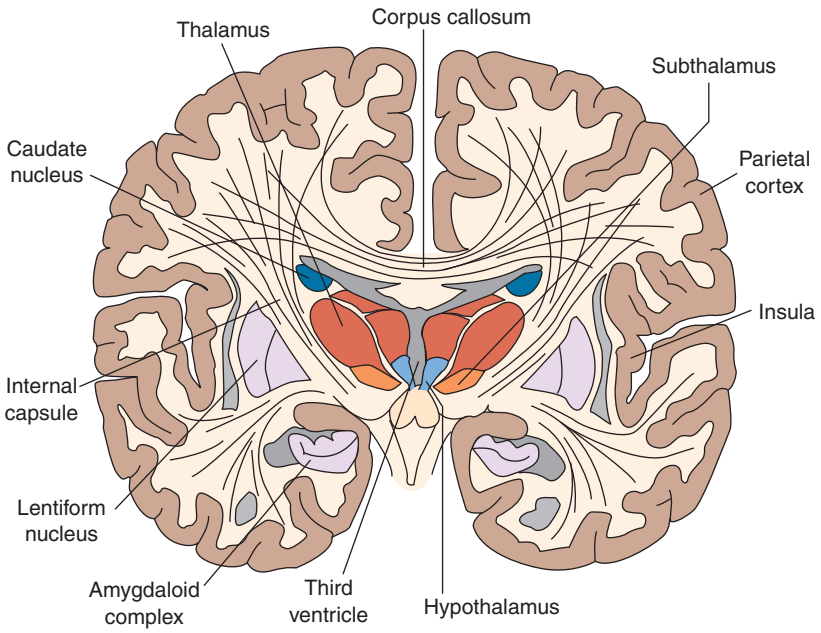

FIGURE 34-16. Frontal section of the brain passing through the third ventricle, showing the thalamus, subthalamus, hypothalamus, internal capsule, corpus callosum, basal ganglia (caudate nucleus, lentiform nucleus), amygdaloid complex, insula, and parietal cortex.

master-level integration of homeostatic control of the body's internal environment. Maintenance of blood gas concentration, water balance, food consumption, and major aspects of endocrine and ANS control require hypothalamic function.

The internal capsule is a broad band of projection fibers that lies between the thalamus medially and the basal ganglia laterally (see Fig. 34-16). It contains all of the fibers that connect the cerebral cortex with deeper structures, including the basal ganglia, thalamus, midbrain, pons, medulla, and spinal cord.

Cerebral Hemispheres. The two cerebral hemispheres are lateral outgrowths of the diencephalon. The cerebral hemispheres contain the lateral ventricles, which are connected with the third ventricle of the diencephalon by a small opening called the *interventricular foramen* (see Fig. 34-15). Axons of the olfactory nerve, or cranial nerve I, terminate in the most primitive portion of the cerebrum—the olfactory bulb, where initial processing of olfactory information occurs. Projection axons from the olfactory bulb relay information through the olfactory tracts to the thalamus and to other parts of the cerebral cortex (i.e., orbital cortex), where olfactory-related reflexes and olfactory experience occur.

The *corpus callosum* is a massive commissure, or bridge, of myelinated axons that connects the cerebral cortex of the two sides of the brain (see Fig. 34-16). Two smaller commissures, the anterior and posterior commissures, connect the two sides of the more specialized regions of the cerebrum and diencephalon.

The surface of the hemispheres, which contains the six-layered neocortex, can be described as lateral (side), medial (area between the two sides of the brain), and basal (ventral). The surface of the hemispheres contains many ridges and grooves. A *gyrus* is the ridge between two grooves, and the groove is called a *sulcus* or *fissure*. The cerebral cortex is arbitrarily divided into lobes named after the bones that cover them: the frontal, parietal, temporal, and occipital lobes (Fig. 34-17A).

Frontal Lobe. The frontal lobe extends from the frontal pole to the central sulcus and is separated from the temporal lobe by the lateral sulcus. The frontal lobe can be subdivided rostrally into the frontal pole and laterally into the superior, middle, and inferior gyri, which continue on the undersurface over the eyes as the orbital cortex. These areas are associated with the medial thalamic nuclei, which also are related to the limbic system. In terms of function, the prefrontal cortex is thought to be involved in anticipation and prediction of consequences of behavior.

The precentral gyrus (area 4), next to the central sulcus, is the *primary motor cortex* (see Fig. 34-17B). This area of the cortex provides precise movement control for distal flexor muscles of the hands and feet and of the phonation apparatus required for speech. Just rostral to the precentral gyrus is a region of the frontal cortex called the *premotor* or *motor association cortex*. This region (area 8 and rostral area 6) is involved in the planning of complex learned movement patterns. The primary motor cortex and the association motor cortex are connected with lateral thalamic nuclei, through which they receive feedback information from the basal ganglia and cerebellum. On the medial surface of the hemisphere, the premotor area includes a *supplementary motor cortex* involved in the control of bilateral movement patterns requiring great dexterity.

Parietal Lobe. The parietal lobe of the cerebrum lies behind the central sulcus and above the lateral sulcus. The strip of cortex bordering the central sulcus is called the *primary somatosensory cortex* (areas 3, 1, and 2) because it receives very discrete sensory information

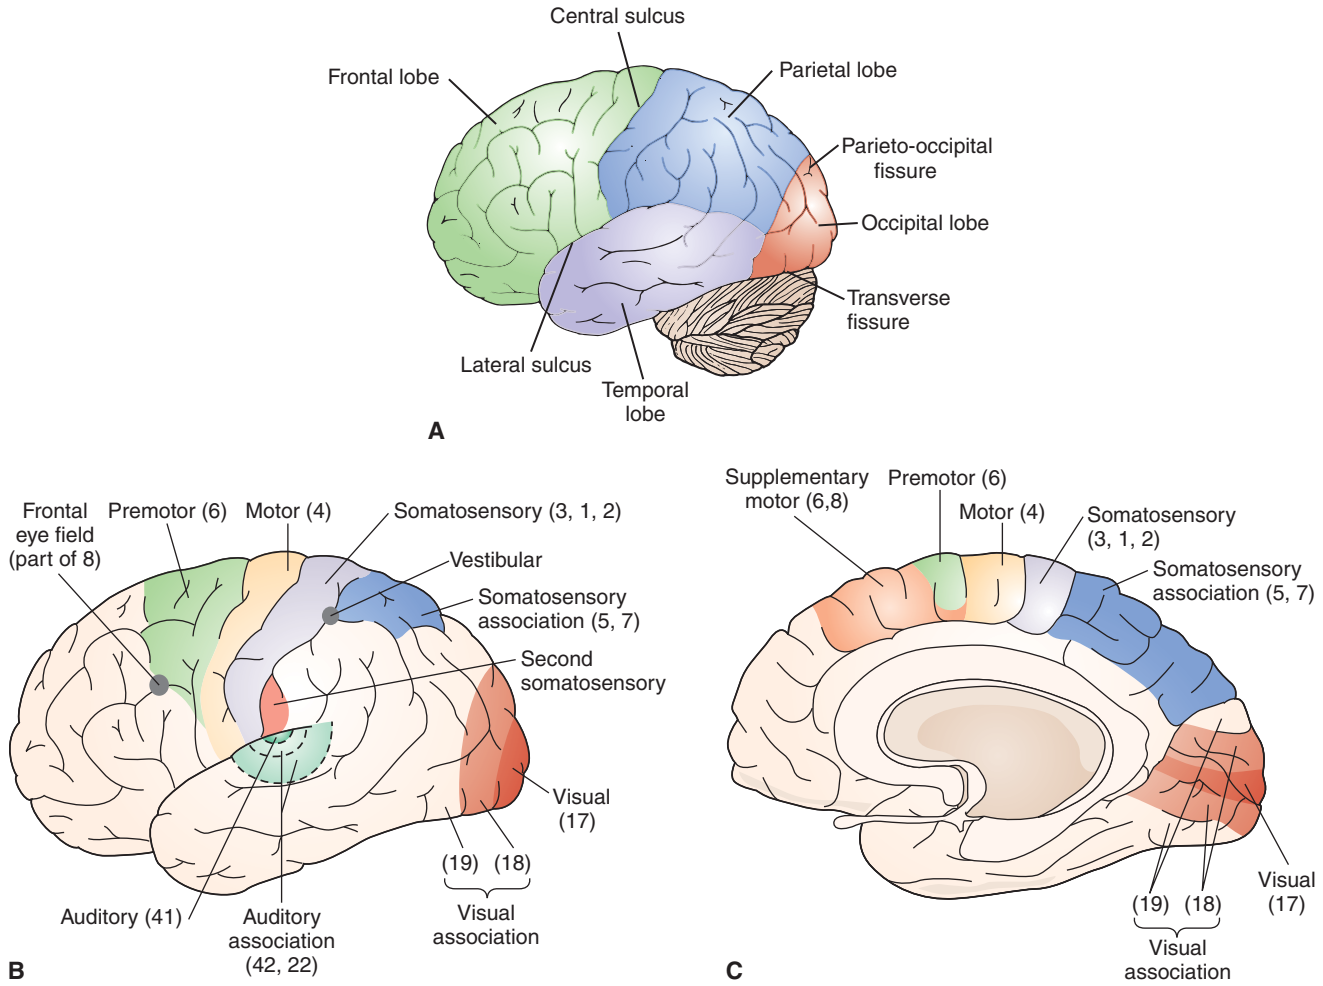

FIGURE 34-17. Cerebral hemispheres. **(A)** Lateral view of the cerebral hemispheres showing the frontal, parietal, occipital, and temporal lobes. **(B)** Left lateral view of the motor and sensory areas of the cerebral cortex. **(C)** Areas of the motor and sensory cortex in a brain that has been sectioned in the median plane.

from the lateral nuclei of the thalamus. Just behind the primary sensory cortex is the *somatosensory association cortex* (areas 5 and 7), which is connected with the thalamic nuclei and with the primary sensory cortex. This region is necessary for perceiving the meaningfulness of integrated sensory information from various sensory systems, especially the perception of "where" the stimulus is in space and in relation to body parts. Localized lesions of this region can result in the inability to recognize the meaningfulness of an object (i.e., agnosia). With the person's eyes closed, a screwdriver can be felt and described as to shape and texture. Nevertheless, the person cannot integrate the sensory information required to identify it as a screwdriver.

Temporal Lobe. The temporal lobe lies below the lateral sulcus and merges with the parietal and occipital lobes. It includes the temporal pole and three primary gyri: the superior, middle, and inferior gyri. The primary auditory cortex (area 41) involves the part of the superior temporal gyrus that extends into the lateral sulcus. This area is particularly important in discrimination of sounds entering opposite ears. It receives auditory input projections by way of the inferior colliculus of the midbrain and a ventrolateral thalamic nucleus. The more exposed part of the superior temporal gyrus involves the auditory association area (area 22). The recognition of certain sound patterns and their meaning requires the function of this area. The remaining portion of the temporal cortex is less defined functionally but apparently is important in long-term memory recall. This is particularly true with respect to perception and memory of complex sensory patterns, such as geometric figures and faces (i.e., recognition of "what" or "who" the stimulus is). Irritation or stimulation can result in vivid hallucinations of long-past events.

Occipital Lobe. The occipital lobe lies posterior to the temporal and parietal lobes and is only arbitrarily separated from them. The medial surface of the occipital lobe contains a deep sulcus extending from the limbic lobe to the occipital pole, the *calcarine sulcus,* which is surrounded

by the primary visual cortex (area 17). Stimulation of this cortex causes the experience of bright lights called *phosphenes* in the visual field. Just superior and inferior and extending onto the lateral side of the occipital pole is the *visual association cortex* (areas 18 and 19). This area is closely connected with the primary visual cortex and with complex nuclei of the thalamus. Integrity of the association cortex is required for *gnostic visual function*, by which the meaningfulness of visual experience, including experiences of color, motion, depth perception, pattern, form, and location in space, occurs.

The neocortical areas of the parietal lobe, between the somatosensory and the visual cortices, have a function in relating the texture, or "feel," and location of an object with its visual image. Between the auditory and visual association areas, the *parieto-occipital region* is necessary for relating the meaningfulness of a sound and image to an object or person.

Limbic System. The medial aspect of the cerebrum is organized into concentric bands of cortex, the *limbic system* (from the Latin *limbus,* "border"), which surrounds the connection between the lateral and third ventricles. The innermost band just above and below the cut surface of the corpus callosum is folded out of sight but is a three-layered cortex ending as the hippocampus in the temporal lobe. Just outside the folded area is a band of transitional cortex, which includes the cingulate and the parahippocampal gyri (Fig. 34-18). The limbic lobe has reciprocal connections with the medial and the intralaminar nuclei of the thalamus, with the deep nuclei of the cerebrum (e.g., amygdaloid nuclei, septal nuclei), and with the hypothalamus. Overall, this region of the brain is involved in emotional experience and in the control of emotion-related behavior. Stimulation of specific areas in this system can lead to feelings of dread, high anxiety, or exquisite pleasure. It also can result in violent behaviors, including attack, defense, or explosive and emotional speech.

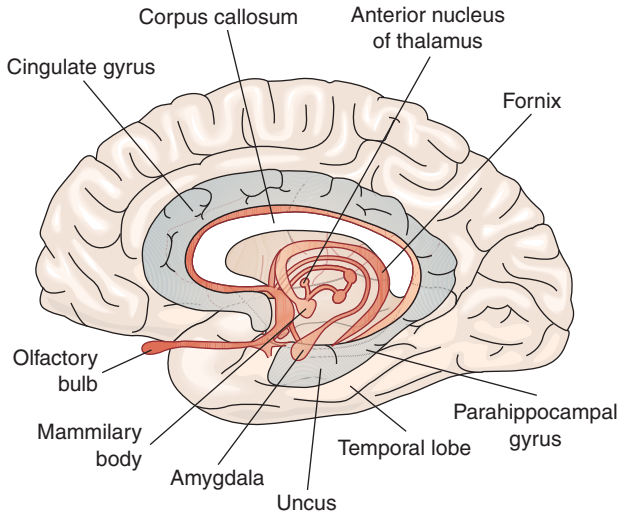

FIGURE 34-18. The limbic system includes the limbic cortex (cingulate gyrus, parahippocampal gyrus, uncus) and associated subcortical structures (mammilary body, amygdala).

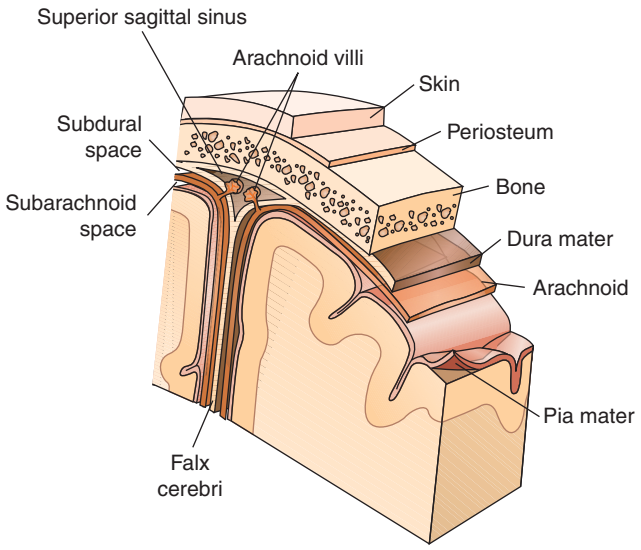

FIGURE 34-19. The cranial meninges. Arachnoid villi, shown within the superior sagittal sinus, are one site of cerebrospinal fluid absorption into the blood.

Meninges

Inside the skull and vertebral column, the brain and spinal cord are loosely suspended and protected by several connective tissue sheaths called the *meninges* (Fig. 34-19). The surfaces of the spinal cord, brain, and segmental nerves are covered with a delicate connective tissue layer called the *pia mater* (Latin for "delicate mother"). The surface blood vessels and those that penetrate the brain and spinal cord are encased in this protective tissue layer. A second, very delicate, nonvascular, and waterproof layer, called the *arachnoid,* encloses the entire CNS. The arachnoid layer is named for its spider-web appearance. The CSF is contained in the subarachnoid space. Immediately outside the arachnoid is a continuous sheath of strong connective tissue, the *dura mater* (Latin for "tough mother"), which provides the major protection for the brain and spinal cord. The cranial dura often splits into two layers, with the outer layer serving as the periosteum of the inner surface of the skull.

The inner layer of the dura forms two major folds. The first, a longitudinal fold called the *falx cerebri,* separates the cerebral hemispheres and fuses with a second transverse fold, called the *tentorium cerebelli* (Fig. 34-20). The tentorium cerebelli separates the anterior and middle depression in the skull (cranial fossae), which contains the cerebral hemispheres, from the posterior fossa, found interiorly and containing the brain stem and cerebellum. A semicircular gap, or incisura, is formed at the midline to permit the midbrain to pass forward from the posterior fossa.

Ventricular System and Cerebrospinal Fluid

The ventricular system is a series of CSF-filled cavities in the brain (Fig. 34-21). Cerebrospinal fluid is a clear, colorless ultrafiltrate of blood plasma, composed of 99% water with other constituents, making it close to the composition of the brain extracellular fluid. Humans

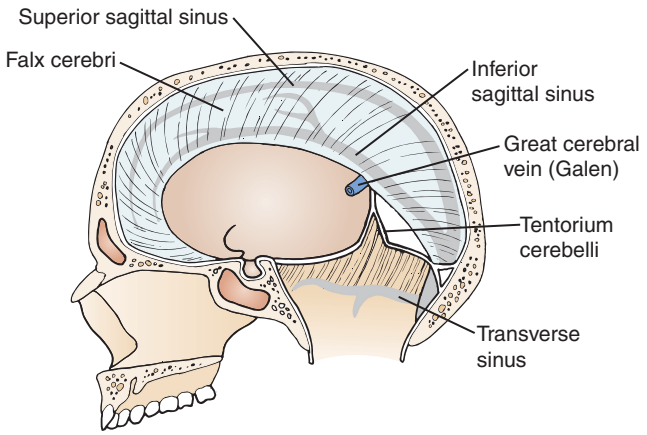

FIGURE 34-20. Cranial dura mater. The skull is open to show the falx cerebri and the right and left portions of the tentorium cerebelli, as well as some of the cranial venous sinuses.

secrete approximately 500 mL of CSF each day. However, only approximately 150 mL is in the ventricular system at any one time, meaning that the CSF is continuously being absorbed.

The CSF provides a supporting and protective fluid in which the brain and spinal cord float, and it helps to maintain a constant ionic environment that serves as a medium for diffusion of nutrients, electrolytes, and metabolic end products into the extracellular fluid surrounding CNS neurons and glia. Filling the ventricles, the CSF supports the mass of the brain. Because it fills the subarachnoid space surrounding the CNS, a physical force delivered to either the skull or spine is to some extent diffused and cushioned.

The CSF is produced by tiny reddish masses of specialized capillaries from the pia mater, called the *choroid plexus*, that project into the ventricles. Once produced,

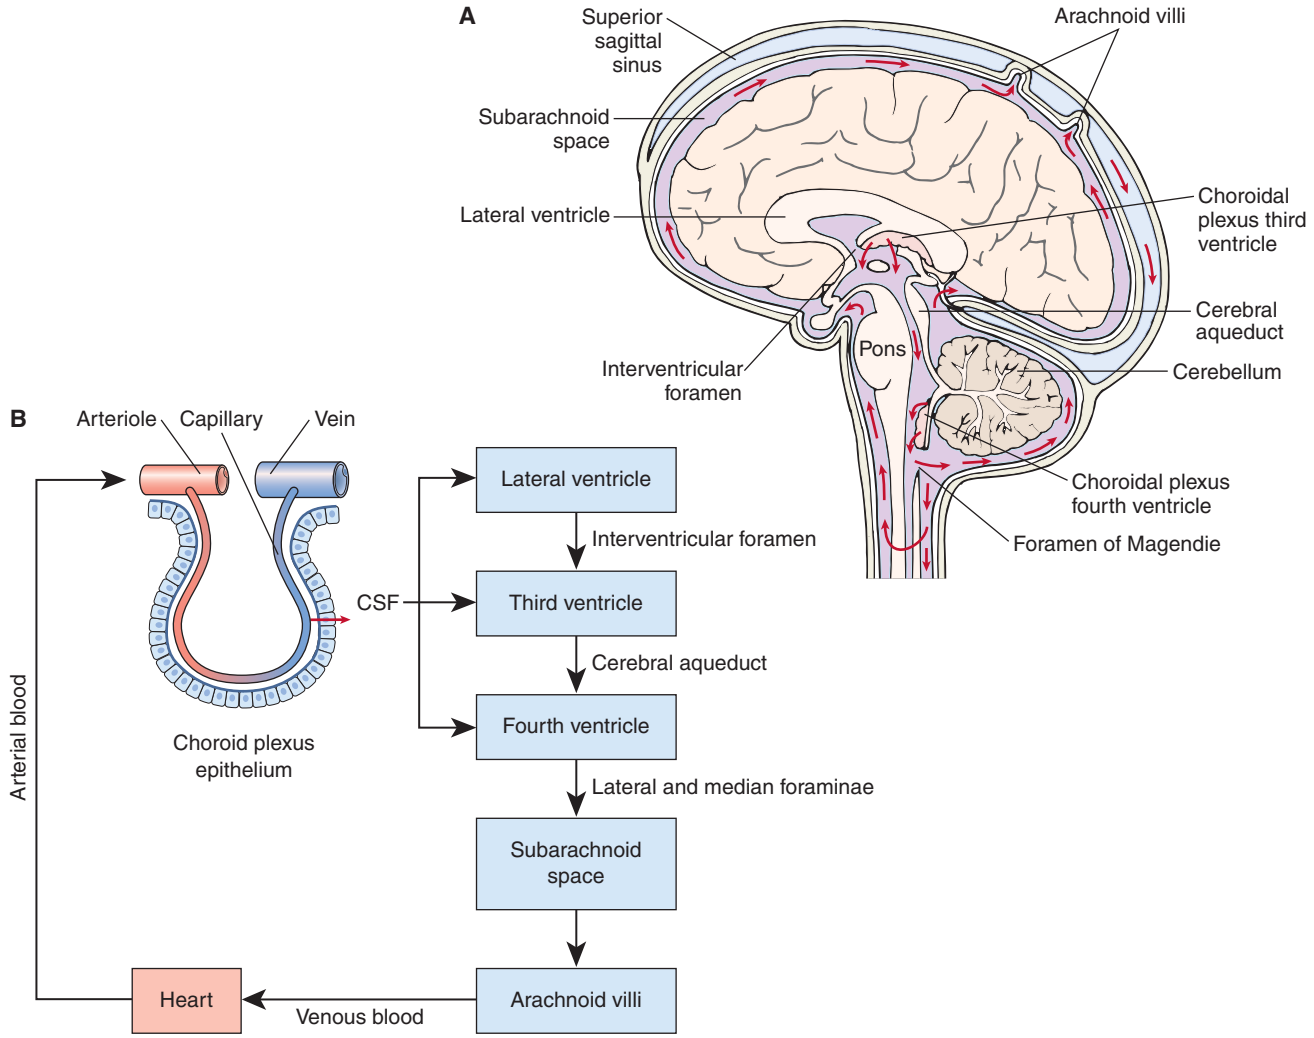

FIGURE 34-21. **(A)** The flow of cerebrospinal fluid (CSF) from the time of its formation from blood in the choroid plexuses until its return to the blood in the superior sagittal sinus. Plexuses in the lateral ventricles are not illustrated. **(B)** CSF is a blood filtrate produced by the choroid plexus epithelium that is found in each brain ventricle. The flow of CSF from the lateral ventricles flows through the interventricular foramen (Monroe) into the third ventricle. From the third ventricle, CSF is conveyed to the fourth ventricle via the cerebral aqueduct (Sylvius). Three openings, a midline foramen of Magendie and two lateral foramina (Luschka), pass the CSF into the subarachnoid space, where it is returned to the venous circulation through the arachnoid villi.

the CSF flows freely through the ventricles. Three openings, or foramina, allow the CSF to pass into the subarachnoid space. Two of these, the foramina of Luschka, are located at the lateral corners of the fourth ventricle. The third, the median foramen of Magendie, is in the midline at the caudal end of the fourth ventricle (see Fig. 34-21B). Approximately 30% of the CSF passes down into the subarachnoid space that surrounds the spinal cord, mainly on its dorsal surface, and moves back up to the cranial cavity along its ventral surface.

Reabsorption of CSF into the vascular system occurs along the sides of the superior sagittal sinus in the anterior and middle fossa. Here, the waterproof arachnoid has protuberances, the *arachnoid villi,* that penetrate the inner dura and venous walls of the superior sagittal sinus (see Fig. 34-21A). The arachnoid villi function as one-way valves, permitting CSF outflow into the blood but not allowing blood to pass into the arachnoid spaces.

Blood-Brain and Cerebrospinal Fluid–Brain Barriers

Maintenance of a chemically stable environment is essential to the function of the brain. In most regions of the body, extracellular fluid undergoes small fluctuations in pH and concentrations of hormones, amino acids, and potassium ions during routine daily activities such as eating and exercising. If the brain were to undergo such fluctuations, the result would be uncontrolled neural activity because some substances such as amino acids act as neurotransmitters, and ions such as potassium influence the threshold for neural firing. Two barriers, the blood-brain barrier and the CSF-brain barrier, provide the means for maintaining the stable chemical environment of the brain. Only water, carbon dioxide, and oxygen enter the brain with relative ease; the transport of other substances between the brain and the blood is slower and more controlled.

Blood-Brain Barrier. The blood-brain barrier depends on the unique characteristics of the brain capillaries. The endothelial cells of brain capillaries are joined by continuous tight junctions. In addition, most brain capillaries are completely surrounded by a basement membrane and by the processes of previously described supporting astrocyte cells of the brain (Fig. 34-22). The blood-brain barrier permits passage of essential substances while excluding unwanted materials. Reverse transport systems remove materials from the brain. Large molecules such as proteins and peptides are largely excluded from crossing the blood-brain barrier. Acute cerebral lesions, such as trauma and infection, increase the permeability of the blood-brain barrier and alter brain concentrations of proteins, water, and electrolytes.

The blood-brain barrier prevents many drugs from entering the brain. Most highly water-soluble compounds are excluded from the brain, especially molecules with high ionic charge, such as many of the catecholamines. In contrast, many lipid-soluble molecules cross the lipid layers of the blood-brain barrier with ease. Alcohol, nicotine, and heroin are very lipid soluble and rapidly enter the brain. Some substances that enter the capillary endothelium are converted by metabolic processes to a chemical form incapable of moving into the brain.

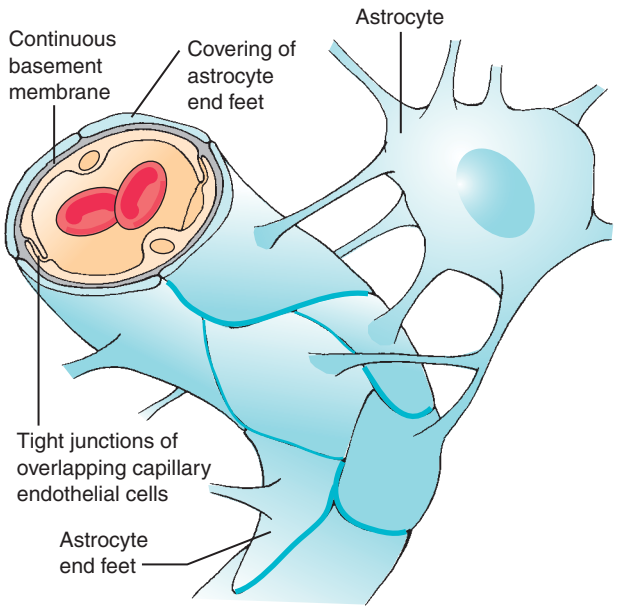

FIGURE 34-22. The three components of the blood-brain barrier: the astrocyte and astrocyte end feet that encircle the capillary, the capillary basement membrane, and the tight junctions that join the overlapping capillary endothelial cells.

The cerebral capillaries are much more permeable at birth than in adulthood, and the blood-brain barrier develops during the early years of life. In severely jaundiced infants, bilirubin can cross the immature blood-brain barrier, producing kernicterus and brain damage (see Chapter 13). In adults, the mature blood-brain barrier prevents bilirubin from entering the brain, and the nervous system is not affected.

Cerebrospinal Fluid–Brain Barrier. The ependymal cells covering the choroid plexus are linked together by tight junctions, forming a blood-CSF barrier to diffusion of many molecules from the blood plasma of choroid plexus capillaries to the CSF. Water is transported through the choroid epithelial cells by osmosis. Oxygen and carbon dioxide move into the CSF by diffusion, resulting in partial pressures roughly equal to those of plasma. The high sodium and low potassium contents of the CSF are actively regulated and kept relatively constant. Lipids and nonpeptide hormones diffuse through the barrier rather easily, but most large molecules, such as proteins, peptides, many antibiotics, and other medications, do not normally get through. Many substances such as proteins, sodium ions, and a number of micronutrients such as vitamins C, B_6 (pyridoxine), and folate are actively secreted into the CSF by the choroid epithelium. Because the brain and spinal cord have no lymphatic channels, the CSF serves this function.

There are several specific areas of the brain where the blood-CSF barrier does not exist. One area is at the

caudal end of the fourth ventricle, where specialized receptors for the carbon dioxide level of the CSF influence respiratory function. Another area consists of the walls of the third ventricle, which permit hypothalamic neurons to monitor blood glucose levels. This mechanism permits hypothalamic centers to respond to these blood glucose levels, contributing to hunger and eating behaviors.

In summary, in the adult, the spinal cord is in the upper two thirds of the spinal canal of the vertebral column. On transverse section, the spinal cord has an oval shape, and the internal gray matter has the appearance of a butterfly or letter "H." The dorsal horns contain the IA neurons and receive afferent information from dorsal root and other connecting neurons. The ventral horns contain the output association neurons and lower motor neurons that leave the cord by the ventral roots. Thirty-two pairs of spinal nerves (i.e., 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 2 or more coccygeal) are present. Each pair communicates with its corresponding body segments. The spinal nerves and the blood vessels that supply the spinal cord enter the spinal canal through an intervertebral foramen. After entering the foramen, they divide into two branches, or roots, one of which enters the dorsolateral surface of the cord (i.e., dorsal root), carrying the axons of afferent neurons into the CNS. The other root leaves the ventrolateral surface of the cord (i.e., ventral root), carrying the axons of efferent neurons into the periphery. These two roots fuse at the intervertebral foramen, forming the mixed spinal nerve.

The brain can be divided into three regions: the hindbrain, the midbrain, and the forebrain. The hindbrain, consisting of the medulla oblongata, pons, and cerebellum, contains the neuronal circuits for the eating, breathing, and locomotive functions required for survival. Cranial nerves XII, XI, X, IX, VIII, VII, VI, and V are located in the hindbrain. The midbrain contains cranial nerves IV and III.

The forebrain is the most rostral part of the brain; it consists of the diencephalon and the telencephalon. The diencephalon forms the core of the forebrain, and the telencephalon forms the cerebral hemispheres. The dorsal horn part of the diencephalon contains the thalamus and subthalamus, and the ventral horn contains the hypothalamus. All sensory pathways have direct projections to the thalamic nuclei, which convey the information to restricted parts of the sensory cortex. The hypothalamus functions in the homeostatic control of the internal environment. The cerebral hemispheres are the lateral outgrowths of the diencephalon and are arbitrarily divided into lobes—the frontal, parietal, temporal, and occipital lobes. The premotor area and primary motor cortex are located in the frontal lobe; the primary sensory cortex and somatosensory association area are in the parietal cortex; the primary auditory cortex and the auditory association area are in the temporal lobe; and the primary visual cortex and association visual cortex are in the occipital lobe. The limbic system, which is involved in emotional experience and release of emotional behaviors, is located in the medial aspect of the cerebrum.

The brain is enclosed and protected by connective tissue sheaths (i.e., the pia mater, arachnoid, and dura mater) called the *meninges*. The protective CSF in which the brain and spinal cord float isolates them from minor and moderate trauma. The CSF is secreted into the ventricles, circulates through the ventricular system, passes outside to surround the brain, and is reabsorbed into the venous system through the arachnoid villi. The blood-brain barrier and CSF-brain barrier protect the brain from substances in the blood that would disrupt brain function.

The Autonomic Nervous System

The ability to maintain homeostasis and perform the activities of daily living in an ever-changing physical environment is largely vested in the ANS. The ANS functions at the subconscious level and is involved in regulating, adjusting, and coordinating vital visceral functions such as blood pressure and flow. The ANS is strongly affected by emotional influences and is involved in many of the expressive aspects of behavior. Blushing, pallor, palpitations of the heart, clammy hands, and dry mouth are several emotional expressions that are mediated through the ANS.

As with the somatic nervous system, the ANS is represented in both the CNS and the PNS. Traditionally, the ANS has been defined as a general efferent system innervating visceral organs. The efferent outflow from the ANS has two divisions: the sympathetic nervous system and the parasympathetic nervous system. The afferent input to the ANS is provided by visceral afferent neurons, usually not considered to be part of the ANS.

The functions of the sympathetic nervous system include maintaining body temperature, respiration, digestion, and elimination and adjusting blood flow and blood pressure to meet the changing needs of the body. The sympathoadrenal system also can discharge as a unit when there is a critical threat to the integrity of the individual—the so-called fight-or-flight response. During a stress situation, the heart rate accelerates, the blood pressure rises, blood flow shifts from the skin and gastrointestinal tract to the skeletal muscles and brain, blood sugar increases, the bronchioles and pupils dilate, the sphincters of the stomach and intestine and the internal sphincter of the urethra constrict, and the rate of secretion of exocrine glands that are involved in digestion diminishes. Emergency situations often require vasoconstriction and shunting of blood away from the skin and into the muscles and brain, a mechanism that, should a wound occur, provides for a reduction in blood flow and preservation of vital functions needed for survival.

In contrast to the sympathetic nervous system, the functions of the parasympathetic nervous system are concerned with conservation of energy, resource replenishment and storage, and maintenance of organ function

The Autonomic Nervous System (ANS)

- The ANS functions at the subconscious level and is responsible for maintaining homeostatic functions of the body.
- The ANS has two divisions: the sympathetic and parasympathetic systems. Although the two divisions function in concert, they are generally viewed as having opposite and antagonistic actions.
- The sympathetic division functions in maintaining vital functions and responding when there is a critical threat to the integrity of the individual—the "fight-or-flight" response.
- The parasympathetic nervous system is concerned with conservation of energy, resource replenishment, and maintenance of organ function during periods of minimal activity.
- The outflow of both divisions of the ANS consists of a two-neuron pathway: a preganglionic and a postganglionic neuron. Acetylcholine is the neurotransmitter for the preganglionic neurons for both ANS divisions, as well as the postganglionic neurons of the parasympathetic nervous system. Norepinephrine and epinephrine are the neurotransmitters for most sympathetic postganglionic neurons.

during periods of minimal activity. The parasympathetic nervous system slows heart rate, stimulates gastrointestinal function and related glandular secretion, promotes bowel and bladder elimination, and contracts the pupil, protecting the retina from excessive light during periods when visual function is not vital to survival.

The two divisions of the ANS usually are viewed as having opposite and antagonistic actions (i.e., if one activates, the other inhibits a function). Exceptions are functions, such as sweating and regulation of arteriolar blood vessel diameter, that are controlled by a single division of the ANS, in this case the sympathetic nervous system.

The sympathetic and parasympathetic nervous systems are continually active. The effect of this continual or basal (baseline) activity is referred to as *tone*. The tone of an effector organ or system can be increased or decreased and usually is regulated by a single division of the ANS. For example, vascular smooth muscle tone is controlled by the sympathetic nervous system. Increased sympathetic activity produces local vasoconstriction from increased vascular smooth muscle tone, and decreased activity results in vasodilatation caused by decreased tone. In structures such as the sinoatrial node and atrioventricular node of the heart, which are innervated by both divisions of the ANS, one division predominates in controlling tone. In this case, the tonically active parasympathetic nervous system exerts a constraining or braking effect on heart rate, and when parasympathetic outflow is withdrawn, similar to releasing a brake, the heart rate increases. The increase in heart rate that occurs with vagal withdrawal can be further augmented by sympathetic stimulation.

Autonomic Efferent Pathways

The outflow of both divisions of the ANS follows a two-neuron pathway. The first motor neuron, called the *preganglionic neuron,* lies in the intermediolateral cell column in the ventral horn of the spinal cord or its equivalent location in the brain stem. The second motor neuron, called the *postganglionic neuron,* synapses with a preganglionic neuron in an autonomic ganglion located in the PNS. The two divisions of the ANS differ in terms of location of preganglionic cell bodies, relative length of preganglionic fibers, general function, nature of peripheral responses, and preganglionic and postganglionic neuromediators (Table 34-3). This two-neuron outflow pathway and the interneurons in the autonomic ganglia that add further modulation to ANS function are features distinctly different from the arrangement in somatic motor innervation.

Most visceral organs are innervated by both sympathetic and parasympathetic fibers. Exceptions include structures such as blood vessels and sweat glands that have input from only one division of the ANS. The fibers of the sympathetic nervous system are distributed to effectors throughout the body, and as a result, sympathetic actions tend to be more diffuse than those of the parasympathetic nervous system, in which there is a more localized distribution of fibers. The preganglionic fibers of the sympathetic nervous system may traverse a considerable distance and pass through several ganglia before synapsing with postganglionic neurons, and their terminals make contact with a large number of postganglionic fibers. In some ganglia, the ratio of preganglionic to postganglionic cells may be 1:20; because of this, the effects of sympathetic stimulation are diffuse. There is considerable overlap, and one ganglion cell may be supplied by several preganglionic fibers. In contrast to the sympathetic nervous system, the parasympathetic nervous system has its postganglionic neurons located very near or in the organ of innervation. Because the ratio of preganglionic to postganglionic communication often is 1:1, the effects of the parasympathetic nervous system are much more circumscribed.

Sympathetic Nervous System

The preganglionic neurons of the sympathetic nervous system are located primarily in the thoracic and upper lumbar segments (T1 to L2) of the spinal cord; thus, the sympathetic nervous system often is referred to as the *thoracolumbar division* of the ANS. These preganglionic neurons, which are located primarily in the ventral horn intermediolateral cell column, have axons that are largely myelinated and relatively short. The postganglionic

TABLE 34-3 Characteristics of the Sympathetic and Parasympathetic Nervous Systems

Characteristic	Sympathetic Outflow	Parasympathetic Outflow
Location of preganglionic cell bodies	T1–T12, L1 and L2	Cranial nerves: III, VII (intermedius), IX, and X; sacral segments 2, 3, and 4
Relative length of preganglionic fibers	Short—to paravertebral chain of ganglia or to aortic prevertebral of ganglia	Long—to ganglion cells near or in the innervated organ
General function	Catabolic—mobilizes resources in anticipation of challenge for survival (preparation for "fight-or-flight" response)	Anabolic—concerned with conservation, renewal, and storage of resources
Nature of peripheral response	Generalized	Localized
Transmitter between preganglionic terminals and postganglionic neurons	ACh	ACh
Transmitter of postganglionic neuron	ACh (sweat glands and skeletal muscle vasodilator fibers); norepinephrine (most synapses); norepinephrine and epinephrine (secreted by adrenal gland)	Ach

ACh, acetylcholine.

neurons of the sympathetic nervous system are located in the paravertebral ganglia of the sympathetic chain that lie on either side of the vertebral column, or in prevertebral sympathetic ganglia such as the celiac ganglia (Fig. 34-23). Besides postganglionic efferent neurons, the sympathetic ganglia contain neurons of the internuncial, short-axon type, similar to those associated with complex circuitry in the brain and spinal cord. Many of these inhibit and others modulate preganglionic-to-postganglionic transmission.

The axons of the preganglionic neurons leave the spinal cord through the ventral root of the spinal nerves (T1 to L2), enter the ventral primary rami, and leave the spinal nerve through white rami of the rami communicantes to reach the paravertebral ganglionic chain (Fig. 34-24). In the sympathetic chain of ganglia, preganglionic fibers may synapse with neurons of the ganglion they enter, pass up or down the chain and synapse with one or more ganglia, or pass through the chain and move outward through a splanchnic nerve to terminate in one of the prevertebral ganglia (i.e., celiac, superior mesenteric, or inferior mesenteric) that are scattered along the dorsal aorta and its branches. The adrenal medulla, which is part of the sympathetic nervous system, contains postganglionic sympathetic neurons that secrete sympathetic neurotransmitters directly into the bloodstream.

Parasympathetic Nervous System

The preganglionic fibers of the parasympathetic nervous system, also referred to as the *craniosacral division* of the ANS, originate in some segments of the brain stem and sacral segments of the spinal cord (see Fig. 34-23). The central regions of origin are the midbrain, pons, medulla oblongata, and sacral part of the spinal cord. The outflow from the midbrain passes through the oculomotor nerve (cranial nerve III) to supply the pupillary sphincter muscle of each eye and the ciliary muscles that control lens thickness for accommodation. Caudal pontine outflow comes from branches of the facial nerve (cranial nerve VII) that supply the lacrimal and nasal glands. The medullary outflow develops from cranial nerves VII, IX, and X. Fibers in the glossopharyngeal nerve (cranial nerve IX) supply the parotid salivary glands. Approximately 75% of parasympathetic efferent fibers are carried in the vagus nerve (cranial nerve X). The vagus nerve provides parasympathetic innervation for the heart, trachea, lungs, esophagus, stomach, small intestine, proximal half of the colon, liver, gallbladder, pancreas, kidneys, and upper portions of the ureters.

Sacral preganglionic axons leave the S2 to S4 segmental nerves by gathering into the pelvic nerves. The pelvic nerves leave the sacral plexus on each side of the cord and distribute their peripheral fibers to the bladder, uterus, urethra, prostate, distal portion of the transverse colon, descending colon, and rectum. The sacral parasympathetic fibers also supply the venous outflow from the external genitalia to facilitate erectile function.

With the exception of cranial nerves III, VII, and IX, which synapse in discrete ganglia, the long parasympathetic preganglionic fibers pass uninterrupted to short postganglionic fibers located in the organ wall. In the walls of these organs, postganglionic neurons send axons to smooth muscle and glandular cells that modulate their functions.

Central Integrative Pathways

General visceral afferent fibers accompany the sympathetic and parasympathetic outflow into the spinal and cranial nerves, bringing chemoreceptor, pressure, and nociceptive information from organs of the viscera to the brain stem, thoracolumbar cord, and sacral cord. Local reflex circuits relating visceral afferent and autonomic efferent activity are integrated into a hierarchic control system in the spinal cord and brain stem. Progressively greater complexity in the responses and greater precision in their control occur at each higher level of the nervous system. Most visceral reflexes contain contributions from

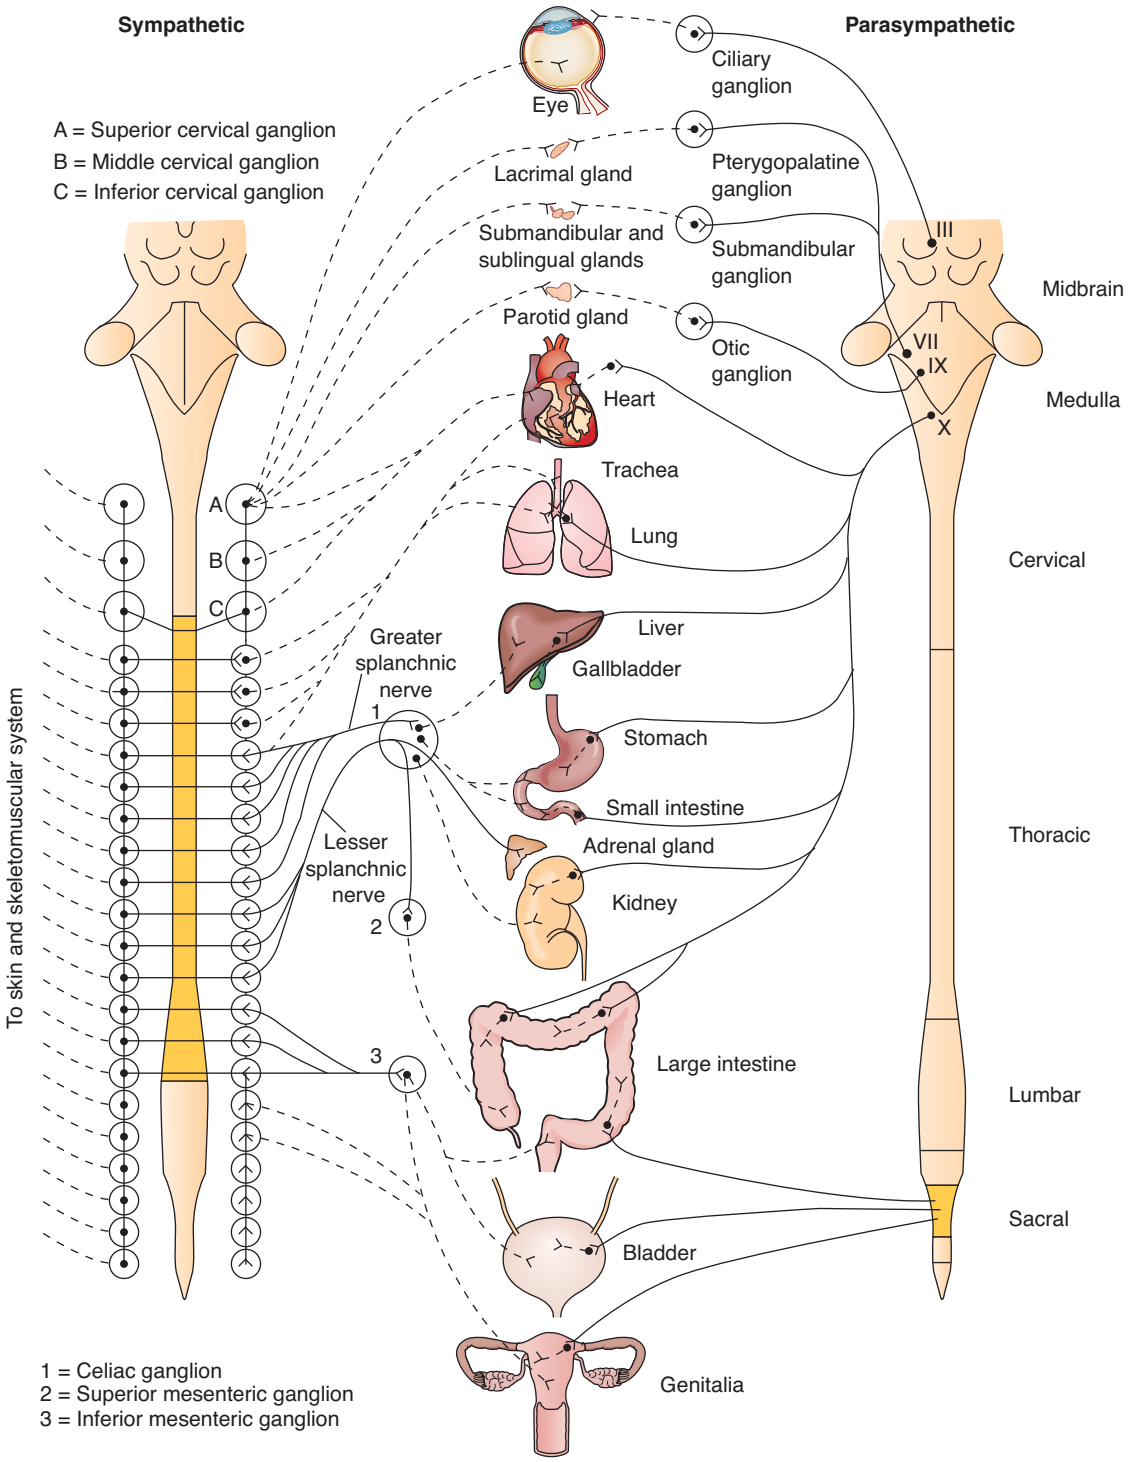

FIGURE 34-23. The autonomic nervous system. The involuntary organs are depicted with their parasympathetic innervation (craniosacral) indicated on the right and sympathetic innervation (thoracolumbar) on the left. Preganglionic fibers are *solid lines;* postganglionic fibers are *dashed lines.* For purposes of illustration, the sympathetic outflow to the skin and skeletomuscular system is shown separately (to the far left); effectors include sweat glands, pilomotor muscles and blood vessels of the skin, and blood vessels of the skeletal muscles and bones. (Modified from Hemer L. [1983]. *The human brain and spinal cord: Functional neuroanatomy and dissection guide.* New York: Springer-Verlag.)

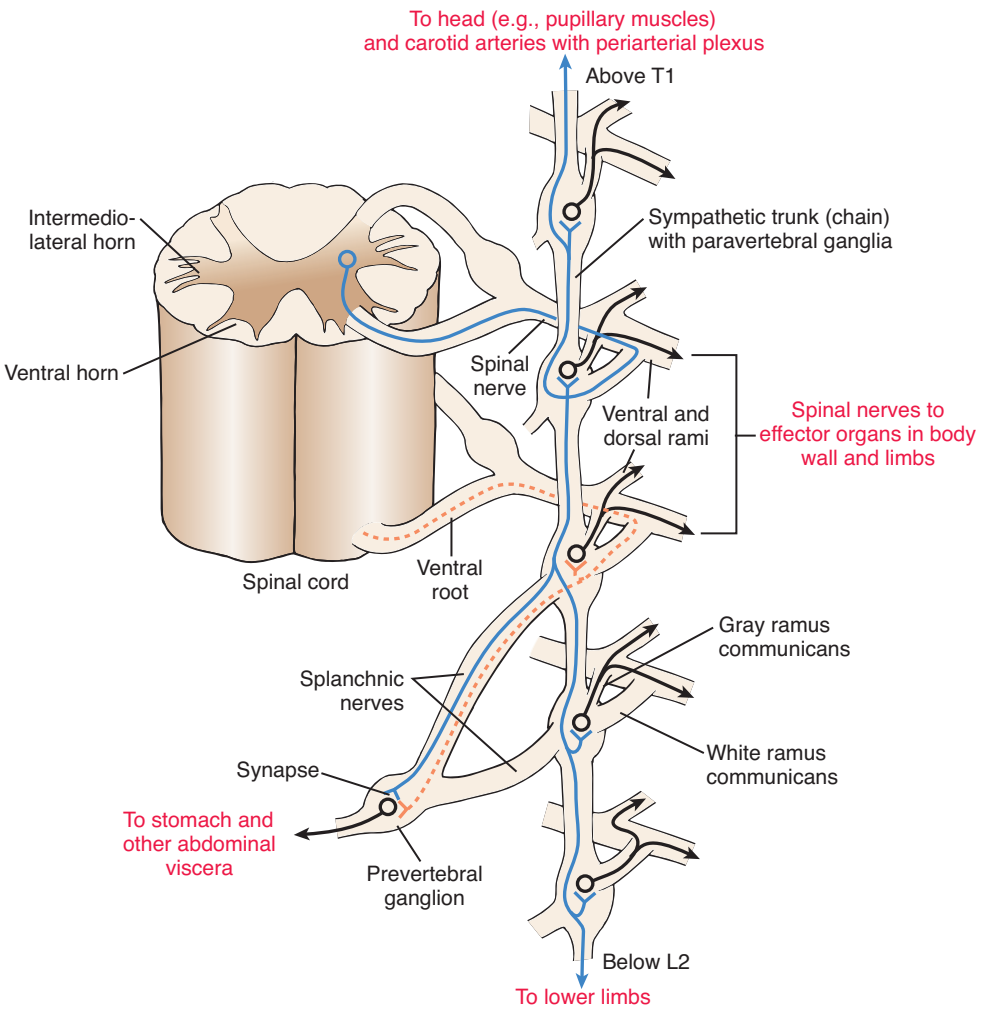

FIGURE 34-24. Sympathetic pathways. Sympathetic preganglionic fibers (*blue*) leave the spinal cord by way of the ventral root of the spinal nerves, enter the ventral primary rami, and pass through the white rami to the prevertebral or paravertebral ganglia of the sympathetic chain, where they synapse with postganglionic neurons (*black*). Other preganglionic neurons (*red dotted lines*) travel directly to their destination in the various effector organs.

the LMNs that innervate skeletal muscles as part of their response patterns.

For most autonomic-mediated functions, the hypothalamus serves as the major control center. The hypothalamus, which has connections with the cerebral cortex, the limbic system, and the pituitary gland, is in a prime position to receive, integrate, and transmit information to other areas of the nervous system. The neurons concerned with thermoregulation, thirst, and feeding behaviors are found in the hypothalamus. The hypothalamus also is the site for integrating neuroendocrine function. Hypothalamic releasing and inhibiting hormones control the secretion of anterior pituitary hormones (see Chapter 31).

The organization of many life-support reflexes occurs in the reticular formation of the medulla and pons. These areas of reflex circuitry, often called *centers*, produce complex combinations of autonomic and somatic efferent functions required for the cough, sneeze, swallow, and vomit reflexes, as well as for the more purely autonomic control of the cardiovascular system. One of the striking features of ANS function is the rapidity and intensity with which it can change visceral function. Within 3 to 5 seconds, it can increase heart rate to approximately twice its resting level. Bronchial smooth muscle tone is largely controlled by parasympathetic fibers carried in the vagus nerve. These nerves produce mild to moderate constriction of the bronchioles.

Other important ANS reflexes are located at the level of the spinal cord. As with other spinal reflexes, these reflexes are modulated by input from higher centers. When there is loss of communication between the higher centers and the spinal reflexes, as occurs in spinal cord injury, these reflexes function in an unregulated manner (see Chapter 36).

Autonomic Neurotransmission

The generation and transmission of impulses in the ANS occur in the same manner as in the CNS. There are self-propagating action potentials with transmission of impulses across synapses and other tissue junctions by way of neurohumoral transmitters. The postganglionic fibers of the ANS form a diffuse neural plexus at the site of innervation. The membranes of the cells of many smooth muscle fibers are connected by conductive protoplasmic bridges, called *gap junctions*, that permit rapid conduction of impulses through whole sheets of smooth

FIGURE 34-25. muscle, often in repeating waves of contraction. Autonomic neurotransmitters released near a limited portion of these fibers provide a modulating function extending to a large number of effector cells. The muscle layers of the gut and of the bladder wall are examples.

The main neurotransmitters of the ANS are acetylcholine and the catecholamines epinephrine and norepinephrine. Acetylcholine is released at all of the sites of preganglionic transmission in the autonomic ganglia of sympathetic and parasympathetic nerve fibers and at the sites of postganglionic transmission in parasympathetic nerve endings. It also is released at sympathetic nerve endings that innervate the sweat glands and cholinergic vasodilator fibers found in skeletal muscle. Norepinephrine is released at most sympathetic nerve endings. The adrenal medulla, which is a modified neural crest tissue, produces epinephrine along with small amounts of norepinephrine. Dopamine, which is an intermediate compound in the synthesis of norepinephrine, also acts as a neurotransmitter. It is the principal inhibitory transmitter of internuncial neurons in the sympathetic ganglia. It also has vasodilator effects on renal, splanchnic, and coronary blood vessels when given intravenously and is sometimes used in the treatment of shock (see Chapter 20).

Acetylcholine and Cholinergic Receptors

Acetylcholine is synthesized in the cholinergic neurons from choline and acetyl coenzyme A (acetyl CoA). After acetylcholine is secreted by the cholinergic nerve endings, it is rapidly broken down by the enzyme acetylcholinesterase (Fig. 34-25A). The choline molecule is transported back into the nerve ending, where it is used again in the synthesis of acetylcholine.

Cell membrane receptors that respond to acetylcholine are called *cholinergic receptors*. There are two types of cholinergic receptors: muscarinic and nicotinic. Muscarinic receptors are present on the innervational

targets of postganglionic fibers of the parasympathetic nervous system and the sweat glands, which are innervated by the sympathetic nervous system. Nicotinic receptors are found in autonomic ganglia and the endplates of skeletal muscle. Acetylcholine has an excitatory effect on muscarinic and nicotinic receptors, except for those in the heart and lower esophagus, where it has an inhibitory effect. The drug atropine is an antimuscarinic or muscarinic cholinergic-blocking drug that prevents the action of acetylcholine at excitatory and inhibitory muscarinic receptor sites. Because it is a muscarinic-blocking drug, it exerts little effect at nicotinic receptor sites.

Catecholamines and Adrenergic Receptors

The catecholamines, which include norepinephrine, epinephrine, and dopamine, are synthesized in the sympathetic nervous system. Synthesis of dopamine and norepinephrine begins in the axoplasm of sympathetic nerve terminals with the conversion of the amino acid tyrosine to dopa, dopa to dopamine, and dopamine to norepinephrine (Fig. 34-25B). In the adrenal gland an additional step takes place during which approximately 80% of the norepinephrine is transformed into epinephrine.

Each of the steps in sympathetic neurotransmitter synthesis requires a different enzyme, and the type of neurotransmitter that is produced depends on the types of enzymes that are available in a nerve terminal. For example, the postganglionic sympathetic neurons that supply blood vessels have the needed enzymes for the synthesis of norepinephrine, whereas those in the adrenal medulla have the enzymes needed to convert norepinephrine into epinephrine. As the catecholamines are synthesized, they are stored in vesicles. The final step of norepinephrine synthesis occurs in these vesicles. When an action potential reaches an axon terminal, the neurotransmitter molecules are released from the storage vesicles. The storage vesicles provide a means for concentrated storage of the catecholamines and protect them from the cytoplasmic enzymes that degrade the neurotransmitters.

In addition to neuronal synthesis, there is a second major mechanism for replenishment of norepinephrine in sympathetic nerve terminals. This mechanism consists of the active reuptake of the released neurotransmitter into the nerve terminal. Between 50% and 80% of the norepinephrine that is released during an action potential is removed from the synaptic area by an active reuptake process. This process terminates the action of the neurotransmitter and allows it to be reused by the neuron. The remainder of the released catecholamines diffuse into the surrounding tissue fluids or are degraded by two special enzymes: catechol-*O*-methyltransferase, which is diffusely present in all tissues, and monoamine oxidase (MAO), which is found in the nerve endings themselves.

Catecholamines can cause excitation or inhibition of smooth muscle contraction, depending on the site, dose, and type of receptor present. The excitatory or inhibitory responses of organs to sympathetic neurotransmitters are mediated by interaction with cell membrane receptors. There are two types of sympathetic receptors: α and β receptors. In vascular smooth muscle, excitation of α-adrenergic receptors causes vasoconstriction, and excitation of β-adrenergic receptors causes vasodilatation. Constriction of blood vessels in the skin, kidneys, and splanchnic circulation is mediated by α-adrenergic receptors. The β-adrenergic receptors are most prevalent in the heart, the blood vessels of skeletal muscle, and the bronchioles.

β-Adrenergic receptors have been further subdivided into α_1 and α_2 receptors, and β-adrenergic receptors into β_1 and β_2 receptors. β_1-Adrenergic receptors are found primarily in the heart and can be selectively blocked by β_1-receptor–blocking drugs. β_2-Adrenergic receptors are found in the bronchioles and in other sites that have β-mediated functions. The α_1 receptors are found primarily in postsynaptic effector sites; they mediate responses in vascular smooth muscle. The α_2 receptors are mainly located presynaptically and can inhibit the release of norepinephrine from sympathetic nerve terminals. The α_2 receptors are abundant in the CNS and are thought to influence the central control of blood pressure.

In summary, the autonomic nervous system (ANS) regulates, adjusts, and coordinates the visceral functions of the body. The ANS, which is divided into the sympathetic and parasympathetic systems, is an efferent system. It receives its afferent input from visceral afferent neurons. The ANS has central nervous system and peripheral nervous system components. The outflow of the sympathetic and parasympathetic nervous system follows a two-neuron pathway, which consists of a preganglionic neuron located in the central nervous system (CNS) and a postganglionic neuron located outside the CNS. Sympathetic fibers leave the CNS at the thoracolumbar level, and the parasympathetic fibers leave at the craniosacral level.

In general, the sympathetic and parasympathetic nervous systems have opposing effects on visceral function—if one excites, the other inhibits. The hypothalamus serves as the major control center for most ANS functions; local reflex circuits relating visceral afferent and autonomic efferent activity are integrated in a hierarchic control system in the spinal cord and brain stem.

The main neurotransmitters for the ANS are acetylcholine and the catecholamines epinephrine and norepinephrine. Acetylcholine is the transmitter for all preganglionic neurons, for postganglionic parasympathetic neurons, and for selected postganglionic sympathetic neurons. The catecholamines are the neurotransmitters for most postganglionic sympathetic neurons. The ANS neurotransmitters exert their action through specialized cell surface receptors—cholinergic receptors that bind acetylcholine and adrenergic receptors that bind the catecholamines. The cholinergic receptors are divided into nicotinic and muscarinic receptors, and adrenergic receptors are divided into α and β receptors.

REVIEW EXERCISES

1. An event such as cardiac arrest, which produces global ischemia of the brain, can produce a selective loss of recent memory and cognitive skills, while the more vegetative and life-sustaining functions such as breathing are preserved.

A. Use principles related to the development of the nervous system and hierarchy of control to explain why.

2. Usually spinal cord injury or disease produces both sensory and motor deficits. An exception is infection by the poliomyelitis virus, which produces muscle weakness and paralysis without loss of sensation in the affected extremities.

A. Explain, using information on the cell column organization of the spinal cord.

3. The functions of the sympathetic nervous system are often described in relation to the "fight-or-flight" response. Using this description, explain the physiologic advantage for the following distribution of sympathetic nervous system receptors:

A. The presence of β_2 receptors on the blood vessels that provide blood flow to the skeletal muscles during "fight or flight," and the presence of α_1 receptors on the resistance vessels that control blood pressure.

4. The presence of acetylcholine receptors on the sweat glands that allow for evaporative loss of body heat during "fight or flight," and the presence of α_1 receptors that constrict the skin vessels that control blood flow to the skin.

A. The presence of β_2 receptors that produce relaxation in the detrusor muscle of the bladder during "fight or flight," and the presence of α_1 receptors that produce contraction of the smooth muscle in the internal sphincter of the bladder.

Chapter 35

Somatosensory Function, Pain, and Headache

Sensory mechanisms provide individuals with a continuous stream of information about their bodies, the outside world, and the interactions between the two. The somatosensory component of the nervous system provides an awareness of the body's deep and superficial parts as compared to the specialized senses of sight and hearing (discussed in Chapter 38), which provide awareness of external world. Between 2 and 3 million nerve endings in the skin and deep body tissues provide a steady stream of encoded somatosensory information to the central nervous system. Only a small portion of this information reaches awareness; most provides input essential for the myriad of reflexes and automatic mechanisms that keep us alive and manage our functioning.

This chapter is organized into two distinct parts. The first part describes the organization and control of somatosensory function, and the second focuses on pain as a somatosensory modality.

Organization and Control of Somatosensory Function

The somatosensory sensory system is designed to provide the central nervous system (CNS) with information related to deep and superficial body structures. There are three types of sensory neurons that vary in terms of distribution and type of sensation that is detected—general somatic, special somatic, and general visceral. *General somatic afferent neurons* have branches with widespread distribution throughout the body and with many distinct types of receptors that result in sensations such as pain, touch, and temperature. *Special somatic afferent neurons* have receptors located primarily in muscles, tendons, and joints. These receptors sense position and movement of the body. *General visceral afferent neurons* have receptors on various visceral structures that sense fullness and discomfort.

Somatosensory Systems

Sensory systems can be conceptualized as a series of neurons consisting of first-order, second-order, and third-order neurons. *First-order neurons* transmit sensory information from the periphery to the CNS. *Second-order neurons* communicate with various reflex networks and sensory pathways in the spinal cord and travel directly to the thalamus. *Third-order neurons* relay information from the thalamus to the cerebral cortex (Fig. 35-1).

This organizing framework corresponds with the three primary levels of neural integration in the somatosensory system: the sensory units, which contain the sensory receptors; the ascending pathways; and the central processing centers in the thalamus and cerebral cortex. Sensory information usually is relayed and processed in a cephalad (toward the head) direction by the three orders of neurons. Many interneurons process and modify the sensory information at the level of the second- and third-order neurons, and many more participate before coordinated and appropriate learned-movement responses occur. The number of participating neurons increases exponentially from the primary through the secondary and the secondary through the tertiary levels.

The Somatosensory System

- The somatosensory system relays information about four major modalities: touch, temperature, pain, and body position.
- The system is organized segmentally into dermatomes, with each segment supplied by a single dorsal root ganglion that contains the neuronal cell bodies for the sensory units of the segment.
- Somatosensory information is sequentially transmitted over three types of neurons: first-order neurons, which transmit information from sensory receptors to dorsal horn neurons; second-order CNS association neurons, which communicate with various reflex circuits and transmit information to the thalamus; and third-order neurons, which forward the information from the thalamus to the sensory cortex.

The Sensory Unit

The somatosensory experience arises from information provided by a variety of receptors distributed throughout the body. These receptors monitor four major types or modalities of sensation: discriminative touch, which is required to identify the size and shape of objects and their movement across the skin; temperature sensation; sense of movement of the limbs and joints of the body; and nociception, or pain.

Each of the somatosensory modalities is mediated by a distinct system of receptors and pathways to the brain; however, all somatosensory information from the limbs and trunk shares a common class of sensory neurons called *dorsal root ganglion neurons*. Somatosensory information from the face and cranial structures is transmitted by the trigeminal sensory neurons, which function in the same manner as the dorsal root ganglion neurons. The cell body of the dorsal root ganglion neuron, its peripheral branch (which innervates a small area of periphery), and its central axon (which projects to the CNS) form what is called a *sensory unit*.

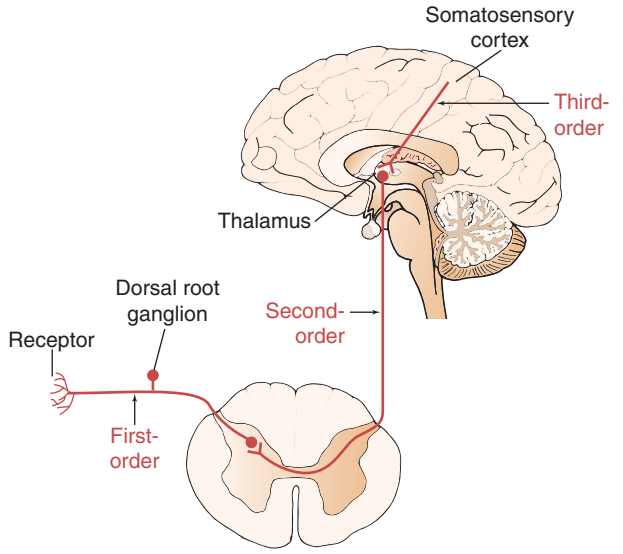

FIGURE 35-1. Arrangement of first-order, second-order, and third-order neurons of the somatosensory system.

The fibers of different dorsal root ganglion neurons conduct impulses at varying rates, ranging from 0.5 to 120 m/second. This rate depends on the diameter of the nerve fiber. There are three types of nerve fibers that transmit somatosensory information: types A, B, and C. Type A fibers, which are myelinated, have the fastest rate of conduction.[1,2] Type A fibers convey cutaneous pressure and touch sensation, cold sensation, mechanical pain, and heat pain. Type B fibers, which also are myelinated, transmit information from cutaneous and subcutaneous mechanoreceptors. The unmyelinated type C fibers have the smallest diameter and the slowest rate of conduction. They convey warm–hot sensation and mechanical and chemical as well as heat- and cold-induced pain sensation.

Dermatomal Pattern of Innervation

The somatosensory innervation of the body, including the head, retains a basic segmental pattern that was established during embryonic development. Thirty-three paired spinal (i.e., segmental) nerves provide sensory and motor innervation of the body wall, the limbs, and the viscera (see Chapter 34, Fig. 34-12). Sensory input to each spinal cord segment is provided by sensory neurons with cell bodies in the dorsal root ganglia. The head and face are innervated by the three branches of the trigeminal cranial nerve (CN V).

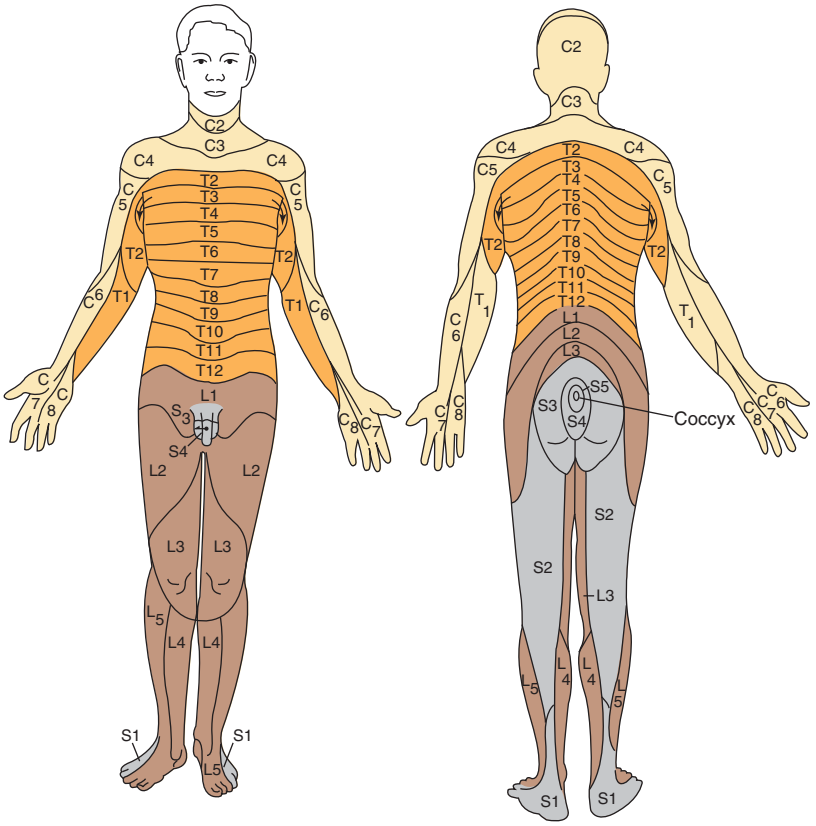

FIGURE 35-2. Cutaneous distribution of spinal nerves (dermatomes). (From Barr M. [1993]. *The human nervous system.* New York: Harper & Row.)

The region of the body wall that is supplied by a single pair of dorsal root ganglia is called a *dermatome*. These dorsal root ganglion–innervated strips occur in a regular sequence moving upward from the second coccygeal segment through the cervical segments, reflecting the basic segmental organization of the body and the nervous system (Fig. 35-2). The trigeminal nerve branches that innervate the head send their axons to equivalent nuclei in the brain stem. Neighboring dermatomes overlap one another sufficiently so that a loss of one dorsal root or root ganglion results in reduced but not total loss of sensory innervation of a dermatome (Fig. 35-3). Dermatome maps are helpful in interpreting the level and extent of sensory deficits that are the result of segmental nerve and spinal cord damage. For example, on the basis of the dermatomal map we can predict that sensory changes limited to the distal forearm and fourth and fifth fingers are the result of injury to the cervical (C) 8 and thoracic (T) 1 dorsal roots.

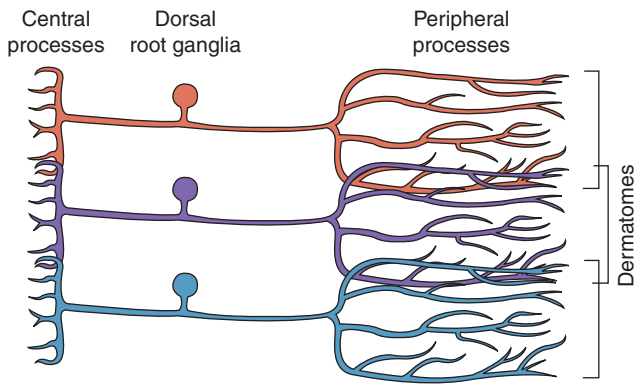

FIGURE 35-3. The dermatomes formed by the peripheral processes of adjacent spinal nerves overlap on the body surface. The central processes of these fibers also overlap in their spinal distribution.

Spinal Circuitry and Ascending Neural Pathways

On entry into the spinal cord, the central axons of the somatosensory neurons branch extensively and project to neurons in the spinal cord gray matter. Some branches become involved in local spinal cord reflexes and directly initiate motor reflexes (e.g., flexor-withdrawal reflex). Two parallel pathways, the *discriminative pathway* and the *anterolateral pathway,* carry the information from the spinal cord to the thalamic level of sensation, each taking a different route through the CNS.[1,2] Having a two-pathway system has several advantages. It adds richness to the sensory input by allowing sensory information to be handled in two different ways, and it ensures that if one pathway is damaged, the other still can provide input.

Dorsal Column–Medial Lemniscal Pathway. The dorsal column–medial lemniscal pathway, also known as the *discriminative pathway*, is used for the rapid transmission of sensory information such as discriminative touch. It contains branches of primary afferent axons that travel

up the ipsilateral (i.e., same side) dorsal columns of the spinal cord white matter and synapse with highly evolved somatosensory input association neurons in the medulla. The discriminative pathway uses only three neurons to transmit information from a sensory receptor to the somatosensory strip of parietal cerebral cortex of the opposite side of the brain: (1) the dorsal root ganglion neurons, which project their central axons to the dorsal horn in the spinal cord; (2) the dorsal column nuclei, which send their axons upward and across the midline of the medulla where they form a band of white matter called the *medial lemniscus* that passes upward to the thalamus; and (3) the thalamic neurons, which project through the somatosensory radiation to the primary sensory cortex (Fig. 35-4A). As the fibers in the medial lemniscus ascend through the brain stem, they are joined by sensory fibers from the trigeminal nerve that supplies the head and face. Sensory information arriving at the sensory cortex by this route can be discretely localized and discriminated in terms of intensity.

One of the distinct features of the discriminative pathway is that it relays precise information regarding spatial orientation. This is the only pathway taken by the sensations of muscle and joint movement, vibration, and delicate discriminative touch, as is required to differentiate correctly the location of touch on the skin at two neighboring points (i.e., two-point discrimination). One of the important functions of the discriminative pathway is to integrate the input from multiple receptors. The sense of shape and size of an object in the absence of visualization, called *stereognosis,* is based on precise afferent information from muscle, tendon, and joint receptors. For example, a screwdriver is perceived as being different from a knife in terms of its texture (tactile sensibility) and shape based on the relative position of the fingers as they move over the object. This complex interpretive perception requires that both the discriminative system and the higher-order parietal association cortex are functioning properly. If the discriminative somatosensory pathway is functional but the parietal association cortex has become discretely damaged, the person can correctly describe the object but does not recognize that it is a screwdriver. This deficit is called *astereognosis*.

Anterolateral Pathway. The anterolateral pathway (anterior and lateral spinothalamic tracts) consists of bilateral, multisynaptic, slow-conducting tracts (see Chapter 34, Fig. 34-11). These tracts provide for transmission of

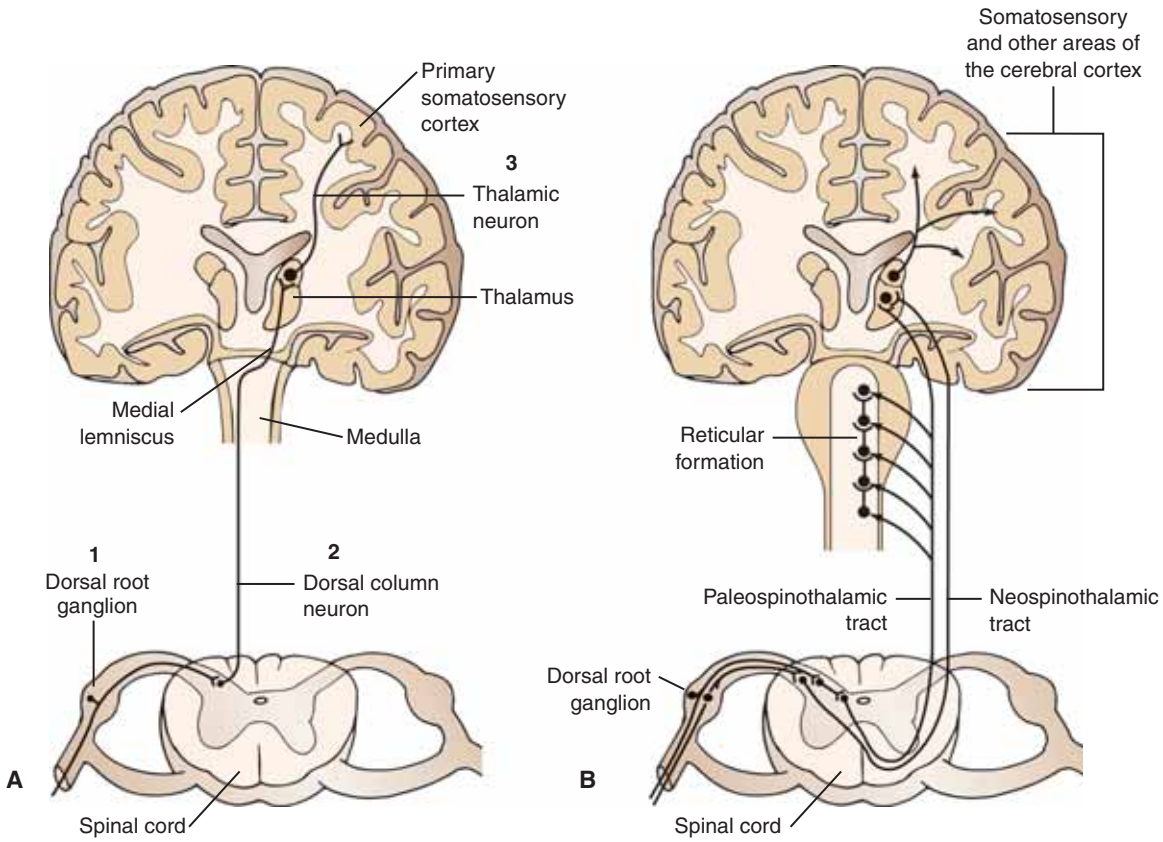

FIGURE 35-4. **(A)** Rapid-transmitting discriminative (dorsal column–medial lemniscal) pathway carrying axons mediating tactile sensation and proprioception. **(B)** Neospinothalamic and paleospinothalamic subdivisions of the anterolateral sensory pathway. The neurons of anterolateral pathways cross within the same segment as the cell body and ascend in the contralateral side of the spinal cord. The neospinothalamic tract travels mainly to thalamic nuclei that have third-order fibers projecting to the somatosensory cortex. The paleospinothalamic tract sends collaterals to the reticular formation and other structures, from which further fibers project to the thalamus.

sensory information such as pain, thermal sensations, crude touch, and pressure that does not require discrete localization of signal source or fine discrimination of intensity. The fibers of the anterolateral pathway originate in the dorsal horns at the level of the segmental nerve, where the dorsal root ganglion neurons enter the spinal cord. These spinal neurons cross in the anterior commissure, within a few segments of origin, to the anterolateral column on the opposite side of the cord, where they ascend upward toward the brain. The anterolateral tract fibers synapse with several nuclei in the thalamus, but en route they give off numerous branches that travel to the reticular activating system of the brain stem. These projections provide the basis for increased wakefulness or awareness after strong somatosensory stimulation and for the generalized startle reaction that occurs with sudden and intense stimuli. They also stimulate autonomic nervous system responses, such as a rise in heart rate and blood pressure, dilation of the pupils, and the pale, moist skin that results from constriction of the cutaneous blood vessels and activation of the sweat glands.

There are two subdivisions in the anterolateral pathway: the neospinothalamic and the paleospinothalamic tracts[1] (see Fig. 35-4B). The *neospinothalamic tract* consists of a sequence of at least three neurons with long axons. It provides for relatively rapid transmission of sensory information to the thalamus. The *paleospinothalamic tract*, which is phylogenically older than the neospinothalamic system, consists of bilateral, multisynaptic, slow-conducting tracts that transmit sensory signals that do not require discrete localization or discrimination of fine gradations in intensity. This slower-conducting pathway also projects into the intralaminar nuclei of the thalamus, which have close connections with the limbic cortical systems. This circuitry gives touch its affective or emotional aspects, such as the particular unpleasantness of heavy pressure and the peculiar pleasantness of the tickling and gentle rubbing of the skin.

Central Processing of Somatosensory Information

Perception, or the final processing of somatosensory information, involves awareness of the stimuli, localization and discrimination of their characteristics, and interpretation of their meaning.[1,2] As sensory information reaches the thalamus, it begins to enter the level of consciousness. In the thalamus, the sensory information is roughly localized and perceived as a crude sense. The full localization, discrimination of the intensity, and interpretation of the meaning of the stimuli require processing by the somatosensory cortex.

The somatosensory cortex is located in the parietal lobe, which lies behind the central sulcus and above the lateral sulcus (Fig. 35-5). The strip of parietal cortex that borders the central sulcus is called the *primary somatosensory cortex* because it receives primary sensory information by direct projections from the thalamus. A distorted map of the body and head surface, called the *sensory homunculus,* reflects the density of cortical neurons devoted to sensory input from afferents in

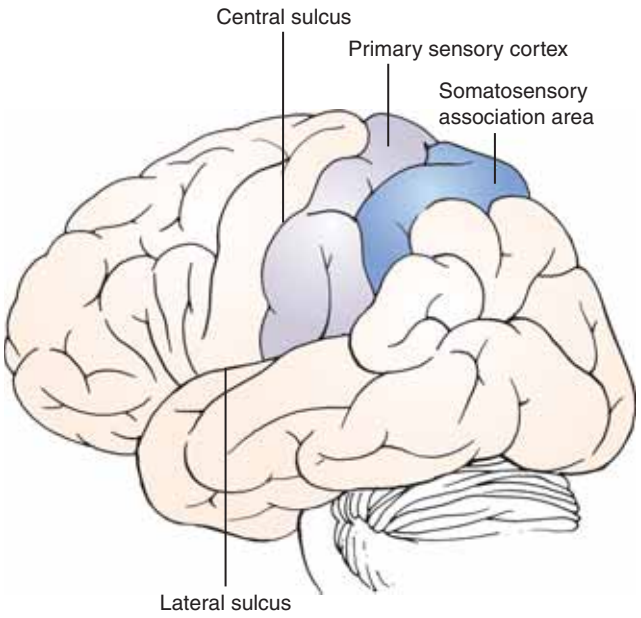

FIGURE 35-5. Primary somatosensory cortex and somatosensory association area.

corresponding peripheral areas. As depicted in Figure 35-6, most of the cortical surface is devoted to areas of the body such as the thumb, forefinger, lips, and tongue, where fine touch and pressure discrimination are essential for normal function.

Parallel to and just behind the primary somatosensory cortex (i.e., toward the occipital cortex) lie the somatosensory association areas, which are required to transform

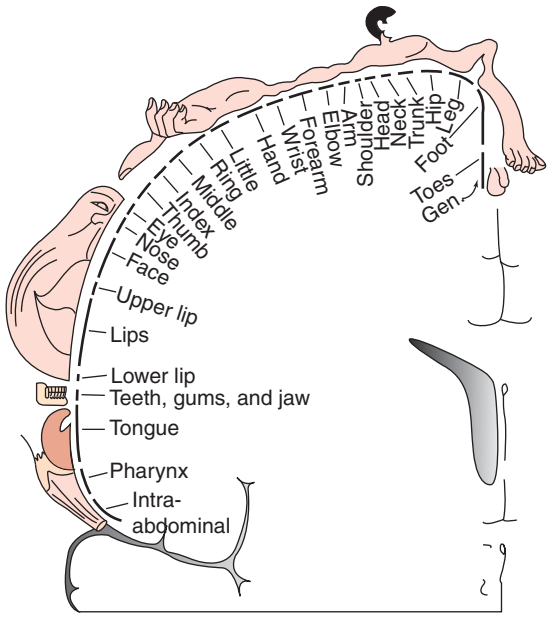

FIGURE 35-6. Homunculus, as determined by stimulation studies on the human cortex during surgery. (From Penfield E., Rasmussen T. [1955]. *The cerebral cortex of man.* New York: Macmillan. Copyright © by Macmillan Publishing Co., Inc., renewed 1978 by Theodore Rasmussen.)

the raw material of sensation into meaningful learned perception. Most of the perceptive aspects of body sensation, or somesthesia, require the function of this parietal association cortex. The perceptive aspect, or meaningfulness, of a stimulus pattern involves the integration of present sensation with past learning. For instance, a person's past learning plus present tactile sensation provides the perception of sitting on a soft chair rather than on a hard bicycle seat.

Somatosensory Modalities

Somatosensory experience can be divided into *modalities*, a term used for qualitative, subjective distinctions between sensations such as touch, temperature, and pain.[1,2] Such experiences require the function of sensory receptors and forebrain structures in the thalamus and cerebral cortex. Sensory experience also involves quantitative sensory discrimination or the ability to distinguish between different levels of sensory stimulation.

The receptive endings of different afferent neurons are particularly sensitive to specific forms of physical and chemical energy. They can initiate action potentials to many forms of energy at high energy levels, but they usually are highly tuned to be differentially sensitive to low levels of a particular energy type. For instance, a receptive ending may be particularly sensitive to a small increase in local skin temperature. Stimulating the ending with electric current or strong pressure also can result in action potentials. The amount of energy required, however, is much greater than it is for a change in temperature. Other afferent sensory terminals are most sensitive to slight indentations of the skin, and their signals are subjectively interpreted as touch. Cool versus warm, sharp versus dull pain, and delicate touch versus deep pressure are all based on different populations of afferent neurons or on central integration of simultaneous input from several differently tuned afferents.

Tactile Sensation

The tactile system, which relays sensory information regarding touch, pressure, and vibration, is considered the basic somatosensory system. Loss of temperature or pain sensitivity leaves the person with no awareness of deficiency. If the tactile system is lost, however, total anesthesia (i.e., numbness) of the involved body part results.

Touch sensation results from stimulation of tactile receptors in the skin and in tissues immediately beneath the skin, pressure from deformation of deeper tissues, and vibration from rapidly repetitive sensory signals. There are at least six types of specialized tactile receptors in the skin and deeper structures: free nerve endings, Meissner corpuscles, Merkel disks, pacinian corpuscles, hair follicle end-organs, and Ruffini end-organs[1,2] (Fig. 35-7).

Free nerve endings are found in skin and many other tissues, including the cornea. They detect touch and pressure. *Meissner corpuscles* are elongated, encapsulated nerve endings present in nonhairy parts of the skin. They are particularly abundant in the fingertips, lips, and other areas where the sense of touch is highly developed. *Merkel disks* are dome-shaped receptors found in nonhairy areas and in hairy parts of the skin. In contrast to Meissner corpuscles, which adapt within a fraction of a second, Merkel disks transmit an initial strong signal that diminishes in strength but is slow in adapting. For this reason, Meissner corpuscles are particularly sensitive to the movement of very light objects over the surface of the skin and to low-frequency vibration. Merkel disks are responsible for giving steady-state signals that allow for continuous determination of touch against the skin.

The *pacinian corpuscle* is located immediately beneath the skin and deep in the fascial tissues of the body. This type of receptor, which is stimulated by rapid movements of the tissues and adapts within a few hundredths of a second, is important in detecting tissue vibration. The *hair follicle end-organ* consists of afferent unmyelinated fibers entwined around most of the length of the hair follicle. These receptors, which are rapidly adapting, detect movement on the surface of the body. *Ruffini end-organs* are found in the skin and deeper structures, including the joint capsules. These receptors, which have multibranched encapsulated endings, have very little adaptive capacity and are important for signaling continuous states of deformation, such as heavy and continuous touch and pressure.

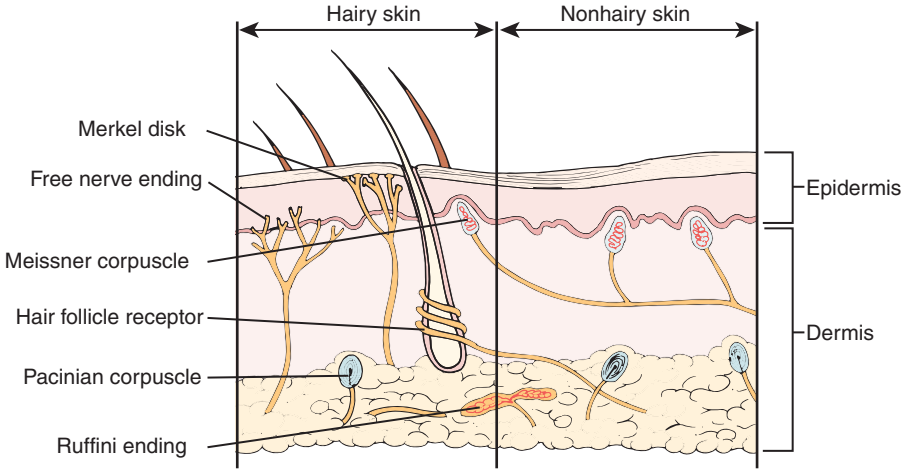

FIGURE 35-7. Somatic sensory receptors in the skin. Hairy skin and nonhairy skin have a variety of sensory receptors. (Adapted from Bear M.F., Connors B.W., Paradiso M.A. [1996]. *Neuroscience: Exploring the brain* [p. 311]. Baltimore: Williams & Wilkins.)

Almost all the specialized touch receptors, with the exception of free nerve endings, transmit their signals through large myelinated nerve fibers (i.e., types Aα, Aβ) that have transmission velocities ranging from 25 to 70 m/second. Most free nerve endings transmit signals by way of small myelinated fibers (i.e., type Aδ) with conduction velocities of 10 to 30 m/second.

The sensory information for tactile sensation enters the spinal cord through the dorsal roots of the spinal nerves. All tactile sensation that requires rapid transmission is transmitted through the discriminative pathway to the thalamus by way of the medial lemniscus. This includes touch sensation requiring a high degree of localization or fine gradations of intensity, vibratory sensation, and sensation that signals movement against the skin. In addition to the ascending discriminative pathway, tactile sensation uses the more primitive and crude anterolateral pathway. The afferent axons that carry tactile information up the dorsal columns have many branches or collaterals, some of which synapse in the dorsal horn near the level of dorsal root entry. After several synapses, axons are projected up both sides of the anterolateral aspect of the spinal cord to the thalamus. Few fibers travel all the way to the thalamus. Most synapse on reticular formation neurons that then send their axons on toward the thalamus. The thalamus is capable of contributing a crude, poorly localized sensation from the opposite side of the body. From the thalamus, some projections travel to the somatosensory cortex, especially to the side opposite the stimulus.

Because of these multiple routes, total destruction of the anterolateral pathway seldom occurs. The only time this crude alternative system becomes essential is when the discriminative pathway is damaged. Then, despite projection of the anterolateral system information to the somatosensory cortex, only a poorly localized, high-threshold sense of touch remains. Such persons lose all sense of joint and muscle movement, body position, and two-point discrimination.

Thermal Sensation

Thermal sensation is discriminated by three types of receptors: cold, warmth, and pain. The cold and warmth receptors are located immediately under the skin at discrete but separate points, each serving an area of approximately 1 mm^2. In some areas, there are more cold receptors than warmth receptors. For example, the lips have 15 to 25 cold receptors per square centimeter, compared with 3 to 5 in the same-sized area of the finger.[1] Different gradations of heat and cold reception result from the relative degrees of stimulation of the different types of nerve endings. Warmth receptors respond proportionately to increases in skin temperature above resting values of 34°C and cold receptors to temperatures below 34°C.[2] The thermal pain receptors are stimulated only by extremes of temperature such as "freezing cold" (temperatures below 5°C) and "burning hot" (temperatures above 45°C) sensations.[2] Thermal receptors respond rapidly to sudden changes in temperature and then adapt over the next few minutes. They do not adapt completely, however, but continue to respond to steady states of temperature. For example, the sensation of heat one feels on entering a tub of hot water or the extreme degree of cold experienced when going outside on a cold day is the initial response to a change in temperature, followed by an adaptation in which one gets accustomed to the temperature change but still feels the heat or cold because the receptors have not adapted completely.

Thermal afferents, with receptive thermal endings in the skin, send their central axons into the segmental dorsal horn of the spinal cord. On entering the dorsal horn, thermal signals are processed by second-order input association neurons. These association neurons activate projection neurons whose axons then cross to the opposite side of the cord and ascend in the multisynaptic, slow-conducting anterolateral system to the opposite side of the brain. Thalamic and cortical somatosensory regions for temperature are mixed with those for tactile sensibility.

Conduction of thermal information through peripheral nerves is quite slow compared with the rapid tactile afferents that travel through the discriminative system. If a person places a foot in a tub of hot water, the tactile sensation occurs well in advance of the burning sensation. The foot has been removed from the hot water by the local withdrawal reflex well before the excessive heat is perceived by the forebrain. Local anesthetic agents block the small-diameter afferents that carry thermal sensory information before they block the large-diameter axons that carry discriminative touch information.

Position Sense

Position sense refers to the sense of limb and body movement and position without using vision. It is mediated by input from proprioceptive receptors (muscle spindle receptors and Golgi tendon organs) found primarily in muscles, tendons, and joint capsules (see Chapter 36). There are two submodalities of proprioception: the stationary or static component (limb position sense) and the dynamic aspects of position sense (kinesthesia). Both of these depend on constant transmission of information to the CNS regarding the degree of angulation of all joints and the rate of change in angulation. In addition, stretch-sensitive receptors in the skin (Ruffini end-organs, pacinian corpuscles, and Merkel cells) also signal postural information. Signals from these receptors are processed through the dorsal column–medial lemniscus pathway. In addition to the transmission of signals from the periphery to the cerebral cortex, the signals are processed in the thalamus before reaching the cerebral cortex. Lesions affecting the posterior column of the spinal cord impair position sense. The vestibular system (see Chapter 38) also plays an essential role in position sense.

In summary, the somatosensory component of the nervous system provides an awareness of body sensations such as touch, temperature, position sense, and pain. There are three primary levels of neural integration

in the somatosensory system: the sensory units containing the sensory receptors, the ascending pathways, and the central processing centers in the thalamus and cerebral cortex. A sensory unit consists of a single dorsal root ganglion neuron, its receptors, and its central axon that terminates in the dorsal horn of the spinal cord or medulla. The part of the body innervated by the somatosensory afferent neurons of one set of dorsal root ganglia is called a *dermatome.* Ascending pathways include the discriminative pathway, which crosses at the base of the medulla, and the anterolateral pathway, which crosses within the first few segments of entering the spinal cord. Perception, or the final processing of somatosensory information, involves centers in the thalamus and somatosensory cortex. In the thalamus, the sensory information is crudely localized and perceived. The full localization, discrimination of the intensity, and interpretation of the meaning of the stimuli require processing by the somatosensory cortex. A distorted map of the body and head surface, called the *sensory homunculus,* reflects the density of cortical neurons devoted to sensory input from afferents in corresponding peripheral areas.

The tactile system relays the sensations of touch, pressure, and vibration. It uses two anatomically separate pathways to relay touch information to the opposite side of the forebrain: the dorsal column discriminative pathway and the anterolateral pathway. Delicate touch, vibration, position, and movement sensations use the discriminative pathway to reach the thalamus, where third-order relay occurs to the primary somatosensory strip of the parietal cortex. Crude tactile sensation is carried by the bilateral slow-conducting anterolateral pathway. Temperature sensations of warm–hot and cool–cold are the result of stimulation of thermal receptors of sensory units projecting to the thalamus and cortex through the anterolateral system on the opposite side of the body. Position sense or proprioception is processed through the rapid-transmitting dorsal column–medial lemniscus pathway.

Pain Sensation

Pain is an unpleasant sensory and emotional sensation associated with actual and potential tissue damage.[1–4] Unlike other somatic modalities, pain has an urgent and primitive quality, a quality responsible for the psychological, social, cultural, and cognitive aspects of the pain experience. Despite its unpleasantness, pain can serve a useful purpose in that it warns of impending tissue injury, motivating the person to seek relief. For example, an inflamed appendix could progress in severity, rupture, and even cause death were it not for the warning afforded by pain.

Pain is a common symptom that varies widely in intensity and spares no age group. It can be equally devastating for infants and children, young and middle-aged adults, and the young-old and the old-old. Both acute pain and chronic pain can be major health problems. It is the most common reason for visits to health care facilities. Acute pain often results from injury, surgery, or invasive medical procedures. It also can be a presenting symptom of infections, such as otitis media. Chronic pain can be symptomatic of a wide range of health problems including arthritis, back injury, and cancer.

Pain Theories

Traditionally, two theories have been offered to explain the physiologic basis for the pain experience. The first, *specificity theory,* regards pain as a separate sensory modality evoked by the activity of specific receptors that transmit information by special nerve endings to pain centers or regions in the forebrain where pain is experienced.[5] The second theory includes a group of theories collectively referred to as *pattern theory.* It proposes that pain receptors share endings or pathways with other sensory modalities, but that different patterns of activity (i.e., spatial or temporal) of the same neurons can be used to signal painful and nonpainful stimuli.[5] For example, light touch applied to the skin would produce the sensation of touch through low-frequency firing of the receptor; intense pressure would produce pain through high-frequency firing of the same receptor. Both theories focus on the neurophysiologic basis of pain, and both probably apply. Specific nociceptive afferents have been identified; however, almost all afferent stimuli, if driven at a very high frequency, can be experienced as painful.

Gate control theory, a modification of specificity theory, was proposed by Melzack and Wall in 1965 to meet the challenges presented by the pattern theories. This theory postulated the presence of neural gating mechanisms at the segmental spinal cord level to account for interactions between pain and other sensory modalities.[6] The original gate control theory proposed a spinal cord–level network of transmission or projection cells and internuncial neurons that inhibits the transmission cells, forming a segmental-level gating mechanism that could block projection of pain information to the brain.

According to the gate control theory, the internuncial neurons involved in the gating mechanism are activated by large-diameter, faster-propagating fibers that carry tactile information. The simultaneous firing of the large-diameter touch fibers has the potential for blocking the transmission of impulses from the small-diameter myelinated and unmyelinated pain fibers. Pain therapists have long known that pain intensity can be temporarily modified by the stimulation of other sensory fibers. For example, repeated sweeping of a soft-bristled brush on the skin (i.e., brushing) over or near a painful area may result in pain reduction for several minutes to several hours.

Pain modulation is now known to be a much more complex phenomenon than that proposed by the original gate control theory. Tactile information is transmitted by small- and large-diameter fibers. Major interactions between sensory modalities, including the so-called gating phenomenon, occur at several levels of the CNS rostral to the input segment. Perhaps the most puzzling

aspect of locally applied stimuli, such as brushing, that can block the experience of pain is the relatively long-lasting effect (minutes to hours) of such treatments. This prolonged effect has been difficult to explain on the basis of specificity theories, including the gate control theory. Other important factors include the effect of endogenous opioids and their receptors at the segmental and brain stem level, descending feedback modulation, altered sensitivity, learning, and culture. Despite this complexity, the Melzack and Wall theory has served a useful purpose. It sparked interest in pain and stimulated research and clinical activity related to the pain-modulating systems.

More recently, Melzack has developed the *neuromatrix theory* to address further the brain's role in pain as well as the psychological and emotional sequelae that contribute to the multiple dimensions and determinants of pain.[7] This theory is particularly useful in understanding chronic pain and phantom limb pain, in which there is not a simple one-to-one relationship between tissue injury and pain experience. The neuromatrix theory proposes that the brain contains a widely distributed neural network, called the *body–self neuromatrix,* that has multiple somatosensory, limbic, and thalamocortical components. Genetic and sensory influences determine the synaptic architecture of an individual's neuromatrix that integrates multiple sources of input and yields the neurosignature pattern that evokes the sensory, affective, and cognitive dimensions of pain experience and behavior. These multiple sources include somatosensory inputs; other sensory inputs affecting interpretation of the situation; phasic and tonic inputs from the brain addressing such things as attention, expectation, culture, and personality; intrinsic neural inhibitory modulation; and various components of stress regulation systems. The neuromatrix theory of pain, which places genetic and neuroendocrine mechanisms of stress on a level equal to that of the neural mechanisms of sensory transmission, has important implications for research and therapy.[7]

Pain Sensation

- Pain is both a protective and an unpleasant physical and emotionally disturbing sensation originating in pain receptors that respond to a number of stimuli that threaten tissue integrity.
- There are two pathways for pain transmission:
  - The pathway for fast, sharply discriminated pain that moves directly from the receptor to the spinal cord using myelinated Aδ fibers and from the spinal cord to the thalamus using the neospino-thalamic tract
  - The pathway for slow, continuously conducted pain that is transmitted to the spinal cord using unmyelinated C fibers and from the spinal cord to the thalamus using the more circuitous and slower-conducting paleospinothalamic tract
- The central processing of pain information includes transmission to the somatosensory cortex, where pain information is perceived and interpreted; the limbic system, where the emotional components of pain are experienced; and to brain stem centers, where autonomic nervous system responses are recruited.
- Modulation of the pain experience occurs by way of the endogenous analgesic center in the midbrain, the pontine noradrenergic neurons, and the nucleus raphe magnus in the medulla, which sends inhibitory signals to dorsal horn neurons in the spinal cord or trigeminal nerve.

Pain Mechanisms and Pathways

Pain can be either nociceptive or neuropathic in origin. The term *nociception,* which means "pain sense," comes from the Latin word *nocere,* "to injure." *Nociceptive pain* is initiated by nociceptors that are activated by noxious insults to peripheral tissues. *Neuropathic pain,* on the other hand, arises from direct injury or dysfunction of the sensory axons of peripheral or central nerves.

Two aspects of pain affect an individual's response to a painful stimulus—pain threshold and tolerance. Although the terms often are used interchangeably, pain threshold and pain tolerance have distinct meanings. *Pain threshold* is closely associated with the point at which a nociceptive stimulus is perceived as painful. *Pain tolerance* relates more to the total pain experience; it is defined as the maximum intensity or duration of pain that a person is willing to endure before the person wants something done about the pain. Psychological, familial, cultural, and environmental factors significantly influence the amount of pain a person is willing to tolerate. The threshold for pain is fairly uniform from one person to another, whereas pain tolerance is extremely variable.

The mechanisms of pain are many and complex. As with other forms of somatosensation, the pathways are composed of first-, second-, and third-order neurons[1,2] (Fig. 35-8). The first-order neurons and their receptive endings detect stimuli that threaten the integrity of innervated tissues. Second-order neurons are located in the spinal cord and process nociceptive information. Third-order neurons project pain information to the brain. The thalamus and somatosensory cortex integrate and modulate pain as well as the person's subjective reaction to the pain experience.

Pain Receptors and Primary Afferent Pathways

Nociceptors, or pain receptors, are sensory receptors that are activated by noxious insults to peripheral tissues. Structurally, the receptive endings of the peripheral pain fibers are free nerve endings. These receptive endings,

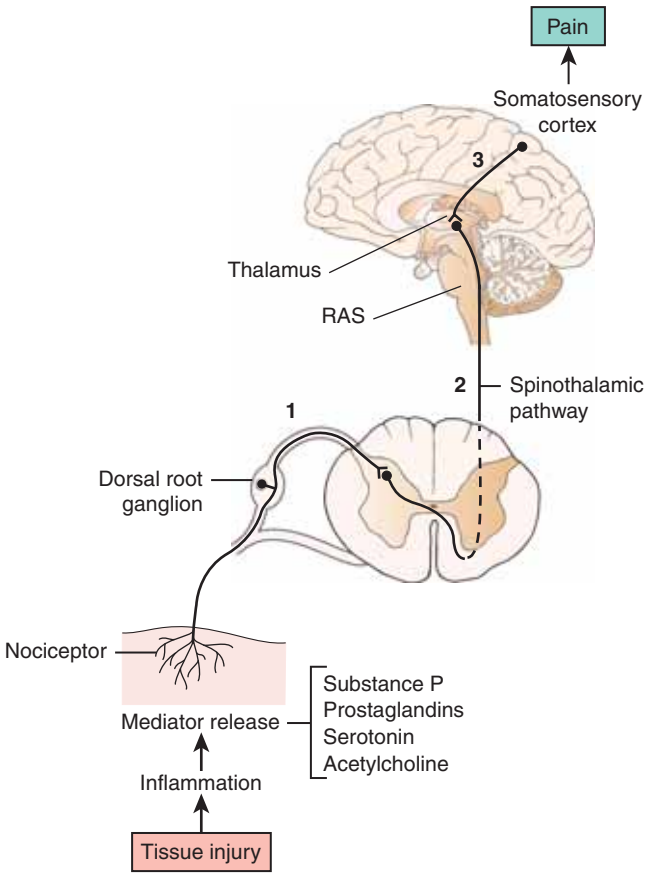

FIGURE 35-8. Mechanism of acute pain. Tissue injury leads to release of inflammatory mediators with subsequent nociceptor stimulation. Pain impulses are then transmitted to the dorsal horn of the spinal cord, where they make contact with second-order neurons that cross to the opposite side of the cord and ascend by the spinothalamic tract to the reticular activating system (RAS) and thalamus. The localization and meaning of pain occur at the level of the somatosensory cortex. 1, first-order sensory neurons; 2, second-order sensory neurons; 3, third-order sensory neurons.

which are widely distributed in the skin, dental pulp, periosteum, meninges, and some internal organs, translate the noxious stimuli into action potentials that are transmitted by a dorsal root ganglion to the dorsal horn of the spinal cord.

Nociceptive Simulation. Unlike other sensory receptors, nociceptors respond to several forms of stimulation, including mechanical, thermal, and chemical. Some receptors respond to a single type of stimuli (mechanical or thermal) and others, called *polymodal receptors*, respond to all three types of stimuli (mechanical, thermal, and chemical). Mechanical stimuli can arise from intense pressure applied to skin or from the violent contraction or extreme stretch of a muscle. Both extremes of heat and cold can stimulate nociceptors. Chemical stimuli arise from a number of sources, including tissue trauma, ischemia, and inflammation. A wide range of chemical mediators are released from injured and inflamed tissues, including hydrogen and potassium ions, prostaglandins, leukotrienes, histamine, bradykinin, acetylcholine, and serotonin. These chemical mediators produce their effects by directly stimulating nociceptors or sensitizing them to the effects of nociceptive stimuli; perpetuating the inflammatory responses that lead to the release of chemical agents that act as nociceptive stimuli; or inciting neurogenic reflexes that increase the response to nociceptive stimuli. For example, bradykinin, histamine, serotonin, and potassium activate and also sensitize nociceptors.[8] Other chemical mediators act alone or in concert to sensitize nociceptors through other chemical agents such as prostaglandins. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) are effective in controlling pain because they block the enzyme needed for prostaglandin synthesis.

Peripheral Pain Fibers. There are two types of afferent fibers that transmit pain signals from the free nerve endings into the CNS: myelinated Aδ fibers and unmyelinated C fibers.[1,2] The larger Aδ fibers have considerably greater conduction velocities, transmitting impulses at a rate of 10 to 30 m/second. The C fibers are the smallest of all peripheral nerve fibers; they transmit impulses at the rate of 0.5 to 2.5 m/second. Pain conducted by Aδ fibers traditionally is called *fast pain* or first pain and typically is elicited by mechanical or thermal stimuli. C-fiber pain often is described as *slow-wave pain* or second pain because it is slower in onset and longer in duration, continuing to elicit pain for up to 80 hours.[9] It typically is incited by chemical stimuli or by persistent mechanical or thermal stimuli. The slow postexcitatory potentials generated in C fibers are now believed to be responsible for central sensitization to chronic pain.

Nociceptive stimulation that activates C fibers can cause a response known as *neurogenic inflammation* that produces vasodilation and an increased release of chemical mediators to which nociceptors respond.[8] This mechanism is thought to be mediated by a dorsal root neuron reflex that produces retrograde transport and release of chemical mediators, which in turn causes increasing inflammation of peripheral tissues. This reflex can set up a vicious cycle, which has implications for persistent pain and hyperalgesia.

The transmission of impulses between the peripheral nociceptive neurons and dorsal horn neurons in the spinal cord is mediated by neurotransmitters released from nerve endings of the nociceptive neurons.[10] Some of these neurotransmitters are amino acids (e.g., glutamate), others are amino acid derivatives (e.g., norepinephrine), and still others are low–molecular-weight peptides composed of two or more amino acids. The amino acid glutamate is a major excitatory neurotransmitter released from the central nerve endings of the nociceptive neurons. Substance P, a neuropeptide, also is released in the dorsal horn by C fibers in response to nociceptive stimulation. Substance P elicits slow excitatory potentials in dorsal horn neurons. Unlike glutamate, which confines its action to the immediate area of the synaptic terminal, some neuropeptides released in the dorsal horn can diffuse some distance because they are not inactivated by reuptake mechanisms. In persistent pain, this may help to explain the excitability and unlocalized

nature of many painful conditions. Neuropeptides such as substance P also appear to prolong and enhance the action of glutamate. If these neurotransmitters are released in large quantities or over extended periods, they can lead to secondary hyperalgesia, a condition in which the second-order neurons are overly sensitive to low levels of noxious stimulation.

Spinal Cord Circuitry and Ascending Pathways

On entering the spinal cord through the dorsal roots, the pain fibers bifurcate and ascend or descend one or two segments before synapsing with association neurons in the dorsal horn. From the dorsal horn, the axons of association projection neurons cross through the anterior commissure to the opposite side and then ascend upward in the previously described neospinothalamic and anterolateral pathways (Fig. 35-9).

The faster-conducting fibers in the neospinothalamic tract are associated mainly with the transmission of sharp–fast pain information to the thalamus. In the thalamus, synapses are made and the pathway continues to the contralateral parietal somatosensory area to provide the precise location of the pain. Typically, the pain is experienced as bright, sharp, or stabbing in nature.

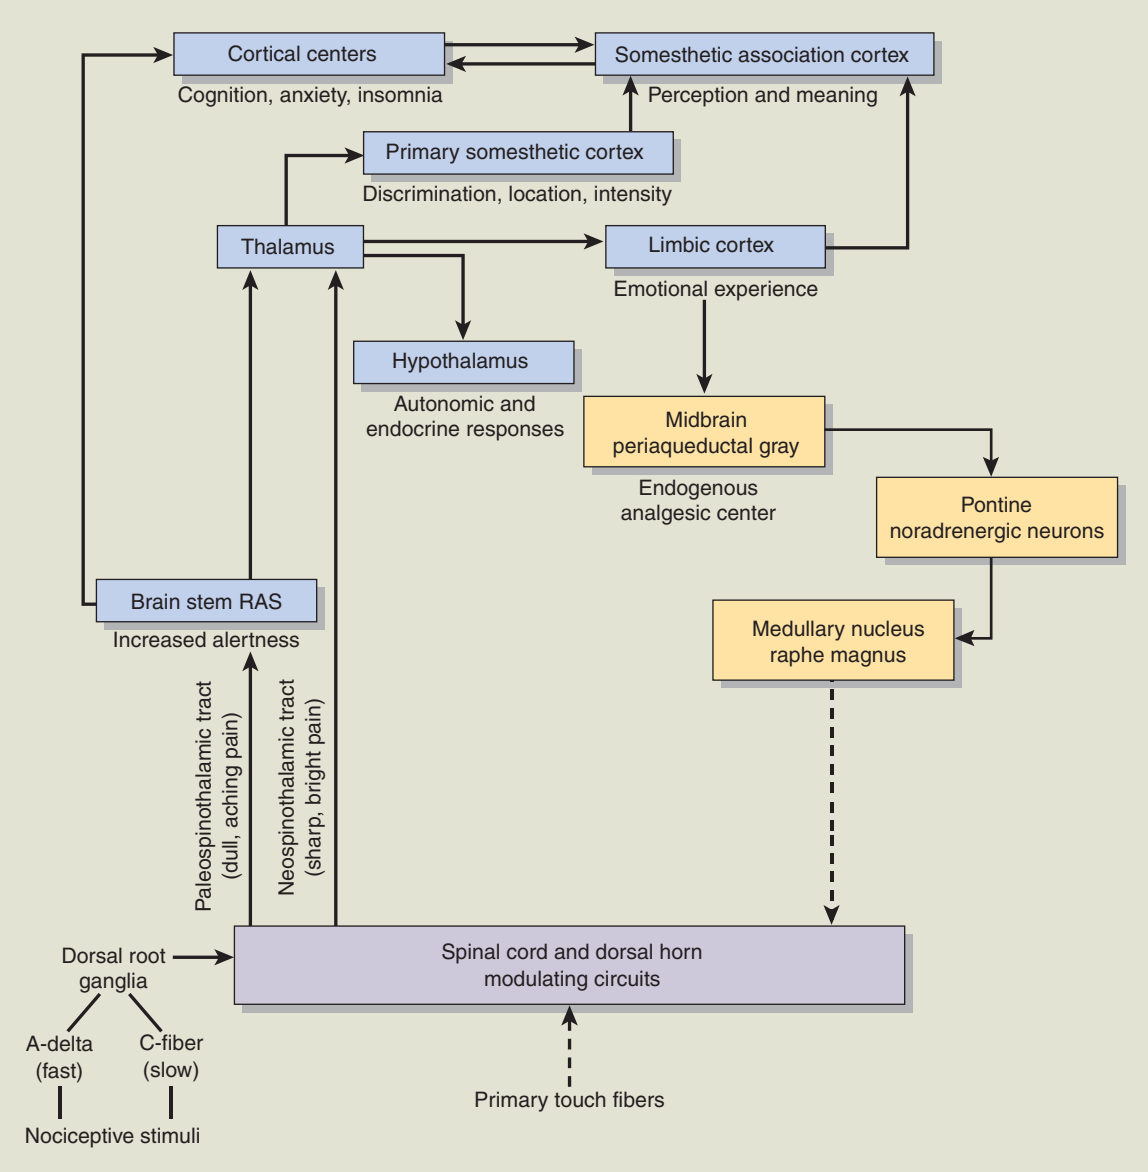

FIGURE 35-9. Primary pain pathways. The transmission of incoming nociceptive impulses is modulated by dorsal horn circuitry that receives input from primary touch receptors and from descending pathways that involve the limbic cortical systems (orbital frontal cortex, amygdala, and hypothalamus), the periaqueductal endogenous analgesic center in the midbrain, pontine noradrenergic neurons, and the nucleus raphe magnus (NRM) in the medulla. *Dashed lines* indicate inhibition or modulation of pain transmission by dorsal horn projection neurons. RAS, reticular activating system.

The paleospinothalamic tract is a slower-conducting, multisynaptic tract concerned with the diffuse, dull, aching, and unpleasant sensations that commonly are associated with chronic and visceral pain. Fibers of this system also travel up the contralateral (i.e., opposite) anterolateral pathway to terminate in several thalamic regions, including the intralateral nuclei, which project to the limbic system. These projections are associated with the emotional or affective–motivational aspects of pain. Spinoreticular fibers from this pathway project bilaterally to the reticular formation of the brain stem. This component of the paleospinothalamic system facilitates avoidance reflexes at all levels. It also contributes to elevated levels of alertness and increased heart rate and blood pressure that can occur with pain.

Brain Centers and Pain Perception

Information from tissue injury is carried from the spinal cord to brain centers in the thalamus where the basic sensation of hurtfulness, or pain, occurs (see Fig. 35-9). In the neospinothalamic system, interconnections between the lateral thalamus and the somatosensory cortex are necessary to add precision, discrimination, and meaning to the pain sensation. The paleospinothalamic system projects diffusely from the intralaminar nuclei of the thalamus to large areas of the limbic cortex. These connections probably are associated with the hurtfulness and the mood-altering and attention-narrowing effect of pain.

Recent research has demonstrated cortical representation of fast–sharp and slow–chronic types of pain sensation. In healthy adults, nociceptive Aδ afferent stimulation is related to activation in the contralateral primary somatosensory cortex in the parietal lobe, whereas C afferent stimulation is related to activation of the secondary somatosensory cortices and the anterior cingulated cortex, which is part of the limbic system. With both afferents there is activation of the bilateral secondary somatosensory cortices in the posterior parietal lobes.[11]

Central Pathways for Pain Modulation

A major advance in understanding pain was the discovery of neuroanatomic pathways that arise in the midbrain and brain stem, descend to the spinal cord, and modulate ascending pain impulses. One such pathway begins in an area of the midbrain called the *periaqueductal gray* (PAG) region. Through research it was found that electrical stimulation of the midbrain PAG regions produced a state of analgesia that lasted for many hours. This stimulation-induced analgesia was found to be remarkably specific and was not associated with changes in either the levels of consciousness or the reactions to auditory and visual stimuli.[2] Subsequently, opioid receptors were found to be highly concentrated in this and other regions of the CNS where electrical stimulation produced analgesia through the release of endorphins, enkephalins and dynorphines, endogenous opioids. Because of these findings, the PAG area of the midbrain often is referred to as the *endogenous analgesia center.*[1]

The PAG area receives input from widespread areas of the CNS, including the cerebral cortex, hypothalamus, brain stem reticular formation, and spinal cord, by way of the paleospinothalamic and neospinothalamic tracts. This region is intimately connected to the limbic system, which is associated with emotional experience. The neurons of the PAG have axons that descend into an area in the rostral medulla called the *nucleus raphe magnus* (NRM). The axons of these NRM neurons project to the dorsal horn of the spinal cord, where they terminate in the same layers as the entering primary pain fibers (see Fig. 35-9). In the spinal cord these descending pathways inhibit pain transmission by dorsal horn projection neurons.[2] Serotonin has been identified as a neurotransmitter in the NRM medullary nuclei. Tricyclic antidepressant drugs, such as amitriptyline, which enhance the effects of serotonin by blocking its presynaptic uptake, have been found to be effective in the management of certain types of chronic pain.[12] Additional inhibitory spinal projections arise from noradrenergic neurons in the pons and medulla, which also receive input from the PAG.[2] The discovery that norepinephrine can block pain transmission led to studies directed at the combined administration of opioids and clonidine, a central-acting α-adrenergic agonist, for pain relief.

Endogenous Analgesic Mechanisms

There is evidence that opioid receptors and endogenously synthesized opioid peptides are found on the peripheral processes of primary afferent neurons, in human synovia, and in many regions of the CNS.[13] Three families of opioid peptides have been identified—the enkephalins, endorphins, and dynorphins. Although the endogenous opioid peptides appear to function as neurotransmitters, their full significance in pain control and other physiologic functions is not completely understood. Probably of greater importance in understanding the mechanisms of pain control has been the characterization of receptors that bind the endogenous opioid peptides. The identification of these receptors has facilitated a more thorough understanding of the actions of available opioid drugs, such as morphine, and it also has facilitated ongoing research into the development of new preparations that are more effective in relieving pain, but with fewer side effects than existing preparations.[13]

Types of Pain

The most widely accepted classifications of pain are according to source or location (somatic or visceral), referral, and duration (acute or chronic). Classification based on associated medical diagnosis (e.g., surgery, trauma, cancer, sickle cell disease, fibromyalgia) is useful in planning appropriate interventions.

Cutaneous and Deep Somatic Pain

Cutaneous pain arises from superficial structures, such as the skin and subcutaneous tissues. A paper cut on the finger is an example of easily localized superficial, or cutaneous, pain. It is a sharp pain with a burning quality and may be abrupt or slow in onset. It can be localized

Types of Pain

- Pain can be classified according to location (cutaneous or deep and visceral), duration (acute or chronic), and site of referral.
- Cutaneous pain is a sharp, burning pain that has its origin in the skin or subcutaneous tissues.
- Deep pain is a more diffuse and throbbing pain that originates in structures such as the muscles, bones, and tendons and radiates to the surrounding tissues.
- Visceral pain is a diffuse and poorly defined pain that results from stretching, distention, or ischemia of tissues in a body organ.
- Acute pain is a self-limiting pain that remits when the underlying cause is removed.
- Chronic pain is persistent pain that lasts longer than expected, lacks the autonomic and somatic responses associated with acute pain, and is accompanied by loss of appetite, sleep disturbances, depression, and other debilitating responses.
- Referred pain is pain that originates at a visceral site but is perceived as originating in the part of the body wall that is innervated by neurons entering the same segment of the nervous system.

accurately and may be distributed along the dermatomes. Because there is an overlap of nerve fiber distribution between the dermatomes, the boundaries of pain frequently are not as clear-cut as dermatome diagrams indicate.

Deep somatic pain originates in deep body structures, such as the periosteum, muscles, tendons, joints, and blood vessels. This pain is more diffuse than cutaneous pain. Various stimuli, such as strong pressure exerted on bone, ischemia to a muscle, and tissue damage, can produce deep somatic pain. This is the type of pain a person experiences from a sprained ankle. Radiation of pain from the original site of injury can occur. For example, damage to a nerve root can cause a person to experience pain radiating along its fiber distribution.

Visceral Pain

Visceral, or splanchnic, pain has its origin in the visceral organs and is one of the most common pains produced by disease. While similar to somatic pain in many ways, both the neurologic mechanisms and the perception of visceral pain differ from somatic pain. One of the most important differences between somatic and visceral pain is the type of damage that causes pain. For example, "a surgeon can cut the bowel entirely in two in a patient who is awake without causing significant pain."[1] In contrast, strong contractions, distention, or ischemia affecting the walls of the viscera can induce severe pain. Also, visceral pain is not evoked from all viscera (e.g., the liver, lung parenchyma).[14] Another difference is the diffuse and poorly localized nature of visceral pain—its tendency to be referred to other locations and to be accompanied by symptoms associated with autonomic reflexes (e.g., nausea).[15] There are several explanations for this. There is a low density of nociceptors in the viscera compared with the skin. There is functional divergence of visceral input within the CNS, which occurs when many second-order neurons respond to a stimulus from a single visceral afferent. There is also convergence between somatic and visceral afferents in the spinal cord and in the supraspinal centers and possibly also between visceral afferents (e.g., bladder, uterus, cervix, and vagina).

Visceral afferents are predominantly small, unmyelinated pain fibers that terminate in the dorsal horn of the spinal cord and express peptide neurotransmitters such as substance P.[14] There are thought to be two classes of nociceptive receptors that innervate the viscera: high-threshold and intensity-coding receptors.[14,15] High-threshold receptors have a high threshold for stimulation and respond only to stimuli within the nociceptive range. Intensity-coding receptors have a lower threshold for stimulation and an encoding function that incorporates the intensity of the stimulus into the magnitude of their discharge. Acute visceral pain, such as pain produced by intense contraction of a hollow organ, is thought to be triggered initially by high-threshold receptors. More extended forms of visceral stimulation, such as that caused by hypoxia and inflammation, often result in sensitization of the receptors. Once sensitized, these receptors begin to respond to otherwise innocuous stimuli (e.g., motility and secretory activity) that normally occur in the viscera. This sensitization may resolve more slowly than the initial injury and thus visceral pain may persist longer than expected based on the initial injury.[14]

Referred Pain

Referred pain is pain that is perceived at a site different from its point of origin but innervated by the same spinal segment. It is hypothesized that visceral and somatic afferent neurons converge on the same dorsal horn projection neurons (Fig. 35-10). For this reason, it can be difficult for the brain to correctly identify the original source of pain. Pain that originates in the abdominal or thoracic viscera is diffuse and poorly localized and often perceived at a site far removed from the affected area. For example, the pain associated with myocardial infarction commonly is referred to the left arm, neck, and chest, which may delay diagnosis and treatment of a potentially life-threatening condition.

Referred pain may arise alone or concurrent with pain located at the origin of the noxious stimuli. This lack of correspondence between the location of the pain and the location of the painful stimuli can make diagnosis difficult. Although the term *referred* usually is applied to pain that originates in the viscera and is experienced as if originating

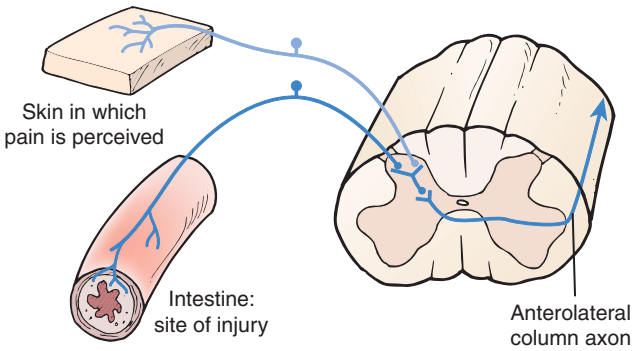

FIGURE 35-10. Convergence of cutaneous and visceral inputs onto the same second-order projection neuron in the dorsal horn of the spinal cord. Although virtually all visceral inputs converge with cutaneous inputs, most cutaneous inputs do not converge with other sensory inputs.

from the body wall, it also may be applied to pain that arises from somatic structures. For example, pain referred to the chest wall could be caused by nociceptive stimulation of the peripheral portion of the diaphragm, which receives somatosensory innervation from the intercostal nerves. An understanding of pain referral is of great value in diagnosing illness. The typical pattern of pain referral can be derived from understanding that the afferent neurons from visceral or deep somatic tissue enter the spinal cord at the same level as the afferent neurons from the cutaneous areas to which the pain is referred (Fig. 35-11).

The sites of referred pain are determined embryologically with the development of visceral and somatic structures that share the same site for entry of sensory information into the CNS and then move to more distant locations. For example, a person with peritonitis may complain of pain in the shoulder. Internally, there is inflammation of the peritoneum that lines the central part of the diaphragm. In the embryo, the diaphragm originates in the neck, and its central portion is innervated by the phrenic nerve, which enters the cord at the level of the third to fifth segments (C3 to C5). As the fetus develops, the diaphragm descends to its adult position between the thoracic and abdominal cavities while maintaining its embryonic pattern of innervation. Thus, fibers that enter the spinal cord at the C3 to C5 levels carry information from both the neck area and the diaphragm, and the diaphragmatic pain is interpreted by the forebrain as originating in the shoulder or neck area.

Although the visceral pleura, pericardium, and peritoneum are said to be relatively free of pain fibers, the parietal pleura, pericardium, and peritoneum do react to nociceptive stimuli. Visceral inflammation can involve parietal and somatic structures, and this may give rise to diffuse local or referred pain. For example, irritation of the parietal peritoneum resulting from appendicitis typically gives rise to pain directly over the inflamed area in the lower right quadrant, while producing referred pain in the umbilical area.

Muscle spasm, or *guarding,* occurs when somatic structures are involved. Guarding is a protective reflex rigidity; its purpose is to protect the affected body parts

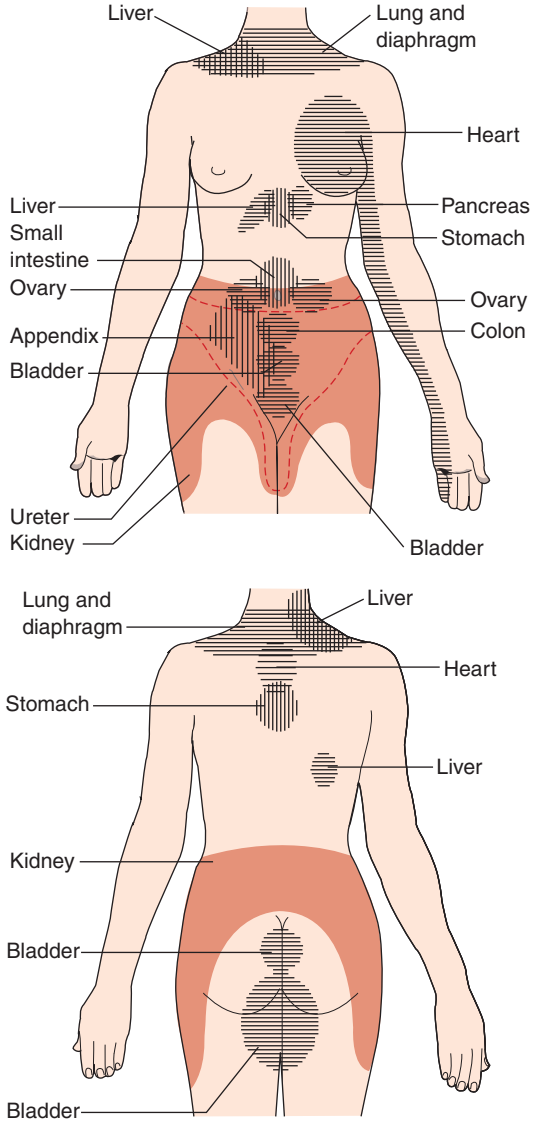

FIGURE 35-11. Areas of referred pain. (*Top*) Anterior view. (*Bottom*) Posterior view.

(e.g., an abscessed appendix or a sprained muscle). This protective guarding may cause blood vessel compression and give rise to the pain of muscle ischemia, causing local and referred pain.

Acute and Chronic Pain

It is common to classify pain according to its duration. Pain research of the last several decades has emphasized the importance of differentiating acute pain from chronic pain. The diagnosis and therapy for each is distinctive because they differ in cause, function, mechanisms, and psychological sequelae (Table 35-1).

Traditionally, the distinction between acute and chronic pain has relied on a single continuum of time with some interval (e.g., 6 months) since the onset of pain used to designate the onset of acute pain or the transition when acute pain became chronic.[16] A more recent conceptualization includes both time and pathophysiologic dimensions.

TABLE 35-1 Characteristics of Acute and Chronic Pain

Characteristic	Acute Pain	Chronic Pain
Onset	Recent	Continuous or intermittent
Duration	Short (<6 months)	6 months or more
Autonomic responses	Consistent with sympathetic fight-or-flight response* Increased heart rate Increased stroke volume Increased blood pressure Increased pupillary dilation Increased muscle tension Decreased gut motility Decreased salivary flow (dry mouth)	Absence of autonomic responses
Psychological component	Associated anxiety	Increased irritability Associated depression Somatic preoccupation Withdrawal from outside interests Decreased strength of relationships
Other types of response		Decreased sleep Decreased libido Appetite changes

Some conditions such as osteoarthritis exhibit dimensions of both acute and chronic pain.

Acute Pain. Acute pain is generally of short duration and remits when the underlying pathologic process has resolved.[16] The purpose of acute pain is to serve as a warning system. Besides alerting the person to the existence of actual or impending tissue damage, it prompts a search for professional help. The pain's location, radiation, intensity, and duration, as well as those factors that aggravate or relieve it, provide essential diagnostic clues.

Acute pain is pain that is elicited by surgery or trauma to body tissues and activation of nociceptive stimuli at the site of tissue damage.[17,18] This may induce an early wave of hyperexcitability of neurons within the CNS. The development of an inflammatory reaction to the tissue injury, with sensitization of peripheral receptors, often results in a second wave of longer-acting afferent input and a new increase in central hyperexcitability.[18,19] The resulting hyperalgesia can lead to an increased postoperative and posttraumatic pain, usually about the second or third day, and in some cases an increased likelihood of developing chronic pain. A number of chronic pain syndromes, including whiplash injury and phantom pain, develop after trauma and surgery.[18]

Because acute pain is self-limited, in that it resolves as the injured tissues heal, long-term therapy usually is not needed. Acute pain (i.e., pain from acute illness, trauma, surgery, or medical procedures) should be aggressively managed and preemptive analgesia provided before the pain becomes severe. The use of preemptive and multimodal therapy (two or more analgesics with differing analgesic mechanisms) not only allows the person to be more comfortable and active, but also helps to prevent peripheral sensitization of pain receptors and hyperexcitability of central pain centers.[19] Usually, less medication is needed when the drug is given before the pain becomes severe and the pain pathways become sensitized. Interventions that alleviate acute pain also relieve the anxiety and musculoskeletal spasms, as well increasing mobility and respiratory movements such as deep breathing and coughing.

Chronic Pain. Chronic pain is pain that persists longer than might be reasonably expected after an inciting event and is sustained by factors that are both pathologically and physically remote from the originating cause.[16,20,21] Chronic pain is highly variable. It may be unrelenting and extremely severe, as in metastatic bone pain. It can be relatively continuous with or without periods of escalation, as with some forms of back pain. Some conditions with recurring episodes of acute pain are particularly problematic because they have characteristics of both acute and chronic pain, as in sickle cell crisis or migraine headaches.

The biologic factors that contribute to chronic pain include peripheral mechanisms, peripheral–central mechanisms, and central mechanisms.[20] Peripheral mechanisms result from persistent stimulation of nociceptors, termed *peripheral sensitization*. Inflammatory mediators released from injured tissues increase the sensitivity of the C fibers and lead to increased duration of pain associated with chronic musculoskeletal, visceral, and vascular disorders. Peripheral–central mechanisms involve abnormal function of the peripheral and central portions of the somatosensory system.[21] These disorders include conditions such as those resulting from partial or complete loss of descending inhibitory pathways or spontaneous firing of regenerated nerve fibers. They include conditions such as causalgia, phantom limb pain, and postherpetic neuralgia. Central pain

mechanisms are associated with disease or injury of the CNS. Central pain is characterized by burning, aching, hyperalgesia, dysesthesia, and other abnormal sensations and is experienced as superficial (skin) or deep (bone or muscle) pain.[22] Central pain is associated with conditions such as thalamic lesions (thalamic pain), spinal cord injury, surgical interruption of pain pathways, and multiple sclerosis.

Unlike acute pain, chronic pain serves no useful purpose. To the contrary, it imposes physiologic, psychological, familial, and economic stresses and may exhaust a person's resources. Persons with chronic pain may not exhibit the somatic, autonomic, or affective behaviors often associated with acute pain. In addition, chronic pain often is associated with loss of appetite, sleep disturbances, and depression. Amazingly, depression commonly is relieved once the pain is removed.

Chronic pain management is complex and treatment depends on the cause of the pain, the natural history of the underlying health problem, and the life expectancy of the individual.[20,21] If the organic illness causing the pain cannot be cured, then noncurative methods of pain control become the cornerstone of treatment. Chronic pain is best handled by a multidisciplinary team that includes specialists in areas such as anesthesiology, nursing, physical therapy, social services, and surgery.

Cancer is a common cause of chronic pain.[23–25] The goal of chronic cancer pain management should be pain alleviation and prevention. Preemptive therapy tends to reduce sensitization of pain pathways and provides for more effective pain control. Pharmacologic and nonpharmacologic interventions are the same as those used for other types of chronic pain. Depending on the form and stage of the cancer, other treatments such as palliative radiation, antineoplastic therapies, and palliative surgery may help to control the pain. In 1986, the World Health Organization (WHO) developed a three-step ladder that assists clinicians in choosing the appropriate analgesic medications.[26] Step 1 involves the use of nonopioid analgesics, and steps 2 and 3 involve the use of opioid analgesics.

Pain Management

Assessment

Careful assessment of pain assists clinicians in diagnosing, managing, and relieving the patient's pain. Reports of pain are almost entirely subjective. Assessment includes such things as the nature, severity, location, and radiation of the pain. As with other disease states, eliminating the cause of the pain is preferable to simply treating the symptom. A careful history often provides information about the triggering factors (i.e., injury, infection, or disease) and the site of nociceptive stimuli (i.e., peripheral receptor or visceral organ).[21] A comprehensive pain history should include pain onset; description, localization, radiation, intensity, quality, and pattern of the pain; anything that relieves or exacerbates it; and the individual's personal reaction to the pain. Probably, the single most reliable indicator of the existence and intensity of acute pain is the person's self-report.

Unlike many other bodily responses, such as temperature and blood pressure, the nature, severity, and distress of pain cannot be measured objectively. To overcome this problem, various methods have been developed for quantifying pain based on the person's report. They include numeric pain intensity, visual analog, and verbal descriptor scales. Most pain questionnaires assess a single aspect of pain such as pain intensity. For example, a *numeric pain intensity* scale would have patients select which number best represents the intensity of their pain, where 0 represents no pain and 10 represents the most intense pain imaginable. A *visual analog* scale also can be used; it is a straight line, often 10 cm in length, with a word description (e.g., "no pain" and "the most intense pain imaginable") at each of the ends of the line representing the continuum of pain intensity.

Nonpharmacologic Interventions

A number of nonpharmacologic methods of pain control are used in pain management. These include cognitive behavioral interventions (e.g., relaxation, distraction, imagery, and biofeedback), physical agents (e.g., heat and cold), electroanalgesia (transcutaneous electrical nerve stimulation [TENS]), and acupuncture. Often these methods are used in addition to analgesics rather than as the sole form of pain management.

Pharmacologic Treatment

Pharmacologic treatment involves the use of drugs in the management of pain. It includes the use of nonnarcotic and narcotic analgesics, as well as adjuvant medications, such as depressants, anticonvulsants, and muscle relaxants. Topical medications (e.g., fentanyl patch) are a new aspect of pain management, whose full potential has yet to be determined.

An analgesic drug is a medication that acts on the nervous system to decrease or eliminate pain without inducing unconsciousness. Analgesic drugs do not cure the underlying cause of the pain, but their appropriate use makes the pain more tolerable and, in the case of acute pain, may prevent it from progressing to chronic pain. The ideal analgesic would be effective and nonaddictive and produce minimal adverse effects. Although long-term treatment with opioids can result in opioid tolerance (i.e., increasingly greater drug dosages being needed to achieve the same effect) and physical dependence, this should not be confused with addiction. Long-term drug-seeking behavior is rare in persons who are treated with opioids only during the time that they require pain relief. The unique needs and circumstances presented by each person in pain must be addressed to achieve satisfactory pain management.

Nonnarcotic Analgesics. Nonnarcotic oral analgesic medications include aspirin, other NSAIDs, and acetaminophen. Aspirin, or acetylsalicylic acid, acts peripherally

and centrally to block the transmission of pain impulses. It also has antipyretic and anti-inflammatory properties. The action of aspirin and other NSAIDs is through the inhibition of the cyclooxygenase (COX) enzymes, which mediate the biosynthesis of prostaglandins. Prostaglandins (particularly prostaglandin E_2) exert their effect through peripheral sensitization of nociceptors to chemical mediators such as bradykinin and histamine.[27] The NSAIDs also decrease the sensitivity of blood vessels to bradykinin and histamine, affect cytokine production by T lymphocytes, inhibit vasodilation, and decrease the release of inflammatory mediators from granulocytes and mast cells. Acetaminophen is an alternative to the NSAIDs. Although usually considered equivalent to aspirin as an analgesic and antipyretic agent, it lacks anti-inflammatory properties.

Opioid Analgesics. The term *opioid* or *narcotic* is used to refer to a group of medications, natural or synthetic, with morphinelike actions. The opioids (e.g., morphine, codeine, and many other semisynthetic congeners of morphine) exert their action through opioid receptors. There are three major categories of opioid receptors in the CNS, designated as mu (μ, for "morphine"), delta (δ), and kappa (κ).[27] Analgesia, as well as respiratory depression, miosis, reduced gastrointestinal motility (causing constipation), feelings of well-being or euphoria, and physical dependence, results principally from morphine and morphinelike opioid analgesics that act at the mu receptors. Part of the pain-relieving properties of exogenous opioids such as morphine involve the release of endogenous opioids.[27]

Opioids are used in the management of acute and chronic pain. When given for temporary relief of severe pain, such as that occurring after surgery, there is much evidence that opioids given routinely before the pain starts or becomes extreme are far more effective than those administered in a sporadic manner. Persons who are treated in this manner usually require fewer doses and are able to resume regular activities sooner. Opioids also are used for persons with chronic pain such as that caused by cancer. Morphine remains the most useful strong opioid, and the WHO has recommended that oral morphine be part of the essential medication list and be made available throughout the world as the medication of choice for cancer pain.[24,27]

Adjuvant Analgesics. Adjuvant analgesics include medications such as tricyclic antidepressants, antiseizure medications, and neuroleptic anxiolytic agents.[28] The fact that the pain suppression system has nonendorphin synapses raises the possibility that potent, centrally acting, nonopiate medications may be useful in relieving pain. Serotonin has been shown to play an important role in producing analgesia. The tricyclic antidepressant medications that block the removal of serotonin from the synaptic cleft have been shown to produce pain relief in some persons. These medications are particularly useful in some chronic painful conditions, such as postherpetic neuralgia. Certain antiseizure medications, which suppress spontaneous neuronal firing, are particularly useful in the management of pain that occurs after nerve injury (neuropathic pain), including diabetic neuropathy and chronic regional pain syndrome. Other agents, such as the corticosteroids, may be used to decrease inflammation and the nociceptive stimuli responsible for pain.

Surgical Interventions

If surgery removes the problem causing the pain, such as a tumor pressing on a nerve or an inflamed appendix, it can be curative. In other situations, surgery is used for symptom management rather than for cure. However, with rare exceptions, noninvasive analgesic approaches for pain relief should precede invasive surgical approaches.[17] Surgery for severe, intractable pain of peripheral or central origin has met with some success. It can be used to remove the cause or block the transmission of intractable pain from phantom limb pain, severe neuralgia, inoperable cancer of certain types, and causalgia.

In summary, pain is an elusive and complex phenomenon; it is a symptom common to many illnesses. It is a highly individualized experience that is shaped by a person's culture and previous life experiences, and it is difficult to measure. Traditionally, there have been two principal theories of pain, specificity and pattern theories. Scientifically, pain is viewed within the context of nociception. Nociceptors are receptive nerve endings that respond to noxious stimuli. Pain receptors respond to mechanical, thermal, and chemical stimuli. Nociceptive neurons transmit impulses to the dorsal horn neurons using chemical neurotransmitters. The neospinothalamic and the paleospinothalamic pathways are used to transmit pain information to the brain. Several neuroanatomic pathways as well as endogenous opioid peptides modulate pain in the CNS.

Pain can be classified according to location, referral, and duration as well as associated medical diagnoses. Pain can arise from cutaneous, deep somatic, or visceral locations. Referred pain is pain perceived at a site different from its origin. Acute pain is self-limiting pain that ends when the injured tissue heals, whereas chronic pain is pain that lasts much longer than the anticipated healing time for the underlying cause of the pain. Pain threshold, pain tolerance, age, sex, and other factors affect an individual's reaction to pain.

Treatment modalities for pain include the use of nonpharmacologic and pharmacologic agents either singly or in combination. In acute pain, therapy is directed at providing preemptive pain relief by interrupting the nociceptive stimulus. Chronic pain management is much more complex and is based on multiple considerations, including life expectancy. It is becoming apparent that with both acute and chronic pain, the most effective approach is early interventions.

Alterations in Pain Sensitivity and Special Types of Pain

Alterations in Pain Sensitivity

Sensitivity to and perception of pain varies among persons and in the same person under different conditions and in different parts of the body. Irritation, mild hypoxia, and mild compression of a peripheral nerve often result in hyperexcitability of the sensory nerve fibers or cell bodies. This is experienced as unpleasant hypersensitivity (i.e., *hyperesthesia*) or increased painfulness (i.e., *hyperalgesia*). Primary hyperalgesia describes pain sensitivity that occurs directly in damaged tissues. Secondary hyperalgesia occurs in the surrounding uninjured tissue. An example of primary hyperalgesia is the extreme sensitivity of sunburned skin, which results from sensitization of the skin pain endings by local products from the burn. Secondary hyperalgesia frequently results from lesions of the spinal cord or thalamus.

More severe pathologic processes can result in reduced or lost tactile (e.g., *hypoesthesia, anesthesia*), temperature (e.g., *hypothermia, athermia*), and pain sensation (i.e., *hypoalgesia*). *Analgesia* is the absence of pain on noxious stimulation or the relief of pain without loss of consciousness. The inability to sense pain may result in trauma, infection, and even loss of a body part or parts. Inherited insensitivity to pain may take the form of congenital indifference or congenital insensitivity to pain. In the former, transmission of nerve impulses appears normal but appreciation of painful stimuli at higher levels appears to be absent. In the latter, a peripheral nerve defect apparently exists such that transmission of painful nerve impulses does not result in perception of pain. Whatever the cause, persons who lack the ability to perceive pain are at constant risk of tissue damage because pain is not serving its protective function.

Allodynia (Greek *allo,* "other," and *odynia,* "painful") is the term used for the puzzling phenomenon of pain that follows a nonnoxious stimulus to apparently normal skin.[2] Nonnoxious stimuli may include wind, touching sheets, and showering. This term is intended to refer to instances in which otherwise normal tissues may be abnormally innervated or may be referral sites for other loci that give rise to pain with nonnoxious stimuli. It can result from increased responsiveness within the spinal cord (central sensitization) or a reduction in the threshold for nociceptor activation (peripheral sensitization). One type of allodynia involves *trigger points,* which are highly localized points on the skin or mucous membrane that can produce immediate intense pain at that site or elsewhere when stimulated by light tactile stimulation. Myofascial trigger points are foci of exquisite tenderness found in many muscles and can be responsible for pain projected to sites remote from the points of tenderness.

Special Types of Pain

Neuropathic Pain

"Neuropathic pain refers to pain that originates from pathology of the nervous system."[29] When peripheral nerves are affected by injury or disease, it can lead to unusual and sometimes intractable sensory disturbances. The notable features that point to neuropathic processes as a cause of pain include widespread pain that is not otherwise explainable, evidence of sensory deficit (e.g., numbness, paresthesias), burning pain, pain that occurs with light stroking of the skin, and attacks of pain that occur without seeming provocation.[29] Depending on the cause, few or many axons could be damaged and the condition could be unilateral or bilateral. Neuropathic pain is distinguished from other pain conditions where the pain stimulus begins in nonneuronal tissues.

Causes of neuropathic pain can be categorized according to the extent of peripheral nerve involvement. Conditions that can lead to pain by causing damage to peripheral nerves in a single area include nerve entrapment, nerve compression from a tumor mass, and various neuralgias (e.g., trigeminal, postherpetic, and posttraumatic). Conditions that can lead to pain by causing damage to peripheral nerves in a wide area include diabetes mellitus, long-term alcohol use, hypothyroidism, renal insufficiency, and drug treatment with neurotoxic agents.[30] Diabetes often causes a length-dependent neuropathy (meaning that the longest axons in a peripheral nerve are most vulnerable). Injury to a nerve also can lead to a multisymptom, multisystem syndrome, called *complex regional pain syndrome.* Nerve damage associated with amputation is believed to be a cause of phantom limb pain.

Neuropathic pain can vary with the extent and location of disease or injury. There may be allodynia or pain that is stabbing, jabbing, burning, or shooting. The pain may be persistent or intermittent. The diagnosis depends on the mode of onset, the distribution of abnormal sensations, the quality of the pain, and other relevant medical conditions (e.g., diabetes, hypothyroidism, alcohol use, rash, or trauma). Injury to peripheral nerves sometimes results in pain that persists beyond the time required for the tissues to heal. Peripheral pathologic processes (e.g., neural degeneration, neuroma formation, and generation of abnormal spontaneous neural discharges from the injured sensory neuron) and neural plasticity (i.e., changes in CNS function) are the primary working hypotheses to explain persistent neuropathic pain.

Treatment methods include measures aimed at restoring or preventing further nerve damage (e.g., surgical resection of a tumor causing nerve compression, improving glycemic control for diabetic patients with painful neuropathies) and interventions for the palliation of pain. Although many adjuvant analgesics are used for neuropathic pain, pain control often is difficult. The initial approach in seeking adequate pain control is to try these drugs in sequence and then in combination. The adjuvant analgesics can be divided into three general classes according to the pain they are used to treat: burning, tingling, or aching pain; stabbing or shooting pain; and neurogenic pain. For pain that is burning, tingling, or aching, tricyclic antidepressants and the α_2-adrenergic agonist clonidine frequently are used. For the stabbing or shooting pain of neuralgias, antiseizure medications or baclofen, a drug used in the treatment of spasticity,

may be used.[30] Nonpharmacologic therapies such as electrical stimulation of the peripheral or spinal nerves can be used for radiculopathies and neuralgias. As a last resort, neurolysis or neurosurgical blockade sometimes is used.

Neuralgia

Neuralgia is characterized by severe, brief, often repetitive attacks of lightninglike or throbbing pain. It occurs along the distribution of a spinal or cranial nerve and usually is precipitated by stimulation of the cutaneous region supplied by that nerve.

Trigeminal Neuralgia. Trigeminal neuralgia, or *tic douloureux*, is one of the most common and severe neuralgias. It is manifested by facial tics or spasms and characterized by paroxysmal attacks of stabbing pain that usually are limited to the unilateral sensory distribution of one or more branches of the trigeminal cranial nerve (CN V), most often the maxillary or mandibular divisions.[30,31] Although intermittent, the pain often is excruciating and may be triggered by light touch, movement, drafts, and eating. Considerable controversy remains regarding the pathophysiology of trigeminal neuralgia. One theory suggests that peripheral injury or disease of the trigeminal nerve increases afferent firing in the nerve. Failure of central inhibitory mechanisms may be involved as well.[31]

Treatment of trigeminal neuralgia includes pharmacologic and surgical modalities. Other interventions include avoidance of precipitating factors (e.g., stimulation of trigger spots) and eye injury due to irritation; provision for adequate nutrition; and avoidance of social isolation. Carbamazepine, an antiseizure drug, is recognized as a first-line agent for treatment of trigeminal neuralgia. Surgical release of vessels, dural structures, or scar tissue surrounding the semilunar ganglion or root in the middle cranial fossa often eliminates the symptoms. If not, percutaneous blocking or partial destruction of peripheral branches of the trigeminal nerve with heat, glycerol, or balloon compression may be used.[31] Gamma knife radiosurgery, a form of stereotactic radiosurgery, is one of the newest techniques for trigeminal neuralgia. The procedure uses a stereotactic head frame, stereotactic imaging of the trigeminal nerve root entry zone, and radiation of the trigeminal nerve. There has also been recent interest in the use of botulinum toxin as a treatment modality.[31]

Postherpetic Neuralgia. Herpes zoster (also called *shingles*) is caused by the same herpes virus (varicella-zoster virus) that causes chickenpox and is thought to represent a localized recurrent infection by the varicella-zoster virus that has remained latent in the dorsal root ganglia since the initial attack of chickenpox[32] (see Chapter 46). Reactivation of viral replication is associated with a decline in cellular immunity, such as occurs with aging. Thus, the probability of developing herpes zoster increases strikingly with aging, and most cases occur in the elderly. Impaired cellular immunity also increases the risk of herpes zoster.

During the acute attack of herpes zoster, the reactivated virus travels from the affected sensory ganglia and peripheral nerve to the skin of the corresponding dermatomes, causing a unilateral localized vesicular eruption and hyperpathia (i.e., abnormally exaggerated subjective response to pain). In the acute infection, proportionately more of the large nerve fibers are destroyed. Regenerated fibers appear to have smaller diameters. Because there is a relative loss of large fibers with age, elderly persons are particularly prone to suffering because of the shift in the proportion of large- to small-diameter nerve fibers.

Persons with postherpetic neuralgia may suffer from constant pain ("burning, aching, throbbing"), intermittent pain ("stabbing, shooting"), and stimulus-evoked pain (allodynia). Persons with allodynia often suffer from excruciating pain after the slightest touch to affected skin by such things as cold wind or clothing. These subtypes of pain may interfere with sleep and basic activities of living, causing chronic fatigue, depression, anorexia, weight loss, and social isolation.

Early treatment of shingles with antiviral drugs such as acyclovir or valacyclovir that inhibit herpes virus deoxyribonucleic acid (DNA) replication may reduce the severity of herpes zoster. Initially, postherpetic neuralgia can be treated with a topical anesthetic agent, lidocaine–prilocaine cream or 5% lidocaine gel. A tricyclic antidepressant medication, such as amitriptyline or desipramine, may be used for pain relief. Regional nerve blockade (i.e., stellate ganglion, epidural, local infiltration, or peripheral nerve block) has been used with limited success.

A live attenuated vaccine is now available for prevention of herpes zoster among adults 60 years of age and older. The vaccine is not indicated for treatment of herpes zoster or postherpetic neuralgia.[33]

Complex Regional Pain Syndrome

The complex regional pain syndrome (CRPS), formerly known as *reflex sympathetic dystrophy* (RSD), is a rare disorder of the extremities characterized by autonomic and vasomotor instability.[34–36] There are two forms of the CRPS: CRPS I (equivalent of RSD) and CRPS II, also known as *causalgia*. The International Association for the Study of Pain (IASP) lists the diagnostic criteria for CRPS I as the presence of an initiating traumatic event, continuing pain, allodynia (perception of pain from a nonpainful stimulus), or hyperalgesia disproportionate to the inciting event with evidence at some time of edema, changes in skin blood flow, or abnormal sensorimotor activity in the area of pain. The diagnosis is excluded by the existence of any condition that would otherwise account for the degree of pain and dysfunction.[37]

According to the IASP, CRPS II (i.e., causalgia) is diagnosed as the presence of continuing pain, allodynia, or hyperalgesia after a nerve injury, not necessarily limited to the distribution of the injured nerve, with evidence at some time of edema, changes in skin blood flow, or abnormal sensorimotor activity in the region of pain. The diagnosis is excluded by the existence of any condition that would otherwise account for the degree of pain and

dysfunction. The primary difference between type I and type II is the identification of a definable nerve injury.

The hallmark of both types of CRPS is pain and mobility problems more severe than the injury warrants. Characteristically, the pain is severe and burning with or without deep aching. Usually, the pain can be elicited with the slightest movement or touch to the affected area, it increases with repetitive stimulation, and it lasts even after the stimulation has stopped. The pain can be exacerbated by emotional upsets or any increased peripheral sympathetic nerve stimulation. All the variations of CRPS include sympathetic components. These are characterized by vascular and trophic (e.g., dystrophic or atrophic) changes to the skin, soft tissue, and bone, and can include rubor or pallor, sweating or dryness, edema (often sharply demarcated), and, with time, patchy osteoporosis.

The pathophysiologic process of CRPS remains uncertain. Although abnormalities in sympathetic activity are observed, recent experimental data suggest that sensitization of small-diameter, polymodal C and Aδ fibers to noxious stimuli may be the basis for hyperalgia to heat and nociceptive stimuli.[36] There is also evidence that central mechanisms may play a role in sensitization of central neurons that occurs after intense peripheral mechanical stimuli or continuous activity in nociceptors. The sympathetic nervous system, either directly or indirectly through prostaglandin or α_1-adrenergic receptor activity, is considered to contribute to the excitation and sensitization of the nociceptive afferents. Other proposed mechanisms include neurogenic inflammation caused by the activation of neuromediators, such as substance P, calcitonin gene–related peptide, and histamine, which also mediates inflammation and vasodilation of microvessels.[34] Recent research demonstrated the presence of autoantibodies against autonomic nervous system structures in patients with CRPS, especially CRPS II, suggesting that the disorder may result from dysfunction of the autonomic nervous system caused by an autoimmune attack.[37]

Early mobilization after injury or surgery reduces the likelihood of developing the syndrome.[36] In addition to addressing the underlying disorder, treatment is directed at restoration of function. Physical therapy is a cornerstone of therapy. Pain management involves the use of standard pharmacologic agents used in the management of neuropathic pain, namely, antidepressants (e.g., amitriptyline) and antiseizure drugs (e.g., gabapentin). Short-term corticosteroid (prednisone) treatment may be used in resistant cases. If this does not lead to improvement, treatment by sympathetic blockade may be used to provide pain relief and determine the extent to which the pain is sympathetically maintained. The latter mechanism, when present, might respond to the use of an α_1-adrenergic receptor antagonist (e.g., terazosin, phenoxybenzamine). Electrical neurostimulation of the spinal cord may also be considered. Neurostimulation not only may provide analgesia, but also may reduce the burning dysesthesia of which many patients complain. It may also improve circulation in the affected extremity by blocking the sympathetic efferent pathways.[36]

Phantom Limb Pain

Phantom limb pain, a type of neurologic pain, follows amputation of a limb or part of a limb. As many as 70% of amputees experience phantom limb pain.[38] The pain often begins as sensations of tingling, heat and cold, or heaviness, followed by burning, cramping, or shooting pain. It may disappear spontaneously or persist for many years. One of the more troublesome aspects of phantom pain is that the person may experience painful sensations that were present before the amputation, such as that of a painful ulcer or bunion.

Several theories have been proposed as to the causes of phantom limb pain.[38] One theory is that the end of a regenerating nerve becomes trapped in the scar tissue of the amputation site. It is known that when a peripheral nerve is cut, the scar tissue that forms becomes a barrier to regenerating outgrowth of the axon. The growing axon often becomes trapped in the scar tissue, forming a tangled growth (i.e., neuroma) of small-diameter axons, including primary nociceptive afferents and sympathetic efferent neurons. It has been proposed that these afferents show increased sensitivity to innocuous mechanical stimuli and to sympathetic activity and circulating catecholamines. A related theory proposes that the source of phantom limb pain is in the spinal cord, suggesting that the pain is due to the spontaneous firing of spinal cord neurons that have lost their normal sensory input from the body. In this case, a closed self-exciting neuronal loop in the posterior horn of the spinal cord is postulated to send impulses to the brain, resulting in pain. Even the slightest irritation to the amputated limb area can initiate this cycle. Other theories propose that the phantom limb pain may arise in the brain itself. In one hypothesis, the pain is caused by changes in the flow of signals through somatosensory areas of the brain. In other words, there appears to be plasticity even in the adult CNS. Treatment of phantom limb pain has been accomplished by the use of sympathetic blocks, TENS of the large myelinated afferents innervating the area, hypnosis, and relaxation training.

In summary, pain may occur with or without an adequate stimulus, or it may be absent in the presence of an adequate stimulus—either of which describes a pain disorder. There may be analgesia (absence of pain), hyperalgesia (increased sensitivity to pain), hypoalgesia (a decreased sensitivity to painful stimuli), hyperpathia (an unpleasant and prolonged response to pain), hyperesthesia (an abnormal increase in sensitivity to sensation), hypoesthesia (an abnormal decrease in sensitivity to sensations), paresthesia (abnormal touch sensation such as tingling or "pins and needles" in the absence of external stimuli), or allodynia (pain produced by stimuli that do not normally cause pain).

Neuropathic pain may be due to trauma or disease of neurons in a focal area or in a more global distribution (e.g., from endocrine disease or neurotoxic medications).

Neuralgia is characterized by severe, brief, often repetitive attacks of lightninglike or throbbing pain that occurs along the distribution of a spinal or cranial nerve and usually is precipitated by stimulation of the cutaneous region supplied by that nerve. Trigeminal neuralgia is one of the most common and severe neuralgias. It is manifested by facial tics or spasms. Postherpetic neuralgia is a chronic pain that can occur after shingles, an infection of the dorsal root ganglia and corresponding areas of innervation by the varicella-zoster virus. CRPS types I and II are pain syndromes characterized by severe pain or hyperalgesia, edema, changes in skin blood flow, and abnormal sensorimotor activity that typically follow an initiating traumatic event. The primary difference between CRPS I and II is the identification of a definable nerve injury. Phantom limb pain, a neurologic pain, can occur after amputation of a limb or part of a limb.

Headache and Associated Pain

Headache is a common health problem, with approximately 25% of adults reporting recurrent headaches and 4% reporting daily or nearly daily headaches.[39] Although head and facial pain have characteristics that distinguish them from other pain disorders, they also share many of the same features.

Headache

Headache is caused by a number of conditions. Some headaches represent primary disorders and others occur secondary to other disease conditions in which head pain is a symptom. In 2004, the International Headache Society (IHS) published the second edition of *The International Classification of Headache Disorders* (ICHD-2). The classification system is divided into three sections: (1) primary headaches, (2) headaches secondary to other medical conditions, and (3) cranial neuralgias and facial pain.[40,41] The most common types of primary or chronic headaches are migraine headache, tension-type headache, cluster headache, and chronic daily headache.

Although most causes of secondary headache are benign, some are indications of serious disorders such as meningitis, brain tumor, or cerebral aneurysm. The sudden onset of a severe, intractable headache in an otherwise healthy person is more likely related to a serious intracranial disorder, such as subarachnoid hemorrhage or meningitis, than to a chronic headache disorder. Headaches that disturb sleep, exertional headaches (e.g., triggered by physical or sexual activity or a Valsalva maneuver), and headaches accompanied by neurologic symptoms such as drowsiness, visual or limb disturbances, or altered mental status also are suggestive of underlying intracranial lesions or other pathologic processes. Other red flags for secondary headache disorder include a fundamental change or progression in headache pattern or a new headache in individuals younger than 5 or older than 50 years of age, or in individuals with cancer, immunosuppression, or pregnancy.[39]

The diagnosis and classification of headaches often is difficult. It requires a comprehensive history and physical examination to exclude secondary causes. The history should include factors that precipitate headache, such as foods and food additives, missed meals, and association with the menstrual period. A careful medication history is essential because many medications can provoke or aggravate headaches. Alcohol also can cause or aggravate headache. A headache diary in which the person records his or her headaches and concurrent or antecedent events may be helpful in identifying factors that contribute to headache onset. Appropriate laboratory and imaging studies of the brain may be done to rule out secondary headaches.

Migraine Headache

Migraine headaches affect approximately 20 million persons in the United States. They occur in about 18% of women and 6% of men and result in considerable time lost from work and other activities.[42] Migraine headaches tend to run in families and are thought to be inherited as an autosomal dominant trait with incomplete penetrance.

There are two major types of migraine headache—migraine without aura and migraine with aura. *Migraine without aura*, which accounts for approximately 85% of migraines, is a pulsatile, throbbing, unilateral headache that typically lasts 1 to 2 days and is aggravated by routine physical activity. The headache is accompanied by nausea and vomiting, which often is disabling, and sensitivity to light and sound. Visual disturbances occur quite commonly and consist of visual hallucinations such as stars, sparks, and flashes of light.[41] *Migraine with aura* has similar symptoms, but with the addition of reversible visual symptoms, including positive features (e.g., flickering lights, spots, or lines) or negative features (loss of vision); fully reversible sensory symptoms, including positive features (feeling of pins or needles) or negative features (numbness); and fully reversible speech disturbances or neurologic symptoms that precede the headache. The aura usually develops over a period of 5 to 20 minutes and lasts from 5 minutes to 1 hour.[41] Although only a small percentage of persons with migraine experience an aura before an attack, many persons without aura have prodromal symptoms, such as fatigue and irritability, that precede the attack by hours or even days.

Other migraine headache categories are retinal migraine, complications of migraine (e.g., chronic migraine, migrainous infarction, and migraine-triggered seizures), and childhood periodic syndromes that are commonly precursors of migraine. Retinal migraines are a rare form of migraine characterized by recurrent attacks of fully reversible scintillations (visual sensation of sparks or flashes of light), scotomata (visual blind spots), or blindness affecting one eye, followed within an hour by migrainous headache. Chronic migraine headaches represent a condition in which the headaches are present on 15 or more days per month for 3 months or more, in the

absence of medication overuse. Migrainous infarction is an uncommon occurrence in which one or more otherwise typical aura symptoms persist beyond 1 hour and neuroimaging confirms ischemic infarction. Strictly applied, these criteria distinguish this disorder from stroke, which must be excluded.[41] Migraine headache also can present as a mixed headache, including symptoms typically associated with tension-type headache, sinus headache, or chronic daily headache. These are called *transformed migraine* and are difficult to classify. Although nasal symptoms are not one of the diagnostic criteria for migraine, they frequently accompany migraine and are probably due to cranial parasympathetic activation. Sinus pain may indicate either a headache due to sinus inflammation or migraine.[43]

Migraine headaches occur in children as well as adults.[44,45] Before puberty, migraine headaches are equally distributed between the sexes. The essential diagnostic criterion for migraine in children is the presence of recurrent headaches separated by pain-free periods. Diagnosis is based on at least three of the following symptoms or associated findings: abdominal pain, nausea or vomiting, throbbing headache, unilateral location, associated aura (visual, sensory, motor), relief during sleep, and a positive family history.[45] Symptoms vary widely among children, from those that interrupt activities and cause the child to seek relief in a dark environment to those detectable only by direct questioning. A common feature of migraine in children is intense nausea and vomiting. The vomiting may be associated with abdominal pain and fever; thus, migraine may be confused with other conditions such as appendicitis. More than half of children with migraine undergo spontaneous prolonged remission after their 10th birthday. Because headaches in children can be a symptom of other, more serious disorders, including intracranial lesions, it is important that other causes of headache that require immediate treatment be ruled out.

The pathophysiologic mechanisms of the pain associated with migraine headaches remain poorly understood. Although many alternative theories exist, it is well established that during a migraine the trigeminal cranial nerve (CN V) becomes activated.[46] Activation of the trigeminal sensory fibers may lead to the release of neuropeptides, causing painful neurogenic inflammation within the meningeal vasculature characterized by plasma protein extravasation, vasodilation, and mast cell degranulation. Another possible mechanism implicates neurogenic vasodilation of meningeal blood vessels as a key component of the inflammatory processes that occur during migraine. Supporting the neurogenic basis for migraine is the frequent presence of premonitory symptoms before the headache begins; the presence of focal neurologic disturbances, which cannot be explained in terms of cerebral blood flow; and the numerous accompanying symptoms, including those related to autonomic and somatic nervous system dysfunction.

Fluctuations in hormone levels, particularly in estrogen levels, are thought to play a role in the pattern of migraine attacks. For many women, migraine headaches coincide with their menstrual periods. The greater predominance of migraine headaches in women is thought to be related to the aggravating effect of estrogen on the migraine mechanism. Dietary substances, such as monosodium glutamate, aged cheese, and chocolate, also may precipitate migraine headaches. The actual triggers for migraine are the chemicals in the food, not allergens.

The treatment of migraine headaches includes preventive and abortive nonpharmacologic and pharmacologic treatment.[47] Nonpharmacologic treatment includes the avoidance of migraine triggers, such as foods, that precipitate an attack. Many persons with migraines benefit from maintaining regular eating and sleeping habits. Measures to control stress, which also can precipitate an attack, also are important. During an attack, many persons find it helpful to retire to a quiet, darkened room until symptoms subside.

Pharmacologic treatment involves both abortive therapy for acute attacks and preventive therapy. A wide range of medications is used to treat the acute symptoms of migraine headache. Based on clinical trials, first-line agents include acetylsalicylic acid; combinations of acetaminophen, acetylsalicylic acid, and caffeine; NSAIDs (e.g., naproxen sodium, ibuprofen); serotonin (5-HT_1) receptor agonists (e.g., sumatriptan); ergotamine derivatives (e.g., dihydroergotamine); and antiemetic medications (e.g., ondansetron, metoclopramide). Nonoral routes of administration may be preferred in individuals who develop severe pain rapidly or on awakening, or in those with severe nausea and vomiting. Both sumatriptan and dihydroergotamine have been approved for intranasal administration. For intractable migraine headache, dihydroergotamine may be administered parenterally with an antiemetic or opioid analgesic.[48] Frequent use of abortive headache medications may cause rebound headache. Because of the risk of coronary vasospasm, the 5-HT_1 receptor agonists should not be given to persons with coronary artery disease. Ergotamine preparations can cause uterine contractions and should not be given to pregnant women. They also can cause vasospasm and should be used with caution in persons with peripheral arterial disease.

Preventive pharmacologic treatment may be necessary if migraine headaches become disabling, if they occur more than two or three times a month, if abortive treatment is being used more than two times a week, or if the individual has hemiplegic migraine, migraine with prolonged aura, or migrainous infarction.[47] In most cases, preventative treatment must be taken daily for months to years. First-line agents include β-adrenergic blocking medications (e.g., propranolol, atenolol), antidepressants (amitriptyline), and antiseizure medications (e.g., divalproex, valproic acid). When a decision to discontinue preventive therapy is made, the medications should be gradually withdrawn.

Cluster Headache

Cluster headaches are relatively uncommon headaches that occur in about 1 in 1000 individuals, affecting men (80% to 85%) more frequently than women. They typically begin in the third decade of life and seldom

extend beyond age 70 years.[49] These headaches tend to occur in clusters over weeks or months, followed by a long, headache-free remission period. Cluster headache is a type of primary neurovascular headache that typically includes severe, unrelenting, unilateral pain located, in order of decreasing frequency, in the orbital, retro-orbital, temporal, supraorbital, and infraorbital regions.[49–51] The pain is of rapid onset and builds to a peak in approximately 10 to 15 minutes, and lasts for 15 to 180 minutes. The pain behind the eye radiates to the ipsilateral trigeminal nerve (e.g., temple, cheek, gum). The headache frequently is associated with one or more symptoms such as restlessness or agitation, conjunctival redness, lacrimation, nasal congestion, rhinorrhea, forehead and facial sweating, miosis, ptosis, and eyelid edema. Because of their location and associated symptoms, cluster headaches are often mistaken for sinus infections or dental problems.

The underlying pathophysiologic mechanisms of cluster headaches are not completely known. It is thought that heredity, through an autosomal dominant gene, plays some role in the pathogenesis of the headaches. The most likely pathophysiologic mechanisms include the interplay of vascular, neurogenic, metabolic, and humoral factors. Activation of the trigeminovascular system and the cranial autonomic parasympathetic reflexes is thought to explain the pain and autonomic symptoms. The hypothalamus is believed to play a key role. The possible role of the regulating centers in the anterior hypothalamus is implicated from observations of circadian biologic changes and neuroendocrine disturbances (e.g., changes in cortisol, prolactin, and testosterone) that occur in both active periods and during clinical remission.

Because of the relatively short duration and self-limited nature of cluster headache, oral preparations typically take too long to reach therapeutic levels. The most effective treatments are those that act quickly (e.g., oxygen inhalation and subcutaneous sumatriptan). Intranasal lidocaine also may be effective.[50,51] Oxygen inhalation may be indicated for home use. Prophylactic medications for cluster headaches include ergotamine derivatives, verapamil (a calcium channel blocker), corticosteroids, and valproic acid. Deep-brain surgical neurostimulation is an experimental approach beginning to show promise in the elimination of cluster headaches.[50]

Tension-Type Headache

The most common type of headache is tension-type headache. Unlike migraine and cluster headaches, tension-type headache usually is not sufficiently severe that it interferes with daily activities. Tension-type headaches frequently are described as dull, aching, diffuse, nondescript headaches, occurring in a hatband distribution around the head, and not associated with nausea or vomiting or worsened by activity. They can be infrequent, episodic, or chronic.

The exact mechanisms of tension-type headache are not known and the hypotheses of causation are contradictory. One popular theory is that tension-type headache results from sustained tension of the muscles of the scalp and neck; however, some research has found no correlation between muscle contraction and tension-type headache. Many authorities now believe that tension-type headaches are forms of migraine headache.[52] It is thought that migraine headache may be transformed gradually into chronic tension-type headache. Tension-type headaches also may be caused by oromandibular dysfunction, psychogenic stress, anxiety, depression, and muscular stress. They also may result from overuse of analgesics or caffeine. Daily use of caffeine, whether in beverages or medications, can produce addiction, and a headache can develop in such persons who go without caffeine for several hours.[53]

Tension-type headaches often are more responsive to nonpharmacologic techniques, such as biofeedback, massage, acupuncture, relaxation, imagery, and physical therapy, than other types of headache. For persons with poor posture, a combination of range-of-motion exercises, relaxation, and posture improvement may be helpful.

The medications of choice for acute treatment of tension-type headaches are analgesics, including acetylsalicylic acid, acetaminophen, and NSAIDs.[53] Persons with infrequent tension-type headache usually self-medicate using over-the-counter analgesics to treat the acute pain, and do not require prophylactic medication. These agents should be used cautiously because rebound headaches can develop when the medications are taken regularly.

Because the "dividing lines" between tension-type headache, migraine, and chronic daily headache often are vague, addition of medications as well as the entire range of migraine medications may be tried in refractory cases. Other medications used concomitantly with analgesics include sedating antihistamines (e.g., promethazine and diphenhydramine), antiemetics (e.g., metoclopramide and prochlorperazine), or sedatives (e.g., butalbital). Prophylactic treatment for chronic tension-type headaches can include antidepressants (e.g., amitriptyline) and selective serotonin reuptake inhibitors (e.g., paroxetine, venlafaxine, and fluoxetine).[53]

Chronic Daily Headache

The term *chronic daily headache* (CDH) is used to refer to headaches that occur 15 days or more a month, including those due to medication overuse.[54,55] Little is known about the prevalence and incidence of CDH. Diagnostic criteria for CDH are not provided in the IHS Classification System. The cause of CDH is unknown, although there are several hypotheses. They include transformed migraine headache, evolved tension-type headache, new daily persistent headache, and posttraumatic headache. In many persons, CDH retains certain characteristics of migraine, whereas in others it resembles chronic tension-type headache. CDH may be associated with chronic and episodic tension-type headache. New daily persistent headache may have a fairly rapid onset, with no history of migraine, tension-type headache, trauma, or psychological stress. Although overuse of symptomatic medications (e.g., analgesics, ergotamine) has been related to CDH, there is a group of patients in whom CDH is unrelated to excessive use of medications.

For patients with CDH, a combination of pharmacologic and behavioral interventions may be necessary. As with tension-type headaches, nonpharmacologic techniques, such as biofeedback, massage, acupuncture, relaxation, imagery, and physical therapy, may be helpful. Measures to reduce or eliminate medication, including caffeine, overuse may be helpful. If the patient is abusing medications, the overuse must be managed before prophylactic agents will be effective. Most of the medications used for prevention of CDH have not been examined in well-designed, double-blind studies.

Temporomandibular Joint Pain

A common cause of head pain is temporomandibular joint (TMJ) syndrome. It usually is caused by an imbalance in joint movement because of poor bite, bruxism (i.e., teeth grinding), or joint problems such as inflammation, trauma, and degenerative changes.[56] The pain almost always is referred and commonly presents as facial muscle pain, headache, neck ache, or earache. Referred pain is aggravated by jaw function. Headache associated with this syndrome is common in adults and children and can cause chronic pain problems.

Treatment of TMJ pain is aimed at correcting the problem, and in some cases this may be difficult. The initial therapy for TMJ pain should be directed toward relief of pain and improvement in function. Pain relief often can be achieved with use of the NSAIDs. Muscle relaxants may be used when muscle spasm is a problem. In some cases, the selected application of heat or cold, or both, may provide relief. Referral to a dentist who is associated with a team of therapists, such as a psychologist, physical therapist, or pain specialist, may be indicated.

In summary, head pain is a common disorder that is caused by a number of conditions. Some headaches represent primary disorders and others occur secondary to another disease state in which head pain is a symptom. Primary headache disorders include migraine headache, tension-type headache, cluster headache, and chronic daily headache. Although most causes of secondary headache are benign, some are indications of serious disorders such as meningitis, brain tumor, or cerebral aneurysm. TMJ syndrome is one of the major causes of headaches. It usually is caused by an imbalance in joint movement because of poor bite, teeth grinding, or joint problems such as inflammation, trauma, and degenerative changes.

Pain in Children and Older Adults

Pain frequently is underrecognized and undertreated in both children and the elderly. In addition to the common obstacles to adequate pain management, such as concern about the effects of analgesia on respiratory status and the potential for addiction to opioids, there are additional deterrents to adequate pain management in children and the elderly. With regard to both children and the elderly, there are stereotypic beliefs that they feel less pain than other patients. In very young children and confused elderly, there are several additional factors. These include the extreme difficulty of assessing the location and intensity of pain in individuals who are cognitively immature or cognitively impaired, and the argument that even if they feel pain, they do not remember it. Research during the past few decades has added a great deal to the body of knowledge about pain in children and the elderly.

Pain in Children

Human responsiveness to painful stimuli begins in the neonatal period and continues through the life span. Although the specific and localized behavioral reactions are less marked in the neonate, protective or withdrawal reflexes in response to nociceptive stimuli are clearly demonstrated. Pain pathways, cortical and subcortical centers, and neurochemical responses associated with pain transmission are developed and functional by the last trimester of pregnancy. Neonates clearly perceive pain, as demonstrated by their integrated physiologic response to nociceptive stimuli.[57–59] In fact, pain may be accentuated because descending inhibitory pathways to the dorsal horn are not as well developed at birth.[58] Furthermore, dorsal horn neurons in neonates have a wider receptive field and lower excitatory threshold than those in older children.

As infants and children mature, their responses to pain become more complex and reflective of their maturing cognitive and developmental processes. Children do feel pain and have been shown to reliably and accurately report pain at as young as 3 years of age.[59] They also remember pain, as evidenced in studies of children with cancer, whose distress during painful procedures increases over time without intervention, and in newborns in the neonatal intensive care (NICU), who demonstrate protective withdrawal responses to a heel stick after repeated episodes. The recognition that untreated pain can lead to serious short- and long-term consequences has resulted in a shift to the more liberal use of opioids for treatment of pain in the newborn, particularly those in the NICU.[59]

To manage pain adequately, ongoing assessment of the presence of pain and response to treatment is essential.[58,59] Behavior and physiologic signs are useful, but can be misleading. A toddler may scream during an ear examination because of fear rather than pain, and a child with inadequately relieved cancer pain may withdraw from his or her surroundings. Investigators have devised a range of behavioral distress scales for infants and young children, mostly emphasizing the child's facial expressions, crying, and bodily movements. Children 3 to 7 years of age become more articulate in describing the intensity, location, and severity of the pain. There are self-report measures for children of this age, including

scales with faces of actual children or cartoon faces. With children 8 years of age or older, numeric scales (i.e., 1 to 10) and word graphic scales (i.e., "none," "a little," "most I have ever experienced") can be used. Another supplementary strategy for assessing a child's pain is to use a body outline and ask the child to indicate where the hurt is located. Some physiologic measures, such as heart rate, are convenient to measure and respond rapidly to brief nociceptive stimuli, but they are nonspecific. Relying on indicators of sympathetic nervous system activity and behaviors can also be problematic because they can be caused by things other than pain (e.g., anxiety and activity) and they do not always accompany pain, particularly chronic pain.

The management of children's pain basically falls into two categories: pharmacologic and nonpharmacologic. In terms of pharmacologic interventions, many of the analgesics used in adults can be used safely and effectively in children and adolescents. However, it is critical when using specific medications to determine that the medication has been approved for use with children and that it is dosed appropriately according to the child's weight and level of physiologic development. Age-related differences in physiologic functioning, notably in neonates, will affect drug action. Neonates have decreased fat and muscle and increased water, which increases the duration of action for some water-soluble drugs; neonates also have decreased concentration of plasma proteins (albumin and α_1-glycoprotein), which increases the unbound concentration of protein-bound drugs.[58] Neonates and infants also have decreased levels of the hepatic enzymes needed for metabolism of many analgesics. The levels of these hepatic enzymes quickly increase to adult levels in the first few months of life. Drug clearance in the 2- to 6-year-old age group is actually higher than adult levels because of the larger hepatic mass relative to body weight.[58,60] The renal excretion of drugs depends on renal blood flow, glomerular filtration rate, and tubular secretion, all of which are decreased in neonates, particularly premature neonates. Renal function reaches adult levels by 1 year of age.[58,60]

As with any person in pain, the type of analgesic used should be matched to the type and intensity of pain; whether the patient is a child or adult, the management of chronic pain may require a multidisciplinary team.[60] The overriding principle in all pediatric pain management is to treat each child's pain on an individual basis and to match the analgesic agent with the cause and the level of pain. A second principle involves maintaining the balance between the level of side effects and pain relief such that pain relief is obtained with as little opioid and sedation as possible. One strategy toward this end is to time the administration of analgesia so that a steady blood level is achieved and, as much as possible, pain is prevented. This requires that the child receive analgesia on a regular dosing schedule, not "as needed." Also, most drugs are packaged primarily for adult use, and dose calculations and serial dilutions may predispose to medication errors. Common errors include milligram–microgram errors, decimal point errors, confusion between daily dose and fractional dose (e.g., 100 mg/kg per day divided by 6 hours versus 100 mg/kg per dose every 6 hours), and dilution errors.[60]

Nonpharmacologic strategies can be very effective in reducing the overall amount of pain and amount of analgesia used. In addition, some nonpharmacologic strategies can reduce anxiety and increase the child's level of self-control during pain. Pacifiers and sucrose are being used in the NICU. The effects of sucrose (sweet taste) are believed to be opioid mediated because its effects are reversed by naloxone (an opioid antagonist).[59] Distraction helps children of any age divert their attention away from pain and onto other activities. Common attention diverters include bubbles, music, television, conversation, and games. Relaxation techniques and massage therapy are particularly useful in children with chronic pain. Other nonpharmacologic techniques can be taught to the child to provide psychological preparation for a painful procedure or surgery. These include positive self-talk, imagery, play therapy, modeling, and rehearsal. The nonpharmacologic interventions must be developmentally appropriate and, if possible, the child and parent should be taught these techniques when the child is not in pain (e.g., before surgery or a painful procedure) so that it is easier to practice the technique.

Pain in Older Adults

Among adults, the prevalence of pain in the general population increases with age. Prevalence reports for persistent pain in older adults ranges from 25% to 80%, depending on whether the older adults are community dwelling or reside in a nursing home.[61] Among the common causes of pain in older adults are musculoskeletal disorders such as osteoarthritis and chronic low back pain; rheumatologic diseases such as rheumatoid arthritis and polymyalgia rheumatica; and neurologic conditions such as diabetic neuropathy, postherpetic neuralgia, and central post-stroke pain.

Unrelieved pain can have significant functional, cognitive, emotional, and societal effects in the elderly.[61,62] Decreased activity because of pain can lead to myofascial deconditioning and gait disturbances, which in turn can result in injuries from falls. Pain in the elderly has been associated with impaired appetite, increased sleep disturbances, and in some cases a decrease in cognitive function. These consequences can lead to less than optimal participation in rehabilitation efforts and decreased quality of life. Increased costs because of health care use have also been attributed to unrelieved pain in the elderly.

The assessment of pain in the elderly can range from relatively simple in a well-informed, alert, cognitively intact individual with pain from a single source and no comorbidities to extraordinarily difficult in a frail individual with severe dementia and many concurrent health problems.[61,63,64] When possible, a patient's report of pain is the gold standard, but behavioral signs of pain should be considered as well. Accurately diagnosing pain when the individual has many health problems or some decline in cognitive function can be particularly challenging. In recent years, there has been increased awareness of the

need to address issues of pain in individuals with dementia. The Assessment for Discomfort in Dementia Protocol is one example of the efforts to improve assessment and pain management in these individuals. It includes behavioral criteria for assessing pain and recommended interventions for pain. Its use has been shown to improve pain management.[65]

When prescribing pharmacologic and nonpharmacologic methods of pain management for the older population, care must be taken to consider the cause of the pain, the patient's health status, concurrent therapies, and mental status. In the older population, where the risk of adverse events is higher, the nonpharmacologic options are usually less costly and cause fewer side effects.

Common nonpharmacologic interventions include application of cold (which suppresses the release of products from tissue damage) and heat (which promotes the release of endogenous endorphins).[66] The role of mental focus and anxiety is important, and relaxation techniques, massage, and biofeedback may be useful. Physical therapy and occupational therapy bring a variety of modalities, including the use of braces or splints, changes in biomechanics, and exercise, all of which have been shown to promote pain relief.[65]

Although efficacy is important when considering the use of pharmacologic agents for pain relief in the elderly population, cost and safety must also be considered. Safety issues that must be considered among older adults include changes in drug metabolism, other disease comorbidity, and polypharmacy. The elderly may have physiologic changes that affect the pharmacokinetics of medications prescribed for pain management. These changes include decreased blood flow to organs, delayed gastric motility, reduced kidney function, and decreased albumin related to poor nutrition.[66] The elderly also often have many coexisting health problems, leading to polypharmacy. On average, a 70-year-old takes seven different medications.[66] The addition of analgesics to a complex medication regimen is even more likely to cause drug interactions and complicate compliance in the elderly. However, these considerations should not preclude the appropriate use of analgesic drugs to achieve pain relief. Nonopioids are generally the first line of therapy for mild to moderate pain, and acetaminophen is usually the first choice because it is relatively safe for older adults.[66] Opioids are used for more severe pain and for palliative care. As with younger persons, adjuvant analgesics are effectively used for treatment of pain in older adults. The use of some assessment tool to evaluate the level of pain and effectiveness of treatment is essential. Monitoring for side effects is also critical.

In summary, children experience and remember pain, and even fairly young children are able to accurately and reliably report their pain. Recognition of this has changed the clinical practice of health professionals involved in the assessment of children's pain. Pharmacologic (including opioids) and nonpharmacologic pain management interventions have been shown to be effective in children. Nonpharmacologic techniques must be based on the developmental level of the child and should be taught to both children and parents.

Pain is a common symptom in the elderly. Assessment, diagnosis, and treatment of pain in the elderly can be complicated. The elderly may be reluctant or cognitively unable to report their pain. Diagnosis and treatment can be complicated by comorbidities and age-related changes in cognitive and physiologic function.

REVIEW EXERCISES

1. A 25-year-old man is admitted to the emergency department with acute abdominal pain that began in the epigastric area and has now shifted to the lower right quadrant of the abdomen. There is localized tenderness and guarding or spasm of the muscle over the area. His heart rate and blood pressure are elevated, and his skin is moist and cool from perspiring. He is given a tentative diagnosis of appendicitis and referred for surgical consultation.

A. Describe the origin of the pain stimuli and the neural pathways involved in the pain that this man is experiencing.
B. Explain the neural mechanisms involved in the spasm of the overlying abdominal muscles.
C. What is the significance of his cool, moist skin and increased heart rate and blood pressure?

2. A 65-year-old woman with breast cancer is receiving hospice care in her home. She is currently receiving a long-acting opioid analgesic supplemented with a short-acting combination opioid and nonnarcotic medication for breakthrough pain.

A. Explain the difference between the mechanisms and treatment of acute and chronic pain.
B. Describe the action of opioid drugs in the treatment of pain.
C. Define the term *tolerance* as it refers to the use of opioids for treatment of pain.

3. A 42-year-old woman presents with sudden, stabbing-type facial pain that arises near the right side of her mouth and then shoots toward the right ear, eye, and nostril. She is holding her hand to protect her face because the pain is "triggered by touch, movement, and drafts." Her initial diagnosis is trigeminal neuralgia.

A. Explain the distribution and mechanisms of the pain, particularly the triggering of the pain by stimuli applied to the skin.
B. What are possible treatment methods for this woman?

4. A 21-year-old woman presents to the student health center with complaints of a throbbing pain on the left side of her head, nausea and vomiting, and extreme sensitivity to light, noise, and head movement. She also tells you she had a similar headache 3 months ago that lasted for 2 days and states that she thinks she is developing migraine headaches like her mother. She is concerned because she has been unable to attend classes and has exams next week.

A. Are this woman's history and symptoms consistent with migraine headaches? Explain.
B. Use the distribution of the trigeminal nerve and the concept of neurogenic inflammation to explain this woman's symptoms.

5. A 48-year-old man presents with complaints of severe pain in his right foot after a crush injury. He reports that although he had his ankle pinned surgically, it still causes severe pain now, almost 1 year after injury. He states that he cannot stand to have the sheets touch his foot, and even wearing shoes is painful. His physician has diagnosed chronic regional pain syndrome type I.

A. Differentiate chronic regional pain syndrome type I from type II.
B. Explain the proposed theories of why this pain syndrome develops.

Chapter 36

Disorders of Neuromuscular Function

Just as our perceptual skills reflect the ability of our sensory systems to detect, analyze, and estimate the significance of our physical environment, the ability to carry out skilled movements requires skeletal muscles that contract and neural pathways that plan, coordinate, and execute these contractions in a manner that provides for smooth, purposeful, and coordinated movement. In some cases, purposeless and disruptive movements can be almost as disabling as relative or complete absence of movement. This chapter provides an introduction to the organization and control of motor function, followed by a discussion of disorders of motor function, including muscular dystrophy, and disorders of the neuromuscular junction, peripheral nerves, the basal ganglia and cerebellum, and upper motor neurons.

Organization and Control of Motor Function

Motor function, whether it involves walking, running, or precise finger movements, requires movement and maintenance of posture. Posture can be described as the relative position of various parts of the body with respect to one another (limb extension, flexion) or to the environment (standing, supine).[1] Posture also can be described as the active muscular resistance to the displacement of the body by gravity or acceleration. The structures that control posture and movement are located throughout the neuromuscular system. The system consists of the motor unit (motor neuron and the muscle fibers it innervates); the spinal cord, which contains the basic reflex circuitry for posture and movement; and the descending pathways from brain stem circuits, the cerebellum, the basal ganglia, and the motor cortex.

Organization of Movement

As with other parts of the nervous system, the motor systems are organized in a functional hierarchy, each concerned with increased levels of complexity.[2] The lowest

Motor Systems

- Motor systems require upper motor neurons (UMNs) that project from the motor cortex to the brain stem or spinal cord, where they directly or indirectly innervate the lower motor neurons (LMNs) of the contracting muscles; sensory feedback from the involved muscles that is continuously relayed to the cerebellum, basal ganglia, and sensory cortex; and a functioning neuromuscular junction that links nervous system activity with muscle contraction.
- The pyramidal motor system originating in the motor cortex provides control of delicate muscle movement, and the extrapyramidal system originating in the basal ganglia provides the background for the more crude, supportive movement patterns.
- The efficiency of the movement by the motor system depends on a background of muscle tone provided by the stretch reflex and vestibular system input to maintain stable postural support.

level of the hierarchy occurs at the spinal cord, which contains the basic reflex circuitry needed to coordinate the function of the motor units. Above the spinal cord is the brain stem, and above the brain stem are the cerebellum and basal ganglia, structures that modulate the actions of the brain stem systems. Overseeing these supraspinal structures are the motor centers in the cerebral cortex. The highest level of function, which occurs at the level of the frontal cortex, is concerned with the purpose and planning of motor movements. The efficiency of movement depends on input from sensory systems that operate in parallel with the motor systems.

The Spinal Cord

The spinal cord is the lowest level of motor hierarchical organization.[2] It contains the neuronal circuits that mediate a variety of reflexes and automatic rhythmic movements. Similar circuits governing reflex movements of the face and mouth are located in the brain stem. The simplest circuits are monosynaptic, containing only a primary motor neuron. However, most reflexes are polysynaptic, involving one or more interposed interneurons. Interneurons and motor neurons also receive input from axons descending from higher centers. These supraspinal signals can modify reflex responses to peripheral stimuli by facilitating or inhibiting different populations of interneurons. They also coordinate movements through these interneurons.

The Brain Stem

The next level of motor hierarchy is in the brain stem. The brain stem contains, in addition to the facial nerves,

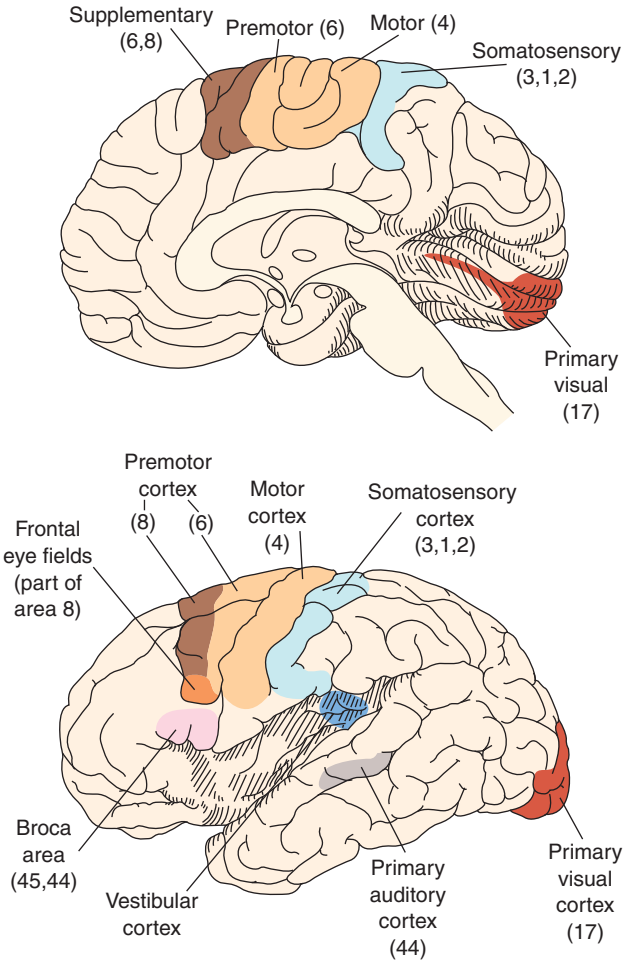

FIGURE 36-1. Primary motor cortex. (*Top*) The location of the primary, premotor, and supplementary cortex on the medial surface of the brain. (*Bottom*) The location of the primary and premotor cortex on the lateral surface of the brain.

many groups of neurons that project from the spinal gray matter. These projections are grouped into two main systems: the medial and lateral brain stem systems, which receive input from the cerebral cortex and subcortical nuclei and project to the spinal cord.[2] The medial descending systems contribute to the control of posture by integrating visual, vestibular, and somatosensory information. The lateral descending systems control more distal limb muscles and are thus more concerned with goal-directed movements, especially of the arm and hand. Brain stem circuits also control movements of the eyes and head.

The Motor Cortex

The cortex represents the highest level of motor function. Precise, skillful, and intentional movements of the distal and especially flexor muscles of the limbs and speech apparatus are initiated and controlled by the primary, premotor, and supplementary motor cortices located in the posterior part of the frontal lobe[1,3] (Fig. 36-1). These motor areas receive information from the thalamus and somatosensory cortex and, indirectly, from the cerebellum and basal ganglia.

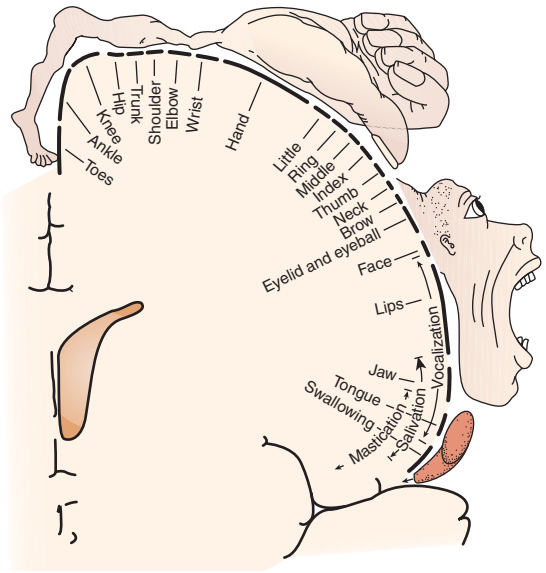

FIGURE 36-2. Representation of the relative extent of motor cortical area 4 devoted to muscles of the various body regions. Medial surface is at the left, lateral fissure is at the right, with pharyngeal and laryngeal muscle representation extending toward the insula. (From Penfield E., Rasmussen T. [1968]. *The cerebral cortex in man: A clinical study of localization of function.* New York: Macmillan.)

The primary motor cortex (area 4), also called the *motor strip,* is located on the rostral surface and adjacent portions of the central sulcus. The primary motor cortex controls specific muscle movement sequences and is the first level of descending control for precise motor movements. The neurons in the primary motor cortex are arranged in a somatotopic array or distorted map of the body called the *motor homunculus*[4] (Fig. 36-2). The areas of the body that require the greatest dexterity have the largest cortical areas devoted to them. More than half of the primary motor cortex is concerned with controlling the muscles of the hands, of facial expression, and of speech.

The premotor cortex (areas 6 and 8), which is located just anterior to the primary motor cortex, sends some fibers into the corticospinal tract but mainly innervates the primary motor strip. Nerve signals generated by the premotor cortex produce much more complex "patterns" of movement than the discrete patterns generated by the primary motor cortex. For example, the movement pattern to accomplish a particular objective, such as throwing a ball or picking up a fork, is programmed by the prefrontal association cortex and associated thalamic nuclei.

The supplementary motor cortex, which contains representations of all parts of the body, is located on the medial surface of the hemisphere in the premotor region (areas 6 and 8). It is intimately involved in the performance of complex, skillful movements that involve both sides of the body.

The Cerebellum and Basal Ganglia

In addition to the brain stem and cerebral cortex, two other parts of the brain assist in the planning and execution of motor movements. The cerebellum and basal ganglia provide feedback circuits that regulate cortical and brain stem motor areas.[2] They receive input from various areas of the cortex and project to the motor cortex through the thalamus. The cerebellum and basal ganglia do not send significant output directly to the spinal cord, but act directly on motor neurons in the brain stem.

Although the precise contributions of the cerebellum and basal ganglia are still unclear, both are necessary for smooth movement and posture. The basal ganglia provide the gracefulness of performance as well as the supportive posture for highly skilled movements. As will be discussed, degenerative diseases of the basal ganglia such as Parkinson disease produce involuntary movements. Cerebellar circuits are involved with the timing and coordination of movements that are in progress and with learning of motor skills. Damage to the cerebellum by vascular lesions of certain familial degenerative disorders produces cerebellar ataxia, a characteristic loss of coordination and accuracy of limb movement.

The Motor Unit

The neurons that control motor function are referred to as *motor neurons* or sometimes as *alpha motor neurons*.[3] The motor neuron and the group of muscle fibers it innervates in a muscle is called a *motor unit*. When the motor neuron develops an action potential, all of the muscle fibers in the motor unit it innervates develop action potentials, causing them to contract simultaneously. Thus, a motor neuron and the muscle fibers it innervates function as a single unit—the basic unit of motor control.

Each motor neuron undergoes multiple branchings, making it possible for a single motor neuron to innervate a few to thousands of muscle fibers. In general, large muscles—those containing hundreds or thousands of muscle fibers and providing gross motor movement—have large motor units. This contrasts sharply with those that control the hand, tongue, and eye movements, for which the motor units are small and permit very precise control.

The motor neurons supplying a motor unit are located in the ventral horn of the spinal cord and are called *lower motor neurons* (LMNs). Upper motor neurons (UMNs), which exert control over LMNs, project from the motor strip in the cerebral cortex to the ventral horn and are fully contained in the central nervous system (CNS; Fig. 36-3).

Spinal Reflexes

Reflexes are coordinated, involuntary motor responses that are initiated by a stimulus applied to peripheral receptors.[3,5] Some reflexes, such as the flexor-withdrawal reflex, initiate movements to avoid hazardous situations, whereas others, such as the stretch reflex or crossed-extensor reflex, serve to integrate motor movements so they function in a coordinated manner. The anatomic basis of a reflex consists of an afferent neuron that synapses either directly with an effector neuron that innervates a muscle or with an interneuron that synapses with an effector neuron. Reflexes are essentially "wired into" the CNS so that

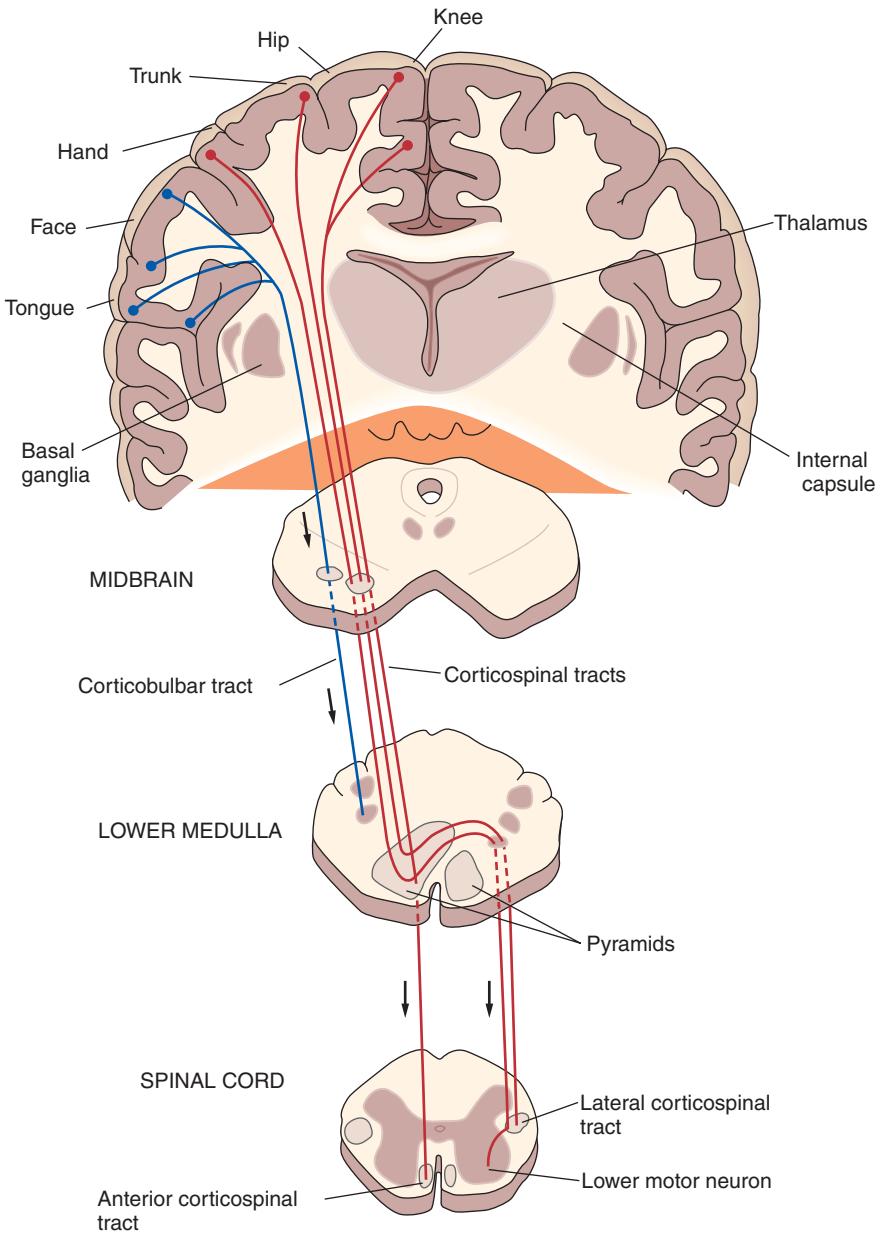

FIGURE 36-3. Upper motor neuron pathways: corticospinal (red) and corticobulbar tracts (blue). (Modified from Bickley L.S. [2003]. *Bates guide to physical examination and history taking* [8th ed., p. 543]. Philadelphia: Lippincott Williams & Wilkins.)

they are always ready to function; with training, most reflexes can be modulated to become parts of more complicated movements. A reflex may involve neurons in a single cord segment (i.e., segmental reflexes), several or many segments (i.e., intersegmental reflexes), or structures in the brain (i.e., suprasegmental reflexes).

In most cases, reflex activities go on without our conscious awareness. There is a significant amount of reflex circuitry in the spinal cord for the coordinated control of movements, particularly stereotyped movements concerned with locomotion. Many of these reflexes work equally well in decerebrate animals (those in which the brain has been destroyed) as long as the spinal cord is intact. Other spinal reflexes require the activity of the brain for their successful completion. In addition, the brain is advised of many types of spinal cord reflex activities and can either inhibit or facilitate them.

The Stretch and Deep Tendon Reflexes. If the skeletal muscles of the body are to perform normally, the brain must be continually informed of the current state of contraction, and the muscles must exhibit healthy tone (resistance to active and passive stretch at rest). The first requirement depends on the transmission of information regarding the sense of body position, movement, and muscle tone to the CNS. Information from these sensory afferents is relayed to the cerebellum and cerebral cortex and is experienced as *proprioception* or the sense of body movement and position, independent of vision. To provide this information, the muscles and their tendons are supplied with two types of receptors: muscle spindles and Golgi tendon organs. The *muscle spindles*, which are distributed throughout the belly of a muscle, relay information about muscle length and rate of stretch. The *Golgi tendon organs* are found in muscle

tendons and transmit information about muscle tension or force of contraction at the junction of the muscle and the tendon that attaches to bone.

Normal muscle tone depends on stretch reflexes initiated by the muscle spindles, which monitor changes in muscle length (see Understanding the Stretch Reflex and Muscle Tone). The neural circuits responsible for stretch reflexes provide higher centers of the nervous system with a mechanism for adjusting muscle tone under different circumstances. Disorders of muscle tone are frequently associated with lesions of the motor system, especially those that interfere with descending pathways. Stretch reflexes are hyperactive when lesions of the corticospinal tract (e.g., stroke or spinal cord injury) reduce or disrupt the inhibitory effect of the brain on the spinal cord, and they are hypoactive or absent in cases of peripheral nerve damage or anterior spinal cord injury.

The muscle spindles consist of a group of specialized miniature skeletal muscle fibers called *intrafusal fibers* that are encased in a connective tissue capsule and attached to the extrafusal fibers of a skeletal muscle. In the center of the receptor area, a large sensory neuron spirals around the intrafusal fiber, forming the so-called *primary* or *annulospiral ending*. The intrafusal muscle fibers function as stretch receptors that increase their firing when the muscle is stretched. Axons of these spindle fiber neurons enter the spinal cord through several branches of the dorsal root. Some branches end in the segment of entry; others ascend to adjacent segments, influencing intersegmental reflex function; and still others ascend in the dorsal column of the cord to the brain stem. Segmental branches establish monosynaptic contact with each of the LMNs that have motor units in the muscle containing the spindle receptor. This produces an opposing muscle contraction. Another segmental branch of the same afferent neuron innervates an internuncial neuron that is inhibitory to motor units of antagonistic muscle groups. This disynaptic inhibitory pathway is the basis for the reciprocal activity of agonist and antagonist muscles (i.e., when an agonist muscle is stretched, the antagonists relax). Reciprocal innervation is useful not only for the stretch reflex, but also for voluntary movements. Relaxation of the antagonist muscle during movements enhances the speed and efficiency because the muscles that act as prime movers are not working against contraction of the opposing muscle.[1]

Another function of the stretch reflex is to inform the CNS of the status of muscle length. Ascending impulses from stretch receptors in the contracting muscle fibers ultimately provide information about muscle length to higher centers in the cerebellum and cerebral cortex. When a skeletal muscle lengthens or shortens against tension, a feedback mechanism needs to be available for readjustment such that the spindle apparatus remains sensitive to moment-to-moment changes in muscle stretch, even while changes in muscle length are occurring. This is accomplished by the *gamma motor neurons* that adjust spindle fiber length to match the length of the extrafusal muscle fiber. Descending fibers of motor pathways synapse with and simultaneously activate both alpha and gamma motor neurons so that the sensitivity of the spindle fibers is coordinated with muscle movement.

Central control over the gamma motor neurons also permits increases or decreases in muscle tone in anticipation of changes in the muscle force. The CNS, through its coordinated control of the muscle's alpha and the spindle's gamma motor neurons, can suppress the stretch reflex. This occurs during centrally programmed movements, such as pitching a baseball, that require a muscle to produce a full range of unopposed motion. Without this programmed adjustability of the stretch reflex, any movement is immediately opposed and prevented.

Motor Pathways

The primary motor cortex contains many layers of pyramid-shaped output neurons that project to the premotor and somatosensory areas on the same side of the cortex, project to the opposite side of the cortex, or descend to subcortical structures such as the basal ganglia and thalamus. The large pyramidal cells located in the fifth layer project to the brain stem and spinal cord. The axons of these UMNs project through the subcortical white matter and internal capsule to the deep surface of the brain stem, through the ventral bulge of the pons, and to the ventral surface of the medulla, where they form a ridge or pyramid (see Fig. 36-3). The majority of corticospinal UMNs cross the midline in the pyramidal decussation at the junction of the medulla and cervical spinal cord to form the lateral corticospinal tract in the white matter of the spinal cord. A few of the fibers do not cross to the opposite side of the cord, but pass down the ventral column of the cord, mainly to cervical levels, where they cross and innervate contralateral LMNs.

Traditionally, motor tracts have been classified as belonging to one of two motor systems: the pyramidal and extrapyramidal systems. According to this classification system, the *pyramidal* system consists of the motor pathways originating in the motor cortex and terminating in the corticobulbar fibers in the brain stem and the corticospinal fibers in the spinal cord. Other fibers from the cortex and basal ganglia project to the brain stem reticular formation and reticulospinal systems, following a more ancient pathway to LMNs of proximal and extensor muscles. These fibers do not decussate in the pyramids, hence the name *extrapyramidal system*. Disorders of the pyramidal tracts (e.g., stroke) are characterized by spasticity and paralysis, whereas those affecting the extrapyramidal tracts (e.g., Parkinson disease) result in involuntary movements, muscle rigidity, and immobility without paralysis. As increased knowledge regarding motor pathways has emerged, it has become evident that the extrapyramidal and pyramidal systems are extensively interconnected and cooperate in the control of movement.[1]

Assessment of Motor Function

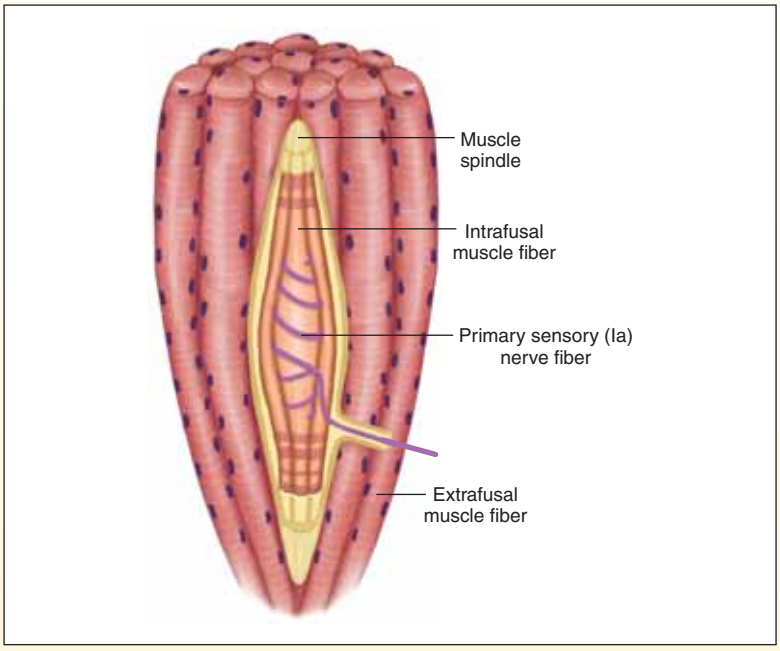
Disorders of the motor system produce signs and symptoms that can be used in localizing the disorder. These

UNDERSTANDING → The Stretch Reflex and Muscle Tone

Muscle tone is controlled by the stretch reflex, which monitors changes in muscle length. The activity of the stretch reflex can be divided into three steps: (1) activation of the stretch receptors, (2) integration of the reflex in the spinal cord, and (3) regulation of reflex sensitivity by higher centers in the brain. Testing the (4) knee-jerk reflex provides a means of assessing that reflex.

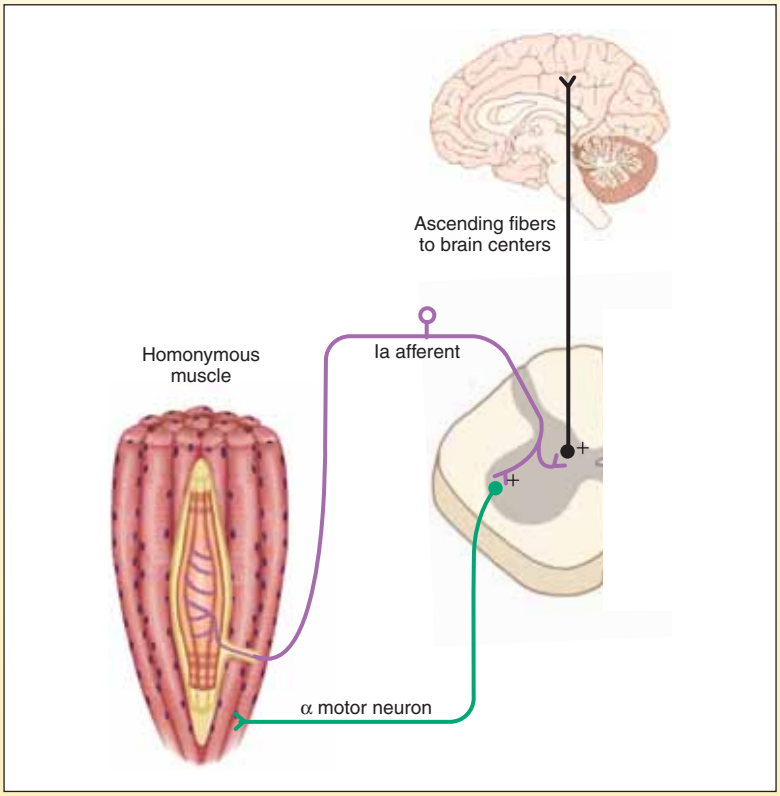
1

Stretch Reflex Receptors. Skeletal muscle is composed of two types of muscle fibers: a large number of extrafusal fibers, which control muscle movement, and a smaller number of intrafusal fibers, which control muscle tone. The intrafusal fibers are encapsulated in sheaths, forming a muscle spindle that runs parallel to the extrafusal fibers. Each intrafusal fiber is innervated by a large Ia sensory nerve fiber, which encircles the central noncontractile portion of the fiber to form the so-called *annulospiral ending*. Because the spindles are oriented parallel to the extrafusal muscle fibers, stretching of the extrafusal fibers also stretches the spindle fibers and stimulates the receptive endings of the Ia afferent neuron.



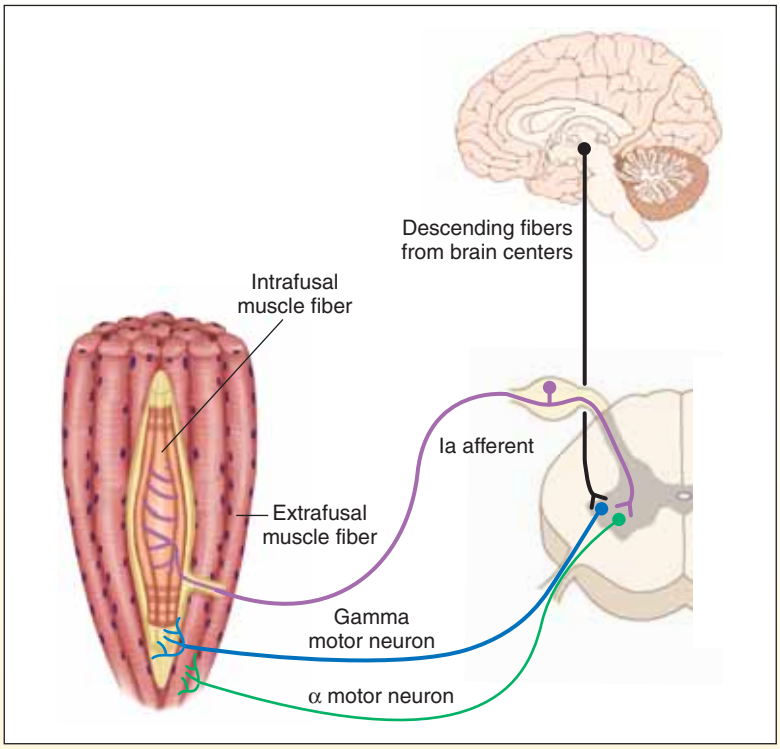
2

Spinal Reflex Centers. Afferent impulses from the Ia sensory fiber of the muscle spindle are transmitted to the spinal cord, where they synapse with alpha motor neurons of the stretched muscle to form a monosynaptic reflex arc—"monosynaptic" because only one synapse separates the primary sensory input from the motor neuron output. The reflex muscle contraction that follows resists further stretching of the muscle. As this spinal reflex activity is occurring, impulses providing information on muscle length are transmitted to higher centers in the brain. It is the coordinated activity of all the monosynaptic reflexes supplying the extrafusal fibers in a skeletal muscle that provides the muscle tone needed for organized movement.



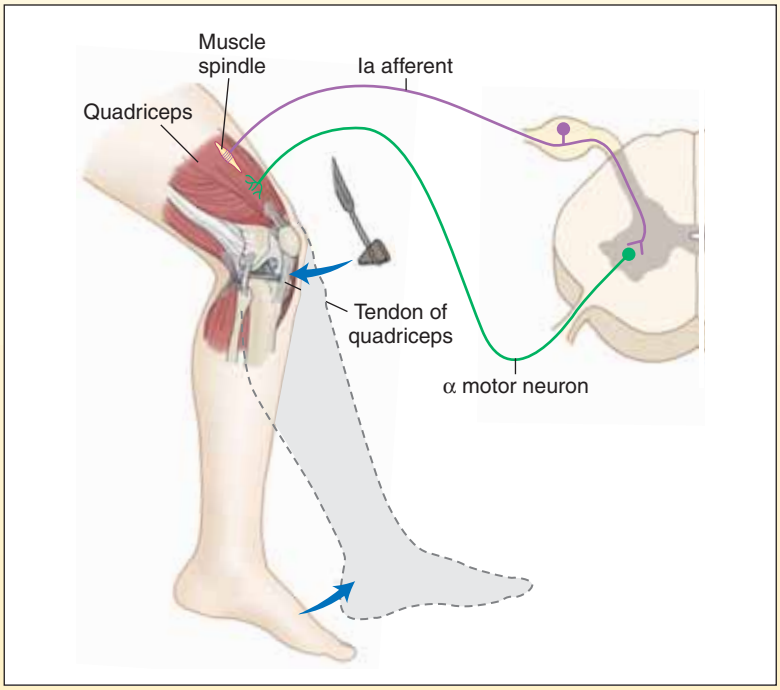
3

Brain Center Connections. Although a spinal reflex can function independently, its sensitivity is adjusted by higher centers in the brain. Both types of muscle fibers are supplied with motor neurons—the extrafusal fibers with large alpha motor neurons, which produce muscle contraction; and the intrafusal fibers with smaller gamma motor neurons, which control the sensitivity of the stretch reflex. Descending fibers of motor pathways synapse with both alpha and gamma motor neurons, and the impulses are sent simultaneously to the large extrafusal fibers and to the intrafusal fibers to maintain muscle spindle tension (and sensitivity) during muscle contraction.



4

The Knee-Jerk Reflex. The knee-jerk reflex that occurs when the knee is tapped with a reflex hammer tests for the intactness of the stretch reflex arc in the quadriceps muscle. Stretching of the extrafusal fibers by tapping with a reflex hammer leads to lengthening of the intrafusal fibers and increased firing of the type Ia afferent neuron. Impulses from the Ia fiber enter the dorsal horn of the spinal cord and make monosynaptic contact with the ventral horn alpha motor neuron supplying the extrafusal fibers in the quadriceps muscle. The resultant reflex contraction (shortening) of the quadriceps muscle is responsible for the knee jerk. These muscle reflexes are called *deep tendon reflexes* (DTRs). They can be checked at the wrists, elbows, knees, and ankles as a means of assessing the components of the stretch reflex at different spinal cord segments.



signs and symptoms include changes in muscle characteristics (strength, bulk, and tone), spinal reflex activity, and motor coordination.[6] For diagnostic purposes, clinicians often use the terms *LMN,* referring to neurons that are located in the spinal cord and brain stem and directly innervate skeletal muscle, and *UMN,* referring to neurons that originate in higher regions of the brain, such as the motor cortex, and synapse with motor neurons. The distinction between LMNs and UMNs is important because each class of neurons produces distinctive symptoms.

Muscle Strength, Bulk, and Tone

Muscle Strength. Abnormalities in any part of the motor pathway can produce impaired strength or muscle weakness. *Paralysis* refers to loss of movement, and *paresis* to weakness or incomplete loss of strength. The pattern of weakness may be helpful in the localization of the lesion. *Monoparesis* or *monoplegia* results from the destruction of pyramidal UMN innervation of one limb; *hemiparesis* or *hemiplegia,* both limbs on one side; *diparesis* or *diplegia* or *paraparesis* or *paraplegia,* both upper or lower limbs; and *tetraparesis* or *tetraplegia,* also called *quadriparesis* or *quadriplegia,* all four limbs (Fig. 36-4).

Paresis or paralysis can be further designated as of UMN or LMN origin. UMN lesions of the motor cortex or corticospinal tract typically affect the extensors in the upper extremities more than the flexors, whereas in the lower extremities, the flexors are more affected. In LMN or peripheral nerve disorders, the weakness is predominantly in the distal limb, whereas in muscle disorders, such as muscular dystrophy, proximal limb function may be affected sooner than distal limb function.

Muscle Bulk. The size of muscle (whether muscles are normal sized, enlarged, or atrophied) also helps localize the lesion, and sometimes provides helpful hints to the pathologic process. Muscular atrophy, or loss of muscle bulk, usually results from LMN lesions as well as diseases of the muscles themselves. Hypertrophy refers to an increase in muscle bulk with a proportionate increase in strength. Pseudohypertrophy, as occurs with Duchenne muscular dystrophy, refers to an increase in bulk without an accompanying increase in strength.

Muscle Tone. Muscle tone is the normal state of muscle tension. It is assessed by palpating the muscle while at rest and during passive stretching. With the person at rest, the joints are put through the normal range of motion (flexion and extension) by the examiner. Disorders of skeletal muscle tone are characteristic of many nervous system lesions. Any interruption of the myotatic or stretch reflex circuitry by peripheral nerve injury, pathologic process of the neuromuscular junction, injury to the spinal cord, or damage to the corticospinal system can result in disturbances of muscle tone.

Abnormalities of muscle tone may be described as hypotonia (less than normal), flaccidity (absent), or hypertonia, rigidity, spasticity, or tetany (all indicating higher-than-normal tone). Typically, UMN lesions produce increased tone, whereas LMN lesions produce decreased tone. Increased resistance that varies and commonly becomes worse at the extremes of the range of motion is called *spasticity.* Resistance that becomes worse throughout the range and in both directions is called *lead-pipe rigidity.* Decreased resistance suggests disease of the LMNs or the acute stages of spinal cord injury. Marked floppiness indicates hypotonic or flaccid muscles.

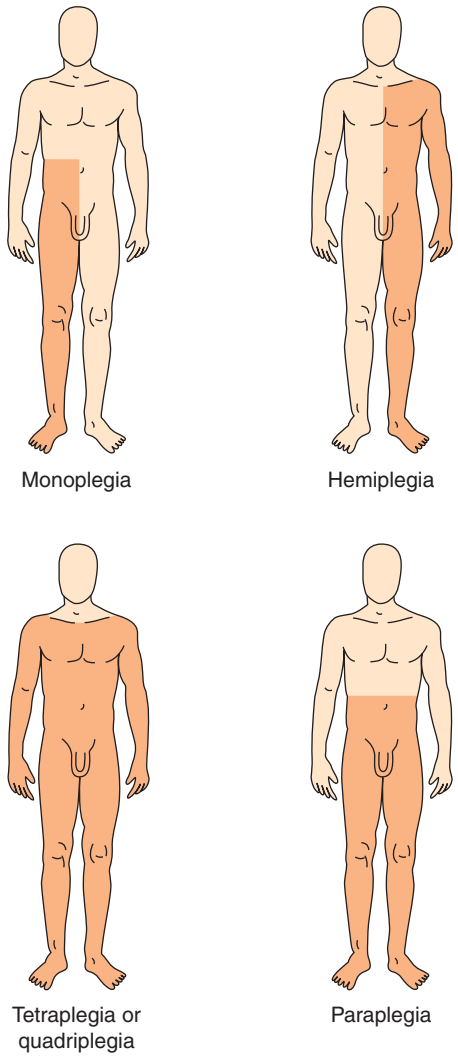


FIGURE 36-4. Areas of the body affected by monoplegia, hemiplegia, tetraplegia or quadriplegia, and paraplegia. The *shaded area* shows the extent of motor and sensory loss. (From Hickey J.V. [1997]. *The clinical practice of neurological and neurosurgical nursing* [3rd ed.]. Philadelphia: J.B. Lippincott.)

Fasciculations. Fasciculations are visible squirming and twitching movements of muscle fibers that can be seen as flickers under the skin.[7] They are caused by spontaneous contractions of all the muscle fibers in a motor unit due to irritation and hyperexcitability of the cell body and its motor neuron, and suggest LMN disease.

Spinal Reflex Activity

Testing of deep tendon reflexes (see Understanding the Stretch Reflex and Muscle Tone) can provide important

information about the status of the CNS in controlling muscle function. Hyperactive reflexes are suggestive of a UMN disorder. *Clonus* is the rhythmic contraction and alternate relaxation of a limb that is caused by suddenly stretching a muscle and gently maintaining it in the stretched position. It is seen in the hypertonia of spasticity associated with UMN lesions, such as spinal cord injury. *Hyporeflexia* or *areflexia* suggests the presence of an LMN lesion. The distribution of abnormality in the reflexes is also helpful in determining the location of the lesion. For example, hyperreflexia in both lower extremities would suggest a lesion in the spinal cord, whereas hyperreflexia on one side of the body would suggest a lesion in the UMN along the motor pathway (e.g., in the motor cortex or internal capsule).

Coordination of Movement

Coordination of muscle movement requires that four areas of the nervous system function in an integrated manner—the motor system for muscle strength, the cerebellar system for rhythmic movement and steady posture, the vestibular system for posture and balance, and the sensory system for position sense.

In cerebellar disease, one movement cannot be followed quickly by its opposite movement and movements are slow, irregular, clumsy, unsteady, and inappropriately varying in their speed, force, and direction. *Dysdiadochokinesia* is the failure to accurately perform rapid alternating movements. *Ataxia* is a term used to describe a wide-based, unsteady gait. *Dysmetria* is a term used to describe inaccuracies of movements leading to a failure to reach a specified target. This can be tested by having the person touch the examiner's finger and then alternately touch his or her finger. These movements are normally smooth and accurate. Asking the person to touch the examiner's finger with an outstretched arm and finger, first with the eyes open and then closed, provides a test for position sense. Repetitive and consistent deviation to one side (referred to as past pointing), which is worse with the eyes closed, suggests cerebellar or vestibular disease.

Chorea (abnormal writhing movements), *dystonia* (abnormal simultaneous contractions of agonist and antagonist muscles, leading to abnormal postures), *tremor* (rhythmic movements of a particular body part), *bradykinesia* (slowness of movements), and *myoclonus* (involuntary jerking movement) indicate abnormalities in the basal ganglia, although the exact localization may be difficult to determine.

In summary, motor function, whether it involves walking, running, or precise finger movements, requires movement and maintenance of posture. The system consists of the LMNs, which are located in the ventral horn of the spinal cord and the group of muscle fibers it innervates in the muscle; spinal cord circuitry and reflexes; and the descending UMNs, which project from the motor cortex to the opposite side of the medulla, where they form a pyramid before crossing the midline to form the lateral corticospinal tract in the spinal cord. Voluntary control of motor function is directed by the motor cortex, which consists of the primary, premotor, and supplementary motor cortex. The primary motor cortex is responsible for execution of a movement, the premotor cortex for generating a plan of movement, and the supplemental motor cortex for rehearsing the motor sequences of a movement, including those involving both sides of the body. As with other parts of the nervous system, the motor systems are organized in a functional hierarchy of, from bottom to top, the spinal cord, brain stem, and motor cortex, each with circuits that, through their input and output connections, can contribute to the organization and regulation of complex motor responses.

Proper control of muscle function requires not only excitation of the muscle by the LMNs located in the spinal cord, but also the function of reflex circuitry that monitors the functional status of the muscle fibers on a moment-by-moment basis. The muscle spindles of the stretch reflex function to monitor and correct for changes in muscle length when extrafusal fibers are either shortened (by contraction) or lengthened (by stretch).

Assessments of muscle strength and muscle bulk, muscle tone and motor reflexes, and patterns of motor movement and posture provide the means for determining the location of disorders of motor function. Paresis (weakness) and paralysis (loss of muscle movement) reflect a loss of muscle strength. UMN lesions tend to produce spastic paralysis, and LMN lesions flaccid paralysis. Changes in muscle bulk are characterized by a loss of muscle mass (atrophy) or an increase in muscle mass (hypertrophy). Muscle tone is maintained through the combined function of the spinal cord stretch reflex and higher centers that monitor and buffer UMN innervation of the LMNs. Hypotonia is a condition of less-than-normal muscle tone, and hypertonia or spasticity is a condition of excessive tone. Abnormal and uncoordinated movements and postures are suggestive of a cerebellar or basal ganglia pathologic process.

Disorders of the Motor Unit

Most of the diseases of the motor unit cause weakness and wasting of skeletal muscles. The distinguishing features of these diseases vary depending on which of the components of the motor unit is primarily affected—the cell body of the motor neuron, its axon, the neuromuscular junction, or the muscle fibers.[7–9] Disorders affecting the nerve cell body are often referred to as *lower motor neuron disorders*, those affecting the nerve axon as *peripheral neuropathies*, and primary disorders affecting the muscle fibers as *myopathies*.

Skeletal Muscle Disorders

Muscle Atrophy

Maintenance of muscle strength requires relatively frequent movements against resistance. Reduced use results in muscle atrophy, which is characterized by a reduction in the diameter of the muscle fibers because of a loss of protein filaments.[8] When a normally innervated muscle is not used for long periods, the muscle cells shrink in diameter, and although the muscle cells do not die, they lose much of their contractile proteins and become weakened. This is called *disuse atrophy,* and it occurs with conditions such as immobilization and chronic illness.

The most extreme examples of muscle atrophy are found in persons with disorders that deprive muscles of their innervation. This is called *denervation atrophy.* During early embryonic development, outgrowing skeletal nerves innervate partially mature muscle cells. If the developing muscle cells are not innervated, they do not mature and eventually die. In the process of innervation, randomly contracting muscle cells become enslaved by the innervating neurons, and from then on, the muscle cell contracts only when stimulated by that particular neuron. If the LMN dies or its axon is destroyed, the skeletal muscle cell is again free of neural domination. When this occurs, it begins to have temporary spontaneous contractions, called *fibrillations.* In contrast to previously described fasciculations, fibrillations are not visible clinically and can be detected only by electromyography.[7] The muscle also begins to lose its contractile proteins and, after several months, if not reinnervated, it is replaced by fibrous connective tissue, which makes rehabilitation difficult. Atrophy of denervation can often be delayed by periodic electrical stimulation while waiting to determine if the damaged nerve fiber regenerates.

Muscular Dystrophy

Muscular dystrophy is a term applied to a number of genetic disorders that produce progressive degeneration and necrosis of skeletal muscle fibers and eventual replacement with fat and connective tissue. They are primary diseases of muscle tissue and probably do not involve the nervous system. As the muscle undergoes necrosis, fat and connective tissue replace the muscle fibers, which increases muscle size and results in muscle weakness. The increase in muscle size resulting from connective tissue infiltration is called *pseudohypertrophy.* The muscle weakness is insidious in onset but continually progressive, varying with the type of disorder.

The two most common forms of muscular dystrophy are Duchene muscular dystrophy (DMD) and Becker muscular dystrophy (BMD), both of which are inherited as an X-linked recessive trait. DMD is the most common and severe form of muscular dystrophy, with an incidence of 1 in every 3500 to 3600 live male births.[8,10] Despite the X-lined inheritance in DMD, about 30% of cases are new mutations, and the mother is not a carrier. Female carriers are usually asymptomatic; affected girls are occasionally encountered, but usually have much milder symptoms than boys. BMD, which shares the same genetic locus as DMD, manifests later in childhood or adolescence and has a slower and less severe course of progression.

Both DMD and BMD are caused by mutations in the dystrophin gene, located on the short arm of the X chromosome. Dystrophin is a large protein that is expressed in a variety of tissues, including all types of muscle cells.[8–11] It attaches portions of the sarcomere to the cell membrane, maintaining the structural integrity of skeletal and cardiac muscle cells. The role of dystrophin in transferring the force of contraction to the extracellular connective tissue matrix has been proposed as the basis for muscle cell degeneration that occurs with dystrophin defects or changes in other proteins that interact with dystrophin. The dystrophin gene is one of the largest in the human genome, spanning 2.3 million base pairs, a factor that is thought to make it particularly vulnerable to mutations that affect different aspects of dystrophin synthesis. Muscle biopsy specimens from individuals with DMD show little or no dystrophin. In comparison, individuals with BMD, who also have mutations in the dystrophin gene, show diminished amounts of dystrophin, usually of an abnormal molecular weight, reflecting mutations that allow synthesis of an abnormal protein of smaller size.[8]

Clinical Course. Boys with DMD are usually asymptomatic at birth and during infancy.[8,10] Early gross movements such as rolling, sitting, and standing are usually achieved at the proper age. The postural muscles of the hips and shoulders are usually the first to be affected. Pseudohypertrophy (enlargement of the muscle due to excessive replacement of muscle fibers with fibroadipose tissue) of the calf muscle eventually develops (Fig. 36-5). Signs of muscle weakness usually become evident beginning at 2 to 3 years, when frequent falling begins to occur. Imbalances between agonist and antagonist muscles lead to abnormal postures and the development of contractures and joint immobility. Scoliosis is common. Wheelchairs usually are needed at approximately 7 to 12 years of age.[10] The function of the distal muscles usually is preserved well enough that the child can continue

FIGURE 36-5. A boy with Duchenne muscular dystrophy demonstrating pseudohypertrophy of his calves and climbing from a sitting position because of proximal muscle weakness. (From Bird T., Sumi S. [2002]. *Atlas of clinical neurology.* Edited by Roger N. Rosenberg. © Current Medicine, Inc.)

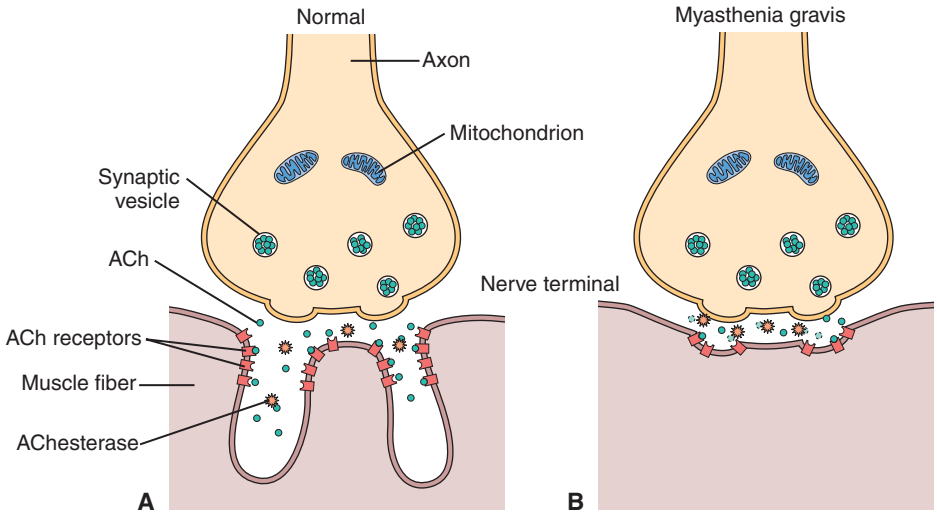

FIGURE 36-6. Neuromuscular junction. **(A)** Acetylcholine (ACh) released from the motor neurons in the myoneural junction crosses the synaptic space to reach receptors that are concentrated in the folds of the endplate of the muscle fiber. Once released, ACh is rapidly broken down by the enzyme acetylcholinesterase (AChesterase). **(B)** Decrease in ACh receptors in myasthenia gravis.

to use eating utensils and a computer keyboard. The function of the extraocular muscles also is well preserved, as is the function of the muscles controlling urination and defecation. Incontinence is an uncommon and late event. Respiratory muscle involvement results in weak and ineffective cough, frequent respiratory infections, and decreasing respiratory reserve. Cardiomyopathy is a common feature of the disease. The severity of cardiac involvement, however, does not necessarily correlate with skeletal muscle weakness. Some persons die early as the result of severe cardiomyopathy, whereas others maintain adequate cardiac function until the terminal stages of the disease. Death from respiratory and cardiac muscle involvement usually occurs in young adulthood.

Observation of the child's voluntary movement and a complete family history provide important diagnostic data for the disease. Serum levels of the enzyme creatine kinase, which leaks out of damaged muscle fibers, can be used to confirm the diagnosis. Muscle biopsy, which shows a mixture of muscle cell degeneration and regeneration and reveals fat and scar tissue replacement, is diagnostic of the disorder. Echocardiography, electrocardiography, and chest radiography are used to assess cardiac function. A specific molecular genetic diagnosis is possible by demonstrating defective dystrophin through the use of immunohistochemical staining of sections of muscle biopsy tissue or by deoxyribonucleic acid (DNA) analysis from the peripheral blood. The same methods of DNA analysis may be used on blood samples to establish carrier status in female relatives at risk, such as sisters and cousins. Prenatal diagnosis is possible as early as 12 weeks' gestation by sampling chorionic villi for DNA analysis[10] (see Chapter 6).

Management of the disease is directed toward maintaining ambulation and preventing deformities. Passive stretching, correct or counterposturing, and splints help to prevent deformities. Precautions should be taken to avoid respiratory infections. Although there have been exciting advances in identifying the gene and gene product involved in DMD, there is no known cure.

Disorders of the Neuromuscular Junction

The neuromuscular junction serves as a synapse between a motor neuron and a skeletal muscle fiber.[3] It consists of the axon terminals of a motor neuron and a specialized region of the muscle membrane called the *endplate*. The transmission of impulses at the neuromuscular junction is mediated by the release of the neurotransmitter *acetylcholine* from the axon terminals. Acetylcholine binds to specific receptors in the endplate region of the muscle fiber surface to cause muscle contraction (Fig. 36-6A). Acetylcholine is active in the neuromuscular junction only for a brief period, during which an action potential is generated in the innervated muscle cell. Some of the transmitter diffuses out of the synapse, and the remaining transmitter is rapidly inactivated by an enzyme called *acetylcholinesterase* (see Chapter 34, Fig. 34-25A). The rapid inactivation of acetylcholine allows repeated muscle contractions and gradations of contractile force.

Drug- and Toxin-Induced Disorders

A number of drugs and agents can alter neuromuscular function by changing the release, inactivation, or receptor binding of acetylcholine. Curare acts on the postjunctional membrane of the motor endplate to prevent the depolarizing effect of the neurotransmitter. Neuromuscular transmission is blocked by curare-type drugs during many types of surgical procedures to facilitate relaxation of involved musculature. Drugs such as physostigmine and neostigmine inhibit the action of acetylcholinesterase and allow acetylcholine released from the motor neuron to accumulate. These drugs are used in the treatment of myasthenia gravis.

Neurotoxins from the botulism organism (*Clostridium botulinum*) produce paralysis by blocking acetylcholine release.[3] Clostridia are anaerobic, gram-positive, spore-forming bacilli found worldwide in soils, marine and fresh water sediments, and the intestines of many animals. Classic food-borne botulism occurs through ingestion of

soil-grown foods that are not properly cooked or preserved.[12] Spores can be dormant, are resistant to heat, and germinate in low-acidity and low-nitrate environments. Canned vegetables, items preserved in garlic oil, and soups are usually the cause of sporadic outbreaks. Ingestion of the spores leads to toxin synthesis and absorption of the toxins from the intestinal tract. Wound botulism occurs through colonization of wounds with *C. botulinum*.

Pharmacologic preparations of the botulinum toxin (botulinum type A toxin [Botox] and botulinum type B toxin [Myobloc]) have become available for use in treating eyelid and eye movement disorders such as blepharospasm and strabismus.[13] These agents also are used for treatment of spasmodic torticollis, spasmodic dysphonias (laryngeal dystonia), and other dystonias. The drug is injected into the target muscle using the electrical activity recorded from the tip of a special electromyographic injection needle to guide the injection. The treatment is not permanent and usually needs to be repeated approximately every 3 months.

The aminoglycoside antibiotics (e.g., gentamicin) may produce a clinical disturbance similar to botulism by preventing the release of acetylcholine from nerve endings. The symptoms usually subside rapidly once the drug is eliminated from the body. These drugs are particularly dangerous in persons with preexisting disturbances of neuromuscular transmission, such as myasthenia gravis.

The organophosphates (e.g., malathion, parathion) that are used in some insecticides bind acetylcholinesterase to prevent the breakdown of acetylcholine. They produce excessive and prolonged acetylcholine action with a depolarization block of cholinergic receptors, including those of the neuromuscular junction.[13] The organophosphates are well absorbed from the skin, lungs, gut, and conjunctiva of the eye, making them particularly effective as insecticides but also potentially dangerous to humans. Malathion and certain other organophosphates are rapidly metabolized to inactive products in humans and are considered safe for sale to the general public. The sale of other insecticides, such as parathion, which is not effectively metabolized to inactive products, has been banned. Other organophosphate compounds (e.g., soman) were developed as "nerve gases"; if absorbed in high enough concentrations, they produce lethal effects through depolarization block and loss of respiratory muscle function.

Myasthenia Gravis

Myasthenia gravis is a disorder of the neuromuscular junction that affects impulse transmission between the motor neuron and the innervated muscle cell.[8,14–16] Women are affected nearly three times more commonly than men during early adulthood (age <40 years), whereas the incidence is roughly equal during puberty and after the age of 40 years. After 50 years of age, the incidence is higher in men. The Lambert-Eaton myasthenic syndrome is a special type of myasthenic syndrome that develops in association with neoplasms, particularly small cell carcinoma of the lung[8] (see Chapter 7).

Now recognized as an autoimmune disease, the disorder is caused by an antibody-mediated loss of acetylcholine receptors in the neuromuscular junction[8,14–16] (see Fig. 36-6B). Three mechanisms are thought to underlie the loss of functional acetylcholine receptors: (1) complement-mediated injury to the postsynaptic muscle membrane, (2) accelerated acetylcholine receptor degradation by receptor specific antibodies, and (3) blockade of the receptors by antibodies attached to the acetylcholine-binding sites. The pathogenic antibodies are immunoglobulin G (IgG) and are T-cell dependent. Neonatal myasthenia gravis, caused by placental transfer of the acetylcholine receptor antibody, occurs in about 10% to 15% of infants born to mothers with the disease.[14,15] Spontaneous resolution of symptoms usually occurs within a few months of birth.

The trigger or inciting factor leading to the autoimmune derangement in myasthenia gravis remains unclear, but several lines of evidence implicate the thymus gland in the process. Approximately 75% of persons with myasthenia gravis also have thymic abnormalities, such as a thymoma (i.e., thymus tumor) or thymic hyperplasia (i.e., increased thymus weight from an increased number of thymus cells).[16]

Clinical Manifestations. In persons with myasthenia gravis who have a loss of functional acetylcholine receptors, each release of acetylcholine from the presynaptic membrane results in diminished motor response. This results in both muscle weakness and fatigability with sustained effort. Most commonly affected are the eye and periorbital muscles, with ptosis due to eyelid weakness or diplopia due to weakness of the extraocular muscles as an initial symptom.[14–16] The disease may progress from ocular muscle weakness to generalized weakness, including respiratory muscle weakness. Chewing and swallowing may be difficult. Weakness in limb movement usually is more pronounced in proximal than in distal parts of the extremity, so that climbing stairs and lifting objects are difficult. As the disease progresses, the muscles of the lower face are affected, causing speech impairment. In most persons, symptoms are least evident when arising in the morning, but grow worse with effort and as the day proceeds.

Persons with myasthenia gravis may experience a sudden exacerbation of symptoms and weakness known as *myasthenic crisis*. Myasthenic crisis occurs when muscle weakness becomes severe enough to compromise ventilation to the extent that ventilatory support and airway protection are needed. This usually occurs during a period of stress, such as infection, emotional upset, pregnancy, alcohol ingestion, cold exposure, or surgery. It also can result from inadequate or excessive doses of the anticholinesterase drugs used in treatment of the disorder.

Diagnosis and Treatment. The diagnosis of myasthenia gravis is based on history and physical examination and confirmed by the response to a short-acing anticholinesterase test. Edrophonium (Tensilon) commonly is used for the test.[14–16] The drug, which is administered intravenously, decreases the breakdown of acetylcholine in the neuromuscular junction. When weakness is caused by myasthenia gravis, a dramatic transitory improvement in muscle function occurs. Electrophysiologic studies can be done to demonstrate a decremental

muscle response to repetitive 2- or 3-Hz stimulation of motor nerves. An immunoassay test can be used to detect the presence of antiacetylcholine receptor antibodies circulating in the blood.

Treatment methods include the use of pharmacologic agents; immunosuppressive therapy, including corticosteroid drugs; management of myasthenic crisis; thymectomy; and plasmapheresis or intravenous immunoglobulin.[14–16] Medications that may exacerbate myasthenia gravis, such as the aminoglycoside antibiotics, should be avoided. Pharmacologic treatment with reversible anticholinesterase drugs (i.e., neostigmine, pyridostigmine) inhibits the breakdown of acetylcholine at the neuromuscular junction by acetylcholinesterase. Corticosteroid drugs, which suppress the immune response, are used in cases of a poor response to anticholinesterase drugs and thymectomy. Immunosuppressant drugs (e.g., azathioprine, cyclosporine) also may be used, often in combination with plasmapheresis.

Plasmapheresis removes antibodies from the circulation and provides short-term clinical improvement. It is used primarily to stabilize the condition of persons in myasthenic crisis or for short-term treatment in persons undergoing thymectomy. Intravenous immunoglobulin also produces improvement in persons with myasthenia gravis. Although the effect is temporary, it may last for weeks to months. Intravenous immunoglobulin therapy is very expensive, which limits its use.

Thymectomy, or surgical removal of the thymus, may be used as a treatment for myasthenia gravis. Because the mechanism whereby surgery exerts its effect is unknown, the treatment is controversial. Thymectomy is performed in persons with thymoma, regardless of age, and in persons with generalized myasthenia gravis with onset before 50 years of age.[16]

Peripheral Nerve Disorders

Peripheral nervous system (PNS) disorders involve neurons that are located outside the CNS. They include disorders of the motor and sensory branches of the somatic and visceral nervous systems and the peripheral branches of the autonomic nervous system (see Chapter 34). The result usually is muscle weakness, with or without atrophy, and sensory changes. The disorder can involve a single nerve (mononeuropathy) or multiple nerves (polyneuropathy).

Unlike the nerves of the CNS, peripheral nerves are fairly strong and resilient. They contain a series of connective tissue sheaths that enclose their nerve fibers. An outer fibrous sheath called the *epineurium* surrounds the medium-sized to large nerves; inside, a sheath called the *perineurium* invests each bundle of nerve fibers; and within each bundle, a delicate sheath of connective tissue known as the *endoneurium* surrounds each nerve fiber (see Chapter 34, Fig. 34-2). Inside the endoneurial sheath are the Schwann cells that produce the myelin sheath that surrounds the peripheral nerves. Each Schwann cell can myelinate only one segment of a single axon—the one that it covers—so that myelination of an entire axon requires the participation of a long line of these cells.

Peripheral Nerve Injury and Repair

There are two main types of peripheral nerve injury based on the target of the insult: segmental demyelination involving the Schwann cell and axonal degeneration involving the neuronal cell body or its axon.[8,17] The peripheral nerve disorders can affect a spinal nerve, a peripheral nerve trunk (mononeuropathies), or multiple peripheral nerves (polyneuropathies).

Segmental Demyelination. Segmental demyelination occurs when there is a disorder of the Schwann cell (as in hereditary motor and sensory neuropathies) or damage to the myelin sheath (e.g., Guillain-Barré syndrome) without a primary abnormality of the axon. It typically affects some Schwann cells while sparing others. The disintegrated myelin is engulfed initially by Schwann cells and then by macrophages. The denuded axon provides a stimulus for remyelination and the population of cells within the endoneurium has the capacity to replace the injured Schwann cells. These cells proliferate and encircle the axon, and in time remyelinate the denuded portion. However, the new myelin sheath is thin in proportion to the axon, and in time, many chronic demyelinating neuropathies give way to axonal injury.

Axonal Degeneration. Axonal degeneration is caused by primary injury to a neuronal cell body or its axon. Damage to the axon may be due either to a focal event occurring at some point along the length of the nerve (e.g., trauma or ischemia) or to a more generalized abnormality affecting the neuronal cell body (neuropathy).

Damage to a peripheral nerve axon, whether by injury or neuropathy, results in degenerative changes, followed by breakdown of the myelin sheath and Schwann cells. In distal axonal degeneration, the proximal axon and neuronal cell body, which synthesizes the material required for nourishing and maintaining the axon, remain intact. In neuropathies and crushing injuries, in which the endoneurial tube remains intact, the outgrowing fiber grows down this tube to the structure that was originally innervated by the neuron (Fig. 36-7). However, it can take weeks or months for the regrowing fiber to reach its target organ and for communicative function to be reestablished. More time is required for the Schwann cells to form new myelin segments and for the axon to recover its original diameter and conduction velocity.

The successful regeneration of a nerve fiber in the PNS depends on many factors. If a nerve fiber is destroyed relatively close to the neuronal cell body, the chances are that the nerve cell will die, and if it does, it will not be replaced. If a crushing type of injury has occurred, partial or often full recovery of function occurs. Cutting-type trauma to a nerve is an entirely different matter. Connective scar tissue forms rapidly at the wound site, and when it does, only the most rapidly regenerating axonal branches are able to get through to the intact distal endoneurial tubes. A number of scar-inhibiting agents have been used in an effort to reduce this hazard, but have met with only moderate success. In another attempt to improve nerve regeneration, various types of tubular

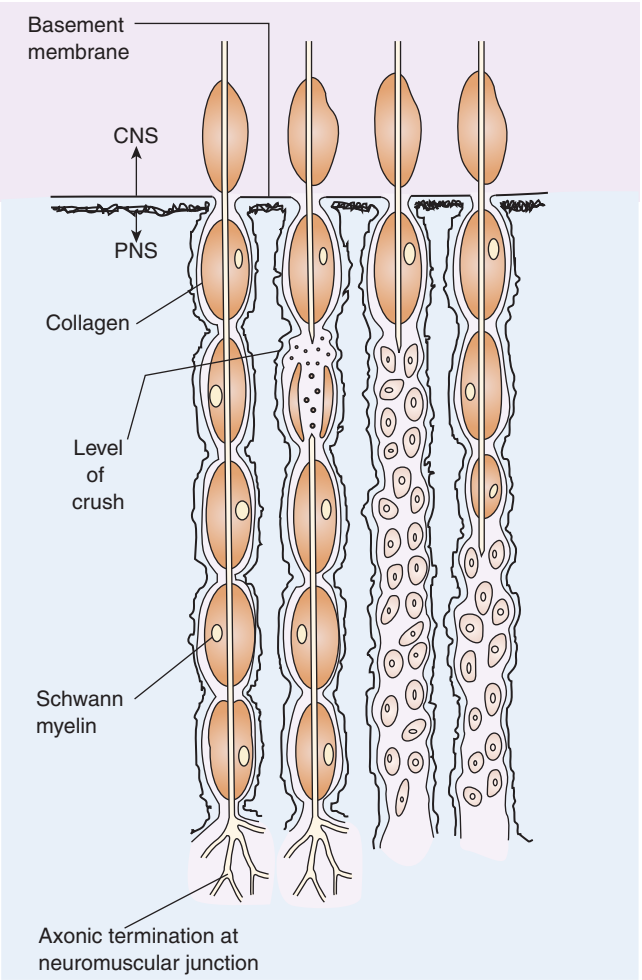

FIGURE 36-7. Sequential stages of efferent axon degeneration and regeneration within its endoneurial tube, after peripheral nerve crush injury.

implants have been placed to fill longer gaps in the endoneurial tube.

Neuropathies involving the neuronal cell body are much less common than those affecting the axons. In these cases, there is little potential for recovery of function because death of the neuronal cells precludes axonal regeneration.

Mononeuropathies

Mononeuropathies usually are caused by localized conditions such as trauma, compression, or infections that affect a single spinal nerve, plexus, or peripheral nerve trunk. Fractured bones may lacerate or compress nerves, excessively tight tourniquets may injure nerves directly or produce ischemic injury, and infections such as herpes zoster may affect a single segmental afferent nerve. Recovery of nerve function usually is complete after compression lesions and incomplete or faulty after nerve transection.

Carpal Tunnel Syndrome. Carpal tunnel syndrome is a relatively common entrapment mononeuropathy.[18–20] It

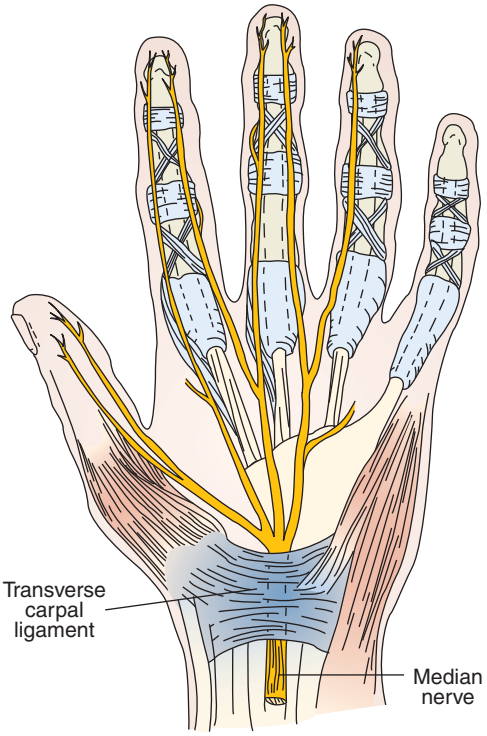

FIGURE 36-8. Carpal tunnel syndrome: compression of the median nerve by the transverse carpal ligament. (Courtesy of Carole Russell Hilmer, C.M.I.)

is caused by compression of the median nerve as it travels with the flexor tendons through a canal made by the carpal bones and transverse carpal ligament (Fig. 36-8). The condition can be caused by a variety of conditions that produce a reduction in the capacity of the carpal tunnel (i.e., bony or ligamentous changes) or an increase in the volume of the tunnel contents (i.e., inflammation of the tendons, synovial swelling, or tumors). Carpal tunnel syndrome may be a feature of a number of systemic diseases, such as rheumatoid arthritis, hyperthyroidism, acromegaly, and diabetes mellitus. Most cases, however, are due to repetitive use of the wrist (i.e., flexion–extension movements and stress associated with pinching and gripping motions).

Carpal tunnel syndrome is characterized by pain, paresthesia (tingling), and numbness of the thumb and first, second, third, and half of the fourth digits of the hand; pain in the wrist and hand, which worsens at night; atrophy of the abductor pollicis muscle; and weakness in precision grip. All of these abnormalities may contribute to clumsiness of fine motor activity.

Diagnosis usually is based on sensory disturbances confined to median nerve distribution and a positive Tinel or Phalen sign.[18,20] The *Tinel sign* is the development of a tingling sensation radiating into the palm of the hand that is elicited by light percussion over the median nerve at the wrist. The *Phalen maneuver* is performed by having the person hold the wrist in complete flexion for approximately a minute; if numbness and paresthesia along the median nerve are reproduced or

exaggerated, the test result is considered to be positive. Electromyography and nerve conduction studies often are done to confirm the diagnosis and exclude other causes of the disorder.

Treatment includes a variety of options including nonsteroidal anti-inflammatory agents, injection of corticosteroids, immobilization of the wrist with splints, rehabilitation modalities (e.g., ultrasound, stretching, and strengthening exercises), and surgery. Measures to decrease the causative repetitive movements should be initiated. Splints may be confined to nighttime use. When splinting is ineffective, corticosteroids may be injected into the carpal tunnel to reduce inflammation and swelling. Surgical intervention consists of operative division of the volar carpal ligaments as a means of relieving pressure on the median nerve.

Polyneuropathies

Polyneuropathies involve demyelination or axonal degeneration of multiple peripheral nerves that leads to symmetric sensory, motor, or mixed sensorimotor deficits. Typically, the longest axons are involved first, with symptoms beginning in the distal part of the extremities. If the autonomic nervous system is involved, there may be postural hypotension, constipation, and impotence. Polyneuropathies can result from immune mechanisms (e.g., Guillain-Barré syndrome), toxic agents (e.g., arsenic polyneuropathy, lead polyneuropathy, alcoholic polyneuropathy), and metabolic diseases (e.g., diabetes mellitus, uremia). Different causes tend to affect axons of different diameters and to affect sensory, motor, or autonomic neurons to different degrees.

Guillain-Barré Syndrome. Guillain-Barré syndrome is an acute life-threatening polyneuropathy.[18,21–24] The syndrome defines a clinical entity that is characterized by rapidly progressive limb weakness and loss of tendon reflexes. It has been described as the most common cause of acute, flaccid paralysis in developed countries of the world, now that poliomyelitis has been eliminated. As a syndrome, there are several subtypes of the disorder, including pure motor axonal degeneration, axonal degeneration of both motor and sensory nerves, and a variant characterized by ophthalmoplegia, ataxia, and areflexia.

Guillain-Barré syndrome is thought to be an acute-onset immune-mediated demyelinating neuropathy. Approximately two thirds of patients report having had an acute, influenza-like illness before the onset of symptoms.[18] Controlled epidemiologic studies have linked it to infection with *Campylobacter jejuni,* cytomegalovirus, Epstein-Barr virus, and mycoplasma pneumoniae. A *C. jejuni* infection is often an antecedent to symptoms. In a few cases, the patient reports receiving a vaccination prior to onset of Guillain-Barré syndrome.

The disorder is characterized by progressive ascending muscle weakness of the limbs, producing a symmetric flaccid paralysis. Symptoms of paresthesia and numbness often accompany the loss of motor function. The rate of disease progression varies, and there may be disproportionate involvement of the upper or lower extremities. Paralysis may progress to involve the respiratory muscles. Autonomic nervous system involvement that causes postural hypotension, arrhythmias, facial flushing, abnormalities of sweating, and urinary retention is common. Pain is another common feature of Guillain-Barré syndrome. It is most common in the shoulder girdle, back, and posterior thighs and occurs with even the slightest of movements.

Guillain-Barré syndrome usually is a medical emergency. There may be a rapid development of ventilatory failure and autonomic disturbances that threaten circulatory function. Treatment includes support of vital functions and prevention of complications such as skin breakdown and thrombophlebitis. Clinical trials have shown the effectiveness of plasmapheresis in decreasing morbidity and shortening the course of the disease. Treatment is most effective if initiated early in the course of the disease. High-dose intravenous immunoglobulin therapy also has proved effective. Approximately 80% to 90% of persons with the disease achieve a full and spontaneous recovery within 6 to 12 months.[23]

Back Pain and Spinal Nerve Root Disorders

Back pain is a common problem that affects an estimated two thirds of people at least once in their lifetime.[25] Back pain can result from a number of causes, including problems involving the vertebrae and intervertebral joints, back muscles and ligaments, and disorders of the spinal nerve roots. Perhaps the most common are musculoligamentous injuries and age-related degenerative changes in the intervertebral disks and facet joints.[26] Other causes include spinal nerve root compression due to intervertebral disk herniation and narrowing of the central canal due to spinal stenosis.

The spinal cord and spinal nerve roots are located within the vertebral canal. The anterior portion of the spine consists of cylindrical vertebral bodies separated by intervertebral disks and held together by the anterior and posterior longitudinal ligaments (Fig. 36-9A).

The posterior portion of the spine consists of the vertebral arches, each consisting of paired transverse processes, one posterior spinous process, and two superior articular facets. The functions of the posterior spine are to protect the spinal cord and nerves within the spinal canal and to stabilize the spine by providing sites for the attachment of muscles and ligaments.

Pain-sensitive structures in the spine include the periosteum of the vertebrae, dura, facet joints, annulus fibrosus of the intervertebral disk, and posterior longitudinal ligament. Pain sensation is conveyed through afferent fibers in the spinal nerves. Local pain is caused by stretching of pain-sensitive structures that compress or irritate sensory nerve endings. Pain referred to the back may arise from abdominal or pelvic structures. Pain associated with muscle spasm is usually dull, and often accompanied by abnormal posture and stiff paraspinal muscles.

Nerve root injury (radiculopathy) is a common cause of neck, arm, low back, and leg pain. The pain is typically

FIGURE 36-9. sharp and radiates to the arm or leg within the territory of the spinal root. Disorders affecting the upper lumbar segments tend to be referred to the lumbar area, groin, or anterior thigh; and those affecting the lower lumbar and upper sacral segments, to the buttocks and posterior thighs.

Diagnosis and Treatment. Although back problems are commonly attributed to a herniated disk, most acute back disorders are cause by less serious problems.[18,25–28] The diagnostic challenge is to identify those persons who require further evaluation for more serious problems such as malignancies, compression fractures, and vascular disorders. The diagnostic measures used in the evaluation of back pain include history and physical examination, including a thorough neurologic examination. Other diagnostic methods may include radiographs of the back and magnetic resonance imaging (MRI).

Treatment of back pain usually is conservative and consists of analgesic medications, muscle relaxants, and instruction in the correct mechanics for lifting and methods of protecting the back. Pain relief is usually provided using nonsteroidal anti-inflammatory drugs. Muscle relaxants may be used on a short-term basis. Bed rest, once the mainstay of conservative therapy, is now understood to be ineffective for acute back pain. Conditioning exercises of the trunk muscles, particularly the back extensors, are often recommended.

Intervertebral Disk Disorders. The intervertebral disk is considered the most critical component of the load-bearing structures of the spinal column. It consists of a soft, gelatinous center called the *nucleus pulposus,* which is encircled by a strong, ringlike collar of fibrocartilage called the *annulus fibrosus.*[29] The structural components of the disk make it capable of absorbing shock and changing shape while allowing movement. With dysfunction, the nucleus pulposus can be squeezed out of place and herniate through the annulus fibrosus, a condition referred to as a *herniated* or *slipped disk* (see Fig. 36-9A, B).

The intervertebral disk can become dysfunctional because of trauma, the effects of aging, or degenerative disorders of the spine. Protrusion of the nucleus pulposus usually occurs posteriorly and toward the intervertebral foramen and its contained spinal nerve root, where the annulus fibrosus is relatively thin and poorly supported by either the posterior or anterior ligaments[28,29] (see Fig. 36-9A). Trauma results from activities such as lifting while in the flexed position, slipping, falling on the buttocks or back, or suppressing a sneeze. With aging,

the gelatinous center of the disk dries out and loses much of its elasticity.

The level at which a herniated disk occurs is important (see Fig. 36-9C). The cervical and lumbar regions are the most flexible areas of the spine and are most often involved in disk herniations. Usually, herniation occurs at the lower levels of the lumbar spine, where the mass being supported and the bending of the vertebral column are greatest. When the injury occurs in the lumbar area, only the nerve fibers of the cauda equina are involved. Because these elongated dorsal and ventral roots contain endoneurial tubes of connective tissue, regeneration of the nerve fibers is likely. However, months may be required for full recovery to occur because of the distance to the innervated muscle or skin of the lower limbs.

The signs and symptoms of a herniated disk are localized to the area of the body innervated by the spinal nerve roots and include both motor and sensory manifestations (Fig. 36-10). Pain is the first and most common symptom of a herniated disk. The nerve roots of L4, L5, S1, S2, and S3 give rise to a syndrome of back pain, sometimes referred to as *sciatica*, which spreads down the back of the leg and over the sole of the foot. The pain is usually intensified with coughing, sneezing, straining, stooping, standing, and the jarring motions that occur during walking or riding. Slight motor weakness may occur, although major weakness is rare. The most common sensory deficits from spinal nerve root compression are paresthesias and numbness, particularly of the leg and foot. Knee and ankle reflexes also may be diminished or absent.

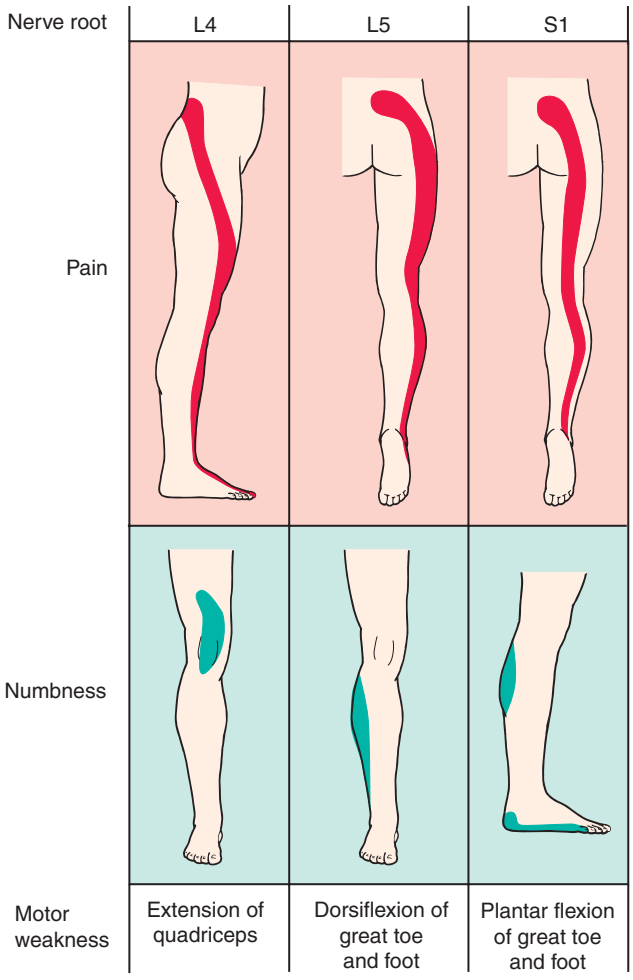

FIGURE 36-10. Dermatomes of the leg (L1 through S5) where pain and numbness would be experienced with spinal root irritation.

A herniated disk must be differentiated from other causes of acute back pain. Diagnostic measures include history and physical examination. Neurologic assessment includes testing of muscle strength and reflexes. The straight-leg test is an important diagnostic maneuver. It is done in the supine position and is performed by passively raising the person's leg. The test can also be done by slowly extending the knee while the person sits on a table, with both hip and knee flexed at 90 degrees. The maneuver is designed to apply traction along the nerve root, which exacerbates pain if the nerve root is acutely inflamed. Normally, it is possible to raise the leg approximately 90 degrees without causing discomfort of the hamstring muscles. The test result is positive if pain is produced when the leg is raised to 60 degrees or less. Other diagnostic methods include radiographs of the back, MRI, computed tomography (CT), and CT myelography.

Treatment usually is similar to that for back pain. Surgical treatment may be indicated when there is documentation of herniation by an imaging procedure, consistent pain, or consistent neurologic deficit that failed to respond to conservative therapy.

Back Pain Emergencies. Although acute back pain is usually a non–life-threatening condition, in 5% to 10% of persons it is a manifestation of a more serious pathologic process.[30] Vascular catastrophes (ruptured abdominal aortic aneurysms and dissecting aortic aneurysms), malignancy, spinal cord compression syndromes, and infectious processes may all present as acute back pain.

Clinical findings, commonly referred to as *red flags,* that indicate the possibility of more serious disease include gradual onset of pain; age younger than 20 years or older than 50 years; thoracic back pain; history of trauma, fever, chills, night sweats, immunosuppression, or malignancy; unintentional weight loss; recent procedure known to cause bacteremia; and history of intravenous drug use.[30] The gradual onset of pain may be indicative of malignancy or infection. Back pain that begins before 20 years of age suggests congenital or developmental disorders, and new-onset pain in persons 50 years of age or older is more likely to be a manifestation of serious conditions such as an aortic aneurysm, malignancy, or compression fracture. Pain that is aggravated by lying down is a red flag for malignancy or infection, and pain that improves with sitting or slight flexion of the spine suggests the presence of spinal stenosis. Persons with symptoms of large or rapidly evolving neurologic deficits require urgent evaluation for possible cauda equina masses, epidural abscess, or central disk herniation. Signs and symptoms that suggest possible cauda equina syndrome are low back pain associated with bilateral leg weakness (from multiple lumbar nerve root compressions), saddle area numbness, bowel and bladder

incontinence, or impotence (indicating multiple sacral nerve compressions).[25,30] Reports of neurologic symptoms such as paresthesia, motor weakness, and gait abnormalities also require additional diagnostic tests to rule out spinal cord compression.

In summary, the motor unit consists of the LMN, the neuromuscular junction, and the skeletal muscle that the nerve innervates. Disorders of the neuromuscular unit include muscular dystrophy, myasthenia gravis, and peripheral nerve disorders. *Muscular dystrophy* is a term used to describe a number of disorders that produce progressive deterioration of skeletal muscle. Muscle necrosis is followed by fat and connective tissue replacement. One form, Duchenne muscular dystrophy, is inherited as an X-linked trait and transmitted by the mother to her male offspring. Myasthenia gravis is a disorder of the neuromuscular junction resulting from a deficiency of functional acetylcholine receptors, which causes weakness of the skeletal muscles. Because the disease affects the neuromuscular junction, there is no loss of sensory function. The most common manifestations are weakness of the eye muscles, with ptosis and diplopia.

Peripheral nerve disorders involve motor and sensory neurons outside the CNS. There are two main types of peripheral nerve injury based on the target of the insult: segmental demyelination involving the Schwann cell and axonal degeneration involving the nerve axon or its cell body. Peripheral nerve disorders include mononeuropathies, involving a single spinal nerve, plexus, or peripheral nerve, and polyneuropathies, involving demyelination or axonal degeneration of multiple peripheral nerves that leads to symmetric sensory, motor, or mixed sensorimotor deficits. Carpal tunnel syndrome, a mononeuropathy, is caused by compression of the medial nerve as it passes through the carpal tunnel in the wrist. Guillain-Barré syndrome is a subacute polyneuropathy, probably due to immune mechanisms, that causes progressive ascending motor, sensory, and autonomic nervous system manifestations. Respiratory involvement may occur and necessitate mechanical ventilation.

Back pain can result from a number of causes, including muscle and ligament strains, age-related degenerative spine disorders, disk herniation, and narrowing of the central vertebral canal due to spinal stenosis. Most cases of back pain are thought to be due to muscular or ligamentous injuries that are self-limited and treated conservatively. Herniation or protrusion of the gelatinous pulposus through the anulus fibrosus of an intervertebral disk causes pain and numbness related to the area of the body that is innervated by the affected nerve root. Although back pain is most commonly caused by nonspecific conditions such as muscle strain, the diagnostic challenge is to identify persons who require urgent evaluation for conditions such as vascular disorders (ruptured abdominal aneurysm, aortic dissection), osteomyelitis, malignancies, compression fractures, and cauda equina syndrome.

Disorders of the Cerebellum and Basal Ganglia

Disorders of the Cerebellum

The cerebellum is a cauliflower-shaped structure located in the posterior fossa and attached to the pons, medulla, and midbrain by the three paired cerebellar peduncles[3,31] (see Chapter 34). It has sometimes been referred to as the *silent area* of the brain because electrical stimulation does not produce any conscious sensation and rarely causes any motor movements.[3] However, removal or damage to the cerebellum causes movements to become highly abnormal. The cerebellum is especially vital during rapid muscular activities such as running, typing, and even talking. Loss of cerebellar function can result in total incoordination of these functions even though paralysis does not occur.

The functions of the cerebellum are integrated into many connected afferent and efferent pathways throughout the brain. An extensive and important afferent pathway is the *corticopontocerebellar* pathway, which originates in the cerebral motor and premotor cortices as well as the somatosensory cortex. Other important afferent pathways link the cerebellum to input from the basal ganglia, muscle and joint tension information from the stretch receptors, visual input from the eyes, and balance and equilibrium sensation from the vestibular system in the inner ear. There are three general efferent pathways leading out of the cerebellum: (1) the *vestibulocerebellar pathway* that functions in close association with the brain stem vestibular nuclei to maintain equilibrium and posture; (2) the *spinocerebellar pathway* that provides the circuitry for coordinating the movements of the distal portions of the limbs, especially the hands and fingers; and (3) the *cerebrocerebellar pathway* that transmits output information in the upward direction to the cerebral cortex, functioning in a feedback manner with the motor and somatosensory systems to coordinate sequential body and limb movements.

Cerebellum-Associated Movement Disorders

The signs of cerebellar dysfunction can be grouped into three classes: vestibulocerebellar disorders, cerebellar ataxia or decomposition of movement, and cerebellar tremor. These disorders occur on the side of cerebellar damage, whether because of congenital defect, vascular accident, or growing tumor. Visual monitoring of movement cannot compensate for cerebellar defects, and the movement abnormalities occur whether the eyes are open or closed.

Damage to the part of the cerebellum associated with the vestibular system leads to difficulty or inability to maintain a steady posture of the trunk, which normally requires constant readjusting movements. This is seen as an unsteadiness of the trunk, called *truncal ataxia,* and can be so severe that standing is not possible. The ability to fix the eyes on a target also can be affected. Constant conjugate readjustment of eye position, called *nystagmus,* results and makes reading extremely difficult,

especially when the eyes are deviated toward the side of cerebellar damage.

Cerebellar ataxia and tremor are different aspects of defects in the smooth, continuously correcting functions. Cerebellar dystaxia or, if severe, ataxia is characterized by a decomposition of movement, with each succeeding component of a complex movement occurring separately instead of being blended into a smoothly proceeding action. Because ethanol specifically affects cerebellar function, persons who are inebriated often walk with a staggering and unsteady gait. Rapid alternating movements such as supination–pronation–supination of the hands are jerky and performed slowly. Reaching to touch a target breaks down into small sequential components, each going too far, followed by overcorrection. The finger moves jerkily toward the target, misses, corrects in the other direction, and misses again, until the target is finally reached. This is called *over- and underreaching* or *dysmetria*.

Cerebellar tremor is a rhythmic back-and-forth movement of a finger or toe that worsens as the target is approached. The tremor results from the inability of the damaged cerebellar system to maintain ongoing fixation of a body part and to make smooth, continuous corrections in the trajectory of the movement; overcorrection occurs, first in one direction and then the other. Often, the tremor of an arm or leg can be detected during the beginning of an intended movement. The common term for cerebellar tremor is *intention tremor.* Cerebellar function, as it relates to tremor, can be assessed by asking a person to touch one heel to the opposite knee, to gently move the toes along the back of the opposite shin, or to touch the nose with a finger.

Cerebellar function also can affect the motor skills of chewing, swallowing, and speech. Normal speech requires smooth control of respiratory muscles and highly coordinated control of the laryngeal, lip, and tongue muscles. Cerebellar dysarthria is characterized by slow, slurred speech of continuously varying loudness. Rehabilitative efforts directed by speech therapists include learning to slow the rate of speech and to compensate as much as possible through the use of less affected muscles.

Disorders of the Basal Ganglia

The basal ganglia are a group of deep, interrelated subcortical nuclei that play an essential role in control of movement. They function in the organization of inherited and highly learned and rather automatic movement programs, especially those affecting the trunk and proximal limbs. The basal ganglia are thought to be particularly important in starting, stopping, and monitoring movements executed by the cortex, especially those that are relatively slow and sustained, or stereotyped. They also help to regulate the intensity of these movements, and they act to inhibit antagonistic or unnecessary movements. The function of the basal ganglia is not limited to motor functions; they also are involved in cognitive and perceptual functions.

The structural components of the basal ganglia include the caudate nucleus, putamen, and globus pallidus.[3,32] They are located lateral and caudal to the thalamus, occupying a large portion of the interior of both cerebral hemispheres. The caudate and putamen are collectively referred to as the *striatum,* and the putamen and globus pallidus form a wedge-shaped region called the *lentiform nucleus.* Two other structures, the *substantia nigra* of the midbrain and the *subthalamic nucleus* of the diencephalon, are considered part of the basal ganglia (Fig. 36-11). The dorsal part of the substantia nigra contains cells that synthesize dopamine and are rich in a black pigment called *melanin.* The high concentration of melanin gives the structure a black color, hence the name *substantia nigra.* The axons of the substantia nigra form the *nigrostriatal pathway,* which supplies dopamine to the striatum. The subthalamic nucleus lies just below the thalamus and above the anterior portion of the substantia nigra. The glutaminergic cells of this nucleus are the only excitatory projections to the basal ganglia.

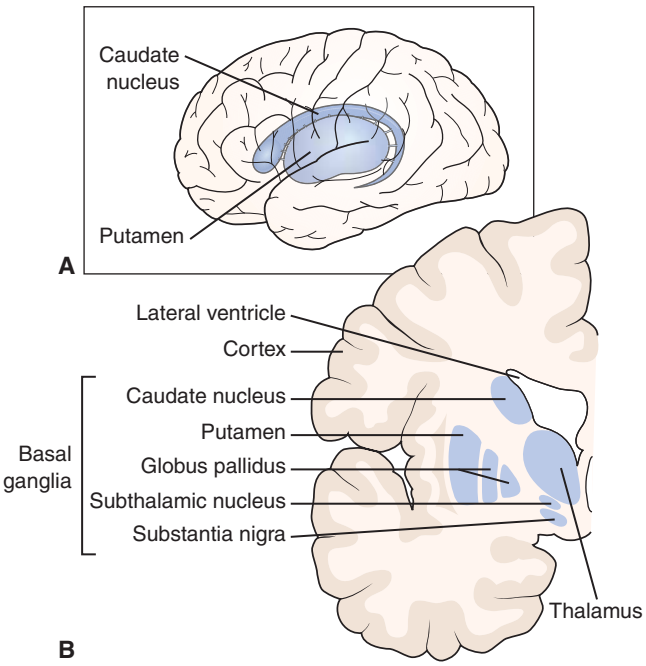

FIGURE 36-11. **(A)** Lateral view of the basal ganglia. **(B)** Coronal section showing the basal ganglia in relation to surrounding structures.

The basal ganglia have input structures that receive afferent information from the cerebral cortex and thalamus, internal circuits that connect the various structures of the basal ganglia, and output structures that deliver information to other brain centers. The neostriatum represents the major input structure for the basal ganglia. Virtually all areas of the cortex and afferents from the thalamus project to the neostriatum. The output areas of the basal ganglia, including the lateral globus pallidus, have both ascending and descending components. The major ascending output is transmitted to thalamic nuclei, which process all incoming information that is transmitted to the cerebral cortex. Descending output is directed to the midbrain, brain stem, and spinal cord.

The output functions of the basal ganglia are mainly inhibitory. Looping circuits from specific cortical areas

pass through the basal ganglia to modulate the excitability of specific thalamic nuclei and control the cortical activity involved in highly learned, automatic, and stereotyped motor functions. The most is known about the inhibitory basal ganglia loop that is involved in modulating cortical motor control. This loop regulates the release of stereotyped movement patterns that add efficiency and gracefulness to cortically controlled movements. These movements include inherited patterns that add precision, efficiency, and balance to motion, such as the swinging of the arms during walking and running and the highly learned automatic postural and follow-through movements of throwing a ball or swinging a bat.

The basal ganglia also have a cognitive function in that they monitor sensory information coming into the brain and apply it to information stored in memory as a means of planning and sequencing motor movements.[3] The cognitive control of motor activities determines, subconsciously and within seconds, which patterns of movement will be needed to achieve a goal. The caudate nucleus, which receives large amounts of input from the association areas of the brain, plays a major role in the cognitive control of motor activity.

Multiple pathways provide excitatory signals that balance the large number of inhibitory signals transmitted by γ-aminobutyric acid (GABA) and dopaminergic neurons. One of these circuits involves a *neostriatal inhibitory projection* on the substantia nigra. The substantia nigra projects dopaminergic axons back on the striatum. A deficiency in the dopaminergic projection of this modulating circuit is implicated in parkinsonism. The function of the striatum also involves local excitatory cholinergic interneurons, and their destruction is thought to be related to the choreiform movements of Huntington disease, another basal ganglia–related syndrome (see Chapter 37).

Basal Ganglia–Associated Movement Disorders

Disorders of the basal ganglia comprise a complex group of motor disturbances characterized by tremor and other involuntary movements, changes in posture and muscle tone, and poverty and slowness of movement. They include tremors and tics, hypokinetic disorders, and hyperkinetic disorders[1] (Table 36-1).

Unlike disorders of the motor cortex and corticospinal (pyramidal) tract, lesions of the basal ganglia disrupt movement but do not cause paralysis. The various types of involuntary movements often occur in combination and appear to have a common underlying cause. Recent studies indicate that hypokinetic and hyperkinetic disorders can be explained as specific disturbances in the indirect and direct pathways that link the basal ganglia with the thalamocortical motor circuit.[32] Accordingly, overactivity of the indirect pathway relative to the direct pathway would result in hypokinetic disorders such as Parkinson disease, and underactivity of the indirect pathway would result in hyperkinetic disorders such as chorea and ballismus.

Parkinson Disease

Parkinson disease is a progressive degenerative disorder of basal ganglia function that results in variable combinations of tremor, rigidity, and bradykinesia.[33,34] Parkinson disease is the second most common neurodegenerative disease

TABLE 36-1 Characteristics of Basal Ganglia–Associated Movement Disorders

Movement Disorder	Characteristics
Tremor	Involuntary, oscillating contractions of opposing muscle groups around a joint Usually fairly uniform in frequency and amplitude Can occur as resting tremors and postural tremors, which occur when the part is maintained in a stable position
Hypokinetic disorders	Slowness in initiating movement, and reduced range and force of the movement (bradykinesia)
Chorea	Irregular wriggling and writhing movements Accentuated by movement and by environmental stimulation; they often interfere with normal movement patterns May be grimacing movements of the face, raising the eyebrows, rolling of the eyes, and curling, protrusion, withdrawal of the tongue In the limbs, the movements largely are distal; there may be piano playing–type movements with alternating extension and flexion of the fingers
Athetosis	Continuous, wormlike, twisting and turning motions of the joints of a limb or the body
Ballismus	Violent, sweeping, flinging motions, especially of the limbs on one side of the body (hemiballismus)
Dystonia	Abnormal maintenance of a posture resulting from a twisting, turning movement of the limbs, neck, or trunk Often the result of simultaneous contraction of agonist and antagonist muscles Can result in grotesque and twisted postures
Dyskinesias	Bizarre wriggling and writhing movements Frequently involve the face, mouth, jaw, and tongue, causing grimacing, pursing of the lips, or protrusion of the tongue Limbs affected less often Tardive dyskinesia is an untoward reaction that can develop with long-term use of some antipsychotic medications

after Alzheimer disease. It usually begins after 50 years of age, with the prevalence increasing to 4% to 5% in those older than 85 years of age.[33]

The clinical syndrome arising from the degenerative changes in basal ganglia function often is referred to as *parkinsonism*. Parkinson disease, the most common form of parkinsonism, is named after James Parkinson, a British physician who first described the disease in a paper he published in 1817 on the "shaking palsy."[35] In Parkinson disease, also known as *idiopathic parkinsonism,* dopamine depletion results from degeneration of the dopamine nigrostriatal system. Parkinsonism can also develop as a postencephalitic syndrome, as a side effect of therapy with antipsychotic drugs that block dopamine receptors, as a toxic reaction to a chemical agent, or as an outcome of severe carbon monoxide poisoning.[36] Postencephalitic parkinsonism was a particular problem in the 1930s and 1940s as a result of an outbreak of lethargic encephalitis (sleeping sickness) that occurred in 1914 to 1918. Drug-induced parkinsonism can follow the administration of antipsychotic drugs in high doses (e.g., phenothiazines, butyrophenones). These drugs block dopamine receptors and dopamine output by the cells of the substantia nigra. Symptoms of parkinsonism also may accompany conditions such as cerebral vascular disease, brain tumors, repeated head trauma, or degenerative neurologic diseases that structurally damage the nigrostriatal pathway.

The primary brain abnormality found in persons with Parkinson disease is degeneration of the nigrostriatal pathway, with subsequent reduction in striatal concentrations of dopamine. Other brain areas are affected to a lesser extent.[37,38] Although the cause of Parkinson disease is still unknown, it is widely believed that most cases are caused by an interaction of environmental and genetic factors. Over the past several decades, several pathologic processes (e.g., oxidative stress, apoptosis, and mitochondrial disorders) that might lead to degeneration have been identified. Of interest in terms of research was the development of Parkinson disease in several persons who had attempted to make a narcotic drug and instead synthesized a compound called *MPTP (1-methyl-phenyl-2,3,6-tetrahydropyridine)*.[36] This compound selectively destroys the dopaminergic neurons of the substantia nigra. This incident prompted investigations into the role of toxins that are produced by the body as a part of metabolic processes and those that enter the body from outside sources in the pathogenesis of Parkinson disease. One theory is that the auto-oxidation of catecholamines such as dopamine may injure neurons in the substantia nigra. There is increasing evidence that the development of Parkinson disease may be related to oxidative metabolites of this process and the inability of neurons to render these products harmless. MPTP is an inhibitor of the mitochondrial electron transport system that functions in the inactivation of these metabolites, suggesting that it may produce Parkinson disease in a manner similar to that of the naturally occurring disease.[36,37]

The recent discovery of inherited forms of Parkinson disease suggests that genetic factors may also play a role in the pathogenesis of early-onset Parkinson disease.[37–39] The first genetic mutation associated with Parkinson disease was found in the gene encoding α-*synuclein*, a member of a small family of proteins that are expressed preferentially in the substantia nigra.[37,38] Although mutations in this gene cause a very rare, autosomal dominant form of the disease, the mutation has received considerable attention because α-synuclein is one of the major components of the Lewy bodies that are found in the brain tissue of persons with Parkinson disease. Mutations in a second gene that encodes the protein *parkin* is associated with an autosomal recessive, early-onset form of Parkinson disease.[37] Numerous other genetic loci have been linked to Parkinson disease, but the genes remain to be mapped. Thus, the genetics of Parkinson disease are beginning to provide molecular clues that help explain the etiology of parkinsonism, just as epidemiologic studies have delineated an array of environmental modulators of susceptibility, which can now be explored in the context of gene expression.[39]

Clinical Manifestations. The cardinal manifestations of Parkinson disease are tremor, rigidity, and bradykinesia or slowness of movement (Fig. 36-12).[40,41] Tremor is the most visible manifestation of the disorder. The tremor

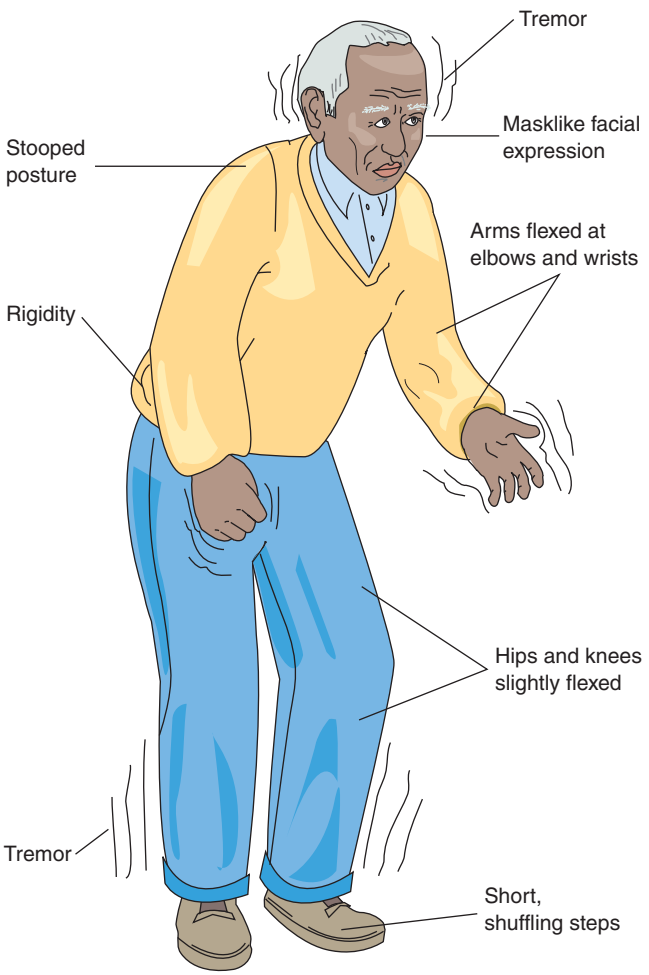

FIGURE 36-12. The clinical features of Parkinson disease. (From Timby B.K., Smith N.E. [2003]. *Introductory medical–surgical nursing* [8th ed., p. 626]. Philadelphia: Lippincott Williams & Wilkins.)

affects the distal segments of the limbs, mainly the hands and feet; head, neck, face, lips, and tongue; or jaw. It is characterized by rhythmic, alternating flexion and contraction movements (four to six beats per minute) that resemble the motion of rolling a pill between the thumb and forefinger. The tremor usually is unilateral, occurs when the limb is supported and at rest, and disappears with movement and sleep. The tremor eventually progresses to involve both sides of the body.

Rigidity is defined as resistance to movement of both flexors and extensors throughout the full range of motion. It is most evident during passive joint movement and involves jerky, cogwheel-type or ratchetlike movements that require considerable energy to perform. Flexion contractions may develop as a result of the rigidity. As with tremor, rigidity usually begins unilaterally but progresses to involve both sides of the body.

Bradykinesia is characterized by slowness in initiating and performing movements and difficulty with sudden, unexpected stopping of voluntary movements. Unconscious associative movements occur in a series of disconnected steps rather than in a smooth, coordinated manner. This is the most disabling of the symptoms of Parkinson disease. Persons with the disease have difficulty initiating walking and difficulty turning. While walking, they may freeze in place and feel as if their feet are glued to the floor, especially when moving through a doorway or preparing to turn. When they walk, they lean forward to maintain their center of gravity and take small, shuffling steps without swinging their arms, and they have difficulty changing their stride.

Manifestations of advanced-stage parkinsonism include falls, fluctuations in motor function, neuropsychiatric disorders, and sleep disorders. Loss of postural reflexes predisposes to falling, often backward. Emotional and voluntary facial movements become limited and slow as the disease progresses, and facial expression becomes stiff and masklike. There is loss of the blinking reflex and a failure to express emotion. The tongue, palate, and throat muscles become rigid; the person may drool because of difficulty in moving the saliva to the back of the mouth and swallowing it. The speech becomes slow and monotonous, without modulation, and poorly articulated.

Because the basal ganglia also influence the autonomic nervous system, persons with Parkinson disease often have excessive and uncontrolled sweating, sebaceous gland secretion, and salivation. Autonomic symptoms, such as lacrimation, dysphagia, orthostatic hypotension, thermal regulation, constipation, impotence, and urinary incontinence, may be present, especially late in the disease.

Cognitive dysfunction may also be an important feature associated with Parkinson disease. It occurs in approximately 20% to 30% of persons with the disease and develops late in the course of the disease.[40] Deficits in executive functioning may be among the earliest signs of cognitive decline, as evidenced by difficulty in planning, starting, and carrying out tasks. Dementia, when it does occur, is usually a late manifestation of the disease, and the rate of decline is slow compared with Alzheimer disease.

Treatment. The approach to treatment of Parkinson disease must be highly individualized. It includes nonpharmacologic, pharmacologic, and, when indicated, surgical methods.[33,34,41] Nonpharmacologic interventions offer group support, education, daily exercise, and adequate nutrition. Botulinum toxin injections may be used in the treatment of dystonias such as eyelid spasm and limb dystonias that frequently are associated with Parkinson disease. Persons with parkinsonism other than idiopathic Parkinson disease usually do not respond significantly to medications developed for Parkinson disease.

Pharmacologic treatment usually is determined by the severity of symptoms. Antiparkinson drugs act by increasing the functional ability of the underactive dopaminergic system, or by reducing the excessive influence of excitatory cholinergic neurons. Drugs that improve the function of the dopaminergic system include those that increase dopamine levels (levodopa), stimulate dopamine receptors (dopamine receptor agonists), or retard the breakdown of dopamine (monoamine oxidase inhibitors). Dopamine does not cross the blood-brain barrier. Levodopa does cross the blood-brain barrier, but only in small amounts due to its high metabolism outside the brain. However, when levodopa (a decarboxylase inhibitor) is given in combination with carbidopa, the peripheral metabolism of levodopa is reduced, plasma levels of levodopa are increased and its half-life is longer, more levodopa is available for entry into the brain, and a smaller dose is needed. A later adverse effect of levodopa treatment is the so-called *on–off phenomenon*, in which frequent, abrupt, and unpredictable fluctuations in motor performance occur during the day. These fluctuations include "on" periods without dyskinesia, "on" periods with dyskinesia, and periods of bradykinesia (the "off" response). Some fluctuations reflect the timing of drug administration, in which case the "on" response coincides with peak drug levels and the "off" response with low drug levels.

Bromocriptine, pramipexole, and ropinirole are dopamine agonists that act directly to stimulate dopamine receptors.[13] Rotigotine is a dopamine agonist that is supplied in a transdermal system. The dopamine agonists can be used as initial or adjunctive therapy in Parkinson disease and can be given in combination with carbidopa/levodopa. Apomorphine is another dopamine agonist that can be given intravenously. Rotigotine is only approved by the U.S. Food and Drug Administration (FDA) for initial treatment of Parkinson disease, whereas apomorphine is used as a rescue medication in patients experiencing sudden "off" periods or delayed "on" periods. Amantadine is thought to augment release of dopamine from the remaining intact dopaminergic terminals in the nigrostriatal pathway of persons with Parkinson disease. It is used to treat persons with mild symptoms but no disability. Selegiline and rasagiline are monoamine oxidase type B inhibitors that inhibit the metabolic breakdown of dopamine. Selegiline and rasagiline may be used as adjunctive treatment to reduce mild on–off fluctuations in the responsiveness of persons who are receiving levodopa.

Because dopamine transmission is disrupted in Parkinson disease, there is a preponderance of cholinergic activity,

which may be treated with anticholinergic drugs. Anticholinergic drugs (e.g., trihexyphenidyl, benztropine) are thought to restore a "balance" between reduced dopamine and uninhibited cholinergic neurons in the striatum. They are more useful in alleviating tremor and rigidity than bradykinesia. The anticholinergic drugs lessen the tremors and rigidity and afford some improvement of function. However, their potency seems to decrease over time, and increasing the dosage merely increases side effects such as blurred vision, dry mouth, bowel and bladder problems, cognitive dysfunction, and hallucinations.

Before the advent of deep brain stimulation, surgical treatment for Parkinson disease was limited to thalamotomy and pallidotomy performed using stereotactic surgery.[39–41] With these procedures, part of the thalamus or globus pallidus in the basal ganglia is destroyed using an electrical stimulator or supercooled tip of a metal probe (cryothalamotomy). Brain mapping is done during the surgery to identify and prevent injury to sensory and motor tracts. Thalamotomy and pallidotomy are generally confined to one side of the brain because of adverse effects associated with bilateral lesioning procedures. Surgical transplantation of adrenal medullary tissue or fetal substantia nigra tissue was studied in clinical trials, but neither was proven to be helpful.

Today, deep brain stimulation, which involves the implantation of electrodes into the subthalamic nuclei or the pars interna of the globus pallidus, is performed more frequently for treatment of Parkinson disease in the United States.[39,42] The electrodes are connected to a surgically implanted impulse generator that delivers electrical simulation to block the abnormal nerve activity that causes tremor and abnormal motor activity in Parkinson disease. The deep brain stimulation system allows the stimulation to be programmed to control the individual patient's symptoms, and the stimulation parameters can be changed over time as the disease progresses. Deep brain stimulation is used for persons with Parkinson disease who respond to levodopa but experience side effects associated with it (e.g., motor fluctuation or dyskinesia). It is not a cure but serves to increase the duration of the "on" periods, allows for a reduction in medication dosages (in subthalamic nuclei stimulation), and improves function. Of note, other movement disorders can be treated by placing electrodes in different target sites (e.g., thalamus for tremor and globus pallidus internus for dystonia).

In summary, alterations in coordination of muscle movements and abnormal muscle movements result from disorders of the cerebellum and basal ganglia. The functions of the cerebellum, which are especially vital during rapid muscular movements, use afferent input from various sources, including stretch receptors, proprioceptors, tactile receptors in the skin, visual input, and the vestibular system. Cerebellar disorders include vestibulocerebellar dysfunction, cerebellar ataxia, and cerebellar tremor.

The basal ganglia organize basic movement patterns into more complex patterns and release them when commanded by the motor cortex, contributing gracefulness to cortically initiated and controlled skilled movements. Disorders of the basal ganglia are characterized by involuntary movements, alterations in muscle tone, and disturbances in posture. These disorders include tremor, tics, hemiballismus, chorea, athetosis, dystonias, and dyskinesias.

Parkinsonism, a disorder of the basal ganglia, is characterized by destruction of the nigrostriatal pathway, with a subsequent reduction in striatal concentrations of dopamine. This results in an imbalance between the inhibitory effects of dopaminergic basal ganglia functions and an increase in the excitatory cholinergic functions. The disorder is manifested by resting tremor, increased muscle tonus and rigidity, slowness of movement (i.e., bradykinesia), gait disturbances, and impaired autonomic postural responses. The disease usually is slowly progressive over several decades, but the rate of progression varies from 2 to 30 years. The tremor often begins in one or both hands and then becomes generalized. Postural changes and gait disturbances continue to become more pronounced, resulting in significant disability.

Upper Motor Neuron Disorders

Upper motor neuron disorders involve neurons that are fully contained within the CNS. They include the motor neurons arising in the motor areas of the cortex and their fibers as they project through the brain and descend in the spinal cord. Disorders that affect UMNs include multiple sclerosis and spinal cord injury. Stroke, which is a common cause of UMN damage, is discussed in Chapter 37. Amyotrophic lateral sclerosis is a mixed UMN and LMN disorder.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), also known as *Lou Gehrig disease* after the famous New York Yankees baseball player, is a devastating neurologic disorder that selectively affects motor function. ALS has an annual incidence of about 2 cases per 100,000 population.[37] It is primarily a disorder of middle to late adulthood, with men being affected more frequently than women. The disease typically follows a progressive course, with a mean survival period of 2 to 5 years from the onset of symptoms.

ALS affects motor neurons in three locations: the anterior horn cells (LMNs) of the spinal cord; the motor nuclei of the brain stem, particularly the hypoglossal nuclei; and the UMNs of the cerebral cortex.[37,38,43–45] The fact that the disease is more extensive in the distal parts of the affected tracts in the lower spinal cord rather than the proximal parts suggests that affected neurons first undergo degeneration at their distal terminals and that the disease proceeds in a centripetal direction until ultimately the parent

nerve cell dies. The death of LMNs leads to denervation, with subsequent shrinkage of musculature and muscle fiber atrophy. It is this fiber atrophy, called *amyotrophy,* that appears in the name of the disease. The loss of nerve fibers in lateral columns of the white matter of the spinal cord, along with fibrillary gliosis, imparts a firmness or sclerosis to this CNS tissue; the term *lateral sclerosis* designates these changes. A remarkable feature of the disease is that the entire sensory system, the regulatory mechanisms of control and coordination of movement, and the intellect remain intact. The neurons for ocular motility and the parasympathetic neurons in the sacral spinal cord also are spared.

The etiology of ALS is largely unknown. Five percent to 10% of cases are familial; the others are believed to be sporadic, with no family history of the disease.[18,37] The gene for a subset of familial ALS has been mapped to superoxide dismutase 1 (*SOD1*) gene on chromosome 21. Possible targets of *SOD1*-induced toxicity include the neurofilament proteins, which function in the axonal transport of molecules necessary for maintenance of the axon.[44] Another suggested mechanism of pathogenesis in ALS is exotoxic injury through activation of glutamate-gated ion channels, which are distinguished by their sensitivity to *N*-methyl-D-aspartic acid (see Chapter 37). Although autoimmunity has been suggested as a cause of ALS, the disease does not respond to the immunosuppressant agents that normally are used in treatment of autoimmune disorders.

The symptoms of ALS may be referable to UMN or LMN involvement. Manifestations of UMN lesions include weakness, spasticity or stiffness, and impaired fine motor control.[43–45] Manifestations of LMN destruction include fasciculations, weakness, muscle atrophy, and hyporeflexia. Muscle cramps involving the distal legs often are an early symptom. The most common clinical presentation is slowly progressive weakness and atrophy in distal muscles of one upper extremity. This is followed by regional spread of clinical weakness, reflecting involvement of neighboring areas of the spinal cord. Eventually, UMNs and LMNs involving multiple limbs and the head are affected. In the more advanced stages, muscles of the palate, pharynx, tongue, neck, and shoulders become involved, causing impairment of chewing, swallowing (dysphagia), and speech. Dysphagia with recurrent aspiration and weakness of the respiratory muscles produces the most significant acute complications of the disease. Death usually results from involvement of cranial nerves and respiratory musculature.

Currently, there is no cure for ALS. The treatment of persons with ALS, which requires management of medical problems, severe disability, and psychosocial problems, is best provided by a multidisciplinary team.[43–45] Measures to assist persons with the disorder to manage their symptoms (e.g., weakness and muscle spasms, dysphagia, communication difficulty, excessive watery saliva, and emotional lability), nutritional status, and respiratory muscle weakness allow people with the disorder to survive longer than would otherwise have been the case. An antiglutamate drug, riluzole, is the only drug approved for the treatment of ALS.[43] The drug is designed to decrease glutamate accumulation and slow the progression of the disease.

Demyelinating Disorders of the Central Nervous System

Multiple Sclerosis

Multiple sclerosis (MS) is a demyelinating disorder characterized by inflammation and selective destruction of CNS myelin.[37,38,46–52] The peripheral nervous system is spared and there is usually no evidence of an associated systemic disease. It is the most common of the demyelinating disorders, having a prevalence of approximately 1 per 1000 persons in the United States and Europe.[37] The age of onset is typically between 20 and 40 years, with women being affected twice as frequently as men.

Multiple sclerosis is thought to be an immune-mediated disorder that occurs in genetically susceptible people. Although the target antigen has not been identified, the data suggest an immune response against the components of the myelin sheath. As with other autoimmune disorders, the pathogenesis appears to involve both genetic and environmental influences. The risk for developing MS is 15-fold higher when the disease is present in a first-degree relative, and is even greater in monozygotic twins.[37] People with the human leukocyte antigen (HLA)-DR2 haplotype (see Chapter 15) are particularly susceptible.

Pathophysiology. The pathophysiology of MS involves the demyelination of nerve fibers in the white matter of the brain, spinal cord, and optic nerve. In the CNS, myelin is formed by the oligodendrocytes, chiefly those lying among the nerve fibers in the white matter. This function of the oligodendrocytes is equivalent to that of the Schwann cells in the peripheral nervous system (see Chapter 34). The properties of the myelin sheath—high electrical resistance and low capacitance—permit it to function as an electrical insulator. Demyelinated nerve fibers display a variety of conduction abnormalities, ranging from decreased conduction velocity to conduction blocks.

The lesions of MS consist of hard, sharp-edged, demyelinated or sclerotic patches that are macroscopically visible throughout the white matter of the CNS (Fig. 36-13). These lesions, which represent the end result of acute myelin breakdown, are called *plaques*. The lesions have a predilection for the optic nerves, periventricular white matter, brain stem, cerebellum, and spinal cord white matter. In an active plaque, there is evidence of ongoing myelin breakdown. The sequence of myelin breakdown is not well understood, although it is known that the lesions contain small amounts of myelin basic proteins and increased amounts of proteolytic enzymes, macrophages, lymphocytes, and plasma cells. Oligodendrocytes are decreased in number and may be absent, especially in older lesions. Acute, subacute, and chronic lesions often are seen at multiple sites throughout the CNS.

MRI, which has had a major impact on the diagnosis and subsequent follow-up of MS, has shown that the lesions of MS may occur in two stages: a first stage that involves the sequential development of small inflammatory

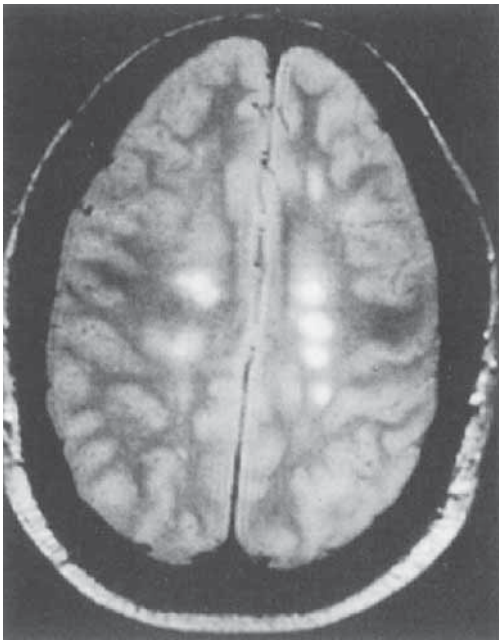

FIGURE 36-13. Axial T2-weighted image shows ovoid hyperintense lesions of multiple sclerosis in both hemispheres. (From Hickey J.V. [2008]. *The clinical practice of neurological & neurosurgical nursing* [6th ed., p. 699]. Philadelphia: Wolters Kluwer Health/Lippincott Williams & Wilkins.)

lesions, and a second stage during which the lesions extend and consolidate and when demyelination and gliosis (scar formation) occur. It is not known whether the inflammatory process, present during the first stage, is directed against myelin or against the oligodendrocytes that produce myelin. Remyelination of the nervous system was considered to be impossible until the late 1990s. Evidence now suggests that remyelination can occur in the CNS if the process that initiated the demyelination is halted before the oligodendrocyte dies.[50]

Manifestations and Clinical Course. The interruption of neural conduction in the demyelinated nerves in MS is manifested by a variety of symptoms, depending on the location and extent of the lesion.[48,51,52] Areas commonly affected are the optic nerve (visual field), corticobulbar tracts (speech and swallowing), corticospinal tracts (muscle strength), cerebellar tracts (gait and coordination), spinocerebellar tracts (balance), medial longitudinal fasciculus (conjugate gaze function of the extraocular eye muscles), and posterior cell columns of the spinal cord (position and vibratory sensation). Typically, an otherwise healthy person presents with an acute or subacute episode of paresthesias, optic neuritis (i.e., visual clouding or loss of vision in part of the visual field with pain on movement of the globe), diplopia, or specific types of gaze paralysis.

Paresthesias are evidenced as numbness, tingling, burning sensations, or pressure on the face or involved extremities, with symptoms ranging from annoying to severe. The *Lhermitte sign* is an electric shock–like tingling down the back and onto the legs that is produced by flexion of the neck. Pain from spasticity also may be a factor that can be alleviated by appropriate stretching exercises. Other common symptoms are abnormal gait, bladder and sexual dysfunction, vertigo, nystagmus, fatigue, and speech disturbance. These symptoms usually last for several days to weeks, and then completely or partially resolve. After a period of normal or relatively normal function, new symptoms appear. Psychological manifestations, such as mood swings, may represent an emotional reaction to the nature of the disease or, more likely, involvement of the white matter of the cerebral cortex. Depression, euphoria, inattentiveness, apathy, forgetfulness, and loss of memory may occur.

Fatigue is one of the most common problems for persons with MS. Fatigue often is described as a generalized low-energy feeling not related to depression and different from weakness. Fatigue has a harmful impact on activities of daily living and sustained physical activity. Interventions such as spacing activities and setting priorities often are helpful.

The course of the disease may fall into one of four categories: relapsing-remitting, secondary progressive, primary progressive, or progressive relapsing.[47] The *relapsing-remitting* form of the disease is characterized by episodes of acute worsening with recovery and a stable course between relapses. *Secondary progressive disease* involves a gradual neurologic deterioration with or without superimposed acute relapses in a person with previous relapsing-remitting disease. *Primary progressive disease* is characterized by nearly continuous neurologic deterioration from onset of symptoms. The *progressive relapsing* category of disease involves gradual neurologic deterioration from the onset of symptoms but with subsequent superimposed relapses.

Diagnosis. The diagnosis of MS is based on evidence of CNS lesions that are disseminated in time and space (i.e., occur in different parts of the CNS at least 3 months apart), with no explanation for the disease process.[51,52] MRI is a sensitive diagnostic tool that is used as an adjunct to clinical diagnosis. MRI studies can detect lesions even when CT scans appear normal. A computer-assisted method of MRI can measure lesion size. Many new areas of myelin abnormality are asymptomatic. Serial MRI studies can be done to detect asymptomatic lesions, monitor the progress of existing lesions, and evaluate the effectiveness of treatment. Although MRI can be used to provide evidence of disseminated lesions in persons with the disease, normal findings do not exclude the diagnosis. Electrophysiologic evaluations (e.g., evoked potential studies) and CT scans may assist in the identification and documentation of lesions.

Although no laboratory test can be used to diagnose MS, examination of the cerebrospinal fluid is helpful. A large percentage of patients with MS have elevated IgG levels, and some have oligoclonal patterns (i.e., discrete electrophoretic bands) even with normal IgG levels. Total

protein or lymphocyte levels may be mildly elevated in the cerebrospinal fluid. These test results can be altered in a variety of inflammatory neurologic disorders and are not specific for MS.

Treatment. Most treatment measures for MS are directed at modifying the course and managing the primary symptoms of the disease.[48,51,52] The variability in symptoms, unpredictable course, and lack of specific diagnostic methods has made the evaluation and treatment of MS difficult. Persons who are minimally affected by the disorder require no specific treatment. The person should be encouraged to maintain as healthy a lifestyle as possible, including good nutrition and adequate rest and relaxation. Physical therapy may help maintain muscle tone. Every effort should be made to avoid excessive fatigue, physical deterioration, emotional stress, viral infections, and extremes of environmental temperature, which may precipitate an exacerbation of the disease.

The pharmacologic agents used in the treatment of MS fall into three categories: those used to (1) treat acute attacks or initial demyelinating episodes, (2) modify the course of the disease, and (3) treat symptoms of the disorder. Corticosteroids are the mainstay of treatment for acute attacks of MS. These agents are thought to reduce the inflammation, improve nerve conduction, and have important immunologic effects. Long-term administration does not, however, appear to alter the course of the disease and can have harmful side effects. Adrenocorticotropic hormone (ACTH) also may be used in the treatment of MS. Plasmapheresis has also proved beneficial in some cases.

Disease-modifying agents include interferon-β1a, glatiramer acetate, and mitoxantrone.[48,51,53] These agents have shown some benefit in reducing exacerbations in persons with relapsing-remitting MS. Interferon-β is a cytokine that acts as an immune enhancer. Two forms of recombinant interferon have been approved by the FDA for treatment of MS—interferon-β1a and interferon-β1b. Both types of interferon are administered by injection, and both are usually well tolerated. Glatiramer acetate is a synthetic polypeptide that simulates parts of the myelin basic protein. Although the exact mechanism of action is unknown, the drug appears to block myelin-damaging T cells by acting as a myelin decoy. The drug is given daily by subcutaneous injection. Mitoxantrone, an anticancer drug, is recommended for persons with worsening forms of the disease. Because it is an anticancer drug, it is recommended that it only be administered by experienced health care professionals. Recently, natalizumab has also been approved for relapsing-remitting MS. Natalizumab is a monoclonal antibody against leukocyte α4 integrins, and its primary mechanism of action is suppression of leukocyte entry into the CNS. Other promising therapies that focus on immune-mediated disease mechanisms are currently in the development stages.

Among the medications used to manage the chronic problems associated with MS are dantrolene, baclofen, or diazepam for spasticity; cholinergic drugs for bladder problems; and antidepressant drugs for depression.

Vertebral and Spinal Cord Injury

Spinal cord injury (SCI) represents damage to the neural elements of the spinal cord. SCI is primarily a disorder of young people, with most injuries occurring in the 16- to 30-year age group.[54] The most common cause of SCI is motor vehicle accidents, followed by falls, violence (primarily gunshot wounds), and recreational sporting activities.[54] Life expectancy for persons with SCI continues to increase, but is somewhat below life expectancy for those without SCI. Mortality rates are significantly higher during the first year after injury than during subsequent years, particularly for severely injured persons.[54]

Most SCIs involve damage to the vertebral column or supporting ligaments as well as the spinal cord. Because of extensive tract systems that connect sensory afferent neurons and LMNs with higher brain centers, SCIs commonly involve both sensory and motor function. Although the discussion in this section of the chapter focuses on traumatic SCI, much of the content is applicable to SCI caused by other disorders, such as congenital deformities (e.g., spina bifida), tumors, ischemia and infarction, and bone disease with pathologic fractures of the vertebrae.

Injury to the Vertebral Column

Injuries to the vertebral column include fractures, dislocations, and subluxations. A fracture can occur at any part of the bony vertebrae, causing fragmentation of the bone. It most often involves the pedicle, lamina, or processes (e.g., facets). Dislocation or subluxation (partial dislocation) injury causes the vertebral bodies to become displaced, with one overriding another and preventing correct alignment of the vertebral column. Damage to the ligaments or bony vertebrae may make the spine unstable. In an unstable spine, further unguarded movement of the spinal column can impinge on the spinal canal, causing compression or overstretching of neural tissue.

Most injuries result from some combination of compressive force or bending movements.[18] Flexion injuries occur when forward bending of the spinal column exceeds the limits of normal movement. Typical flexion injuries result, for example, when the head is struck from behind, as in a fall with the back of the head as the point of impact. Extension injuries occur with excessive forced bending (i.e., hyperextension) of the spine backward. A typical extension injury involves a fall in which the chin or face is the point of impact, causing hyperextension of the neck. Injuries of flexion and extension occur more commonly in the cervical spine (C4 to C6) than in any other area. Limitations imposed by the ribs, spinous processes, and joint capsules in the thoracic and lumbar spine make this area less flexible and less susceptible to flexion and extension injuries than the cervical spine.

A compression injury, causing the vertebral bones to shatter, squash, or even burst, occurs when there is spinal loading from a high-velocity blow to the top of the head or when landing forcefully on the feet or buttocks[18] (Fig. 36-14A). This typically occurs at the cervical level (e.g., diving injuries) or in the thoracolumbar area (e.g., falling from a distance and landing on the

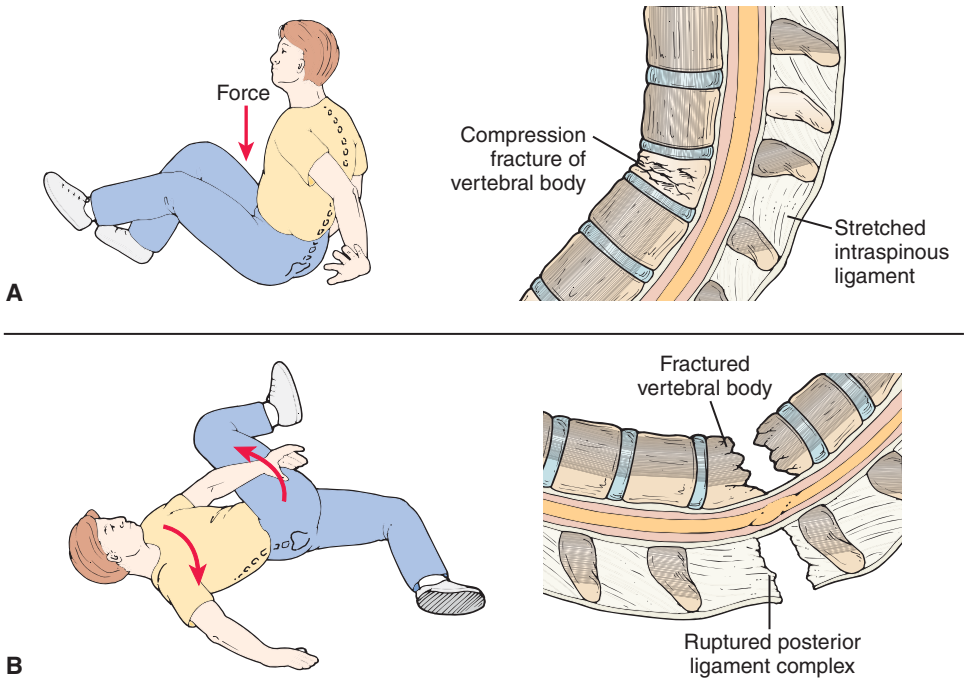

FIGURE 36-14. **(A)** Compression vertebral fracture secondary to axial loading as occurs when a person falls from a height and lands on the buttocks. **(B)** Rotational injury, in which there is concurrent fracture and tearing of the posterior ligamentous complex, is caused by extreme lateral flexion or twisting of the head or neck. (Modified from Hickey J.V. [2003]. *The clinical practice of neurological and neurosurgical nursing* [5th ed., pp. 411–412]. Philadelphia: Lippincott Williams & Wilkins.)

buttocks). Compression injuries may occur when the vertebrae are weakened by conditions such as osteoporosis and cancer with bone metastasis. Axial rotation injuries can produce highly unstable injuries. Maximal axial rotation occurs in the cervical region, especially between C1 and C2, and at the lumbosacral joint[18] (see Fig. 36-14B). Coupling of vertebral motions is common in injury when two or more individual motions occur (e.g., lateral bending and axial rotation).

Acute Spinal Cord Injury

Spinal cord injury involves damage to the neural elements of the spinal cord. The damage may result from direct trauma to the cord from penetrating wounds or indirect injury resulting from vertebral fractures, fracture-dislocations, or subluxations of the spine. The spinal cord may be contused, not only at the site of injury but also above and below the trauma site.[18] Traumatic injury may be complicated by the loss of blood flow to the cord, with resulting infarction.

Sudden, complete transection of the spinal cord results in complete loss of motor, sensory, reflex, and autonomic function below the level of injury. The immediate response to SCI is often referred to as *spinal cord shock*. It is characterized by flaccid paralysis with loss of tendon reflexes below the level of injury, absence of somatic and visceral sensations below the level of injury, and loss of bowel and bladder function. Loss of systemic sympathetic vasomotor tone may result in vasodilation, increased venous capacity, and hypotension. These manifestations occur regardless of whether the level of the lesion eventually will produce spastic (UMN) or flaccid (LMN) paralysis. The basic mechanisms accounting for transient spinal shock are unknown. Spinal shock may last for hours, days, or weeks. Usually, if reflex function returns by the time the person reaches the hospital, the neuromuscular changes are reversible. This type of reversible spinal shock may occur in football-type injuries, in which jarring of the spinal cord produces a concussion-like syndrome with loss of movement and reflexes, followed by full recovery within days. In persons in whom the loss of reflexes persists, hypotension and bradycardia may become critical but manageable problems. In general, the higher the level of injury, the greater is the effect.

Pathophysiology. The pathophysiology of acute SCI can be divided into two types: primary and secondary.[18,55–59] The *primary neurologic injury* occurs at the time of mechanical injury and is irreversible. It is characterized by small hemorrhages in the gray matter of the cord, followed by edematous changes in the white matter that lead to necrosis of neural tissue. This type of injury results from the forces of compression, stretch, and shear associated with fracture or compression of the spinal vertebrae, dislocation of vertebrae (e.g., flexion, extension, subluxation), and contusions due to jarring of the cord in the spinal canal. Penetrating injuries produce lacerations and direct trauma to the cord and may occur with or without spinal column damage. Lacerations occur when there is cutting or tearing of the spinal cord, which injures nerve tissue and causes bleeding and edema.

Secondary injuries follow the primary injury and promote the spread of injury. Although there is considerable debate about the pathogenesis of secondary injuries, the tissue destruction that occurs ends in progressive neurologic damage. After SCI, several pathologic mechanisms come into play, including vascular damage, neuronal injury that leads to loss of reflexes below the level of injury, and release of vasoactive agents and cellular enzymes. Vascular lesions (i.e., vessel trauma and hemorrhage) can lead to

ischemia, increased vascular permeability, and edema. Blood flow to the spinal cord may be further compromised by spinal shock that results from a loss of vasomotor tone and neural reflexes below the level of injury. The release of vasoactive substances (i.e., norepinephrine, serotonin, dopamine, and histamine) from the wound tissue causes vasospasm and impedes blood flow in the microcirculation, producing further necrosis of blood vessels and neurons. The release of proteolytic and lipolytic enzymes from injured cells causes delayed swelling, demyelination, and necrosis in the neural tissue in the spinal cord.

Management. The goal of management of acute SCI is to reduce the neurologic deficit and prevent any additional loss of neurologic function. The specific steps in resuscitation and initial evaluation can be carried out at the trauma site or in the emergency department, depending on the urgency of the situation.[18] Most traumatic injuries to the spinal column render it unstable, mandating measures such as immobilization with collars and backboards and limiting the movement of persons at risk for or with known SCI. Every person with multiple trauma or head injury, including victims of traffic and sporting accidents, should be suspected of having sustained an acute SCI.

The nature of the injury determines further methods of stabilization and treatment. In unstable injuries of the cervical spine, cervical traction improves or restores spinal alignment, decompresses neural structures, and facilitates recovery. Fractures and dislocations of the thoracic and lumbar vertebrae may be initially stabilized by restricting the person to bed rest and turning him or her in a log-rolling manner to keep the spine rigid. Gunshot or stab wounds of the spinal column may not produce structural instability and may not require immobilization.

The goal of early surgical intervention for an unstable spine is to provide internal skeletal stabilization so that early mobilization and rehabilitation can occur. One of the more important aspects of early SCI care is the prevention and treatment of spinal or systemic shock and the hypoxia associated with compromised respiration. Correcting hypotension or hypoxia is essential to maintaining circulation to the injured cord.[60]

The recognition that much of the posttraumatic degeneration of the spinal cord following injury is caused by secondary injuries has led to the search for neuroprotective strategies that would prevent or minimize these processes. Randomized controlled trials in the 1990s reported beneficial effects from a high-dose regimen of the glucocorticoid methylprednisolone administered soon after spinal cord injury.[61] In recent years, the use of high-dose methylprednisolone has become controversial, largely based on the risk of serious adverse effects (e.g., gastric bleeding, wound infection, venous thrombosis, and steroid myopathy) versus what is perceived to be a modest neurologic benefit.[62] Other neuroprotective agents, including monosialoganglioside sodium (GM-1 ganglioside), naloxone, and tirilazad, have been tested in multicenter clinical trials, but primary end points have not been achieved.[62] Recent investigations are exploring the effects of early cooling strategies (i.e., mild and moderate hypothermia) on recovery outcomes in persons with spinal cord injury.[63]

Types and Classification of Spinal Cord Injury

Alterations in body function that result from SCI depend on the level of injury and the amount of cord involvement. *Tetraplegia,* sometimes referred to as *quadriplegia,* is the impairment or loss of motor or sensory function (or both) after damage to neural structures in the cervical segments of the spinal cord.[18,64] It results in impairment of function in the arms, trunk, legs, and pelvic organs (see Fig. 36-4). *Paraplegia* refers to impairment or loss of motor or sensory function (or both) from damage of neural elements in the spinal canal in the thoracic, lumbar, or sacral segments of the spinal cord. With paraplegia, arm functioning is spared, but depending on the level of injury, functioning of the trunk, legs, and pelvic organs may be impaired. Paraplegia includes conus medullaris and cauda equina injuries (discussed later).

Further definitions of SCI describe the extent of neurologic damage as *complete* or *incomplete*[64] (Chart 36-1). Complete cord injuries can result from severance of the cord, disruption of nerve fibers although they remain intact, or interruption of blood supply to that segment, resulting in complete destruction of neural tissue and UMN or LMN paralysis. With complete injuries, no motor or

CHART 36-1 American Spinal Injury Association (ASIA) Impairment Scale

A = Complete: No motor or sensory function is preserved in sacral segments S4–S5.
B = Incomplete: Sensory but not motor function is preserved below the neurologic level and includes sacral segments S4–S5.
C = Incomplete: Motor function is preserved below the neurologic level, and more that half of the key muscles below the neurologic level have a muscle grade less than 3.
D = Incomplete: Motor function is preserved below the neurologic level, and at least half of the key muscles below the level of injury have a muscle grade of 3 or more.
E = Normal: Motor and sensory functions are normal.

Muscle grading: (0) total paralysis; (2) active movement, full range of motion, gravity eliminated; (3) active movement, full range of motion, against gravity; (4) active movement, full range of motion, against gravity and provides some resistance; (5) active movement, full range of motion, against gravity and provides normal resistance

Developed from the American Spinal Injury Association. (2002). *International standards for neurological classification of SCI, revised 2002.* Chicago: American Spinal Cord Injury Association.

sensory function is preserved in sacral segments S4 to S6. Incomplete SCI implies there is some residual motor or sensory function below the level of injury. The prognosis for return of function is better in an incomplete injury because of preservation of axonal function. Incomplete injuries may manifest in a variety of patterns, but can be organized into certain patterns or "syndromes" that occur more frequently and reflect the predominant area of the cord that is involved. Types of incomplete lesions include the central cord syndrome, anterior cord syndrome, Brown-Séquard syndrome, and conus medullaris syndrome.

Central Cord Syndrome. A condition called *central cord syndrome* occurs when injury is predominantly in the central gray or white matter of the cord (Fig. 36-15).[18] Because the corticospinal tract fibers are organized with those controlling the arms located more centrally and those controlling the legs located more laterally, some external axonal transmission may remain intact. Motor function of the upper extremities is affected, but the lower extremities may not be affected or may be affected to a lesser degree, with some sparing of sacral sensation. Bowel, bladder, and sexual functions usually are affected to various degrees, and this may parallel the degree of lower extremity involvement. This syndrome occurs almost exclusively in the cervical cord, rendering the lesion a UMN lesion with spastic paralysis. Central cord damage is more frequent in elderly persons with narrowing or stenotic changes in the spinal canal that are related to arthritis. Damage also may occur in persons with congenital stenosis.

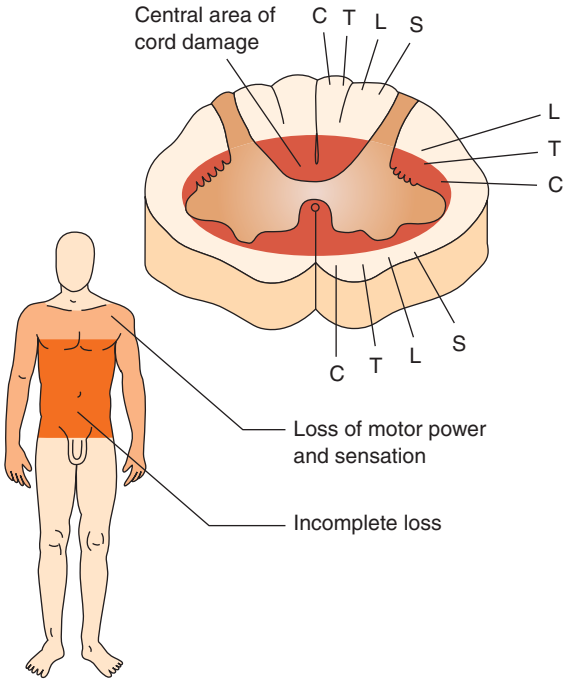

FIGURE 36-15. Central cord syndrome. A cross-section of the cord shows central damage and the associated motor and sensory loss. C, cervical; L, lumbar; S, sacral; T, thoracic. (From Kitt S., Kaiser J. [1990]. *Emergency nursing: A physiological and clinical perspective.* Philadelphia: W.B. Saunders.)

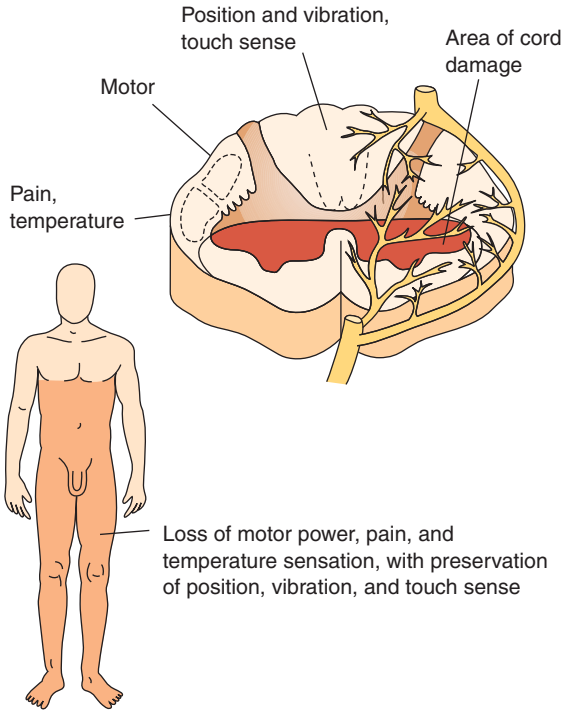

FIGURE 36-16. Anterior cord syndrome. Cord damage and associated motor and sensory loss are illustrated. (From Kitt S., Kaiser J. [1990]. *Emergency nursing: A physiological and clinical perspective.* Philadelphia: W.B. Saunders.)

Anterior Cord Syndrome. Anterior cord syndrome usually is caused by damage from infarction of the anterior spinal artery, resulting in damage to the anterior two thirds of the cord[18] (Fig. 36-16). The deficits include loss of motor function provided by the corticospinal tracts and loss of pain and temperature sensations from damage to the lateral spinothalamic tracts. The posterior one third of the cord is relatively unaffected, preserving the dorsal column axons that convey position, vibration, and touch sensations.

Brown-Séquard Syndrome. A condition called *Brown-Séquard syndrome* results from damage to a hemisection of the anterior and posterior cord[18] (Fig. 36-17). The effect is a loss of voluntary motor function from the corticospinal tract, proprioception loss from the ipsilateral side of the body, and contralateral loss of pain and temperature sensations from the lateral spinothalamic tracts for all levels below the lesion.

Conus Medullaris Syndrome. The conus medullaris syndrome involves damage to the conus medullaris or the sacral cord (i.e., conus) and lumbar nerve roots in the neural canal.[18] Functional deficits resulting from this type of injury usually result in flaccid bowel and bladder and altered sexual function. Sacral segments occasionally show preserved reflexes if only the conus is affected. Motor function in the legs and feet may be impaired

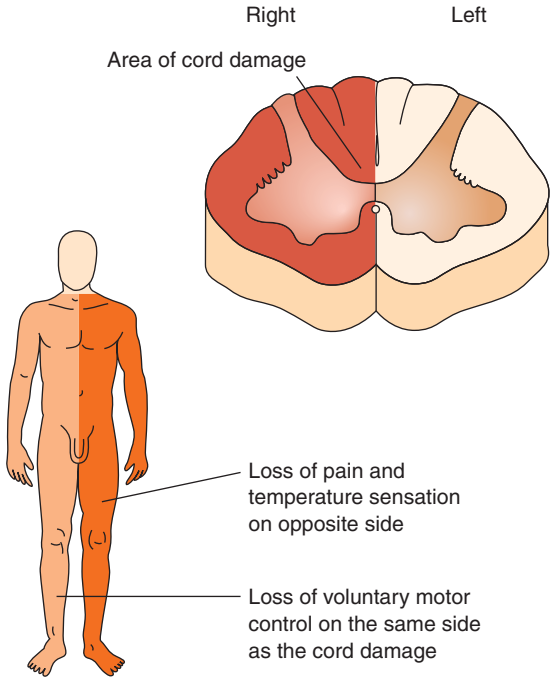

FIGURE 36-17. Brown-Séquard syndrome. Cord damage and associated motor and sensory loss are illustrated. (From Kitt S., Kaiser J. [1990]. *Emergency nursing: A physiological and clinical perspective.* Philadelphia: W.B. Saunders.)

without significant sensory impairment. Damage to the lumbosacral nerve roots in the spinal canal usually results in LMN and sensory neuron damage known as *cauda equina syndrome*. Functional deficits present as various patterns of asymmetric flaccid paralysis, sensory impairment, and pain.

Disruption of Somatosensory and Skeletal Muscle Function

Functional abilities after SCI are subject to various degrees of somatosensory and skeletal muscle function loss and altered reflex activity based on the level of cord injury and extent of cord damage (Table 36-2).

Motor and Somatosensory Function. Skeletal muscle function in cervical injuries ranges from complete dependence to independence with or without assistive devices in activities of mobility and self-care. The functional levels of cervical injury are related to C5, C6, C7, or C8 innervation. At the C5 level, deltoid and biceps function is spared, allowing full head, neck, and diaphragm control with good shoulder strength and full elbow flexion. At the C6 level, wrist dorsiflexion by the wrist extensors is functional, allowing tenodesis, which is the natural bending inward and flexion of the fingers when the wrist is extended and bent backward. Tenodesis is a

TABLE 36-2 Functional Abilities by Level of Cord Injury

Injury Level	Segmental Sensorimotor Function	Dressing, Eating	Elimination	Mobility*
C1	Little or no sensation or control of head and neck; no diaphragm control; requires continuous ventilation	Dependent	Dependent	Limited. Voice-controlled or sip-n-puff electric wheelchair
C2–C3	Head and neck sensation; some neck control. Independent of mechanical ventilation for short periods	Dependent	Dependent	Same as for C1
C4	Good head and neck sensation and motor control; some shoulder elevation; diaphragm movement	Dependent; may be able to eat with adaptive sling	Dependent	Limited to voice-, mouth-, head-, chin-, or shoulder-controlled electric wheelchair
C5	Full head and neck control; shoulder strength; elbow flexion	Independent with assistance	Maximal assistance	Electric or modified manual wheelchair, needs transfer assistance
C6	Fully innervated shoulder; wrist extension or dorsiflexion	Independent or with minimal assistance	Independent or with minimal assistance	Independent in transfers and wheelchair
C7–C8	Full elbow extension; wrist plantar flexion; some finger control	Independent	Independent	Independent; manual wheelchair
T1–T5	Full hand and finger control; use of intercostal and thoracic muscles	Independent	Independent	Independent; manual wheelchair
T6–T10	Abdominal muscle control, partial to good balance with trunk muscles	Independent	Independent	Independent; manual wheelchair
T11–L5	Hip flexors, hip abductors (L1–3); knee extension (L2–4); knee flexion and ankle dorsiflexion (L4–5)	Independent	Independent	Short distance to full ambulation with assistance
S1–S5	Full leg, foot, and ankle control; innervation of perineal muscles for bowel, bladder, and sexual function (S2–4)	Independent	Normal to impaired bowel and bladder function	Ambulate independently with or without assistance

*Assistance refers to adaptive equipment, setup, or physical assistance.

key movement because it can be used to pick up objects when finger movement is absent. A functional C7 injury allows full elbow flexion and extension, wrist plantar flexion, and some finger control. At the C8 level, finger flexion is added.

Thoracic cord injuries (T1 to T12) allow full upper extremity control with limited to full control of intercostal and trunk muscles and balance. Injury at the T1 level allows full fine motor control of the fingers. Because of the lack of specific functional indicators at the thoracic levels, the level of injury usually is determined by sensory level testing.

Functional capacity in the L1 through L5 nerve innervations allows hip flexion, hip abduction (L1 to L3), movement of the knees (L2 to L5), and ankle dorsiflexion (L4 to L5). Sacral (S1 to S5) innervation allows for full leg, foot, and ankle control and innervation of perineal musculature for bowel, bladder, and sexual function.

Reflex Activity. Spinal cord reflexes are fully integrated in the spinal cord and can function independent of input from higher centers. Altered spinal reflex activity after SCI is essentially determined by the level of injury and whether UMNs or LMNs are affected. With UMN injuries at T12 and above, the cord reflexes remain intact, whereas communication pathways with higher centers have been interrupted. This results in spasticity of involved skeletal muscle groups and of smooth and skeletal muscles that control bowel, bladder, and sexual function. In LMN injuries at T12 or below, the reflex circuitry itself has been damaged at the level of the spinal cord or spinal nerve, resulting in a decrease or absence of reflex function. The LMN injuries cause flaccid paralysis of involved skeletal muscle groups and the smooth and skeletal muscles that control bowel, bladder, and sexual function. However, injuries near the T12 level may result in mixed UMN and LMN deficits (e.g., spastic paralysis of the bowel and bladder with flaccid muscle tone).

After the period of spinal shock in a UMN injury, isolated spinal reflex activity and muscle tone that are not under the control of higher centers return. This may result in hypertonia and spasticity of skeletal muscles below the level of injury.[18] These spastic movements are involuntary instead of voluntary, a distinction that needs to be explained to persons with SCI and their families. The antigravity muscles, the flexors of the arms and extensors of the legs, are predominantly affected. Spastic movements are usually heightened initially after injury, reaching a peak and then becoming stable in approximately 1.5 to 2 years.[18]

The stimuli for reflex muscle spasm arise from somatic and visceral afferent pathways that enter the cord below the level of injury. The most common of these stimuli are muscle stretching, bladder infections or stones, fistulas, bowel distention or impaction, pressure areas or irritation of the skin, and infections. Because the stimuli that precipitate spasms vary from person to person, careful assessment is necessary to identify the factors that precipitate spasm in each person. Passive range-of-motion exercises to stretch the spastic muscles help to prevent spasm induced by muscle stretching, such as occurs with a change in body position.

Spasticity in itself is not detrimental and may even facilitate maintenance of muscle tone to prevent muscle wasting, improve venous return, and aid in mobility. Spasms become detrimental when they impair safety; they also reduce the ability to make functional gains in mobility and activities of daily living. Spasms also may cause trauma to bones and tissues, leading to joint contractures and skin breakdown.

Respiratory Muscle Function. Ventilation requires movement of the expiratory and inspiratory muscles, all of which receive innervation from the spinal cord.[65] The main muscle of ventilation, the diaphragm, is innervated by segments C3 to C5 through the phrenic nerves. The intercostal muscles, which function in elevating the rib cage and are needed for coughing and deep breathing, are innervated by spinal segments T1 through T7. The major muscles of expiration are the abdominal muscles, which receive their innervation from levels T6 to T12.

Although the ability to inhale and exhale may be preserved at various levels of SCI, functional deficits in ventilation are most apparent in the quality of the breathing cycle and the ability to oxygenate tissues, eliminate carbon dioxide, and mobilize secretions. Cord injuries involving C1 to C3 result in a lack of respiratory effort, and affected patients require assisted ventilation. Although a C3 to C5 injury allows partial or full diaphragmatic function, ventilation is diminished because of the loss of intercostal muscle function, resulting in shallow breaths and a weak cough. Below the C5 level, as less intercostal and abdominal musculature is affected, the ability to take a deep breath and cough is less impaired. Maintenance therapy consists of muscle training to strengthen existing muscles for endurance and mobilization of secretions. The ability to speak is compromised with assisted ventilation, whether continuous or intermittent. Thus, ensuring adequate communication of needs is also essential.

Disruption of Autonomic Nervous System Function

In addition to its effects on skeletal muscle function, SCI interrupts autonomic nervous system function below the site of injury.[66] This includes sympathetic outflow from the thoracic and upper lumbar cord and parasympathetic outflow from the sacral cord. Because of their sites of exit from the CNS, the cranial nerves, such as the vagus, are unaffected. Depending on the level of injury, the spinal reflexes that control autonomic nervous system function are largely isolated from the rest of the CNS. Afferent sensory input that enters the spinal cord is unaffected, as is the efferent motor output from the cord. Lacking are the regulation and integration of reflex function by centers in the brain and brain stem. This results in a situation in which the autonomic reflexes below the level of injury are uncontrolled, whereas those above the level of injury function in a relatively controlled manner.

Sympathetic nervous system regulation of circulatory function and body temperature (i.e., thermoregulation)

presents some of the most severe problems in SCI. The higher the level of injury and the greater the surface area affected, the more profound are the effects on circulation and thermoregulation. Persons with injury at the T6 level or above experience problems in regulating vasomotor tone, whereas those with injuries below the T6 level usually have sufficient sympathetic function to maintain adequate vasomotor function. The level of injury and its corresponding problems may vary among persons, and some dysfunctional effects may be seen at levels below T6. With lower lumbar and sacral injuries, sympathetic function remains essentially unaltered.

Vasovagal Response. The vagus nerve (cranial nerve X), which is unaffected in SCI, normally exerts a continuous inhibitory effect on heart rate. Vagal stimulation that causes a marked bradycardia is called the *vasovagal response*. Visceral afferent input to the vagal centers in the brain stem of persons with tetraplegia or high-level paraplegia can produce marked bradycardia when unchecked by a dysfunctional sympathetic nervous system. Severe bradycardia and even asystole can result when the vasovagal response is elicited by deep endotracheal suctioning or rapid position change. Preventive measures, such as hyperoxygenation before, during, and after tracheal suctioning, are advised. Rapid position changes should be avoided or anticipated, and anticholinergic drugs should be immediately available to counteract severe episodes of bradycardia.

Autonomic Dysreflexia. Autonomic dysreflexia, also known as *autonomic hyperreflexia,* represents an acute episode of exaggerated sympathetic reflex responses that occur in persons with injuries at T6 and above, in which CNS control of spinal reflexes is lost (Fig. 36-18). It does not occur until spinal shock has resolved and autonomic

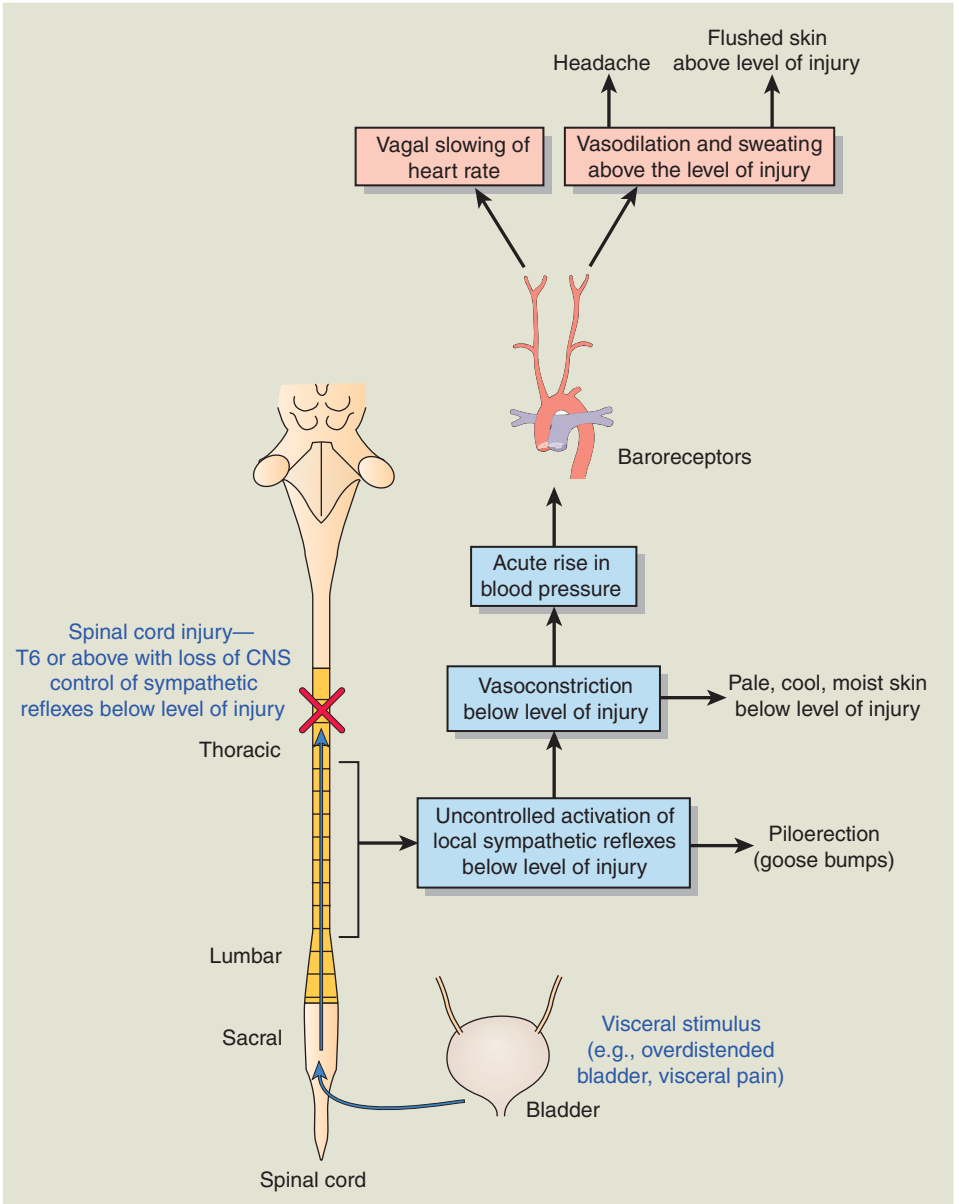

FIGURE 36-18. Mechanisms of autonomic dysreflexia.

reflexes return, most often within the first 6 months after injury. It is most unpredictable during the first year after injury, but can occur throughout the person's lifetime.

Autonomic dysreflexia is characterized by vasospasm, hypertension ranging from mild (20 mm Hg above baseline) to severe (as high as 240/120 mm Hg, or higher), skin pallor, and gooseflesh associated with the piloerector response.[67] Because baroreceptor function and parasympathetic control of heart rate travel by way of the cranial nerves, these responses remain intact. Continued hypertension produces a baroreflex-mediated vagal slowing of the heart rate to bradycardic levels. There is an accompanying baroreflex-mediated vasodilation, with flushed skin and profuse sweating above the level of injury, headache ranging from dull to severe and pounding, nasal stuffiness, and feelings of anxiety. A person may experience one, several, or all of the symptoms with each episode.

The stimuli initiating the dysreflexic response include visceral distention, such as a full bladder or rectum; stimulation of pain receptors, as occurs with pressure ulcers, dressing changes, and diagnostic or operative procedures; and visceral contractions, such as ejaculation, bladder spasms, or uterine contractions. In many cases, the dysreflexic response results from a full bladder.

Autonomic dysreflexia is a clinical emergency, and without prompt and adequate treatment, convulsions, loss of consciousness, and even death can occur. The major components of treatment include monitoring blood pressure while removing or correcting the initiating cause or stimulus. The person should be placed in an upright position, and all support hose or binders should be removed to promote venous pooling of blood and reduce venous return, thereby decreasing blood pressure. If the stimuli have been removed or the stimuli cannot be identified and the upright position is established, but the blood pressure remains elevated, drugs that block autonomic function are administered. Prevention of the type of stimuli that trigger the dysreflexic event is advocated.

Postural Hypotension. Postural, or orthostatic, hypotension usually occurs in persons with injuries at T4 to T6 and above and is related to the interruption of descending control of sympathetic outflow to blood vessels in the extremities and abdomen.[66] Pooling of blood, along with gravitational forces, impairs venous return to the heart, and there is a subsequent decrease in cardiac output when the person is placed in an upright position. The signs of orthostatic hypotension include dizziness, pallor, excessive sweating above the level of the lesion, complaints of blurred vision, and possibly fainting. Postural hypotension usually is prevented by slow changes in position and measures to promote venous return.

Disruption of Bladder, Bowel, and Sexual Function

Among the most devastating consequences of SCI is the loss of bowel, bladder, and sexual function.[68] Loss of bladder function results from disruption of neural pathways between the bladder and the reflex voiding center at the S2 to S4 level (i.e., a LMN lesion) or between the reflex voiding center and higher brain centers for communication and coordinated sphincter control (i.e., a UMN lesion). Persons with UMN lesions or spastic bladders lack awareness of bladder filling (i.e., storage) and voluntary control of voiding (i.e., evacuation). In LMN lesions or flaccid bladder dysfunction, lack of awareness of bladder filling and lack of bladder tone render the person unable to void voluntarily or involuntarily (see Chapter 27).

Bowel elimination is a coordinated function involving the enteric nervous system, the autonomic nervous system, and the CNS. Persons with SCI above S2 to S4 develop spastic functioning of the defecation reflex and loss of voluntary control of the external anal sphincter. Damage to the cord at the S2 to S4 level causes flaccid functioning of the defecation reflex and loss of anal sphincter tone. Even though the enteric nervous system innervation of the bowel remains intact, without the defecation reflex, peristaltic movements are ineffective in evacuating stool.

Sexual function, like bladder and bowel control, is mediated by the S2 to S4 segments of the spinal cord.[18] The genital sexual response in SCI, which is manifested by an erection in men and vaginal lubrication in women, may be initiated by mental or touch stimuli, depending on the level of injury. The T11 to L2 cord segments have been identified as the mental-stimulus, or psychogenic, sexual response area, where autonomic nerve pathways in communication with the forebrain leave the cord and innervate the genitalia. The S2 to S4 cord segments have been identified as the sexual-touch reflex center. In T10 or higher injuries, reflex sexual response to genital touch may occur freely. However, a sexual response to mental stimuli (T11 to L2) does not occur because of the spinal lesion blocking the communication pathway. In an injury at T12 or below, the sexual reflex center may be damaged, and there may be no response to touch.

In men, the lack of erectile ability or inability to experience penile sensations or orgasm is not a reliable indicator of fertility, which should be evaluated by an expert. In women, fertility is normally reestablished with the return of menses, which usually occurs at about 3 months to 5 months after injury. There are hazards to pregnancy, labor, and use of birth control devices relative to SCI that require the services of knowledgeable health care providers.

Disruption of Other Functions

Temperature Regulation. The central mechanisms for thermoregulation are located in the hypothalamus. In response to cold, the hypothalamus stimulates vasoconstrictor responses in peripheral blood vessels, particularly those of the skin. This results in decreased loss of body heat. Heat production results from increased metabolism, voluntary activity, or shivering. To reduce heat, hypothalamus-stimulated mechanisms produce vasodilation of skin blood vessels to dissipate heat and sweating to increase evaporative heat losses.

After SCI, the communication between the thermoregulatory centers in the hypothalamus and the sympathetic effector responses below the level of injury is

disrupted; the ability to control blood vessel responses that conserve or dissipate heat is lost, as are the abilities to sweat and shiver. Higher levels of injury tend to produce greater disturbances in thermoregulation. In tetraplegia and high paraplegia, there are few defenses against changes in the environmental temperature, and body temperature tends to assume the temperature of the external environment, a condition known as *poikilothermy*. Persons with lower-level injuries have various degrees of thermoregulation. Disturbances in thermoregulation are chronic and may cause continual loss of body heat. Treatment consists of education in the adjustment of clothing and awareness of how environmental temperatures affect the person's ability to accommodate to these changes.

Deep Vein Thrombosis and Edema. Persons with SCI are at high risk for development of deep vein thrombosis (DVT) and pulmonary embolism, particularly during the first 2 to 3 weeks after injury.[69] The high risk for DVT in patients with acute SCI is due to immobility, decreased vasomotor tone below the level of injury, and hypercoagulability and stasis of blood flow. Prevention strategies include the use of low–molecular-weight heparin, thigh-high graduated compression stockings, sequential compression boots, and early mobilization.[18] Electrical stimulation applied to the lower limbs has been reported to provide some benefit by achieving muscular contraction and improving venous flow. Local pain, a common symptom of DVT, is often absent because of sensory deficits. Thus, a regular schedule of visual inspection for local signs of DVT (e.g., swelling) is important. Testing of persons at high risk for DVT includes plethysmography and duplex ultrasonography.

Edema is also a common problem in persons with SCI. The development of edema is related to decreased peripheral vascular resistance, decreased muscle tone in the paralyzed limbs, and immobility that causes increased venous pressure and abnormal pooling of blood in the abdomen, lower limbs, and upper extremities. Edema in the dependent body parts usually is relieved by positioning to minimize gravitational forces or by using compression devices (e.g., support stockings, binders) that encourage venous return.

Skin Integrity. The entire surface of the skin is innervated by cranial or spinal nerves organized into dermatomes that show cutaneous distribution. The CNS and autonomic nervous system also play a vital role in skin function. The sympathetic nervous system, through control of vasomotor and sweat gland activity, influences the health of the skin by providing adequate circulation, excretion of body fluids, and temperature regulation. The lack of sensory warning mechanisms and voluntary motor ability below the level of injury, coupled with circulatory changes, places the spinal cord–injured person at major risk for disruption of skin integrity (see Chapter 46). Significant factors associated with disruption of skin integrity are pressure, shearing forces, and localized trauma and irritation. Relieving pressure, allowing adequate circulation to the skin, and skin inspection are primary ways of maintaining skin integrity. Of all the complications after SCI, skin breakdown is the most preventable.

Future Directions in Repair of the Injured Spinal Cord

There is a continued effort to determine new and innovative strategies for repairing the injured spinal cord.[70,71] At present, these strategies focus on promoting the regrowth of interrupted nerve fiber tracts, using nerve growth–stimulating factors or molecules that suppress inhibitors of neuronal extension; bridging spinal cord lesions with scaffolds that are impregnated with nerve growth factors, which promote axon growth and reduce the barriers caused by scar tissue; repairing damaged myelin and restoring nerve fiber conductivity in the lesion area; and enhancing CNS plasticity by promoting compensatory growth of spared, intact nerve fibers above and below the level of injury. Although these strategies may not allow for complete repair of the spinal cord so as to recreate what was present before the injury, even small successes may be useful for someone with SCI. For a person with an injury in the cervical region, "a return of function over even one spinal segment would improve the quality of life, while return to function over three or four segments would transform it."[71]

In summary, UMN lesions are those involving neurons completely contained in the CNS. Amyotrophic lateral sclerosis is a progressive and devastating neurologic disorder that selectively affects motor function. It affects LMNs in the spinal cord as well as UMNs in the brain stem and cerebral cortex. Multiple sclerosis is a slowly progressive demyelinating disease of the CNS. The most common symptoms are paresthesias, optic neuritis, and motor weakness. The disease is usually characterized by exacerbations and remissions. Initially, near-normal function returns between exacerbations.

Spinal cord injury (SCI) is a disabling neurologic condition most commonly caused by motor vehicle accidents, falls, and sports injuries. Dysfunctions of the nervous system after SCI consist of various degrees of sensorimotor loss and altered reflex activity based on the level of injury and extent of cord damage. Depending on the level of injury, the physical problems of SCI include spinal shock; ventilation and communication problems; autonomic nervous system dysfunction that predisposes to the vasovagal response, autonomic hyperreflexia, impaired body temperature regulation, and postural hypotension; impaired muscle pump and venous innervation leading to edema of dependent areas of the body and risk for deep vein thrombosis; altered sensorimotor integrity that contributes to uncontrolled muscle spasms, altered pain responses, and threats to skin integrity; alterations in bowel and bladder elimination; and impaired sexual function.

REVIEW EXERCISES

1. A 32-year-old woman presents with complaints of "drooping eyelids," difficulty chewing and swallowing, and weakness of her arms and legs that is less severe in the morning but becomes worse as the day progresses. She complains that climbing stairs and lifting objects are becoming increasingly difficult. Clinical examination confirms weakness of the eyelid and jaw muscles. She is told that she may have myasthenia gravis and is scheduled for testing using the short-acting acetylcholinesterase inhibitor edrophonium (Tensilon).

A. Explain the pathogenesis of this woman's symptoms as it relates to myasthenia gravis.
B. Explain how information from the administration of the acetylcholinesterase inhibitor edrophonium can be used to assist in the diagnosis of the disorder.

2. A 20-year-old man suffered spinal cord injury at the C2 to C3 level as the result of a motorcycle accident.

A. Explain the effects of this man's injury on ventilation and communication; sensorimotor function; autonomic nervous system function; bowel, bladder, and sexual function; and temperature regulation.
B. Autonomic dysreflexia, which is a threat to persons with spinal cord injuries at T6 or above, is manifested by hypertension, often to extreme levels, and bradycardia; constriction of skin vessels below the level of injury; and severe headache and nasal stuffiness. Explain the origin of the elevated blood pressure and bradycardia. The condition does not occur until spinal shock has resolved, and usually occurs only in persons with injuries at T6 and above. Explain.

Chapter 37

Disorders of Brain Function

Anatomically and functionally, the brain is the most complex structure in the body. It controls our ability to think, our awareness of things around us, and our interactions with the outside world. Signals to and from various parts of the body are controlled by very specific areas in the brain. Therefore, the brain is much more vulnerable to focal lesions that in other organs might produce no significant effects. For example, an isolated renal infarct would not be expected to have a significant effect on kidney function, whereas an infarct of comparable size in a specific area of the brain could produce complete paralysis on one side of the body.[1]

Mechanisms and Manifestations of Brain Injury

The brain is protected from external forces by the rigid confines of the skull and the cushioning afforded by the cerebrospinal fluid (CSF). The metabolic stability required by its electrically active cells is maintained by a number of regulatory mechanisms, including the blood-brain barrier and autoregulatory mechanisms that ensure its blood supply.

Mechanisms of Brain Injury

Injury to brain tissue can result from a number of conditions, including ischemia, trauma, infections, tumors, and degenerative processes. Brain damage resulting from these disorders involves several common pathways, including hypoxia and ischemia, the effects of excitatory amino acid injury, and cerebral edema. In many cases, the mechanisms of injury are interrelated.

Hypoxic and Ischemic Injury

The brain relies on the ability of the cerebral circulation to deliver sufficient oxygen for its energy needs. Although the brain makes up only 2% of the body weight, it receives one sixth of the resting cardiac output and accounts for 20% of the body's oxygen consumption.[1,2] By definition, *hypoxia* denotes a deprivation of oxygen with maintained blood flow, whereas *ischemia* represents

a situation of greatly reduced or interrupted blood flow. The cellular effects of hypoxia and ischemia are quite different, and the brain tends to have different sensitivities to the two conditions. Hypoxia interferes with the delivery of oxygen, while ischemia interferes with the delivery of oxygen and glucose as well as the removal of metabolic wastes.

Hypoxia usually is seen in conditions such as exposure to reduced atmospheric pressure, carbon monoxide poisoning, severe anemia, and failure of the lungs to oxygenate the blood. Contrary to popular belief, hypoxia is fairly well tolerated, particularly in situations of chronic hypoxia. Neurons are capable of substantial anaerobic metabolism and are fairly tolerant of pure hypoxia; it commonly produces euphoria, listlessness, drowsiness, and impaired problem solving. Unconsciousness and convulsions may occur when hypoxia is sudden and severe. However, the effects of severe hypoxia (i.e., anoxia) on brain function seldom are seen because the condition rapidly leads to cardiac arrest and ischemia.

Ischemia is seen in conditions of low blood flow. Cerebral ischemia can be focal, as in a stroke due to cerebral artery occlusion, or global, as in cardiac arrest.[3] Cerebral arterial occlusion leads to focal ischemia, and if sustained, to infarction of brain tissue in the distribution of the affected vessel. The location of the infarct and extent of tissue damage that results is determined by modifying variables, of which collateral blood flow is the most important. The collateral perfusion may even provide sufficient substrates to the borders of the focal ischemic region to maintain a low level of metabolic activity, thereby preserving tissue integrity.

Global Ischemia. Global ischemia occurs when blood flow is inadequate to meet the metabolic needs of the entire brain.[3] The result is a spectrum of neurologic disorders reflecting diffuse brain dysfunction. Unconsciousness occurs within seconds of severe global ischemia, such as that resulting from cardiac arrest. If cerebral circulation is restored immediately, consciousness is regained quickly. The unique vulnerability of the brain is attributed to its limited tolerance of ischemia and its response to reperfusion. The metabolic depletion of energy associated with ischemia can result in inappropriate release of excitatory amino acid neurotransmitters, disrupted calcium homeostasis, free radical formation, mitochondrial injury, and activation of cell-death pathways.[1,4] Although the threshold for ischemic neuronal injury is unknown, there is a period during which neurons can survive if blood flow is reestablished. Unfortunately, brain injury may not be reversible if the duration of ischemia is such that the threshold of injury has been reached. Even after circulation has been reestablished, damage to blood vessels and changes in blood flow can prevent return of adequate tissue perfusion. This period of postischemic hypoperfusion is thought to be associated with mechanisms such as the level of desaturation of venous blood, capillary and venular clotting, or sludging of blood.

Within the brain, certain regions and cell populations are more susceptible than others to hypoxic-ischemic injury[5] (Fig. 37-1). Selective neuronal sensitivity to a lack of oxygen is most apparent in the Purkinje cells of the cerebellum and neurons in the Sommer sector of the hippocampus, where cell death occurs earliest after global ischemia. The anatomic arrangement of the cerebral blood vessels predisposes to two types of injury: watershed infarcts and laminar necrosis. Areas of the brain located at the border zones between the overlapping territories supplied by the major cerebral arteries, sometimes called the *watershed areas*, are extremely vulnerable to ischemia. During events such as severe hypotension, these distal territories undergo a profound lowering of blood flow, predisposing to ischemia and infarction of brain tissues. As a consequence, areas of the cortex that are supplied by the major cerebral arteries usually regain function on recovery of adequate blood flow; however, infarctions may occur in the watershed boundary strips, resulting in focal neurologic deficits.

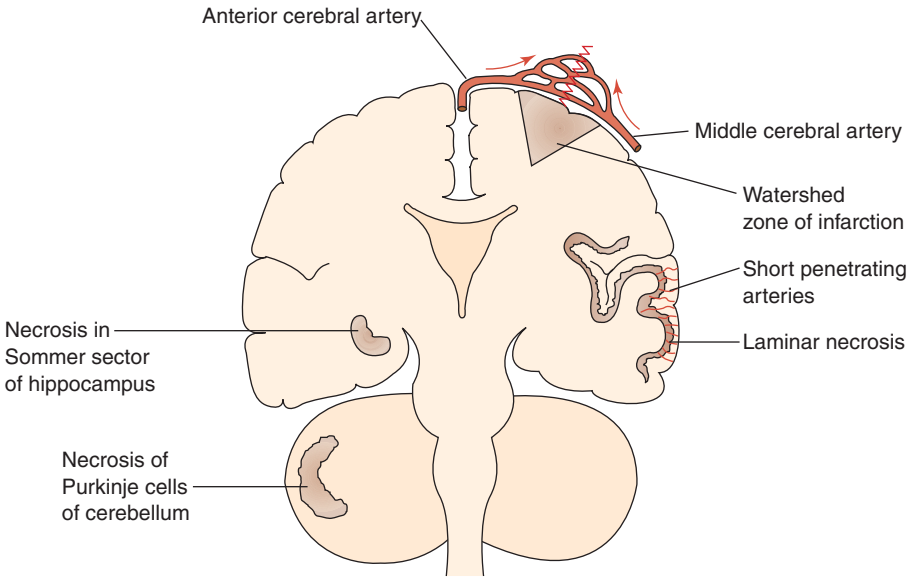

FIGURE 37-1. Consequences of global ischemia. A global insult induces lesions that reflect the vascular architecture (watershed infarcts, laminar necrosis) and the sensitivity of individual neuronal systems (pyramidal cells of the Sommer section, Purkinje cells). (Courtesy of Dmitri Karetnikov, artist.) (From Trojanowsi J.Q., Kenyon L. [2008]. The central nervous system. In Rubin R., Strayer D.E. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1191]. Philadelphia: Lippincott Williams & Wilkins.)

Laminar necrosis refers to short, creeping segments of necrosis that occur within and parallel to the cerebral cortex, in areas supplied by the penetrating arteries. The gray matter of the cerebral cortex receives its major blood supply through short penetrating arteries that emerge at right angles from larger vessels in the pia mater and then form a cascade as they repeatedly branch, forming a rich capillary network. An abrupt loss of arterial blood pressure markedly diminishes flow through these capillary channels.

Treatment of global cerebral ischemia varies with the underlying cause (e.g., cardiac arrest, shock, asphyxia). General goals common to all causes are aimed at providing oxygen to the troubled brain and decreasing the metabolic needs of brain tissue during the nonflow state. Hemodynamic support aimed at restoring systemic and cerebral perfusion is required. Respiratory support including mechanical ventilation and supplemental oxygen may be indicated. Mild therapeutic hypothermia (i.e., 32°C to 34°C) for 12 to 24 hours is now recommended as an effective therapy for post–cardiac arrest syndrome.[4,6] Normovolemic hemodilution may be used to overcome sludging of cerebral blood flow during reperfusion. Because both hypoglycemia and hyperglycemia adversely affect the outcome in persons with global ischemia, control of blood glucose within a range of 80 to 110 mg/dL (4.4 to 6.1 mmol/L) is appropriate.[4]

Excitatory Amino Acid Injury

In many neurologic disorders, injury to neurons may be caused by various mediators, including excitatory amino acids, catecholamines, free radicals, inflammatory cells, and intracellular proteases.[3] The earliest and most studied of these is the overstimulation of receptors for specific amino acids such as glutamate.[7,8] The neurologic conditions involved in excitotoxic injury range from acute insults due to conditions such as stroke, hypoglycemic injury, and trauma to chronic degenerative disorders such as Huntington disease and possibly Alzheimer dementia.

Many of the actions of glutamate are coupled with receptor-operated ion channels. One subtype in particular, the glutamate *N*-methyl-D-aspartate (NMDA) receptor, has been implicated in causing central nervous system (CNS) injury. This glutamate receptor subtype opens a large-diameter calcium channel that permits calcium ions to enter the cell. During prolonged ischemia, metabolic depletion of adenosine triphosphate (ATP) results in the inappropriate release of glutamate, initiating cell damage by allowing excessive influx of calcium ions. Excess intracellular calcium leads to a series of calcium-mediated processes called the *calcium cascade* (Fig. 37-2), which results in the release of intracellular enzymes that cause protein breakdown, free radical formation, lipid peroxidation, deoxyribonucleic acid (DNA) fragmentation, mitochondrial injury, nuclear breakdown, and eventually cell death.

The effects of acute glutamate toxicity may be reversible if the excess glutamate can be removed or if its effects can be blocked before the full cascade of events progresses. Various strategies that would protect viable brain cells from irreversible damage in the setting of excitotoxicity are currently under investigation. Pharmacologic strategies being explored include those that inhibit the synthesis or release of excitatory amino acid transmitters; block the NMDA receptors; prevent initiation of the calcium cascade; and block intracellular proteases, endonucleases, and lipases that are known to be cytotoxic.

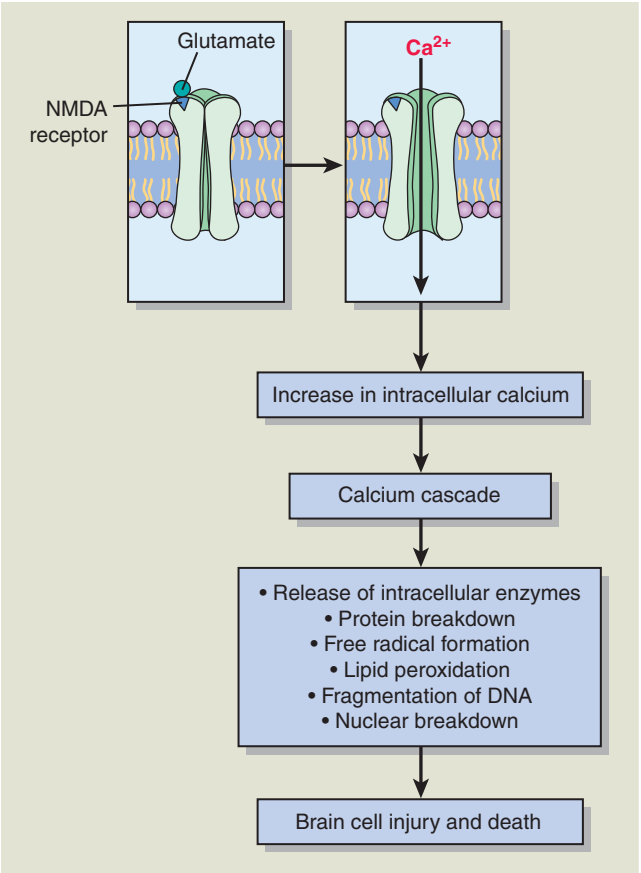

FIGURE 37-2. The role of the glutamate–*N*-methyl-D-aspartate (NMDA) receptor in brain cell injury.

Cerebral Edema

Cerebral edema, or brain swelling, is an increase in tissue volume secondary to abnormal fluid accumulation. There are two types of brain edema: vasogenic and cytotoxic.[1,9] Vasogenic edema occurs when integrity of the blood-brain barrier is disrupted, allowing fluid to escape into the extracellular fluid that surrounds brain cells. Cytotoxic edema involves the actual swelling of brain cells themselves.

Vasogenic Edema. Vasogenic edema occurs with conditions that impair the function of the blood-brain barrier and allow transfer of water and proteins from the vascular into the interstitial space. It occurs in conditions such as hemorrhage, brain injury, and infectious processes (e.g., meningitis). Vasogenic edema occurs primarily in the white matter of the brain, possibly because the white matter is more compliant than the gray matter.

Vasogenic edema can displace a cerebral hemisphere and can be responsible for various types of brain herniation. The functional manifestations of vasogenic edema include focal neurologic deficits, disturbances in consciousness, and severe intracranial hypertension.

Cytotoxic Edema. Cytotoxic edema involves an increase in intracellular fluid. It can result from hypo-osmotic states such as water intoxication or severe ischemia that impair the function of the sodium-potassium membrane pump. Ischemia also results in the inadequate removal of anaerobic metabolic end products such as lactic acid, producing extracellular acidosis. If blood flow is reduced to low levels for extended periods or to extremely low levels for a few minutes, cellular edema can cause the cell membrane to rupture, allowing the escape of intracellular contents into the surrounding extracellular fluid. This leads to damage of neighboring cells. The altered osmotic conditions result in water entry and cell swelling. Major changes in cerebral function, such as stupor and coma, occur with cytotoxic edema. The edema associated with ischemia may be severe enough to produce cerebral infarction with necrosis of brain tissue.

Increased Intracranial Pressure, Herniation, and Hydrocephalus

Intracranial pressure is, literally, the pressure inside the cranium. Increased intracranial pressure (ICP) is a common pathway for brain injury from different types of insults and agents. Excessive ICP can obstruct cerebral blood flow, destroy brain cells, displace brain tissue (as in herniation), and otherwise damage delicate brain structures.

Mechanisms of Increased Intracranial Pressure

The cranial cavity contains blood (approximately 10%), brain tissue (approximately 80%), and CSF (approximately 10%) in the rigid confines of a nonexpandable skull.[9] Each of these three volumes contributes to the ICP, which normally is maintained within a range of 0 to 15 mm Hg when measured in the lateral ventricles. The volumes of each of these components can vary slightly without causing marked changes in ICP. This is because small increases in the volume of one component can be compensated for by a decrease in the volume of one or both of the other two components.[10] This association is called the *Monro-Kellie hypothesis*.

Abnormal variation in intracranial volume with subsequent changes in ICP can be caused by a volume change in any of the three intracranial components. For example, an increase in tissue volume can result from a brain tumor, brain edema, or bleeding into brain tissue. An increase in blood volume develops when there is vasodilation of cerebral vessels or obstruction of venous outflow. Excess production, decreased absorption, or obstructed circulation of CSF affords the potential for an increase in the CSF component.

According to the modified Monro-Kellie hypothesis, reciprocal compensation occurs among the three intracranial compartments.[9] Of the three intracranial volumes, tissue volume is relatively restricted in its ability to undergo change; CSF and blood volume are best able to compensate for changes in ICP. Initial increases in ICP are buffered by a translocation of CSF to the spinal subarachnoid space and increased reabsorption of CSF. The compensatory ability of the blood compartment is limited by the small amount of blood that is in the cerebral circulation. The cerebral blood vessels contain less than 10% of the intracranial volume, most of which is contained in the low-pressure venous system. As the volume-buffering capacity of this compartment becomes exhausted, venous pressure increases, and cerebral blood volume and ICP rise. Also, cerebral blood flow is highly controlled by autoregulatory mechanisms, which affect its compensatory capacity. For example, conditions such as ischemia and an elevated partial pressure of carbon dioxide (PCO_2) in the blood produce a compensatory vasodilation of the cerebral blood vessels. A decrease in PCO_2 has the opposite effect; for this reason, hyperventilation, which results in a decrease in PCO_2 levels, is sometimes used in the treatment of ICP.

The impact of increases in blood, brain tissue, or CSF volumes on ICP varies among individuals and depends on the amount of increase, effectiveness of compensatory mechanisms, and compliance of brain tissue. *Compliance* represents the ratio of change in volume to the resulting change in pressure (compliance = change in volume/change in pressure).[9] In the case of intracranial volumes and pressure, an increase in intracranial volume will have little, or no, effect on ICP as long as compliance is high. Factors that influence compliance include the amount of volume increase, the time frame for accommodation, and the size of the intracranial compartments. For example, small volume increments over long periods of time can be accommodated more easily than a comparable amount introduced over a short time.

The cerebral perfusion pressure (CPP), which represents the difference between the mean arterial blood pressure (MABP) and the ICP (CPP = MABP – ICP), is the pressure perfusing the brain.[9,10] CPP is determined by the pressure gradient between the internal carotid artery and the subarachnoid veins. The MABP and ICP are monitored frequently in persons with brain conditions that increase ICP and impair brain perfusion. Normal CPP ranges from 70 to 100 mm Hg. In the laboratory, brain ischemia is not seen until the CPP falls below 40 mm Hg.[10] When the pressure in the cranial cavity approaches or exceeds the MABP, tissue perfusion becomes inadequate, cellular hypoxia results, and neuronal death may occur. The highly specialized cortical neurons are the most sensitive to oxygen deficit; a decrease in the level of consciousness is one of the earliest and most reliable signs of increased ICP. The continued cellular hypoxia leads to general neurologic deterioration; the level of consciousness may deteriorate from alertness through confusion, lethargy, obtundation, stupor, and coma.

One of the late reflexes seen with a marked increase in ICP is the CNS ischemic response, which is triggered by

ischemia of the vasomotor center in the brain stem. Neurons in the vasomotor center respond directly to ischemia by producing a marked increase in MABP in an attempt to increase CPP, sometimes to levels as high as 270 mm Hg, accompanied by a widening of the pulse pressure and reflex slowing of the heart rate. These three signs (i.e., hypertension, bradycardia, and widened pulse pressure), sometimes called the *Cushing reflex*, are important but late indicators of increased ICP.[11]

Brain Herniation

The brain is protected by the nonexpandable skull and two supporting septa, the falx cerebri and the tentorium cerebelli, which divide the intracranial cavity into fossae or compartments that normally protect against excessive movement.[1,9] The *falx cerebri* is a sickle-shaped septum that separates the two hemispheres. The *tentorium cerebelli* divides the cranial cavity into anterior and posterior fossae (Fig. 37-3A). This inflexible dural sheath extends posteriorly from the bony petrous ridges and anteriorly to the clinoid process, sloping downward and outward from its medial edge to attach laterally to the occipital bone. Extending posteriorly into the center of the tentorium is a large semicircular opening called the *incisura* or *tentorial notch*. The temporal lobe rests on the tentorial incisura, and the midbrain occupies the anterior portion of the tentorial notch. The cerebellum is closely opposed to the dorsum of the midbrain and fills the posterior part of the notch. Other important anatomic associations exist among the anterior cerebral, internal carotid, posterior communicating, and posterior and superior cerebellar arteries and the incisura (see Fig. 37-3B). The oculomotor nerve (cranial nerve [CN] III) emerges from the mediolateral surface of each peduncle just caudal to the tentorium.

Brain herniation represents a displacement of brain tissue under the falx cerebri or through the tentorial notch or incisura of the tentorium cerebelli. It occurs when an elevated ICP in one brain compartment causes displacement of the cerebral tissue toward an area of lower pressure. The different types of herniation syndromes are based on the area of the brain that has herniated and the structure under which it has been pushed. They commonly are divided into two broad categories, *supratentorial* and *infratentorial*, based on whether they are located above or below the tentorium.

Supratentorial Herniations. Progressive supratentorial lesions develop sequential clinical signs and symptoms of ocular, motor, and respiratory function. This pattern follows the predictable continuum of rostral-to-caudal failure that proceeds from the diencephalon to the midbrain, followed by the pons, and eventually medullary function. The pattern of deterioration is fairly predictable unless vascular or obstructive complications occur and exaggerate the condition.

There are two major types of supratentorial herniation: cingulate and transtentorial.[1,9] A *cingulate herniation* (see Fig. 37-3C [1]), which poses the less serious threat in terms of clinical outcomes, involves displacement of the cingulate gyrus and hemisphere beneath the sharp edges of the falx cerebri to the opposite side of the brain.[9] This displacement can compress local blood supply and cerebral tissue, causing edema and ischemia, which further increase the degree of ICP elevation. There may also be compression of branches of the anterior cerebral artery with unilateral or bilateral leg weakness.

Transtentorial herniations result in two distinct syndromes: a central syndrome and an uncal syndrome, which is the most common herniation syndrome.[9,12] Clinically, they display distinct patterns early in their course, but both merge in a similar pattern once they begin to involve the midbrain level and below. *Central transtentorial*

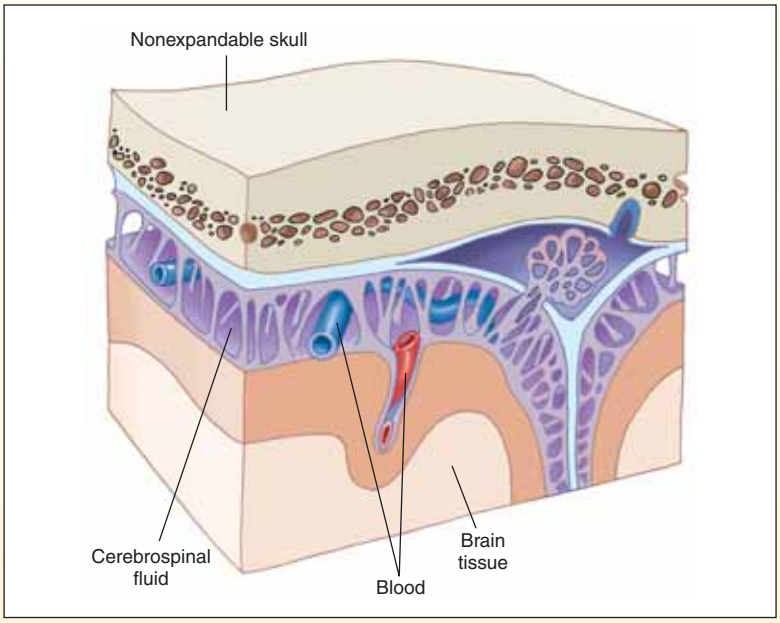
UNDERSTANDING → Intracranial Pressure

The intracranial pressure (ICP) is the pressure within the intracranial cavity. It is determined by (1) the pressure-volume relationships among the brain tissue, cerebrospinal fluid (CSF), and blood in the intracranial cavity; (2) the Monro-Kellie hypothesis, which relates to reciprocal changes among the intracranial volumes; and (3) the compliance of the brain and its ability to buffer changes in intracranial volume.

1

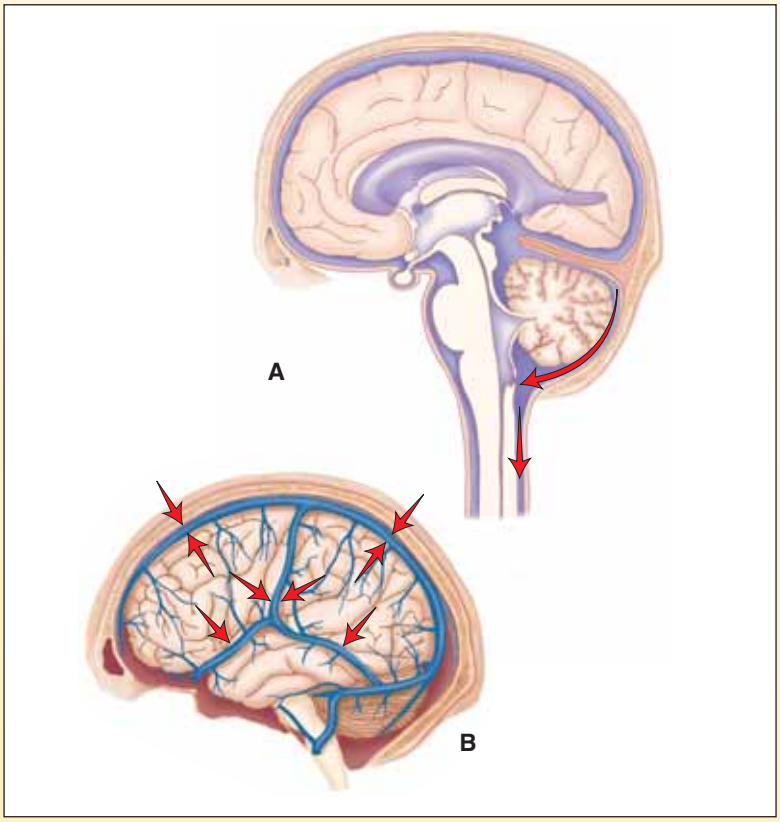
Intracranial Volumes and Pressure. The ICP represents the pressure exerted by the essentially incompressible tissue and fluid volumes of the three compartments contained within the rigid confines of the skull—the brain tissue and interstitial fluid (80%), the blood (10%), and the CSF (10%).



2

Monro-Kellie Hypothesis. Normally, a reciprocal relationship exists among the three intracranial volumes such that the ICP is maintained within normal limits. Because these volumes are practically incompressible, a change in one component must be balanced by an almost equal and opposite effect in one or both of the remaining components. This is known as the *Monro-Kellie hypothesis*.

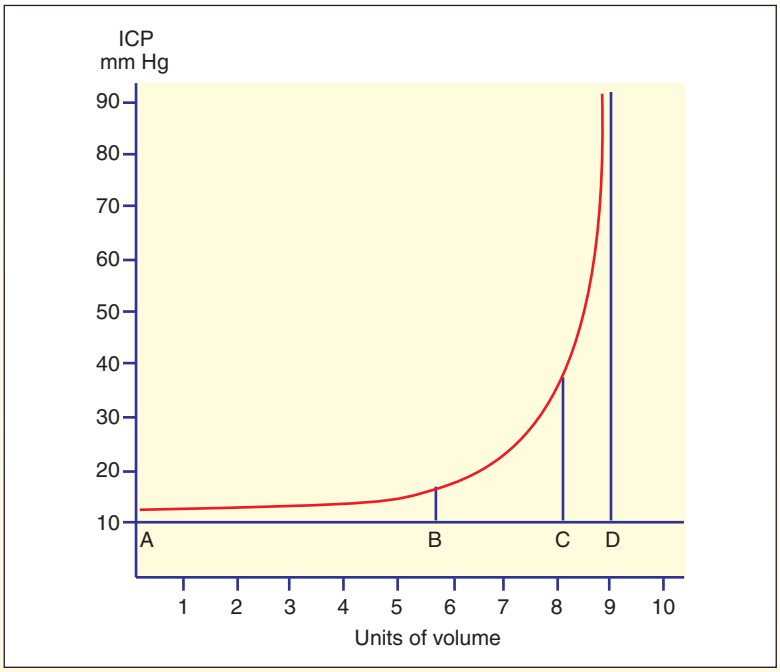
Of the three intracranial volumes, the fluid in the CSF compartment is the most easily displaced. The CSF (**A**) can be displaced from the ventricles and cerebral subarachnoid space to the spinal subarachnoid space, and it can also undergo increased absorption or decreased production. Because most of the blood in the cranial cavity is contained in the low-pressure venous system, venous compression (**B**) serves as a means of displacing blood volume.



3

Compliance and the Volume-Pressure Curve. Compliance, which refers to the ease with which a substance can be compressed or deformed, is a measure of the brain's ability to maintain its ICP during changes in intracranial volume. Compliance (C) represents the ratio of change (Δ) in volume (V) to change in pressure (P): $C = \Delta V/\Delta P$.

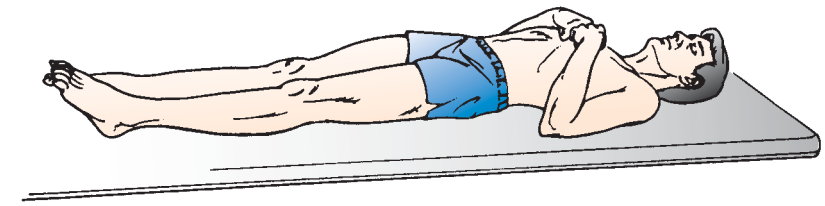
The dynamic effects of changes in intracranial volume and compliance on ICP can be illustrated on a graph with the volume represented on the horizontal axis and ICP on the vertical axis. The shape of the curve demonstrates the effect on ICP of adding volume to the intracranial cavity. From points A to B, the compensatory mechanisms are adequate, compliance is high, and the ICP remains relatively constant as volume is added to the intracranial cavity. At point B, the ICP is relatively normal, but the compensatory mechanisms have reached their limits, compliance is decreased, and ICP begins to rise with each change in volume. From points C to D, the compensatory mechanisms have been exceeded and ICP rises significantly with each increase in volume as compliance is lost.



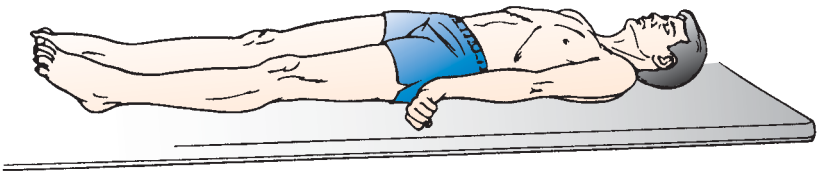
(From Hickey J.V. [2003]. *Neurological and neurosurgical nursing* [5th ed., p. 286]. Philadelphia. Lippincott Williams & Wilkins.)

herniations (see Fig. 37-3C [2]) involve the downward displacement of the cerebral hemispheres, basal ganglia, diencephalon, and midbrain through the tentorial incisura. Bilateral small, reactive pupils and drowsiness are heralding signs. The *uncal herniation syndrome* occurs when an expanding lesion pushes the medial aspect of the temporal lobe, which contains the uncus and hippocampal gyrus, through the incisura of the tentorium (see Fig 36-3C [3]). As a result, the diencephalon and midbrain are compressed and displaced laterally to the opposite side of the tentorium. The oculomotor nerve (CN III) and the posterior cerebral artery frequently are caught between the uncus and the tentorium. The oculomotor nerve controls pupillary constriction; entrapment of this nerve results in ipsilateral pupillary dilation, which usually is an early sign of uncal herniation. Consciousness may be unimpaired because the reticular activating system, which is responsible for wakefulness, has not yet been affected. As uncal herniations progress, there are changes in motor strength and coordination of voluntary movements because of compression of the descending motor pathways. It is not unusual for initial changes in motor function to occur ipsilateral to the side of the brain damage because of compression of the contralateral cerebral peduncles. Changes in consciousness and coma may follow due to compression of the midbrain against the opposite tentorial edge. Decerebrate posturing (Fig. 37-4B) may develop, followed by dilated, fixed pupils; flaccidity; and respiratory arrest.

Infratentorial Herniation. Infratentorial herniation results from increased pressure in the infratentorial compartment.[9] Herniation may occur superiorly (upward) through the tentorial incisura or inferiorly (downward)



A Flexor or decorticate posturing



B Extensor or decerebrate posturing

FIGURE 37-4. Abnormal posturing. **(A)** Decorticate rigidity. In decorticate rigidity, the upper arms are held at the sides, with elbows, wrists, and fingers flexed. The legs are extended and internally rotated. The feet are plantar flexed. **(B)** Decerebrate rigidity. In decerebrate rigidity, the jaws are clenched and neck extended. The arms are adducted and stiffly extended at the elbows with the forearms pronated, wrists and fingers flexed. (From Fuller J., Schaller-Ayers J. [1994]. *Health assessment: A nursing approach* [2nd ed.]. Philadelphia: J.B. Lippincott.)

through the foramen magnum. Upward displacement of brain tissue can cause blockage of the aqueduct of Sylvius and lead to hydrocephalus and coma. Downward herniation involves displacement of the midbrain through the tentorial notch or the cerebellar tonsils through the foramen magnum (Fig. 37-3C[4]). It often progresses rapidly and can cause death because it is likely to involve the lower brain stem centers that control vital cardiopulmonary functions.

In cases of preexisting ICP elevations, herniation may occur when the pressure is released from below, such as in a lumbar puncture. If the CSF pathway is blocked and fluid cannot leave the ventricles, the volume expands, and fluid is displaced downward through the tentorial notch. The result of this displacement is brain stem ischemia and hemorrhage extending from the diencephalon to the pons. If the lesion expands rapidly, displacement and obstruction occur quickly, leading to irreversible infarction and hemorrhage.

Hydrocephalus

Hydrocephalus represents a progressive enlargement of the ventricular system due to an abnormal increase in CSF volume (see Chapter 34, Fig. 34-21). It can result because of overproduction of CSF, impaired reabsorption of CSF, or obstruction of CSF flow in the ventricular system.

There are two types of hydrocephalus: noncommunicating and communicating.[1,9] *Noncommunicating* or *obstructive hydrocephalus* occurs when obstruction in the ventricular system prevents the CSF from reaching the arachnoid villi. CSF flow can be obstructed by congenital malformations, from tumors encroaching on the ventricular system, or by inflammation or hemorrhage. *Communicating hydrocephalus* is caused by impaired reabsorption of CSF from the arachnoid villi into the venous system. Decreased absorption can result from a block in the CSF pathway to the arachnoid villi or a failure of the villi to transfer the CSF to the venous system. It can occur if too few villi are formed, if postinfective (meningitis) scarring occludes them, or if the villi become obstructed with fragments of blood or infectious debris. Adenomas of the choroid plexus can cause an overproduction of CSF. This form of hydrocephalus is much less common than that resulting from decreased absorption of CSF.

Similar pathologic patterns occur with noncommunicating and communicating types of hydrocephalus. The cerebral hemispheres become enlarged, and the ventricular system beyond the point of obstruction is dilated. The sulci on the surface of the brain become effaced and shallow, and the white matter is reduced in volume. Computed tomographic (CT) and magnetic resonance imaging (MRI) scans are used to diagnose all types of hydrocephalus. The usual treatment is a shunting procedure, which provides an alternative route for return of CSF to the circulation.

Signs and symptoms of hydrocephalus vary greatly, depending on the rapidity of onset. When hydrocephalus develops in utero or before the cranial sutures have fused in infancy, the ventricles expand beyond the point of obstruction, the cranial sutures separate, the head expands, and there is bulging of the fontanels. Because the skull is able to expand, signs of increased ICP may be absent, and intelligence spared. However, seizures are not uncommon, and in severe cases, optic nerve atrophy leads to blindness. Weakness and uncoordinated movement are common. Surgical placement of a shunt allows for diversion of excess CSF fluid, preventing extreme enlargement of the head and neurologic deficits.

In adults and children in whom the cranial sutures have fused, head enlargement does not occur. Acute-onset hydrocephalus usually is marked by symptoms of increased ICP, including headache, vomiting, and papilledema or deviation in eye movements due to pressure on the cranial nerves. If the obstruction is not relieved, progression to herniation ensues (see previous discussion of herniation). Treatment includes surgical decompression and shunting.

An important type of communicating hydrocephalus that is seen in older adults is called *normal-pressure hydrocephalus*. In normal-pressure hydrocephalus, there is ventricular enlargement with compression of cerebral

tissue, but a normal CSF pressure. The signs and symptoms of normal-pressure hydrocephalus, which include memory changes, disturbances in gait, and urinary incontinence, usually have an insidious onset. The changes occur so slowly that they can be easily overlooked by the patient or his or her family or they may be attributed to the aging process in older persons.[9] The accepted treatment for normal-pressure hydrocephalus is a ventricular shunt.

Traumatic Brain Injury

The term *head injury* is used to describe all structural damage to the head and has become synonymous with *traumatic brain injury*.[13] The main causes of head injury are motor vehicle and bicycle crashes, pedestrian impacts, sports, falls, and assaults, with the most common cause of fatal head injuries being motor vehicle accidents.[14]

The physical forces associated with head injury may result in skull fractures, brain injury, and vascular damage, all three of which can coexist. Two thirds of skull fractures are accompanied by intracranial lesions, and the presence of skull fracture greatly increases the risk of an underlying subdural and/or epidural hemorrhage.[14] Skull fractures also provide pathways for the entry of bacteria (meningitis) or air (pneumocephalus) to the CSF and for leakage of CSF out of the dura. Skull fractures can also cause damage to the cranial nerves as they exit the cranial vault. The cranial nerves likely to be injured with head trauma include the olfactory (CN I), optic (CN II), oculomotor (CN III), and trochlear (CN IV); the first and second branches of the trigeminal (CN V); and the facial (CN VII) and auditory (CN VIII).[9]

Types of Injury

The effects of traumatic head injuries can be divided into two categories: primary or direct injuries, in which damage is caused by impact, and secondary injuries, in which damage results from the subsequent brain swelling, infection, or cerebral hypoxia.[9,14–17] The direct brain injuries include diffuse axonal injury and the focal lesions of lacerations, contusion, and hemorrhage. Secondary brain injuries are often diffuse or multifocal, including concussion, infection, and hypoxic brain injury. Although the skull and CSF provide protection for the brain, they also can contribute to trauma. When the mechanical forces inducing head injury cause bouncing of the brain in the closed confines of the rigid skull, a coup–contrecoup injury occurs. Because the brain floats freely in the CSF, blunt force to the head accelerates the brain within the skull, and then the brain decelerates abruptly upon hitting the inner skull surfaces[5,9] (Fig. 37-5). The direct contusion of the brain at the site of external force is referred to as a *coup* injury, whereas the rebound injury on the opposite side of the brain is the *contrecoup* injury. As the brain

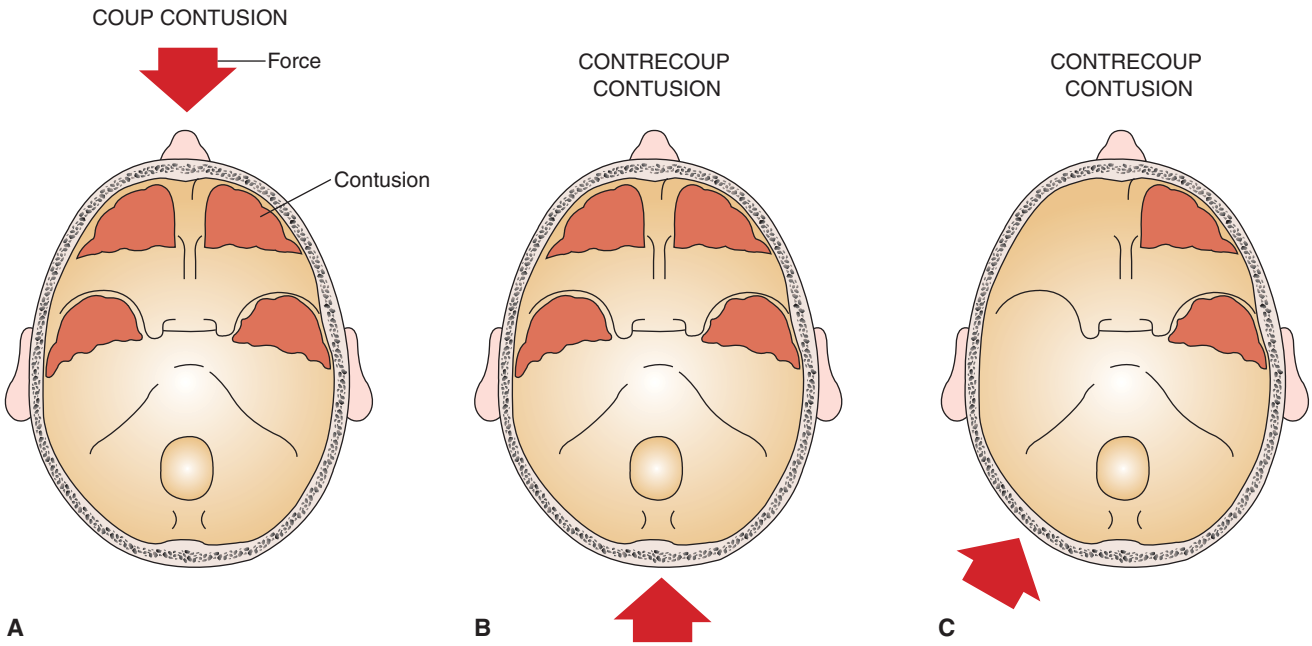


FIGURE 37-5. Mechanisms of cerebral contusion in coup–contrecoup injuries. **(A)** A focal area of cerebral injury (coup contusion) at the point of impact. The cerebral hemispheres float in the cerebrospinal fluid. **(B)** Rapid deceleration or, less commonly, acceleration causes the cortex to impact forcefully into the anterior or middle fossa, causing injury to the side of the brain opposite the site of injury (contrecoup contusion). **(C)** The position of a contrecoup contusion is determined by the direction of the force and the intracranial anatomy. (Courtesy of Dmitri Karetnikov, artist.) (From Trojanowski J.Q. [2005]. The central nervous system. In Rubin E., Gorstein F., Rubin R., et al. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [4th ed., p. 1430]. Philadelphia: Lippincott Williams & Wilkins.)

strikes the rough surface of the cranial vault, brain tissue, blood vessels, nerve tracts, and other structures are bruised and torn, resulting in contusions and hematomas.

Ischemia is considered the most common cause of secondary brain injury. It can result from the hypoxia and hypotension that occur during the resuscitation process or from the impairment of regulatory mechanisms by which cerebrovascular responses maintain an adequate blood flow and oxygen supply.[16,17] Insults that occur immediately after injury or in the course of resuscitation efforts are important determinants of the outcome from severe brain injury. More than 25% of patients with severe head injury sustain one or more secondary insults in the time between injury and resuscitation, indicating the need for improved airway management and circulatory status.[17] The significance of secondary injuries depends on the extent of damage caused by the primary injury. Certain secondary injuries have been discussed, such as increased ICP, cerebral edema, and brain herniation.

In *mild head injury*, there may be momentary loss of consciousness without demonstrable neurologic symptoms or residual damage, except for possible residual amnesia. Microscopic changes usually can be detected in the neurons and neuroglia within hours of injury, but brain imaging is negative. Concussion refers to an immediate and transient loss of consciousness accompanied by a brief period of amnesia after a blow to the head.[15,18] Although recovery usually takes place within 24 hours, mild symptoms, such as headache, irritability, insomnia, and poor concentration and memory, may persist for months. This is known as the *postconcussion syndrome*. The memory loss usually includes an interval of time preceding the injury (retrograde amnesia) and following the injury (anterograde amnesia). The duration of retrograde amnesia correlates with the severity of the brain injury. Because these cognitive complaints are vague and subjective, they sometimes are regarded as being of psychological origin. Postconcussion syndrome can have a significant effect on activities of daily living and return to employment. Persons with postconcussion syndrome may need cognitive retraining, medications, or psychological support.

In *moderate head injury*, many small hemorrhages and some swelling of brain tissue occur. These contusions often are distributed along the rough, irregular inner surface of the brain and are more likely to occur in the frontal or temporal lobes, resulting in cognitive and motor deficits. Moderate head injury is characterized by a period of unconsciousness and may be associated with focal manifestations such as hemiparesis, aphasia, and cranial nerve palsy. In this type of injury, the contusions often can be visualized on CT scan.

Severe head injury involves extensive mechanical and secondary damage to brain structures and deficits in arousal, usually coma. In severe head injury, the mechanical injury is instantaneous and irreversible, resulting from shearing and pressure forces that cause diffuse axonal injury, disruption of blood vessels, and tissue damage. It often is accompanied by severe neurologic deficits such as coma, hemiplegia, and all the other signs of elevated ICP. Contusions and intracerebral, subdural, epidural, and subarachnoid hemorrhages are often evident on CT scan. Severe head injuries often occur with injury to other parts of the body such as the extremities, chest, and abdomen, which often limits the examiner's ability to carefully assess the neurologic deficits.

Hematomas

Hematomas result from vascular injury and bleeding. Depending on the anatomic position of the ruptured vessel, bleeding can occur in any of several compartments, including the epidural, subdural, and subarachnoid spaces, or into the brain itself (intracerebral hematoma).

Epidural Hematoma. An epidural hematoma is one that develops between the inner bones of the skull and the dura (Fig. 37-6). It usually results from a tear in an artery, most often the middle meningeal, usually in association with a head injury in which the skull is fractured.[1,5,17] Because bleeding is arterial in origin, rapid expansion of the hematoma compresses the brain. Epidural hematoma is more common in a young person because the dura is less firmly attached to the skull surface than in an older person; as a consequence, the dura can be easily separated from the inner surface of the skull, allowing the hematoma to grow.

Typically, a person with an epidural hematoma presents with a history of head injury and a brief period of unconsciousness followed by a lucid period in which consciousness is regained, followed by rapid progression to

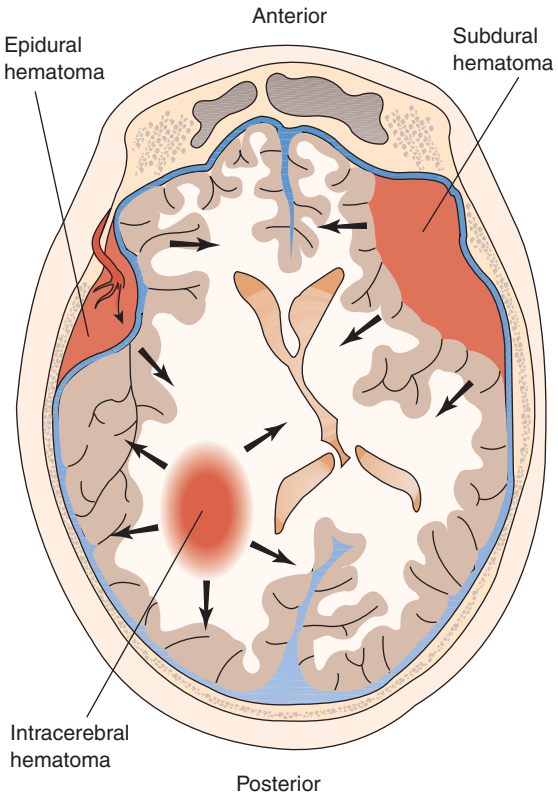

FIGURE 37-6. Location of epidural, subdural, and intracerebral hematomas.

unconsciousness. The lucid interval does not always occur, but when it does, it is of great diagnostic value. With rapidly developing unconsciousness, there are focal symptoms related to the area of the brain involved. These symptoms can include ipsilateral (same side) pupil dilation and contralateral (opposite side) hemiparesis from uncal herniation. If the hematoma is not removed, the condition progresses, with increased ICP, tentorial herniation, and death. However, prognosis is excellent if the hematoma is removed before loss of consciousness occurs.

Subdural Hematoma. A subdural hematoma develops in the area between the dura and the arachnoid (subdural space) and usually is the result of a tear in the small bridging veins that connect veins on the surface of the cortex to dural sinuses. The bridging veins pass from the pial vessels through the CSF-filled subarachnoid space, penetrate the arachnoid and the dura, and empty into the intradural sinuses.[1,5] These veins are readily snapped in head injury when the brain moves suddenly in relation to the cranium (Fig. 37-7). Bleeding can occur between the dura and arachnoid (i.e., subdural hematoma) or into the CSF-filled subarachnoid space (i.e., subarachnoid hematoma).

The venous source of bleeding in a subdural hematoma develops more slowly than the arterial bleeding in an epidural hematoma. Subdural hematomas are classified as acute, subacute, or chronic. This classification system is based on the approximate time before the appearance of symptoms. Symptoms of acute hematoma are seen within 24 hours of the injury, whereas subacute hematoma does not produce symptoms until 2 to 10 days after injury. Symptoms of chronic subdural hematoma may not arise until several weeks after the injury.

Acute subdural hematomas progress rapidly and have a high mortality rate because of the severe secondary injuries related to edema and increased ICP. The high mortality rate has been associated with uncontrolled ICP increase, loss of consciousness, decerebrate posturing (Fig. 37-4B), and delay in surgical removal of the hematoma. The clinical picture is similar to that of epidural hematoma, except that there usually is no lucid interval. By contrast, in subacute subdural hematoma, there may be a period of improvement in the level of consciousness and neurologic symptoms, only to be followed by deterioration if the hematoma is not removed.

Symptoms of chronic subdural hematoma develop weeks after a head injury, so much later that the person may not remember having had a head injury. Chronic subdural hematoma is more common in older persons because brain atrophy causes the brain to shrink away from the dura and stretch fragile bridging veins. These veins rupture, causing slow seepage of blood into the subdural space. Fibroblastic activity causes the hematoma to become encapsulated. The sanguineous fluid in this encapsulated area has high osmotic pressure and draws in fluid from the surrounding subarachnoid space; the mass expands, exerting pressure on the cranial contents. In some instances, the clinical picture is less defined, with the most prominent symptom being a decreasing level of consciousness indicated by drowsiness, confusion, headache, and apathy.

Traumatic Intracerebral Hematomas. Traumatic intracerebral hematomas may be single or multiple. They can occur in any lobe of the brain but are most common in the frontal or temporal lobes, related to the bony prominences on the inner skull surface (Fig. 37-8). They may occur in association with the severe motion that the brain undergoes during head injury, or a contusion can coalesce into a hematoma. Intracerebral hematomas occur more frequently in older persons and alcoholics, whose cerebral vessels are more friable.

The signs and symptoms produced by an intracerebral hematoma depend on its size and location in the brain. Signs of increased ICP can be manifested if the hematoma

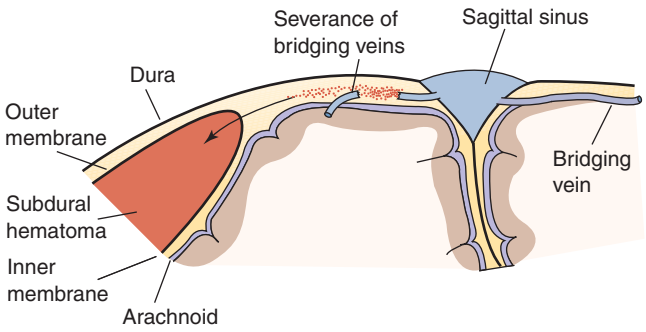

FIGURE 37-7. Mechanism of bleeding in subdural hematoma. (Courtesy of Dmitri Karetnikov, artist.) (From Trojanowski J.Q. [2005]. The central nervous system. In Rubin E., Gorstein F., Rubin R., et al. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [4th ed., p. 1430]. Philadelphia: Lippincott Williams & Wilkins.)

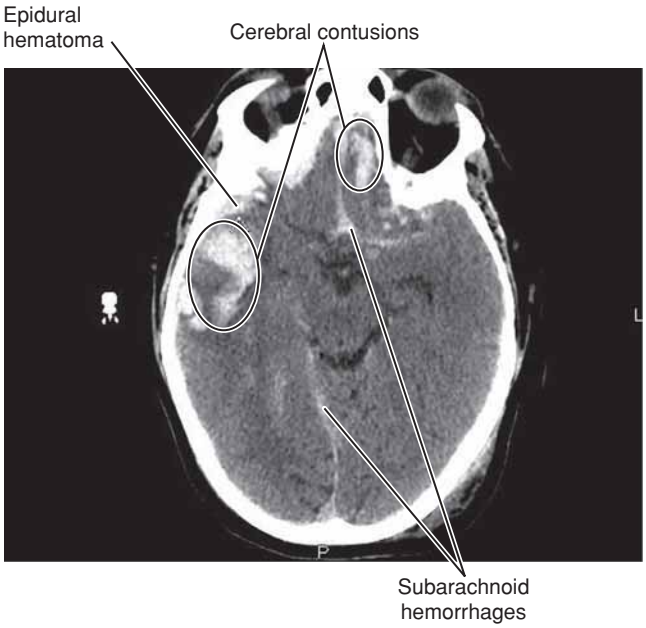

FIGURE 37-8. Computed tomography scan of brain in traumatic brain injury, showing hemorrhagic cerebral contusions in right temporal and bifrontal lobes, subarachnoid hemorrhages, and epidural hematoma.

is large and encroaching on vital structures. A hematoma in the temporal lobe can be dangerous because of the potential for lateral herniation.

Manifestations of Diffuse Brain Injury

Global or diffuse brain injury, whether due to head trauma, stroke, or other pathologic processes, is manifested by alterations in sensory, motor, and cognitive function and by changes in the level of consciousness. In contrast to a localized injury, which causes focal neurologic deficits without altered consciousness, global injury nearly always results in altered levels of consciousness, ranging from inattention to stupor or coma. Severe injury that seriously compromises brain function may result in brain death.

The cerebral hemispheres are the most susceptible to damage, and the most frequent sign of brain dysfunction is an altered level of consciousness and change in behavior. As the brain structures in the diencephalon, midbrain, pons, and medulla are sequentially affected, additional signs related to pupillary and eye movement reflexes, motor function, and respiration become evident (Table 37-1). Hemodynamic and respiratory instability are the last signs to occur because their regulatory centers are located low in the medulla.

In progressive brain deterioration, the person's neurologic capabilities appear to deteriorate in stepwise fashion. Similarly, as neurologic function returns, there usually is a stepwise progression to higher levels of consciousness. Deterioration of brain function from supratentorial lesions tends to follow a stepwise rostral-to-caudal progression, which is observed as the brain initially compensates for injury and subsequently decompensates with loss of autoregulation and cerebral perfusion. Infratentorial (brain stem) lesions may lead to an early, sometimes abrupt disturbance in consciousness without any orderly rostral to caudal progression of neurologic signs.

Consciousness

Consciousness is the state of awareness of self and the environment and of being able to become oriented to new stimuli.[19–21] It has traditionally been divided into two components: (1) arousal and wakefulness and (2) content and cognition. The content and cognition aspects of consciousness are determined by a functioning cerebral cortex. Arousal and wakefulness require the concurrent functioning of both cerebral hemispheres and an intact reticular activating system (RAS) in the brain stem.

The RAS is a diffuse, primitive system of interlacing nerve cells and fibers in the brain stem that receives input from multiple sensory pathways (Fig. 37-9). Anatomically, the RAS constitutes the central core of the brain stem, extending from the medulla through the pons to the midbrain, which is continuous caudally with the spinal cord and rostrally with the subthalamus, the hypothalamus, and the thalamus. Fibers from the reticular formation also project to the autonomic nervous system and motor systems. The hypothalamus plays a predominant role in maintaining homeostasis through integration of somatic, visceral, and endocrine functions. Inputs from the reticular formation, vestibulospinal projections, and other motor systems are integrated to provide a continuously adapting background of muscle tone and posture to facilitate voluntary motor actions. Reticular formation neurons that function in regulation of cardiovascular, respiratory, and other visceral functions are intermingled with those that maintain other reticular formation functions.

Ascending fibers of the reticular formation, known as the *ascending reticular activating system*, transmit activating information to all parts of the cerebral cortex. The

Brain Injury and Levels of Consciousness

- Consciousness is a global function that depends on a diffuse neural network that includes activity of the reticular activating system (RAS) and both cerebral hemispheres.
- Impaired consciousness implies diffuse brain injury to the RAS at any level (medulla through thalamus) or both cerebral hemispheres simultaneously.
- In contrast, local brain injury causes focal neurologic deficit but does not disrupt consciousness.

TABLE 37-1 Key Signs in Rostral-to-Caudal Progression of Brain Lesions

Level of Brain Injury	Key Clinical Signs
Diencephalon	Impaired consciousness; small, reactive pupils; intact oculocephalic reflex; decorticate posturing; Cheyne-Stokes respirations
Midbrain	Coma; fixed, midsize pupils; impaired oculocephalic reflex; neurogenic hyperventilation; decerebrate posturing
Pons	Coma; fixed, irregular pupils; dysconjugate gaze; impaired cold caloric stimulation; loss of corneal reflex; hemiparesis/quadriparesis; decerebrate posturing; apneustic respirations
Medulla	Coma; fixed pupils, flaccidity, loss of gag and cough reflexes, ataxic/apneic respirations

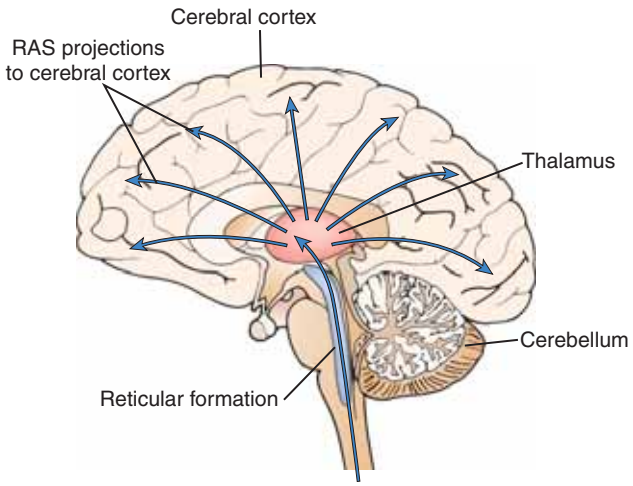

FIGURE 37-9. The reticular activating system (RAS). Ascending sensory tracts send axon collateral fibers to the reticular formation. These give rise to fibers synapsing in the nonspecific nuclei of the thalamus. From there, the nonspecific thalamic projections influence widespread areas of the cerebral cortex and limbic system.

flow of information in the ascending RAS activates the hypothalamic and limbic structures that regulate emotional and behavioral responses such as those that occur in response to pain and loud noises, and they exert facilitatory effects on cortical neurons. Without cortical activation, a person is less able to detect specific stimuli, and the level of consciousness is reduced.

The pathways for the ascending RAS travel from the medulla through the midbrain, such that lesions of the brain stem can interrupt RAS activity, leading to altered levels of consciousness and coma. Any deficit in level of consciousness, from mild confusion to stupor or coma, indicates injury to either the RAS or to both cerebral hemispheres concurrently. For example, consciousness may decline owing to severe systemic metabolic derangements that affect both hemispheres, or from head trauma causing shear injuries to white matter of both the RAS and the cerebral hemispheres. Brain injuries that affect a hemisphere unilaterally and also spare the RAS, such as cerebral infarction, usually do not impair consciousness.

Levels of Consciousness. Levels of consciousness reflect awareness and response to the environment. A fully conscious person is totally aware of his or her surroundings and able to react to stimuli in the environment.[19] Levels of consciousness exist on a continuum that includes consciousness, confusion, delirium, obtundation, stupor, and coma (Table 37-2).

The earliest signs of diminution in level of consciousness are inattention, mild confusion, disorientation, and blunted responsiveness. With further deterioration, the delirious person becomes markedly inattentive and variably lethargic or agitated. The person may progress to become obtunded and may respond only to vigorous or noxious stimuli.

Because of its simplicity of application, the Glasgow Coma Scale has gained almost universal acceptance as a method for assessing the level of consciousness in persons with brain injury[22,23] (Table 37-3). Numbered scores are given to responses of eye opening, verbal utterances, and motor responses. The total score is the sum of the best response in each category.

Other Manifestations of Deteriorating Brain Function

Additional elements in the initial neurologic evaluation of a person with brain injury include checking for abnormalities in the size of the pupils and their reaction to light, evidence of decorticate or decerebrate posturing, and altered patterns of respiration.

Pupillary Reflexes and Eye Movements. Although the pupils may initially respond briskly to light, they become unreactive and dilated as brain function deteriorates. A bilateral loss of the pupillary light response is indicative of lesions of the brain stem. A unilateral loss

TABLE 37-2 Descending Levels of Consciousness and Their Characteristics

Level of Consciousness	Characteristics
Confusion	Disturbance of consciousness characterized by impaired ability to think clearly, and to perceive, respond to, and remember current stimuli; also disorientation
Delirium	State of disturbed consciousness with motor restlessness, transient hallucinations, disorientation, and sometimes delusions
Obtundation	Disorder of decreased alertness with associated psychomotor retardation
Stupor	A state in which the person is not unconscious but exhibits little or no spontaneous activity
Coma	A state of being unarousable and unresponsive to external stimuli or internal needs; often determined by the Glasgow Coma Scale

Data from Bates D. (1993). The management of medical coma. *Journal of Neurology, Neurosurgery, and Psychiatry* 56, 590.

of the pupillary light response may be due to a lesion of the optic or oculomotor pathways. The oculocephalic reflex (doll's-head eye movement) can be used to determine whether the brain stem centers for eye movement are intact (Fig. 37-10). If the oculocephalic reflex is inconclusive, and if there are no contraindications, the oculovestibular test (i.e., cold caloric test, in which cold water is instilled into the ear canal) may be used to elicit nystagmus (see Chapter 38).

Decorticate and Decerebrate Posturing. With the early onset of unconsciousness, there is some combative and purposeful movement in response to pain. As coma progresses, noxious stimuli can initiate rigidity and abnormal postures if the motor tracts are interrupted at specific levels. These abnormal postures are classified as decorticate and decerebrate.[9] Decorticate (flexion) posturing is characterized by flexion of the arms, wrists, and fingers, with abduction of the upper extremities, internal rotation, and plantar flexion of the lower extremities (see Fig. 37-4A). Decorticate posturing results from lesions of the cerebral hemisphere or internal capsule. Decerebrate (extensor) posturing results from increased muscle excitability (see Fig. 37-4B). It is characterized by rigidity of the arms with palms of the hands turned away from the body and with stiffly extended legs and plantar flexion of the feet. This response occurs with rostral-to-caudal deterioration, when lesions of the diencephalon extend to involve the midbrain and upper brain stem. Both decerebrate and decorticate posturing are poor prognostic signs.

Respiratory Responses. Early respiratory changes include yawning and sighing, with progression to Cheyne-Stokes breathing, in which there is waxing and waning of respirations with variable periods of apnea. With progression of injury continuing to the midbrain, respirations change to neurogenic hyperventilation, in which the frequency of respirations may exceed 40 breaths per minute because of uninhibited stimulation of inspiratory and expiratory centers. With medullary involvement, respirations become ataxic (i.e., totally uncoordinated and irregular). Apnea may occur because of a lack of responsiveness to carbon dioxide stimulation. Complete ventilatory assistance is often required at this point.

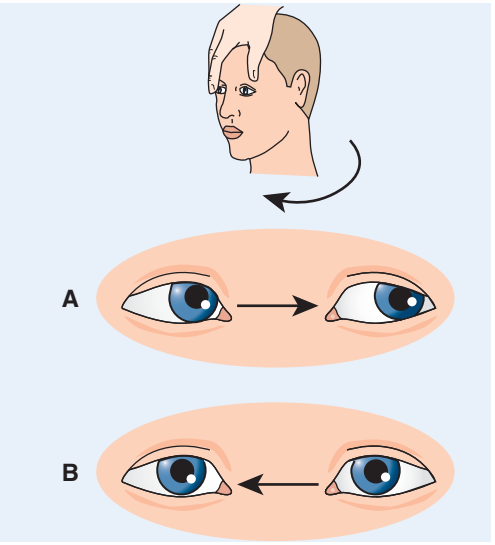

FIGURE 37-10. The *doll's-head eye response* demonstrates the always-present vestibular static reflexes without forebrain interference or suppression. Severe damage to the forebrain or to the brain stem rostral to the pons often results in loss of rostral control of these static vestibular reflexes. If the person's head is moved from side to side or up and down, the eyes will move in conjugate gaze to the opposite side **(A)**, much like those of a doll with counterweighted eyes. If the doll's-head phenomenon is observed, brain stem function at the level of the pons is considered intact (in a comatose person). In the unconscious person without intact brain stem function and vestibular static reflexes, the eyes stay in midposition (fixed) or turn in the same direction **(B)** as the head is turned.

In summary, many of the agents that cause brain damage do so through common pathways, including hypoxia or ischemia, accumulation of excitatory neurotransmitters, cerebral edema, and increased ICP. Deprivation of oxygen (i.e., hypoxia) or blood flow (i.e., ischemia) can have deleterious effects on the brain structures. Ischemia can be focal, as in stroke, or global. Global ischemia occurs when blood flow is inadequate to meet the metabolic needs of the entire brain, as in cardiac arrest. The term *excitotoxicity* has been coined for the final common pathway for neuronal cell injury and death associated with excessive activity of excitatory neurotransmitters, particularly glutamine.

Cerebral edema represents an increase in tissue volume secondary to abnormal fluid accumulation.

Vasogenic edema occurs when integrity of the blood-brain barrier is disrupted, allowing fluid to escape into the extracellular fluid that surrounds brain cells, whereas cytotoxic edema involves the swelling of brain cells. The ICP is the pressure exerted by the essentially incompressible tissue and fluid volumes of the three compartments contained within the rigid confines of the skull—brain tissue, blood, and CSF. Excessive ICP can obstruct cerebral blood flow, destroy brain cells, displace brain tissue as in herniation, and otherwise damage delicate brain structures. Hydrocephalus represents enlargement of the CSF compartment owing to an abnormal CSF volume. It can result from impaired reabsorption from the arachnoid villi into the venous system (communicating hydrocephalus) or from obstruction of the ventricular system (noncommunicating hydrocephalus), which prevents the CSF from reaching the arachnoid villi.

Head injury is the term used to describe injuries associated with skull fractures, brain injuries, and associated cerebral vascular injuries. The effects of traumatic head injuries can be divided into two categories: primary or secondary injuries. Primary injuries come from direct impact of the head and brain as an immediate result of the initial insult. The injuries may be focal (contusion or laceration) or diffuse (concussion and diffuse axonal injury). Hematomas result from vascular injury and bleeding. Depending on its location, the bleeding may result in an epidural hematoma, subdural hematoma, or intracerebral hematoma. Secondary injuries result from complicating processes that are initiated at the time of injury.

Deterioration of brain function is manifested by alterations in sensory and motor function and changes in the level of consciousness. Consciousness is a state of awareness of self and environment. It exists on a normal continuum from normal wakefulness and sleep to the pathologic continuum of stupor and coma. Any deficit in level of consciousness, from mild confusion to stupor or coma, indicates injury to either the ascending reticular activating system or to both cerebral hemispheres concurrently. In progressive brain injury, coma may follow a rostral-to-caudal progression with characteristic changes in levels of consciousness, breathing patterns, level of arousal and motor responses, and the pupillary light response and eye movements.

Cerebrovascular Disease

Cerebrovascular disease encompasses a number of disorders involving vessels in the cerebral circulation. These disorders include ischemic and hemorrhage stroke, aneurysmal subarachnoid hemorrhage, and arteriovenous malformations.

The Cerebral Circulation

The blood flow to the brain is supplied by the two internal carotid arteries anteriorly and the vertebral arteries posteriorly[24,25] (Fig. 37-11A). The internal carotid artery, a terminal branch of the common carotid artery, branches into several arteries—the ophthalmic, posterior communicating, anterior choroidal, anterior cerebral, and middle cerebral arteries (see Fig. 37-11B). Most of the arterial blood in the internal carotid arteries is distributed through the anterior and middle cerebral arteries. The anterior cerebral arteries supply the medial surface of the frontal and parietal lobes and the anterior half of the thalamus, the corpus striatum, part of the corpus callosum, and the anterior limb of the internal capsule. The genu and posterior limb of the internal capsule and medial globus pallidus are fed by the anterior choroidal branch of the internal carotid artery.

The middle cerebral artery passes laterally, supplying the lateral basal ganglia and the insula, and then emerges on the lateral cortical surface, supplying the inferior frontal gyrus, the motor and premotor frontal cortex concerned with delicate face and hand control (Fig. 37-12). It is the major vascular source for the language cortices (frontal and superior temporal), the primary and association auditory cortex (superior temporal gyrus), and the primary and association somesthetic cortex for the face and hand (postcentral gyrus, parietal). The middle cerebral artery is functionally a continuation of the internal carotid; emboli of the internal carotid most frequently become lodged in branches of the middle cerebral artery. The consequences of ischemia of these areas may be the most devastating, resulting in damage to the fine manipulative skills of the face and upper limbs and to receptive and expressive communication functions (e.g., aphasia).

The two vertebral arteries arise from the subclavian artery and enter the foramina in the transverse spinal processes at the level of the sixth cervical vertebra and continue upward through the foramina of the upper six vertebrae; they wind behind the atlas and enter the skull through the foramen magnum and unite to form the basilar artery, which then diverges to terminate in the posterior cerebral arteries. Branches of the basilar and vertebral arteries supply the medulla, pons, cerebellum, midbrain, and caudal part of the diencephalon. The posterior cerebral arteries supply the remaining occipital and inferior regions of the temporal lobes and the thalamus.

The distal branches of the internal carotid and vertebral arteries communicate at the base of the brain through the circle of Willis; this anastomosis of arteries can provide continued circulation if blood flow through one of the main vessels is disrupted (see Fig. 37-11B). For instance, occlusion of one middle cerebral artery may have limited consequences if the anterior and posterior communicating arteries are patent, allowing collateral flow from the ipsilateral posterior cerebral and opposite carotid arteries. Without collateral input, cessation of blood flow in cerebral arteries results in ischemic neural damage as metabolic needs of electrically active cells exceed nutrient supply.

The cerebral circulation is drained by two sets of veins that empty into the dural venous sinuses: the deep (great) cerebral venous system and the superficial venous system. In contrast to the superficial cerebral veins that travel through the pia mater on the surface of the cerebral

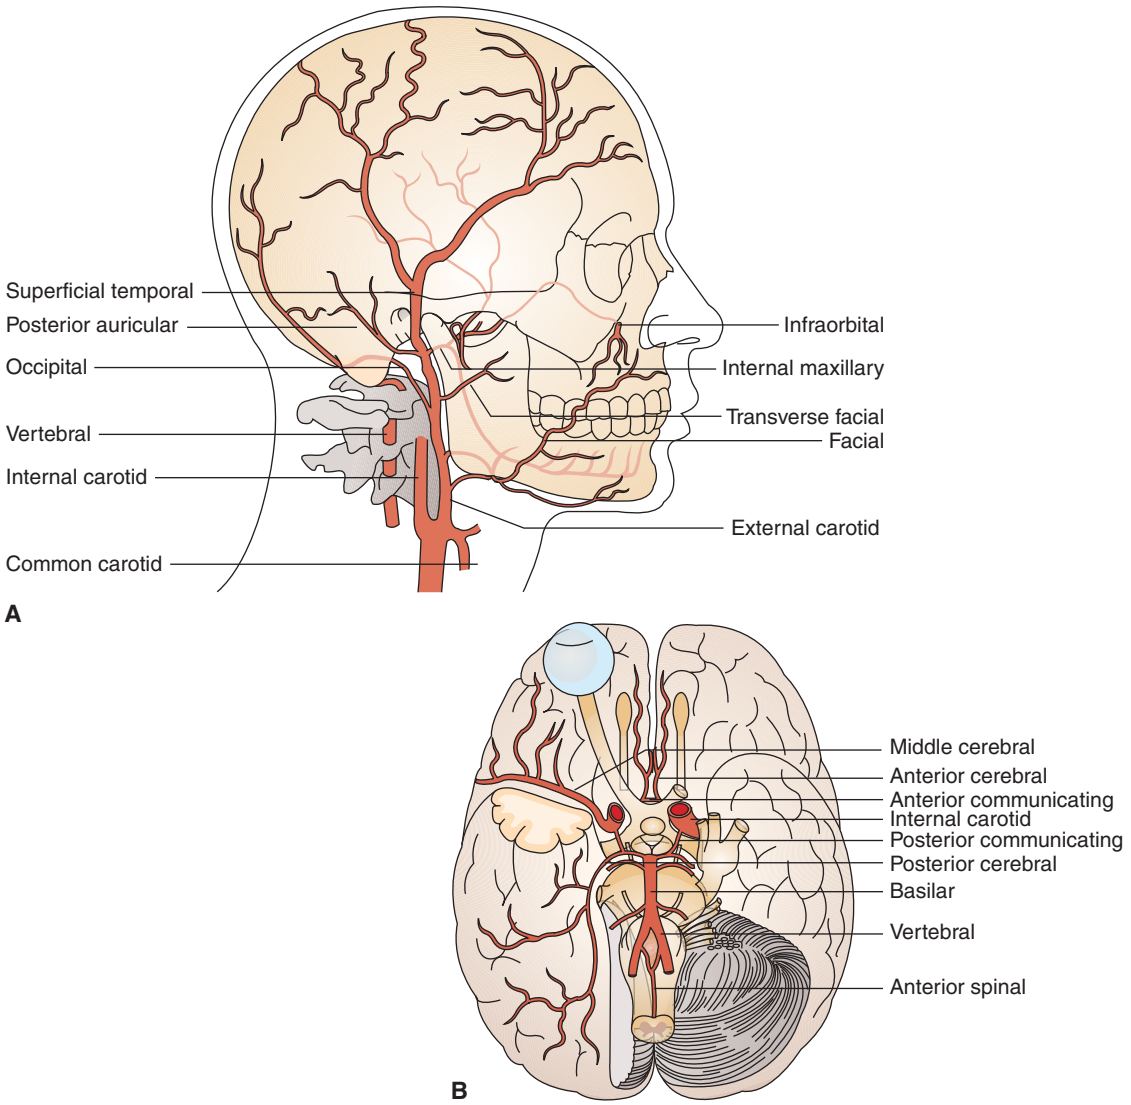

FIGURE 37-11. Cerebral circulation. **(A)** The internal carotid artery ascends to the base of the brain. The right vertebral artery is also shown as it ascends through the transverse foramina of the cervical vertebrae. **(B)** The cerebral arterial circle (circle of Willis).

cortex, the deep venous system is well protected. These vessels connect directly to the sagittal sinuses in the falx cerebri by bridging veins. They travel through the CSF-filled subarachnoid space and penetrate the arachnoid and then the dura to reach the dural venous sinuses. This system of sinuses returns blood to the heart primarily through the internal jugular veins. The intracranial veins do not have valves. The direction of flow depends on gravity and pressures in the venous sinuses as compared with those of the extracranial veins. Increases in intrathoracic pressure, as can occur with coughing or performance of the Valsalva maneuver (i.e., exhaling against a closed glottis), produce a rise in central venous pressure that is reflected back into the internal jugular veins and then to the dural sinuses. This briefly raises the ICP.

Regulation of Cerebral Blood Flow

The blood flow to the brain is maintained at approximately 750 to 900 mL/minute or 15% of the resting cardiac output.[11] The regulation of blood flow to the brain is controlled largely by autoregulatory or local mechanisms that respond to the metabolic needs of the brain. Cerebral autoregulation has been classically defined as the ability of the brain to maintain constant cerebral blood flow despite changes in systemic arterial pressure. This allows the cerebral cortex to adjust cerebral blood flow locally to satisfy its metabolic needs. The autoregulation of cerebral blood flow is efficient within an MABP range of approximately 60 to 140 mm Hg.[11] Although total cerebral blood flow remains relatively stable throughout marked changes in cardiac output and arterial blood pressure, regional blood flow may vary markedly in response to local changes in metabolism. If blood pressure falls below 60 mm Hg, cerebral blood flow becomes severely compromised, and if it rises above the upper limit of autoregulation, blood flow increases rapidly and overstretches the cerebral vessels. In persons with hypertension, this autoregulatory range shifts to higher MABP levels.

At least three metabolic factors affect cerebral blood flow—an increase in carbon dioxide and hydrogen ion concentrations and an oxygen deficiency. Increased carbon dioxide provides a potent stimulus for vasodilation—a doubling of the PCO_2 in the blood results in a doubling of cerebral blood flow. Carbon dioxide is thought to increase cerebral blood flow by first combining with water to form carbonic acid, with subsequent dissociation into hydrogen ions, which then causes vasodilation of the cerebral vessels. Other substances, such as lactic acid and pyruvic acid, which increase the acidity of brain tissues, will produce a similar increase in cerebral blood flow. Except during periods of intense brain activity, the rate of oxygen utilization by the brain remains within a narrow range. If blood flow to the brain becomes insufficient to supply this needed amount of oxygen, the oxygen deficiency causes the cerebral vessels to dilate, returning cerebral blood flow to near normal.

The sympathetic nervous system also contributes to the control of blood flow in the large brain arteries and the arteries that penetrate into the brain substance.[11] Under normal physiologic conditions, local regulatory and autoregulatory mechanisms override the effects of sympathetic stimulation. However, when local mechanisms fail, sympathetic control of cerebral blood pressure becomes important. For example, when the arterial pressure rises to very high levels during strenuous exercise or in other conditions, the sympathetic nervous system constricts the large and intermediate-sized superficial blood vessels as a means of protecting the smaller, more easily damaged vessels. Sympathetic reflexes are believed to cause vasospasm in the intermediate and large arteries in some types of brain damage, such as that caused by rupture of a cerebral aneurysm.

Stroke (Brain Attack)

Stroke is the syndrome of acute focal neurologic deficit from a vascular disorder that injures brain tissue. Stroke remains one of the leading causes of mortality and morbidity in the United States. Each year, about 795,000 Americans are afflicted with stroke, and approximately 20% of these persons die; many survivors are left with at least some degree of neurologic impairment.[26] The term *brain attack* has been promoted to raise awareness that time-dependent tissue damage occurs and that rapid emergency treatment is necessary, similar to that with heart attack.

There are two main types of strokes: ischemic and hemorrhagic. Ischemic strokes are caused by an interruption of blood flow in a cerebral vessel and are the most common type of stroke, accounting for about 87% of all strokes.[26] The less common hemorrhagic strokes are caused by bleeding into brain tissue. This type of stroke usually is from a blood vessel rupture caused by hypertension, aneurysm, arteriovenous malformation, head injury, or blood dyscrasias and has a much higher fatality rate than ischemic strokes.

Among the major risk factors for ischemic stroke are age, gender, race, family history, hypertension, cigarette smoking, diabetes mellitus, asymptomatic carotid stenosis, sickle cell disease, hyperlipidemia, and atrial fibrillation[26,27] (Table 37-4). The incidence of stroke increases

TABLE 37-4 Modifiable and Unmodifiable Risk Factors for Stroke

• Cocaine use	

Stroke/Brain Attack

- Stroke is an acute focal neurologic deficit due to a disturbance in the blood vessels supplying the brain. It can be due to ischemia caused by thrombi or emboli that interrupt blood flow or rupture of a blood vessel with bleeding into brain tissue.
- The term *brain attack* as a description for stroke is intended to alert people to the need for immediate treatment at the first sign of a stroke.
- During the evolution of an ischemic stroke, there usually is a central core of dead or dying cells surrounded by an ischemic band of minimally perfused cells called a *penumbra*. Whether the cells of the penumbra continue to survive depends on the successful timely return of adequate circulation.
- The realization that there is a window of opportunity during which ischemic but viable brain tissue can be salvaged has led to the use of thrombolytic agents in the early treatment of ischemic stroke.

with age, with men's stroke incidence rates being greater than women's at younger ages, but not at older ages. Because women live longer than men, more women die of stroke each year. African Americans have almost twice the risk of first-ever strokes as whites. Blood pressure is a powerful determinant of stroke risk. Individuals with a blood pressure less than 120/80 mm Hg have about half the lifetime risk of stroke compared with persons with hypertension. Heart disease, particularly atrial fibrillation and other conditions that predispose to clot formation on the wall of the heart or valve leaflets, or to paradoxical embolism through right-to-left shunting, predisposes to cardioembolic stroke. Polycythemia, sickle cell disease (during sickle cell crisis), and blood disorders predispose to clot formation in the cerebral vessels.

Other, less well-documented risk factors include obesity, physical inactivity, alcohol and drug abuse, hypercoagulability disorders, hormone replacement therapy, and oral contraceptive use.[26–28] Clinical trial data indicate that estrogen plus progestin, as well as estrogen alone, increase stroke risk in postmenopausal, generally healthy women, and provide no protection for women with established heart disease. Although extensively used in the past, the use of hormone therapy is no longer recommended (see Chapter 40). Heavy alcohol consumption can lead to hypertension, hypercoagulability of blood, reduction of cerebral blood flow, and greater likelihood of atrial fibrillation. Cocaine use causes both ischemic and hemorrhagic strokes by inducing vasospasm, enhanced platelet activity, and increased blood pressure, heart rate, body temperature, and metabolic rate. Cocaine stroke victims range in age from newborn (i.e., from maternal cocaine use) to elderly.[29]

Ischemic Stroke

Ischemic strokes are caused by cerebrovascular obstruction by thrombosis or emboli (Fig. 37-13). Various methods have been used to classify ischemic cerebrovascular disease. A common classification system identifies the five main mechanisms of stroke as stroke subtypes and their frequency: 20% large artery atherosclerotic disease (both thrombosis and arterial emboli); 25% small vessel or penetrating artery disease (so-called lacunar stroke); 20% cardiogenic embolism; 30% cryptogenic stroke (undetermined cause); and 5% other, unusual causes[28] (i.e., migraine, vessel dissection, coagulopathy).

Ischemic Penumbra in Evolving Stroke. During the evolution of a stroke, there usually is a central core of dead or dying cells, surrounded by an ischemic band or area of minimally perfused cells called the *penumbra* ("halo"). Brain cells of the penumbra receive marginal blood flow, and their metabolic activities are impaired; although the area undergoes an "electrical failure," the

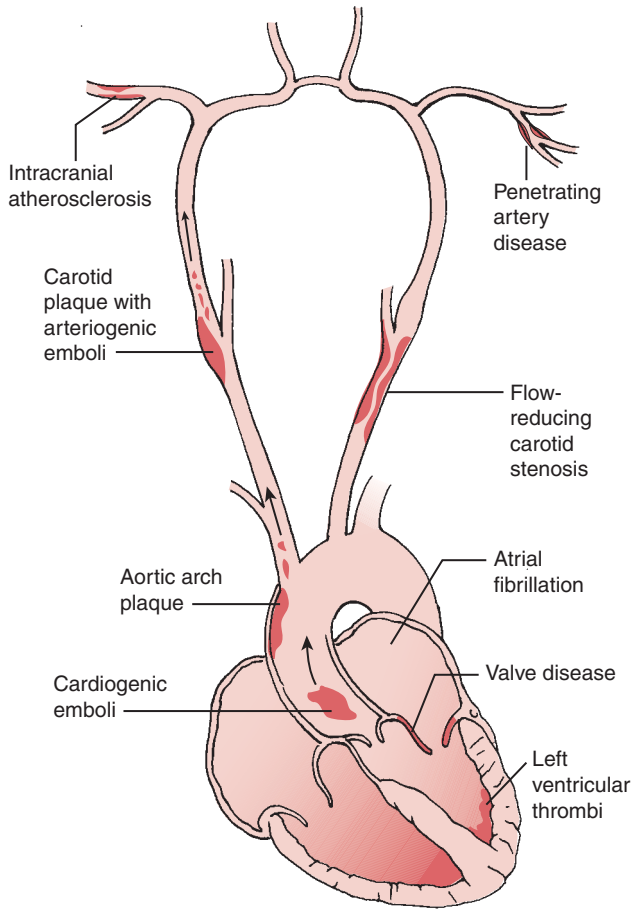

FIGURE 37-13. The most frequent sites of arterial and cardiac abnormalities causing ischemic stroke. (From Albers G.W., Easton D., Sacco R.L., et al. [1999]. Antithrombotic and thrombotic therapy for ischemic stroke. *Chest* 114[5], 684S.)

structural integrity of the brain cells is maintained.[25,30] Whether the cells of the penumbra continue to survive depends on the successful timely return of adequate circulation, the volume of toxic products released by the neighboring dying cells, the degree of cerebral edema, and alterations in local blood flow. If the toxic products result in additional death of cells in the penumbra, the core of dead or dying tissue enlarges, and the volume of surrounding ischemic tissue increases.

Transient Ischemic Attacks. Transient ischemic attacks (TIAs) are brief episodes of neurologic dysfunction resulting from focal cerebral ischemia not associated with infarction.[31,32] A TIA or "ministroke" is equivalent to "brain angina" and reflects a temporary disturbance in cerebral blood flow, which reverses before infarction occurs, analogous to angina in relation to heart attack. The traditional definition of TIAs as a neurologic deficit resolving within 24 hours was developed before the mechanisms of ischemic cell damage and the penumbra were known and before the newer, more advanced methods of neuroimaging became available. A more accurate definition now is a deficit lasting less than 1 hour, and it may best be described as a zone of penumbra without central infarction.[31] The causes of TIAs are the same as those of ischemic stroke and include atherosclerotic disease of cerebral vessels and emboli. TIAs are important because they may provide warning of impending stroke. In fact, the risk for stroke after a TIA is 15% within 3 months.[31] Diagnosis of TIA before a stroke may permit surgical or medical intervention that prevents an eventual stroke and the associated neurologic deficits.

Large Vessel (Thrombotic) Stroke. Thrombi are the most common cause of ischemic strokes, usually occurring in atherosclerotic blood vessels. In the cerebral circulation, atherosclerotic plaques are found most commonly at arterial bifurcations. Common sites of plaque formation include larger vessels of the brain, notably the origins of the internal carotid and vertebral arteries, and junctions of the basilar and vertebral arteries. Cerebral infarction can result from an acute local thrombosis and occlusion at the site of chronic atherosclerosis, with or without embolization of the plaque material distally, or from critical perfusion failure distal to a stenosis (watershed). These infarcts often affect the cortex, causing aphasia or neglect, visual field defects, or transient monocular blindness (amaurosis fugax). In most cases of stroke, a single cerebral artery and its territories are affected. Usually, thrombotic strokes are seen in older persons and frequently are accompanied by evidence of atherosclerotic heart or peripheral arterial disease. The thrombotic stroke is not associated with activity and may occur in a person at rest.

Small Vessel Stroke (Lacunar Infarct). Lacunar infarcts are small (<15 mm wide) to very small infarcts located in the deep, noncortical parts of the brain or in the brain stem.[1] They are found in the territory of single deep penetrating arteries supplying the internal capsule, basal ganglia, or brain stem. They result from occlusion of the smaller penetrating branches of large cerebral arteries, commonly the middle cerebral and posterior cerebral arteries. In the process of healing, lacunar infarcts leave behind small cavities, or *lacunae* ("lakes"). They are thought to result from arteriolar sclerosis, commonly in the settings of chronic hypertension or diabetes. Because of their size and location, lacunar infarcts usually do not cause cortical deficits such as aphasia or apraxia. Instead, they produce classic recognizable "lacunar syndromes" such as pure motor hemiplegia, pure sensory hemiplegia, and dysarthria with the clumsy hand syndrome. Because CT scans are not sensitive enough to detect these tiny infarcts, diagnosis used to depend on clinical features alone. The use of MRI has allowed frequent visualization of small vessel infarcts and is obligatory to confirm such a lesion.

Cardiogenic Embolic Stroke. An embolic stroke is caused by a moving blood clot that travels from its origin to the brain. It usually affects the larger proximal cerebral vessels, often lodging at bifurcations. The most frequent site of embolic strokes is the middle cerebral artery, reflecting the large territory of this vessel and its position as the terminus of the carotid artery. Although most cerebral emboli originate from a thrombus in the left heart, they also may originate in an atherosclerotic plaque in the carotid arteries. The embolus travels quickly to the brain and becomes lodged in a smaller artery through which it cannot pass. Embolic stroke usually has a sudden onset with immediate maximum deficit.

Various cardiac conditions predispose to formation of emboli that produce embolic stroke, including rheumatic heart disease, atrial fibrillation, recent myocardial infarction, ventricular aneurysm, and bacterial endocarditis. More recently, the use of transesophageal echocardiography, which better images the interatrial septum, has implicated a patent foramen ovale as a source for paradoxical venous emboli to the arterial system. Advances in the diagnosis and treatment of heart disease can be expected to alter favorably the incidence of embolic stroke.

Hemorrhagic Stroke

The most frequently fatal stroke is a spontaneous hemorrhage into the brain substance resulting in an intracerebral hemorrhage.[33,34] With rupture of a blood vessel, hemorrhage into the brain tissue occurs, resulting in a focal hematoma and sometimes intraventricular hemorrhage, edema, compression of the brain contents, or spasm of the adjacent blood vessels. The most common predisposing factors are advancing age and hypertension. Other causes of hemorrhage are aneurysm, trauma, erosion of the vessels by tumors, arteriovenous malformations, blood coagulation disorders, vasculitis, and drugs. A cerebral hemorrhage occurs suddenly, usually when the person is active. Vomiting commonly occurs at the onset, and headache often occurs. Focal symptoms depend on which vessel is involved. In the most common situation, hemorrhage into the basal ganglia results in contralateral hemiplegia, with initial flaccidity progressing to spasticity. The hemorrhage and resultant edema exert great pressure

on the brain substance, and the clinical course progresses rapidly to coma and frequently to death.

Treatment of hemorrhagic stroke focuses on management of the increased arterial pressure and intracranial pressure and prevention of recurrent hemorrhage. Recombinant factor VII is available and has been approved for treating bleeding in persons with hemophilia who have antibodies to factor VIII and IX (see Chapter 12). It is also being studied for use in early treatment of hemorrhagic stroke due to other causes.[34]

Acute Stroke Management

The specific manifestations of stroke or TIA are determined by the cerebral artery that is affected, by the area of brain tissue that is supplied by that vessel, and by the adequacy of the collateral circulation.[9,25] Symptoms of stroke/TIA always are sudden in onset and focal, and usually are one-sided. The most common symptom is weakness of the face and arm, sometimes also of the leg. Other frequent stroke symptoms are unilateral numbness, vision loss in one eye (amaurosis fugax) or to one side (hemianopia), language disturbance (aphasia), slurred speech (dysarthria), and sudden, unexplained imbalance or ataxia. In the event of TIA, symptoms rapidly resolve spontaneously, usually within minutes, although the underlying mechanisms are the same as for stroke. The specific stroke signs depend on the specific vascular territory compromised (Table 37-5). As a generalization, carotid ischemia causes monocular visual loss or aphasia (dominant hemisphere) or hemineglect (nondominant hemisphere), contralateral sensory or motor loss, or other discrete cortical signs such as apraxia and agnosia. Vertebrobasilar ischemia induces ataxia, diplopia, hemianopia, vertigo, cranial nerve deficits, contralateral hemiplegia, sensory deficits (either contralateral or crossed, i.e., contralateral body and ipsilateral face), and arousal defects. Discrete subsets of these vascular syndromes usually occur, depending on which branches of the involved artery are blocked.

Diagnosis. Accurate diagnosis of acute stroke, based on a complete history and thorough physical and neurologic examination, should aim to determine the presence of hemorrhage or ischemia, identify the stroke or TIA mechanism (i.e., large vessel or small vessel atherothrombotic, cardioembolic, hemorrhagic, other or cryptogenic), characterize the severity of clinical deficits, and unmask the presence of risk factors.[25,35–37] A careful history, including documentation of previous TIAs, the time of onset and pattern and rapidity of system progression, the specific focal symptoms (to determine the likely vascular territory), and any coexisting diseases, can help to determine the type of stroke that is involved.

CT scans and MRI have become essential brain imaging tools in diagnosing stroke, differentiating cerebral hemorrhage from ischemia, and excluding intracranial lesions that mimic stroke clinically. CT scans are a necessary screening tool in the acute setting for rapid identification of hemorrhage, but are insensitive to ischemia within 24 hours and to any brain stem or small infarcts. MRI is superior for imaging ischemic lesions in all territories and differentiating other nonstroke pathologic processes (e.g., tumors, contusion, infection). Newer

TABLE 37-5 Signs and Symptoms of Stroke by Involved Cerebral Artery

Cerebral Artery	Brain Area Involved	Signs and Symptoms*
Anterior cerebral	Infarction of the medial aspect of one frontal lobe if lesion is distal to communicating artery; bilateral frontal infarction if flow in other anterior cerebral artery is inadequate	Paralysis of contralateral foot or leg; impaired gait; paresis of contralateral arm; contralateral sensory loss over toes, foot, and leg; problems making decisions or performing acts voluntarily; lack of spontaneity, easily distracted; slowness of thought; aphasia depends on the hemisphere involved; urinary incontinence; cognitive and affective disorders
Middle cerebral	Massive infarction of most of lateral hemisphere and deeper structures of the frontal, parietal, and temporal lobes; internal capsule; basal ganglia	Contralateral hemiplegia (face and arm); contralateral sensory impairment; aphasia; homonymous hemianopia; altered consciousness (confusion to coma); inability to turn eyes toward paralyzed side; denial of paralyzed side or limb (hemiattention); possible acalculia, alexia, finger agnosia, and left–right confusion; vasomotor paresis and instability
Posterior cerebral	Occipital lobe; anterior and medial portion of temporal lobe	Homonymous hemianopia and other visual defects such as color blindness, loss of central vision, and visual hallucinations; memory deficits, perseveration (repeated performance of same verbal or motor response)
	Thalamus involvement	Loss of all sensory modalities; spontaneous pain; intentional tremor; mild hemiparesis; aphasia
Basilar and vertebral	Cerebral peduncle involvement	Oculomotor nerve palsy with contralateral hemiplegia
	Cerebellum and brain stem	Visual disturbance such as diplopia, dystaxia, vertigo, dysphagia, dysphonia

*Depend on hemisphere involved and adequacy of collaterals.

MRI techniques such as perfusion- and diffusion-weighted imaging (DWI) can reveal cerebral ischemia immediately after onset and identify areas of potentially reversible damage (i.e., penumbra).

Vascular imaging is accomplished with CT angiography (CTA), magnetic resonance angiography (MRA), catheter-based "conventional" arteriography, and ultrasonography. All except ultrasonography can demonstrate the site of vascular abnormality (intracranial and extracranial) and afford visualization of most intracranial vascular areas. MRA is noninvasive and most widely available, but less sensitive and specific than CTA or catheter angiography. CTA is exquisitely detailed for a noninvasive technique, but is limited in availability and requires iodinated contrast, which is nephrotoxic. Catheter angiography remains the gold standard in sensitivity and allows visualization of dynamic patterns of collateral flow, but is invasive and requires significant contrast doses. CTA and MRA have largely replaced angiography as a screening tool for vascular lesions. Ultrasonographic techniques allow quick bedside assessment of the carotid bifurcation (duplex ultrasonography) or of flow velocities in the cerebral circulation (transcranial Doppler).

Treatment. Treatment of acute ischemic stroke has changed markedly since the early 1990s, with an emphasis on salvaging brain tissue, preventing secondary stroke, and minimizing long-term disability. The care of patients with stroke has shifted away from the "nearest hospital" to stroke centers that have been certified by some external agency, most commonly the state or joint commission.[38,39] Certification establishes that a hospital can manage stroke patients with appropriate care throughout the continuum, from emergency treatments, through the inpatient stay, and into the rehabilitation phase. With this advancement, the medical and lay communities acknowledge that care of the patient with stroke requires specialized personnel and resources to minimize the devastating effects from stroke, the leading cause of adult disability in the United States.

Stroke care begins with emergency treatments aimed at reversing the evolving ischemic brain injury. The realization that there is a window of opportunity during which ischemic but viable brain tissue can be salvaged has led to the use of reperfusion techniques and neuroprotective strategies in the early treatment of ischemic stroke.[25,35–39] Although the results of emergent treatment of hemorrhagic stroke have been less dramatic, continued efforts to reduce disability have been promising.

Reperfusion techniques include thrombolytic therapy (administered either intravenously or intra-arterially), catheter-directed mechanical clot disruption, and augmentation of CPP during acute stroke. The first and only agent approved by the U.S. Food and Drug Administration (FDA) for treatment of acute ischemic stroke is tissue plasminogen activator (tPA), which was approved in 1996.[40] A subcommittee of the Stroke Council of the American Heart Association has developed guidelines for the use of tPA for acute stroke.[35] These guidelines recommend that in persons with suspected stroke, the diagnosis of hemorrhagic stroke be excluded through the use of CT scanning before administration of thrombolytic therapy, which must be administered within 3 hours of onset of symptoms. Generally, although patient selection is more stringent for these invasive methods, patients can be treated past the 3-hour time window with intravenous tPA.[41] The major risk of treatment with thrombolytic agents is intracranial hemorrhage of the infarcted brain. A number of conditions, including therapeutic levels of oral anticoagulant medications, a history of gastrointestinal or urinary tract bleeding in the previous 21 days, prior stroke or head injury within 3 months, major surgery within the past 14 days, and a blood pressure greater than 185/110 mm Hg, are considered contraindications to intravenous thrombolytic therapy.[35]

Emerging experimental treatments for ischemic stroke are being increasingly used as alternative methods of reperfusion beyond intravenous thrombolysis. New catheter-based methods allow recanalization of a directly visualized cerebral clot with intra-arterial techniques. The interventional specialist might mechanically disrupt the clot, deliver the thrombolytic drug intra-arterially at the clot surface, or urgently stent intracranial vessels to restore flow. However, these methods require an experienced interventional angiography team and extensive institutional infrastructure, and thus remain limited to tertiary care centers. Other experimental treatments include neuroprotection with drugs that limit the calcium cascade (see Fig. 37-2) and treatments such as hypothermia that decrease brain metabolic demands in the setting of ischemia. All are being actively tested in clinical trials.

Poststroke Management and Deficits

Poststroke treatment is aimed at preventing recurrent stroke and medical complications while promoting the fullest possible recovery of function.[42] The risk of stroke recurrence is highest in the first week after a stroke or TIA, so the early implementation of antiplatelet agents in most cases, or warfarin (an anticoagulant) in cardioembolic stroke, is imperative. Long-term stroke recurrence is most effectively prevented with aggressive reduction of risk factors, primarily hypertension, diabetes, smoking, and hyperlipidemia. In cases of carotid territory stroke with carotid stenosis, revascularization with surgery or stenting should be considered. Early hospital care also requires careful prevention of aspiration, deep vein thrombosis, and falls. Recovery is maximized with early and aggressive rehabilitation efforts that include all members of the rehabilitation team—physician, nurse, speech therapist, physical therapist, and occupational therapist—and the family.

Poststroke Motor Deficits. Poststroke motor deficits are most common, followed by deficits of language, sensation, and cognition. After a stroke affecting the corticospinal tract such as the motor cortex, posterior limb of the internal capsule, basis pontis, or medullary pyramids, there is profound weakness on the contralateral side (hemiparesis; see Chapter 36, Fig. 36-4). Involvement at the level of the motor cortex is most often in the territory of the middle cerebral artery, usually with a sparing of

the leg, which is supplied by the anterior cerebral artery. Subcortical lesions of the corticospinal tracts cause equal weakness of the face, arm, and leg. Within 6 to 8 weeks, the initial weakness and flaccidity are replaced by hyperreflexia and spasticity. Spasticity involves an increase in the tone of affected muscles and usually an element of weakness. The flexor muscles usually are more strongly affected in the upper extremities and the extensor muscles more strongly affected in the lower extremities. There is a tendency toward foot drop; outward rotation and circumduction of the leg with gait; flexion at the wrist, elbow, and fingers; lower facial paresis; slurred speech; an upgoing toe to plantar stimulation (Babinski sign); and dependent edema in the affected extremities. A slight corticospinal lesion may be indicated only by clumsiness in carrying out fine coordinated movements rather than obvious weakness. Passive range-of-motion exercises help to maintain joint function and to prevent edema, shoulder subluxation (i.e., incomplete dislocation), and muscle atrophy, and may help to reestablish motor patterns. If no voluntary movement or movement on command appears within a few months, significant function usually will not return to that extremity.

Poststroke Dysarthria and Aphasia. Two key aspects of verbal communication are speech and language. Speech involves the mechanical act of articulating language, the "motor act" of verbal expression, whereas language involves the written or spoken use of symbolic formulations, such as words or numbers. *Dysarthria* is a disorder of speech, which manifests as the imperfect articulation of speech sounds or changes in voice pitch or quality. It results from a stroke affecting the muscles of the pharynx, palate, tongue, lips, or mouth and does not relate to the content of speech. A person with dysarthria may demonstrate slurred speech while still retaining language ability, or may have a concurrent language problem as well. *Aphasia* is a general term that encompasses varying degrees of inability to comprehend, integrate, and express language. Aphasia may be localized to the dominant cerebral cortex or thalamus, usually the left side in 95% of people who are right handed and 70% of people who are left handed. In children, language dominance can readily shift to the unaffected hemisphere, resulting in more transient language deficits after stroke. A stroke in the territory of the middle cerebral artery is the most common aphasia-producing stroke.

Aphasia can be categorized as receptive or expressive, or as fluent or nonfluent. Receptive or fluent speech requires little or no effort, is intelligible, and is of increased quantity. The term *fluent* refers only to the ease and rate of verbal output, and does not relate to the content of speech or the ability of the person to comprehend what is being said. Verbal utterances are often paraphrasic, meaning that letters, syllables, or whole words are substituted for the target words. There are three categories of fluent aphasia: Wernicke, anomic, and conductive aphasia. *Wernicke aphasia* is characterized by an inability to comprehend the speech of others or to comprehend written material. Lesions of the posterior superior temporal or lower parietal lobe (areas 22 and 39) are associated with receptive or *fluent aphasia*. *Anomic aphasia* is speech that is nearly normal except for a difficulty with finding singular words. Conductive aphasia is manifest as impaired repetition and speech riddled with letter substitutions, despite good comprehension and fluency. *Conductive aphasia* (i.e., disconnection syndrome) results from destruction of the fiber system under the insula that connects the Wernicke and Broca areas.

Expressive or *nonfluent aphasia* is characterized by an inability to easily communicate spontaneously or translate thoughts or ideas into meaningful speech or writing. Speech production is limited, effortful, and halting and often may be poorly articulated because of a concurrent dysarthria. The person may be able, with difficulty, to utter or write two or three words, especially those with an emotional overlay. Comprehension is normal, and the person seems to be fully aware of his or her deficits but is unable to correct them. This often leads to frustration, anger, and depression. Expressive, nonfluent aphasia is associated with lesions of the Broca area at the dominant inferior frontal lobe cortex (areas 44 and 45).

Poststroke Cognitive and Other Deficits. Stroke can also cause cognitive, sensory, visual, and behavioral deficits. One distinct cognitive syndrome is that of hemineglect or hemi-inattention. Usually caused by strokes affecting the nondominant (right) hemisphere, hemineglect is the inability to attend to and react to stimuli coming from the contralateral (left) side of space. Affected persons may not visually track, orient, or reach to the neglected side. They may neglect to use the limbs on that side, despite normal motor function, and may not shave, wash, or comb that side. Such persons are unaware of this deficit, which is another form of their neglect (*anosognosia*). Other cognitive deficits include impaired ability to carry out previously learned motor activities despite normal sensory and motor function (*apraxia*), impaired recognition with normal sensory function (*agnosia*), memory loss, behavioral syndromes, and depression. Sensory deficits affect the body contralateral to the lesion and can manifest as numbness, tingling paresthesias, or distorted sensations such as dysesthesia and neuropathic pain. Visual disturbances from stroke are diverse, but most common are hemianopia from a lesion of the optic radiations between the lateral geniculate body and the temporal or occipital lobes, and monocular blindness from occlusion of the ipsilateral central retinal artery, a branch of the internal carotid artery.

Aneurysmal Subarachnoid Hemorrhage

An aneurysm is a bulge at the site of a localized weakness in the muscular wall of an arterial vessel. Most cerebral aneurysms are small saccular aneurysms called *berry aneurysms*. They usually occur in the anterior circulation and are found at bifurcations and other junctions of vessels such as those in the circle of Willis (Fig. 37-14). They are thought to arise from a congenital defect in the media of the involved vessels. Their incidence is higher in

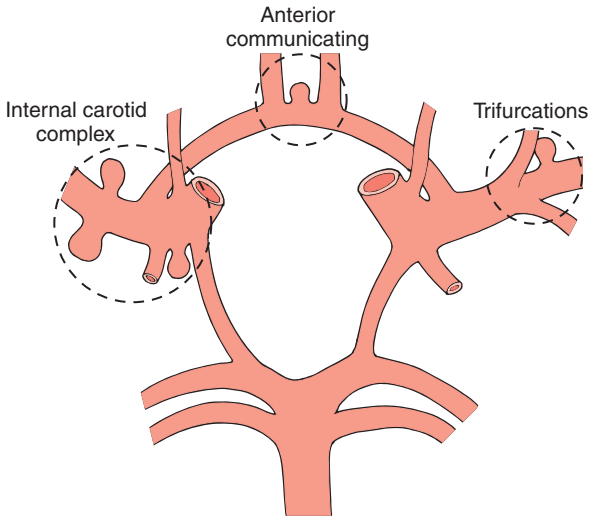

FIGURE 37-14. Common sites of berry aneurysms.

persons with certain disorders, including polycystic kidney disease, fibromuscular dysplasia, coarctation of the aorta, and arteriovenous malformations of the brain.[1,5] Other causes of cerebral aneurysms are atherosclerosis, hypertension, and bacterial infections.

Aneurysmal subarachnoid hemorrhage represents bleeding into the subarachnoid space caused by a ruptured cerebral aneurysm. Bleeding into the subarachnoid space can extend well beyond the site of origin, flooding the basal cistern, ventricles, and spinal subarachnoid space. The incidence of rupture increases with age, occurring most commonly between 40 and 60 years of age.[43] The probability of rupture increases with the size of the aneurysm; aneurysms larger than 10 mm in diameter have a 50% chance of bleeding per year.[1] Of the various environmental factors that may predispose to aneurysmal subarachnoid hemorrhage, cigarette smoking, hypertension, and excessive alcohol intake appear to constitute the greatest threat.[43] Rupture may occur at any time, but often occurs with acute increases in ICP, such as with straining at stool. The mortality rate for subarachnoid hemorrhage is high (33% to 50%), with the majority of deaths occurring within the first few days of hemorrhage.[43]

The signs and symptoms of cerebral aneurysms can be divided into two phases: those presenting before rupture and those presenting after rupture. Most small aneurysms are asymptomatic; intact aneurysms frequently are found at autopsy as an incidental finding. Large aneurysms may cause chronic headache, neurologic deficits, or both.[43,44] Persons with subarachnoid hemorrhage often have a history of atypical headaches occurring days to weeks before the onset of hemorrhage, suggesting the presence of a small leak. These headaches are characterized by sudden onset and often are accompanied by nausea, vomiting, and dizziness. Persons with these symptoms may be mistakenly diagnosed as having tension or migraine headaches.

The onset of subarachnoid aneurysmal rupture often is heralded by a sudden and severe headache, described as "the worst headache of my life."[43] If the bleeding is severe, the headache may be accompanied by collapse and loss of consciousness. Vomiting may accompany the presenting symptoms. Other manifestations include signs of meningeal irritation such as nuchal rigidity (neck stiffness) and photophobia (light intolerance); cranial nerve deficits, especially CN II, and sometimes CN III and CN IV (diplopia and blurred vision); stroke syndromes (focal motor and sensory deficits); cerebral edema and increased ICP; and pituitary dysfunction (diabetes insipidus and hyponatremia). Hypertension, a frequent finding, and cardiac arrhythmias result from massive release of catecholamines triggered by the subarachnoid hemorrhage.

The diagnosis of subarachnoid hemorrhage and intracranial aneurysms is made by clinical presentation, CT scan, lumbar puncture, and angiography.[43,44] Lumbar puncture may reveal the presence of blood in the CSF, whereas CT may demonstrate the location and extent of subarachnoid blood. To identify the aneurysm at the source of bleeding, conventional angiography, MRA, and helical (spiral) CTA are used. Conventional catheter angiography is the definitive diagnostic tool for detecting the aneurysm.

The course of treatment after aneurysm rupture depends on the extent of neurologic deficit. The best outcomes are achieved when the aneurysm can be secured early and prevention of complications initiated.[44] Persons with mild to no neurologic deficits may undergo cerebral arteriography and early surgery, usually within 24 to 72 hours. Surgery involves craniotomy and inserting a specially designed silver clip that is tightened around the neck of the aneurysm. This procedure offers protection from rebleeding and may permit removal of the hematoma. The use of endovascular techniques such as balloon embolization and platinum coil electrothrombosis is emerging as an alternative to surgery, particularly in surgically inaccessible aneurysms or poor surgical candidates. Some persons with subarachnoid hemorrhage are managed medically for 10 days or more in an attempt to improve their clinical status before surgery.

The complications of aneurysmal rupture include rebleeding, vasospasm with cerebral ischemia, hydrocephalus, hypothalamic dysfunction, and seizure activity. Rebleeding and vasospasm are the most serious and most difficult to treat. Rebleeding, which usually occurs on the first day after the initial rupture, results in further and usually catastrophic neurologic deficits.

Cerebral vasospasm is a dreaded complication of aneurysmal rupture. The condition is difficult to treat and is associated with a high incidence of morbidity and mortality. Usually, the condition develops within 3 to 10 days (peak, 7 days) after aneurysm rupture and involves a focal narrowing of the cerebral artery or arteries that can be visualized on arteriography or by transcranial Doppler. The neurologic status gradually deteriorates as blood supply to the brain in the region of the spasm is decreased; this usually can be differentiated from the rapid deterioration seen in rebleeding. Vasospasm is treated by attempting to maintain adequate CPP through the use of vasoactive drugs or administration of large amounts of intravenous fluids to increase intravascular

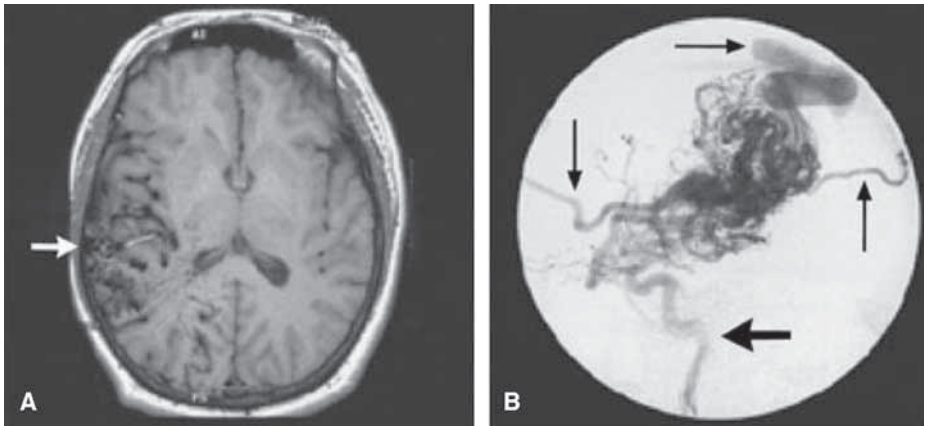

FIGURE 37-15. **(A)** Computed tomography scan of an arteriovenous malformation in the right parietal region of the brain (*arrow*). **(B)** Angiographic study of the internal carotid artery delineating the malformation in the middle cerebral artery distribution (*large arrow*), with draining veins (*small arrows*) to the superior sagittal sinus. volume and produce hemodilution. There is risk for rebleeding from this therapy. Early surgery may provide some protection from vasospasm. Endovascular techniques, including balloon dilation, have been developed to treat spasmodic arterial segments mechanically. Nimodipine, a drug that blocks calcium channels and selectively acts on cerebral blood vessels, may be used to prevent or treat vasospasm.

Another complication of aneurysm rupture is the development of hydrocephalus. It is caused by plugging of the arachnoid villi with products from lysis of blood in the subarachnoid space. Hydrocephalus is diagnosed by serial CT scans showing increasing size of the ventricles and by the clinical signs of increased ICP. Hydrocephalus may respond to osmotic diuretics, but if neurologic deterioration is significant, surgical placement of a shunt is indicated.

Arteriovenous Malformations

Arteriovenous malformations are a complex tangle of abnormal arteries and veins linked by one or more fistulas[45,46] (Fig. 37-15). These vascular networks lack a capillary bed, and the small arteries have a deficient muscularis layer. Arteriovenous malformations are thought to arise from failure in development of the capillary network in the embryonic brain. As the child's brain grows, the malformation acquires additional arterial contributions that enlarge to form a tangled collection of thin-walled vessels that shunt blood directly from the arterial to the venous circulation. Arteriovenous malformations typically present before 40 years of age and affect men and women equally. Rupture of vessels in the malformation causing hemorrhagic stroke accounts for approximately 2% of all strokes.[46]

The hemodynamic effects of arteriovenous malformations are twofold. First, blood is shunted from the high-pressure arterial system to the low-pressure venous system without the buffering advantage of the capillary network. The draining venous channels are exposed to high levels of pressure, predisposing them to rupture and hemorrhage. Second, the elevated arterial and venous pressures divert blood away from the surrounding tissue, impairing tissue perfusion. Clinically, this is evidenced by slowly progressive neurologic deficits. The major clinical manifestations of arteriovenous malformations are intracerebral and subarachnoid hemorrhage, seizures, headache, and progressive neurologic deficits. Headaches often are severe, and persons with the disorder may describe them as throbbing and synchronous with their heartbeat. Other, focal symptoms depend on the location of the lesion and include visual symptoms (i.e., diplopia and hemianopia), hemiparesis, mental deterioration, and speech deficits.

Definitive diagnosis often is obtained through cerebral angiography. Treatment methods include surgical excision, endovascular occlusion, and radiation therapy.[46] Because of the nature of the malformation, each of these methods is accompanied by some risk for complications. If the arteriovenous malformation is accessible, surgical excision usually is the treatment of choice. Endovascular treatment involves the insertion of microcatheters into the cerebral circulation for delivery of embolic materials (e.g., microballoons, sclerosing agents, microcoils, or quick-drying glue) into the arteriovenous malformation vessels.[47] Radiation therapy (also known as *radiosurgery*) may involve the use of a gamma knife, proton beam, or linear accelerator.

In summary, a stroke, or brain attack, is an acute focal neurologic deficit caused by a vascular disorder that injures brain tissue. It is a leading cause of death in the United States and a major cause of disability. There are two main types of stroke: ischemic and hemorrhagic. Ischemic stroke, which is the most common type, is caused by cerebrovascular obstruction by a thrombus or embolus. Hemorrhagic stroke, which is associated with greater morbidity and mortality, is caused by the rupture of a blood vessel and bleeding into the brain. The acute manifestations of stroke depend on the location of the blood vessel that is involved and can include motor, sensory, language, speech, and cognitive disorders. Early diagnosis and treatment with thrombolytic therapy have improved the outlook for many persons with ischemic stroke.

A subarachnoid hemorrhage involves bleeding into the subarachnoid space. Most subarachnoid hemorrhages are the result of a ruptured cerebral aneurysm. Presenting symptoms include headache, nuchal rigidity, photophobia, and nausea. Complications include rebleeding, vasospasm, and hydrocephalus. Arteriovenous malformations are congenital abnormal communications between arterial and venous channels that result from failure in the development of the capillary network in the embryonic brain. The vessels in the arteriovenous malformations may enlarge to form a space-occupying lesion, become weak and predispose to bleeding, and divert blood away from other parts of the brain; they can cause brain hemorrhage, seizures, headache, and other neurologic deficits.

Infections and Brain Tumors

Infections

Infections of the CNS may be classified according to the structure involved—meninges (meningitis), parenchymal brain tissue (encephalitis), spinal cord (myelitis), or brain and spinal cord (encephalomyelitis). They also may be classified by the type of invading organism: bacterial, viral, or other. In general, the pathogen enters the CNS through the bloodstream by crossing the blood-brain barrier or by direct invasion through skull fracture, or, rarely, by contamination during surgery or lumbar puncture.

Meningitis

Meningitis is an inflammation of the pia mater, the arachnoid, and the CSF-filled subarachnoid space. Inflammation spreads rapidly because of CSF circulation around the brain and spinal cord. The inflammation usually is caused by an infection, but chemical meningitis can occur. There are two types of acute infectious meningitis: acute purulent meningitis (usually bacterial) and acute lymphocytic (usually viral) meningitis.[1] Factors responsible for the severity of meningitis include virulence factors of the pathogen, host factors, brain edema, and the presence of permanent neurologic sequelae.

Bacterial Meningitis. Most cases of bacterial meningitis are caused by *Streptococcus pneumoniae* (the pneumococcus) or *Neisseria meningitidis* (the meningococcus), except in neonates (infected most by group B streptococci).[1,5,48,49] *Haemophilus influenzae* infection was a leading cause of meningitis in decades past, but its incidence has declined dramatically during recent years because of vaccination against *H. influenza*. Epidemics of meningococcal meningitis occur in settings such as colleges and the military, where young people reside in close contact. Other pathogens in adults are gram-negative bacilli and *Listeria monocytogenes*. The very young and the very old are at highest risk for pneumococcal meningitis. Risk factors associated with contracting meningitis include head trauma with basilar skull fractures, otitis media, sinusitis or mastoiditis, neurosurgery, dermal sinus tracts, systemic sepsis, or immunocompromise.

In the pathophysiologic process of bacterial meningitis, the bacterial organisms replicate and undergo lysis in the CSF, releasing endotoxins or cell wall fragments. These substances initiate the release of inflammatory mediators, which set off a complex sequence of events permitting pathogens, neutrophils, and albumin to move across the capillary wall into the CSF. As the pathogens enter the subarachnoid space, they cause inflammation, characterized by a cloudy, purulent exudate. Thrombophlebitis of the bridging veins and dural sinuses or obliteration of arterioles by inflammation may develop, causing vascular congestion and infarction in the surrounding tissues. Ultimately, the meninges thicken and adhesions form. These adhesions may impinge on the cranial nerves, giving rise to cranial nerve palsies, or may impair the outflow of CSF, causing hydrocephalus.

The most common symptoms of acute bacterial meningitis are sudden onset of headache, fever, and stiffness of the neck (nuchal rigidity), sometimes accompanied by nausea, vomiting, photophobia, and altered mental status.[48,50] Other signs include seizures, cranial nerve palsies, and focal cerebral signs. Meningococcal meningitis is characterized by a petechial rash with palpable purpura in most people. These petechiae vary in size from pinhead to large ecchymoses or even areas of skin gangrene, often associated with rapid onset of hypotension, acute adrenal hemorrhage (the Waterhouse-Friderichsen syndrome), and multiple organ failure. Persons infected with *H. influenzae* or *S. pneumoniae* may present with difficulty in arousal and seizures, whereas those with *N. meningitidis* infection may present with delirium or coma. Cranial nerve damage (especially CN VIII, with resulting deafness) and hydrocephalus may occur as complications of pyogenic meningitis.

Diagnosis of bacterial meningitis is based on the history and physical examination, along with laboratory data. Two assessment techniques can help determine whether meningeal irritation is present. The *Kernig sign* is resistance to extension of the knee while the person is lying with the hip flexed at a right angle. The *Brudzinski sign* is elicited when flexion of the neck induces flexion of the hip and knee. These postures reflect resistance to the painful stretching of the inflamed meninges from the lumbar level to the head. Lumbar puncture findings, which are necessary for accurate diagnosis, include a cloudy and purulent CSF under increased pressure. Bacteria can be seen on smears and can easily be cultured with appropriate media. Occasionally, previous antibiotic use limits culture sensitivities, in which case latex agglutination or polymerase chain reaction (PCR) testing for *N. meningitidis, H. influenzae,* and *Listeria* species can be used. Because complications associated with lumbar puncture include life-threatening cerebral herniation, at-risk patients (i.e., those who are immunocompromised, had a seizure within a week, have papilledema, or have specific neurologic abnormalities) should have a CT scan before undergoing the procedure.

Treatment includes urgent antibiotics while diagnostic testing ensues.[49–51] Delay in initiation of antimicrobial

therapy, most frequently because of performance of medical imaging before performance of lumbar puncture or transfer to another medical facility, can result in poor outcomes.[49,50] Initial choice of antibiotics includes broad-spectrum coverage with a third-generation cephalosporin, vancomycin, and sometimes ampicillin. Further adjustment of antibiotics is driven by results of CSF cultures. Effective antibiotics produce rapid lysis of the pathogen, which produces inflammatory mediators that have the potential for exacerbating the abnormalities of the blood-brain barrier. To suppress this pathologic inflammation, adjunctive corticosteroid therapy is increasingly administered with or just before the first dose of antibiotics in patients of all ages.[49,50]

Persons who have been exposed to someone with meningococcal meningitis should be treated prophylactically with antibiotics.[49] A quadrivalent polysaccharide–protein conjugate vaccine is now available to protect against meningococcal meningitis. The vaccine is recommended for all persons aged 11 to 18 years and for persons 19 to 55 years who are at increased risk for meningococcal disease (e.g., military recruits, college students living in dormitories, microbiologists who are routinely exposed to *N. meningitides*, and persons with complement deficiencies or anatomic or functional asplenia).[52]

Viral Meningitis. Viral meningitis manifests in much the same way as bacterial meningitis, but the course is less severe and the CSF findings are markedly different. There are lymphocytes in the fluid rather than polymorphonuclear cells, the protein content is only moderately elevated, and the sugar content usually is normal. The acute viral meningitides are self-limited and usually require only symptomatic treatment, except for herpes simplex virus (HSV) type 2, which responds to intravenous acyclovir. Viral meningitis can be caused by many different viruses, most often enteroviruses, including coxsackievirus, poliovirus, and echovirus. Others include Epstein-Barr virus, mumps virus, HSV, and West Nile virus. Although often the virus cannot be identified, newer assays are emerging that allow in some circumstances for rapid identification of viral ribonucleic acid (RNA) in CSF.

Encephalitis

Encephalitis represents a generalized infection of the parenchyma of the brain or spinal cord. It usually is caused by a virus, but it also may be caused by bacteria, fungi, and other organisms. The nervous system is subject to invasion by many viruses, such as arbovirus, poliovirus, and rabies virus. The mode of transmission may be the bite of a mosquito (arbovirus), a rabid animal (rabies virus), or ingestion (poliovirus). Common causes of encephalitis in the United States are HSV and West Nile virus. Less frequent causes of encephalitis are toxic substances such as ingested lead and vaccines for measles and mumps. Encephalitis caused by human immunodeficiency virus (HIV) infection is discussed in Chapter 16.

The pathologic picture of encephalitis includes local necrotizing hemorrhage, which ultimately becomes generalized, with prominent edema. There is progressive degeneration of nerve cell bodies. The histologic picture, although rather general, may demonstrate some specific characteristics. For example, the poliovirus selectively destroys the cells of the anterior horn of the spinal cord.

Like meningitis, encephalitis is characterized by fever, headache, and nuchal rigidity, but more often patients also experience neurologic disturbances, such as lethargy, disorientation, seizures, focal paralysis, delirium, and coma. Diagnosis of encephalitis is made by clinical history and presenting symptoms, in addition to traditional CSF studies.

Brain Tumors

Primary brain tumors account for 2% of all cancers in the United States.[5,53] Metastasis to the brain from other sites is even more common. One estimate suggests that more than 100,000 people per year die with symptomatic intracranial metastasis.[54] In children, primary brain tumors are second only to leukemia as a cause of death from cancer, with 2200 primary brain tumors being diagnosed each year.[55] The mortality rate among this age group approaches 45%.[55]

The etiology of brain tumors is largely unknown. Several CNS tumors are associated with rare genetic conditions, most commonly the autosomal dominant disorder neurofibromatosis 1 (see Chapter 6). Although a large number of studies have examined the relationship between environmental and occupational factors, only high-dose radiation has been shown to be a proven risk factor.[53,55] Irradiation given to treat intracranial and extracranial cancers, including prophylactic irradiation for leukemia, increases the incidence of brain tumors.

Types of Tumors

The term *brain tumor* refers to a collection of intracranial neoplasms, each with its own histology, site of origin, prognosis, and treatment.[1,5,9] For most neoplasms, the term *malignant* is used to describe the tumor's lack of cell differentiation, its invasive nature, and its ability to metastasize. However, the terms *benign* and *malignant* do not apply to brain tumors in the same sense as they do to tumors in other parts of the body. In the brain, even a well-differentiated and histologically benign tumor may grow and cause death because of its location. Also, tumors in the brain are rarely benign because surgery rarely cures. Most histologically benign tumors infiltrate the normal brain tissue, preventing total resection and allowing for tumor recurrence. Furthermore, brain tumors seldom metastasize, except within the CNS itself.

Brain tumors can be divided into three basic types: primary intracranial tumors of neuroepithelial tissue (e.g., neuroglia, neurons), primary intracranial tumors that originate in the cranial cavity but are not derived from the brain tissue itself (e.g., meninges, primary CNS lymphoma, pituitary gland tumors [discussed in Chapter 32]), and metastatic tumors.[5] Collectively, neurogliomas of astrocytic origin are the most common type of primary

brain tumor in adults, and medulloblastomas the most common type in children. Whatever the type, brain tumors commonly present with symptoms related to a disruption in neuronal activity (seizures), signs of increased ICP (progressive headache, nausea and vomiting, drowsiness, visual abnormalities), focal motor or sensory deficits, and cognitive dysfunction.[56,57]

Neuroglial Tumors. Neuroglial tumors, which are the most common form of primary brain tumors, derive from astrocytes, oligodendrocytes, and ependymal cells.[1,5,58] Gliomas are divided into four grades: grades I and II are low-grade tumors, whereas grade III and IV are high-grade tumors.

Astrocyte tumors are generally divided into two categories: infiltrating astrocytomas and noninfiltrating astrocytomas. Infiltrating astrocytomas account for 80% of adult primary brain tumors.[1] They occur most commonly in the fourth through the sixth decade. Although they usually are found in the cerebral hemispheres, they also can occur in the cerebellum, brain stem, or spinal cord. The most common presenting signs and symptoms are seizures, headaches, and focal neurologic deficits related to the location of the tumor. Infiltrating astrocytomas are characterized by a spectrum of histologic differentiation that includes diffuse astrocytomas (grade II); anaplastic astrocytomas (grade III); and the least differentiated and most aggressive, glioblastomas (grade IV).[1] The grade I designation is reserved for the noninfiltrating pilocytic astrocytomas, which are distinguished from other astrocytomas by their cellular appearance and their benign behavior. Typically, they occur in children and young adults and usually are located in the cerebellum, but they also can be found in the floor and walls of the third ventricle, in the optic chiasm and nerves, and occasionally in the cerebral hemispheres. These tumors grow slowly and, in the cerebellum particularly, may be treated by resection.

Oligodendrogliomas are tumors of the oligodendrocytes or their precursors.[1] They represent approximately 5% to 15% of neuroglial tumors and are most common in the fourth and fifth decades of life. The tumors are found mostly in the cerebral hemispheres, with a predilection for white matter. The prognosis of persons with oligodendrogliomas is less predictable than for persons with infiltrating astrocytomas. It depends on the histologic grade of the tumor, its location, and, more recently, recognition of molecular features that can be linked to chemosensitivity.[54] The oligodendroglial tumors are prone to spontaneous hemorrhage owing to their delicate vasculature.

Ependymomas are derived from the single layer of epithelium that lines the ventricles and spinal canal. Although they can occur at any age, they are most likely to occur in the first two decades of life and most frequently affect the fourth ventricle; they constitute 5% to 10% of brain tumors in this age group.[1] In adults, the spinal cord is the most common location. The clinical features depend on the location of the neoplasm. Intracranial tumors are often associated with hydrocephalus and evidence of increased ICP.

Medulloblastoma. Tumors of neuronal origin (e.g., medulloblastoma) usually occur during infancy and childhood.[55,59] This is in accord with the principle that a cell must be capable of replication to undergo neoplastic transformation. Medulloblastoma is thought to originate from a primitive cell type in the cerebellum, arising from one of two cerebellar germinal zones: the ventricular zone that forms the outermost boundary or the external germinal layer that lines the outside of the cerebellum.

Medulloblastomas have a bimodal distribution, peaking at 3 to 4 years and then again between 8 and 9 years of age.[59] About 10% to 15% of cases are diagnosed in infancy.[59] Children usually present with signs and symptoms of increased ICP (i.e., headache, nausea, vomiting, mental status changes, hypertension) and cerebellar dysfunction (i.e., ataxia, balance problems, movement disorders). The tumor is highly malignant, and the prognosis for untreated children is dismal. However, the tumor is highly radiosensitive; with total excision and irradiation, the 5-year survival rate may be as high as 75%.

Meningiomas. Meningiomas develop from the meningothelial cells of the arachnoid and are outside the brain. They usually have their onset in the middle or later years of life and constitute approximately 20% of primary brain tumors in this age group.[1] Meningiomas are slow-growing, well-circumscribed, and often highly vascular tumors. They usually are benign, and complete removal is possible if the tumor does not involve vital structures.

Primary Central Nervous System Lymphomas. Primary CNS lymphoma has increased in incidence by a factor of 10 in the past two decades.[1,5] These deep, periventricular, and diffuse tumors are especially common in immunocompromised persons, including those with acquired immunodeficiency syndrome (AIDS) and immunosuppression after transplantation.

Most primary brain lymphomas are of B-cell origin. Overall primary lymphomas of the CNS are highly aggressive, and recurrence is common despite treatment. Behavioral and cognitive changes, which are the most common presenting symptoms, occur in about 65% of patients; hemiparesis, aphasia, and visual field deficits in about 50%; and seizures in 15% to 20%.[54]

Metastatic Tumors. Metastatic tumors, mostly carcinomas, affect approximately 20% to 40% of persons with cancer.[60] The five most common primary sites are the lung, breast, skin (melanoma), kidney, and gastrointestinal tract.[1,60] Within the brain there is regional selectivity for growth metastasis from the different primary types of cancer: melanoma is more typically found in the frontal and temporal lobes, breast cancer in the cerebellum and basal ganglia, and non–small cell lung cancer in the occipital lobe. Thus, it appears that tumor-specific interactions with brain physiology mediate the establishment and proliferation of brain metastasis. Recent investigations have begun to elucidate the mechanisms of such molecular mechanisms. For women with breast cancer, hormone receptor and human epidermal growth factor receptor-2 (HER2)/neu status is predictive of brain metastasis risk.[60]

Clinically evident brain metastases present with signs of increased ICP, mental status changes, seizures, and focal neurologic deficits. Management of persons with CNS metastasis consists of symptomatic and definitive therapies. The mainstays of symptomatic control are corticosteroids for tumor-related edema, antiepileptic drugs for seizure control, and multidisciplinary interventions aimed at minimizing neurologic disability.[60]

Clinical Features

The clinical manifestations of brain tumors depend on the size and location of the tumor. General signs and symptoms include headache, nausea, vomiting, mental changes, papilledema, visual disturbances (e.g., diplopia), alterations in sensory and motor function, and seizures.[9,56,57] Because the volume of the intracranial cavity is fixed, brain tumors cause a generalized increase in ICP when they reach sufficient size or produce edema. Cerebral edema usually is of the vasogenic type, which develops around the tumors and is characterized by an increased extracellular fluid volume. The edema is thought to result from increased permeability of tumor capillary endothelial cells. Tumors can also obstruct the flow of CSF in the ventricular cavities and produce hydrocephalic dilation of the proximal ventricles and atrophy of the cerebral hemispheres. With very slow-growing tumors, complete compensation of ventricular volumes can occur, but with rapidly growing tumors, increased ICP is an early sign.

The brain itself is insensitive to pain. The headache that accompanies brain tumors results from compression or distortion of pain-sensitive dural or vascular structures. It may be felt on the same side of the head as the tumor, but more commonly is diffuse. In the early stages, the headache is mild and occurs in the morning on awakening and improves with head elevation. The headache becomes more constant as the tumor enlarges and often is worsened by coughing, bending, or sudden movements of the head.

Vomiting occurs with or without nausea, may be projectile, and is a common symptom of increased ICP and brain stem compression. Direct stimulation of the vomiting center, which is located in the medulla, may contribute to the vomiting that occurs with brain tumors. The vomiting is often associated with headache. Papilledema (edema of the optic disk) results from increased ICP and obstruction of the CSF pathways. It is associated with decreased visual acuity, diplopia, and deficits in the visual fields. Visual defects associated with papilledema often are the reason that persons with brain tumor seek medical care.

Personality and mental changes such as depression are common with brain tumors. Persons with brain tumors often are irritable initially and later become quiet and apathetic. They may become forgetful, seem preoccupied, and appear to be psychologically depressed. Because of the mental changes, a psychiatric consultation may be sought before a diagnosis of brain tumor is made.

Focal signs and symptoms are determined by the location of the tumor. Tumors arising in the frontal lobe may grow to a large size, increase the ICP, and cause signs of generalized brain dysfunction before focal signs are recognized. Tumors that impinge on the visual system cause visual loss or visual field defects long before generalized signs develop. Certain areas of the brain have a relatively low threshold for seizure activity. Temporal lobe tumors often produce seizures as their first symptom. Hallucinations of smell or hearing and déjà vu phenomena are common focal manifestations of temporal lobe tumors. Brain stem tumors commonly produce upper and lower motor neuron signs, such as weakness of facial muscles and ocular palsies that occur with or without involvement of sensory or long motor tracts. Cerebellar tumors often cause ataxia of gait.

Diagnosis and Treatment. The diagnosis of brain tumors rests mainly on MRI.[54,56,57] Gadolinium-enhanced MRI is the test of choice for identifying and localizing the presence and extent of tumor involvement. CT scans may fail to reveal certain mass lesions such as low-grade tumors or posterior fossa masses. Diagnostic maneuvers that suggest a possible tumor and indicate the need for MRI include physical and neurologic examinations, visual field and funduscopic examination, and sometimes electroencephalography (EEG). Approximately 75% of persons with a brain tumor have an abnormal EEG, which can indicate an underlying structural lesion warranting MRI. Cerebral angiography can be used to visualize the tumor's vascular supply, information that is important when planning surgery. MRI may be supplemented with positron emission tomography to better characterize the metabolic properties of the tumor, useful in planning treatment.[54] MRA and CTA can be used to distinguish vascular masses from tumors.

The three general methods for treatment of brain tumors are surgery, irradiation, and chemotherapy. Surgery is part of the initial management of virtually all brain tumors; it establishes the diagnosis and achieves tumor removal in many cases. The development of microsurgical neuroanatomy, the operating microscope, and advanced stereotactic and ultrasonographic technology; the fusion of imaging systems with resection techniques; and the intraoperative monitoring of evoked potentials or the EEG have improved the effectiveness of surgical resection. However, the degree of removal may be limited by the location of the tumor and its invasiveness. Stereotactic surgery uses three-dimensional coordinates and CT and MRI to localize a brain lesion precisely. Ultrasonographic technology has been used for localizing and removing tumors. The ultrasonic aspirator, which combines a vibrating head with suction, permits atraumatic removal of tumors from cranial nerves and important cortical areas. Intraoperative monitoring of evoked potentials is an important adjunct to some types of surgery. For example, evoked potentials can be used to monitor auditory, visual, speech, or motor responses during surgery done under local anesthesia.

Most malignant brain tumors respond to external irradiation. Irradiation can increase longevity and sometimes can allay symptoms when tumors recur. The treatment

dose depends on the tumor's histologic type, radioresponsiveness, and anatomic site and on the level of tolerance of the surrounding tissue. A newer technique called *gamma knife* combines stereotactic localization of tumor with radiosurgery, allowing delivery of high-dose radiation to deep tumors while sparing surrounding brain. Radiation therapy is avoided in children younger than 2 years of age because of the long-term effects, which include developmental delay, panhypopituitarism, and secondary tumors. The use of chemotherapy for brain tumors is somewhat limited by the blood-brain barrier. Chemotherapeutic agents can be administered intravenously, intra-arterially, intrathecally (i.e., into the spinal canal), as wafers impregnated with a drug and implanted into the tumor at the time of surgery, or intraventricularly.

In summary, infections of the CNS may be classified according to the structures involved—the meninges (meningitis) or brain parenchyma (encephalitis)—and the type of organism causing the infection (bacteria or virus). The damage caused by infection may predispose to hydrocephalus, seizures, or other neurologic defects.

Brain tumors account for 2% of all aggressive neoplasms and are the second most common type of cancer in children. Brain tumors can be divided into primary intracranial tumors of neuroepithelial tissue (e.g., neuroglia, neurons), primary intracranial tumors that originate in the skull cavity but are not derived from the brain tissue itself (e.g., meninges, primary CNS lymphoma, pituitary gland tumors), and metastatic tumors. Neuroglial tumors, the most common type of brain tumors, are broadly classified into astrocytomas, oligodendrogliomas, and ependymomas. Metastatic tumors, mostly carcinomas, affect approximately 20% to 40% of persons with cancer, with cancers of the lung, breast, skin (melanoma), kidney, and gastrointestinal tract being the common site of the primary cancer. The clinical manifestations of brain tumor depend on the size and location of the tumor. Focal disturbances result from brain compression, tumor infiltration, disturbances in blood flow, and cerebral edema. General signs and symptoms include headache, nausea, vomiting, mental changes, papilledema, visual disturbances, alterations in motor and sensory function, and seizures. Diagnostic tests include physical examination, visual field testing and funduscopic examination, CT scans, MRI studies, skull x-ray films, brain scans, EEG, and cerebral angiography. Treatment includes surgery, irradiation, and chemotherapy.

Seizure Disorders

A seizure represents an abrupt and temporary alteration in cerebral activity resulting in changes in electrical discharge from neurons in the cerebral cortex.[9,61] A seizure is a discrete clinical event with associated signs and symptoms that vary according to the site of neuronal discharge in the brain. Manifestations of seizure generally include sensory, motor, autonomic, or psychic phenomena. A convulsion refers to the specific type of a motor seizure involving the entire body. Seizure activity is the most common disorder encountered in pediatric neurology, and among adults its incidence is exceeded only by cerebrovascular disorders. In most persons, the first seizure episode occurs before 20 years of age.[62] After 20 years of age, a seizure is caused most often by a structural change, trauma, tumor, or stroke.

A seizure is not a disease but a symptom of underlying CNS dysfunction. Seizures may occur during almost all serious illnesses or injuries affecting the brain, including metabolic derangements, infections, tumors, drug abuse, vascular lesions, congenital deformities, and brain injury. *Epilepsy* is characterized by recurrent seizures that are not provoked by other illnesses or circumstances.[63–65]

Seizures

- Seizures are paroxysmal motor, sensory, or cognitive manifestations of spontaneous, abnormally synchronous electrical discharges from collections of neurons in the cerebral cortex.
- Seizures are thought to result directly or indirectly from changes in excitability of single neurons or groups of neurons.
- The site of seizure generation and the extent to which the abnormal neural activity is conducted to other areas of the brain determine the type and manifestations of the seizure activity.
- Partial seizures originate in a small group of neurons in one hemisphere with secondary spread of seizure activity to other parts of the brain. Simple partial seizures usually are confined to one hemisphere and do not involve loss of consciousness. Complex partial seizures begin in a localized area, spread to both hemispheres, and involve impairment of consciousness.
- Generalized seizures show simultaneous disruption of normal brain activity in both hemispheres from the onset. They include unconsciousness and varying bilateral degrees of symmetric motor responses with evidence of localization to one hemisphere. Absence seizures are generalized nonconvulsive seizure events that are expressed mainly by brief periods of unconsciousness. Tonic-clonic seizures involve unconsciousness along with both tonic and clonic muscle contractions.

Provoked and Unprovoked Seizures

Many theories have been proposed to explain the cause of the abnormal brain electrical activity that occurs with seizures. Seizures may be caused by alterations in cell membrane permeability or distribution of ions across the neuronal cell membranes.[63] Another cause may be decreased inhibition of cortical or thalamic neuronal activity or structural changes that alter the excitability of neurons. Neurotransmitter imbalances such as an acetylcholine excess or γ-aminobutyric acid (GABA, an inhibitory neurotransmitter) deficiency have also been proposed as causes. Certain epilepsy syndromes have been linked to specific genetic mutations causing ion channel defects.

Clinically, seizures may be categorized as unprovoked (primary or idiopathic) or provoked (secondary or acute symptomatic).[9,61] Unprovoked or idiopathic seizures are those for which no identifiable cause can be determined, and are thought to be genetic. Most unprovoked seizures occur in the setting of an epileptic syndrome. These patients usually require chronic administration of antiepileptic medications to limit seizure recurrences. Provoked or symptomatic seizures include febrile seizures, seizures precipitated by systemic metabolic conditions, and those that follow a primary insult to the CNS. Most provoked seizures are best prevented by treatment of the underlying cause. For example, the most common subgroup is that of febrile seizures in children.[62] In susceptible children, a high fever, usually over 104°F, will provoke a generalized seizure. Treatment includes aggressive use of antipyretics to prevent seizures during a febrile illness. Transient systemic metabolic disturbances may precipitate seizures. Examples include electrolyte imbalances, hypoglycemia, hypoxia, hypocalcemia, uremia, alkalosis, and rapid withdrawal of sedative drugs. Specific CNS injuries such as toxemia of pregnancy, water intoxication, meningitis, trauma, cerebral hemorrhage and stroke, and brain tumors may precipitate a seizure. In all cases of provoked seizures, treatment of the immediate underlying cause often results in their resolution.

Classification

The International Classification of Epileptic Seizures determines seizure type by clinical symptoms and EEG activity. It divides seizures into two broad categories: partial seizures, in which the seizure begins in a specific or focal area of one cerebral hemisphere, and generalized seizures, which begin simultaneously in both cerebral hemispheres[66,67] (Chart 37-1). Further classification of epileptic syndromes characterizes the underlying diseases that cause the seizures, and divides seizures into idiopathic (suspected to be genetic), symptomatic (resulting from some CNS injury), and cryptogenic (presumed to be symptomatic of some unidentified cause). The system also has categories for seizures of undetermined origin such as neonatal seizures and a category of special syndromes such as febrile seizures.

CHART 37-1 Classification of Epileptic Seizures

Partial Seizures

Simple partial seizures (no impairment of consciousness)
- With motor symptoms
- With sensory symptoms
- With autonomic signs
- With psychic symptoms

Complex partial seizures (impairment of consciousness)
- Simple partial onset followed by impaired consciousness
- Impairment of consciousness at onset

Partial seizures evolving to secondarily generalized seizures
- Simple partial leading to generalized seizures
- Complex partial leading to generalized seizures

Unclassified Seizures

Classification not possible because of inadequate or incomplete data

Generalized Seizures

Absence seizures (typical or atypical)
Atonic seizures
Myoclonic seizures
Clonic seizures
Tonic
Tonic-clonic seizures

Adapted from Commission on Classification and Terminology of the International League Against Epilepsy. (1981). Proposal for revised clinical and electroencephalographic classification of epileptic seizures. *Epilepsia* 22, 489.

Partial Seizures

Partial or focal seizures are the most common type of seizure among newly diagnosed cases in all groups older than 10 years of age. Partial seizures can be subdivided into three major groups: simple partial (consciousness is not impaired), complex partial (impairment of consciousness), and secondarily generalized partial seizures. These categories are based primarily on current neurophysiologic theories related to seizure propagation and the extent of involvement of the brain's hemispheres.

Simple Partial Seizures. Simple partial seizures usually involve only one hemisphere and are not accompanied by loss of consciousness or responsiveness. These seizures also have been referred to as elementary partial seizures, partial seizures with elementary symptoms, or focal seizures. Simple partial seizures are classified according to motor signs, sensory symptoms, autonomic manifestations, and psychic symptoms.[66]

The observed clinical signs and symptoms depend on the area of the brain where the abnormal neuronal discharge is taking place. If the motor area of the brain is involved, the earliest symptom is motor movement corresponding to the location of onset on the contralateral

side of the body. The motor movement may remain localized or may spread to other cortical areas, with sequential involvement of body parts in an epileptic-type "march," known as a *Jacksonian seizure*. If the sensory portion of the brain is involved, there may be no observable clinical manifestations. Sensory symptoms correlating with the location of seizure activity on the contralateral side of the brain may involve somatic sensory disturbance (e.g., tingling and crawling sensations) or special sensory disturbance (i.e., visual, auditory, gustatory, or olfactory phenomena). When abnormal cortical discharge stimulates the autonomic nervous system, flushing, tachycardia, diaphoresis, hypotension or hypertension, or pupillary changes may be evident.

The term *prodrome* or *aura* traditionally has meant a stereotyped warning sign of impending seizure activity described by the affected person. The aura actually represents a simple partial seizure, reflecting only a small area of abnormal electrical activity in the brain. Simple partial seizures may progress to complex partial seizures or generalized tonic-clonic seizures that result in unconsciousness. Most patients perceive the aura as a warning sign of impending complex partial seizures or other generalized seizures.

Complex Partial Seizures. Complex partial seizures involve impairment of consciousness and often arise from the temporal lobe. The seizure begins in a localized area of the brain but may progress rapidly to involve both hemispheres. These seizures are sometimes referred to as *psychomotor seizures,* reflecting their typical manifestations.

Complex partial seizures often are accompanied by automatisms. Automatisms are repetitive, nonpurposeful activities such as lip smacking, grimacing, patting, or rubbing clothing. Confusion during the postictal state (after a seizure) is common. Hallucinations and illusional experiences such as déjà vu (familiarity with unfamiliar events or environments) or jamais vu (unfamiliarity with a known environment) have been reported. There may be overwhelming fear, uncontrolled forced thinking or a flood of ideas, and feelings of detachment and depersonalization. A person with a complex partial seizure disorder sometimes is misdiagnosed as having a psychiatric disorder.

Secondarily Generalized Partial Seizures. These seizures are focal at onset but then become generalized as the neuronal discharge spreads, involving deeper structures of the brain, such as the thalamus or the reticular formation. Discharges spread to both hemispheres, resulting in progression to tonic-clonic seizure activity. These seizures may start as simple or complex partial seizures and may be preceded by an aura. The aura, often a stereotyped peculiar sensation that precedes the seizure, is the result of partial seizure activity. A history of an aura is clinically useful to identify the seizure as partial and not generalized in onset. However, absence of an aura does not reliably exclude a focal onset because many partial seizures generalize too rapidly to generate an aura.

Generalized Seizures

Generalized-onset seizures are the most common type in young children. These seizures are classified as primary or generalized when clinical signs, symptoms, and supporting EEG changes indicate involvement of both hemispheres at onset. The clinical symptoms include unconsciousness and involve varying bilateral degrees of symmetric motor responses without evidence of localization to one hemisphere.

These seizures are divided into four broad categories: absence seizures (typical and atypical), atonic (akinetic) seizures, myoclonic seizures, and major motor seizures, characterized by tonic, clonic, or tonic-clonic activity.[62,67]

Absence Seizures. Absence seizures are generalized, nonconvulsive epileptic events and are expressed mainly as disturbances in consciousness. Formerly referred to as *petit mal seizures,* absence seizures typically occur only in children and cease in adulthood or evolve to generalized motor seizures. Children may present with a history of school failure that predates the first evidence of seizure episodes. Although typical absence seizures have been characterized as a blank stare, motionlessness, and unresponsiveness, motion occurs in many cases of absence seizures. This motion takes the form of automatisms such as lip smacking, mild clonic motion (usually in the eyelids), increased or decreased postural tone, and autonomic phenomena. There often is a brief loss of contact with the environment. The seizure usually lasts only a few seconds, and then the child is able to resume normal activity immediately. The manifestations often are so subtle that they may pass unnoticed. Because automatisms and unresponsiveness are common to complex partial seizures, the latter often are mistakenly labeled as "petit mal" seizures.

Atypical absence seizures are similar to typical absence seizures except for greater alterations in muscle tone and less abrupt onset and cessation. In practice, it is difficult to distinguish typical from atypical absence seizures without the benefit of supporting EEG findings. However, it is important to distinguish between complex partial and absence seizures because the drugs of choice for treatment are different. Medications that are effective for partial seizures may increase the frequency of absence seizures.

Atonic Seizures. In akinetic or atonic seizures, there is a sudden, split-second loss of muscle tone leading to slackening of the jaw, drooping of the limbs, or falling to the ground. These seizures also are known as *drop attacks*.

Myoclonic Seizures. Myoclonic seizures involve brief involuntary muscle contractions induced by stimuli of cerebral origin. A myoclonic seizure involves bilateral jerking of muscles, generalized or confined to the face, trunk, or one or more extremities. Tonic seizures are characterized by a rigid, violent contraction of the muscles, fixing the limbs in a strained position. Clonic

seizures consist of repeated contractions and relaxations of the major muscle groups.

Tonic-Clonic Seizures. Tonic-clonic seizures, formerly called *grand mal seizures,* are the most common major motor seizure. Frequently, a person has a vague warning (probably a simple partial seizure) and experiences a sharp tonic contraction of the muscles with extension of the extremities and immediate loss of consciousness. Incontinence of bladder and bowel is common. Cyanosis may occur from contraction of airway and respiratory muscles. The tonic phase is followed by the clonic phase, which involves rhythmic bilateral contraction and relaxation of the extremities. At the end of the clonic phase, the person remains unconscious until the RAS begins to function again. This is called the *postictal phase*. The tonic-clonic phases last approximately 60 to 90 seconds.

Unclassified Seizures

Unclassified seizures are those that cannot be placed in one of the previous categories. These seizures are observed in the neonatal and infancy periods. Determination of whether the seizure is focal or generalized is not possible. Unclassified seizures are difficult to control with medication.

Diagnosis and Treatment

Diagnosis

The diagnosis of seizure disorders is based on a thorough history and neurologic examination, including a full description of the seizure.[9,61,65] The physical examination and laboratory studies help exclude any metabolic disorder (e.g., hyponatremia) that could precipitate seizures. MRI scans are used to identify structural defects such as temporal lobe sclerosis or underlying congenital malformations causing the seizure. One of the most useful diagnostic tests is the EEG, which is used to record changes in the brain's electrical activity. It is used to support the clinical diagnosis of epilepsy, to provide a guide for prognosis, and to assist in classifying the seizure disorder.

Pharmacologic Treatment

The management of seizure disorders focuses on treatment of the underlying conditions that cause or contribute to the seizures, avoidance of precipitating factors, suppression of recurrent seizures by prophylactic therapy with antiepileptic medications or by surgery, and addressing psychological and social issues.[61] Treatment must be individualized for each patient based on the different types and causes of seizures as well as the efficacy and side effects of antiepileptic drugs. Persons with epilepsy should be advised to avoid situations that could be dangerous or life-threatening if seizures occur.

Antiepileptic drug therapy is the mainstay of treatment for most persons with epilepsy. Antiepileptic drugs act mainly by suppressing repetitive firing of isolated neurons that act as epileptogenic foci for seizure activity or by inhibiting the transmission of electrical impulses involved in seizure activity.[68] Because of their selective mechanisms of action, different drugs are used to treat the different types of seizures. For example, ethosuximide, which suppresses the brain wave activity associated with lapses of consciousness, is used in the treatment of absence seizures, but is not effective for tonic-clonic seizures that progress from partial seizures.

More than 20 drugs are available for the treatment of epilepsy. This group includes nine antiepileptic drugs that have been approved for use in the United States in the past several decades.[64] The goal of pharmacologic treatment is to bring the seizures under control with the least possible disruption in lifestyle and the minimum of side effects from medication.[64,65,69,70] Whenever possible, a single drug should be used. Monotherapy eliminates drug interactions and additive side effects. Determining the proper dose of the anticonvulsant drug is often a long and tedious process, which can be very frustrating for the person with epilepsy. Often blood tests are used to determine that the blood concentration is within the therapeutic range. Consistency in taking the medication is essential. Antiepileptic drug use never should be discontinued abruptly. Special consideration is needed when a person taking an antiepileptic medication becomes ill and must take additional medications. Some drugs act synergistically, and others interfere with the actions of other antiepileptic medications. This situation needs to be carefully monitored to avoid overmedication or interference with successful seizure control.

Women of child-bearing age require special consideration concerning fertility, contraception, and pregnancy. Many of the drugs interact with oral contraceptives; some affect hormone function or decrease fertility. All such women should be advised to take folic acid supplementation. For women with epilepsy who become pregnant, antiseizure drugs increase the risk for congenital abnormalities and other perinatal complications. Carbamazepine, phenytoin, phenobarbital, primidone, and valproic acid can interfere with vitamin D metabolism and predispose to osteoporosis.

Surgical Therapy

Surgical treatment may be an option for persons with epilepsy that is refractory to drug treatment.[9,61] With the use of modern neuroimaging and surgical techniques, a single epileptogenic lesion can often be identified and removed without leaving a neurologic deficit. The most common surgery consists of removal of the amygdala and an anterior part of the hippocampus and entorhinal cortex, as well as a small part of the temporal pole, leaving the lateral temporal neocortex intact. Another surgical procedure involves partial removal of the corpus callosum to prevent spread of a unilateral seizure to a generalized seizure. Some refractory patients benefit from an implantable electrical stimulator of the vagus nerve.

Generalized Convulsive Status Epilepticus

Seizures that do not stop spontaneously or occur in succession without recovery are called *status epilepticus*. There

are as many types of status epilepticus as there are types of seizures. Tonic-clonic status epilepticus is a medical emergency and, if not promptly treated, may lead to respiratory failure and death. The disorder occurs most frequently in the young and old. Morbidity and mortality rates are highest in elderly persons and persons with acute symptomatic seizures, such as those related to anoxia or cerebral infarction.[61] If status epilepticus is caused by neurologic or systemic disease, the cause needs to be identified and treated immediately because the seizures probably will not respond until the underlying cause has been corrected.

Treatment consists of appropriate life support measures. Medications are given to control seizure activity. Intravenously administered diazepam or lorazepam is considered first-line therapy for the condition. The prognosis is related to the underlying cause as well as the duration of the seizures themselves.

In summary, seizures are caused by spontaneous transitory neuronal discharges from cortical centers in the brain. Seizures may occur as a reversible symptom of another disease condition or as a recurrent condition called *epilepsy.* Epileptic seizures are classified as partial or generalized seizures. Partial seizures have evidence of local onset, beginning in one hemisphere. They include simple partial seizures, in which consciousness is not lost, and complex partial seizures, which begin in one hemisphere but progress to involve both. Generalized seizures involve both hemispheres and include unconsciousness and rapidly occurring, widespread, bilateral symmetric motor responses. They include absence, atonic, myotonic, and tonic-clonic seizures. Control of seizures is the primary goal of treatment and is accomplished with anticonvulsant medications. Anticonvulsant medications can interact with each other and need to be monitored closely when more than one medication is used.

Disorders of Memory and Cognition

Memory is the process by which information is encoded, stored, and later retrieved, while cognition is the process by which information is reduced, elaborated, transformed, and used. Cognition involves the perception of sensory input and the ability to learn and manipulate new information, recognize familiar objects and recollect past experiences, solve problems, think abstractly, and make judgments. Cognition can be impaired as the result of a number of conditions, including global ischemia, traumatic brain injury, and stroke.

Dementia

Dementia or nonnormative cognitive decline can be caused by any disorder that permanently damages large association areas of the cerebral hemispheres or subcortical areas subserving memory and learning.[71,72] It is a common and disabling disorder in the elderly and is becoming a growing public heath problem, because of rapidly increasing numbers of elderly people.

Based on criteria in the fourth edition, text revision of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR), the essential feature of dementia is impairment of short- and long-term memory, which is associated with deficits in abstract thinking, impaired judgment and other higher cortical functions, or personality change.[73] The disturbance should be sufficiently severe as to interfere significantly with work or social activities. Common causes of dementia are Alzheimer disease, vascular dementia, frontotemporal dementia, Wernicke-Korsakoff syndrome, and Huntington chorea.

The diagnosis of dementia is based on assessment of the presenting problem; history about the person that is provided by an informant (someone who has known the person, usually a family member); complete physical and neurologic examination; evaluation of cognitive, behavioral, and functional status; and laboratory and imaging studies. Depression is the most common treatable illness that may masquerade as dementia, and it must be excluded when a diagnosis of dementia is considered. This is important because cognitive functioning usually returns to baseline levels after depression is treated. Screening evaluations for subdural hematoma, cerebral infarcts, cerebral tumors, and normal-pressure hydrocephalus are also recommended. These and other reversible forms of dementia that should be ruled out can be remembered by the mnemonic DEMENTIA: *D*rugs (drugs with anticholinergic activity), *E*motional (depression), *M*etabolic (hypothyroidism), *E*yes and ears (declining vision and hearing), *N*ormal-pressure hydrocephalus, *T*umor or other space-occupying lesions, *I*nfection (human immunodeficiency virus infection or syphilis), *A*nemia (vitamin B_{12} or folate deficiency).[72]

Alzheimer Disease

Dementia of the Alzheimer type occurs in middle or late life and accounts for 60% to 80% of all cases of dementia. The disorder affects more than 4.5 million Americans and is the fourth leading cause of death in the United States.[72,74] The risk for development of Alzheimer disease increases with age, starting at a level of 1% for the 60- to 64-year-old population and increasing to 40% or more for the 85- to 89-year-old cohort.[1]

Alzheimer disease most often presents with a subtle onset of memory loss followed by slowly progressive dementia that has a course of several years. Pathologically, there is diffuse atrophy of the cerebral cortex with enlargement of the ventricles (Fig. 37-16). The major microscopic features of Alzheimer disease are the presence of neuritic (senile) plaques, neurofibrillary tangles, and amyloid angiopathy.[1,5] The *neuritic plaques* are patches or flat areas composed of clusters of degenerating nerve terminals arranged around a central amyloid core. The *neurofibrillary tangles,* found in the cytoplasm of abnormal neurons, consist of fibrous proteins that are

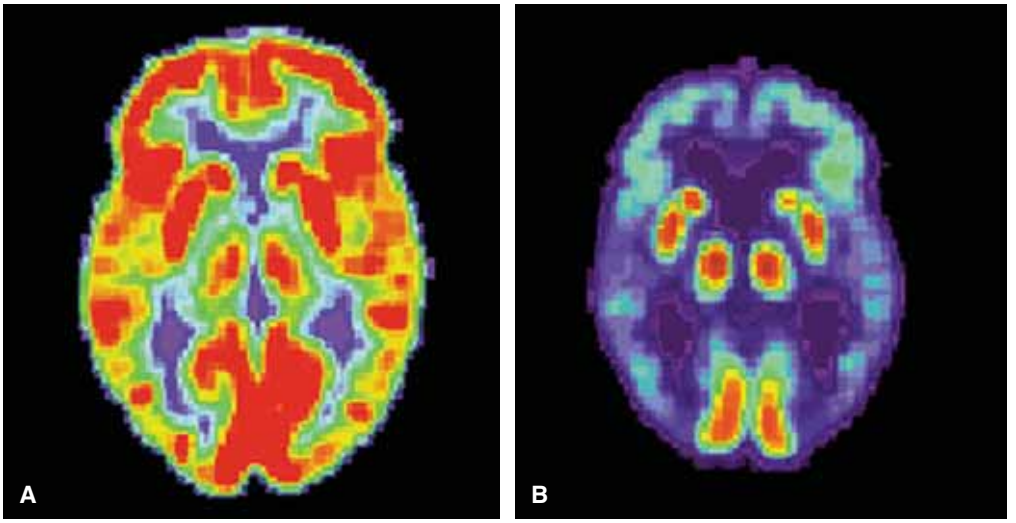

FIGURE 37-16. Functional imaging of the brain with positron emission tomography (PET). Perfusion and metabolism in a normal brain **(A)** and hypoperfusion and hypometabolism due to brain atrophy in a brain with Alzheimer disease **(B)** (From *Alzheimer's disease: Unraveling the mystery images.* National Institute of Health, National Institute of Aging.)

wound around each other in a helical fashion. These tangles are resistant to chemical or enzymatic breakdown, and they persist in brain tissue long after the neuron in which they arose has died and disappeared.

Evidence from familial forms of Alzheimer disease indicates that the accumulation of a peptide (amyloid beta or Aβ) in the brain initiates a chain of events that result in the morphologic changes of Alzheimer disease and dementia. This peptide is derived from a larger membrane-spanning protein known as *amyloid precursor protein* (APP), which can be processed in either of two ways. It can be cleaved by the enzymes, α-secretase and γ-secretase, in a proteolytic pathway that prevents the formation of Aβ, or it can be cleaved by β-secretase and γ-secretase in a pathway that generates Aβ.[1]

Some plaques and tangles can be found in the brains of older persons who do not show cognitive impairment. The number and distribution of the plaques and tangles appear to contribute to the intellectual deterioration that occurs with Alzheimer disease. In persons with the disease, the plaques and tangles are found throughout the neocortex and in the hippocampus and amygdala, with relative sparing of the primary sensory cortex.[1] Hippocampal function in particular may be compromised by the pathologic changes that occur in Alzheimer disease. The hippocampus is crucial to information processing, acquisition of new memories, and retrieval of old memories.

Neurochemically, Alzheimer disease has been associated with a decrease in the level of choline acetyltransferase activity in the cortex and hippocampus. This enzyme is required for the synthesis of acetylcholine, a neurotransmitter that is associated with memory. The reduction in choline acetyltransferase is quantitatively related to the numbers of neuritic plaques and severity of dementia.

It is likely that Alzheimer disease is caused by several factors that interact differently in different persons. Progress in the genetics of inherited early-onset Alzheimer disease shows that mutations in at least three genes—the *APP* gene on chromosome 21; presenilin-1 (*PS1*), a gene on chromosome 14; and presenilin-2 (*PS2*), a gene on chromosome 1—can cause Alzheimer disease in certain families.[1,5] The *APP* gene is associated with an autosomal dominant form of early-onset Alzheimer disease, and can be tested clinically. Virtually all persons with Down syndrome (trisomy 21) exhibit the pathologic features of Alzheimer disease as they age. PS1 and PS2, both intracellular proteins, are components of γ-secretase and possibly part of a multiprotein complex containing the proteolytic site for breakdown of Aβ. A fourth gene, an allele (ϵ4) of the apolipoprotein E (ApoE) gene found on chromosome 19, increases the risk of Alzheimer disease and lowers the age of onset of the disease.

Manifestations. Alzheimer-type dementia follows an insidious and progressive course.[74] The hallmark symptoms are loss of short-term memory and denial of such memory loss, with eventual disorientation, impaired abstract thinking, apraxias, and changes in personality and affect.[75] Various stages of the disease have been recognized, ranging from the initial to those represented by the advanced stages of the disease. All are characterized by progressive degenerative changes. The initial changes are often subtle, characterized by a short-term memory loss that often is difficult to differentiate from the normal memory loss that often occurs in the elderly, and usually is reported by caregivers and denied by the patient. Although most elderly persons have trouble retrieving from memory incidental information and proper names, persons with Alzheimer disease randomly forget important and unimportant details. They forget where things are placed, get

lost easily, and have trouble remembering appointments and performing novel tasks. Mild changes in personality, such as lack of spontaneity, social withdrawal, and loss of a previous sense of humor, occur during this stage.

As the disease progresses, the person with Alzheimer disease enters the moderate stage. This stage may last several years and is marked by a more global impairment of cognitive functioning. During this stage, there are changes in higher cortical functioning needed for language, spatial relationships, and problem solving. Depression may occur in persons who are aware of their deficits. There is extreme confusion, disorientation, lack of insight, and inability to carry out the activities of daily living. Personal hygiene is neglected, and language becomes impaired because of difficulty in remembering and retrieving words. Behavioral changes can include agitation, sleep problems, restlessness and wandering, aggression, and suspiciousness. Some persons may become hostile and abusive toward family members. Persons who enter this stage become unable to live alone and should be assisted in making decisions about supervised placement with family members or friends or in a community-based facility.

Severe Alzheimer disease is the last stage of the disease. It is characterized by a loss of ability to respond to the environment. Individuals in this stage require total care and spend most of their time bedridden. Death can occur as a result of complications related to chronic debilitation.

Diagnosis and Treatment. Alzheimer disease is essentially a diagnosis of exclusion. There are no peripheral biochemical markers or tests for the disease. The diagnosis can be confirmed only by microscopic examination of tissue obtained from a cerebral biopsy or at autopsy. The diagnosis is based on clinical findings.

The diagnostic procedures for Alzheimer disease involve numerous steps, and a Differential Diagnosis in Alzheimer Algorithm has been developed.[76] A diagnosis of Alzheimer disease requires the presence of dementia established by clinical examination and documented by results of a Mini-Mental State Examination, Blessed Dementia Test, or similar mental status test; no disturbance in consciousness; onset between 40 and 90 years of age, most often after 65 years of age; and absence of systemic or brain disorders that could account for the memory or cognitive deficits. Brain imaging, CT scan, or MRI is done to exclude other brain disease. Metabolic screening should be done for known reversible causes of dementia such as vitamin B_{12} deficiency, thyroid dysfunction, and electrolyte imbalance.

There is no curative treatment for Alzheimer dementia.[74] Drugs are used primarily to slow the progression and to control depression, agitation, or sleep disorders. Two major goals of care are maintaining the person's socialization and providing support for the family. Self-help groups that provide support for family and friends have become available, with support from the Alzheimer Disease and Related Disorders Association. Day care and respite centers are available in many areas to provide relief for caregivers and appropriate stimulation for the patient.

Although there is no current drug therapy that is curative for Alzheimer disease, some show promise in terms of slowing the progress of the disease. Cholinesterase inhibitors have been shown to be effective in slowing the progression of the disease by potentiating the action of available acetylcholine.[74,75] These drugs (e.g., donepezil, rivastigmine, and galantamine) inhibit acetylcholinesterase, preventing the metabolism of endogenous acetylcholine, and are used in the early stages of the disease for mild cognitive impairment. Thus far, such therapy has not halted disease progression, but it can slow the disease progression by approximately 6 to 12 months. The therapeutic effects cease when the medication is discontinued.

Memantine, an *N*-methyl-D-aspartate antagonist, was recently approved by the FDA for treatment of moderate to severe Alzheimer disease.[75] This medication may act by interfering with the glutamatergic excitotoxicity caused by the ischemia and amyloid deposits associated with the disease, or it may provide symptomatic improvement through effects on the function of hippocampal neurons. This medication, like the cholinesterase inhibitors, does not reverse the disease, but does provide a modest delay in functional loss.

Other treatments for Alzheimer disease include agents that are thought to have a neuroprotective effect.[75] Aβ seems to exert its neurotoxic effects through a variety of secondary mechanisms, including oxidative injury and lipid peroxidation of cell membranes, and inflammation. Several strategies have involved the use of anti-inflammatory agents and antioxidants (vitamins E and C and *Ginkgo biloba*).[71,75] Several, but not all, epidemiologic studies provide evidence supporting the concept that vitamin E and vitamin C have a role in delaying the onset of Alzheimer disease. In some, but not all, trials, *G. biloba* had small but statistically significant effects compared with placebo in persons with Alzheimer disease.

Psychotropic medications, such as antipsychotics and mood stabilizers, may be used to assist in the behavioral management of the disease. Interventions also include environmental adjustments, behavioral intervention, and education and support for caregivers. Supports for caregivers is essential because they are responsible for supervising persons who live in the community and continue to visit and provide support after the person has been institutionalized. They are also responsible for administering medications, implementing nonpharmacologic treatments, and promoting the person's general health and well-being.

Other Types of Dementia

Vascular Dementia. Vascular dementia is caused by brain injury resulting from ischemic or hemorrhagic damage. Approximately 20% to 25% of dementias are vascular in origin, making it the second most common cause of dementia. The incidence is closely associated with hypertension, but also with arrhythmias, myocardial infarction, peripheral vascular disease, lipid abnormalities, diabetes mellitus, autoimmune and infectious vasculitis, and smoking.[71,77] The usual onset is between

the ages of 55 and 70 years, and more men are affected than women.[71]

Vascular dementia differs from Alzheimer disease in its presentation and tissue abnormalities. Slowness in psychomotor functioning is a main clinical feature of this dementia, and symptoms of depression present in up to 60% of patients with this disease.[5] The onset may be gradual or abrupt, the course usually is a stepwise progression, and there are focal neurologic symptoms related to local areas of infarction.

Frontotemporal Dementia. Frontotemporal dementia (FTD) refers to a group of disorders associated with atrophy of the frontal and anterior temporal lobes of the brain.[74,78,79] Originally known as *Pick disease,* FTD now refers to a syndrome that includes primary progressive aphasia, corticobasal degeneration, progressive supranuclear palsy, and semantic dementias. The disease often begins between 50 and 70 years of age, with men and women being equally affected.[74]

There are two distinct clinical presentations that reflect the symptoms of FTD: behavior and language. The former is more common, with behavioral presentations of disinhibited and impulsive actions or apathy, with inappropriate social behavior. The behavioral abnormalities can be quite extreme, and can be misdiagnosed as schizophrenia or psychotic depression. The second type of FTD involves disturbances in understanding or expressing language.

Diagnosis is based on evidence of cognitive impairment and exclusion of other illnesses that cause cognitive and behavioral deficits. Neuroimaging can be helpful in distinguishing FTD from other types of cognitive disorders. Typically, structural imaging shows anterior temporal and frontal lobe atrophy. The course of the disease is relentless, with death ensuing within 2 to 10 years. The immediate cause of death usually is infection.

Creutzfeldt-Jakob Disease. Creutzfeldt-Jakob disease (CJD) is a rare, rapidly degenerative form of dementia thought to be caused by an infective protein agent called a *prion*[1,5,80] (see Chapter 14). Variants of the disease occur in animals, including scrapie in sheep and goats and bovine spongiform encephalopathy (BSE; mad cow disease) in cattle.

There are three categories of CJD: hereditary, sporadic, and iatrogenic.[80] Approximately 15% of cases of CJD are familial and associated with different mutations of various codons on chromosome 20. Iatrogenic CJD is rare, representing less than 1% of cases. It was first reported in 1974 in a patient who received a corneal transplant; in addition to corneal tissue, the disease can be spread through other cadaveric neural tissue and inadequately sterilized neurosurgical instruments.[80] Sporadic CJD, in which the disease occurs without known risk factors, is the most common form, accounting for up to 85% of the cases. In 1995, a new and distinct variant of human CJD emerged in the United Kingdom, known as variant CJD.[80] Several features contributed to its distinct clinical picture, including appearance in younger persons than in sporadic CJD and initial prominent psychiatric symptoms. The disease has been linked convincingly to BSE, although the exact mechanism of transmission remains unclear. The average age of onset for variant CJD is 29 years, compared to 65 years for sporadic forms of CJD.

CJD causes degeneration of the pyramidal and extrapyramidal systems and is distinguished most readily by its rapid course. Affected persons usually are demented within 6 months of onset. The disease is uniformly fatal, with death often occurring within months, although a few persons may survive for several years. The early symptoms consist of abnormalities in personality and visual-spatial coordination, and impaired memory and judgment. Extreme dementia, insomnia, and ataxia follow as the disease progresses. There is no medical treatment for the disease.

Wernicke-Korsakoff Syndrome. Wernicke-Korsakoff syndrome most commonly results from chronic alcoholism. Wernicke disease is characterized by acute weakness and paralysis of the extraocular muscles, nystagmus, ataxia, and confusion.[5] The affected person also may have signs of peripheral neuropathy. The person has an unsteady gait and complains of diplopia. There may be signs attributable to alcohol withdrawal such as delirium, confusion, and hallucinations. This disorder is caused by a deficiency of thiamine (vitamin B_{12}), which directly interferes with production of glucose, the brain's main nutrient. Many of the symptoms are reversed when nutrition is improved with supplemental thiamine.

The Korsakoff component of the syndrome involves the chronic phase with severe impairment of recent memory. There often is difficulty in dealing with abstractions, and the person's capacity to learn is defective. Confabulation (i.e., recitation of imaginary experiences to fill in gaps in memory) probably is the most distinctive feature of the disease. Polyneuritis also is common. Unlike Wernicke disease, Korsakoff psychosis does not improve significantly with treatment.

Huntington Disease. Huntington disease (HD) is a hereditary disorder characterized by chronic progressive chorea, psychological changes, and dementia.[1,81] Although the disease is inherited as an autosomal dominant disorder, the age of onset most commonly is in the fourth and fifth decades. By the time the disease has been diagnosed, the person often has passed the gene on to his or her children. Approximately 10% of HD cases involve juvenile onset.[82] Children with the disease rarely live to adulthood.

Huntington disease is caused by a polyglutamine trinucleotide repeat expansion in the HD gene. The HD gene, located on chromosome 4, encodes a protein known *huntingtin*.[1,81,83] Normal HD genes contain 6 to 35 copies of the trinucleotide repeat; an expansion of repeats beyond this level is associated with disease. There is an inverse relationship between repeat number and age of onset, such that longer repeats are associated with earlier onset. Repeat expansions occur during spermatogenesis, so that paternal transmission is associated with early onset in the next generation. Although the biologic function of normal huntingtin remains unknown, there is little evidence to suggest that the disease is caused by an

insufficiency related to the mutated gene. Rather, the expansion of the polyglutamine region of the HD gene seems to bestow a toxic gain of function on the protein.[1]

Huntington disease produces localized death of brain cells. The first and most severely affected neurons are neurons of the basal ganglia that modulate motor output. These neurons normally function to dampen motor activity; thus, their degeneration in HD results in increased motor output, often manifested as choreiform movements. Although chorea is the prototypical movement disorder, the full spectrum of motor impairment in HD includes eye movement disorders, myoclonus, ataxia, dysarthria and dysphagia, and spasticity. Depression and personality changes are the most common early psychological manifestations; memory loss often is accompanied by impulsive behavior, moodiness, antisocial behavior, and a tendency toward emotional outbursts.[71] An estimated 30% of persons with Huntington disease experience major depressive disorder or dysthymic disorder, with about 6% of deaths attributed to suicide.[71] Persons with HD universally go through cognitive decline, mental slowing, and impaired problem-solving abilities, and eventually become demented. Cognitive decline also heralds the juvenile onset of HD.

There is no cure for Huntington disease. The treatment is largely symptomatic. Drugs may be used to treat the dyskinesias and behavioral disturbances. Study of the genetics of Huntington disease led to the discovery that the gene for the disease is located on chromosome 4. The discovery of a marker probe for the gene locus has enabled testing that can predict whether a person will develop the disease.

In summary, cognition refers to all the processes by which sensory input is transformed, reduced, elaborated, stored, recovered, and used. It is important to differentiate what can be termed "normal cognitive aging" from disorders of memory and cognition. Memory problems that are associated with normal aging tend to reflect a generalized decrease in the efficiency with which information is processed and retrieved. Memory of a past event can be based on retrieval that is accompanied by recollection of specific details or on the feeling that the event is old or new based on its familiarity. There is evidence that recollection is more dependent on the hippocampus, whereas familiarity is more dependent on the entorhinal cortex, and that healthy aging has greater effects on recollection than familiarity.

Dementia represents a syndrome of deterioration in cognitive function severe enough to interfere with occupational or social performance. By far the most common cause of dementia (60% to 80%) is Alzheimer disease. It is characterized by cortical atrophy and loss of neurons and the presence of neuritic plaques, granulovacuolar degeneration, and cerebrovascular deposits of amyloid. The disease follows an insidious and progressive course that begins with memory impairment and terminates in an inability to recognize family or friends and the loss of control over bodily functions. Ischemic or hemorrhagic damage is associated with vascular dementia, and frontotemporal dementia with atrophy of the frontal and temporal lobes. Creutzfeldt-Jakob disease is a rare, rapidly progressive form of dementia. Wernicke-Korsakoff syndrome most often results from chronic alcoholism. Huntington disease is a hereditary disorder characterized by chronic and progressive chorea, psychological changes, and dementia.

REVIEW EXERCISES

1. A 20-year-old man who was an unbelted driver involved in a motor vehicle accident presents in coma.

- **A.** What are the clinical signs of coma?
- **B.** Where does the source of coma localize in the brain?
- **C.** Which complications of traumatic head injury might lead to coma?
- **D.** What are the key treatment options to manage elevated intracranial pressure?

2. A 65-year-old woman presents with a 1-hour history of right-sided weakness and aphasia. An immediate CT scan of the brain is negative.

- **A.** Where in the brain is the pathology?
- **B.** What are the indications to administer intravenous tissue plasminogen activator?
- **C.** What are the possible causes of this stroke, and what diagnostic tests would reveal the cause?

3. A child is taken to the emergency department with lethargy, fever, and a stiff neck on examination.

- **A.** What findings on initial lumbar puncture indicate bacterial versus viral meningitis?
- **B.** In the case of bacterial meningitis, what are the most likely organisms, and which antibiotics should be started?

4. A 60-year-old man develops involuntary shaking of his right arm that spreads to the face, after which he collapses with whole-body shaking and loss of consciousness. After 1 minute, the shaking stops and he is confused and disoriented.

- **A.** What type of seizure is suggested by the clinical manifestations?
- **B.** Assuming this is his first seizure, what diagnostic tests should be performed to identify a cause for the seizure?
- **C.** If he has a long history of similar recurrent seizures, what treatments should be instituted? What treatments should be considered if he has failed multiple adequate trials of anticonvulsant medications?

Chapter 38

Disorders of Special Sensory Function: Vision, Hearing, and Vestibular Function

The special senses allow us to view and hear what is going on around us, to maintain our balance, and to communicate effectively with others. This chapter focuses on the eye and disorders of vision; the ear and disorders of hearing; and the vestibular system and disorders of equilibrium and balance.

The Eye and Disorders of Vision

There are 161 million people worldwide who are visually impaired—37 million are blind and 124 million have partial vision loss that cannot be corrected.[1] Among the people who are blind worldwide, 4% are under 14 years of age and 58% are 60 years of age or older. Disorders of vision can result from a number of conditions including those that affect the conjunctiva (conjunctivitis), lens (cataract), vitreous humor and retina (retinopathy and macular degeneration), intraocular pressure (glaucoma), optic pathways and visual cortex, and extraocular muscles and eye movement (Fig. 38-1).

The optic globe, commonly called the *eyeball,* is a remarkably mobile, nearly spherical structure contained in a pyramid-shaped cavity of the skull called the *orbit*. Only the anterior one fifth of the orbit is occupied by the eyeball; the remainder is filled with muscles, nerves, the lacrimal gland, and adipose tissue that support the normal position of the optic globe (Fig. 38-2). The eyeball is composed of three layers: an outer layer, which includes the white, opaque sclera and the transparent cornea; a middle vascular layer called the *uvea*, which includes the choroid and the stroma of the ciliary body and iris; and an inner neural layer, which includes an outer pigment epithelium and inner neural retina.[2] Exposed surfaces of the eyes are protected by the

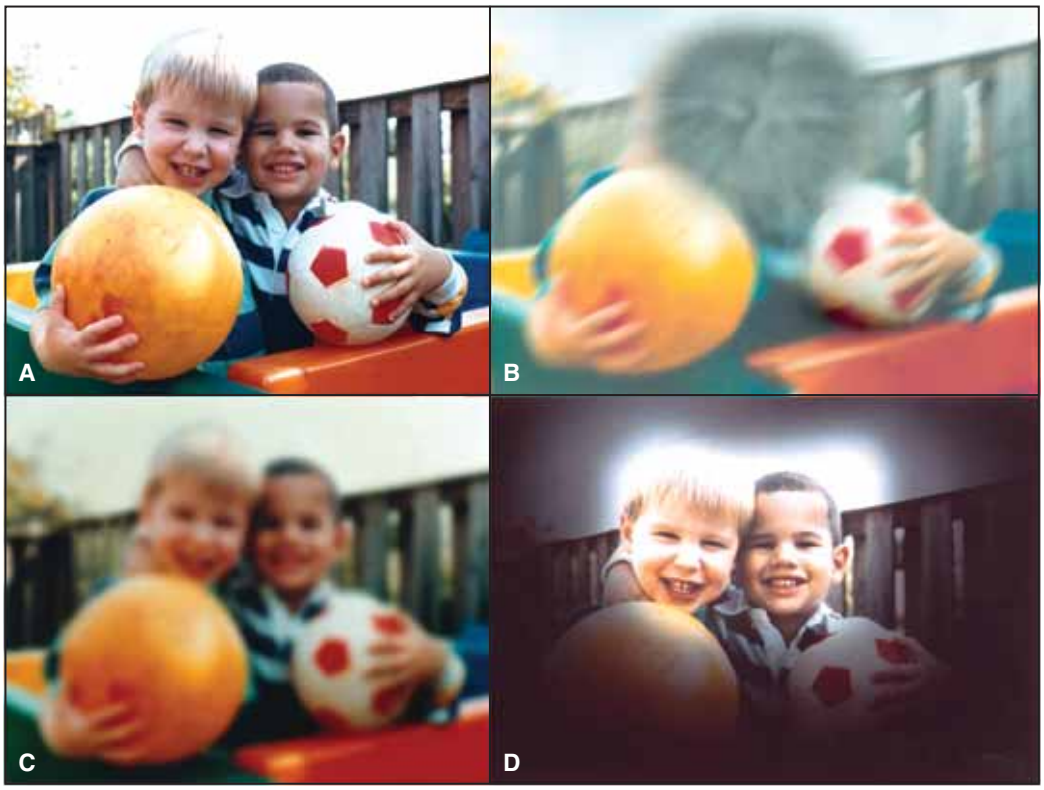

FIGURE 38-1. A scene as it might be viewed by a person with **(A)** normal vision, **(B)** age-related macular degeneration, **(C)** cataract, and **(D)** glaucoma. (From National Eye Institute, National Institutes of Health.)

eyelids, which are mucous membrane–lined skin flaps that provide a means for shutting out most light. Tears bathe the anterior surface of the eye; they prevent friction between it and the lid, maintain hydration of the cornea, and protect the eye from infection and irritation by foreign objects.

The Conjunctiva

The conjunctiva is a thin layer of mucous membrane that lines the anterior surface of both eyelids as the *palpebral conjunctiva* and folds back over the anterior surface of the optic globe as the *ocular* or *bulbar conjunctiva* (see

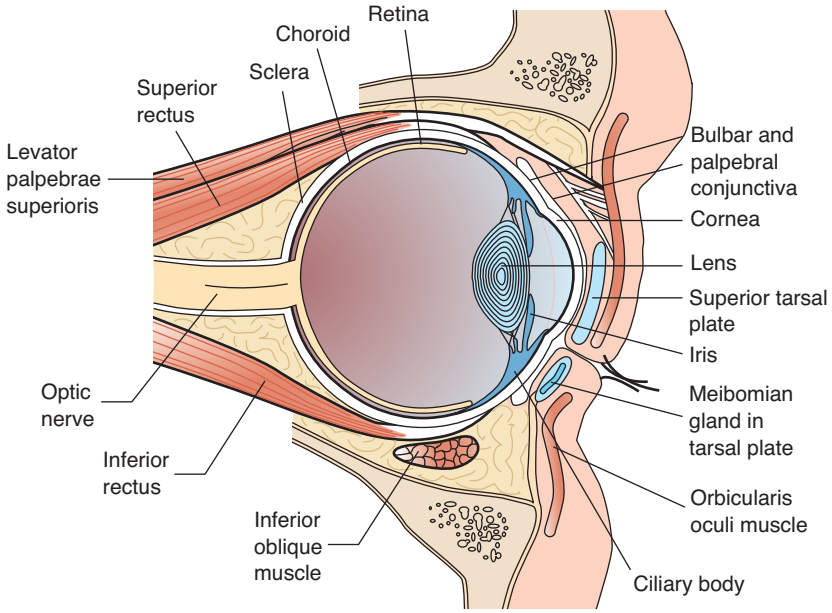

FIGURE 38-2. The eye and its appendages: lateral view.

Fig. 38-2). The ocular conjunctiva covers only the sclera or white portion of the optic globe, not the cornea. When both eyes are closed, the conjunctiva lines the closed conjunctival sac. Although the conjunctiva protects the eye by preventing foreign objects from entering beyond the conjunctival sac, its main function is the production of a lubricating mucus that bathes the eye and keeps it moist.

Conjunctivitis

Conjunctivitis, or inflammation of the conjunctiva (i.e., red or pink eye), is one of the most common forms of eye disease.[3–5] It may result from bacterial or viral infection, allergens, chemical agents, physical irritants, or radiant energy.

Depending on the cause, conjunctivitis can vary in severity from a mild hyperemia (redness) with tearing to severe conjunctivitis with purulent drainage. The conjunctiva is extremely sensitive to irritation and inflammation. Symptoms of conjunctivitis are a foreign body sensation, a scratching or burning sensation, itching, and photophobia. Severe pain suggests corneal rather than conjunctival disease. A discharge, or exudate, may be present. It is usually watery when the conjunctivitis is caused by allergy, a foreign body, or viral infection, and mucopurulent in the presence of bacterial or fungal infection. Infectious forms of conjunctivitis are usually bilateral and may involve other family members and associates. Unilateral disease suggests sources of irritation such as foreign bodies or chemical irritation.

The diagnosis of conjunctivitis is based on history, physical examination, and microscopic and culture studies to identify the cause. Because a red eye may be the sign of several eye conditions, it is important to differentiate between redness caused by conjunctivitis and that caused by more serious eye disorders, such as corneal lesions and acute glaucoma. In contrast to corneal lesions and acute glaucoma, conjunctivitis produces injection (i.e., enlargement and redness) of the peripheral conjunctival blood vessels rather than those radiating around the corneal limbus (Fig. 38-3). Conjunctivitis also produces only mild discomfort compared with the moderate to severe discomfort associated with corneal lesions or the severe and deep pain associated with acute glaucoma.

FIGURE 38-3. Gonococcal conjunctivitis of right eye. Note injection of the peripheral conjunctival blood vessels. (From Centers for Disease Control and Prevention, Public Health Images Library.)

Bacterial Conjunctivitis. Bacterial conjunctivitis may present as an acute, a hyperacute, or a chronic infection. Common agents of *acute bacterial conjunctivitis* are *Streptococcus pneumoniae, Staphylococcus aureus,* and *Haemophilus influenzae*. The infection usually is characterized by large amounts of yellow-green drainage. The eyelids are sticky, and there may be excoriation of the lid margins. Treatment may include local application of antimicrobial agents. The disorder usually is self-limited, lasting approximately 10 to 14 days if untreated and 1 to 3 days if properly treated.[3]

Hyperacute conjunctivitis is a severe, sight-threatening ocular infection. The most common causes of hyperacute purulent conjunctivitis are *Neisseria gonorrhoeae* and *Neisseria meningitidis,* with *N. gonorrhoeae* being the most common.[3–5] The symptoms, which typically are progressive, include conjunctival redness and chemosis (edema); lid swelling and tenderness; and swollen preauricular lymph nodes. Treatment includes systemic antimicrobial drugs supplemented with ocular antimicrobials. Because of the increasing prevalence of penicillin-resistant *N. gonorrhoeae,* the choice of an antimicrobial agent should be determined by current information regarding antimicrobial sensitivity. Gonococcal ocular infections that are left untreated may cause corneal ulceration with ultimate perforation, and sometimes permanent loss of vision.

Chronic bacterial conjunctivitis most commonly occurs in people with obstruction of the nasolacrimal duct or chronic infection of the lacrimal sac (dacryocystitis) and is usually unilateral.[3] The symptoms of chronic bacterial conjunctivitis vary and can include itching, burning, foreign body sensation, and morning eyelash crusting. There may be flaky debris and erythema along the lid margins, as well as eyelash loss and eye redness. Treatment includes good eyelid hygiene and application of topical antimicrobial drugs.

Chlamydial Conjunctivitis. Chlamydial conjunctivitis is usually a benign suppurative conjunctivitis transmitted by the type of *Chlamydia trachomatis* (serotypes D through K) that causes venereal infections[3–6] (see Chapter 41). It is commonly spread by contact with genital secretions and occurs in newborns of mothers with *C. trachomatis* infections of the birth canal. It also can be contracted through swimming in unchlorinated pools. The incubation period varies from 5 to 12 days, and the disease may last for several months if untreated. The infection is usually treated with appropriate oral antimicrobial agents.

A more serious form of infection is caused by a different strain of *C. trachomatis* (serotypes A, B, and C).[6] This form of chlamydial infection affects the conjunctiva and causes ulceration and scarring of the cornea. It is the leading cause of preventable blindness in the world. Although the agent is widespread, it is seen mostly in developing countries, particularly those of Africa, Asia, and the Middle East.[6] It is transmitted by direct human contact, contaminated objects (fomites), and flies.

Viral Conjunctivitis. One of the most common causes of viral conjunctivitis is adenoviruses types 3 and 7 and other serotypes.[3] The infection, which causes generalized conjunctival hyperemia, copious tearing, and minimal exudate, is usually accompanied by pharyngitis, fever, and malaise. Children are affected more often than adults. Swimming pools contaminated because of inadequate chlorination are common sources of infection.

Viral epidemic keratoconjunctivitis is caused by adenoviruses types 8 and 19.[3] It presents with marked discomfort and is highly contagious, with rapid spread from person to person. The disease usually lasts for at least 2 weeks and may be complicated by visual symptoms due to epithelial and subepithelial corneal involvement. There is no specific treatment for this type of viral conjunctivitis. Preventive measures include hygienic measures and avoiding shared use of eyedroppers, eye makeup, goggles, and towels. Persons who use contact lenses should avoid them and wear their prescription glasses until the infection clears.

Allergic Conjunctivitis. Allergic conjunctivitis encompasses a spectrum of conjunctival conditions usually characterized by itching. The most common of these is seasonal allergic rhinoconjunctivitis, or hay fever. Seasonal allergic conjunctivitis is an immunoglobulin E (IgE)-mediated hypersensitivity reaction precipitated by small air-borne allergens such as pollens.[7] It typically causes bilateral tearing, itching, and redness of the eyes.

The treatment of seasonal allergic rhinoconjunctivitis includes allergen avoidance and the use of cold compresses and eye washes with tear substitute. Allergic conjunctivitis also has been successfully treated with topical mast cell stabilizers, histamine type 1 (H_1) receptor antagonists, and topical nonsteroidal anti-inflammatory drugs.[7] Systemic antihistamines may be useful in prolonged allergic conjunctivitis. In severe cases, a short course of topical corticosteroids may be required to afford symptomatic relief.

The Cornea

The cornea functions as a protective membrane and transparent window through which light passes as it moves toward the retina (Fig. 38-4). The cornea also contributes to the refraction (i.e., bending) of light rays and focusing of vision. Three layers of tissue form the cornea: an extremely thin outer epithelial layer, which is continuous with the bulbar conjunctiva; a middle layer called the *substantia propria* or *stroma;* and an inner endothelial layer, which lies next to the aqueous humor of the anterior chamber.[2,8] The substantia propria is composed of regularly arranged collagen bundles embedded in a mucopolysaccharide matrix. This organization of the collagen fibers, which makes the substantia propria transparent, is necessary for light transmission. Hydration within a limited range is necessary to maintain the spacing of the collagen fibers and transparency. The three layers of the cornea are separated by two important basement membranes: Bowman and Descemet membranes. *Bowman membrane,* which lies between the corneal epithelium and the underlying corneal stroma, acts as a barrier to infection. It does not regenerate; if damaged, an opaque scar forms that can impair vision. *Descemet membrane,* which lies between the corneal endothelium and stroma, has a feltlike appearance and consists of interwoven fibers and pores. Unlike Bowman membrane, it regenerates readily after injury.

The cornea is avascular and obtains its nutrient and oxygen supply by diffusion from the blood vessels of the adjacent sclera, the aqueous humor at its deep surface, and tears that bathe its surface. The corneal epithelium is heavily innervated by sensory neurons. Epithelial damage causes discomfort that ranges from a foreign body sensation and burning of the eyes to severe, incapacitating pain. Reflex lacrimation is common.

Corneal Trauma

The integrity of the epithelium and the endothelium is necessary to maintain hydration of the cornea within a limited range.[8] The integrity of the endothelium is more important than the epithelium, and damage to the endothelium is far more serious than damage to the epithelium. Destruction of endothelial cells causes edema of the cornea and loss of transparency. With corneal edema, the cornea appears dull, uneven, and hazy; visual acuity decreases, and iridescent vision (i.e., rainbows around lights) occurs.

Trauma that causes abrasions of the cornea can be extremely painful, but if minor, the abrasions usually heal in a few days. The epithelial layer can regenerate, and small defects heal without scarring. If the stroma is damaged, healing occurs more slowly, and the danger of infection is increased. Injuries to the Bowman membrane and the stromal layer heal with scar formation that impairs the transmission of light.

Keratitis

Keratitis refers to inflammation of the cornea. It can be caused by infections, misuse of contact lenses, hypersensitivity reactions, ischemia, trauma, defects in tearing, and interruption in sensory innervation, as occurs with local anesthesia. Scar tissue formation due to keratitis is the leading cause of blindness and impaired vision throughout the world. Most of this vision loss is preventable if the condition is diagnosed early and appropriate treatment is begun.

Keratitis can be divided into two types: nonulcerative and ulcerative.[8] In *nonulcerative* keratitis, all the layers of the epithelium may be affected, but the epithelium remains intact. There are a number of causes of epithelial keratitis, including epidemic keratoconjunctivitis caused by adenoviruses 8 and 19. *Ulcerative keratitis* is an inflammatory process in which parts of the epithelium, stroma, or both are destroyed. Causes of ulcerative keratitis include infectious agents such as those causing conjunctivitis (e.g., *S. aureus, S. pneumoniae, C. trachomatis*), exposure trauma, and use of extended-wear contact lenses (i.e., *Pseudomonas* and *Acanthamoeba* keratitis). Bacterial keratitis is aggressive and demands immediate care. Mooren ulcer is a chronic,

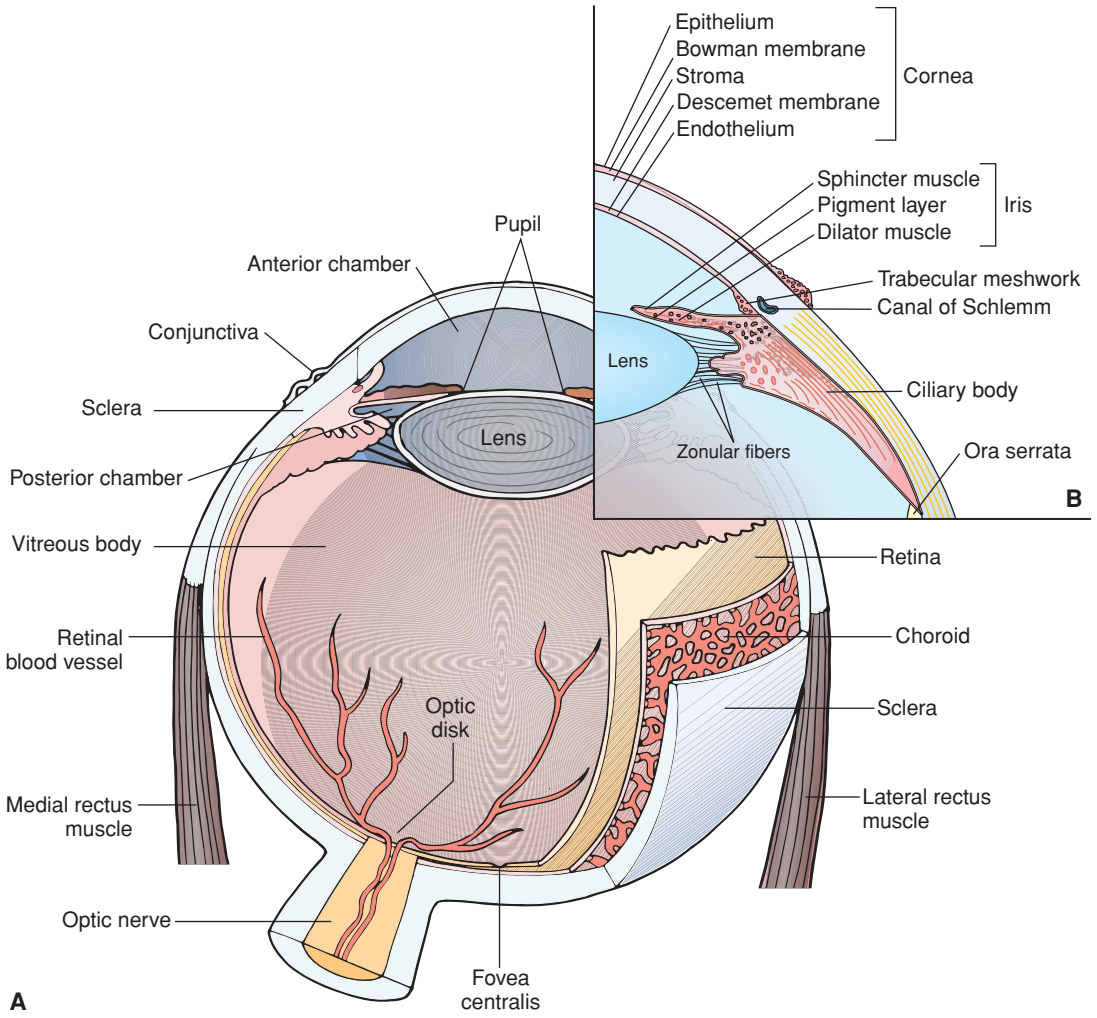

FIGURE 38-4. **(A)** Transverse section of the eyeball. **(B)** Enlargement of the anterior and posterior chambers of the eye, showing the layers of the cornea, the structures of the iris, the aqueous drainage system (trabecular meshwork, canal of Schlemm), and the ciliary process and ciliary muscle.

painful, indolent ulcer that occurs in the absence of infection. It is usually seen in older persons and may affect both eyes. Although the cause is unknown, an autoimmune origin is suspected.

Herpes Simplex Keratitis. Herpes simplex virus (HSV) keratitis is an important cause of ocular morbidity.[8–10] With the exception of neonatal infections, which are usually due to HSV type 2 (genital herpes) acquired during the birth process, most cases of herpes keratitis are caused by HSV type 1 (labial [lip] herpes). The disease can occur as either a primary or recurrent infection. Primary epithelial infections are the optical counterpart of labial herpes with similar immunologic and pathologic features as well as a similar time course (see Chapter 46). During childhood, mild primary HSV infection may go unnoticed. The ability of the virus to colonize the trigeminal ganglion can lead to recurrence precipitated by immunodeficiency or stress-related factors that reactivate the virus. Involvement is usually unilateral.

The first manifestations of recurrent herpes keratitis are irritation, photophobia, and tearing. Some reduction in vision may occur when the lesion affects the central part of the cornea. Because corneal anesthesia occurs early in the disease, the symptoms may be minimal, and the person may delay seeking medical care. A history of fever blisters or other herpetic infection is often noted, but corneal lesions may be the only sign of recurrent herpes infection. Typically, the corneal lesion involves the epithelium and has a typical dendritic (branching) pattern. These epithelial lesions heal without scarring. Herpetic lesions that involve the stromal layer of the cornea produce increasingly severe corneal opacities.

The treatment of HSV keratitis includes the use of topical antiviral agents to promote healing.[8] Oral antiviral agents (e.g., acyclovir) may be helpful for treatment of severe keratitis and as prophylaxis against recurrence, particularly in persons with compromised immune function. Although corticosteroids may control the damaging inflammatory responses, they do so at the expense of

facilitating viral replication. With a few exceptions, their use is contraindicated.[10]

Varicella Zoster Ophthalmicus. Herpes zoster or *shingles* is a relatively common infection due to the herpesvirus that causes varicella (chickenpox).[8,11] Herpes ophthalmicus, which represents 10% to 25% of all cases of herpes zoster, occurs when reactivation of the latent virus occurs in the ganglia of the ophthalmic division of the trigeminal nerve.[11] Immunocompromised persons, particularly those with human immunodeficiency virus (HIV) infection, are at higher risk for developing herpes zoster ophthalmicus than those with a normally functioning immune system.

Herpes zoster ophthalmicus usually presents with malaise, fever, headache, and burning and itching of the periorbital area. These symptoms commonly precede the ocular eruption by a day or two. The rash, which is initially vesicular, becomes pustular and then crusting (see Chapter 46). Involvement of the tip of the nose and lid margins indicates a high likelihood of ocular involvement. Ocular signs include conjunctivitis, keratitis, and anterior uveitis, often with elevated intraocular pressure. Persons with corneal disease present with varying degrees of decreased vision, pain, and sensitivity to light.

Treatment includes the use of oral and intravenous antiviral drugs. Initiation of treatment within the first 72 hours after the appearance of the rash reduces the incidence of ocular complications but not the postherpetic neuralgia[8] (see Chapter 35). Many cases of herpes zoster and herpes zoster ophthalmicus can now be prevented with the herpes zoster vaccine.

Acanthamoeba Keratitis. *Acanthamoeba* is a free-living cyst-forming protozoan that thrives in polluted water containing bacteria and organic material.[8,10,12] *Acanthamoeba* keratitis is a rare but serious and sight-threatening complication associated with wearing of soft contact lens, particularly if they are worn overnight or beyond doctor-recommended periods or when poor disinfection techniques are used. It also may occur in non–contact lens wearers after exposure to contaminated water or soil. *Acanthamoeba* keratitis is characterized by pain that is disproportionate to the clinical manifestations, redness of the eye, and photophobia. The disorder may be misdiagnosed as herpes keratitis. Diagnosis is confirmed by scrapings and culture with specially prepared medium. In the early stages of infection, epithelial débridement may be beneficial. Treatment includes intensive use of topical antimicrobials. However, the organism may encyst within the corneal stroma, making treatment more difficult. Keratoplasty may be necessary in advanced disease to arrest the progression of the infection.

The Lens

The lens is a remarkable structure that functions to bring images into focus on the retina. The lens is an avascular, transparent, biconvex body, the posterior side of which is more convex than the anterior side.[2,13] It is positioned just posterior to the iris and is held in place by suspensory ligaments known as the *zonules*, which are composed of numerous fibrils that arise from the ciliary body (see Fig. 38-4). The pull of the zonular fibers and lens capsule is normally under tension, causing the lens to have a flattened shape for distant vision. Relaxation of the fibers allows the lens to relax to a more spherical shape for near vision.

The lens has three principal components: the lens capsule, a subcapsular epithelium, and lens fibers. The lens capsule is a transparent elastic structure that envelops the entire lens. The subcapsular epithelium is a cuboidal layer of cells that is present on the anterior surface of the lens. The lens fibers, which constitute the bulk of the lens, are derived from the subcapsular epithelium. The subcapsular epithelium continues to produce new lens fibers throughout life, with the older fibers being compressed into the central nucleus of the lens. This causes the lens to gradually become larger and less elastic with age. There are no pain fibers, blood vessels, or nerves in the lens.

Refraction refers to deflection or bending of light as it passes from one transparent medium to another of different density. When parallel light rays pass through the center of a lens, their direction is not changed; however, the divergent rays passing peripherally through a lens are bent (Fig. 38-5). The refractive power of a lens is usually described as the distance (in meters) from its surface to the point at which the rays come into focus on the retina (i.e., focal length). Usually, this is reported as the reciprocal of this distance (i.e., diopters).[14] For example, a lens that brings an object into focus at 0.5 m has a refractive power of 2 diopters (1.0/0.5 = 2.0). The closer the object, the more divergent the peripheral rays, and the stronger and more precise the focusing system must be.

In the eye, the major refraction of light begins at the convex corneal surface. Further refraction occurs as light moves from the posterior corneal surface to the aqueous humor, from the aqueous humor to the anterior lens surface, from the anterior lens surface to the posterior lens surface, and from the posterior lens surface to the vitreous humor.

Disorders of Refraction

A perfectly shaped optic globe and cornea result in optimal visual acuity, producing a sharp image in focus at all points on the retinal surface in the posterior part, or fundus, of the eye. Unfortunately, individual differences in formation and growth of the eyeball and cornea frequently result in inappropriate focal image formation. If the anterior-posterior dimension of the eyeball is too short, the image is theoretically focused posterior to (behind) the retina. This is called *hyperopia,* or *farsightedness* (see Fig. 38-5B). In such cases, the accommodative changes of the lens can bring distant images into focus, but near images become blurred. Hyperopia is corrected by appropriate convex-surface lenses. If the anterior-posterior dimension of the eyeball is too long, the focus point for an infinitely distant target is anterior to the

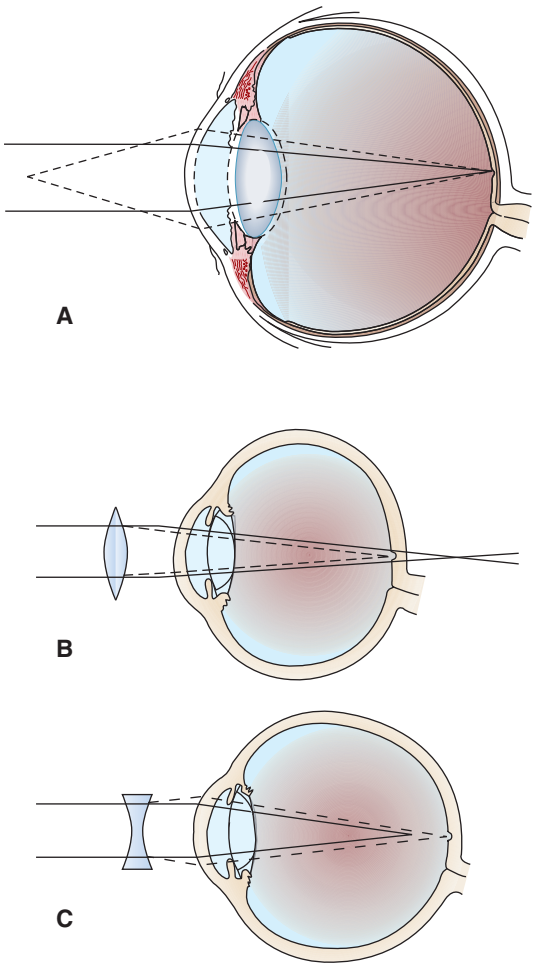

FIGURE 38-5. **(A)** Accommodation. The *solid lines* represent rays of light from a distant object, and the *dotted lines* represent rays from a near object. The lens is flatter for the former and more convex for the latter. In each case, the rays of light are brought to a focus on the retina. **(B)** Hyperopia corrected by a biconvex lens, shown by the *dotted lines.* **(C)** Myopia corrected by a biconcave lens, shown by the *dotted lines.*

retina. This condition is called *myopia*, or *nearsightedness* (see Fig. 38-5C). Persons with myopia can see close objects without problems because accommodative changes in their lens bring near objects into focus, but distant objects are blurred. Myopia can be corrected with an appropriate concave-surface lens. Refractive corneal surgeries such as laser in situ keratomileusis (LASIK), photorefractive keratectomy, and radial keratotomy can be performed to correct the corneal curvature to create accurate optical focus.[15]

Refractive defects of the corneal surface do not permit the formation of a sharp image. Nonuniform curvature of the refractive medium with regard to the horizontal and vertical planes is called *astigmatism*. Astigmatism is usually the result of an asymmetric bowing of the cornea, but it can result from defects in the cornea, lens, or retina. Lens correction is available to sharpen focus in case of such refractive error.

Disorders of Accommodation

Because the retina is at a fixed distance from the lens, adjustability in the refractive power of the lens is needed so that a clear image is maintained as gaze is shifted from a far to a near object. The process by which the refractive power of the lens is increased and the diverging light rays are bent more sharply is called *accommodation*. Accommodation is neurologically associated with convergence of the eyes and pupillary constriction, and results from thickening of the lens through contraction of the ciliary muscle. Contraction of muscle fibers in the ciliary body is controlled mainly by the parasympathetic fibers of the oculomotor cranial nerve (CN III). Paralysis of the ciliary muscle, with loss of accommodation, is called *cycloplegia*. Pharmacologic cycloplegia, using a topical anticholinergic agent, is sometimes necessary to aid refractive examination of the eye, especially in small children who are unable to hold a steady degree of accommodation during the examination.

The term *presbyopia* refers to a decrease in accommodation that occurs because of aging. The normal proliferative process in the lens nucleus that occurs throughout life causes the lens to thicken and its capsule to become less elastic with aging, so that the range of focus or accommodation is diminished. The person with emmetropic eyes (no refractive error) will begin to notice inability to read small print or discriminate close objects. This is usually worse in dim light and usually worse on arising in the morning or when the person is fatigued.

Cataracts

A cataract is a lens opacity that interferes with the transmission of light to the retina. Cataracts are the most common cause of blindness in the world, accounting for nearly 48% of all blindness.[16] Aging is the most common cause of cataracts, with an estimated prevalence of 50% in persons between the ages of 65 and 74 years, and increasing to 75% in those over 75 years of age.[1]

As the lens ages, new layers of fibers are added and the lens nucleus is compressed and becomes harder (nuclear sclerosis cataract), with associated yellowing of the lens. Nuclear sclerosis progresses slowly, over years. The earliest symptom may be improved near vision without glasses. This occurs from an increase in the focus power of the leans, creating a myopic shift in vision.[13,17] With further progression there can be loss of color discrimination and also loss of vision, typically greater for distance than for near vision.

Although aging is the most important cause of cataracts, other factors such as heredity, environmental and metabolic influences, drugs, and trauma may be involved.[13,16] Long-term exposure to sunlight (ultraviolet radiation) and heavy smoking have been associated with increased risk of cataract formation. Metabolically induced cataracts are caused by disorders of carbohydrate metabolism (diabetes) or inborn errors of metabolism. Occasionally, cataracts occur as a developmental defect (i.e., congenital cataracts) or secondary to trauma. Corticosteroids drugs have been implicated as causative agents in cataract formation. Both systemic and inhaled

corticosteroids have been cited as risk factors.[18] Traumatic cataracts are usually caused by foreign body injury to the lens or blunt trauma to the eye. Foreign body injury that interrupts the lens capsule allows aqueous and vitreous humor to enter the lens and initiate cataract formation. Other causes of traumatic cataract are overexposure to heat (e.g., glassblower cataract) or to ionizing radiation. The radiation dose necessary to cause a cataract varies with the amount and type of energy; younger lenses are most vulnerable.

Clinical Manifestations. The manifestations of cataract depend on the extent of opacity and whether the defect is bilateral or unilateral. With the exception of traumatic or congenital cataract, most cataracts are bilateral. Age-related cataracts, which are the most common type, are characterized by increasingly blurred vision and visual distortion[13,17] (see Fig. 38-1C). Dilation of the pupil in dim light improves vision. With nuclear cataracts (those involving the lens nucleus), the refractive power of the anterior segment often increases to produce an acquired myopia, the so-called second sight. Central lens opacities may divide the visual axis and cause an optical defect in which two or more blurred images are seen. Posterior subcapsular cataracts are located in the posterior cortical layer and usually involve the central visual axis. In addition to decreased visual acuity, cataracts tend to cause light entering the eye to be scattered, thereby producing glare or the abnormal presence of light in the visual field.

Diagnosis and Treatment. Diagnosis of cataract is based on ophthalmoscopic examination and the degree of visual impairment on the Snellen vision test. On ophthalmoscopic examination, cataracts may appear as a gross opacity filling the pupillary aperture or as an opacity silhouetted against the red background of the fundus. Other tests that determine the potential ability to see well after surgery, such as electrophysiologic testing in which the response to visual stimuli is measured electronically, may be done.

There is no effective medical treatment for cataract. Strong bifocal lenses, magnification, appropriate lighting, and visual aids may be used as the cataract progresses. Surgery is the only treatment for correcting cataract-related vision loss.[13,17] Surgery usually involves lens extraction and intraocular lens implantation. It is commonly performed on an outpatient basis with the use of local anesthesia. The use of extracapsular surgery, which leaves the posterior capsule of the lens intact, has significantly improved the outcomes of cataract surgery. The cataract lens is usually removed using phacoemulsification techniques. Phacoemulsification involves ultrasonic fragmentation of the lens into fine pieces, which then are aspirated from the eye.

One of the greatest advances in cataract surgery has been the development of reliable intraocular implants. Monofocal intraocular lenses that correct for distance vision are available, and eyeglasses may be needed for near vision, although this has been addressed by the recent introduction of multifocal intraocular lenses.

Congenital Cataract. A congenital cataract is one that is present at birth.[13] About 30% of congenital cataracts are hereditary; another 30% are secondary to metabolic or infectious diseases or associated with a variety of syndromes; and the remaining 30% are due to undetermined causes. Cataracts and other developmental defects of the ocular apparatus depend on the total dose of the agent and the embryonic stage at the time of exposure. During the last trimester of fetal life, genetically or environmentally influenced malformation of the superficial lens fibers can occur. Congenital lens opacities may occur in children of diabetic mothers. Most congenital cataracts are not progressive and are not dense enough to cause significant visual impairment. However, cataracts that are dense, central, and larger than 2 mm in diameter require surgical management on an urgent basis. If not treated within the first 2 months of life, deprivation amblyopia will result (to be discussed).[13]

The Retina

The function of the retina is to receive visual images, partially analyze them, and transmit this modified information to the brain.[14] Disorders of the retina and its function include disorders of the retinal vessels such as retinopathies that cause hemorrhage and the development of opacities; separation of the pigment and sensory layers of the retina (i.e., retinal detachment); and macular degeneration. Because the retina has no pain fibers, most diseases of the retina are painless and do not cause redness of the eye.

The retina is composed of two layers: an outer pigment (melanin-containing) epithelium and an inner neural layer[19] (Fig. 38-6A). The outer surface of the pigmented layer, a single-cell–thick lining called the *Bruch membrane,* abuts the choroid and extends anteriorly to cover the ciliary body and the posterior side of the iris. Its pigmented epithelial cells, like those of the choroid, absorb light and prevent it from scattering. The pigment layer stores large quantities of vitamin A, which is an important precursor of the photosensitive visual pigments.

The inner light-sensitive neural retina covers the inner aspect of the eyeball.[14,19] The neural retina is composed of three layers of neurons: a posterior layer of photoreceptors (rods and cones), a middle layer of bipolar cells, and an inner layer of ganglion cells that communicate with the photoreceptors (see Fig. 38-6B). Light must pass through the transparent inner layers of the sensory retina before it reaches the photoreceptors. Impulses produced in response to light spread from the photoreceptors to the bipolar neurons and other interneurons and then to the ganglionic cells, where action potentials are generated. The interneurons, which have cell bodies in the bipolar layer, play an important role in modulating retinal function. The optic disk, where the optic nerve exits the eye, is the weak part of the eye because it is not reinforced by the sclera. It also forms the blind spot because it is not backed by photoreceptors, and light focused on it cannot be seen. People do not notice the blind spot because of a sophisticated visual

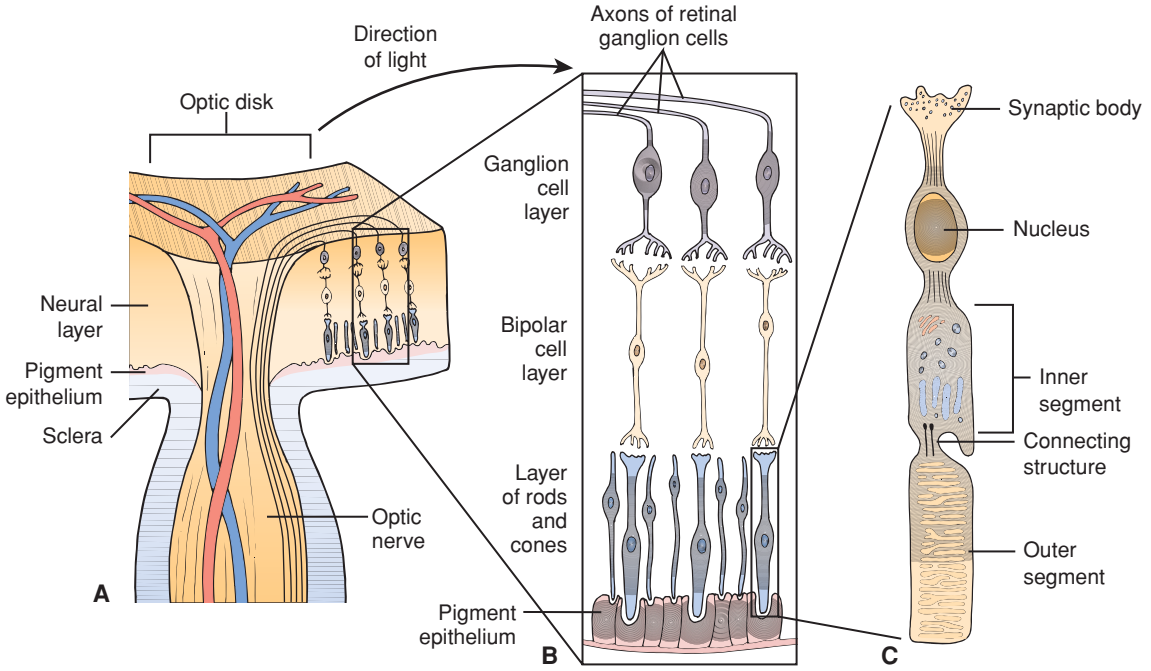

FIGURE 38-6. Organization of the retina. **(A)** Organization of the retina showing the inner neural layer and the outer pigment epithelium. **(B)** The three layers of the neural retina: a posterior layer of photoreceptors (rods and cones), a middle layer of bipolar cells, and an inner layer of ganglionic cells. **(C)** Photoreceptor structure: a retinal rod, showing its component parts and distribution of organelles.

function called "filling in," which the brain uses to deal with missing visual input.

Two types of photoreceptors are present in the retina: rods capable of black–white discrimination and cones capable of color discrimination.[14,19,20] Rod-based vision is particularly sensitive to detecting light, especially moving light stimuli, at the expense of clear pattern discrimination. Rod vision is particularly adapted for night and low-level illumination. Dark adaptation is the process by which rod sensitivity increases to the optimum level. This requires approximately 4 hours in total or near-total darkness and is referred to as *scotopic vision* (night vision). Cone receptors, which are selectively sensitive to different wavelengths of light, provide the basis for color vision. Three types of cones, or cone-color systems, respond to the blue, green, and red portions of the visible electromagnetic spectrum. Cones do not have the dark adaptation capability of rods. Consequently, the dark-adapted eye is a rod receptor eye with only black–gray–white experience (scotopic or night vision). The light-adapted eye (*photopic vision*) adds the capacity for color discrimination.

Both rods and cones contain chemicals that change configuration on exposure to light and, in the process, generate currents that lead to the action potentials generated by the ganglionic cells. The light-sensitive chemical in rods is called *rhodopsin*, and the light-sensitive chemicals in cones are called *cone* or *color pigments*. Both types of photoreceptors are thin, elongated, mitochondria-filled cells with a single, highly modified cilium (Fig. 38-6C). The cilium has a short base, or inner segment, and a highly modified outer segment. The plasma membrane of the outer segment is tightly folded to form membranous disks (rods) or conical shapes (cones) containing visual pigment. These disks are continuously synthesized at the base of the outer segment and shed at the distal end. Discarded membranes are phagocytized by the retinal pigment cells. If this phagocytosis is disrupted, as in a condition called *retinitis pigmentosa*, the sensory retina degenerates.

An area approximately 1.5 mm in diameter near the center of the retina, called the *macula lutea* (i.e., "yellow spot"), is especially adapted for acute and detailed vision.[16,19] This area is composed entirely of cones. In the central portion of the macula, the *fovea centralis* (foveola), the blood vessels and innermost layers are displaced to one side instead of resting on top of the cones. This allows light to pass unimpeded to the cones without passing through several layers of the retina. Many of these cones are connected one to one with ganglionic cells, an arrangement that favors high acuity.

Retinal Blood Supply

The blood supply for the retina is derived from two sources: the choriocapillaris (i.e., the capillary layer of the choroid) and branches of the central retinal artery (Fig. 38-7A). Oxygen and other nutritional substances

needed by the retina and its component parts (pigment cells, rods, and cones) are supplied by diffusion from blood vessels in the choroid. Because the choriocapillaris provides the only blood supply for the fovea centralis, detachment of this part of the sensory retina from the pigment epithelium causes irreparable visual loss. The central artery, which is a branch of the ophthalmic artery, supplies the rest of the retina. Retinal veins follow a distribution parallel to the arterial branches and carry venous blood to the central vein of the retina, which exits the back of the eye through the optic disk.

Funduscopic examination of the eye with an ophthalmoscope provides the means for examining the retinal blood vessels and other aspects of the retina (Fig. 38-7B). Because the retina is an embryonic outgrowth of the brain and the blood vessels are to a considerable extent representative of brain blood vessels, the ophthalmoscopic

Disorders of the Retinal Blood Supply

- The blood supply for the retina is derived from the central retinal artery, which supplies blood flow for the entire inside of the retina, and from vessels in the choroid, which supply the rods and cones.
- The retinopathies, which are disorders of the retinal vessels, interrupt blood flow to the visual receptors, leading to visual impairment.
- Retinal detachment separates the visual receptors from the choroid, which provides their major blood supply.

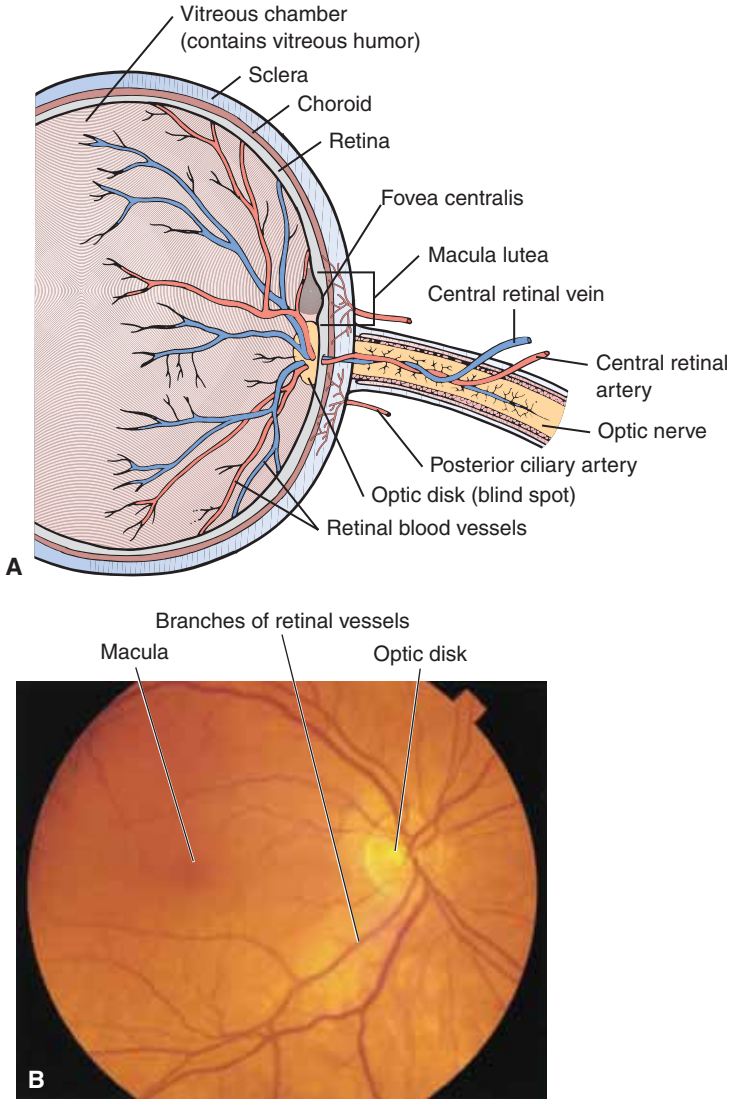

FIGURE 38-7. **(A)** Retinal circulation showing the distribution of the central retinal and posterior ciliary arteries and the central retinal vein. **(B)** Funduscopic image of the normal retina (From Moore K.L., Daley A.F. [2006]. Clinically oriented anatomy [5th ed., p. 967]. Philadelphia: Lippincott Williams & Wilkins.)

examination of the fundus of the eye permits the study and diagnosis of metabolic and vascular diseases of the brain as well as pathologic processes that are specific to the retina.

Papilledema. The central retinal artery enters the eye through the optic papilla in the center of the optic nerve. An accompanying vein exits the eye along the same path. The entrance and exit of the central retinal artery and vein through the tough scleral tissue at the optic papilla can be compromised by any condition causing persistent increased intracranial pressure. The most common of these conditions are cerebral tumors, subdural hematomas, hydrocephalus, and malignant hypertension.

Usually, the thin-walled, low-pressure veins are the first to collapse, with the consequent backup and slowing of arterial blood flow. Under these conditions, capillary permeability increases and leakage of fluid results in edema of the optic papilla, called *papilledema*.[6,21] The interior surface of the papilla is normally cup shaped and can be evaluated for cupping with an ophthalmoscope. With papilledema, sometimes called *choked disk*, the optic cup is distorted by protrusion into the interior of the eye (Fig. 38-8). Because this sign does not occur until the intracranial pressure is significantly elevated, compression damage to fibers of the optic nerve may have begun. As a warning sign, papilledema occurs quite late. Unresolved papilledema results in the destruction of the optic nerve axons and blindness.

Retinopathies

Retinopathies, which involve the small blood vessels of the retina, are characterized by changes in vessel structure and the development of microaneurysms, neovascularization, hemorrhage, and retinal opacities.[22] *Microaneurysms* are outpouchings of the retinal vasculature. On ophthalmoscopic examination, they appear as minute, unchanging red dots associated with blood vessels. Microaneurysms tend to leak plasma, resulting in localized edema that gives the retina a hazy appearance. They may also bleed, but areas of hemorrhage and edema tend to clear spontaneously. However, they reduce visual acuity if they encroach on the macula and cause degeneration before they are absorbed. *Neovascularization* involves the formation of new blood vessels. They can develop from the choriocapillaris, extending between the pigment layer and the sensory layer, or from the retinal veins, extending between the sensory retina and the vitreous cavity and sometimes into the vitreous. These new blood vessels are fragile, leak protein, and are likely to bleed. Although the cause of neovascularization is uncertain, research links the process with a vascular endothelial growth factor (VEGF) produced by the lining of blood vessels.[23,24] Hypoxia is a key regulator of VEGF-induced retinal neovascularization. It is likely that other growth factors and signaling systems are also involved.

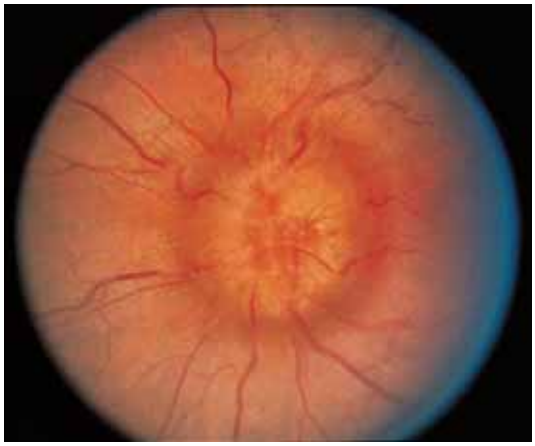

FIGURE 38-8. Chronic papilledema. The optic nerve head is congested and protrudes anteriorly toward the interior of the eye. It has blurred margins, and vessels within it are poorly seen. (From Klintworth G.K. [2008]. The eye. In Rubin R., Strayer D.E. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1262]. Philadelphia: Lippincott Williams & Wilkins.)

Opacities represent loss of retinal transparency due to hemorrhages, exudates, cotton-wool spots, edema, and tissue proliferation. *Exudates* are opacities resulting from inflammatory processes. The development of exudates often results in the destruction of the underlying retinal pigment and choroid layer. *Cotton-wool patches* are retinal opacities with hazy, irregular outlines. They occur in the nerve fiber layer and contain cell organelles. Cotton-wool patches are associated with retinal trauma, severe anemia, papilledema, and diabetic retinopathy.

Diabetic Retinopathy. Diabetic retinopathy is one of the leading causes of blindness in the Western world, particularly among individuals of working age.[6,20,22] Chronic hyperglycemia, hypertension, hypercholesteremia, and smoking are all risk factors for the development and progression of the disorder. People with type 1 (insulin-dependent) diabetes do not develop retinopathy for at least 3 to 5 years after the onset of the disease, whereas those with type 2 diabetes may have retinopathy at the time of diagnosis and it may be a presenting symptom.[20]

Diabetic retinopathy can be divided into two types: nonproliferative (i.e., background) and proliferative retinopathy.[6,20,22,25] *Background* or *nonproliferative* retinopathy is confined to the retina. It involves engorgement of the retinal veins, thickening of the capillary endothelial basement membrane, and development of capillary microaneurysms (Fig. 38-9A, B). Small intraretinal hemorrhages may develop and microinfarcts may cause cotton-wool spots and leakage of exudates. A sensation of glare (because of the scattering of light) is a common complaint. The most common cause of decreased vision in persons with background retinopathy is macular edema. The edema is caused primarily by the breakdown of the blood-retina barrier at the level of the capillary endothelium, allowing leakage of fluid and plasma constituents into the surrounding retina. Diabetic macular edema is more common in persons with type 2 diabetes and requires treatment once it becomes clinically significant.

Proliferative diabetic retinopathy represents a more severe retinal change than background retinopathy

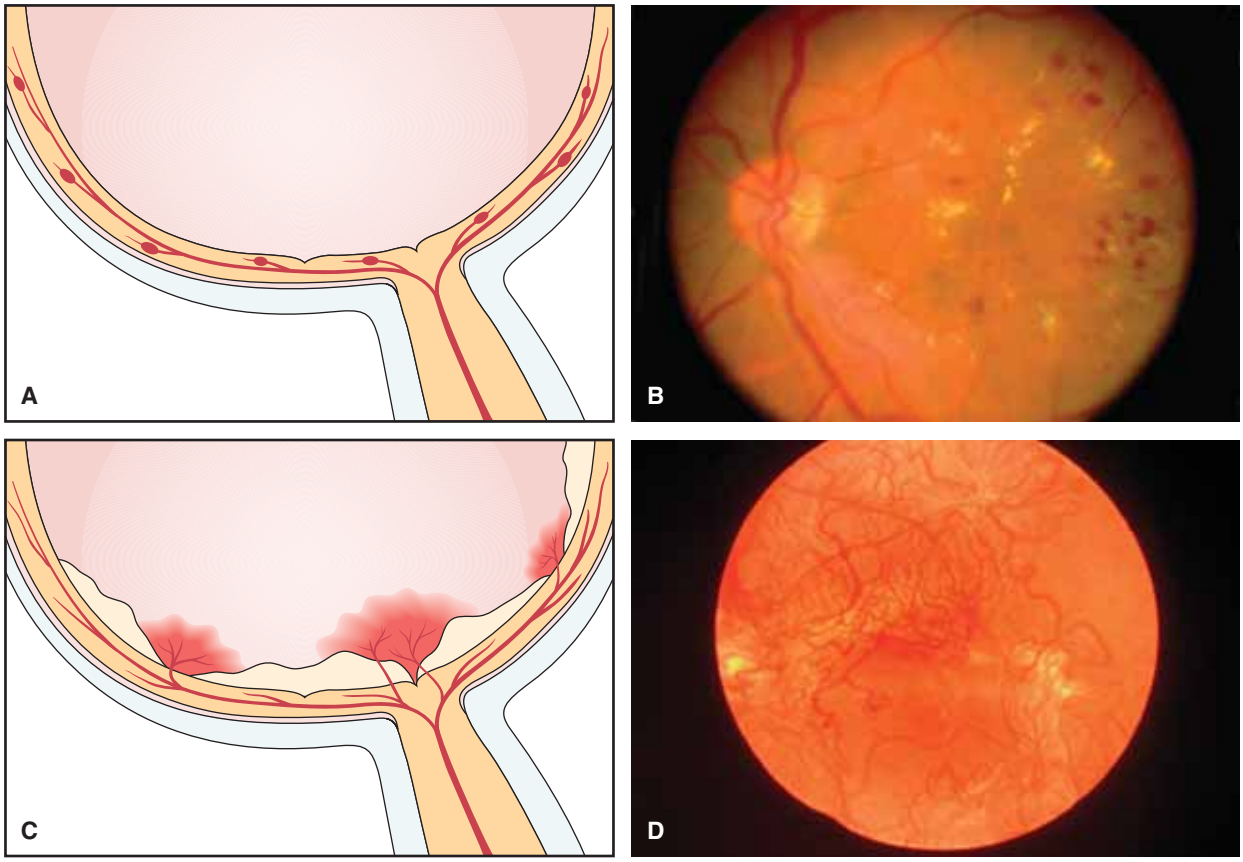

FIGURE 38-9. **(A)** Nonproliferative (background) retinopathy showing microaneurysms. **(B)** Ocular fundus of a patient with background diabetic retinopathy. Several yellowish "hard" exudates (which are rich in lipids) and several relatively small retinal hemorrhages are present. **(C)** Proliferative retinopathy. **(D)** Ocular fundus in a patient with proliferative retinopathy. A vascular frond (branching pattern of preretinal neovascularization) has extended anterior to the retina. (B and D from Klintworth G.K. [2008]. The eye. In Rubin R., Strayer D.E. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1257]. Philadelphia: Lippincott Williams & Wilkins.)

(Fig. 38-9C, D). It is characterized by formation of new, fragile blood vessels (i.e., neovascularization) at the optic disk and elsewhere in the retina. These vessels grow in front of the retina along the posterior surface of the vitreous or into the vitreous. They threaten vision in two ways. First, because they are abnormal, they often bleed easily, leaking blood into the vitreous cavity and decreasing visual acuity. Second, the blood vessels attach firmly to the retinal surface and posterior surface of the vitreous, such that normal movement of the vitreous may exert a pull on the retina, causing retinal detachment and progressive blindness. While diabetic macular edema is more prevalent in type 2 diabetes, proliferative diabetic retinopathy is the most common sight-threatening lesion in type 1 diabetes.

Because early proliferative diabetic retinopathy is likely to be asymptomatic, it must be identified early, before bleeding occurs and obscures the view of the fundus or leads to fibrosis and retinal detachment. Current guidelines recommend that persons with diabetes have yearly eye examinations, although deviations from this guideline are appropriate in certain low-risk groups.[24] For persons with moderate to severe nonproliferative retinopathy, more frequent examinations are often necessary to determine when to initiate treatment. Persons with any levels of macular edema, severe nonproliferative diabetic retinopathy, or any proliferative retinopathy require the prompt care of an ophthalmologist who is knowledgeable and experienced in the management and treatment of diabetic retinopathy. Women with preexisting diabetes who plan to become pregnant or become pregnant should have a comprehensive eye examination and be counseled about the risk for initiation or progression of diabetic retinopathy.

Preventing diabetic retinopathy from developing or progressing is considered the best approach to preserving vision. Growing evidence suggests that careful control of blood glucose levels in persons with diabetes mellitus may retard the onset and progression of retinopathy. There also is a need for intensive management of hypertension and hyperlipidemia, both of which have been shown to increase the risk of diabetic retinopathy in persons with diabetes.[24]

Photocoagulation using an argon laser provides the major direct treatment modality for diabetic retinopathy.[20] Treatment strategies include laser photocoagulation

applied directly to leaking microaneurysms and grid photocoagulation with a checkerboard pattern of laser burns applied to diffuse areas of leakage and thickening. Because laser photocoagulation destroys the proliferating vessels and the ischemic retina, it reduces the stimulus for further neovascularization. Intravitreal injections of anti-VEGF agents are also being used to reduce active neovascularization and vitreous hemorrhage.[20] Vitrectomy may be used for removing vitreous hemorrhage and severing vitreoretinal membranes that develop.

Hypertensive Retinopathy. As with other blood vessels in the body, the retinal vessels undergo changes in response to chronically elevated blood pressure. In the initial, vasoconstrictor stage, there is vasospasm and an increase in retinal arterial tone because of local autoregulatory mechanisms. On ophthalmoscopy, this stage is represented by a general narrowing of the retinal arterioles. Persistently elevated blood pressure results in the compensatory thickening of arteriolar walls, which effectively reduces capillary perfusion pressure.[26] With severe uncontrolled hypertension, there is disruption of the blood-retina barrier, necrosis of smooth muscle and endothelial cells, exudation of blood and lipids, and retinal ischemia. These changes are manifested in the retina by microaneurysms, intraretinal hemorrhages, hard exudates, and cotton-wool patches. Swelling of the optic disk may occur at this stage and usually indicates severely elevated blood pressure (malignant hypertension). Elderly persons often have more rigid vessels that are unable to respond to the same degree as those in younger individuals.

Retinal Detachment

Retinal detachment involves the separation of the neurosensory retina from the pigment epithelium (Fig. 38-10). It occurs when traction on the inner sensory layer or a tear in this layer allows fluid, usually vitreous, to accumulate between the two layers.[6,20,27] There are three types of retinal detachments: exudative, traction, and rhegmatogenous.

Exudative (or serous) *retinal detachment* results from the accumulation of serous or hemorrhagic fluid in the subretinal space due to severe hypertension, inflammation, or neoplastic effusions. It usually resolves with successful treatment of the underlying disease and without visual impairment. *Traction retinal deattachment* occurs with mechanical forces on the retina, usually mediated by fibrotic tissue, resulting from previous hemorrhage (e.g., from diabetic retinopathy), injury, infection, or inflammation. Intraocular surgery such as cataract extraction may produce traction on the peripheral retina that causes eventual detachment months or even years after surgery. Correction of traction retinal detachment requires disengaging scar tissue from the retinal surface, and vision outcomes are often poor.

Rhegmatogenous detachment (*rhegma* is the Greek word for "rent" or "hole") is the most common type of retinal detachment. The vitreous is a hydrated gel whose

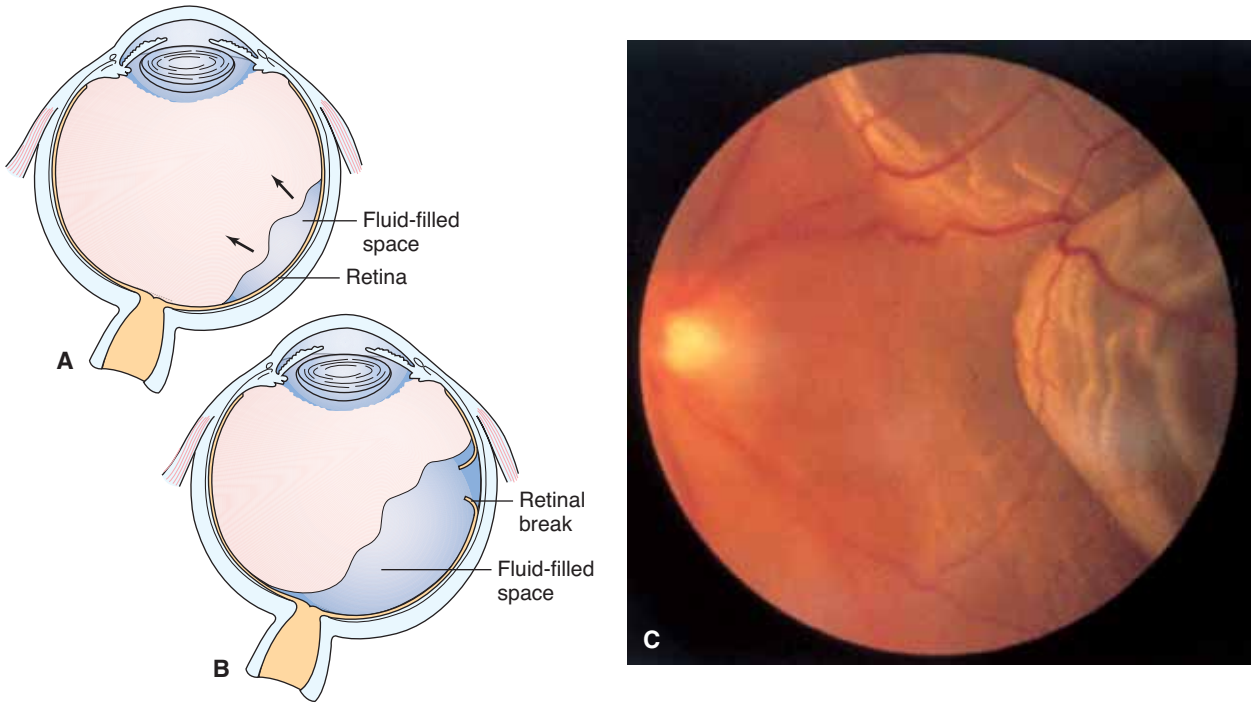

FIGURE 38-10. Pathogenesis of rhegmatogenous retinal detachment. **(A)** Changes in the vitreous structure cause it to shrink and separate from the retina, causing posterior vitreous detachment. **(B)** Sustained fluid collection and tractional forces cause the retina to tear (rhegmatogenous retinal detachment). **(C)** Ophthalmoscopic photograph of retinal detachment. (From Moore K.L., Dalley A.F. [2006]. *Clinically oriented anatomy* [5th ed., p. 967]. Philadelphia: Lippincott Williams & Wilkins.)

structure is maintained by a collagenous and mucopolysaccharide matrix. As persons age, this macromolecular network begins to liquefy and collapse. As this occurs, the vitreous shrinks and partly separates from the retinal surface, a condition known as *posterior vitreous detachment* (see Fig. 38-10A). Rhegmatogenous detachment occurs when the liquid vitreous enters the subretinal space through the retinal tear (see Fig. 38-10B). Detachment of the neural retina from the retinal pigment layer separates the receptors from their major blood supply, the choroid. If retinal detachment continues for some time, permanent destruction and blindness of that part of the retina occur. Risk factors that predispose to retinal detachment include advancing age and myopia. Approximately one in four persons between the ages of 61 and 70 years develops a posterior vitreous detachment. In about 10% to 15% of these persons, a retinal tear or hole forms as the vitreous pulls away from the retina, especially in the periphery where the retina is thinner.[27] Persons with high grades of myopia may have abnormalities in the peripheral retina that predispose to sudden detachment. In moderate to severe myopia or nearsightedness, the axial (anteroposterior) length of the eye is increased, and the retina tends to be thinner and more prone to formation of a hole or tear.[27] As a result, there is greater vitreoretinal traction, and posterior vitreous detachment may occur at a younger age than in persons without myopia. Other, less common risk factors include a family history of retinal detachment, a history of congenital eye disease (glaucoma, cataracts), and hereditary vitreopathies with abnormal vitreous gel.

The primary symptom of retinal detachment consists of painless changes in vision. Commonly, flashing lights or sparks, followed by small floaters or spots in the field of vision, occur as the vitreous pulls away from the posterior pole of the eye. As detachment progresses, the person perceives a shadow or dark curtain progressing across the visual field. Because the process begins in the periphery and spreads circumferentially and posteriorly, initial visual disturbances may involve only one quadrant of the visual field. Large peripheral detachments may occur without involvement of the macula, so that visual acuity remains unaffected.

Diagnosis is based on a history of visual disturbances (e.g., presence of floaters, luminous rays, or light flashes) and the ophthalmoscopic appearance of the retina. The direct (hand-held) ophthalmoscope is useful in detecting an altered red reflex sometimes associated with retinal detachment. However, because the view is narrow, a negative examination with direct ophthalmoscopy cannot exclude the diagnosis of retinal detachment. Ophthalmologists and optometrists use indirect examination techniques that greatly enhance visualization of the peripheral retina (Fig. 38-10C).[27]

Because there is a variable interval between a retinal break and retinal detachment, treatment methods focus on early detection and prevention of further vitreous detachment and retinal tear formation. Symptomatic retinal breaks are usually treated with laser or cryotherapy to seal the retinal tears so that the vitreous can no longer leak into the subretinal space. The treatment is more than 95% effective in preventing progression of a retinal tear and preventing retinal detachment.[27] The primary treatment of traction retinal detachment is vitreoretinal surgery and may involve vitrectomy, membrane removal, scleral buckling, or pneumatic retinopexy. Scleral buckling is the primary surgical procedure performed to reattach the retina.[20,27] With scleral buckling, a piece of silicone (i.e., the buckle) is sutured and infolded into the sclera, physically indenting the sclera so it contacts the separated pigment and retinal layers. A less invasive procedure, pneumatic retinopexy, involves the intraocular injection of an expandable gas instead of a piece of silicone to form the indentation.

Macular Degeneration

Macular degeneration is characterized by degenerative changes in the central portion of the retina (the macula) that result primarily in loss of central vision (see Fig. 38-1B). Age-related macular degeneration is the most common cause of reduced vision in the elderly population.[20,22,28–30] The causes of age-related macular degeneration are poorly understood. In addition to older age, identifiable risk factors include female sex, white race, and cigarette smoking. Increasing evidence suggests that genetic factors may play a role.

Age-related macular degeneration is commonly described as *nonneovascular* (nonexudative or "dry") or neovascular (exudative or "wet"). The nonneovascular form of age-related macular degeneration is characterized by various degrees of atrophy and degeneration of the outer retina, Bruch membrane, and choriocapillaris. It does not involve leakage of blood or serum; hence, it is called *dry age-related macular degeneration.* On ophthalmoscopic examination, there are visible changes in the retinal pigmentary epithelium and pale yellow spots, called *drusen,* that may occur individually or in groups throughout the macula (Fig. 38-11A). With time, the drusen enlarge, coalesce, and increase in number. The level of associated visual impairment is variable and may be minimal. Most people with macular drusen do not experience significant loss of central vision, and the atrophic changes may stabilize or progress slowly. However, people with the nonneovascular form of age-related macular degeneration need to be followed closely because the exudative stage may develop suddenly, at any time. Careful monitoring for *metamorphopsia*, or distorted vision of straight lines, can aid in the early detection of retinal damage.

The *neovascular* form of age-related macular degeneration is characterized by the formation of a choroidal neovascular membrane that separates the pigmented epithelium from the neuroretina. These new blood vessels have weaker walls than normal and are prone to leakage. The leakage of serous or hemorrhagic fluid into the subretinal space causes separation of the pigmented epithelium from the neurosensory retina. Over time, the subretinal hemorrhages organize to form scar tissue, causing death of the underlying retinal tissue and loss of all visual function in the corresponding macular area (see Fig. 38-11B). The early stages of subretinal neovascularization

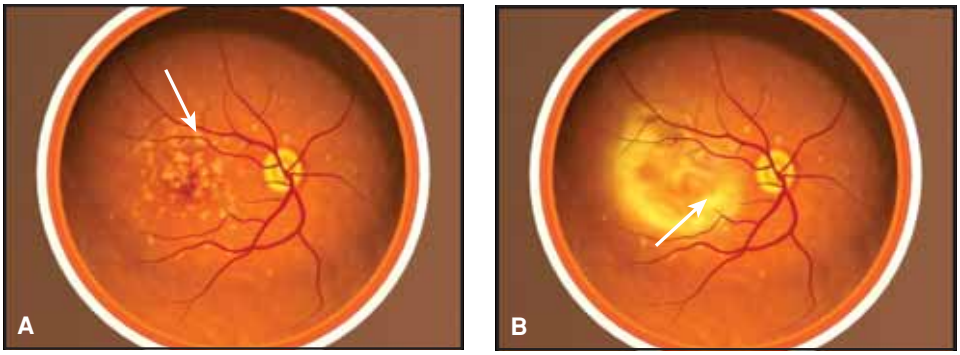

FIGURE 38-11. Funduscopic view of age-related macular degeneration (AMD). **(A)** Intermediate AMD with pale yellow spots or drusen scattered throughout the retina. **(B)** Advanced AMD with formation of scar tissue representing loss of death of the underlying retinal tissue and loss of all visual function in the corresponding macular area. (From the National Eye Institute, National Institutes of Health.)

may be difficult to detect with an ophthalmoscope. Therefore, there is a need to be alert for recent or sudden changes in central vision, blurred vision, or scotomata (visual field areas in which vision is depressed or absent) in persons with evidence of age-related macular degeneration. Although some subretinal neovascular membranes may regress spontaneously, the natural course of exudative macular degeneration is toward irreversible loss of central vision. Persons with late-stage disease often find it difficult to see at long distances (e.g., in driving), do close work (e.g., reading), see faces clearly, or distinguish colors. However, they may not be severely incapacitated because the peripheral retinal function usually remains intact. With the use of low-vision aids, many of them are able to continue many of their normal activities.

Effective therapies for the proliferative or exudative type macular degeneration include thermal laser photocoagulation, photodynamic therapy, intravitreal and periocular corticosteroid injections, and intravitreal injections of VEGF inhibitors.[20,28–30] The decision about specific therapies must take into account the likelihood of visual recovery, which is greater with smaller, more recent lesions, as well as the risks of the various therapies. Conventional retinal laser photocoagulation can achieve direct destruction of a choroidal neovascular membrane. Photodynamic laser therapy involves the intravenous injection of a dye that is subsequently activated by retinal laser irradiation to produce selective vascular damage. The corticosteroids have an angiostatic activity that appears to be independent of their hormone activity. The intravitreal injection of these agents bypasses the blood-ocular barrier, achieving therapeutic levels in the eye while avoiding systemic side effects.[20,29] Vascular endothelial growth factor plays a crucial role in the expansion of choroidal neovascular membranes. It induces both angiogenesis and increased permeability. The intravitreal injection of VEGF inhibitors has been shown to be beneficial for treating choroidal neovascularization.[20,29]

In addition to currently used and forthcoming treatments, there is interest in the so-called preventative category of treatments. Tobacco smoking is consistently identified as a preventable age-related macular degeneration risk; thus, its elimination should be one the first therapeutic recommendations. Preventative recommendations also include dietary supplementation with antioxidants and minerals such as vitamin E (α-tocopherol), vitamin C (ascorbic acid), zinc, and β-carotene for persons at risk for developing macular degeneration and for slowing the progression of age-related macular degeneration in persons with the disease.[30] However, more experimental data and randomized clinical trials are needed to support their therapeutic value, the most effective composition in terms of single- or multiple-supplement combinations, and dosing of the particular supplements.

Intraocular Pressure and Glaucoma

Glaucoma is a chronic, degenerative optic neuropathy characterized by optic disk cupping and visual field loss. It usually is associated with an elevation in intraocular pressure. Glaucoma is the second leading cause of blindness in the world.[1] About 100,000 Americans are blind from glaucoma, making it the leading cause of preventable blindness in the United States.[31] The condition often is asymptomatic, and a significant loss of peripheral vision may occur before medical attention is sought (see Fig. 38-1D).

The intraocular pressure largely reflects that of the aqueous humor that fills the anterior and posterior chambers of the eye. The aqueous humor is produced by the ciliary body and passes from the posterior chamber through the pupil into the anterior chamber[6,22,31] (Fig. 38-12A). Aqueous humor leaves through the iridocorneal angle between the anterior surface of the iris and the sclera. Here it filters through the trabecular meshwork and enters the canal of Schlemm, a thin-walled vein that extends circumferentially around the iris of the eye, for return to the venous circulation. Intraocular pressure results from a balance of several factors, including the rate of aqueous humor production by the ciliary body, the resistance to flow between the iris and ciliary body, and its rate of removal by the drainage system (trabecular meshwork and canal of Schlemm). Normally, the rate of aqueous humor secretion is equal to

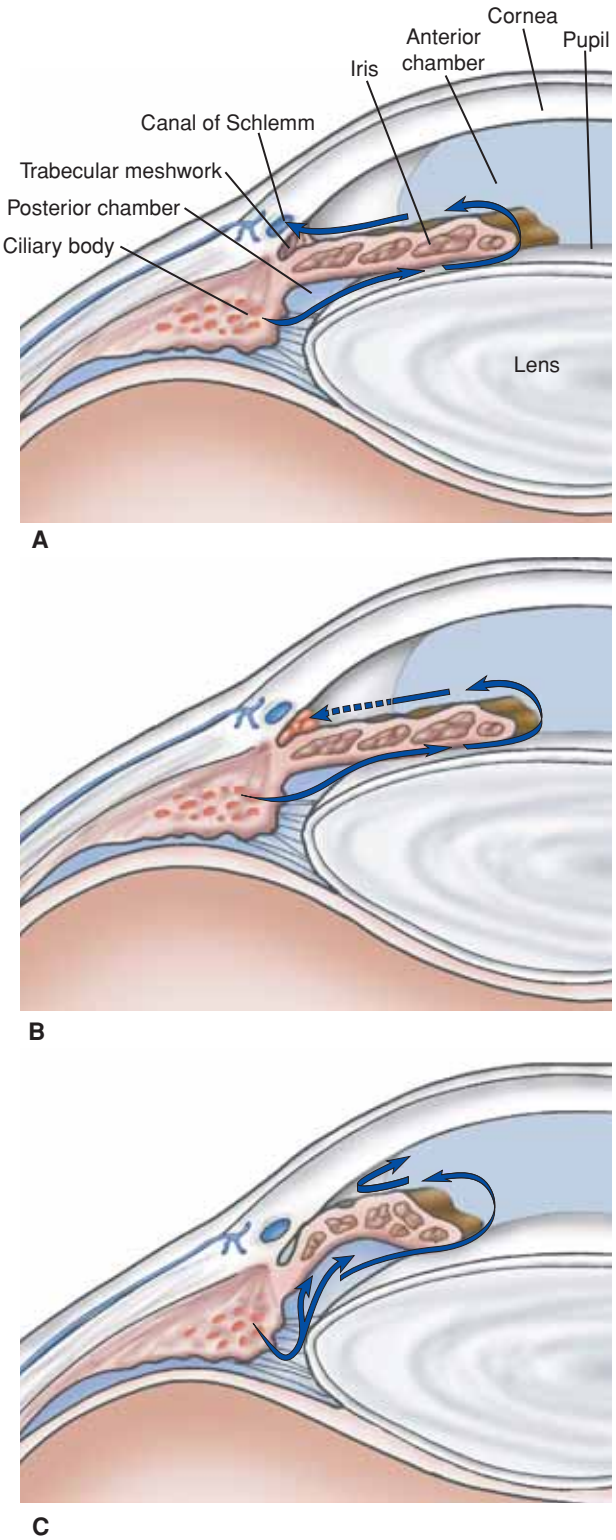

FIGURE 38-12. **(A)** Normally, aqueous humor, which is secreted in the posterior chamber, gains access to the anterior chamber by flowing through the pupil. In the angle of the anterior chamber, it passes through the canal of Schlemm into the venous system. **(B)** In open-angle glaucoma, the outflow of aqueous humor is obstructed at the trabecular meshwork. **(C)** In angle-closure glaucoma, the aqueous humor encounters resistance to flow through the pupil. Increased pressure in the posterior chamber produces a forward bowing of the peripheral iris, so that the iris blocks the trabecular meshwork.

the rate of outflow, and the intraocular pressure is maintained within a normal range of 10 to 21 mm Hg.[31]

Glaucoma usually results from congenital or acquired lesions of the anterior segment of the eye that mechanically obstruct aqueous outflow. Glaucoma is commonly classified as open-angle or angle-closure glaucoma depending on the appearance of the iridocorneal angle, and according to whether it is a primary or secondary disorder.[6,22,31] In *open-angle glaucoma*, impaired outflow results from dysfunction of the drainage system, and in *angle-closure glaucoma*, impaired outflow results from occlusion of the iridocorneal angle itself, impairing access to the drainage system.

In persons with glaucoma, permanent impairment of vision results from degenerative changes in the optic nerve. Damage to optic nerve axons can be recognized on ophthalmoscopic examination. The normal optic disk has a central depression called the *optic nerve cup*. In glaucoma, the neuroretinal rim of the optic nerve becomes progressively thinner, thereby enlarging the optic nerve cup, a phenomenon referred to as *optic nerve cupping*. Its cause is loss of retinal ganglionic cell axons, along with supporting glia and vasculature (see Fig. 38-7). The loss of nerve fibers causes a permanently decreased visual field. Because changes in the optic cup precede visual field loss, regular ophthalmoscopic examinations are important for detecting eye changes that occur with increased intraocular pressure. Advances in computer technology allow detection and quantification of visual changes due to glaucoma. These tests include white-on-white and blue-on-yellow visual field testing, testing of contrast sensitivity, and dark adaptation. Scanning laser technology and optical coherence tomography tests can often detect damage to retinal ganglion axons before visual field loss occurs.

Open-Angle Glaucoma

Open-angle glaucoma is the most common form of glaucoma.[32,33] The chief pathologic feature in primary open-angle glaucoma is an abnormality of the trabecular meshwork that controls the flow of aqueous humor into the canal of Schlemm (see Fig. 38-12B). It occurs without obstruction at the iridocorneal angle, hence the name *open-angle glaucoma*. Open-angle glaucoma is usually asymptomatic and chronic, causing progressive damage to the optic nerve and visual field loss unless it is appropriately treated. Elevated intraocular pressure is a primary factor in open-angle glaucoma, but it is not the only diagnostic factor. Some eyes tolerate elevated intraocular pressure without developing disk or visual field changes; others develop glaucomatous changes with consistently normal intraocular pressures (normal-tension glaucoma).

Open-angle glaucoma can develop as a primary or secondary condition. Primary glaucoma occurs in anatomically predisposed eyes without other pathology. Major risk factors include an age of 40 years and older, black race, a family history of glaucoma, and severe myopia.[32,33] Primary open-angle glaucoma includes both adult-onset disease (occurring after 40 years of age) and juvenile-onset disease (occurring before 40 years of age). Approximately 4% of persons with adult-onset and more than 10% of those with juvenile-onset primary-angle glaucoma have

mutations that have been mapped to a glaucoma-related gene on chromosome 1.[32] Secondary open-angle glaucoma occurs as a result of conditions such as inflammatory processes that affect the eye, formation of red cell fragments after trauma, lens changes, and intraocular tumors. Other risk factors include hypertension, type 2 diabetes, hyperthyroidism, and migraine headaches. In some persons, the use of moderate amounts of topical or inhaled corticosteroid medications can cause an increase in intraocular pressure. Sensitive persons also may sustain an increase in intraocular pressure with the use of systemic corticosteroid drugs.

Diagnostic methods include applanation tonometry (measurement of intraocular pressure), ophthalmoscopic visualization of the optic nerve, and central visual field testing. Measurement of intraocular pressures provides a means of assessing glaucoma risk. Because the condition is usually asymptomatic, persons at risk for open-angle glaucoma should have regular direct ophthalmoscopic examinations, on both eyes, concentrating on the optic disk. Optic disk changes frequently are noted before visual field defects become apparent.

The elevation in intraocular pressure in persons with open-angle glaucoma is usually treated pharmacologically or, in cases where pharmacologic treatment fails, by increasing aqueous outflow through a surgically created pathway. Drugs used in the long-term management of glaucoma fall into five classes: β-adrenergic antagonists, prostaglandin analogs, adrenergic agonists, carbonic anhydrase inhibitors, and cholinergic agonists.[31,34] Most glaucoma drugs are applied topically. However, systemic side effects may occur.

Topical β-adrenergic antagonists are usually the drugs of first choice for lowering intraocular pressure. The β-adrenergic antagonists are thought to lower intraocular pressure by decreasing aqueous humor production in the ciliary body. Prostaglandin analogs increase the outflow of aqueous humor through the iris root and ciliary body, either by decreasing the extracellular matrix or by relaxing the ciliary musculature. They are highly effective first-line or adjuvant agents.[31] Adrenergic agonists cause an early decrease in production of aqueous humor by constricting the vessels supplying the ciliary body. Carbonic anhydrase inhibitors reduce the secretion of aqueous humor by the ciliary epithelium. Until recently, these drugs had to be taken orally, and systemic side effects were common. A topical carbonic anhydrase inhibitor, which acts locally, is now available. Cholinergic drugs exert their effects by increasing the effects of acetylcholine. Acetylcholine is the postganglionic neurotransmitter for the parasympathetic nervous system; it increases aqueous outflow through contraction of the ciliary muscle and pupillary constriction (miosis). Pilocarpine, a parasympathomimetic miotic and once the mainstay of treatment, has largely been replaced by newer and more effective drugs.

When a reduction in intraocular pressure cannot be maintained through pharmacologic methods, laser or surgical trabeculoplasty may become necessary.[31] With laser trabeculoplasty, the microburns created by the laser treatment scar rather than penetrate the trabecular meshwork, a process thought to enlarge the outflow channels by increasing the tension exerted on the trabecular meshwork. Cryotherapy, diathermy, and high-frequency ultrasound may be used in some cases to destroy the ciliary epithelium and reduce aqueous humor production.

Angle-Closure Glaucoma

Angle-closure glaucoma results from occlusion of the anterior chamber angle by the iris (see Fig. 38-12C). It is most likely to develop in eyes with preexisting shallow anterior chambers. An acute attack is often precipitated by pupillary dilation, which causes the iris to thicken, thus blocking the circulation between the posterior and anterior chambers.[6,22,31] Angle-closure glaucoma usually occurs as the result of an inherited anatomic defect that causes a shallow anterior chamber. It is seen more commonly in people of Asian or Inuit (Eskimo) descent and in people with hypermetropic eyes. This defect is exaggerated by the anterior displacement of the peripheral iris that occurs in older persons because of the increase in lens thickness that occurs with aging.

Manifestations of acute angle-closure glaucoma are related to sudden, intermittent increases in intraocular pressure. These occur after prolonged periods in the dark, emotional upset, and other conditions that cause extensive and prolonged dilation of the pupil. Administration of pharmacologic agents such as atropine that cause pupillary dilation (mydriasis) also can precipitate an acute episode of increased intraocular pressure in persons with the potential for angle-closure glaucoma. Attacks of increased intraocular pressure are manifested by ocular pain and blurred or iridescent vision caused by corneal edema. The pupil may be enlarged and fixed. Symptoms are often spontaneously relieved by sleep and conditions that promote pupillary constriction. With repeated or prolonged attacks, the eye becomes reddened, and edema of the cornea may develop, giving the cornea a hazy appearance. A unilateral, often excruciating, headache is common. Nausea and vomiting may occur, causing the headache to be confused with migraine.

Acute angle-closure glaucoma is an ophthalmic emergency. Treatment is initially directed at reducing the intraocular pressure, usually with pharmacologic agents. Once the intraocular pressure is under control, a laser peripheral iridotomy may be performed to create a permanent opening between the anterior and posterior chambers, allowing the aqueous humor to bypass the pupillary block. The anatomic abnormalities responsible for angle-closure glaucoma are usually bilateral, and prophylactic surgery is often performed on the other eye.

Subacute angle-closure glaucoma is characterized by episodes of elevated intraocular pressure that are of short duration and subside spontaneously. There are recurrent short episodes of unilateral pain, conjunctival redness, and blurring of vision associated with halos around lights. Attacks often occur in the evenings and resolve overnight.[31] Examination between attacks may show only a narrow anterior chamber angle. Although the episodes of angle closure resolve spontaneously, there is accumulated damage to the anterior chamber angle. Subacute angle closure may also progress to acute angle closure.

Congenital and Infantile Glaucoma

Infantile (congenital) glaucoma is defined as glaucoma that begins within the first 3 years of life.[31,35,36] It can occur as a primary or secondary condition. Primary infantile glaucoma is caused by an isolated anomaly in development of the anterior chamber. In secondary glaucoma, other ocular defects or systemic disorders are present.

The clinical manifestations of infantile glaucoma include excessive lacrimation (tearing), conjunctival injection (redness of the eye), photophobia (sensitivity to light), and blepharospasm (eyelid squeezing). Affected infants tend to be fussy, have poor eating habits, and rub their eyes frequently. Because the sclera and cornea are more elastic in early childhood than later in life, chronic elevation of the intraocular pressure causes enlargement of the entire optic globe, including the cornea, and development of what is termed *buphthalmos* ("ox eye"). Diffuse edema of the cornea usually occurs, giving the eye a grayish-white appearance. Children with unilateral glaucoma generally present earlier because differences in the corneal size between the two eyes can be noticed. When both eyes are affected, the parents may not recognize the increased corneal size. Early surgical treatment is necessary to prevent blindness. Many children require several surgeries, as well as long-term medical therapy to maintain a lowering of their intraocular pressure.

Neural Pathways and Cortical Centers

Full visual function requires the normally developed brain-related functions of photoreception and the pupillary reflex. These functions depend on the integrity of all visual pathways, including retinal circuitry and the pathway from the optic nerve to the visual cortex and other visual regions of the brain and brain stem.[14,19,21]

Visual information is carried to the brain by axons of the retinal ganglion cells, which form the optic nerve. The two optic nerves meet and fuse in the optic chiasm, beyond which they are continued as the optic tracts (Fig. 38-13). In the optic chiasm, axons from the nasal retina of each eye cross to the opposite side and join with the axons of the temporal retina of the contralateral eye to form the optic tracts. One optic tract contains fibers from both eyes that transmit information from the same visual field.

Fibers of the optic tracts synapse in the lateral geniculate nucleus (LGN) of the thalamus. Axons from these neurons in the LGN form the optic radiations to the primary visual cortex in the occipital lobe. The pattern of information transmission established in the optic tract is retained in the optic radiations. For example, the axons from the right visual field, represented by the nasal retina of the right eye and the temporal retina of the left eye, are united at the chiasm. They continue through the left optic tract and left optic radiation to the left visual cortex, where visual experience is first perceived. The left primary visual cortex receives two representations of the right visual field. Physical separation of information from the left and right visual fields is maintained in the visual cortex. Interaction between these disparate representations occurs and provides the basis for the sensation of depth in the near visual field.

The primary visual cortex (area 17) surrounds the calcarine fissure, which lies in the occipital lobe. It is at this level that visual sensation is first experienced (Fig. 38-14). Immediately surrounding area 17 are the visual association cortices (areas 18 and 19) and several other association cortices. These association cortices, with their thalamic nuclei, must be functional for added meaningfulness of

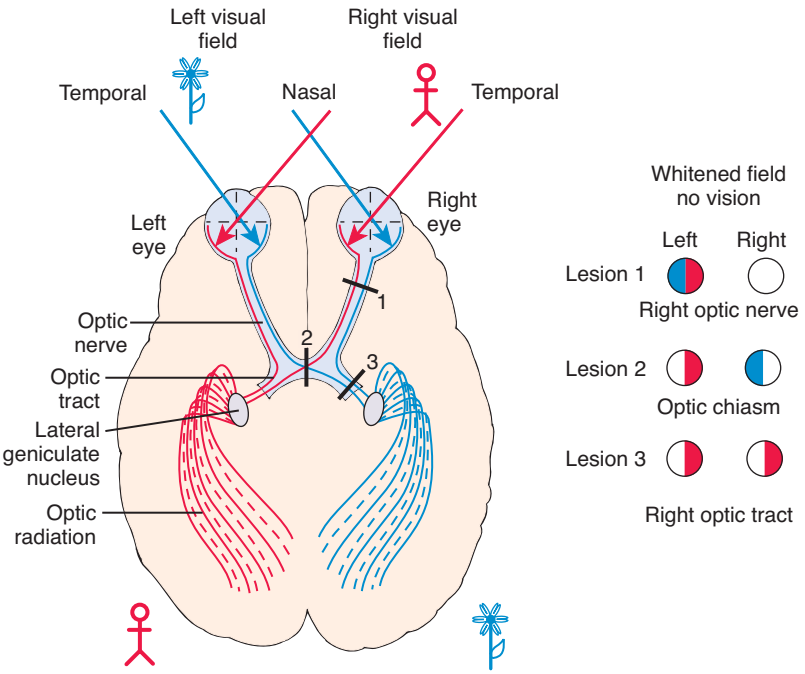

FIGURE 38-13. Diagram of optic pathways. The *red lines* indicate the right visual field and the *blue lines* the left visual field. Note the crossing of fibers from the medial half of each retina at the optic chiasm. Lesion 1 (right optic nerve) produces unilateral blindness. Lesion 2 (optic chiasm) may involve only those fibers that originate in the nasal half of each retina and cross to the opposite side in the optic chiasm; visual loss involves the temporal half of each field (bitemporal hemianopia). Lesion 3 (right optic tract) interrupts fibers (and vision) originating on the same side of both eyes (homonymous), with loss of vision from half of each field (hemianopia).

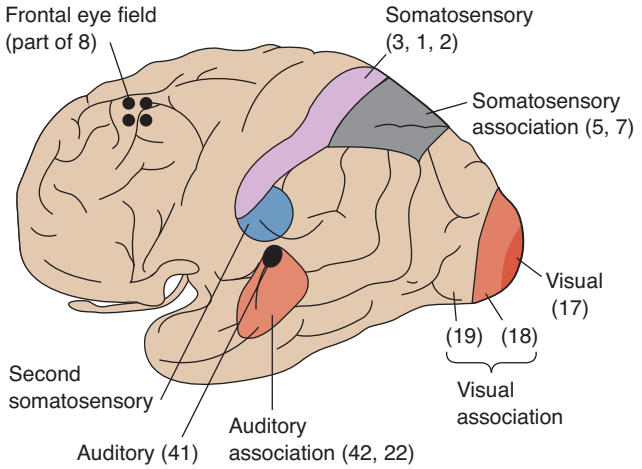

FIGURE 38-14. Lateral view of the cortex illustrating the location of the visual, visual association, auditory, and auditory association areas.

visual perception. This higher-order aspect of the visual experience depends on previous learning.

Disorders of the Optic Pathways

Among the disorders that can interrupt the visual pathway are trauma, tumors, and vascular lesions. Trauma and tumors can produce direct injury or impinge on the optic pathways. Vascular insufficiency in any one of the arterial systems of the retina or visual pathways can seriously affect vision. For example, normal visual function depends on the adequacy of blood flow in the ophthalmic artery and its branches—the central retinal artery; the anterior and middle cerebral arteries, which supply the intracranial optic nerve, chiasm, and optic tracts; and the posterior cerebral artery, which supplies the LGN, optic radiation, and visual cortex. The adequacy of posterior cerebral artery function depends on that of the vertebral and basilar arteries that supply the brain stem.

Visual Field Defects

The *visual field* refers to the area that is visible during fixation of vision in one direction[14,19,21] (see Fig. 38-13). As with a camera, the simple lens system of the eye inverts the image of the external world on each retina. In addition, the right and left sides of the visual field also are reversed. The right binocular visual field (the nasal half of the right eye and the temporal half of the left eye) is seen by the left retinal halves of each eye. Likewise, the left binocular field is seen by the right retinal halves of each eye.

Most of the visual field is *binocular,* or seen by both eyes. This binocular field is subdivided into *central* and *peripheral* portions. Central portions of the retina provide high visual acuity and correspond to the field focused on the central fovea. The peripheral and surrounding portion provides the capacity to detect objects, particularly moving objects. Beyond the visual field shared by both eyes, the left lateral periphery of the visual field is seen exclusively by the left nasal retina, and the right peripheral field by the right nasal retina.

Visual field defects result from damage to the visual pathways or the visual cortex (see Fig. 38-13). The testing of visual fields of each eye and of the two eyes together is useful in localizing lesions affecting the system. Perimetry or visual field testing, in which the visual field of each eye is measured and plotted in an arc, is used to identify defects and determine the location of lesions.

Blindness in one eye is called *anopia*. If half of the visual field for one eye is lost, the defect is called *hemianopia*; if a quarter of the field is lost, it is called *quadrantanopia*. Loss of the temporal or peripheral visual fields on both sides results in a narrow binocular field, commonly called *tunnel vision*. The loss of different half-fields in the two eyes is called a *heteronymous loss,* and the abnormality is called *heteronymous hemianopia*. Destruction of one or both lateral halves of the chiasm is common with multiple aneurysms of the circle of Willis (see Chapter 37). In this condition, the function of one or both temporal retinas is lost, and the nasal fields of one or both eyes are lost. The loss of the temporal fields (nasal retina) of both eyes is called *bitemporal heteronymous anopia*. With both eyes open, the person with bilateral defects still has the full binocular visual field.

Loss of the optic tract, LGN, full optic radiation, or complete visual cortex on one side results in loss of the corresponding visual half-fields in each eye. *Homonymous* means "the same" for both eyes. In left-side lesions, the right visual field is lost for each eye and is called *complete right homonymous hemianopia*. Partial injury to the left optic tract, LGN, or optic radiation can result in the loss of a quarter of the visual field in both eyes. This is called *homonymous quadrantanopia,* and depending on the lesion, it can involve the upper (superior) or lower (inferior) fields. The LGN, optic radiation, and visual cortex all receive their major blood supply from the posterior cerebral artery; unilateral occlusion of this artery results in complete loss of the opposite field (i.e., homonymous hemianopia). Bilateral occlusion of these arteries results in total cortical blindness.

The Extraocular Eye Muscles and Disorders of Eye Movement

For complete function of the eyes, it is necessary that the two eyes point toward the same fixation point and that the retinal and central nervous system (CNS) visual acuity mechanisms function. Despite slight variations in the view of the external world for each eye, it is important that these two images become fused, which is a forebrain function. Binocular fusion is controlled by ocular reflex mechanisms that adjust the orientation of each eye to produce a single image. If these reflexes fail, diplopia or double vision occurs.

Binocular vision depends on three pairs of extraocular muscles—the medial and lateral recti, the superior and inferior recti, and the superior and inferior obliques[14] (Fig. 38-15). Each of the three sets of muscles in each eye is reciprocally innervated so that one muscle relaxes

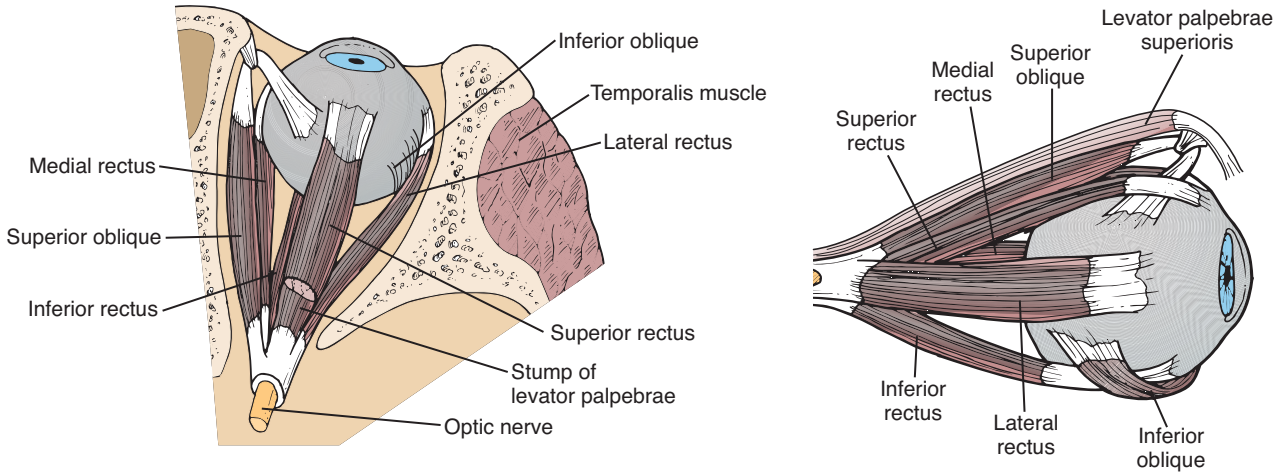

FIGURE 38-15. Extraocular muscles of the right eye.

when the other contracts. Reciprocal contraction of the medial and lateral recti moves the eye from side to side (adduction and abduction); the superior and inferior recti move the eye up and down (elevation and depression). The oblique muscles rotate (intorsion and extorsion) the eye around its optic axis. A seventh muscle, the levator palpebrae superioris, elevates the upper lid.

The extraocular muscles are innervated by three cranial nerves. The trochlear nerve (CN IV) innervates the superior oblique, the abducens nerve (CN VI) innervates the lateral rectus, and the oculomotor nerve (CN III) innervates the remaining four muscles. Table 38-1 describes the function and innervation of the extraocular muscles.

Normal vision depends on the coordinated action of the entire visual system and a number of central control systems. It is through these mechanisms that an object is simultaneously imaged on the fovea of both eyes and perceived as a single image. Strabismus and amblyopia are two disorders that affect this highly integrated system. Although strabismus may develop in later life, it is seen most commonly in children.

Strabismus

Strabismus, or squint, refers to any abnormality of eye coordination or alignment that results in loss of binocular vision. Strabismus affects approximately 4% of children younger than 6 years of age.[36–38] Because 30% to 50% of these children sustain permanent secondary loss

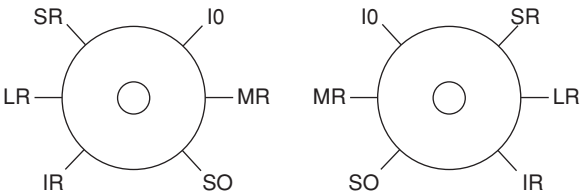

TABLE 38-1 Innervation and Function of the Ocular Muscles

Muscle*	CN Innervation	Primary	Secondary	Tertiary
Medial rectus (MR)	III	Adduction		
Lateral rectus (LR)	VI	Abduction		
Superior rectus (SR)	III	Elevation	Intorsion	Adduction
Inferior rectus (IR)	III	Depression	Extorsion	Adduction
Superior oblique (SO)	IV	Intorsion	Depression	Abduction
Inferior oblique (IO)	III	Extorsion	Elevation	Abduction

*In the schema of the functional roles of the six extraocular muscles, the major directional force applied by each muscle is indicated on the top. These muscles are arranged in functionally opposing pairs per eye and in parallel opposing pairs for conjugate movements of the two eyes. CN, cranial nerve.

of vision, or amblyopia, if the condition is left untreated, early diagnosis and treatment are essential.

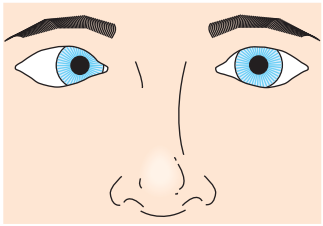
In standard terminology, the disorders of eye movement are described according to the direction of movement. *Esotropia* refers to medial deviation, *exotropia* to lateral deviation, *hypertropia* to upward deviation, *hypotropia* to downward deviation, and *cyclotropia* to torsional deviation. A *concomitant strabismus* refers to strabismus with equal deviation in all directions of gaze, and a *nonconcomitant strabismus* to one that varies with the direction of gaze. Strabismus may be divided into paralytic (nonconcomitant) forms, in which there is weakness or paralysis of one or more of the extraocular muscles, and nonparalytic (concomitant) forms, in which there is no primary muscle impairment. Strabismus is called *intermittent,* or *periodic,* when there are periods in which the eyes are parallel. It is monocular when the same eye always deviates and the fellow eye fixates. Figure 38-16 illustrates abnormalities in eye movement associated with esotropia, hypertropia, and exotropia.

Nonparalytic Strabismus. Nonparalytic esotropia is the most common type of strabismus. The individual ocular muscles have no obvious defect and the amount of deviation is constant or relatively constant in the various directions of gaze. With persistent deviation, secondary abnormalities may develop because of overactivity or underactivity of the extraocular muscles in some fields of gaze.

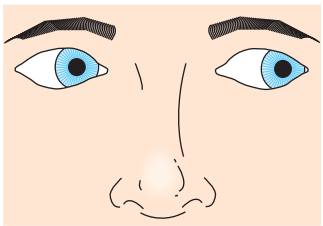
The disorder may be nonaccommodative, accommodative, or a combination of the two. Infantile esotropia is the most common cause of nonaccommodative strabismus. It occurs in the first 6 months of life, with large-angle deviations, in an otherwise developmentally and neurologically normal infant. Eye movements are full, and the child often uses each eye independently to alter fixation (cross-fixation). The cause of the disorder is unclear. Research suggests that idiopathic strabismus may have a genetic basis; siblings often present with similar disorders. Accommodative strabismus is caused by disorders such as uncorrected hyperopia of a significant degree, in which the esotropia occurs with accommodation that is undertaken to focus clearly. Onset of this type of esotropia characteristically occurs between 18 months and 4 years of age because accommodation is not well developed until that time. The disorder most often is monocular but may be alternating.

Paralytic Strabismus. Paralytic strabismus results from paresis (i.e., weakness) or plegia (i.e., paralysis) of one or more of the extraocular muscles. When the normal eye fixates, the affected eye is in the position of primary deviation. In the case of esotropia, there is weakness of one of the lateral rectus muscles. When the affected eye fixates, the unaffected eye is in a position of secondary deviation.[36]

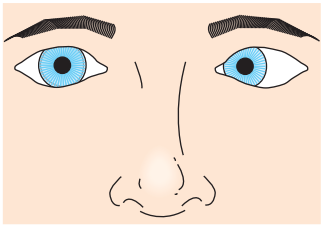
Paralytic strabismus is uncommon in children but accounts for nearly all cases of adult strabismus; it can



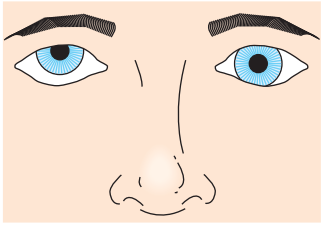
A Primary position: right esotropia



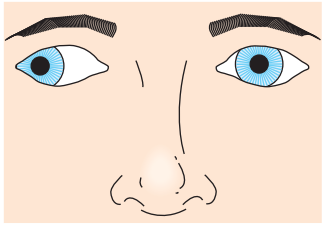
B Left gaze: no deviation



C Right gaze: left esotropia



D Right hypertropia



E Right exotropia

FIGURE 38-16. **(A–C)** Paralytic strabismus associated with paralysis of the right lateral rectus muscle: **(A)** primary position of the eyes (looking straight ahead); **(B)** left gaze with no deviation; **(C)** right gaze with left esotropia. **(D)** Primary position of the eyes with weakness of the right inferior rectus and right hypertropia. **(E)** Primary position of the eyes with weakness of the right medial rectus and right exotropia.

be caused by infiltrative processes (e.g., Graves disease; see Chapter 32), myasthenia gravis, stroke, and direct optical trauma.[38] In infants, paralytic strabismus can be caused by birth injuries affecting the extraocular muscles or the cranial nerves supplying these muscles. In general, paralytic strabismus in an older child or adult does not produce amblyopia, and binocular vision can be maintained when the strabismus is corrected. Most adult strabismus represents deterioration of childhood strabismus, which can occur even decades after good ocular alignment.

Treatment of strabismus is directed toward the development of normal visual acuity, correction of the deviation, and superimposition of the retinal images to provide binocular vision. Early and adequate treatment is crucial because a delay in or lack of treatment can lead to amblyopia and permanent loss of vision.

Treatment includes both surgical and nonsurgical methods. Infantile esotropia is usually treated surgically by weakening the medial rectus muscle on each eye while the infant is under general anesthesia. Surgery in children with esotropia should be done as early as possible to preserve stereoptic acuity. Early surgical treatment also appears to result in better outcomes than later intervention. Recurrent strabismus is common with infantile esotropia, and multiple surgeries are often required.

Nonsurgical treatment includes glasses, occlusive patching, and eye exercises (i.e., pleoptics). Glasses are often used in the treatment of accommodative esotropia that occurs with hypermetropia (farsightedness). Because accommodation is linked with convergence, focusing drives the eyes inward, producing esotropia. Intermittent exotropia is commonly treated with patching, use of over-minus glasses, and eye exercises. Although no appreciable deviation is present when the child with intermittent strabismus sees near objects, the deviation becomes obvious when the child views distant objects or is fatigued. Patching for 1 to 2 hours daily for several months exerts its effects by preventing, rather than treating, suppression of an eye. Patching is most effective in infants, and the efficacy is limited in children older than 3 years of age. The use of over-minus glasses stimulates accommodative convergences, which contracts the exotropic drift. Vision therapy involves exercises to stimulate convergence (e.g., focusing on reading-distance targets up to 30 minutes several times a day) and techniques to train the visual system to recognize the suppressed images. Surgical treatment of intermittent exotropia is indicted when conservative methods fail to correct the deviation. Early treatment of children with intermittent exotropia is not as crucial as it is for those with constant deviations because stereopsis can still develop.

A relatively new form of treatment involves the injection of botulinum toxin type A (Botox) into the extraocular muscle to produce a dose-dependent paralysis of that extraocular muscle.[36] Paralysis of the muscle shifts the eye into the field of action of the antagonist muscle. During the time the eye is deviated, the paralyzed muscle is stretched, whereas the antagonistic muscle is contracted. Usually two or more injections of the drug are necessary to obtain a lasting effect.

Amblyopia

Amblyopia, sometimes called *lazy eye,* describes a decrease in visual acuity resulting from abnormal visual development in infancy or early childhood.[39–41] The vision loss ranges from mild (worse than 20/25) to severe (legal blindness, 20/200 or worse). It is the leading cause of visual impairment, affecting 1% to 4% of the population. With early detection and treatment, most cases of amblyopia are reversible and the most severe forms of the condition can be prevented.

Normal development of the thalamic and cortical circuitry necessary for binocular visual perception requires simultaneous binocular use of each fovea during a critical period early in life (0 to 5 years). Amblyopia can result from visual deprivation (e.g., cataracts, ptosis) or abnormal binocular interactions (e.g., strabismus, anisometropia) during visual immaturity. In infants with unilateral cataracts that are dense, central, and larger than 2 mm in diameter, this period is before 2 months of age.[39] In conditions causing abnormal binocular interactions, one image is suppressed to provide clearer vision. In esotropia, vision of the deviated eye is suppressed to prevent diplopia. A similar situation exists in anisometropia, in which the refractive indexes of the two eyes are different. Although the eyes are correctly aligned, they are unable to focus together, and the image of one eye is suppressed.

The reversibility of amblyopia depends on the maturity of the visual system at the time of onset and the duration of the abnormal experience. Occasionally in strabismus, some persons alternate eye fixation and do not experience deep amblyopia or diplopia. With late adolescent or adult onset, this habit pattern must be unlearned after correction. Amblyopia is remarkably responsive to treatment if the treatment is initiated early in life; thus, all infants and young children should be evaluated for visual conditions that could lead to amblyopia.

The American Academy of Pediatrics in association with the American Association of Certified Orthoptists, American Association of Pediatric Ophthalmology and Strabismus, and American Academy of Ophthalmology recommends that all newborn infants be examined in the nursery for structural abnormalities and have a red reflex test performed to check for abnormalities in the back of the eye (posterior segment) and opacities in the visual axis, such as cataracts or corneal opacity.[42] Visual examinations should then be performed on all well-child visits. These should include age-appropriate evaluation of visual acuity, ocular alignment, and ocular media clarity (cataracts, tumors). Every effort should be made to ensure that eye examinations are performed by properly prepared examiners, using appropriate testing conditions, instruments, and techniques.[42,43]

The treatment of children with the potential for development of amblyopia must be instituted well before the age of 6 years to avoid the suppression phenomenon. Surgery for congenital cataracts and ptosis should be done early. Severe refractive errors should be corrected. In children with strabismus, the alternate blocking of the

vision in one eye and then the other forces the child to use both eyes for form discrimination. The duration of occlusion of vision in the good eye must be short (several hours per day) and closely monitored, or deprivation amblyopia can develop in the good eye as well. Although amblyopia is not likely to occur after 8 or 9 years of age, some plasticity in central circuitry is evident even in adulthood. For example, after refractive correction for long-standing astigmatism in adults, visual acuity improves slowly, requiring several months to reach normal levels.

In summary, the optic globe, or eyeball, is a nearly spherical structure protected posteriorly by the bony structures of the orbit and anteriorly by the eyelids. A conjunctiva lines the inner surface of the eyelids and covers the optic globe to the junction of the cornea and sclera. Conjunctivitis, also called *red eye* or *pink eye,* may result from bacterial or viral infection, allergic reactions, or the injurious effects of chemical agents, physical agents, or radiant energy. Keratitis, or inflammation of the cornea, can be caused by infections, hypersensitivity reactions, ischemia, defects in tearing, or trauma. Trauma or disease that involves the stromal layer of the cornea heals with scar formation and permanent opacification. These opacities interfere with the transmission of light and may impair vision.

The lens is a biconvex, transparent, flexible structure that can change shape to allow precise focusing of light on the retina. Refraction refers to the ability of the lens to bend light rays in order to focus an object on the retina. In hyperopia, or farsightedness, the image falls behind the retina. In myopia, or nearsightedness, the image falls in front of the retina. Accommodation is the process by which a clear image is maintained as the gaze is shifted from a far object to a near object. Presbyopia is a change in the lens that occurs because of aging such that the lens becomes thicker and less able to change shape and accommodate for near vision. A cataract is characterized by increased lens opacity. It can occur as the result of congenital influences, metabolic disturbances, infection, injury, and aging.

The retina covers the inner aspect of the posterior two thirds of the eyeball and is continuous with the optic nerve. It contains the photoreceptors for vision: the rods, for black and white discrimination, and the cones, for color vision. Disorders of retinal vessels can result from a number of local and systemic disorders, including diabetes mellitus and hypertension. The retinopathies involve the small blood vessels of the retina, with changes in blood vessel structure and the development of microaneurysms, neovascularization, hemorrhage, and retinal opacities. Retinal detachment involves separation of the sensory receptors from their blood supply; it causes blindness unless reattachment is accomplished promptly. Macular degeneration, which is a leading cause of blindness in the elderly, is characterized by loss of central vision resulting from destructive changes in the central fovea.

Glaucoma is a chronic, degenerative optic neuropathy characterized by optic disk cupping and visual field loss. It is usually associated with an increase in intraocular pressure that occurs because of impaired outflow of aqueous humor from the anterior chamber of the eye. Glaucoma is commonly classified as open-angle glaucoma, in which impaired outflow of aqueous humor is due to dysfunction of the drainage system, and angle-closure glaucoma, in which impaired outflow results from occlusion of the anterior chamber angle itself, impairing access to the drainage system.

Visual information is carried to the brain by axons of the retinal ganglion cells that form the optic nerve. The two optic nerves meet and cross at the optic chiasm, with the axons from each nasal retina joining the uncrossed fibers of the temporal retina of the opposite eye in the optic tract. The fibers in the optic tract pass to the LGN in the thalamus and then to the primary visual cortex, which is located in the occipital lobe. Damage to the visual pathways causes visual field defects that can be identified through visual field testing or perimetry.

Eye movement, which is controlled by the extraocular muscles, provides for alignment of the eyes and binocular vision. Strabismus refers to abnormalities in the coordination of eye movements with loss of binocular eye alignment. This inability to focus a visual image on corresponding parts of the two retinas results in diplopia. Paralytic strabismus is caused by weakness or paralysis of the extraocular muscles. Nonparalytic strabismus results from the inappropriate length or insertion of the extraocular muscles or from accommodation disorders. The neural pathways for vision develop during infancy. Amblyopia (i.e., lazy eye) is a condition of diminished vision that cannot be corrected by lenses and in which no detectable organic lesion in the eye can be observed. It results from inadequately developed CNS circuitry because of visual deprivation (e.g., cataracts) or abnormal binocular interactions (e.g., strabismus) during the period of visual immaturity.

The Ear and Disorders of Auditory Function

The ears are paired organs consisting of an external and middle ear, which function in capturing, transmitting, and amplifying sound, and an inner ear, which contains the receptive organs that are stimulated by sound waves (i.e., hearing) or head position and movement (i.e., vestibular function).

The External Ear

The external ear is a funnel-shaped structure that conducts sound waves to the tympanic membrane. It consists of the auricle, the external acoustic meatus, and the lateral surface of the tympanic membrane[2,44] (Fig. 38-17). A thin layer of skin containing fine hairs, sebaceous

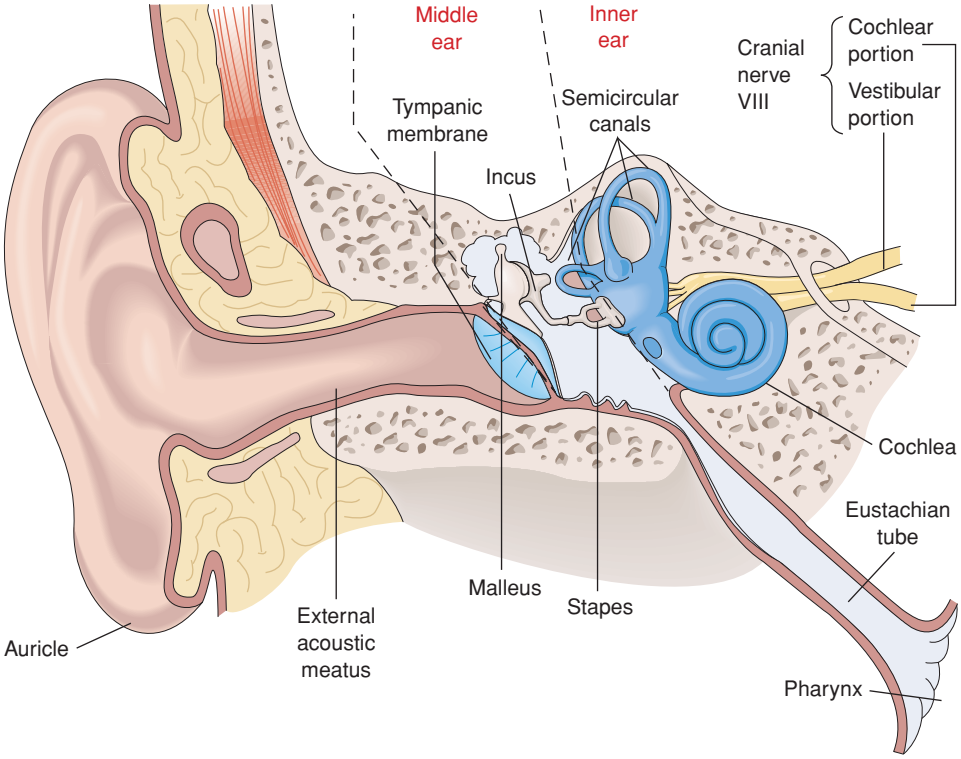


FIGURE 38-17. External, middle, and internal subdivisions of the ear.

glands, and ceruminous glands lines the ear canal. Ceruminous glands secrete cerumen, or earwax, which has certain antimicrobial properties and is thought to serve a protective function.

The tympanic membrane, approximately 1 cm in diameter, is a thin, transparent membrane that separates the external ear from the middle ear. The tympanic membrane is covered with thin skin externally and the mucous membrane of the middle ear internally. The tympanic membrane is attached in a manner that allows it to vibrate freely when audible sound waves enter the external auditory canal. Movements of the membrane are transmitted through the middle ear to the inner ear.

Disorders of the External Ear

The function of the external ear is disturbed when sound transmission is obstructed by impacted cerumen, inflammation (otitis externa), or drainage (otorrhea).

Impacted Cerumen. Cerumen, or earwax, is a protective secretion produced by the sebaceous and ceruminous glands of the skin that lines the ear canal. Although the ear normally is self-cleaning, the cerumen can accumulate and narrow the canal, causing reversible hearing loss.[45,46] Impacted cerumen usually produces no symptoms unless it hardens and touches the tympanic membrane, or the canal becomes irritated by a buildup of hardened cerumen. Clinical symptoms may include pain, itching, and a sensation of fullness. As the canal becomes completely occluded, a person may experience a feeling of fullness, a conductive hearing loss, and tinnitus (i.e., ringing in the ears).

In most cases, cerumen can be removed by gentle irrigation using a bulb syringe and warm tap water. Alternatively, health care professionals may remove cerumen using an otoscope and a wire loop or blunt cerumen curette.

Otitis Externa. Otitis externa is an inflammation of the external ear that can vary in severity from mild allergic dermatitis to severe cellulitis.[46] It can be caused by infectious agents, irritation (e.g., wearing hearing aids or earphones), or allergic reactions. Predisposing factors include frequent exposure to moisture in the ear canal (i.e., swimmer's ear), trauma to the canal caused by cleaning or scratching, and allergies or skin conditions such as psoriasis. The most common bacterial pathogens are gram-negative rods (*Pseudomonas aeruginosa, Proteus* species) and fungi (*Aspergillus*) that grow in the presence of excess moisture.[5] Otitis externa commonly occurs in the summer and is manifested by itching, redness, tenderness, and narrowing of the ear canal because of swelling. Inflammation of the pinna or canal makes movement of the ear painful. There may be watery or purulent drainage and intermittent hearing loss. Treatment usually includes the use of ear drops containing an appropriate antimicrobial or antifungal agent in combination with a corticosteroid to reduce inflammation.

Acute cellulitis of the auricle and external auditory canal is usually caused by *S. aureus*. The skin is red, hot, and firm with a sharply defined border. Fever may be present with little or no exudate in the ear. Treatment usually involves the parenteral administration of an appropriate antimicrobial agent.

The Middle Ear and Eustachian Tube

The middle ear, or tympanic cavity, is a small, mucosa-lined cavity in the petrous portion of the temporal bone[2,44] (see Fig. 38-17). It is spanned by three small bones, the auditory ossicles, which are connected by two synovial joints and are covered with the epithelial lining of the cavity. The middle ear also contains the eustachian (auditory) tube as well as the muscles that attach to the ossicles. The middle ear is bounded anteriorly by the tympanic membrane and posteriorly it is connected with small air pockets in the temporal bone called *mastoid air spaces* or *cells*.

The primary function of the middle ear is to convert sound waves arriving from the external ear into mechanical vibrations that are transmitted to the inner ear. Two openings in the medial wall of the middle ear, the oval (vestibular) window and the round (cochlear) window, are essential components of this conversion process.[2]

Three tiny bones, the auditory ossicles, connect the tympanic membrane with the oval window: the malleus, the incus, and the stapes.[2,44] The *malleus* ("hammer") has its handle firmly fixed to the upper portion of the tympanic membrane. The head of the malleus articulates with the *incus* ("anvil"), which links the malleus to the *stapes* ("stirrup"), whose footplate fits into the oval window. Arrangement of the ear ossicles is such that their lever movements transmit vibrations from the tympanic membrane to the oval window and from there to the fluid in the inner ear.

The middle ear is connected to the nasopharynx by the eustachian or auditory tube, which is located in a gap in the bone between the anterior and medial walls of the middle ear (see Fig. 38-17). The eustachian tube serves three basic functions: (1) ventilation of the middle ear, along with equalization of middle ear and ambient pressures; (2) protection of the middle ear from unwanted nasopharyngeal sound waves and secretions; and (3) drainage of middle ear secretions into the nasopharynx.[47] The nasopharyngeal entrance to the eustachian tube, which usually is closed, is opened by the action of the *tensor veli palatini muscle*, which is innervated by the trigeminal cranial nerve (CN V). Opening of the eustachian tube, which normally occurs with swallowing and yawning reflexes, provides the mechanism for equalizing the pressure of the middle ear with that of the atmosphere. This equalization ensures that the pressures on both sides of the tympanic membrane are the same, so that sound transmission is not reduced and rupture does not result from sudden changes in atmospheric pressure, as occurs during airplane travel. The eustachian tube is lined with a mucous membrane that is continuous with the pharynx and the mastoid air cells. Infections from the nasopharynx can travel from the nasopharynx along the mucous membrane of the eustachian tube to the middle ear, causing acute otitis media. Toward the nasopharynx, the eustachian tube becomes lined by columnar epithelium with mucus-secreting cells. Hypertrophy of the mucus-secreting cells is thought to contribute to the mucoid secretions that develop during certain types of otitis media.

Disorders of the Eustachian Tube

Abnormalities in eustachian tube function are important factors in the pathogenesis of middle ear infections.

Disorders of the Middle Ear

- The middle ear is a small, air-filled compartment in the temporal bone. It is separated from the outer ear by the tympanic membrane; communication between the nasopharynx and the middle ear occurs through the eustachian tube; and tiny bony ossicles that span the middle ear transmit sound to the sensory receptors in the inner ear.
- Otitis media (OM) refers to inflammation of the middle ear. It can represent an acute otitis media (AOM) that has an abrupt onset and is usually related to bacterial infection, or otitis media with effusion (OME) that is associated with fluid in the middle ear without the manifestations of infection and which does not usually require treatment with antimicrobial agents.
- The function of the middle ear is to conduct sound waves from the external to the inner ear. Impaired conduction of sound waves and hearing loss occur when the tympanic membrane has been perforated; air in the middle ear has been replaced with fluid (OME); or the function of the bony ossicles has been impaired (otosclerosis).

There are two important types of eustachian tube dysfunction: abnormal patency and obstruction (Fig. 38-18). The *abnormally patent tube* either does not close or does not close completely. In infants and children with an abnormally patent tube, air and secretions often are pumped into the eustachian tube during crying and nose blowing.

Obstruction can be functional or mechanical. *Functional obstruction* results from the persistent collapse of the eustachian tube due to a lack of tubal stiffness or poor function of the tensor veli palatini muscle that controls the opening of the eustachian tube. It is common in infants and young children because the amount and stiffness of the cartilage supporting the eustachian tube are less than in older children and adults. Changes in the craniofacial base also render the tensor muscle less efficient for opening the eustachian tube in this age group. In addition, craniofacial disorders, such as a cleft palate, alter the attachment of the tensor muscle, producing functional obstruction of the eustachian tube.

Mechanical obstruction results from internal obstruction or external compression of the eustachian tube. Ethnic differences in the structure of the palate may increase the likelihood of obstruction. The most common internal obstruction is caused by swelling and secretions resulting from allergy and viral respiratory infections. With obstruction, air in the middle ear is absorbed, causing a negative pressure and the transudation of serous capillary fluid into the middle ear.

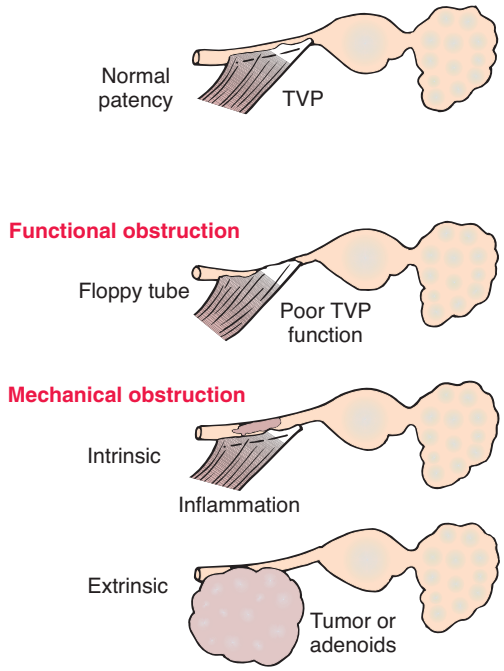

FIGURE 38-18. Pathophysiology of the eustachian tube. TVP, tensor veli palatini. (Developed from Bluestone C.D. [1981]. Recent advances in the pathogenesis, diagnosis, and management of otitis media. *Pediatric Clinics of North America* 28, 737. With permission from Elsevier Science.)

Otitis Media

Otitis media (OM) refers to inflammation of the middle ear without reference to etiology or pathogenesis (Fig. 38-19A). Inflammation of the middle ear may present as acute otitis media or otitis media with effusion.[48–50] *Acute otitis media* (AOM) refers to an acute middle ear infection.[51] It usually has an abrupt onset of signs and symptoms related to middle ear inflammation and effusion. *Otitis media with effusion* (OME) refers to the presence of fluid in the middle ear without signs and symptoms of acute ear infection.[52] OME may occur spontaneously because of poor eustachian tube function or as an inflammatory response following AOM. Because OME does not usually require treatment with antimicrobial agents, it is important to differentiate OME from AOM to avoid unnecessary use of antimicrobial agents.

Risk Factors. Otitis media may occur in any age group, but is seen most frequently in preschool-age children. Infants and young children between the ages of 3 months and 3 years are at highest risk for OM, with the peak incidence between 6 and 11 months.[50] There is a second peak incidence at about 5 years of age that is believed to be associated with entrance into school.[50] Risk factors include premature birth, male gender, ethnicity (Native American, Inuit), family history of recurrent otitis media, presence of siblings in the household, genetic syndromes, and low socioeconomic status.[50,51] Otitis media is more frequent in children with orofacial abnormalities such as cleft lip and palate.

The most important factor that contributes to OM is believed to be a dysfunction of the eustachian tube that allows reflux of fluid and bacteria into the middle ear space from the nasopharynx. There are two reasons for the increased risk of OM in infants and young children: the eustachian tube is shorter, more horizontal, and wider in this age group than in older children and adults; and infection can spread more easily through the eustachian canal

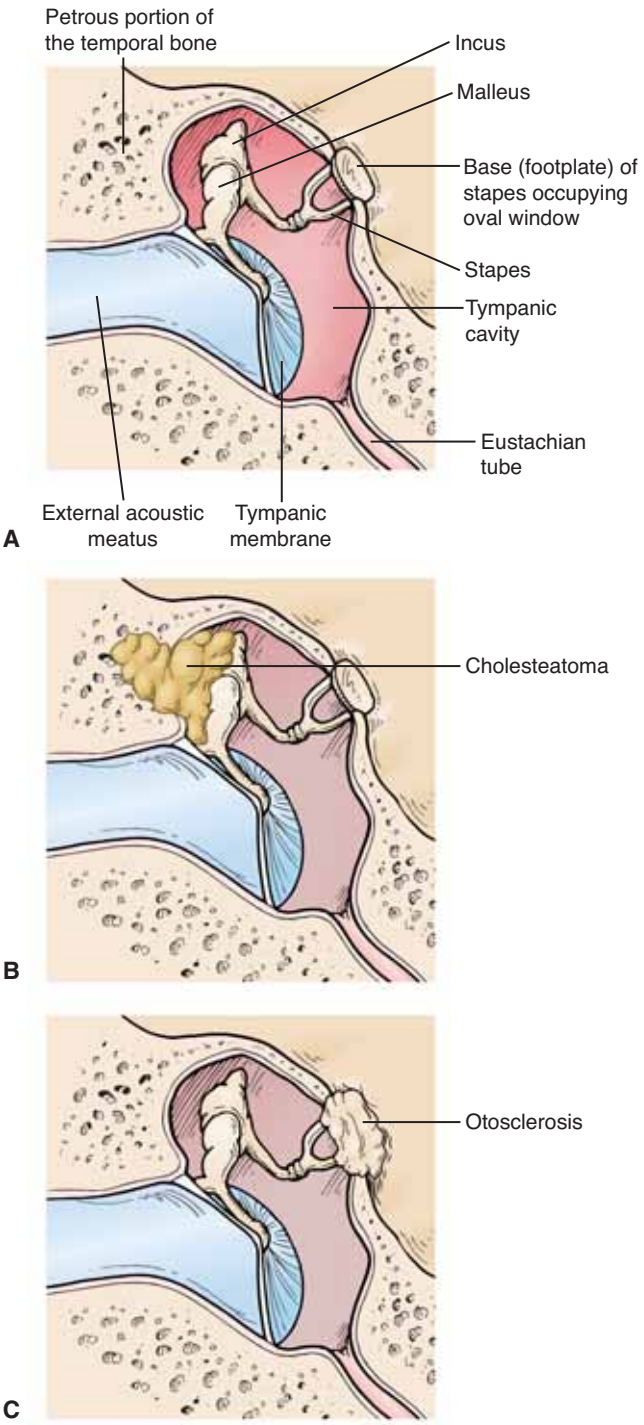

FIGURE 38-19. Disorders of the middle ear. **(A)** Otitis media. Otitis involves inflammation of the tympanic cavity. Infection often enters through the eustachian tube. **(B)** Cholesteatoma, a cystlike mass of the middle ear that often extends to involve the temporal bone. **(C)** Otosclerosis involving formation of new, spongy bone around the stapes and oval window.

of infants who spend most of their day in the supine position.[51] Bottle-fed infants have a higher incidence of OM than breast-fed infants, probably because they are held in a more horizontal position during feeding, and swallowing while in the horizontal position facilitates the reflux of milk into the middle ear. Breast-feeding also provides for the transfer of protective maternal antibodies to the infant.

Measures to reduce the risk for development of OM during the first 6 months of life include breast-feeding and reduction or elimination of pacifier use.[51] Other ways to reduce the risk of developing OM include minimal exposure to group settings and the avoidance or elimination of bottle propping as well as exposure to passive tobacco smoke. Efficacy in prevention of OM during the respiratory illness season has been demonstrated by immunoprophylaxis with influenza vaccines. Immunization with pneumococcal vaccine has also been reported to reduce the incidence of OM caused by vaccine-serotype *Pneumococcus,* but the overall effect has been small.[51]

Etiology. Most cases of AOM follow an uncomplicated upper respiratory tract infection that has been present for several days. The most common bacteria in AOM are *S. pneumoniae, H. influenzae,* and *Moraxella catarrhalis.*[48–51] Penicillin-resistant *S. pneumoniae* is the most common cause of recurrent and persistent AOM. Evidence of respiratory viruses is also found in the middle ear exudates in children with AOM, either alone or, more commonly, in association with pathogenic bacteria. Of these viruses, rhinovirus and respiratory syncytial virus (RSV) are found most often.[49] It remains unclear whether viruses alone can cause AOM or whether their role is limited to setting the stage for bacterial invasion and, perhaps, amplifying the inflammatory response.[49]

The etiology of AOM and OME are interrelated. Acute infection is usually followed by residual inflammation and effusion that, in turn, predisposes to recurrent infection. Middle ear effusion, which is a component of both AOM and OME, is an expression of underlying mucosal inflammation. Persistent middle ear effusion results in decreased motility of the tympanic membrane and serves as a barrier to sound conduction.

Clinical Manifestations. Acute otitis media is characterized by acute onset of otalgia (or pulling of the ears in an infant), fever, and hearing loss. Children older than 3 years of age may have rhinorrhea or running nose, vomiting, and diarrhea. In contrast, younger children often have nonspecific signs and symptoms that manifest as ear tugging, irritability, nighttime awakening, and poor feeding. Key diagnostic criteria include distinct otalgia (earache that interferes with activity or sleep) or tympanic membrane erythema, and middle ear effusion.[51] Ear pain usually increases as the effusion accumulates behind the tympanic membrane. Perforation of the tympanic membrane may occur acutely, allowing purulent material from the middle ear to drain into the external auditory canal. This may prevent spread of the infection into the temporal bone or intracranial cavity. Healing of the tympanic membrane usually follows resolution of the middle ear infection.

Otitis media with effusion is often an asymptomatic condition.[52] There may be mild intermittent ear pain, complaints of ear fullness, and "popping." Secondary manifestations in infants may include ear rubbing, excessive irritability, and sleep disturbances. Hearing loss, even when not suggested by the child, is evidenced by a seeming lack of attentiveness, behavioral changes, and failure to respond to conversation-level speech. There may be problems related to school performance, balance problems and unexplained clumsiness, or delayed speech and language development.[52] The duration of the effusion may range from less than 3 weeks to more than 3 months. Many cases of OME resolve spontaneously, but 30% to 40% of children have recurrent OME, and 5% to 10% of episodes last 1 year or longer.[52]

Diagnosis. Distinguishing between AOM and OME on clinical grounds is often straightforward, but because each condition may evolve into the other without any clearly differentiating physical findings, any system for distinguishing between them is somewhat arbitrary.

Both AOM without otorrhea (drainage from the ear) and OME are accompanied by otoscopic signs of middle ear effusion, namely, the presence of at least two of three tympanic membrane abnormalities: white, yellow, amber, or occasionally blue discoloration; opacification other than scarring; and decreased or absent motility. With OME the tympanic membrane is often cloudy with distinct impairment of mobility, and an air–fluid level or bubble may be visible in the middle ear.

A definitive diagnosis of AOM requires the following: history of acute onset of signs and symptoms, the presence of middle ear effusion, and signs and symptoms of middle ear inflammation.[51] Signs of middle ear inflammation include fullness or bulging of the tympanic membrane with or without erythema, limited or absent mobility of the tympanic membrane, a purulent (pus-containing) effusion, and ear pain that interferes with normal activity.

Although the diagnosis of AOM often can be made by otoscopic examination alone, pneumatic otoscopy usually is performed to document middle ear effusion and immobility of the tympanic membrane. The use of the pneumatic otoscope permits the introduction of air into the ear canal for the purpose of determining tympanic membrane flexibility. The movement of the tympanic membrane is decreased in some cases of AOM and absent in chronic middle ear infection. The diagnosis of AOM can also be confirmed using tympanometry or acoustic reflectometry. A *tympanogram* is obtained by using a small probe that is placed snugly into the external ear canal. A sound stimulus generator then transmits acoustic energy into the canal, while a vacuum pump introduces positive and negative pressures into the ear canal. A microphone in the instrument detects returning sound energy. The tympanogram provides a determination of the degree of negative pressure present in the middle ear. It detects disease when present but is less reliable when disease is absent. *Acoustic reflectometry* detects reflected sound waves from the middle ear and provides information on whether an effusion is absent or present.

Increased reflected sound correlates with an increased likelihood of effusion. This technique is most useful in children older than 3 months, and its success depends on user technique.

Tympanocentesis (puncture of the tympanic membrane with a needle) may be done to relieve pain from an effusion or to obtain a specimen of middle ear fluid for culture and sensitivity testing. In instances where the tympanic membrane has perforated with resultant drainage into the external ear, a specimen can be obtained and microbiologic studies can be done to identify the organism.

Treatment. The treatment of AOM focuses on symptom control and management of the underlying pathologic process. A number of options for pain management are available, including the local application of heat and use of analgesic drugs such as acetaminophen and ibuprofen.[51] Myringotomy (incision in the tympanic membrane) can be used for relief of pressure in the child with severe pain, providing almost immediate relief.

The extensive use of antimicrobial agents contributes to the development of bacterial resistance, and evidence exists for the efficacy and safety of two alternative approaches to routine antimicrobial prescription: delayed prescription and watchful waiting.[51] Observation without antimicrobial agents is an option in a child with uncomplicated AOM. These approaches involve waiting for 72 hours to see if symptoms improve before institution of antimicrobial therapy. Factors to consider when deciding whether to defer treatment include the child's age, severity of illness, and certainty of the diagnosis. Antimicrobial drugs are recommended for children younger than 6 months, for those 6 months to 2 years of age when the diagnosis is certain, and for all children older than 2 years of age with severe infection.[49,51] If observation is recommended, it is essential that the parent or caregiver have ready access to communication, follow-up, and a mechanism for obtaining medication if needed.

Most cases of OME resolve spontaneously within a 3-week to 3-month period. The management options for this duration include observation only, antimicrobial therapy, or combination antimicrobial and corticosteroid therapy. Topical and systemic decongestants usually are of little value in clearing middle ear effusion.[52] Because there is concern over hearing loss and its effect on learning and speech, a hearing evaluation is recommended when OME persists for 3 months or longer or at any time that language delay, learning problems, or a significant hearing loss is suspected.[52] Children with recurrent OM should be evaluated to rule out any anatomic variations (e.g., enlarged adenoids), allergies, and immunologic abnormalities. Referral to an otolaryngologist is indicated if the effusion persists for 4 months or longer.

Surgical treatment (e.g., tympanostomy tubes, adenoidectomy) for OME may be indicated if the effusion has persisted for 4 months or longer and is accompanied by persistent hearing loss and other manifestations; if recurrent or persistent effusion occurs in children at risk regardless of hearing status; or if there is structural damage to the tympanic membrane or middle ear.[52] Tympanostomy tube insertion is the preferred initial procedure and does not typically include the removal of adenoids unless the child has additional indications, such as postnasal obstruction from enlarged adenoids. The tubes usually are inserted under general anesthesia. The ears of children with tubes must be kept out of water. The adverse effects of tube placement include recurrent otorrhea; persistent perforation, scarring, and atrophy of the tympanic membrane; and cholesteatoma. Adenoidectomy plus myringotomy (without tube insertion) has been shown to have comparable efficacy in children 4 years of age or older, but is more invasive, with additional surgical and anesthetic risks.[52]

Complications of Otitis Media. The complications of OM include hearing loss and extratemporal complications, including those affecting the middle ear, mastoid, adjacent structures of the temporal bone, and intracranial structures.

Hearing loss, which is a common complication of OM, usually is conductive and temporary based on the duration of the effusion. Hearing loss that is associated with fluid collection usually resolves when the effusion clears. Permanent hearing loss may occur as the result of damage to the tympanic membrane or other middle ear structures. Cases of sensorineural hearing loss are rare.

The mastoid antrum and air cells constitute a portion of the temporal bone and may become inflamed as an extension of acute or chronic OM.[48] The disorder causes necrosis of the mastoid process and destruction of the bony intercellular matrix, which are visible by radiologic examination. Mastoid tenderness and drainage of exudate through a perforated tympanic membrane can occur. Chronic mastoiditis can develop as the result of chronic middle ear infection. The usefulness of antimicrobial agents for this condition is limited. Mastoid or middle ear surgery, along with other medical treatment, may be indicated.

Cholesteatomas are cystlike lesions of the middle ear, usually associated with chronic otitis media (see Fig. 38-19B). Measuring 1 to 4 cm in diameter, they are lined with keratinizing squamous epithelium or mucus-secreting epithelium and filled with amorphous debris (derived largely from desquamated epithelium).[48,53,54] Although precise mechanisms involved in their development are unclear, it is proposed that chronic inflammation and perforation of the ear drum with ingrowth of squamous epithelium or metaplasia of the secretory epithelium of the middle ear are contributing factors. These lesions can erode the ossicles, the labyrinth, the adjacent mastoid bone, and the surrounding soft tissues. Although often thought of as a complication of otitis media, a cholesteatoma may also occur as a congenital condition. Symptoms commonly include painless drainage from the ear and hearing loss. Treatment involves microsurgical techniques to remove the cholesteatomatous material.

Intracranial complications are uncommon since the advent of antimicrobial therapy. Although rare, these complications can develop when the infection spreads through vascular channels, by direct extension, or through preformed pathways such as the round window.[48] These complications are seen more often with chronic suppurative

OM and mastoiditis. They include otogenic meningitis, brain abscess, lateral sinus thrombophlebitis or thrombosis, labyrinthitis, and facial nerve paralysis. Any child who develops persistent headache, tinnitus, stiff neck, or visual or other neurologic symptoms should be investigated for possible intracranial complications.

Otosclerosis

Otosclerosis refers to the formation of new spongy bone around the stapes and oval window, which results in progressive deafness[54,55] (see Fig. 38-19C). In most cases, the condition is familial and follows an autosomal dominant pattern with variable penetrance. Otosclerosis may begin at any time in life but usually does not appear until after puberty, most frequently between the ages of 20 and 30 years. The disease process accelerates during pregnancy.

Otosclerosis begins with resorption of bone in one or more foci. During active bone resorption, the bone structure appears spongy and softer than normal (i.e., otospongiosis). The resorbed bone is replaced by an overgrowth of new, hard, sclerotic bone. The process is slowly progressive, involving more areas of the temporal bone, especially in front of and posterior to the stapes footplate. As it invades the footplate, the pathologic bone increasingly immobilizes the stapes, reducing the transmission of sound. Pressure of otosclerotic bone on middle ear structures or the vestibulocochlear nerve (CN VIII) may contribute to the development of tinnitus, sensorineural hearing loss, and vertigo.

The symptoms of otosclerosis involve an insidious conductive hearing loss. Initially, the affected person is unable to hear a whisper or someone speaking at a distance. In the earliest stages, the bone conduction by which the person's own voice is heard remains relatively unaffected. At this point, the person's own voice sounds unusually loud, and the sound of chewing becomes intensified. Because of bone conduction, most of these persons can hear fairly well on the telephone, which provides an amplified signal.

The treatment of otosclerosis can be medical or surgical. A carefully selected, well-fitting hearing aid may allow a person with conductive deafness to lead a normal life. Sodium fluoride has been used with some success in the medical treatment of otospongiosis.[55] Because much of the conductive hearing loss associated with otosclerosis is caused by stapedial fixation, surgical treatment involves stapedectomy with stapedial reconstruction using the patient's own stapes or a stapedial prosthesis. The argon laser may be used in the surgical procedure.

The Inner Ear and Central Auditory Pathways

The inner ear contains a labyrinth, or system of intercommunicating channels, and the receptors for hearing and position sense.[14,19] An outer bony wall, or bony labyrinth, encloses a thin-walled, membranous labyrinth, which floats in the bony labyrinth (Fig. 38-20). Two separate fluids are found in the inner ear: the *perilymph* or *periotic fluid*, which separates the bony labyrinth from the membranous labyrinth, and the *endolymph* or *otic fluid*, which fills the membranous labyrinth. Localized dilatations of the membranous labyrinth develop into three specialized sensory regions: the ampulla of each semicircular canal, the maculae of the utricle and sacculus, and the cochlea. The receptors in the cochlea are sensitive to sound, and those in semicircular canals and maculae are sensitive to changes in head position and maintenance of balance.

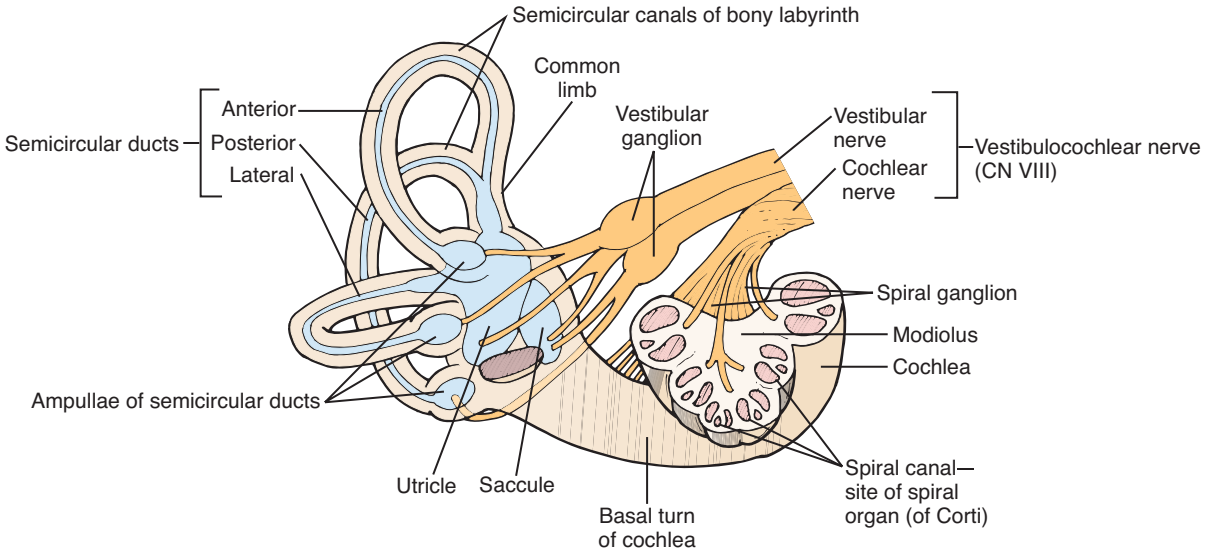

FIGURE 38-20. Schematic lateral view of the bony canals of the vestibular system showing the membranous labyrinth in a closed system of ducts and chambers filled with endolymph and bathed in perilymph with the bony labyrinth. Observe the parts of the membranous labyrinth: the semicircular ducts and the saccule and utricle within the vestibule. (Adapted from Moore K.L., Dalley A.F. [1999]. *Clinically oriented anatomy* [4th ed., p. 1102]. Philadelphia: Lippincott Williams & Wilkins.)

The cochlea is a shell-shaped part of the bony labyrinth that consists of three parallel compartments: the scala media or middle compartment of the cochlear canal, the scala vestibuli, and the scala tympani (Fig. 38-21A). The scala media is an endolymph-containing space that is continuous with the lumen of the saccule and contains the spiral organ of Corti, the receptor organs for hearing. The scala vestibuli and scala tympani are perilymph spaces that communicate with each other at the apex of the cochlea through a small channel called the *helicotrema*. The scala vestibuli begins at the oval window, and the scala tympani ends at the round window.

The organ of Corti, which rests atop the basilar membrane in the scala media, is composed of supporting cells and several long rows of cochlear hair cells: one row of inner hair cells and three rows of outer hair cells (see Fig. 38-21B). Afferent fibers from the cochlear nerve are coiled around the bases of the hair cells. Sound waves, delivered to the oval window by the stapes footplate, are transmitted to the perilymph in the scala vestibuli and scala tympani. Transduction of sound stimuli occurs when the trapped cilia of the hair cells in the organ of Corti are bent by the sound-induced movement of the basilar membrane.

Afferent fibers from the organ of Corti have their cell bodies in the spiral ganglion in the central portion of the cochlea. Nerve fibers from the spiral ganglion (i.e., vestibulocochlear or auditory nerve [CN VIII]) travel to the cochlear nuclei in the caudal pons. Many secondary nerve fibers from the cochlear nuclei pass to the nuclei on the opposite side of the pons or rostrally toward the inferior colliculus of the midbrain. From the inferior colliculus, the auditory pathway passes to the primary auditory cortex (area 41) in the temporal lobe through relays in the medial geniculate nucleus of the thalamus (see Fig. 38-14). The auditory association cortex (areas 42 and 22), which is necessary for the meaningfulness of sound, borders the primary cortex. Because some of the fibers from each ear cross, each auditory cortex receives impulses from both ears.

Tinnitus

Tinnitus is the perception of abnormal ear or head noises not produced by an external stimulus.[56–58] Although it often is described as "ringing of the ears," it may also assume a hissing, roaring, buzzing, or humming sound. Tinnitus may be constant, intermittent, and unilateral or bilateral. The condition affects both sexes equally, is most prevalent between 40 and 70 years of age, and occasionally affects children.

Although tinnitus is a subjective experience, for clinical purposes it is subdivided into objective and subjective tinnitus. *Objective tinnitus* refers to those rare cases in which the sound is detected or potentially detectable by another observer. Typical causes of objective tinnitus include vascular abnormalities or neuromuscular disorders. For example, in some vascular disorders, sounds generated by turbulent blood flow (e.g., arterial bruits or venous hums) are conducted to the auditory system. Vascular disorders typically produce a pulsatile form of tinnitus.

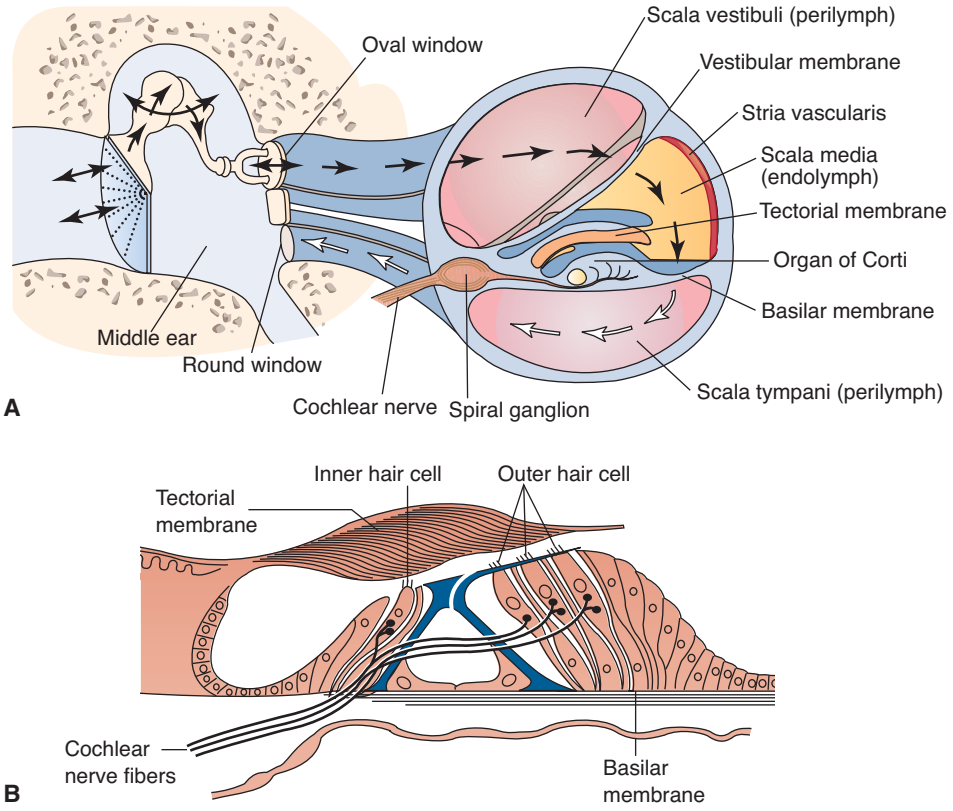

FIGURE 38-21. **(A)** Path taken by sound waves reaching the inner ear. **(B)** Spiral organ of Corti has been removed from the cochlear duct and greatly enlarged to show the inner and outer hair cells, the basilar membrane, and cochlear nerve fibers.

Subjective tinnitus refers to noise perception when there is no noise stimulation of the cochlea. A number of causes and conditions have been associated with subjective tinnitus. Intermittent periods of mild, high-pitched tinnitus lasting for several minutes are common in normal-hearing persons. Impacted cerumen is a benign cause of tinnitus, which resolves after the earwax is removed. Medications such as aspirin and stimulants such as nicotine and caffeine can cause transient tinnitus. Conditions associated with more persistent tinnitus include noise-induced hearing loss, presbycusis (sensorineural hearing loss that occurs with aging), hypertension, atherosclerosis, head injury, and cochlear or labyrinthine infection or inflammation. The physiologic mechanism underlying subjective tinnitus is largely unknown. It seems likely that there are several mechanisms, including abnormal firing of auditory receptors, dysfunction of cochlear neurotransmitter function or ionic balance, and alterations in central processing of the signal.

Treatment measures for tinnitus are designed to treat the symptoms, rather than effect a cure.[56,57] They include elimination of drugs or other substances, such as caffeine, some cheeses, red wine, and foods containing monosodium glutamate, that are suspected of causing tinnitus. Tinnitus retraining therapy, which includes directive counseling and extended use of low-noise generators to facilitate auditory adaptation to the tinnitus, has met with considerable success.

Disorders of the Central Auditory Pathways

The auditory pathways in the brain involve communication between the two sides of the brain at many levels. As a result, strokes, tumors, abscesses, and other focal abnormalities seldom produce more than a mild reduction in auditory acuity on the side opposite the lesion. For intelligibility of auditory language, lateral dominance becomes important. On the dominant side, usually the left side, the more medial and dorsal portion of the auditory association cortex is of crucial importance. This area is called the *Wernicke area,* and damage to it is associated with auditory receptive aphasia. Persons with damage to this area of the brain can speak intelligibly and read normally but are unable to understand the meaning of major aspects of audible speech.

Irritative foci that affect the auditory radiation or the primary auditory cortex can produce roaring or clicking sounds, which appear to come from the auditory environment of the opposite side (i.e., auditory hallucinations). Focal seizures that originate in or near the auditory cortex often are immediately preceded by the perception of ringing or other sounds preceded by a prodrome (i.e., aura). Damage to the auditory association cortex, especially if bilateral, results in deficiencies of sound recognition and memory (i.e., auditory agnosia). If the damage is in the dominant hemisphere, speech recognition can be affected (i.e., sensory or receptive aphasia).

Hearing Loss

Nearly 36 million Americans have some degree of hearing loss.[59] It affects persons of all age groups. Two to 3 of every 1000 children in the United States are born deaf or hard of hearing, and 9 of 10 children who are born deaf are born to parents who can hear.[59] Approximately 30% of adults between the ages of 65 and 75 years old and approximately 47% of those 75 years of age and older have a hearing loss.[59]

The level of hearing is measured in decibels (db), where 0 dB is the threshold for perception of sound at a given frequency in persons with normal hearing. A 10-fold increase in sound pressure level from 0 dB is mea sured as 20 dB. Hearing loss is classified as mild (26 to 40 dB), moderate (41 to 55 dB), severe (71 to 90 dB), or profound (91 dB or greater).[60] "Hard of hearing" is defined as hearing loss greater than 20 to 25 dB in adults and greater than 15 dB in children. Profound deafness is defined as hearing loss greater than 90 dB in adults[61] or 70 dB in children.[62]

There are many causes of hearing loss or deafness. Most fit into the categories of conductive, sensorineural, or mixed deficiencies that involve a combination of conductive and sensorineural function deficiencies of the same ear.[60,61] Chart 38-1 summarizes common causes of hearing loss. Hearing loss may be genetic or acquired, sudden or progressive, unilateral or bilateral, partial or complete, reversible or irreversible. Age and suddenness of onset provide important clues as to the cause of hearing loss.

Hearing Loss

- Hearing is a special sensory function that incorporates the sound-transmitting properties of the external ear canal, the eardrum that separates the external and middle ear, the bony ossicles of the middle ear, the sensory receptors of the cochlea in the inner ear, the neural pathways of the vestibulocochlear or auditory nerve, and the primary auditory and auditory association cortices.
- Hearing loss represents impairment of the ability to detect and perceive sound.
- It can range from mild, affecting sounds of different tones and intensities, to moderate or profound.
- Hearing loss can be caused by conductive disorders, in which auditory stimuli are not transmitted through the structures of the outer and middle ears to the sensory receptors in the inner ear; by sensorineural disorders that affect the inner ear, auditory nerve, or auditory pathways; or by a combination of conductive and sensorineural disorders.

Conductive Hearing Loss

Conductive hearing loss occurs when auditory stimuli are not adequately transmitted through the auditory canal, tympanic membrane, middle ear, or ossicle chain

CHART 38-1 Common Causes of Conductive and Sensorineural Hearing Loss

Conductive Hearing Loss

- External ear conditions
  - Impacted earwax or foreign body
  - Otitis externa
- Middle ear conditions
  - Trauma
  - Otitis media (acute and with effusion)
  - Otosclerosis
  - Tumors

Sensorineural Hearing Loss

- Trauma
  - Head injury
  - Noise
- Central nervous system infections (e.g., meningitis)
- Degenerative conditions
  - Presbycusis
- Vascular
  - Atherosclerosis
  - Sudden deafness
- Ototoxic drugs (e.g., aminoglycosides, salicylates, loop diuretics)
- Tumors
  - Vestibular schwannoma (acoustic neuroma)
  - Meningioma
  - Metastatic tumors
- Idiopathic
  - Ménière disease

Mixed Conductive and Sensorineural Hearing Loss

- Middle ear conditions
  - Barotrauma
  - Cholesteatoma
  - Otosclerosis
- Temporal bone fractures

to the inner ear. Temporary hearing loss can occur as the result of impacted cerumen in the outer ear or fluid in the middle ear. Foreign bodies, including pieces of cotton and insects, may impair hearing. More permanent causes of hearing loss are thickening or damage of the tympanic membrane or involvement of the bony structures (ossicles and oval window) of the middle ear caused by otosclerosis or Paget disease.

Sensorineural Hearing Loss

Sensorineural, or perceptive, hearing loss occurs with disorders that affect the inner ear, auditory nerve, or auditory pathways of the brain. With this type of deafness, sound waves are conducted to the inner ear, but abnormalities of the cochlear apparatus or auditory nerve decrease or distort the transfer of information to the brain. Tinnitus often accompanies cochlear nerve irritation. Abnormal function resulting from damage or malformation of the central auditory pathways and circuitry is included in this category.

Sensorineural hearing loss may have a genetic cause or may result from intrauterine infections, such as maternal rubella, or developmental malformations of the inner ear. Genetic hearing loss may result from mutation in a single gene (monogenetic) or from a combination of mutations in different genes and environmental factors (multifactorial). It has been estimated that 50% of profound deafness in children has a monogenetic basis.[59,60] The inheritance pattern for monogenetic hearing loss is autosomal recessive in approximately 75% of cases.[62] Hearing loss may begin before development of speech (prelingual) or after speech development (postlingual). Most prelingual forms are present at birth. Genetic forms of hearing loss also can be classified as being part of a syndrome in which other abnormalities are present, or as nonsyndromic, in which deafness is the only abnormality.

Sensorineural hearing loss also can result from trauma to the inner ear, tumors that encroach on the inner ear or sensory neurons, vascular disorders with hemorrhage, or thrombosis of vessels that supply the inner ear. Other causes of sensorineural deafness are infections and drugs. Sudden sensorineural hearing loss represents an abrupt loss of hearing that occurs instantaneously or on awakening. It most commonly is caused by viral infections or circulatory disorders. Hypothyroidism is a potential cause of sensorineural hearing loss in older persons.

Environmentally induced deafness can occur through direct exposure to excessively intense sound, as in the workplace or at a concert. This is a particular problem in older adults who were working in noisy environments before the mid-1960s, when there were no laws mandating use of devices for hearing protection. Sustained or repeated exposure to noise pollution at sound intensities greater than 100 to 120 dB can cause corresponding mechanical damage to the organ of Corti. Severe damage can result in permanent sensorineural deafness to the affected sound frequencies. Wearing earplugs or ear protection is important under many industrial conditions and for musicians and music listeners exposed to high sound amplification.

A number of infections can cause sensorineural hearing loss. Deafness or some degree of hearing impairment is the most common serious complication of bacterial meningitis in infants and children, reportedly resulting in sensorineural hearing loss in 5% to 35% of persons who survive the infection.[60] The mechanism causing hearing impairment is thought to be a suppurative labyrinthitis or neuritis resulting in the loss of hair cells and damage to the auditory nerve. Untreated suppurative OM also can extend into the inner ear and cause sensorineural hearing loss through the same mechanisms.

Among the neoplasms that impair hearing are *acoustic neuromas*. Acoustic neuromas are benign Schwann cell tumors affecting CN VIII. These tumors usually are unilateral and cause hearing loss by compressing the cochlear nerve or interfering with blood supply to the nerve and cochlea. Other neoplasms that can affect hearing include meningiomas and metastatic brain tumors. The temporal bone is a common site of metastases.

Drugs that damage inner ear structures are labeled *ototoxic*. Vestibular symptoms of ototoxicity include lightheadedness, giddiness, and dizziness; if toxicity is severe, cochlear symptoms consisting of tinnitus or hearing loss

occur. Hearing loss is sensorineural and may be bilateral or unilateral, transient or permanent. Several classes of drugs, in particular, have been identified as having ototoxic potential, including the aminoglycoside antimicrobials and some other basic antimicrobials, antimalarial drugs, some chemotherapeutic drugs, loop diuretics, and salicylates (aspirin). The symptoms of drug-induced hearing loss may be transient, as often is the case with salicylates and diuretics, or they may be permanent. The risk of ototoxicity depends on the total dose of the drug and its concentration in the bloodstream. It is increased in persons with impaired kidney functioning and in those previously or currently treated with another potentially ototoxic drug.

Diagnosis and Treatment of Hearing Loss

Diagnosis of hearing loss is aided by careful history of associated otologic factors such as otalgia, otorrhea, tinnitus, and self-described hearing difficulties; physical examination to detect the presence of conditions such as otorrhea, impacted cerumen, or injury to the tympanic membrane; and hearing tests. Testing for hearing loss includes a number of methods, including a person's reported ability to hear an observer's voice, use of a tuning fork to test air and bone conduction, audioscopes, and auditory brain stem evoked responses (ABRs).[60]

Tuning forks are used to differentiate conductive and sensorineural hearing loss. Audioscopes can be used to assess a person's ability to hear pure tones at 1000 to 2000 Hz (usual speech frequencies). The ABR uses electroencephalographic (EEG) electrodes and high-gain amplifiers to produce a record of brain wave activity elicited during repeated acoustic stimulations of either or both ears. It involves subjecting the ear to loud clicks and using a computer to analyze nerve impulses as they are processed in the midbrain. Imaging studies such as computed tomography (CT) scans and magnetic resonance imaging (MRI) can be done to determine the site of a lesion and the extent of damage.[63]

Untreated hearing loss can have many consequences. Social isolation and depressive disorders are common in the hearing-impaired elderly. Hearing-impaired people may avoid social situations where background noise makes conversation difficult to hear. Safety issues, both in and out of the home, may become significant. Treatment measures for hearing loss range from simple removal of impacted cerumen in the external auditory canal to surgical procedures, such as those used to reconstruct the tympanic membrane. For other people, particularly the frail elderly, hearing aids remain an option. Cochlear implants also are an option for some people.

Hearing aids remain the mainstay of treatment for many persons with conductive and sensorineural hearing loss. With the advent of microcircuitry, hearing aids are now being designed with computer chips that allow multiple programs to be placed in a single hearing aid. The various programs allow the user to select a specific setting for different listening situations. The development of microcircuitry has also made it possible for hearing aids to be miniaturized to the point that, in many cases, they can be placed deep in the ear where they take advantage of the normal shape of the external ear and ear canal. Although modern hearing aids have improved greatly, they cannot replicate the hearing person's ability to hear both soft and loud noises. They also fail consistently to filter out distorted or background noise.[64] Other aids for the hearing impaired include alert and signal devices, assisted-listening devices from telephone companies, and dogs trained to respond to various sounds.

Surgically implantable cochlear prostheses for the profoundly deaf have been developed and are available for use in adults and children.[65] These prostheses are inserted into the scala tympani of the cochlea and work by providing direct stimulation to the auditory nerve, bypassing the stimulation that typically is provided by transducer cells but that is absent or nonfunctional in a deaf cochlea. For the implant to work, the auditory nerve must be functional. Although early implants used a single electrode, current implants use multielectrode placement, enhancing speech perception. Much of the progress in implant performance has been achieved through improvements in the speech processors that convert sound into electrical stimuli. Advances in the development of the multichannel implant have improved performance such that cochlear implants have been established as an effective option for adults and children with profound hearing impairment.[65,66] Most persons who are deafened after learning speech derive substantial benefit when cochlear implants are used in conjunction with lip reading; some are able to understand some speech without lip reading; and some are able to communicate by telephone.

Hearing Loss in Infants and Children

Even mild or unilateral hearing loss can have a detrimental effect on the language development and hearing-associated learning of the young child.[67,68] The cause of hearing impairment in children depends on whether the hearing loss is conductive or sensorineural. Most conductive hearing loss is caused by middle ear infections. Causes of sensorineural hearing impairment include genetic, infectious, traumatic, and ototoxic factors.

Genetic causes are probably responsible for as much as 50% of sensorineural hearing loss in children. The most common infectious cause of congenital sensorineural hearing loss is cytomegalovirus (CMV), which infects 1 of 100 newborns in the United States each year; of these, about 1200 to 2000 have sensorineural hearing loss.[68] Of particular concern is the fact that congenital CMV infection can cause both symptomatic and asymptomatic hearing loss in the newborn. Some children with congenital CMV infection, who were asymptomatic as newborns, have suddenly lost residual hearing at 4 to 5 years of age. Postnatal causes of sensorineural hearing loss include β-hemolytic streptococcal sepsis in the newborn and bacterial meningitis. *S. pneumoniae* is the most common cause of bacterial meningitis that results in sensorineural hearing loss after the neonatal period; this cause may become less frequent with the routine administration of the conjugate pneumococcal vaccine. Other causes of

sensorineural hearing loss are toxins and trauma. Early in pregnancy, the embryo is particularly sensitive to toxic substances, including ototoxic drugs such as the aminoglycosides and loop diuretics. Trauma, particularly head trauma, may cause sensorineural hearing loss.

Hearing impairment can have a major impact on the development of a child; therefore, early identification through screening programs is strongly advocated.[68–70] The currently recommended screening techniques are either the transient evoked otoacoustic emissions (TEOAEs) or the ABR. Both methodologies are noninvasive, relatively quick (<5 minutes), and easy to perform. The TEOAE measures sound waves generated in the inner ear (cochlea) in response to clicks or tone bursts emitted and recorded by a minute microphone placed in the external ear canals of the infant. The ABR uses three electrodes pasted to the infant's scalp to measure the EEG waves generated by clicks. Because many children become hearing impaired after the neonatal period and are not identified by neonatal screening programs, the American Academy of Pediatricians and the Joint Commission of Infant Hearing recommend that all infants with risk factors for delayed onset of progressive hearing loss receive ongoing audiologic and medical monitoring for 3 years and at appropriate intervals thereafter.

Once hearing loss has been identified, a full developmental and speech and language evaluation is needed. Parental involvement and counseling are essential. Children with sensorineural hearing loss should be evaluated for possible hearing aid use by a pediatric audiologist. Hearing aids may be fitted for infants as young as 2 months of age.[68] Infants and young children with profound congenital or prelingual deafness have benefited from multichannel cochlear implants.[68] Because of the increased risk of pneumococcal meningitis, children who receive implants should receive age-appropriate immunization against pneumococcal disease.

Hearing Loss in the Elderly

The term *presbycusis* is used to describe degenerative hearing loss that occurs with advancing age.[71,72] The degenerative changes that impair hearing may begin in the fifth decade of life and may not be clinically apparent until later. The hearing loss is typically gradual, bilateral, and characterized by high-frequency hearing loss. It is further characterized by reduced hearing sensitivity and speech understanding in noisy environments, slowed central processing of acoustic information, and impaired localization of sound sources. The disorder first reduces the ability to understand speech and, later, the ability to detect, identify, and localize sounds. The most common complaint of persons with presbycusis is not that they cannot hear, but rather that they cannot understand what is being said. For example, they often confuse words like *mash* with *math, map* with *mat,* and *Sunday* with *some day.* High-frequency warning sounds, such as beepers, turn signals, and escaping steam, are not heard and localized, with potentially dangerous results.

Given the high prevalence of hearing loss in people of retirement age and its adverse effects on well-being, screening for hearing loss should be performed at annual health care visits. Clinical measures for hearing loss such as whispered voice tests and finger friction tests are reportedly imprecise and are not reliable methods for screening. Screening audiometry administered by someone trained in its use is a practical and cost-effective method for detecting significant hearing loss.

The majority of hearing loss in the elderly is sensorineural. In mild to severe loss, the most effective treatment is hearing amplification with hearing aids, speech reading, and assistive listening devices (e.g., hearing aids with the telephone, captioning on televised programs, flashing alarms). Cochlear implants are indicated at any age for people with bilateral hearing losses not materially helped by hearing aids.

In summary, disorders of the auditory system include infections of the external and middle ear, otosclerosis, tinnitus, and conduction and sensorineural deafness. Otitis externa is an inflammatory process of the external ear. Otitis media refers to inflammation of the middle ear. Acute otitis media refers to an acute middle ear infection; and otitis media with effusion, the presence of fluid in the middle ear that is not due to infection and does not usually require treatment with antimicrobial agents. Otosclerosis is a familial disorder of the otic capsule that results in hearing loss due to immobilization of the stapes and conduction deafness.

Disorders of the inner ear, which contains the receptors for hearing, can lead to tinnitus (ringing of the ears) or sensorineural hearing loss. Tinnitus can be subjective, in which the sound is perceived by the individual but is not evident to the observer, or it can be objective, in which case the sound, often due to vascular disorders, can be detected by an observer. Disorders of the central auditory pathways, due to conditions such as a stroke, produce a sensorineural hearing loss on the side opposite the lesion.

Deafness, or hearing loss, can develop as the result of a number of auditory disorders. It can be conductive, sensorineural, or mixed. Conduction deafness occurs when transmission of sound waves from the external ear to the inner ear is impaired. Sensorineural deafness can involve cochlear structures of the inner ear or the neural pathways that transmit auditory stimuli. Sensorineural hearing loss can result from genetic or congenital disorders, trauma, infections, vascular disorders, tumors, or ototoxic drugs. Hearing loss that occurs in young children and the elderly can have special implications. Even mild or unilateral hearing loss can affect the development and hearing-associated learning of the young child. The age-related degenerative changes that impair hearing may begin in the fifth decade and not be clinically apparent until later. Treatment of hearing loss includes the use of hearing aids and, in some cases of profound deafness, implantation of a cochlear implant.

The Vestibular System and Disorders of Equilibrium

The equilibrium sense is not easy to describe. Although a mechanism of perception, it does not provide a sensation such as sight, hearing, or touch. Instead, it serves to maintain a stable body position through the control of postural reflexes. The vestibular receptive organs, which are located in the inner ear, and their CNS connections provide for the sense of equilibrium and orientation in space. Because the vestibular apparatus is part of the inner ear and located in the head, it is head position and acceleration that are sensed. The equilibrium sense, which is also dependent on vision and input from stretch receptors in muscles and tendons, serves to maintain and assist recovery of a stable body and head position through control of postural reflexes, and it serves to maintain a stable visual field despite marked changes in head position.

The Vestibular System

The vestibular system is contained in the bony labyrinth of the inner ear next to and continuous with the cochlea of the auditory system. Like the cochlea, the vestibular system consists of two fluid-filled compartments—an outer bony labyrinth that is filled with perilymph and an inner membranous labyrinth that is filled with endolymph[2,14] (Fig. 38-22A). The bony labyrinth is divided into three semicircular canals and a central vestibule or egg-shaped cavity that lies posterior to the cochlea and anterior to the semicircular canals. Suspended in the perilymph and united by a duct are two membranous labyrinth sacs, the saccule and utricle. The specialized sensory regions of the vestibular system consist of sensory hair cells and accessory supporting cells. These regions project from the wall of the membranous labyrinth into the endolymph space in each inner ear.

Located in each semicircular canal is a corresponding semicircular duct, which communicates with the utricle. Each of these ducts has an enlarged swelling at one end called an *ampulla*. The ampulla of each of the semicircular canals contains a ridge that is covered by a sensory epithelium with tufts of hair cells that are covered by a flexible gelatinous cap called the *cupula* (see Fig. 38-22B). These hair cells are sensitive to angular and rotary movements of the head rather than straight-line movement. The cavities of the three semicircular canals, the lateral, anterior, and posterior canals, are oriented in one of three planes of space. The lateral (horizontal) canals are in the same plane, whereas the anterior (superior) canal of one side is parallel with the posterior (inferior) canal on the other side, and the two function as a pair. Thus, regardless of which plane one moves in, there will be receptors to detect movement. Impulses from the semicircular ducts are particularly important in reflex movement of the eyes. Vestibular nystagmus (to be discussed) is a complex phenomenon that occurs during and immediately after rotational motion. During head rotation the eyes slowly drift in the opposite direction and then jump rapidly back toward the direction of rotation to establish a new fixation point.

The saccule and utricle house equilibrium receptors called *maculae* that respond to our sense of static equilibrium (see Fig. 38-22C). The maculae report on changes in space with respect to the pull of gravity when the body is not moving. Because they provide information on which way is up or down, they help to keep the head erect. Each macula is a small, flat epithelial patch containing supporting cells and sensory hair cells, the sides and bases of which synapse with sensory endings of the vestibular nerve. The hair cells of the macula in both the utricular and saccular maculae are embedded in a flattened gelatinous mass, the *otolithic membrane,* which is studded with tiny stones (calcium carbonate crystals) called *otoliths*. Although they are small, the density of the otoliths increases the membrane's weight and its resistance to change in motion. When the head is tilted, the gelatinous mass shifts its position because of the pull of the gravitational field, bending the cilia of the macular hair cells (see Fig. 38-22D). In a condition called *benign paroxysmal positional vertigo* (sensation of whirling or spinning motion), the otoliths become dislodged from their gelatinous base, causing a vertigo that is precipitated by changes in the recumbent head position (to be discussed).

The response to body imbalance, such as stumbling, must be fast and reflexive. Hence, information from the vestibular system goes directly to reflex centers in the brain stem, rather than to the cerebral cortex. Impulses

Disorders of the Vestibular System

- The receptors concerned with the sense of balance and position in space are located in fluid (endolymph)-filled semicircular canals of the vestibular system of the inner ear.
- The vestibular system has extensive interconnections with neural pathways controlling vision, hearing, and autonomic nervous system function. Disorders of the vestibular system are characterized by vertigo, nystagmus, tinnitus, nausea and vomiting, and autonomic nervous system manifestations.
- Disorders of vestibular function can result from repeated stimulation of the vestibular system such as during car, air, and boat travel (motion sickness); acute infection of the vestibular pathways (acute vestibular neuritis); dislodgement of otoliths that participate in the receptor function of the vestibular system (benign paroxysmal positional vertigo); or distention of the endolymphatic compartment of the inner ear (Ménière disease).

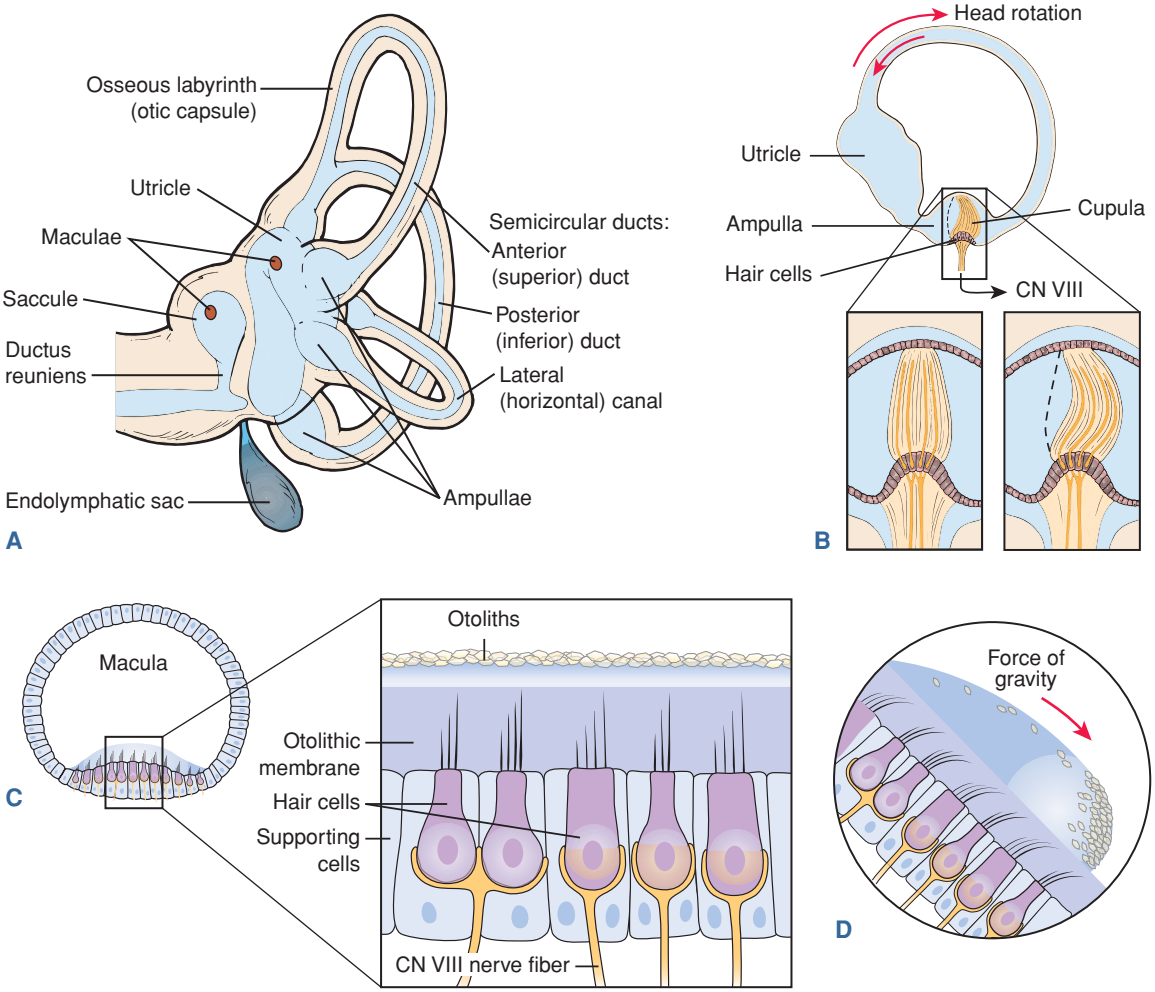

FIGURE 38-22. Vestibular labyrinth. **(A)** Osseous and membranous vestibular labyrinth of the middle ear showing the utricle and saccule with their maculae and three semicircular canals and their ampullae. **(B)** Diagram of the crista ampullaris within the semicircular canal and location of the cupula and movement of the hair cells with head movement. **(C)** Relationship of the otoliths to the sensory hair cells, which synapse with the sensory endings of the vestibular nerve (CN VIII) in the maculae of the utricle and saccule. **(D)** Movement of the otoliths and bending of the macular hair cells when the head is tilted due to the forces of gravity.

from the vestibular nerves initially pass to one of two destinations: the vestibular nuclear complex in the brain stem or the cerebellum. The vestibular nuclei, which form the main integrative center for balance, also receive input from visual and somatic receptors, particularly from stretch receptors in the neck muscles that report the angle or inclination of the head. The vestibular nuclei integrate this information and then send impulses to the brain stem centers that control the extraocular eye movements and reflex movements of the neck, limb, and trunk muscles. These reflex movements include the vestibulo-ocular reflexes that keep the eyes still as the head moves and the vestibulospinal reflexes that enable the skeletomotor system to make the quick adjustments needed to maintain or regain balance.

Neurons of the vestibular nuclei also project to the thalamus, the temporal cortex, the somesthetic area of the parietal cortex, and the chemoreceptor trigger zone. The thalamic and cortical projections provide the basis for the subjective experiences of position in space and of rotation. Connections with the chemoreceptor trigger zone stimulate the vomiting center, accounting for the nausea and vomiting that often are associated with motion sickness and vestibular disorders.

Nystagmus

The term *nystagmus* refers to the involuntary rhythmic and oscillatory eye movements that preserve eye fixation on stable objects in the visual field during angular and rotational movements of the head.[14] The vestibulo-ocular reflexes produce slow compensatory conjugate eye rotations that occur in the direction precisely opposite to ongoing head rotation and provide for continuous, ongoing reflex stabilization of the binocular fixation point. When compensatory vestibulo-ocular reflexes carry the conjugate eye

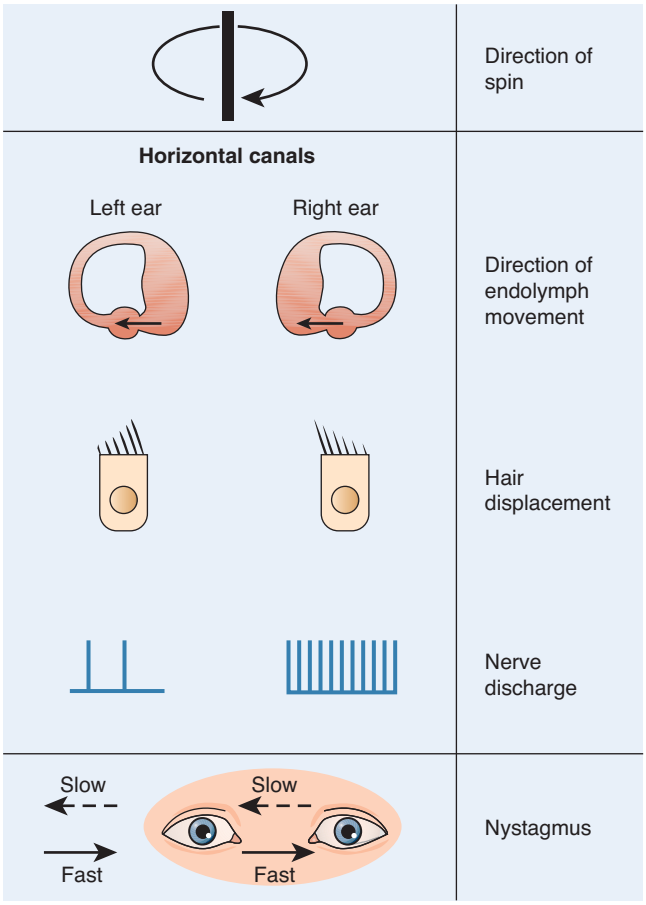

FIGURE 38-23. Effect of spinning a subject clockwise. On acceleration, the endolymph in the horizontal canals will lag behind with respect to movement of the canal wall. The hairs of cristae will be displaced to the left. In the left semicircular canal, hair displacement is away from the kinocilium, leading to decreased nerve discharges below the resting level. On the right, hair displacement is toward the kinocilium, leading to an increase in nerve discharge above the resting level. (From Sekurt F.E. [1982]. *Basic physiology for the health professions* [2nd ed., p. 140]. Boston: Little, Brown.)

rotations to their physical limit, a very rapid conjugate movement moves the eyes in the direction of head rotation to a new fixation point, followed by a slow vestibulo-ocular reflex as the head continues to rotate past the new fixation point. This pattern of slow–fast–slow movements is called *nystagmus* (Fig. 38-23). Clinically, the direction of nystagmus is named for the fast phase of nystagmus.

Spontaneous nystagmus that occurs without head movement or visual stimuli is always pathologic. It seems to appear more readily and more severely with fatigue and to some extent can be influenced by psychological factors. Nystagmus due to a CNS pathologic process, in contrast to vestibular end-organ or vestibulocochlear nerve sources, seldom is accompanied by vertigo. If present, the vertigo is mild. Nystagmus eye movements can be tested by caloric stimulation or rotation (to be discussed).

Vertigo

Disorders of vestibular function are characterized by a condition called *vertigo,* in which an illusion of motion occurs. With vertigo, the person may be stationary and the environment in motion (i.e., objective vertigo) or the person may be in motion and the environment stationary (i.e., subjective vertigo). Persons with vertigo frequently describe a sensation of spinning, "to-and-fro" motion, or falling.

Vertigo should be differentiated from light-headedness, faintness, or syncope.[73–75] Presyncope, which is characterized by a feeling of light-headedness or "blacking out," is commonly caused by postural hypotension (see Chapter 18) or a stenotic lesion in the cerebral circulation that limits blood flow. An inability to maintain normal gait may be described as dizziness despite the absence of objective vertigo. The unstable gait may be caused by disorders of sensory input (e.g., proprioception), peripheral neuropathy, gait problems, or disorders other than vestibular function and usually is corrected by touching a stationary object such as a wall or table.

Vertigo can result from central or peripheral vestibular disorders. Vertigo due to peripheral vestibular disorders tends to be severe in intensity and episodic or brief in duration. In contrast, vertigo due to central vestibular causes tends to be mild and constant and chronic in duration.

Motion Sickness. Motion sickness is a form of normal physiologic vertigo. It is caused by repeated rhythmic stimulation of the vestibular system, such as that encountered in car, air, or boat travel. Vertigo, malaise, nausea, and vomiting are the principal symptoms. Autonomic signs, including lowered blood pressure, tachycardia, and excessive sweating, may occur. Hyperventilation, which commonly accompanies motion sickness, produces changes in blood volume and pooling of blood in the lower extremities, leading to postural hypotension and sometimes to syncope. Some persons experience a variant of motion sickness, complaining of sensing the rocking motion of the boat after returning to ground. This usually resolves after the vestibular system becomes accustomed to the stationary influence of being back on land.

Disorders of Peripheral Vestibular Function

Disorders of peripheral vestibular function occur when signals from the vestibular apparatus are distorted, as in benign paroxysmal positional vertigo, or are unbalanced by unilateral involvement of one of the vestibular organs, as in Ménière disease. The inner ear is vulnerable to injury caused by fracture of the petrous portion of the temporal bones; by infection of nearby structures, including the middle ear and meninges; and by blood-borne toxins and infections. Damage to the vestibular system can occur as an adverse effect of certain drugs or from allergic reactions to foods. The aminoglycosides (e.g., streptomycin, gentamicin) have a specific toxic affinity for the vestibular

portion of the inner ear. Alcohol can cause transient episodes of vertigo. The cause of peripheral vertigo remains unknown in approximately half of the cases.

Severe irritation or damage of the vestibular end-organs or nerves results in severe balance disorders reflected by instability of posture, ataxia, and falling accompanied by vertigo. With irritation, falling is away from the affected side; with destruction, it is toward the affected side. Adaptation to asymmetric stimulation occurs within a few days, after which the signs and symptoms diminish and eventually are lost. After recovery, there usually is a slightly reduced acuity for tilt, and the person walks with a somewhat broadened base to improve postural stability. After adaptation to the loss of vestibular input from one side, the loss of function of the opposite vestibular apparatus produces signs and symptoms identical to those resulting from unilateral rather than bilateral loss. Within weeks, adaptation is again sufficient for locomotion and even for driving a car. Such a person relies heavily on visual and proprioceptive input from muscle and joint sensors and has severe orientation difficulty in the dark, particularly when traversing uneven terrain.

Benign Paroxysmal Positional Vertigo

Benign paroxysmal positional vertigo (BPPV) is the most common cause of pathologic vertigo and usually develops after the fourth decade of life. It is characterized by brief periods of vertigo, usually lasting less than 1 minute, that are precipitated by a change in head position.[76] The most prominent symptom of BPPV is vertigo that occurs in bed when the person rolls into a lateral position. It also commonly occurs when the person is getting in and out of bed, bending over and straightening up, or extending the head to look up. It also can be triggered by amusement rides that feature turns and twists.

Benign paroxysmal positional vertigo is thought to result from damage to the delicate sensory organs of the inner ear, the semicircular ducts, and otoliths (see Fig. 38-22). In persons with BPPV, the calcium carbonate particles (otoliths) from the utricle become dislodged and become free-floating debris within the endolymph of a semicircular canal, most commonly the posterior canal, which is the most dependent part of the inner ear. Movement of the free-floating debris causes this portion of the vestibular system to become more sensitive, such that any movement of the head in the plane parallel to the posterior duct may cause vertigo and nystagmus. There usually is a several-second delay between head movement and onset of vertigo, representing the time it takes to generate the exaggerated endolymph activity. Symptoms usually subside with continued movement, probably because the movement causes the debris to be redistributed throughout the endolymph system and away from the posterior semicircular canal.

Diagnosis is based on tests that involve the use of a change in head position to elicit vertigo and nystagmus. BPPV often is successfully treated with drug therapy to control vertigo-induced nausea. Nondrug therapies using habituation exercises and canalith repositioning are successful in many people. Canalith repositioning involves a series of maneuvers in which the head is moved to different positions in an effort to reposition the free-floating debris in the endolymph of the semicircular canals.

Acute Vestibular Neuronitis

Acute vestibular neuronitis represents an inflammation of the vestibular nerve and is characterized by an acute onset (usually hours) of vertigo, nausea, and vomiting lasting several days and not associated with auditory or other neurologic manifestations. Most persons experience gradual improvement over 1 to 2 weeks, but some develop recurrent episodes.[77,78] A large percentage report an upper respiratory tract illness 1 to 2 weeks before onset of symptoms, suggesting a viral origin. The condition also can occur in persons with herpes zoster oticus. In some persons, attacks of acute vestibulopathy recur over months or years. There is no way to determine whether a person who experiences a first attack will have repeated attacks.

Ménière Disease

Ménière disease is a disorder of the inner ear due to distention of the endolymphatic compartment of the inner ear, causing a triad of hearing loss, vertigo, and tinnitus.[79–81] A number of mechanisms have been postulated, including an increased production of endolymph, decreased production of perilymph accompanied by a compensatory increase in volume of the endolymphatic sac, and decreased absorption of endolymph caused by malfunction of the endolymphatic sac or blockage of endolymphatic pathways.

The cause of Ménière disease is unknown. A number of conditions, such as trauma, infection (e.g., syphilis), and immunologic, endocrine (i.e., adrenal-pituitary insufficiency and hypothyroidism), and vascular disorders have been proposed as possible causes of Ménière disease. The most common form of the disease is an idiopathic form thought to be caused by a single viral injury to the fluid transport system of the inner ear. One area of investigation has been the relation between autoimmune disorders and Ménière disease.

Ménière disease is characterized by fluctuating episodes of tinnitus, feelings of ear fullness, and violent rotary vertigo that often renders the person unable to sit or walk. There is a need to lie quietly with the head fixed in a comfortable position, avoiding all head movements that aggravate the vertigo. Symptoms referable to the autonomic nervous system, including pallor, sweating, nausea, and vomiting, usually are present. The more severe the attack, the more prominent are the autonomic manifestations. A fluctuating hearing loss occurs with a return to normal after the episode subsides. Initially the symptoms tend to be unilateral, resulting in rotary nystagmus caused by an imbalance in vestibular control of eye movements. Because initial involvement usually is unilateral and because the sense of hearing is bilateral, many persons with the disorder are not aware of the full extent

of their hearing loss. However, as the disease progresses, the hearing loss stops fluctuating and progressively worsens, with both ears tending to be affected so that the prime disability becomes one of deafness.[63] The episodes of vertigo diminish and then disappear, although the person may be unsteady, especially in the dark.

Methods used in the diagnosis of Ménière disease include audiograms, vestibular testing by electronystagmography, and petrous pyramid radiographs. The administration of hyperosmolar substances, such as glycerin and urea, often produces acute temporary hearing improvement in persons with Ménière disease and sometimes is used as a diagnostic measure of endolymphatic hydrops. The diuretic furosemide also may be used for this purpose.

The management of Ménière disease focuses on attempts to reduce the distention of the endolymphatic space, and can be medical or surgical. Pharmacologic management consists of suppressant drugs (e.g., prochlorperazine, promethazine, diazepam), which act centrally to decrease the activity of the vestibular system. Diuretics are used to reduce endolymph fluid volume. A low-sodium diet is recommended in addition to these medications. The steroid hormone prednisone may be used to maintain satisfactory hearing and resolve dizziness. Intratympanic gentamicin therapy has been used for ablation of the vestibular system.[81] This treatment is mainly effective in controlling vertigo and does not alter the underlying pathologic process. Surgical methods include the creation of an endolymphatic shunt in which excess endolymph from the inner ear is diverted into the subarachnoid space or the mastoid (endolymphatic sac surgery), and vestibular nerve section. Advances in vestibular nerve section have facilitated the monitoring of CN VII and CN VIII potentials as a means of preventing hearing damage.

Disorders of Central Vestibular Function

Abnormal nystagmus and vertigo can occur as a result of CNS lesions involving the cerebellum and lower brain stem. Central causes of vertigo include brain stem ischemia, tumors, and the demyelinating effects of multiple sclerosis. When brain stem ischemia is the cause of vertigo, it usually is associated with other brain stem signs, such as diplopia, ataxia, dysarthria, or facial weakness. Compression of the vestibular nuclei by cerebellar tumors invading the fourth ventricle results in progressively severe signs and symptoms. In addition to abnormal nystagmus and vertigo, vomiting and a broad-based and dystaxic gait become progressively more evident.

In contrast to peripherally generated nystagmus, CNS-derived nystagmus is relatively constant rather than episodic, can occur in any direction rather than being primarily in the horizontal or torsional (rotatory) dimensions, often changes direction through time, and cannot be suppressed by visual fixation. Repeated induction of nystagmus results in rapid diminution or "fatigue" of the reflex with peripheral abnormalities, but fatigue is not characteristic of central lesions.

Diagnosis and Treatment

Tests of Vestibular Function

Diagnosis of vestibular disorders is based on a description of the symptoms, a history of trauma or exposure to agents that are destructive to vestibular structures, and physical examination. Tests of eye movements (i.e., nystagmus) and muscle control of balance and equilibrium often are used.

Electronystagmography (ENG) is a precise and objective diagnostic method of evaluating nystagmic eye movements. Electrodes are placed lateral to the outer canthus of each eye and above and below each eye, and a ground electrode is placed on the forehead. With ENG, the velocity, frequency, and amplitude of spontaneous or induced nystagmus and the changes in these measurements brought by a loss of fixation, with the eyes open or closed, can be quantified. *Caloric testing* involves elevating the head 30 degrees and irrigating each external auditory canal separately with 30 to 50 mL of ice water. The resulting changes in temperature, which are conducted through the petrous portion of the temporal bone, set up convection currents in the otic fluid that mimic the effects of angular acceleration. In an unconscious person with a functional brain stem and intact vestibulo-ocular reflexes, the eyes exhibit a jerk nystagmus lasting 2 to 3 minutes, with the slow component toward the irrigated ear followed by rapid movement away from the ear. With impairment of brain stem function, the response becomes perverted and eventually disappears. An advantage of the caloric stimulation method is the ability to test the vestibular apparatus on one side at a time. The test is never done on a person who does not have an intact ear drum or those who have blood or fluid collected behind the ear drum.

Rotational testing involves the use of a motor-driven revolving chair or platform. Unlike caloric testing, rotational testing depends only on the inner ear and is unrelated to conditions of the external ear or temporal bone. A major disadvantage of the method is that both ears are tested simultaneously. Motor-driven chairs or platforms can be precisely controlled, and multiple graded stimuli can be delivered in a relatively short period. Testing usually is performed in the dark without visual influence and with selected light stimuli. Eye movements are usually monitored using ENG.

The *Romberg test* is used to demonstrate disorders of static vestibular function. The person being tested is requested to stand with feet together and arms extended forward so that the degree of sway and arm stability can be observed. The person then is asked to close his or her eyes. When visual clues are removed, postural stability is based on proprioceptive sensation from the joints, muscles, and tendons and from static vestibular reception. Deficiency in vestibular static input is indicated by greatly increased sway and a tendency for the arms to drift toward the side of

deficiency. If vestibular input is severely deficient, the subject falls toward the deficient side.

Treatment of Vestibular Disorders

Pharmacologic Treatment. Depending on the cause, vertigo may be treated pharmacologically.[82] There are two types of drugs used in the treatment of vertigo. First are the drugs used to suppress the illusion of motion. These include drugs such as antihistamines (e.g., meclizine, cyclizine, dimenhydrinate, and promethazine) and anticholinergic drugs (e.g., scopolamine, atropine) that suppress the vestibular system. Although the antihistamines have long been used in treating vertigo, little is known about their mechanism of action. The second type includes drugs used to relieve the nausea and vomiting that commonly accompany the condition. Antidopaminergic drugs (e.g., phenothiazines) and benzodiazepines commonly are used for this purpose.

Vestibular Rehabilitation. Vestibular rehabilitation, a relatively new treatment modality for peripheral vestibular disorders, has met with considerable success.[83,84] It commonly is done by physical therapists and uses a home exercise program that incorporates habituation exercises, balance retraining exercises, and a general conditioning program. The habituation exercises take advantage of physiologic fatigue of the neurovegetative response to repetitive movement or positional stimulation and are done to decrease motion-provoked vertigo, light-headedness, and unsteadiness. The exercises are selected to provoke the vestibular symptoms. The person moves quickly into the position that causes symptoms, holds the position until the symptoms subside, relaxes, and then repeats the exercise for a prescribed number of times. The exercises usually are repeated twice daily. The habituation effect is characterized by decreased sensitivity and duration of symptoms. It may occur in as little as 2 weeks or take as long as 6 months.

Balance retraining exercises consist of activities directed toward improving individual components of balance that may be abnormal. General conditioning exercises, a vital part of the rehabilitation process, are individualized to the person's preferences and lifestyle. They should consist of motion-oriented activity that the person is interested in and should be done on a regular basis, usually four to five times per week.

In summary, the vestibular system plays an essential role in the equilibrium sense, which is closely integrated with the visual and proprioceptive (position) senses. Receptors for the vestibular system, in the semicircular ducts of the inner ear, respond to changes in linear and angular acceleration of the head. The vestibular nerve fibers travel in CN VIII to the vestibular nuclei at the junction of the medulla and pons; some fibers pass through the nuclei to the cerebellum.

Disorders of peripheral vestibular function, which involve the inner ear sensory organs, include Ménière disease and BPPV. Ménière disease, which is caused by an overaccumulation of endolymph, is characterized by severe, disabling episodes of tinnitus, feelings of ear fullness, and violent rotary vertigo. BPPV is thought to be caused by free-floating particles in the posterior semicircular canal. It presents as a sudden onset of dizziness or vertigo that is provoked by certain changes in head position. Among the methods used in treatment of the vertigo that accompanies vestibular disorders are habituation exercises (for BPPV) and antivertigo drugs.

REVIEW EXERCISES

1. The mother of a 3-year-old boy notices that his left eye is red and watering when she picks him up from day care. He keeps rubbing his eye as though it itches. The next morning, however, she notices that both eyes are red, swollen, and watering. Being concerned, she takes him to the pediatrician in the morning and is told that he has "pink eye." She is told that the infection should go away by itself.

A. What part of the eye is involved?
B. What type of conjunctivitis do you think this child has (bacterial, viral, or allergic)?
C. Why didn't the pediatrician order an antimicrobial drug?
D. Is the condition contagious? What measures should she take to prevent its spread?

2. During a routine eye examination to get new glasses because she had been having difficulty with her distant vision, a 75-year-old woman is told that she is developing cataracts.

A. What types of visual changes occur as the result of a cataract?
B. What can the woman do to prevent the cataracts from getting worse?
C. What treatment may she eventually need?

3. A 50-year-old woman is told by her eye doctor that her intraocular pressure is slightly elevated and that although there is no evidence of damage to her eyes at this time, she is at risk for developing glaucoma and should have regular eye examinations.

A. Describe the physiologic mechanisms involved in the regulation of intraocular pressure.
B. Differentiate between open-angle and angle-closure glaucoma in terms of their pathology, manifestations, and treatment.
C. Use Figure 38-7 to relate the "optic disk cupping" that occurs with glaucoma to the visual field loss that occurs with the disorder.

4. The parents of a newborn infant have been told that their son has congenital cataracts and will require cataract surgery to prevent losing his sight.

A. Explain why the infant is at risk for losing his sight if the cataracts are not removed.
B. When should this procedure be done to prevent loss of vision?

5. A mother notices that her 13-month-old child is fussy and tugging at his ear and refuses to eat his breakfast. When she takes his temperature, it is 100°F. Although the child attends day care, his mother has kept him home and made an appointment with the child's pediatrician. In the physician's office, his temperature is 100.2°F, he is somewhat irritable, and he has a clear nasal drainage. His left tympanic membrane shows normal landmarks and motility on pneumatic otoscopy. His right tympanic membrane is erythematous and there is decreased motility on pneumatic otoscopy.

A. What risk factors are present that predispose this child to the development of acute otitis media?
B. Are his signs and symptoms typical of otitis media in a child of this age?
C. What are the most likely pathogens? What treatment would be indicated?
D. Later in the week, the mother notices that the child does not seem to hear as well as he did before developing the infection. Is this a common occurrence, and should the mother be concerned about transient hearing loss in a child of this age?

6. A granddaughter is worried that her grandfather is "losing his hearing." Lately, he has been staying away from social gatherings that he always enjoyed, saying everybody mumbles. He is defiant in maintaining that there is nothing wrong with his hearing. However, he does complain that his ears have been ringing a lot lately.

A. What are common manifestations of hearing loss in the elderly?
B. What type of evaluation would be appropriate for determining if this man has a hearing loss, and the extent of his hearing loss?
C. What are some things the granddaughter might do so that her grandfather could hear her better when she is talking to him?

7. A 70-year-old man complains that he gets this terrible feeling "like the room is moving around" and becomes nauseated when he rolls over in bed or bends over suddenly. It usually goes away once he has been up for a while. He has been told that his symptoms are consistent with benign paroxysmal positional vertigo.

A. What is the pathophysiology associated with this man's vertigo?
B. Why do the symptoms subside once he has been up for a while?
C. What methods are available for treatment of the disorder?

Chapter 39

Disorders of the Male Genitourinary System

The male genitourinary system is subject to a number of structural and functional disorders, all of which can affect urine elimination, sexual function, and fertility. This chapter is divided into three parts: (1) the physiologic basis of male reproductive function, including hormone production, spermatogenesis, and neural control of sexual function; (2) disorders of the male genitourinary structures, including the penis, scrotum and testes, and prostate gland; and (3) disorders of childhood and changes that occur as a result of the aging process.

Physiologic Basis of Male Reproductive Function

The male genitourinary system is composed of the paired gonads, or testes; genital ducts; accessory genital organs; and penis (Fig. 39-1). The testes function in the production of androgens or male sex hormones and spermatozoa; the ductile system aids in the storage and transport of spermatozoa; and the accessory genital organs produce the fluid constituents of semen. The penis functions in both urine elimination and sexual function.

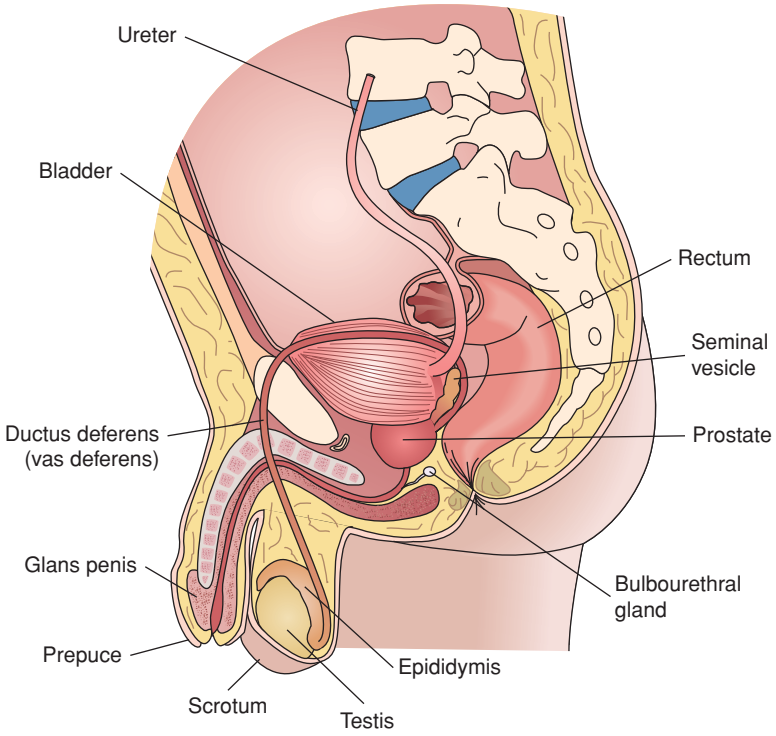

FIGURE 39-1. Structures of the male reproductive system, including the testes, the scrotum, and the excretory ducts.

Testicular Function

The two primary functions of the testes or male gonads are *steroidogenesis*, or synthesis of androgens or male sex hormones, and *spermatogenesis*, or sperm production.[1–3] The testes are paired ovoid organs that lie within the scrotum, which hangs outside the abdominal cavity. The testes are surrounded by two tunics. The outer tunic is the two-layered tunica vaginalis derived from the peritoneum. Deep to this is the *tunica albuginea*, the dense connective tissue capsule of the testes (Fig. 39-2). Septal extensions of the tunica albuginea divide the testes into 200 to 300 wedge-shaped compartments or lobules. Each lobule contains one to four tightly coiled *seminiferous tubules*, in which sperm are produced, and a connective tissue stroma, in which the androgen-producing *Leydig* or *interstitial cells* are located.

Male Reproductive System

- The male genitourinary system functions in both urine elimination and reproduction.
- The testes function in both production of male germ cells (spermatogenesis) and secretion of the male sex hormone, testosterone.
- The ductile system (epididymides, vas deferens, and ejaculatory ducts) transports and stores sperm, and assists in their maturation; and the accessory glands (seminal vesicles, prostate gland, and bulbourethral glands) prepare the sperm for ejaculation.
- Sperm production requires temperatures that are 2°C to 3°C below body temperature. The position of the testes in the scrotum and the unique blood flow cooling mechanisms provide this environment.
- The urethra, which is enclosed in the penis, is the terminal portion of the male genitourinary system. Because it conveys both urine and semen, it serves both urinary and reproductive functions.

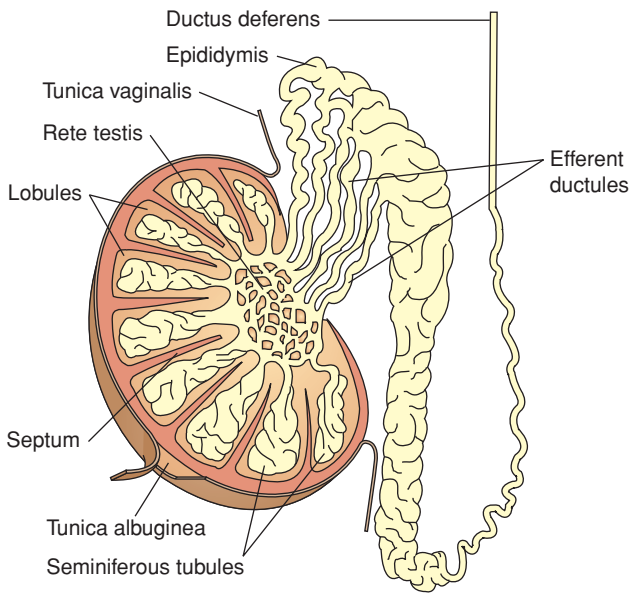

FIGURE 39-2. The parts of the testes and epididymis.

Hormone Production

The testes produce several male sex hormones, including *testosterone, dihydrotestosterone,* and *androstenedione.*[1–3] Testosterone, which is the most abundant of these hormones, is considered the main testicular hormone. The adrenal cortex also produces androgens, albeit in much smaller quantities (<5% of the total male androgens) than the testes. Larger amounts of testosterone are formed from dihydrotestosterone and androstenedione in other tissues of the body, especially the liver.[1] In addition to testosterone, small amounts of estrogens are formed in the male. Some of this estrogen, thought to be formed from testosterone, plays an important role in spermatogenesis.

Testosterone is metabolized in the liver and excreted by the kidneys. In the bloodstream, testosterone exists in an unbound (free) or a bound form. The bound form is attached to plasma proteins, including albumin and the sex hormone–binding protein produced by the liver. Only approximately 3% of circulating testosterone is unbound and therefore able to enter the cell and exert its metabolic effects.[1] Much of the testosterone that becomes fixed to the tissues is converted to dihydrotestosterone, especially in certain target tissues such as the prostate gland. Some of the actions of testosterone depend on this conversion, whereas others do not.

Testosterone exerts a number of biologic effects in the male (Chart 39-1). In the male embryo, testosterone is essential for appropriate differentiation of the internal and external genitalia, and it is necessary for descent of the testes in the fetus. Testosterone is essential to the development of primary and secondary male sex characteristics during puberty and for the maintenance of these characteristics during adult life. It causes growth of pubic, chest, and facial hair; it produces changes in the larynx that result in the male bass voice; and it increases the thickness of the skin and the activity of the sebaceous glands, predisposing to acne.

Most of the actions of testosterone and other androgens result from increased protein synthesis in target tissues.

CHART 39-1 Main Actions of Testosterone

- Induces differentiation of the male genital tract during fetal development
- Induces development of primary and secondary sex characteristics
  - Gonadal function
  - External genitalia and accessory organs
  - Male voice timbre
  - Male skin characteristics
  - Male hair distribution
- Anabolic effects
  - Promotes protein metabolism
  - Promotes musculoskeletal growth
  - Influences subcutaneous fat distribution
- Promotes spermatogenesis (in FSH-primed tubules) and maturation of sperm
- Stimulates erythropoiesis

Androgens function as anabolic agents in males and females to promote metabolism and musculoskeletal growth. Testosterone and the androgens have a great effect on the development of increasing musculature during puberty, with boys averaging approximately 50% more of an increase in muscle mass than girls.[1]

Spermatogenesis and Semen Production

Spermatogenesis, which occurs in the seminiferous tubules of the testes, is the sequence of events that leads to the formation of male germ cells or spermatozoa. The process begins shortly before puberty and continues throughout a man's life.

The seminiferous tubules are composed of two types of cells: Sertoli cells and spermatogenic cells[1–3] (Fig. 39-3A). Sertoli cells are tall columnar cells with extensive

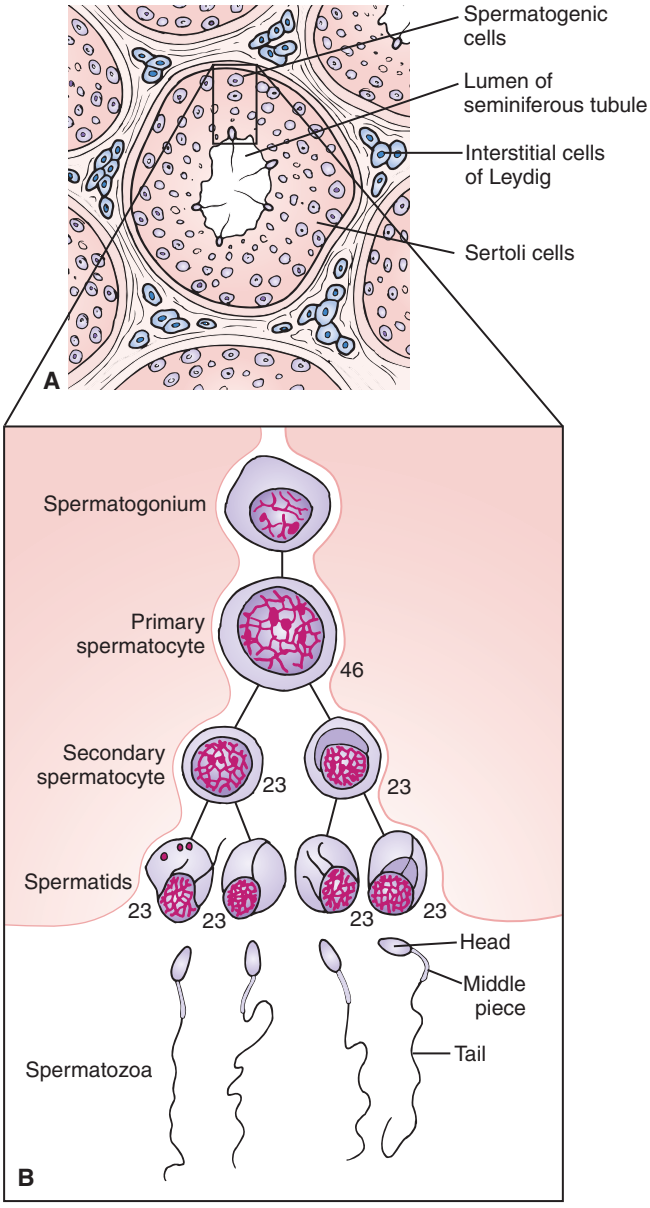

FIGURE 39-3. **(A)** Cross-section of seminiferous tubule and **(B)** stages of development of spermatozoa. (46, 23 = number of chromosomes.)

cytoplasmic processes that surround the spermatogenic cells and form tight junctions with other Sertoli cells. Also known as *supporting* or *sustentacular cells*, Sertoli cells provide structural organization for the tubules; they supply both physical and nutritional support for the developing germ cells; and their tight junctions prevent the passage of proteins from the interstitial space into the lumen of the seminiferous tubules, thus forming a blood-testis barrier.[2,3] In addition, these cells have been shown to be responsible for the movement of spermatozoa from the base of the tubule toward the lumen and for the release of mature sperm into the lumen. They also phagocytose damaged germ cells and residual bodies formed during the last stage of spermatogenesis. Finally, in response to follicle-stimulating hormone (FSH) or testosterone, the Sertoli cells secrete androgen-binding protein. This substance, which has a high affinity for androgens, provides high concentrations of testosterone to the developing germ cells during spermatogenesis.

Spermatogenic cells, the source of spermatozoa, are organized in poorly defined layers of progressive development between adjacent Sertoli cells. Both spermatogenesis and oogenesis, its counterpart in the female, involve a unique kind of nuclear division in which the chromosome number is reduced from 46 to 23 (see Chapter 5). The process of spermatogenesis begins with the spermatogonial phase, during which the spermatogonia undergo mitotic division to form more spermatogonia as well as primary spermatocytes (Fig. 39-3B). During the next phase of spermatogenesis, the primary spermatocyte undergoes meiotic division during which its 46 chromosomes (23 pairs) are divided so that 23 chromosomes go to one secondary spermatocyte and the other 23 to another secondary spermatocyte. During the final stage of spermatogenesis, the secondary spermatocytes divide to form spermatids, which develop into mature spermatozoa or sperm cells.

Ductile Transport. After their development in the seminiferous tubules, the spermatozoa move into a highly convoluted network of ducts called the *rete testis* (Fig. 39-2). The spermatozoa are then transported through the efferent ductules and into a single duct called the *epididymis*, which is the final site for sperm maturation.[1,2] The epididymis also serves as a reservoir for sperm. Sperm can be stored in the epididymis for several months. If held longer they are eventually phagocytized by the epithelial cells of the epididymis. When the male is sexually stimulated and ejaculates, the smooth muscle in the wall of the epididymis contracts vigorously, moving sperm into the next segment of the ductal system, the *ductus deferens*, also called the *vas deferens* (Fig. 39-4). The ductus deferens ascends along the posterior border of the testes and then enters the abdomen in the spermatic cord, which serves as a conduit for all of the structures passing to and from the testes. After leaving the spermatic cord, the ductus deferens descends in the pelvis to the level of the bladder, where its distal end enlarges to form the *ampulla*. Surgical disconnection of the vas deferens in the scrotal area (i.e., vasectomy) serves as an effective method of male contraception. Because sperm are stored in the ampulla, men can remain fertile for 4 to 5 weeks after performance of a vasectomy.

Accessory Genital Glands. The accessory genital glands include the paired seminal vesicles and bulbourethral glands and the single prostate gland (Fig. 39-1).[1,2] These glands secrete fluids that form the bulk of the ejaculatory fluid or semen.

The seminal vesicles, which lie on the posterior wall of the bladder, consist of highly tortuous tubes that secrete

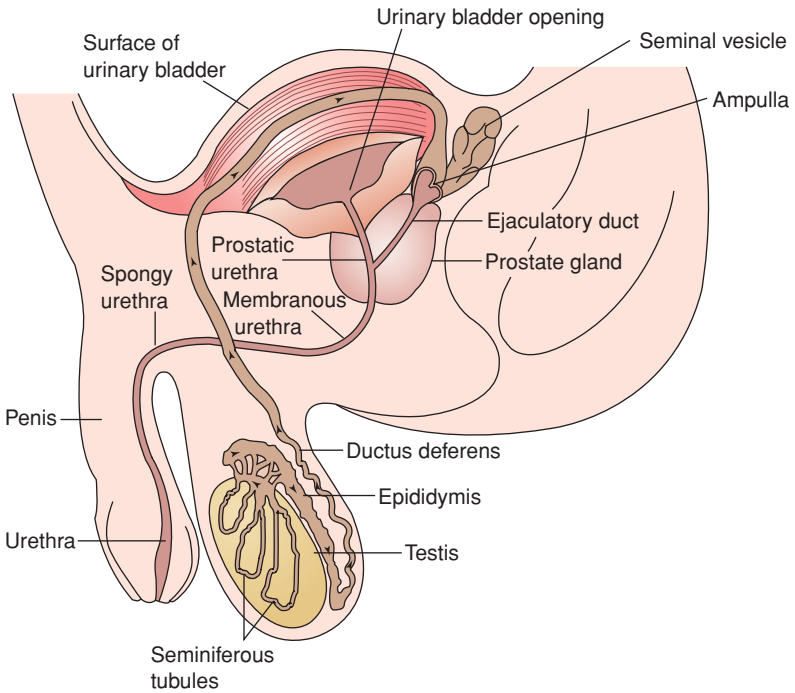

FIGURE 39-4. The excretory ducts of the male reproductive system and the path that sperm follows as it leaves the testis and travels to the urethra.

fluid for the semen. Each of the paired seminal vesicles is lined with secretory epithelium containing an abundance of fructose, prostaglandins, and several other proteins. The fructose secreted by the seminal vesicles provides the energy for sperm motility. The prostaglandins are thought to assist in fertilization by making the cervical mucus more receptive to sperm and by causing reverse peristaltic contractions in the uterus and fallopian tubes to move the sperm toward the ovaries. A short excretory duct from the each seminal vesicle combines with the ampulla of the ductus deferens to form the ejaculatory duct, which enters the posterior part of the prostate and continues through until it ends in the prostatic portion of the urethra. Contraction of the smooth muscle coat of the seminal vesicles during ejaculation discharges their secretion into the ejaculatory ducts and helps to flush sperm out of the urethra.

The prostate, which is the largest of the accessory glands, is located in the pelvis, inferior to the bladder, where it surrounds the prostatic portion of the urethra. The prostate gland secretes a thin, milky, alkaline fluid containing citric acid, calcium, acid phosphate, a clotting enzyme, and a profibrinolysin.[2] During ejaculation, the capsule of the prostate contracts, and the added fluid increases the bulk of the semen. Both vaginal secretions and the fluid from the vas deferens are strongly acidic. Because sperm mobilization occurs at a pH of 6.0 to 6.5, the alkaline nature of the prostatic secretions is essential for successful fertilization of the ovum.

The bulbourethral glands are peanut-sized glands located on either side of the membranous urethra. A duct of each gland joins the initial portion of the penile urethra. The glands, which structurally resemble mucus-secreting glands, produce a clear mucuslike secretion.[2] Sexual stimulation causes release of the secretion, which constitutes the major portion of the preseminal fluid and serves to lubricate the penile urethra.

Hypothalamic/Pituitary Control of Testicular Function

The hypothalamus and the anterior pituitary gland play an essential role in promoting spermatogenesis in the testes and maintaining the endocrine function of the testes by means of the gonadotropic hormones (i.e., anterior pituitary hormones that promote the function and growth of the testes in the male).[1,3] The synthesis and release of the gonadotropic hormones from the pituitary gland are regulated by gonadotropin-releasing hormone (GnRH), which is synthesized by the hypothalamus and secreted into the hypothalamohypophysial portal circulation (Fig. 39-5).

Two gonadotropic hormones are secreted by the pituitary gland: FSH and luteinizing hormone (LH). In the male, LH also is called *interstitial cell–stimulating hormone*. The production of testosterone by the interstitial cells of Leydig is regulated by LH. FSH binds selectively to Sertoli cells surrounding the seminiferous tubules, where it functions in the initiation of spermatogenesis. Under the influence of FSH, Sertoli cells produce androgen-binding protein, plasminogen activator, and inhibin.

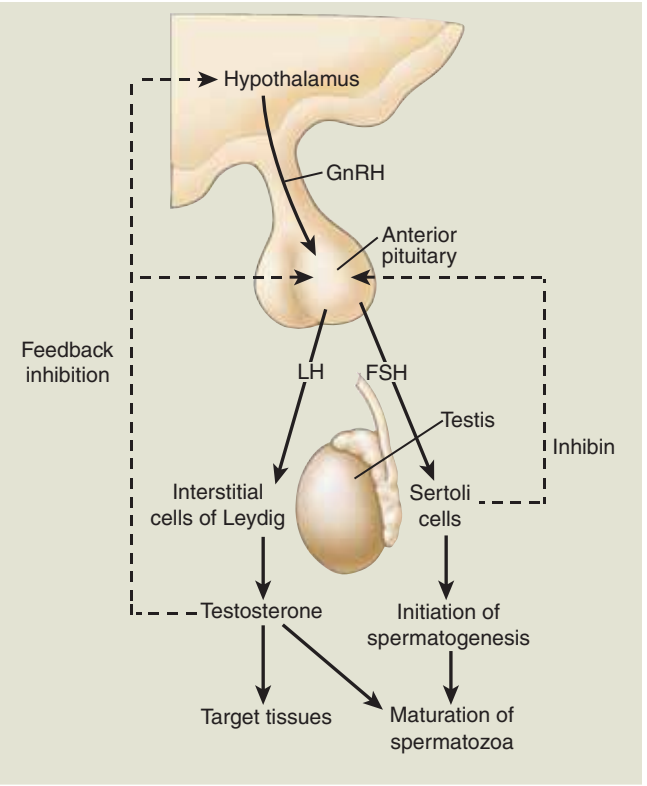

FIGURE 39-5. Hypothalamic-pituitary feedback control of spermatogenesis and testosterone levels in the male. The *dashed line* represents negative feedback. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

Androgen-binding protein binds testosterone and serves as a carrier and storage site for testosterone in Sertoli cells. Although FSH is necessary for the initiation of spermatogenesis, full maturation of the spermatozoa requires testosterone. Androgen-binding protein also serves as a carrier of testosterone from the testes to the epididymis. Plasminogen activator, which converts plasminogen to plasmin, functions in the final detachment of mature spermatozoa from Sertoli cells.

Circulating levels of the gonadotropic hormones are regulated in a negative feedback manner by testosterone.[1,3] High levels of testosterone suppress LH secretion through a direct action on the pituitary and an inhibitory effect on the hypothalamus. FSH is thought to be inhibited by a substance called *inhibin,* produced by Sertoli cells. Although two forms of inhibin have been identified, only inhibin B has been found in males.[3] Inhibin suppresses FSH release from the pituitary gland without effecting LH release. The pituitary gonadotropic hormones and Sertoli cells in the testes form a classic negative feedback loop in which FSH stimulates inhibin secretion and increased inhibin levels suppress FSH release from the hypothalamus. Unlike the cyclic hormonal pattern in the woman, in the man, FSH, LH, and testosterone secretion and spermatogenesis occur at relatively unchanging rates during adulthood.

Neural Control of Male Sexual Function

The penis is the male external genital organ through which the urethra passes. It functions both as a sexual organ and as an organ of urine elimination. Anatomically, the external penis consists of a shaft that ends in a tip called the *glans* (Fig. 39-1). The loose skin of the penis shaft folds to cover the glans, forming what is called the *prepuce*, or *foreskin*. It is the foreskin that is removed during circumcision. The glans of the penis contains many sensory nerves, making this the most sensitive portion of the penile shaft. The cylindrical body or shaft of the penis is composed of three masses of erectile tissue held together by fibrous strands and covered with a thin layer of skin (Fig. 39-6B). The two dorsal masses of tissue are called the *corpora cavernosa* and the third ventral mass, in which the spongy part of the urethra is enclosed, is called the *corpus spongiosum*.[2] The corpora cavernosa and corpus spongiosum are cavernous sinuses that normally are relatively empty but become engorged with blood during penile erection.

The physiology of the male sex act involves a complex interaction between autonomic nervous system–mediated spinal cord reflexes, higher neural centers, and the vascular system[1,2] (Fig. 39-6A). It involves erection, emission, ejaculation, and detumescence. *Erection* involves increased inflow of blood into the corpora cavernosa and penile rigidity, *emission* is the contraction of the vas deferens and ampulla with expulsion of sperm into the internal urethra, and *ejaculation* is the expulsion of semen from the urethra. *Detumescence*, or penile relaxation, results from outflow of blood from the corpora cavernosa.

The penis is innervated by both the autonomic and somatic nervous systems. In the pelvis, the sympathetic and parasympathetic components of the autonomic nervous system merge to form what are called the *cavernous nerves*.[4] Erection is under the control of the parasympathetic nervous system, and ejaculation and detumescence are under the control of the sympathetic nervous system. Somatic innervation, which occurs through the pudendal nerve, is responsible for penile sensation and contraction and relaxation of the extracorporeal striated bulbocavernosus and ischiocavernous muscles.

Erection is a neurovascular process involving the autonomic nervous system, neurotransmitters and endothelial relaxing factors, the vascular smooth muscle of the arteries and veins supplying the penile tissue, and the trabecular smooth muscle of the sinusoids of the corpora cavernosa.[4] It involves increased inflow of blood into the corpora cavernosa due to relaxation of the trabecular smooth muscle that surrounds the sinusoidal spaces and compression of the veins controlling outflow of blood from the venous plexus. Erection is mediated by parasympathetic impulses that pass from the sacral segments of the spinal cord through the pelvic nerves to the penis. Parasympathetic stimulation results in release of nitric oxide, a nonadrenergic-noncholinergic neurotransmitter,

Disorders of Penile Erection

- Erection is a neurovascular process involving the autonomic nervous system, the somatic nervous system by way of the pudendal nerve, the vascular system, and the sinusoidal spaces of the corpora cavernosa.
- Parasympathetic innervation through the pelvic nerves initiates relaxation of the trabecular smooth muscle of the corpora cavernosa through the action of nitric oxide, the inflow of arterial blood, and cessation of venous outflow.
- Erectile failure can result from disorders in one or a combination of the neural, vascular, or chemical mediator aspects of the erectile process.
- Priapism is an abnormal, painful, sustained erection that can lead to ischemic damage of penile structures. It can occur at any age and is one of the possible complications of sickle cell disease.

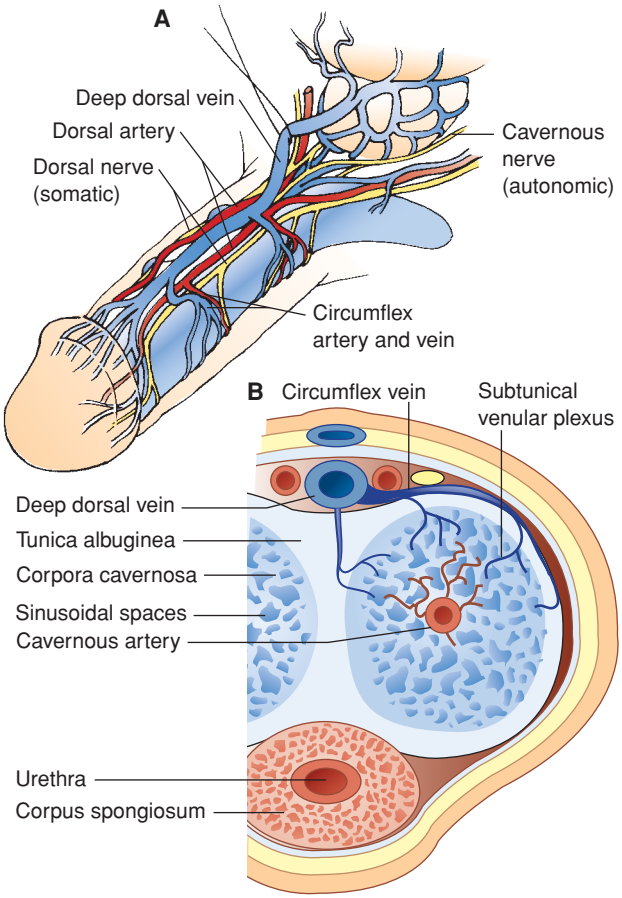

FIGURE 39-6. Anatomy and mechanism of penile erection. **(A)** Innervation and arterial and venous blood supply to penis. **(B)** Cross-section of penis, showing the corpus spongiosum and the sinusoidal system of the corpora cavernosa.

which causes relaxation of the trabecular smooth muscle of the corpora cavernosa. This relaxation permits the inflow of blood into the sinuses of the cavernosa at pressures approaching those of the arterial blood pressure. Because the erectile tissues of the cavernosa are surrounded by a nonelastic fibrous covering, high pressure in the sinusoids causes ballooning of the erectile tissue to such an extent that the penis becomes hard and elongated. At the same time, contraction of the somatic-innervated ischiocavernous muscles forcefully compresses the blood-filled corpora cavernosa, producing a further increase in intercavernous pressures. During this phase of erection, inflow and outflow of blood cease.

Parasympathetic innervation must be intact and nitric oxide synthesis must be active for erection to occur. Nitric oxide activates guanyl cyclase, an enzyme that increases the concentration of cyclic guanosine monophosphate (cGMP), which in turn causes smooth muscle relaxation. Other smooth muscle relaxants (e.g., prostaglandin E_1 analogs and α-adrenergic antagonists), if present in high enough concentrations, can independently cause sufficient cavernosal relaxation to result in erection.[4] Many of the drugs that have been developed to treat erectile dysfunction act at the levels of these mediators.[5,6]

Detumescence or penile relaxation is largely a sympathetic nervous system response. It results from a cessation of neurotransmitter release, the breakdown of second messengers such as cGMP, or sympathetic discharge during ejaculation. Contraction of the trabecular smooth muscle opens the venous channels so that the trapped blood can be expelled and penile flaccidity can return.

Erectile Dysfunction

Erectile dysfunction is defined as the inability to achieve and maintain an erection sufficient to permit satisfactory sexual intercourse.[7] It has been estimated that the disorder affects about 150 million men worldwide.[6] Erectile dysfunction is commonly classified as psychogenic, organic, or mixed psychogenic and organic.[5,6,8] Organic etiologies are the most common.

Psychogenic causes of erectile dysfunction include performance anxiety, a strained relationship with a sexual partner, depression, and overt psychotic disorders such as schizophrenia. Depression is a common cause of erectile dysfunction.[5,8] Psychogenic factors can be further exacerbated by the side effects of many of the therapies used to treat these disorders, which can themselves cause erectile dysfunction.

Organic causes span a wide range of pathologic processes. They include neurogenic, hormonal, vascular, drug-induced, and penile-related etiologies. Neurogenic disorders such as Parkinson disease, stroke, and cerebral trauma often contribute to erectile dysfunction by decreasing libido or preventing the initiation of erection. In spinal cord injury, the extent of neural impairment depends on the level, location, and extent of the lesion. Somatosensory innervation of the genitalia is essential to the reflex mechanisms involved in erection; this becomes important with aging and conditions such as diabetes that impair peripheral nerve function. Extensive pelvis surgery, especially radical prostatectomy (even so-called "nerve-sparing" procedures), are common causes of erectile dysfunction due to both direct and indirect nerve damage.

Hormonal causes of erectile dysfunction include a decrease in androgen levels because of both primary and secondary hypogonadism. Androgen levels may be decreased because of aging (andropause). Hyperprolactinemia from any cause interferes with both reproduction and erectile function. This is because prolactin acts centrally to inhibit the release of the hypothalamic GnRH that controls the release of the pituitary gonadotropic hormones, LH and FSH. Elevated prolactin levels may also interfere with normal functioning at the level of the gonad.

Common risk factors for generalized penile arterial insufficiency include hypertension, hyperlipidemia, cigarette smoking, diabetes mellitus, and pelvic irradiation.[8] In hypertension, erectile function is impaired not so much by the increased blood pressure as by the associated stenotic arterial lesions. Focal stenosis of the common penile artery most often occurs in men who sustained blunt pelvic or perineal trauma (e.g., from bicycling accidents). Failure of the veins to close completely during an erection (veno-occlusive dysfunction) may occur in men with large venous channels that drain the corpora cavernosa. Other disorders that impair venous occlusion are degenerative changes involving the tunica albuginea, as in Peyronie disease.

Many drugs are reported to cause erectile dysfunction, including antidepressant, antipsychotic, antiandrogen, and antihypertensive medications.[5,6,8] Cigarette smoking can induce vasoconstriction and penile venous leakage because of its effects on cavernous smooth muscle and can double the risk of erectile dysfunction.[8] Alcohol in small amounts may increase libido and improve erection; however, in large amounts it can cause central sedation, decreased libido, and transient erectile dysfunction.

Aging is known to increase the risk of erectile dysfunction.[9] After 50 years of age, the overall prevalence of erectile dysfunction is reported to be greater than 50%.[10] Many of the pathologic processes that contribute to erectile dysfunction are more common in older men, including diabetes, hyperlipidemia, vascular disease, and the long-term effects of cigarette smoking. Age-related declines in testosterone may also play a role (andropause). Psychosocial problems such as depression, esteem issues, partner relationships, history of substance abuse, and anxiety and fear of performance failure also may contribute to erectile dysfunction in older men.[10]

A diagnosis of erectile dysfunction requires careful history (medical, sexual, and psychosocial), physical examination, and laboratory tests aimed at determining what other tests are needed to rule out organic causes of the disorder. Because many medications, including prescribed, over-the-counter, and illicit drugs, can cause erectile dysfunction, a careful drug history is indicated.

Erectile dysfunction is now recognized as a marker for cardiovascular disease, and is now considered a component of the metabolic syndrome (a collection of cardiovascular risk factors; see Chapter 33).[5,6,11,12] The association between erectile dysfunction and the metabolic syndrome

may be related to the underlying endothelial dysfunction seen in both conditions (see Chapter 18). Men with erectile dysfunction should be evaluated for coexisting vascular disease and cardiovascular risk factors should be modified or treated (e.g., smoking, diabetes, hypertension, and hyperlipidemia).[5,6,11]

Treatment methods include psychosexual counseling, androgen replacement therapy (when androgen deficiency is confirmed), oral and intracavernous drug therapy, vacuum constriction devices, and surgical treatment (prosthesis and vascular surgery).[5,6,8] Among the commonly prescribed drugs used for the treatment of erectile dysfunction are the selective inhibitors of phosphodiesterase type 5 (PDE-5), the enzyme that inactivates cGMP (sildenafil, vardenafil, and tadalafil). These drugs act by facilitating corporeal smooth muscle relaxation in response to sexual stimulation. The concomitant use of PDE-5 inhibitors and nitrates (used, for example, in ischemic heart disease) is absolutely contraindicated because of the risk of profound hypotension.[11] The PDE-5 inhibitors are taken orally. Alprostadil, a prostaglandin E_1 analog, acts by producing relaxation of cavernous smooth muscle. It is either injected directly into the cavernosa (with diffusion into the opposite cavernosa) or placed in the urethra as a minisuppository. Phentolamine (α_2-adrenergic receptor antagonist) and papaverine (smooth muscle relaxant) are also administered by intracavernous injection.

In summary, the male genitourinary system consists of the testes, genital ducts, accessory genital organs, and penis. The testes or male gonads are divided into lobules that consist of *seminiferous tubules,* in which sperm are produced, and the *Leydig* or *interstitial cells* that produce male sex hormones, mainly testosterone. Testosterone is essential for differentiation of the internal and external genitalia in the male embryo, descent of the testes in the fetus, development of primary and secondary male sex characteristics during puberty, and maintenance of these characteristics during adult life.

Spermatogenesis, which occurs in the seminiferous tubules of the testes, is the sequence of events that leads to the production of spermatozoa or male germ cells. The seminiferous tubules are composed of two types of cells: Sertoli cells, which surround and provide physical and nutritional support for the developing germ cells, and the spermatogenic cells, which develop into mature male germ cells or spermatozoa. After formation in seminiferous tubules, the spermatozoa travel through the efferent tubules to the epididymis, then to the ductus deferens, and on to the ampulla, where they are stored until released through the penis during ejaculation. The seminal vesicles, bulbourethral glands, and prostate gland are accessory genital glands that secrete fluids that form the bulk of the male ejaculate or semen.

The function of the male reproductive system is under the negative feedback control of the hypothalamus and the anterior pituitary gonadotropic hormones—FSH and LH. Spermatogenesis is initiated by FSH, and the production of testosterone is regulated by LH.

The male sex act involves erection, emission, ejaculation, and detumescence. The physiology of these functions involves a complex interaction between autonomic-mediated spinal cord reflexes, higher neural centers, and the vascular system. Erection is mediated by the parasympathetic nervous system and emission and ejaculation by the sympathetic nervous system. Erectile dysfunction is defined as the inability to achieve and maintain an erection sufficient to permit satisfactory sexual intercourse. It can be due to psychogenic factors, organic disorders, or mixed psychogenic and organic conditions. Erectile dysfunction is now recognized as a marker for cardiovascular disease and men with the disorder should be evaluated for coexisting vascular disease.

Disorders of the Penis, the Scrotum and Testes, and the Prostate

Disorders of the Penis

Disorders of the penis include congenital defects (discussed in the section on disorders of childhood), acute and chronic inflammatory conditions, Peyronie disease, priapism, and neoplasms.

Inflammation and Infection

The term *balanitis* refers to local inflammation of the glans penis and *balanoposthitis* to inflammation of the glans penis and overlying prepuce.[13–15] The condition may result from trauma, irritation, or infection caused by a wide array of organisms. Among the most common infectious agents are *Candida albicans*, anaerobic bacteria, and pyogenic bacteria. A significant number of inflammatory conditions are caused by sexually transmitted infections (see Chapter 41). Balanitis due to *C. albicans* infection may be a presenting feature or result from poorly controlled diabetes mellitus.

Acute superficial balanoposthitis is characterized by erythema of the glans and prepuce. An exudate in the form of malodorous discharge may be present. It usually is encountered in males with phimosis (a tight foreskin) or a large, redundant prepuce that interferes with cleanliness and predisposes to bacterial growth in the accumulated secretions and smegma (i.e., debris from the desquamated epithelia). Extension of the erythema and edema may lead to extensive scarring and a condition called *phimosis*, in which the prepuce cannot be retracted easily over the glans prepuce. When the stenotic prepuce is forcibly retracted over the glans prepuce, the circulation can be compromised causing congestion, swelling, and pain, a condition known as *paraphimosis*.

Balanitis xerotica obliterans is a chronic, sclerosing, atrophic process of the glans penis that occurs in uncircumcised men. It is clinically and histologically similar

to the lichen sclerosus that is seen in women[15] (see Chapter 40). Typically, the lesions consist of grayish-white plaques on the surface of the glans penis and the prepuce. The foreskin is thickened and fibrous and is not retractable. Although balanitis xerotica obliterans was once considered a benign condition, it has been associated with several reports of penile cancer and is now recognized as a precancerous state.[16] Treatment measures include circumcision and topical or intralesional injections of corticosteroids.[13]

Peyronie Disease

Peyronie disease involves a localized and progressive fibrosis of unknown origin that affects the tunica albuginea (i.e., the tough, fibrous sheath that surrounds the corpora cavernosa) of the penis. It is named after Francois de la Peyronie, who in 1743 described a patient who had "rosary beads of scar tissue to cause upward curvature of the penis during erection."[17,18] The disorder is characterized initially by an inflammatory process that results in dense fibrous plaque formation. The plaque usually is on the dorsal midline of the shaft, causing upward bowing of the shaft during erection (Fig. 39-7). Some men may develop scarring on both the dorsal and ventral aspects of the shaft, causing the penis to be straight but shortened or have a lateral bend. The fibrous tissue prevents lengthening of the involved area during erection, making intercourse difficult and painful. The disease usually occurs in middle-aged or elderly men.

The manifestations of Peyronie disease include painful erection, bent erection, and the presence of a hard mass at the site of fibrosis. Approximately two thirds of men complain of pain as a symptom. The pain is thought to be generated by inflammation of the adjacent fascial tissue and usually disappears as the inflammation resolves. During the first year or so after formation of the plaque, while the scar tissue is undergoing the process of remodeling, penile distortion may increase, remain static, or resolve and disappear completely. In some cases, the scar tissue may progress to calcification and formation of bonelike tissue.

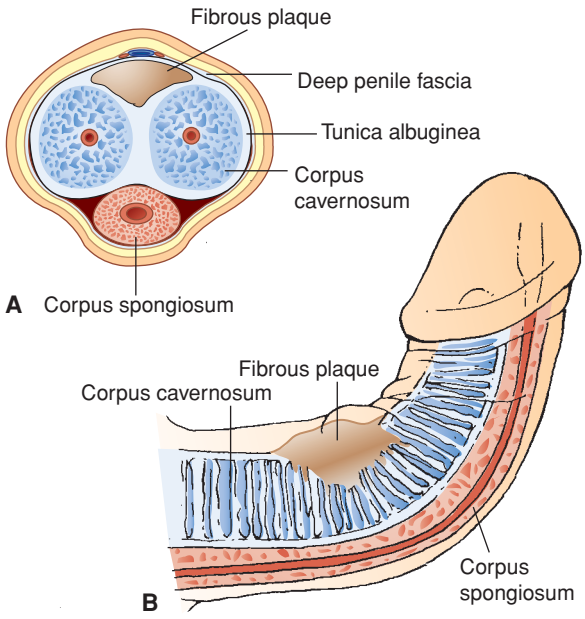

FIGURE 39-7. Peyronie disease. **(A)** Penile cross-section showing plaque between the corpora. **(B)** Penile curvature.

Diagnosis is based on history and physical examination. Doppler ultrasonography may be used to assess the cause of the disorder. Although surgical intervention can be used to correct the disorder, it often is delayed because in many cases the disorder is self-limiting. Less invasive treatments include the administration of oral agents with antioxidant properties (e.g., vitamin E, colchicine) and intralesional treatments, including corticosteroids.

Priapism

Priapism is an involuntary, prolonged (>4 hours), abnormal and painful erection that continues beyond, or is unrelated to, sexual stimulation.[19,20] Priapism is a true urologic emergency because the prolonged erection can result in ischemia and fibrosis of the erectile tissue with significant risk of subsequent impotence. Priapism can occur at any age, in the newborn as well as other age groups. Sickle cell disease or neoplasms are the most common cause in boys between 5 and 10 years of age.[21]

Priapism is caused by impaired blood flow in the corpora cavernosa of the penis. Priapism is classified as primary (idiopathic) or secondary to a disease or drug effect. Secondary causes include hematologic conditions (e.g., leukemia, sickle cell disease, polycythemia), neurologic conditions (e.g., stroke, spinal cord injury), and renal failure. Between 6% and 42% of males with sickle cell disease are affected at some stage by priapism.[21] The relative deoxygenation and stasis of cavernosal blood during erection is thought to increase sickling. Various medications, such as erectile dysfunction drugs, antihypertensive drugs, anticoagulant drugs, antidepressant agents, alcohol, and marijuana, can contribute to the development of priapism. Currently, intracavernous injection therapy for erectile dysfunction is one of the more common causes of priapism.

The diagnosis of priapism usually is based on clinical findings. Color Doppler studies of penile blood flow, penile ultrasonography, and computed tomography (CT) scans may be used to determine intrapelvic pathology. Initial treatment measures include analgesics, sedation, and hydration. Urinary retention may necessitate catheterization. Local measures include ice packs and cold saline enemas, aspiration and irrigation of the corpus cavernosum with plain or heparinized saline, or instillation of α-adrenergic drugs. If less aggressive treatment does not produce detumescence, a temporary surgical shunt may be established between the corpus cavernosum and the corpus spongiosum.

The prognosis for whether fibrosis or erectile failure will occur is determined by the severity and duration of blood stasis. Persistent stasis priapism is known to result in impaired erectile function and tissue fibrosis unless resolved within 24 to 48 hours of onset.[20]

Neoplasms of the Penis

Although relatively rare (<1% of male genital tumors) in developed countries of the world, cancer of the penis may account for 10% to 20% of all genital malignancies in areas such as Africa and South America.[22] When it is diagnosed early, penile cancer is highly curable. The greatest hindrance to early diagnosis is a delay in seeking medical attention.

The cause of penile cancer is unknown.[16,22,23] Several risk factors have been proposed, including poor genital hygiene, human papillomavirus (HPV) infection, ultraviolet radiation exposure, increasing age, and immunodeficiency states. Circumcision confers protection, and hence cancer of the penis is extremely rare in men circumcised at birth.[14,15] It is thought that circumcision is associated with better genital hygiene, which, in turn, reduces exposure to carcinogens that may accumulate in smegma and decreases the likelihood of potentially oncogenic strains of HPV. Ultraviolet radiation is thought have a carcinogenic effect on the penis.[23] Men who were treated for psoriasis with ultraviolet A radiation (i.e., PUVA) have had a reported increased incidence of genital squamous cell carcinomas. Because of this observation, it is suggested that men should shield their genital area when using tanning salons. Immunodeficiency states (e.g., acquired immunodeficiency syndrome [AIDS]) also may play a role in the pathogenesis of penile cancer.[16,23] Dermatologic lesions with precancerous potential include balanitis xerotica obliterans (discussed under penile inflammatory conditions) and giant condylomata acuminata.[22] Giant condylomata acuminata, or genital warts, are cauliflower-like lesions arising on the prepuce or glans as a result of HPV infection (see Chapter 41).

Most penile cancers are of squamous epithelial cell origin and include carcinoma in situ, which is restricted to the epithelium and does not infiltrate the underlying dermis, and invasive carcinomas.[14–16] In situ carcinomas of the penis are known as *Bowen disease* and *erythroplasia of Queyrat*.[15] *Bowen disease* appears as a sharply demarcated, erythematous or grayish-white plaque on the shaft of the penis. Erythroplasia of Queyrat manifests as single or multiple shiny red, sometimes velvety plaques on the glans or foreskin. In approximately 10% of men, these lesions may transform into infiltrating squamous cell cancer.[14,15]

Invasive squamous cell carcinoma of the penis usually begins as a small lump or ulcer on the glans or inner surface of the prepuce. The lesions are usually slow growing and have often been present for a year or more before being brought to medical attention. The lesions are usually nonpainful until they undergo secondary ulceration and infection.[14–16,22] If phimosis is present, there may be painful swelling, purulent drainage, or difficulty urinating. Metastasis to the inguinal lymph is characteristic of early-stage disease, but widespread dissemination is uncommon until the lesion is far advanced.

Diagnosis usually is based on physical examination and biopsy results. CT scans, penile ultrasonographic studies, and magnetic resonance imaging (MRI) may be used in the diagnostic workup. Treatment options vary according to stage, size, location, and invasiveness of the tumor. Carcinoma in situ may be treated conservatively with fluorouracil cream application or laser treatment.[22] Conservative treatment requires frequent follow-up examinations. Surgery remains the mainstay of treatment for invasive carcinoma.

Disorders of the Scrotum and Testes

The testes, or male gonads, are two egg-shaped structures located outside the abdominal cavity in the scrotum. Embryologically, the testes develop in the abdominal cavity and then descend through the inguinal canal into a pouch of peritoneum (which becomes the tunica vaginalis) in the scrotum during the seventh to ninth months of fetal life.[23] As they descend, the testes pull their arteries, veins, lymphatics, nerves, and conducting excretory ducts with them. These structures are encased by the cremaster muscle and layers of fascia that constitute the spermatic cord (Fig. 39-8A). The descent

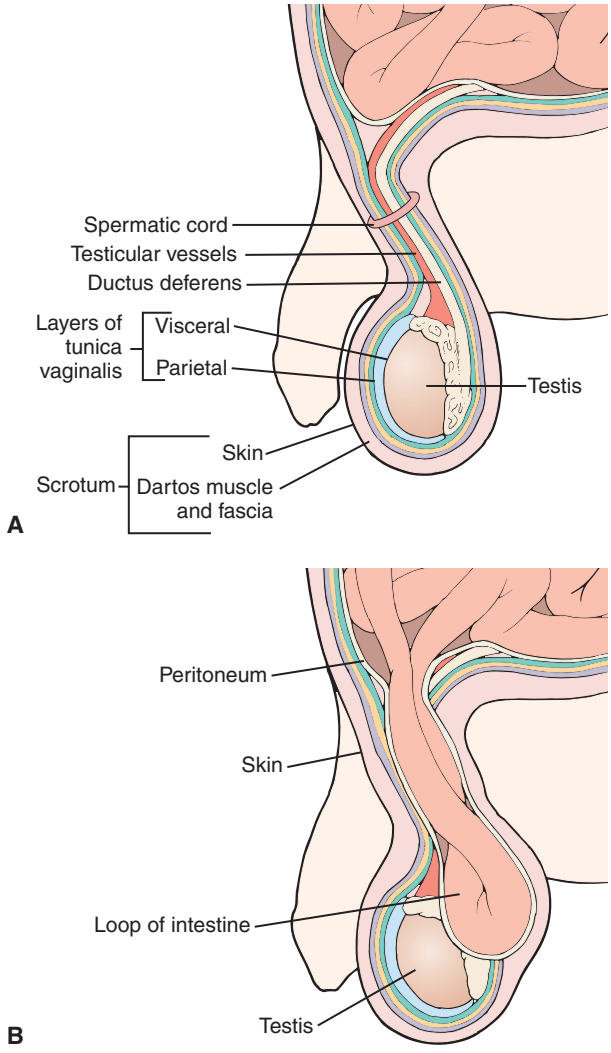

FIGURE 39-8. **(A)** Anterior view of the spermatic cord and inguinal canal and coverings of the spermatic cord and testes. **(B)** Indirect inguinal hernia. (Adapted from Moore K.L., Agur A.M. [2002]. *Essentials of clinical anatomy* [2nd ed., pp. 130, 138]). Philadelphia: Lippincott Williams & Wilkins.)

of the testes is thought to be mediated by testosterone, which is active during this stage of fetal development.

After descent of the testes, the inguinal canal closes almost completely. Failure of this canal to close predisposes to the development of an inguinal hernia later in life (Fig. 39-8B). An inguinal hernia or "rupture" is a protrusion of the parietal peritoneum and part of the intestine through an abnormal opening from the abdominal cavity. A loop of small bowel may become incarcerated in an inguinal hernia (strangulated hernia), in which case the lumen of the bowel may become obstructed and its vascular supply compromised.

The testes and epididymis are completely surrounded by the tunica vaginalis, a serous pouch derived from the peritoneum during fetal descent of the testes into the scrotum. The tunica vaginalis has an outer parietal layer and a deeper visceral layer that adheres to the dense fibrous covering of the testes, the tunica albuginea. The tunica albuginea protects the testes and gives them their ovoid shape. A space exists between these two layers that typically contains a few milliliters of clear fluid. The cremaster muscles, which are bands of skeletal muscle arising from the internal oblique muscles of the trunk, elevate the testes. The testes receive their arterial blood supply from the long testicular arteries, which branch from the aorta. The testicular veins, which drain the testes, arise from a venous network called the *pampiniform plexus* that surrounds the spermatic artery. The testes are innervated by fibers from both divisions of the autonomic nervous system. Associated sensory nerves transmit pain impulses, resulting in excruciating pain, especially when the testes are hit forcibly.

The scrotum, which houses the testes, is made up of a thin outer layer of darkly pigmented skin that is continuous with the outer skin of the groin. Under the outer skin lies the closely related dartos fascia, a fat-free fascial layer with smooth muscle fibers (i.e., dartos muscle) that is responsible for the wrinkled appearance of the scrotum. This layer contains a septum that separates the two testes. Because the dartos muscle attaches to the skin, its contraction causes the scrotum to wrinkle when cold, reducing the surface area of the scrotum and assisting the cremaster muscles in holding the testes closer to the body.

The location of the testes in the scrotum is important for sperm production, which is optimal at 2°C to 3°C (35°C to 37.4°C) below body temperature. Two mechanisms maintain the temperature of the testes at a level consistent with sperm production. One is the pampiniform plexus of testicular veins that surround the testicular artery. This plexus absorbs heat from the arterial blood, cooling it as it enters the testes. The other is the dartos and cremaster muscles, which respond to decreases in testicular temperature by moving the testes closer to the body. Prolonged exposure to elevated temperatures, as a result of prolonged fever or the dysfunction of thermoregulatory mechanisms, can impair spermatogenesis. Some tight-fitting undergarments hold the testes against the body and are thought to contribute to a decrease in sperm counts and infertility by interfering with the thermoregulatory function of the scrotum.

Disorders of the Testicular Tunica

Disorders of the testicular tunica represent scrotal swelling or enlargement due to an accumulation of fluid (hydroceles), blood (hematocele), or sperm (spermatocele) between the layers of the tunica vaginalis, or to dilation of the testicular veins (varicocele) (Fig. 39-9).

Hydrocele. A hydrocele forms when excess fluid collects between the layers of the tunica vaginalis[15,23] (Fig. 39-9B). It may be unilateral or bilateral and can develop as a primary congenital defect or as a secondary condition. Acute hydrocele may develop after local injury, epididymitis or orchitis, gonorrhea, lymph obstruction, or germ cell testicular tumor, or as a side effect of radiation therapy. Chronic hydrocele is more common. Fluid collects about the testis, and the mass grows gradually. Its cause is unknown, and it usually develops in men older than 40 years.

Most cases of hydrocele in male infants and children are caused by a patent processus vaginalis, which is continuous with the peritoneal cavity. There usually are reports that the mass increases in size during the day and decreases at night if the hydrocele communicates with the peritoneal cavity. In many cases they are associated with an indirect inguinal hernia.[24] Most hydroceles of infancy close spontaneously; therefore, they are not repaired before 1 year of age. If the hydrocele persists beyond 2 years of age, surgical treatment usually is indicated.

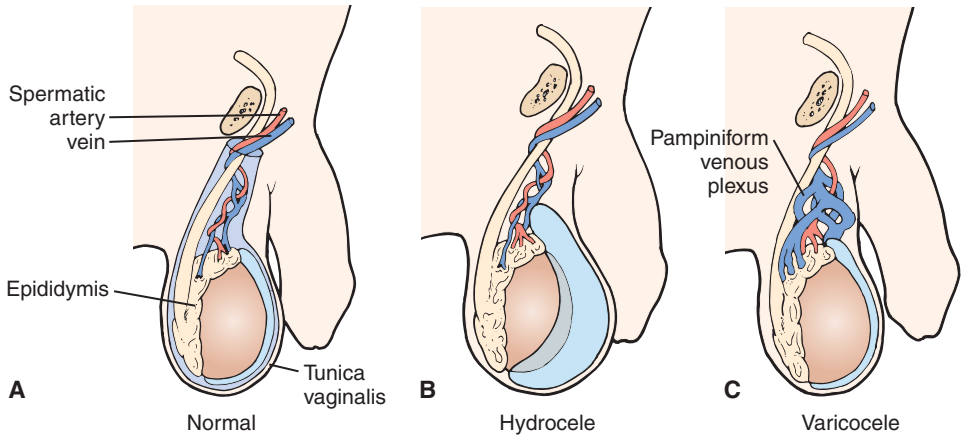

FIGURE 39-9. **(A)** Normal testis and appendages, **(B)** hydrocele, and **(C)** varicocele.

Hydroceles are palpated as cystic masses that may attain massive proportions. If there is enough fluid, the mass may be mistaken for a solid tumor. Transillumination of the scrotum (i.e., shining a light through the scrotum to visualize its internal structures) or ultrasonography can help to determine whether the mass is solid or cystic and whether the testicle is normal. A dense hydrocele that does not illuminate should be differentiated from a testicular tumor. If a hydrocele develops in a young man without apparent cause, careful evaluation is needed to exclude cancer or infection.

In an adult male, a hydrocele is a relatively benign condition. The condition often is asymptomatic, and no treatment is necessary. When symptoms do occur, the feeling may be that of heaviness in the scrotum or pain in the lower back. In cases of secondary hydrocele, the primary condition is treated. If the hydrocele is painful or cosmetically undesirable, surgical correction is indicated.

Hematocele. A hematocele is an accumulation of blood in the tunica vaginalis, which causes the scrotal skin to become dark red or purple.[15] It may develop as a result of an abdominal surgical procedure, scrotal trauma, a bleeding disorder, or a testicular tumor.

Spermatocele. A spermatocele is a painless, sperm-containing cyst that forms at the end of the epididymis.[15] It is located above and posterior to the testis, is attached to the epididymis, and is separate from the testes. Spermatoceles may be solitary or multiple and usually are less than 1 cm in diameter. They are freely movable and should transilluminate. Spermatoceles rarely cause problems, but a large one may become painful and require excision.

Varicocele. A varicocele is characterized by varicosities of the pampiniform plexus, a network of veins supplying the testes[25] (see Fig. 39-9C). The left side is more commonly affected because the left internal spermatic vein inserts into the left renal vein at a right angle, whereas the right spermatic vein has a more oblique insertion into the inferior vena cava. In the standing male, this particular anatomy may cause higher pressures to be transmitted to the left scrotal veins and result in retrograde reflux into veins of the pampiniform plexus. If the condition persists, there may be damage to the elastic fibers and hypertrophy of the vein walls, as occurs in formation of varicose veins in the leg. Sperm concentration and motility are decreased in men with varicoceles.

Varicoceles rarely are found before puberty, and the incidence is highest in males between 15 and 35 years of age. Symptoms of varicocele include an abnormal feeling of heaviness in the left scrotum, although many are asymptomatic. Usually, a varicocele is readily diagnosed on physical examination with the man in the standing and recumbent positions. Typically, the varicocele disappears in the lying position because of venous decompression into the renal vein. Scrotal palpation of a varicocele has been compared to feeling a "bag of worms." Additional diagnostic methods include ultrasonography, radioisotope scanning, and spermatic venography.

Treatment options for varicocele include surgical ligation or sclerosis using a percutaneous transvenous catheter under fluoroscopic guidance. It has been suggested that men with abnormalities in their semen and a varicocele show some degree of improvement in fertility after obliteration of the dilated veins.[25] However, the effectiveness of varicocele treatment in men from subfertile couples is still debated, especially when other assisted reproductive techniques (e.g., intracytoplasmic sperm injection [ICSI]) may be effective with as few as 20 sperm.[25] Aside from improving fertility, other reasons for surgery include the relief of the sensation of "heaviness" and cosmetic improvement.

Testicular Torsion

Testicular torsion is a twisting of the spermatic cord that suspends the testis.[26,27] Testicular torsion can be divided into two distinct types, extravaginal or intravaginal, depending on the level of spermatic cord involvement (Fig. 39-10).

Extravaginal torsion, which occurs in fetuses or neonates, is the less common form of testicular torsion.[28] It occurs when the testicle and the fascial tunicae that surround it rotate around the spermatic cord at a level well above the tunica vaginalis. The torsion probably occurs during fetal or neonatal descent of the testes before the tunica adheres to the scrotal wall. When the torsion occurs in utero, the baby is born with a large firm, nontender testis. Usually the ipsilateral testis is ecchymotic. In these cases the torsed testis is rarely viable because of the time that has elapsed. In other cases the initial examination is normal, and acute scrotal swelling is recognized subsequently. In these cases, the torsed testis may occasionally be saved. The use of surgical treatment (orchiopexy [attachment of the testes to the scrotum] and orchiectomy [removal of the testis]) is controversial. There are multiple animal studies indicating that failure to remove the torsed testis may produce an autoimmune response that affects the normal testis.[28]

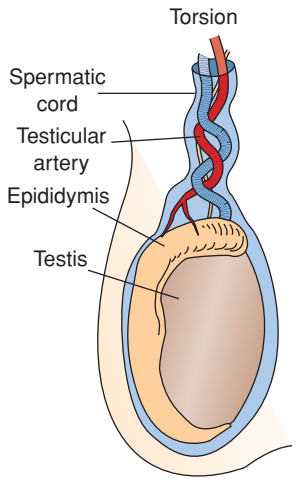

FIGURE 39-10. Testicular torsion with twisting of the spermatic cord that suspends the testis and the spermatic vessels that supply the testis with blood.

Intravaginal torsion involves twisting of the spermatic cord within the tunica vaginalis. It is a true surgical emergency, and early recognition and treatment are necessary if the testicle is to be saved.[26–28] Intravaginal testicular torsion can occur at any age, but is more common during adolescence. Torsion usually occurs in the absence of any precipitating event and is thought to be due to abnormal fixation of the testis within the tunica vaginalis, allowing the testis to twist, especially during periods of testicular growth such as puberty. The torsion obstructs venous drainage, with resultant edema and hemorrhage, and subsequent arterial obstruction. Males usually present in severe distress within hours of onset and often have nausea, vomiting, and tachycardia. The affected testis is large and tender, with pain radiating to the inguinal area.

Testicular torsion must be differentiated from epididymitis, orchitis, and trauma to the testis. On physical examination, the testicle often is high in the scrotum and in an abnormal orientation. These changes are caused by the twisting and shortening of the spermatic cord. The degree of scrotal swelling and redness depends on the duration of symptoms. The cremasteric reflex, normally elicited by stroking the medial aspect of the thigh and observing testicular retraction, frequently is absent. Color Doppler ultrasonography is increasingly used in the evaluation of suspected testicular torsion.

Treatment includes surgical detorsion and orchiectomy. Orchiectomy is carried out when the testis is deemed nonviable after surgical detorsion. Testicular salvage rates are directly related to the duration of torsion. Because the opposite testicle usually is affected by the same abnormal attachments, prophylactic fixation of that testis often is performed.

Epididymitis and Orchitis

Epididymitis. Epididymitis is an inflammation of the epididymis, the elongated cordlike structure that is located along the posterior border of the testis and functions in the transport and storage of sperm[29,30] (Fig. 39-4). The cause of epididymitis varies with age. Most cases of epididymitis in men younger than 35 years are due to sexually transmitted infections such as *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. In men older than 35, epididymitis is generally caused by infection with common urinary tract pathogens, such as *Escherichia coli* and *Pseudomonas*. In prepubertal children, the disorder usually is associated with congenital urinary tract abnormalities and infection with gram-negative rods.

Infections may reach the epididymis through the vas deferens, in which case the pressure associated with voiding or physical strain may force pathogen-containing urine from the urethra or prostate up the ejaculatory duct and through the vas deferens into the epididymis. Infections may also reach the epididymis through the lymphatics of the spermatic cord. Risk factors for epididymitis in all men include sexual activity, heavy physical exertion, and bicycle or motorcycle riding. Recent urinary tract surgery or instrumentation and anatomic abnormalities such as prostatic obstruction are risk factors in older men.

Epididymitis is characterized by unilateral pain and swelling, accompanied by erythema and edema of the overlying scrotal skin that develops over a period of 24 to 48 hours. Initially, the swelling and induration are limited to the epididymis. The distinction between the testis and epididymis becomes less evident as the inflammation progresses, and the testis and epididymis become one mass. There may be tenderness over the groin (spermatic cord) or in the lower abdomen. Symptoms of lower urinary tract infection, such as fever, frequency, urgency, and dysuria, may be present. Whether urethral discharge is present depends on the organism causing the infection; it usually accompanies gonorrheal infections, is common in chlamydial infections, and is less common in infections caused by gram-negative organisms.

Laboratory findings usually reveal an elevated white blood cell count. Urinalysis and urine culture are important in the diagnosis of epididymitis, with bacteriuria and pyuria suggestive of the disorder; however, the urinalysis may be normal. If the diagnosis remains uncertain, color Doppler ultrasonography may be useful, revealing increased blood flow to the affected testis.

Treatment of epididymitis includes bed rest, scrotal elevation and support, analgesics, nonsteroidal anti-inflammatory agents, and antibiotics. Bed rest with scrotal support improves lymphatic drainage.[29,30] The choice of antibiotics is determined by age, physical findings, urinalysis, Gram stain results, cultures, and sexual history. Sexual activity or physical strain may exacerbate the infection and worsen the symptoms, and should be avoided. If a sexually transmitted disease is suspected, it is important to ensure that the sexual partner receives treatment.

Orchitis. Orchitis is an infection of the testes. It can be precipitated by a primary infection in the genitourinary tract, or the infection can be spread to the testes through the epididymis, bloodstream, or lymphatics.[29] It can develop as a complication of a systemic infection, such as parotitis (i.e., mumps), scarlet fever, or pneumonia. Probably the best known of these complications is orchitis caused by the mumps virus.[31]

Mumps orchitis is now rarely seen in children younger than 10, but is the most common complication of mumps infection in the postpubertal male, occurring in approximately 20% to 30% of adolescent boys and young men with mumps. Although the incidence of mumps orchitis has dramatically declined since the introduction of childhood vaccination programs, a sharp increase in mumps and mumps orchitis has recently been reported in both the United States[32] and the United Kingdom.[31] It is also important to note that mumps remains epidemic in many countries throughout the world, and the mumps vaccine is only used in 57% of the World Health Organization member-countries.[31]

The onset of mumps orchitis is sudden; it usually occurs approximately 3 to 4 days after the onset of the parotitis and is characterized by fever, painful enlargement of the testes, and small hemorrhages into the tunica albuginea. Unlike epididymitis, the urinary symptoms are absent. The symptoms usually run their course in 7 to 10 days. The residual effects seen after the acute phase of

the infection include hyalinization of the seminiferous tubules and atrophy of the testes (seen in half of affected men). Spermatogenesis is irreversibly impaired in approximately 30% of testes damaged by mumps orchitis. If both testes are involved (which occurs in 10% to 30% of cases), permanent sterility can result, but is rare.[31] Androgenic hormone function is usually maintained in these cases.

Neoplasms of the Scrotum and Testes

Tumors can develop in the scrotum or the testes. Benign scrotal tumors are common and often do not require treatment. Carcinoma of the scrotum is rare and usually is associated with exposure to carcinogenic agents. Almost all solid tumors of the testes are malignant.

Scrotal Cancer. Cancer of the scrotum was the first cancer directly linked to a specific occupation when, in the 1800s, it was associated with chimney sweeps.[33] Studies have linked this cancer to exposure to tar, soot, and oils. Most squamous cell cancers of the scrotum are linked to poor hygiene and chronic inflammation. Exposure to PUVA or HPV also has been associated with the disease. The mean age of presentation with the disease is 60 years, often preceded by 20 to 30 years of chronic irritation.

In the early stages, cancer of the scrotum may appear as a small tumor or wartlike growth that eventually ulcerates. The thin scrotal wall lacks the tissue reactivity needed to block the malignant process; more than one half of the cases seen involve metastasis to the lymph nodes. Because this tumor does not respond well to chemotherapy or irradiation, the treatment includes wide local excision of the tumor with inguinal and femoral node dissection.[34] Prognosis correlates with lymph node involvement.

Testicular Cancer. Testicular cancer accounts for 1% to 2% of all neoplasms in men.[35] Although relatively rare, it is the most common cause of cancer in the 20- to 35-year-old age group.[35] In the past, testicular cancer was a leading cause of death among men entering their most productive years. Since the late 1970s, however, advances in therapy have transformed an almost invariably fatal disease into one that is highly curable.

Although the cause of testicular cancer is unknown, several predisposing influences may be important: cryptorchidism, genetic factors, and disorders of testicular development.[14,15,35] The strongest association has been with cryptorchid or undescended testis. Genetic predisposition also appears to be important. Family clustering of the disorder has been described, although a well-defined pattern of inheritance has not been established. Men with disorders of testicular development, including those with Klinefelter syndrome and testicular feminization, have a higher risk of germ cell tumors.

The majority of testicular tumors are of germ cell origin.[14,15] Germ cell tumors can be classified as seminomas and nonseminomas. *Seminomas* account for approximately 50% of germ cell tumors and are most frequent in the fourth decade of life.[14,15] Seminomas tend to retain the phenotypic features of spermatogonia and are the type of germ cell tumor most likely to produce a uniform population of cells. The *nonseminoma* tumors include embryonal carcinoma, teratoma, choriocarcinoma, and yolk cell carcinoma derivatives. They usually contain more than one cell type and are less differentiated than seminomas. *Embryonal carcinomas* are the least differentiated of the tumors, with the capacity to differentiate into other nonseminomatous cell types. They occur most commonly in the 20- to 30-year-old age group. *Choriocarcinoma* is a rare and highly malignant form of testicular cancer that is identical to tumors that arise in placental tissue. *Yolk sac tumors* mimic the embryonic yolk sac histologically. They are the most common type of testicular tumors in infants and children up to 3 years of age, and in this age group have a very good prognosis. Teratomas are composed of somatic cell types from two or more germline layers (ectoderm, mesoderm, or endoderm). They constitute less than 2% to 3% of germ cell tumors and can occur at any age from infancy to old age. They usually behave as benign tumors in children, but contain minute foci of cancer cells in adults.

Often the first sign of testicular cancer is a slight enlargement of the testicle that may be accompanied by some degree of discomfort. This may be an ache in the abdomen or groin or a sensation of dragging or heaviness in the scrotum. Frank pain may be experienced in the later stages, when the tumor is growing rapidly and hemorrhaging occurs. Testicular cancer can spread when the tumor may be barely palpable. Approximately 10% of men present with symptoms related to metastatic disease.[35] Signs of metastatic spread include swelling of the lower extremities, back pain, neck mass, cough, hemoptysis, or dizziness. Gynecomastia (breast enlargement) may result from human chorionic gonadotropin (hCG)-producing tumors and occurs in about 5% of men with germ cell tumors. Although routine screening and monthly self-examination in young men has been recommended, studies have not shown that they improve outcomes.[35] However, men with suggestive signs and symptoms should be carefully evaluated to avoid delayed diagnosis or misdiagnosis.

The diagnosis of testicular cancer requires a thorough urologic history and physical examination. A painless testicular mass may be cancer. Conditions that produce an intrascrotal mass similar to testicular cancer include epididymitis, orchitis, hydrocele, or hematocele. The examination for masses should include palpation of the testes and surrounding structures, transillumination of the scrotum, and abdominal palpation. Testicular ultrasonography can be used to differentiate testicular masses. CT scans and MRI are used in assessing metastatic spread.

Tumor markers that measure protein antigens produced by malignant cells may provide information about the existence of a tumor and the type of tumor present. Three tumor markers are of importance in the diagnosis and management of testicular cancer: α-fetoprotein (AFP), β-hCG, and lactic acid dehydrogenase (LDH).[14,35] AFP is normally present in fetal serum in high levels, but should be present in only trace amounts beyond the age of 1 year. β-hCG is a hormone produced by the placenta in pregnant women, and should not be present in significant

levels in the normal male. Elevated serum LDH levels, a cellular enzyme found in muscle, liver, kidneys, and brain, has been shown to correlate with the mass of tumor cells. LDH is often elevated in widespread, metastatic testicular cancer.

The basic treatment of all testicular cancers includes orchiectomy, which is done at the time of diagnostic exploration. Depending on the histologic characteristics of the tumor and the clinical stage of disease, radiation or chemotherapy may be used after orchiectomy. Rigorous follow-up in all men with testicular cancer is necessary to detect recurrences, most of which occur within 2 years of the end of treatment.[35,36] Testicular cancer is a disease in which even recurrence is highly treatable. With appropriate treatment, the prognosis for men with testicular cancer is excellent. Even patients with more advanced disease have excellent chances for long-term survival.

Disorders of the Prostate

The prostate gland is a walnut-sized fibromuscular and glandular organ that encircles the urethra just inferior to the bladder (see Fig. 39-1). The segment of urethra that travels through the prostate gland is called the *prostatic urethra*. The prostatic urethra is lined by a thin layer of smooth muscle that is continuous with the bladder wall. This smooth muscle represents the true involuntary sphincter of the male posterior urethra. Because the prostate surrounds the urethra, it can produce urinary obstruction when it becomes enlarged.

The prostate gland is made up of many secretory glands arranged in three concentric areas surrounding the prostatic urethra, into which they open. The component glands of the prostate include the (1) small mucosal glands associated with the urethral mucosa, (2) intermediate submucosal glands that lie peripheral to the mucosal glands, and (3) large main prostatic glands that are situated toward the outside of the gland. It is the overgrowth of the mucosal glands that causes benign prostatic hyperplasia in older men.

Prostatitis

Prostatitis refers to a variety of inflammatory disorders of the prostate gland, some bacterial and some not. It may occur spontaneously, as a result of catheterization or instrumentation, or secondary to other diseases of the male genitourinary system. As an outcome of two consensus conferences, the National Institutes of Health has established a classification system with four categories of prostatitis syndromes: acute bacterial prostatitis, chronic bacterial prostatitis, chronic prostatitis/pelvic pain syndrome, and asymptomatic inflammatory prostatitis.[37] Men with *asymptomatic inflammatory prostatitis* have no subjective symptoms and are detected incidentally on biopsy or examination of prostatic fluid.

Acute Bacterial Prostatitis. Acute bacterial prostatitis often is considered a subtype of urinary tract infection.[38,39] The most likely etiology of acute bacterial prostatitis is an ascending urethral infection or reflux of infected urine into the prostatic ducts. *E. coli*, other gram-negative rods, and enterococci, organisms known to cause urethritis, are the most common infectious agents. Risk of infection is increased in persons with impaired host defenses (e.g., due to diabetes or human immunodeficiency [HIV] infection), recent catheterization or instrumentation of the urinary tract, or urethral strictures.

The manifestations of acute bacterial prostatitis include fever and chills, malaise, myalgia, arthralgia, frequent and urgent urination, dysuria, and urethral discharge. Dull, aching pain often is present in the perineum, rectum, or sacrococcygeal region. The urine may be cloudy and malodorous because of urinary tract infection. Rectal examination reveals a swollen, tender, warm prostate with scattered soft areas. Prostatic massage produces a thick discharge with white blood cells that grows large numbers of pathogens on culture.

Acute prostatitis usually responds to appropriate antimicrobial therapy chosen in accordance with the sensitivity of the causative agents in the urethral discharge. Depending on the urine culture results, antibiotic therapy usually is continued for at least 4 weeks. Because acute prostatitis often is associated with anatomic abnormalities, a thorough urologic examination usually is performed after treatment is completed.

A persistent fever indicates the need for further investigation for an additional site of infection or a prostatic abscess. CT scans and transrectal ultrasonography of the prostate are useful in the diagnosis of prostatic abscesses. Prostatic abscesses, which are relatively uncommon since the advent of effective antibiotic therapy, are found more commonly in men with diabetes mellitus.

Chronic Bacterial Prostatitis. In contrast to acute bacterial prostatitis, chronic bacterial prostatitis is a subtle disorder that is difficult to treat. Men with the disorder typically present with recurrent urinary tract infections with persistence of the same strain of pathogenic bacteria in the prostatic fluid and urine.[39–41] Organisms responsible for chronic bacterial prostatitis usually are the gram-negative enterobacteria (*E. coli, Proteus,* or *Klebsiella*) or *Pseudomonas*.

The symptoms are variable and include frequent and urgent urination, dysuria, perineal discomfort, and low back pain. Occasionally, myalgia and arthralgia accompany the other symptoms. Secondary epididymitis sometimes is associated with the disorder. Most men are afebrile but have a history of recurrent or relapsing urinary tract infections. Others may be asymptomatic and the diagnosis made after investigation of bacteriuria.

The most accurate method of establishing a diagnosis is by urine cultures. Even after an accurate diagnosis has been established, treatment of chronic prostatitis often is difficult and frustrating.[39–41] Long-term therapy with an appropriate oral antimicrobial agent is the mainstay of treatment. Selection of an appropriate agent is important since antimicrobial drugs penetrate poorly into the chronically inflamed prostate.

Chronic Prostatitis/Chronic Pelvic Pain Syndrome. Chronic prostatitis/pelvic pain syndrome is both the most

common and least understood of the prostatitis syndromes.[42] The category is divided into two types, inflammatory and noninflammatory, based on the presence of leukocytes in the prostatic fluid. The inflammatory type was previously referred to as *nonbacterial prostatitis,* and the noninflammatory type as *prostatodynia.*

A large group of men with prostatitis have pain along the penis, testicles, and scrotum; painful ejaculation; low back pain; rectal pain radiating to the inner thighs; urinary symptoms; decreased libido; and impotence, but they have no bacteria in the urinary system. Men with nonbacterial prostatitis often have inflammation of the prostate with an elevated leukocyte count and abnormal inflammatory cells in their prostatic secretions. The cause of the disorder is unknown, and efforts to prove the presence of unusual pathogens (e.g., mycoplasmas, *Chlamydia,* trichomonads, viruses) have been largely unsuccessful. It also is thought that nonbacterial prostatitis may be an autoimmune disorder.

Men with noninflammatory prostatitis have symptoms resembling those of nonbacterial prostatitis but have negative urine culture results and no evidence of prostatic inflammation (i.e., normal leukocyte count). The cause of noninflammatory prostatitis is unknown, but because of the absence of inflammation, the search for the cause of symptoms has been directed toward extraprostatic sources. In some cases, there is an apparent functional obstruction of the bladder neck near the external urethral sphincter; during voiding, this results in higher-than-normal pressures in the prostatic urethra that cause intraprostatic urine reflux and chemical irritation of the prostate by urine. In other cases, there is an apparent myalgia (i.e., muscle pain) associated with prolonged tension of the pelvic floor muscles. Emotional stress also may play a role.

Treatment methods for chronic prostatitis/pelvic pain syndrome are highly variable and require further study. Antibiotic therapy is used when an occult infection is suspected. Treatment often is directed toward symptom control. In men with irritative urination symptoms, α-adrenergic blocking agents may be beneficial. Noncentered treatment methods such as physical therapy, myofascial trigger point release therapy, and relaxation techniques may provide some symptom relief.[43]

Benign Prostatic Hyperplasia

Nodular hyperplasia of the prostate, also termed benign prostatic hyperplasia (BPH), is an age-related, nonmalignant enlargement of the prostate gland[14,15,44–46] (Fig. 39-11). BPH is one of the most common diseases of aging men. It has been reported that more than 50% of men older than 60 years of age have BPH.[44] The disorder is seen most frequently in Europe and the United States, and is seen least commonly in Asia.[15] The prevalence of the disorder in the United States is higher among blacks than among whites.

The pathogenesis of BPH is not completely understood, but appears to involve an imbalance between cell proliferation and cell death. There is an increased number of epithelial cells and stromal components of the periurethral area of the prostate, but no clear evidence of increased epithelial cell proliferation. Instead, it has been proposed that the cause of the hyperplastic process is decreased cell death, resulting in an accumulation of senescent cells.[14] The main androgen in the prostate is dihydrotestosterone (DHT), which is formed in the prostate from the conversion of testosterone by the enzyme 5α-reductase. It is thought that DHT-induced growth factors contribute to the development of BPH by increasing the proliferation of prostatic stromal cells and

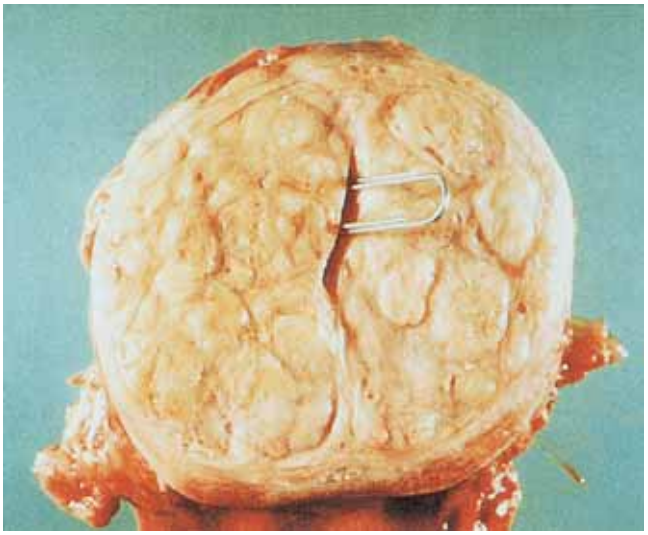

FIGURE 39-11. Nodular hyperplasia of the prostate. Cut surface of a prostate enlarged by nodular hyperplasia shows numerous, well-circumscribed nodules of prostatic tissue. The prostatic urethra (*paper clip*) has been compressed to a narrow slit. (From Damjanov I. [2008]. The lower urinary tract and male reproductive system. In Rubin R., Strayer D.S. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 774]. Philadelphia: Lippincott Williams & Wilkins.)

Hyperplasia and Cancer of the Prostate

- The prostate gland surrounds the urethra and periurethral enlargement causes manifestations of urinary obstruction.
- Benign prostatic hyperplasia is an age-related enlargement of the prostate gland with formation of large, discrete lesions in the periurethral region of the prostate. These lesions compress the urethra and produce symptoms of dysuria or difficulty urinating.
- Prostate cancer begins in the peripheral zones of the prostate gland and usually is asymptomatic until the disease is far advanced and the tumor has eroded the outer prostatic capsule and spread to adjacent pelvic tissues or metastasized.

decreasing the death of the epithelial cells. The discovery that DHT is the active factor in BPH provides the rationale for the use of 5α-reductase inhibitors in the treatment of the disorder.

BPH is characterized by the formation of large, discrete lesions in the periurethral region of the prostate rather than the peripheral zones, which commonly are affected by prostate cancer (Fig. 39-12). The anatomic location of the prostate at the bladder neck contributes to the pathophysiology and symptomatology of BPH. There are two prostatic components to the obstructive properties of BPH and development of lower urinary tract symptoms: dynamic and static.[44,45] The static component of BPH is related to an increase in prostatic size and gives rise to symptoms such as a weak urinary stream, postvoid dribbling, frequency of urination, and nocturia. The dynamic component of BPH is related to prostatic smooth muscle tone, which is mediated by α_1-adrenergic receptors. The recognition of the role of α_1-adrenergic receptors on neuromuscular function in the prostate is the basis for use of α_1-adrenergic receptor blockers in treating BPH. A third component, detrusor instability and impaired bladder contractility, may contribute to the symptoms of BPH independent of the outlet obstruction created by an enlarged prostate (see Chapter 27). It has been suggested that some of the symptoms of BPH might be related to a decompensating or aging bladder rather than being primarily related to outflow obstruction. An example is the involuntary contraction that results in urgency and an attempt to void that occurs because of small bladder volume.[45]

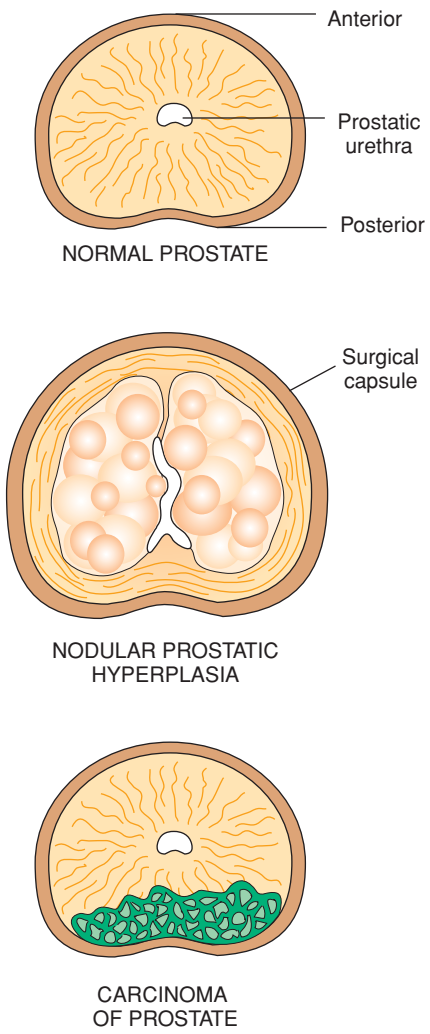

FIGURE 39-12. Normal prostate, nodular benign prostatic hyperplasia, and cancer of the prostate. In prostatic hyperplasia, which involves predominantly the periurethral part of the gland, the nodules compress and distort the urethra. The expansion of the central prostatic glands leads to compression of the peripheral parts and fibrosis, resulting in the formation of the so-called surgical capsule. Prostatic cancer usually arises from the peripheral glands and compression of the urethra is a late clinical event. (From Damjanov I. [2008]. The lower urinary tract and male reproductive system. In Rubin R., Strayer D.S. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 774]. Philadelphia: Lippincott Williams & Wilkins.)

Clinical Course. The clinical significance of BPH resides in its tendency to compress the urethra and cause partial or complete obstruction of urinary outflow. As the obstruction increases, acute retention of urine may occur with overdistention of the bladder. The residual urine in the bladder causes increased frequency of urination and a constant desire to empty the bladder, which becomes worse at night. With marked bladder distention, overflow incontinence may occur with the slightest increase in intra-abdominal pressure. The resulting obstruction to urinary flow can give rise to urinary tract infection, destructive changes of the bladder wall, hydroureter, and hydronephrosis. Hypertrophy and changes in bladder wall structure develop in stages. Initially, the hypertrophied fibers form trabeculations and then herniations, or sacculations; finally, diverticula develop as the herniations extend through the bladder wall (see Chapter 27, Fig. 27-4). Because urine seldom is completely emptied from them, these diverticula are readily infected. Back-pressure on the ureters and collecting system of the kidneys promotes hydroureter, hydronephrosis, and danger of eventual renal failure.

Current practice suggests that the single most important factor in the evaluation and treatment of BPH is the man's own experiences related to the disorder. The American Urological Association Symptom Index consists of seven questions about symptoms regarding incomplete emptying, frequency, intermittency, urgency, weak stream, straining, and nocturia.[46]

The diagnosis of BPH is based on history, physical examination, digital rectal examination, urinalysis, blood tests for serum creatinine and prostate-specific antigen (PSA), and urine flow rate. The digital rectal examination is used to examine the external surface and size of the prostate. An enlarged prostate found during a digital rectal examination does not always correlate with the degree of urinary obstruction. Some men can have greatly enlarged prostate glands with no urinary obstruction, but others may have severe symptoms without a palpable enlargement of the prostate. Urinalysis is done to detect bacteria, white blood cells, or microscopic hematuria in the presence of infection and inflammation.

The serum creatinine test is used as an estimate of the glomerular filtration rate and renal function. The PSA test is used to screen for prostate cancer. These evaluation measures, along with the symptom index, are used to describe the extent of obstruction, determine if other diagnostic tests are needed, and establish the need for treatment.

Treatment of BPH is determined by the degree of symptoms that the condition produces and complications due to obstruction. When a man develops mild symptoms related to BPH, a "watchful waiting" stance often is taken.[44–46] The condition does not always run a predictable course; it may remain stable or even improve. Until the 1980s, surgery was the mainstay of treatment to alleviate urinary obstruction due to BPH. Currently, there is an emphasis on less invasive methods of treatment, including use of pharmacologic agents. However, when more severe signs of obstruction develop, surgical treatment is indicated to provide comfort and avoid serious kidney damage.

Pharmacologic management includes the use of 5α-reductase inhibitors, α_1-adrenergic blocking drugs, or a combination of the two drugs.[44,45] The 5α-reductase inhibitors such as finasteride reduce prostate size by blocking the effect of androgens on the prostate. Finasteride causes atrophy of the prostate glandular epithelial cells, which results in a 20% to 30% reduction in volume. The onset is slow (3 to 6 months), but long-lasting. The presence of α-adrenergic receptors in prostatic smooth muscle has prompted the use of α_1-adrenergic blocking drugs (e.g., prazosin, terazosin) to relieve prostatic obstruction and increase urine flow.

Herbal therapies have been used for many years by men for the treatment of BPH and lower urinary tract symptoms.[44–46] Several studies have looked at the effects of these agents, including the extract of the saw palmetto berry. Improvements in peak urine flow rates and nocturia can occur compared with placebo, but the durability of these effects is unproven. The long-term toxicity and mechanism of action of these agents remain unclear. Standardization of these products is also worrisome (as with all herbal therapies).

The surgical removal of an enlarged prostate can be accomplished by the transurethral, suprapubic, or perineal approach.[44–46] Currently, transurethral prostatectomy (TURP) is the most commonly used technique. With this approach, an instrument is introduced through the urethra, and prostate tissue is removed using a resectoscope and electrocautery. Late complications of TURP include sexual dysfunction, incontinence, and bladder neck constriction. Many new and experimental techniques have also been used to treat BPH including transurethral incision of the prostate, laser surgery, transurethral vaporization, transurethral microwave therapy, and transurethral needle ablation. For men who have heart or lung disease or a condition that precludes major surgery, a stent may be used to widen and maintain the patency of the urethra. A stent is a device made of tubular mesh that is inserted under local or regional anesthesia. Within several months, the lining of the urethra grows to cover the inside of the stent.

Cancer of the Prostate

Globally, prostate cancer is the second most frequently diagnosed cancer in men. An estimated 782,600 new cases were projected to occur 2007. Nearly three quarters of these cases were expected to be diagnosed in developed countries, with the highest rates being recorded in the United States.[47] The increase in diagnosed cases is thought to reflect earlier diagnosis because of widespread use of PSA testing since the early 1990s. African American men have the highest reported incidence rate for prostate cancer at all ages, and the cancer also tends to be diagnosed at a later stage.[47,48] Asians and Native American men have the lowest rate. Prostate cancer also is a disease of aging. The incidence increases rapidly after 50 years of age; more than 85% of all prostate cancers are diagnosed in men older than 65 years of age.[48]

Etiology and Pathogenesis. The precise cause of prostate cancer is unclear. As with other cancers, it appears that the development of prostate cancer is a multistep process involving genes that control cell differentiation and growth. The incidence of prostate cancer appears to be higher in relatives of men with prostate cancer. It has been estimated that men who have an affected first-degree relative (e.g., father, brother) and an affected second-degree relative (e.g., grandfather, uncle) have an eightfold increase in risk.[14,15,49] It has been suggested that dietary patterns, including increased dietary fats, may alter the production of sex hormones and growth factors and increase the risk of prostate cancer. Supporting the role of dietary fats as a risk factor for prostate cancer has been the observation that the diet of Japanese men, who have a low rate of prostate cancer, is much lower in fat content than that of U.S. men, who have a much higher incidence.

Several factors appear to be protective against the development of prostate cancer. These include dietary factors such as dietary fat reduction and supplementation with vitamins D and E and selenium.[50] Dietary intake of soy, green tea, and tomato-rich products (lycopene) may also be important. Vitamin D is not technically a vitamin, but a steroid hormone that has a variety of antiproliferative and proapoptotic effects in prostatic as well as other cancer cell lines. Vitamin E, selenium, and lycopene are all antioxidants, thought to play an important role in cellular defenses to oxidative stress. The low incidence of prostate cancer in Asia has led to an interest in the study of soy and green tea, which are highly consumed in these nations.

In terms of hormonal influence, androgens are believed to play a role in the pathogenesis of prostate cancer.[14] Evidence favoring a hormonal influence includes the presence of steroid receptors in the prostate, the requirement of sex hormones for normal growth and development of the prostate, and the fact that prostate cancer almost never develops in men who have been castrated. The response of prostate cancer to estrogen administration or androgen deprivation further supports a correlation between the disease and testosterone levels.[14]

Clinical Features. Prostatic adenocarcinomas, which account for most primary prostate cancers, are commonly multicentric and located in the peripheral zones of the prostate[14,15] (see Fig. 39-12). The high frequency of invasion of the prostatic capsule by adenocarcinoma relates to its subcapsular location. Invasion of the urinary bladder is less frequent and occurs later in the clinical course. Metastasis to the lung reflects lymphatic spread through the thoracic duct and dissemination from the prostatic venous plexus to the inferior vena cava. Bony metastases, particularly to the vertebral column, ribs, and pelvis, produce pain that often presents as a first sign of the disease.

Most men with early-stage prostate cancer are asymptomatic.[51] The presence of symptoms often suggests locally advanced or metastatic disease. Depending on the size and location in the prostate of the cancer at the time of diagnosis, there may be changes associated with the voiding pattern similar to those found in BPH. These include urgency, frequency, nocturia, hesitancy, dysuria, hematuria, or blood in the ejaculate.[44] On digital rectal examination, the prostate can be nodular and fixed. Bone metastasis often is characterized by low back pain. Pathologic fractures can occur at the site of metastasis. Men with metastatic disease may experience weight loss, anemia, or shortness of breath.

Screening. Whether screening for prostate cancer results in a decrease in prostate cancer deaths is a subject of much debate.[52,53] The screening tests currently available are digital rectal examination, PSA testing, and transrectal ultrasonography. Depending on the population studied, detection using digital rectal examination varies from 1.5% to 7%, with most cancers being far advanced when they are detected.[53] PSA is a glycoprotein secreted into the cytoplasm of benign and malignant prostatic cells that is not found in other normal tissues or tumors. However, a positive PSA test indicates only the possible presence of prostate cancer. It also can be positive in cases of BPH and prostatitis. Thus, the test can result in a large number of men undergoing biopsy and being treated unnecessarily. Transrectal ultrasonography is not used for first-line detection because of its expense, but may benefit men who are at high risk for development of prostate cancer.

The U.S. Preventative Services Task Force (USPSTF) Recommendation states that for men younger than 75 years, there is no quality evidence to show that finding prostate cancer by PSA screening rather than waiting for symptoms to develop leads to fewer men dying of prostate cancer. For men older than 75 years, the benefits of finding prostate cancer by screening are small to none.[52] These recommendations apply to men at average risk for prostate cancer and not to men at high risk, such as those with a father or brother with prostate cancer. The USPSTF and American Cancer Society advocate that men younger than 75 years who are interested in PSA screening should discuss it with their health care provider.[52,53] Before screening, they should understand the benefits and limitations of screening.

Diagnosis. The diagnosis of prostate cancer is based on history and physical examination and confirmed through biopsy methods.[44,51] Transrectal ultrasonography is used to guide a biopsy needle and document the exact location of the sampled tissue. It also is used for providing staging information. Newly developed small probes for transrectal MRI have been shown to be effective in detecting the presence of cancer in the prostate. Radiologic examination of the bones of the skull, ribs, spine, and pelvis can be used to reveal metastases, although radionuclide bone scans are more sensitive.

Prostatic cancer, like other forms of cancer, is graded and staged[14,15] (see Chapter 7). PSA levels are important in the staging and management of prostate cancer. In untreated cases, the level of PSA correlates with the volume and stage of disease. A rising PSA after treatment is consistent with progressive disease, whether it is locally recurring or metastatic. Measurement of PSA is used to detect recurrence after total prostatectomy. Because the prostate is the source of PSA, levels should drop to zero after surgery; a rising PSA indicates recurring disease.

Treatment. Cancer of the prostate is treated by surgery, radiation therapy, and hormonal manipulations.[44,51] Chemotherapy has shown limited effectiveness in the treatment of prostate cancer. Treatment decisions are based on tumor grade and stage and on the age and health of the man. Expectant therapy (watchful waiting) may be used if the tumor is not producing symptoms, is expected to grow slowly, and is small and contained in one area of the prostate. This approach is particularly suited for men who are elderly or have other health problems.

Radical prostatectomy involves complete removal of the seminal vesicles, prostate, and ampullae of the vas deferens. Refinements in surgical techniques ("nerve-sparing" prostatectomy) have allowed maintenance of continence in most men and erectile function in selected cases. Radiation therapy can be delivered by a variety of techniques, including external-beam radiation therapy and transperineal implantation of radioisotopes (brachytherapy).

Metastatic disease often is treated with androgen deprivation therapy. Androgen deprivation may be induced at several levels along the hypothalamic-pituitary-gonadal axis using a variety of methods or agents.[44,51] Orchiectomy or surgical removal of the testes eliminates the source of testosterone. The use of luteinizing hormone–releasing hormone (LHRH) agonists (e.g., leuprolide, goserelin), which act at the hypothalamic-pituitary level to achieve androgen deprivation without orchiectomy or administration of diethylstilbestrol (a synthetic estrogenic compound), currently is the most common method of reducing testosterone levels. Although testosterone is the main circulating androgen, the adrenal gland also secretes androgens. Inhibitors of adrenal androgen synthesis (i.e., ketoconazole and aminoglutethimide) block the synthesis of adrenal androgens. Complete androgen blockade can be achieved by combining an antiandrogen with use of an LHRH agonist or orchiectomy. The nonsteroidal antiandrogens (e.g., flutamide, bicalutamide) block the uptake and actions of androgens in the prostate cells.

In summary, disorders of the penis include balanitis, an acute or chronic inflammation of the glans penis, and balanoposthitis, an inflammation of the glans and prepuce. Peyronie disease is characterized by the growth of a band of fibrous tissue on top of the penile shaft. Priapism is prolonged, painful, and nonsexual erection that can lead to thrombosis with ischemia and necrosis of penile tissue. Cancer of the penis is relatively rare, accounting for less than 1% of genital cancer in developed countries of the world. Although the tumor is slow growing and highly curable when diagnosed early, the greatest hindrance to successful treatment is a delay in seeking medical attention.

Disorders of the scrotum and testes include collection of fluid (hydrocele), blood (hematocele), or sperm (spermatocele) in the tunica vaginalis; varicosities of the veins in the pampiniform venous plexus (varicocele); and twisting of the spermatic cord with a resulting compromise of the blood supply to the testis (testicular torsion). Inflammatory conditions can involve the scrotal sac, epididymis, or testes. Tumors can arise in the scrotum or the testes. Scrotal cancers usually are associated with exposure to petroleum products such as tar, pitch, and soot. Testicular cancer, which accounts for only 1% to 2% of all cancers in men, is the most common cause of cancer in the 20- to 35-year-old age group. With current treatment methods, a large percentage of men with these tumors can be cured.

The prostate gland is a firm walnut-sized structure that surrounds the urethra. Inflammation of the prostate occurs as an acute or a chronic process. Chronic prostatitis probably is the most common cause of relapsing urinary tract infections in men. Chronic prostatitis/pelvic pain syndrome is both the most common and least understood of the prostatitis syndromes. It is manifest by pain along the penis, testicles, and scrotum; painful ejaculation; low back and rectal pain; urinary symptoms; and impotence. BPH is a common disorder in men older than 50 years. Because the prostate encircles the urethra, BPH exerts its effect through obstruction of urinary outflow from the bladder. Advances in the treatment of BPH include pharmacologic treatment with 5α-reductase inhibitors and α-adrenergic blocking agents, laser surgery, and prostatic stents.

Globally, prostate cancer is the second most frequently diagnosed cancer in men. Nearly three quarters of these cases were expected to be diagnosed in developed countries in 2007, with the highest rates being recorded in the United States. Most prostate cancers are asymptomatic and are incidentally discovered on rectal examination. Cancer of the prostate, like other forms of cancer, is graded according to the histologic characteristics of the tumor and staged clinically. Treatment, which is based on the extent of the disease, includes surgery, radiation therapy, and hormonal manipulation.

Disorders in Childhood and Aging Changes

Disorders of Childhood

Disorders of the male reproductive system that present in childhood include hypospadias, epispadias, phimosis and paraphimosis, and cryptorchidism.

Hypospadias and Epispadias

Hypospadias and epispadias are congenital disorders of the penis resulting from embryologic defects in the development of the urethral groove and penile urethra (Fig. 39-13). In hypospadias, which affects approximately 1 in 250 male infants, the termination of the urethra is on the ventral surface of the penis.[54–57] The testes are undescended in 8% to 10% of boys born with hypospadias and chordee (i.e., ventral bowing of the penis), and inguinal hernia also may accompany the disorder.[54] In the newborn with severe hypospadias and cryptorchidism (undescended testes), the differential diagnosis should consider ambiguous genitalia and masculinization that is seen in female infants with congenital adrenal hyperplasia[58] (see Chapter 32). Because many chromosomal aberrations result in ambiguity of the external genitalia, chromosomal studies often are recommended for male infants with hypospadias and cryptorchidism.[57]

Surgery is the treatment of choice for hypospadias.[57] Circumcision is avoided because the foreskin is used for surgical repair. Factors that influence the timing of surgical repair include anesthetic risk, penile size, and the psychological effects of the surgery on the child. In mild cases, the surgery is done for cosmetic reasons only. In more severe cases, surgical repair becomes essential for normal sexual functioning and to prevent the psychological effects of having malformed genitalia. When

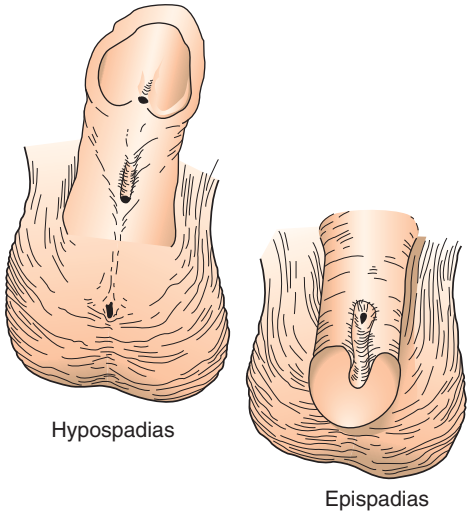

FIGURE 39-13. Hypospadias and epispadias.

indicated, surgical repair is usually done between the ages of 6 and 12 months.[54–57]

Epispadias, in which the opening of the urethra is on the dorsal surface of the penis, is a less common defect. Although epispadias may occur as a separate entity, it often is associated with exstrophy of the bladder, a condition in which the abdominal wall fails to cover the bladder. The treatment depends on the extent of the developmental defect.

Phimosis and Paraphimosis

Phimosis refers to a tightening of the prepuce or penile foreskin that prevents its retraction over the glans.[58] Embryologically, the foreskin begins to develop during the eighth week of gestation as a fold of skin at the distal edge of the penis that eventually grows forward over the base of the glans. By the 16th week of gestation, the prepuce and the glans are adherent. Only a small percentage of newborns have a fully retractable foreskin.[55] With growth, a space develops between the glans and foreskin, and by 3 years of age, approximately 90% of male children have retractable foreskins.

Because the foreskin of many boys cannot be fully retracted in early childhood, it is important that the area be cleaned thoroughly. There is no need to retract the foreskin forcibly because this could lead to infection, scarring, or *paraphimosis*. As the child grows, the foreskin becomes retractable, and the glans and foreskin should be cleaned routinely. If symptomatic phimosis occurs after childhood, it can cause difficulty with voiding or sexual activity. Circumcision is then the treatment of choice.

Cryptorchidism

Cryptorchidism, or undescended testes, occurs when one or both of the testicles fail to move down into the scrotal sac.[59,60] The condition is bilateral in 10% to 20% of cases. The testes develop intra-abdominally in the fetus and usually descend into the scrotum through the inguinal canal during the seventh to ninth months of gestation. The undescended testes may remain in the lower abdomen or at a point of descent in the inguinal canal (Fig. 39-14).

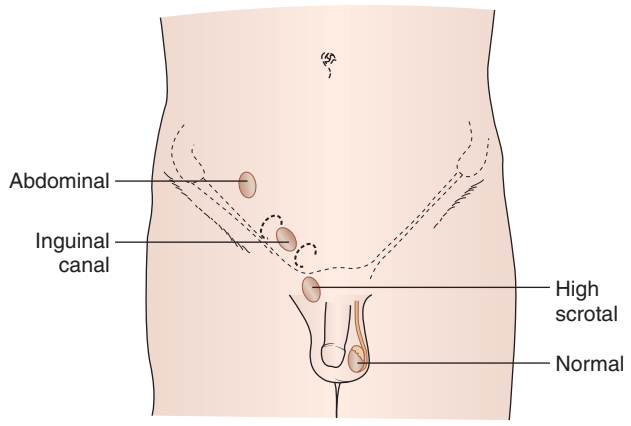

FIGURE 39-14. Possible locations of undescended testicles.

The incidence of cryptorchidism is directly related to birth weight and gestational age; infants who are born prematurely or are small for gestational age have the highest incidence of the disorder. The cause of cryptorchidism in full-term infants is poorly understood. Most cases are idiopathic, but some may result from genetic or hormonal factors.

The major manifestation of cryptorchidism is the absence of one or both of the testes in the scrotum. The testis either is not palpable or can be felt external to the inguinal ring. Spontaneous descent often occurs during the first 3 months of life, and by 6 months of age the incidence decreases to 0.8%.[54] Spontaneous descent rarely occurs after 4 months of age.

In children with cryptorchidism, histologic abnormalities of the testes reflect intrinsic defects in the testicle or adverse effects of the extrascrotal environment. The undescended testicle is normal at birth, but pathologic changes can be demonstrated at 6 to 12 months.[54] There is a delay in germ cell development, changes in the spermatic tubules, and reduced number of Leydig cells. These changes are progressive if the testes remain undescended. When the disorder is unilateral, it also may produce morphologic changes in the contralateral descended testis.

The consequences of cryptorchidism include infertility, testicular torsion, malignancy, and the possible psychological effects of an empty scrotum.[54,59,60] Indirect inguinal hernias usually accompany the undescended testes but rarely are symptomatic. Recognition of the condition and early treatment are important steps in preventing adverse consequences. The risk of malignancy in the undescended testis is 4 to 10 times higher than in the general population.[54] The increased risk of testicular cancer is not significantly affected by orchiopexy, hormonal therapy, or late spontaneous descent after the age of 2 years. However, orchiopexy does allow for earlier detection of a testicular malignancy by positioning the testis in a more easily palpable location.

As a group, men with unilateral or bilateral cryptorchidism usually have decreased sperm counts, poorer-quality sperm, and lower fertility rates than do men whose testicles descend normally. The likelihood of decreased fertility increases when the condition is bilateral. Unlike the risk of testicular cancer, there seems to be some advantage to early orchiopexy for protection of fertility.[60]

Diagnosis is based on careful examination of the genitalia in male infants. Undescended testes due to cryptorchidism should be differentiated from retractable testes that retract into the inguinal canal in response to an exaggerated cremaster muscle reflex. Retractable testes usually are palpable at birth but become nonpalpable later. They can be brought down with careful palpation in a warm room. Retractable testes usually assume a scrotal position during puberty. They have none of the complications associated with undescended testicles due to cryptorchidism.[54] Because imaging has not proven to be 100% reliable, laparoscopy has become standard practice for localization of nonpalpable testes.

The treatment goals for the child with cryptorchidism include measures to enhance future fertility

potential, placement of the gonad in a favorable place for cancer detection, and improved cosmetic appearance. Surgical treatment is the cornerstone of therapy. Current information suggests that placement of the testes in the scrotum should be accomplished by 1 year of age to maximize the potential for fertility. Hormone therapy with hCG or GnRH agonists is used infrequently. Although hormonal treatment has been used in Europe, randomized clinical trials have shown neither hormonal preparation to be effective in stimulating testicular descent.[54]

Treatment of men with undescended testis should include lifelong follow-up, considering the sequelae of testicular cancer and infertility. Parents need to be aware of the potential issues of infertility and increased risk of testicular cancer. On reaching puberty, boys should be instructed in the necessity of testicular self-examination.

Aging Changes

Like other body systems, the male reproductive system undergoes degenerative changes as a result of the aging process; it becomes less efficient with age. The declining physiologic efficiency of male reproductive function occurs gradually and involves the endocrine, circulatory, and neuromuscular systems.[61] Compared with the marked physiologic change in aging women, the changes in the aging man are more gradual and less drastic. Gonadal and reproductive failures usually are not related directly to age because a man remains fertile into advanced age; 80- and 90-year-old men have been known to father children.

As the man ages, his reproductive system becomes measurably different in structure and function from that of the younger man. Male sex hormone levels, particularly testosterone, decrease with age, with the decline starting later on average than in women. The term *andropause* has been used to describe an ill-defined collection of symptoms in aging men, typically those older than 50 years, who may have a low androgen level.[61,62]

The sex hormones play a part in the structure and function of the reproductive system and other body systems from conception to old age; they affect protein synthesis, salt and water balance, bone growth, and cardiovascular function. Decreasing levels of testosterone affect sexual energy, muscle strength, and the genital tissues. The testes become smaller and lose their firmness. The seminiferous tubules, which produce spermatozoa, thicken and begin a degenerative process that finally inhibits sperm production, resulting in a decrease of viable spermatozoa. The prostate gland enlarges, and its contractions become weaker. The force of ejaculation decreases because of a reduction in the volume and viscosity of the seminal fluid. The seminal vesicles change little from childhood to puberty. The pubertal increases in the fluid capacity of the gland remain throughout adulthood and decline after the age of 60 years. After age 60 years, the walls of the seminal vesicles thin, the epithelium decreases, and the muscle layer is replaced by connective tissue. Age-related changes in the penis consist of fibrotic changes in the trabeculae in the corpus spongiosum, with progressive sclerotic changes in arteries and veins. Sclerotic changes also follow in the corpora cavernosa, with the condition becoming generalized in 55- to 60-year-old men.

Erectile dysfunction in the elderly man often is directly related to the general physical condition of the person. Diseases that accompany aging can have direct bearing on male reproductive function. Various cardiovascular, respiratory, hormonal, neurologic, and hematologic disorders can be responsible for secondary impotence. For example, vascular disease affects male potency because it may impair blood flow to the pudendal arteries or their tributaries, resulting in loss of blood volume with subsequent poor distention of the vascular spaces of erectile tissue. Other diseases affecting potency include hypertension, diabetes, cardiac disease, and malignancies of the reproductive organs. In addition, certain medications can have an effect on sexual function.

Testosterone and other synthetic androgens may be used in older men with low androgen levels to improve muscle strength and vigor. Preliminary studies of androgen replacement in aging men with low androgen levels show an increase in lean body mass and a decrease in bone turnover. Before testosterone replacement therapy is initiated, all men should be screened for prostate cancer and other androgen-related diseases. Testosterone is available in an injectable form that is administered every 2 to 4 weeks, as a buccal tablet, or as a transdermal patch or gel. Side effects of replacement therapy may include acne, gynecomastia, and reduced high-density lipoprotein levels. It also may contribute to a worsening of sleep apnea in men who are troubled by this problem.

In summary, childhood disorders of the male reproductive system include congenital disorders in which the urethral opening is located on the ventral surface of the penis (hypospadias) or on the dorsal surface (epispadias). Phimosis is the condition in which the opening of the foreskin is too tight to permit retraction over the glans. Disorders of the scrotum and testes include cryptorchidism or undescended testicles. Early diagnosis and treatment are important because of the risk of malignancy and infertility.

Like other body systems, the male reproductive system undergoes changes as a result of the aging process. The changes occur gradually and involve parallel changes in endocrine, circulatory, and neuromuscular function. Testosterone levels decrease, the size and firmness of the testes decrease, sperm production declines, and the prostate gland enlarges. There often is a decrease in frequency of intercourse or erectile function related to diseases that accompany the aging process.

REVIEW EXERCISES

1. A 64-year-old man presents to his family physician with erectile dysfunction. He is on multiple medications for "his heart disease." An initial physical examination is unremarkable.

A. What additional information should be obtained?
B. Given his medical history, what are possible factors contributing to his problem?

2. A 23-year-old man presents in the emergency department in severe distress. His left testicle is large and tender and he has pain radiating to the inguinal area.

A. What would be a tentative diagnosis for this man?
B. Why would this problem necessitate immediate diagnosis and surgical intervention?

3. A 72-year-old man had a radical prostatectomy for localized prostate cancer. After surgery his PSA level was undetectable. He presents 5 years later having been "lost to follow-up." He complains of pain in his hip and lower back. His PSA level is now markedly elevated.

A. What initial investigations are warranted?
B. What therapies are available for this complication?

Chapter 40

Disorders of the Female Genitourinary System

Disorders of the female reproductive system have widespread effects on physical and psychological function, including general health status, sexuality, and reproductive potential. This chapter provides a review of the structure and function of the female reproductive system and a discussion of disorders of the external and internal female reproductive organs, menstrual disorders, and disorders of the breast.

Structure and Function of the Female Reproductive System

The female reproductive system consists of the external and internal genital structures.[1,2] The external structures, or genitalia, are situated in the anterior part of the perineum, and the internal structures (vagina, uterus, fallopian tubes, and ovaries) are located in the pelvic cavity (Fig. 40-1).

External Genitalia

The external genitalia, which are collectively referred to as the *vulva*, include the mons pubis, labia majora, labia minora, clitoris, and perineal body (Fig. 40-2). Because of their location, the urethra and anus usually are considered in a discussion of the external genitalia.

The *mons pubis* is a rounded, skin-covered fat pad located anterior to the symphysis pubis. Running posteriorly from the mons pubis are two elongated, hair-covered, fatty folds, the *labia majora*. The labia majora enclose the *labia minora*, which are smaller than the labia majora and are composed of skin, fat, and some erectile tissue. The *clitoris* is located below the clitoral hood, which is formed by the joining of the two labia minora. The female clitoris is an erectile organ, rich in vascular and nervous supply. Analogous to the male penis, it is a highly sensitive organ that becomes distended during sexual stimulation.

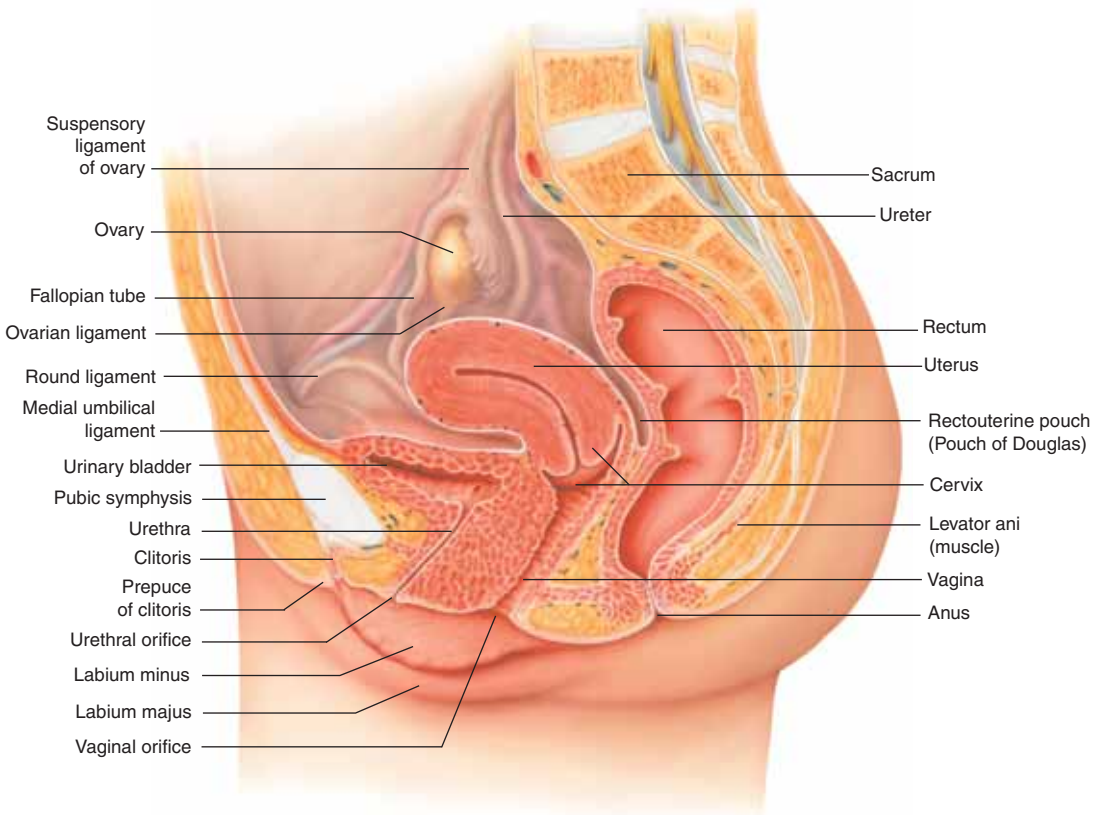

FIGURE 40-1. Female reproductive system as seen in sagittal section. (Adapted from Anatomical Chart Company. [2001]. *Atlas of human anatomy* [p. 253]. Springhouse, PA: Springhouse.)

The area between the labia minora is called the *vestibule*. Located in the vestibule are the urethral and vaginal openings. The urethra is located posterior to the clitoris and usually is closer to the vaginal opening than to the clitoris. The vaginal orifice, commonly known as the *introitus*, is the opening between the external and

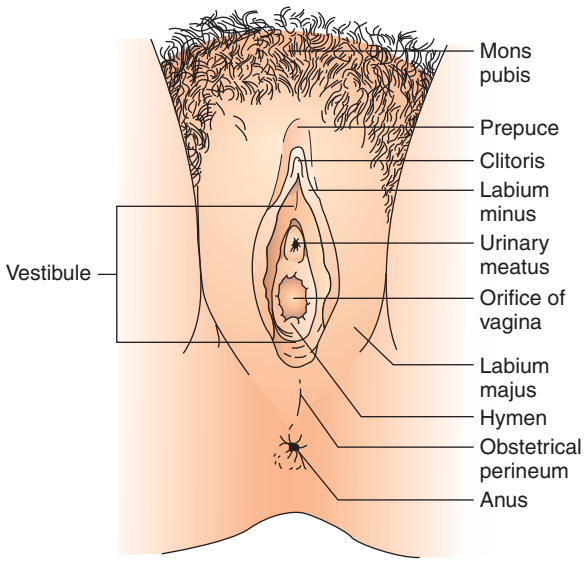

FIGURE 40-2. External genitalia of the female.

The Female Reproductive System

- The female reproductive system, which consists of the external and internal genitalia, has both sexual and reproductive functions.
- The external genitalia (labia majora, labia minora, clitoris, and vestibular glands) surround the openings of the urethra and vagina. Although the female urinary and genital structures are anatomically separate, their close proximity provides a means for cross-contamination and shared symptomatology.
- The internal genitalia of the female reproductive system are specialized to participate in sexual intercourse (the vagina), to produce and maintain the female egg cells (the ovaries), to transport these cells to the site of fertilization (the fallopian tubes), to provide a favorable environment for development of offspring (the uterus), and to produce the female sex hormones (the ovaries).

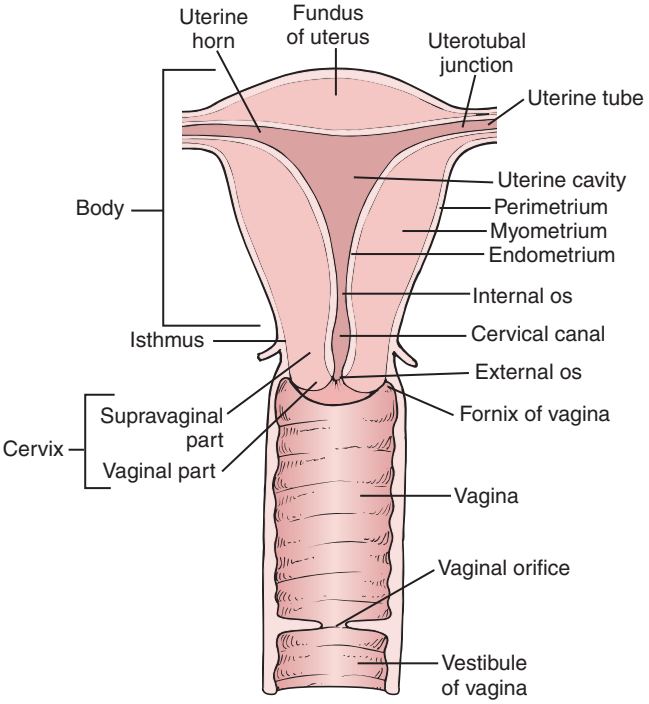

FIGURE 40-3. Median section of the vagina and uterus. (From Moore K.L., Agur A.M.R. [2002]. *Essential clinical anatomy* (2nd ed., p. 238). Philadelphia: Lippincott Williams & Wilkins.)

internal genitalia. The ducts of the Skene (periurethral) and Bartholin glands also open into the vestibule. Secretions from the Bartholin glands are responsible for sexually stimulated vaginal lubrication.

Internal Genitalia

Vagina

The vagina is a fibromuscular tube that connects the external and internal genitalia. The vagina, which is essentially free of sensory nerve fibers, is located behind the urinary bladder and urethra and anterior to the rectum (Fig. 40-3). The uterine cervix projects into the vagina at its upper end, forming recesses called *fornices*. The vagina functions as a route for discharge of menses and other secretions. It also serves as an organ of sexual fulfillment and reproduction.

Uterus and Cervix

The uterus is a thick-walled muscular organ. This pear-shaped, hollow structure is located between the bladder and the rectum. The uterus can be divided into three parts: the upper portion above the insertion of the fallopian tubes, called the *fundus;* the central tapering portion, called the *body;* and the inferior constricted part, called the *cervix*[1,2] (Fig. 40-3). The uterus is supported on both sides by four sets of ligaments: the *broad ligaments,* which run laterally from the body of the uterus to the pelvic side walls; the *round ligaments,* which run from the fundus laterally into each labium majus; the *uterosacral ligaments,* which run from the uterocervical junction to the sacrum; and the *cardinal* or *transverse cervical* ligaments, which are attached to the side of the uterus (Fig. 40-4).

The wall of the uterus is composed of three layers: the perimetrium, the myometrium, and the endometrium.[2] The *perimetrium* is the outer serous covering that is derived from the abdominal peritoneum. This outer layer merges with the peritoneum that covers the broad ligaments. Anteriorly, the perimetrium is reflected over the bladder wall, forming the *vesicouterine pouch*; posteriorly, it extends to form the *rectouterine pouch* (see Fig. 40-1). Because of the proximity of the perimetrium to the urinary bladder, a bladder infection often causes uterine symptoms, particularly during pregnancy.

The middle muscle layer, the *myometrium,* forms the major portion of the uterine wall. It is continuous with the muscle layer of the uterine tubes and the vagina. The smooth muscle also extends into the ligaments connected to the uterus. The inner fibers of the myometrium run in various directions, giving it an interwoven appearance. Contractions of these muscle fibers help to expel menstrual flow and the products of conception during miscarriage or childbirth.

The *endometrium,* or inner layer of the uterus, is continuous with the epithelial lining of the uterine tubes and vagina. It is actively involved in the menstrual cycle, differing in structure with each stage of the cycle (to be discussed). If conception occurs, the products of conception are implanted in this layer; if conception does not occur, the inner surface of this layer is shed through menstruation.

The round cervix forms the neck of the uterus. The opening, or os, of the cervix forms a pathway between the uterus and the vagina. The vaginal opening is called the *external os,* and the uterine opening, the *internal os*. The space between these two openings is called the *endocervical (cervical) canal.* Secretions from the columnar epithelium of the endocervix protect the uterus from infection, alter receptivity to sperm, and form a mucoid "plug" during pregnancy. The endocervical canal provides a route for menstrual discharge and entry of sperm.

Fallopian (Uterine) Tubes

The *fallopian*, or *uterine*, tubes are slender cylindrical structures attached bilaterally to the uterus and supported by the upper folds of the broad ligament.[1,2] The end of the fallopian tube nearest the ovary forms a funnel-like opening with fringed, fingerlike projections, called *fimbriae,* that pick up the ovum after its release into the peritoneal cavity after ovulation (see Fig. 40-4). The fallopian tubes are formed of smooth muscle and lined with a ciliated, mucus-producing epithelial layer. The beating of the cilia, along with contractile movements of the smooth muscle, propels the nonmobile ovum toward the uterus. Besides providing a passageway for ova and sperm, the fallopian tubes permit drainage of tubal secretions into the uterus.

Ovaries

The ovaries are paired organs located on either side of the uterus below the ends of the two fallopian tubes. In the

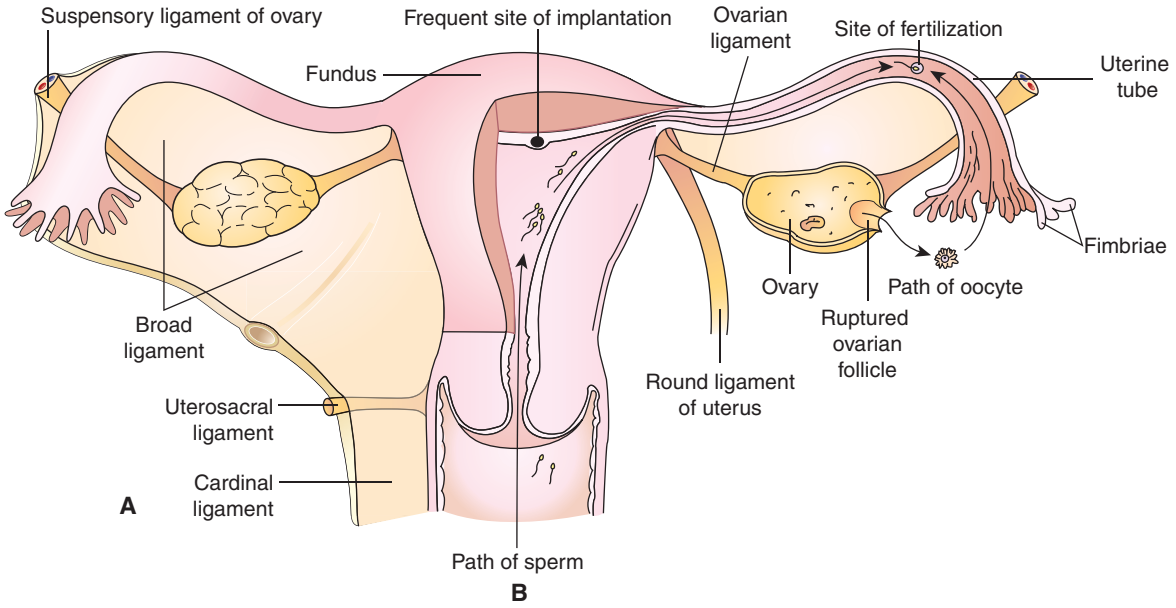

FIGURE 40-4. Schematic drawing of female reproductive organs, showing **(A)** suspensory ligament of the ovary and the broad, uterosacral, and cardinal ligaments on the left, and **(B)** the path of the oocyte as it moves from the ovary into the fallopian (uterine) tube; the path of sperm is also shown, as is the usual site of fertilization.

adult, the ovaries are flat, almond-shaped structures that measure 3 cm in length.[2] The ovaries are attached to the posterior surface of the broad ligament and to the uterus by the ovarian ligament (see Fig. 40-4). Structurally, the mature ovary is divided into a highly vascular inner medulla and an outer cortex. The medulla or medullary region is located in the central part of the ovary. It contains loose connective tissue, blood vessels, lymphatic vessels, and nerves. The ovarian cortex is composed of a connective tissue framework, the stroma (also known as the interstitial compartment), as well as ovarian follicles in various stages of development. The surface of the ovary is covered with a thin layer of surface epithelium that is continuous with the lining of the peritoneum. The integrity of this covering is periodically broken at the time of ovulation.

The Menstrual Cycle

Between menarche (i.e., first menstrual bleeding) and menopause (i.e., last menstrual bleeding), the female reproductive system undergoes cyclic changes called the *menstrual cycle*. This includes the maturation and release of oocytes from the ovary during ovulation and periodic vaginal bleeding resulting from the shedding of the endometrial lining. It is not necessary for a woman to ovulate to menstruate; anovulatory cycles do occur. The menstrual cycle produces changes in the breasts, uterus, skin, ovaries, and perhaps other, unidentified tissues.

The menstrual cycle is regulated by a complex interaction between the hypothalamic-pituitary axis, the ovaries, and the uterus[3,4] (Fig. 40-5). Although each part of the system is essential to normal function, the ovaries are primarily responsible for controlling the cyclic changes and the length of the menstrual cycle. In most women in the middle reproductive years, menstrual bleeding occurs every 25 to 35 days, with a median of 28 days.

The Hypothalamic-Pituitary Axis

The ovaries perform two interrelated functions—steroidogenesis, or production of the female sex hormones, and gametogenesis, or production of ova. Both of these functions are regulated by follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary gland[3,4] (Fig. 40-6). Because these hormones promote the growth of cells in the ovaries and testes as a means of stimulating the production of sex hormones, they are called the *gonadotropic hormones*. The secretion of LH and FSH is stimulated by gonadotropin-releasing hormone (GnRH) from the hypothalamus. These gonadotropins then trigger the ovary to release an oocyte that is capable of being fertilized. Concurrently, the ovary secretes hormones that act on the endometrial lining of the uterus to prepare for implantation. In addition, the ovarian hormones feed back to the hypothalamus and pituitary regarding the secretion of gonadotropins during the menstrual cycle.

In addition to LH and FSH, the anterior pituitary secretes a third hormone called *prolactin*. The primary function of prolactin is the stimulation of lactation in the postpartum period. During pregnancy, prolactin, along with other hormones such as estrogen, progesterone, insulin, and cortisol, contributes to breast development in preparation for lactation. Although prolactin does not appear to play a physiologic role in ovarian function, hyperprolactinemia can lead to hypogonadism. This may include an initial shortening of the luteal phase with subsequent anovulation, oligomenorrhea or amenorrhea, and infertility. The hypothalamic control of prolactin

secretion is primarily inhibitory, and dopamine is the most important inhibitory factor. Hyperprolactinemia may occur as an adverse effect of drug treatment using phenothiazine derivatives (i.e., antipsychotic drugs that block dopamine receptors).

Ovarian Hormones

The ovaries produce estrogens, progesterone, and androgens. In the ovary, the main source of hormone production is the maturing follicle, including the theca cells, granulosa cells, and corpus luteum (to be discussed). The theca cells produce androgens, the granulosa cells produce estrogen, and the corpus luteum produces progesterone. The other stromal cells that contribute to the production of androgens can be divided into two populations: the secondary interstitial cells (derived from the theca) and the hilum cells. These cells are the major ones involved in androgen production during menopause.[3,4]

Estrogens. Estrogens are a family of structurally related female sex hormones synthesized and secreted by cells in the ovaries and, in small amounts, by cells in the adrenal cortex.[3–5] Androgens can be converted to estrogens peripherally, especially in adipose tissue. Three estrogens occur naturally in humans: estrone, estradiol, and estriol. Of these, estradiol is the most biologically potent and the most abundantly secreted product of the ovary. Estrogens are transported in the blood bound to specific plasma globulins, inactivated and conjugated in the liver, and then excreted in the bile.

Estrogens are necessary for normal female development.[3–5] They stimulate the development of the vagina, uterus, and uterine tubes in the embryo. They also stimulate the stromal development and ductal growth of the breasts at puberty, are responsible for the accelerated pubertal skeletal growth phase and for closure of the epiphyses of the long bones, contribute to the growth of

axillary and pubic hair, and alter the distribution of body fat to produce the typical female body contours. In concert with other hormones, estrogens provide for the reproductive processes of ovulation, implantation of the products of conception, pregnancy, parturition, and lactation by stimulating the development and maintaining the growth of the reproductive organs.

Estrogens also have a number of important other metabolic effects. They are responsible for maintaining the normal structure of skin and blood vessels in women. Estrogens decrease the rate of bone resorption by antagonizing the effects of calcitonin on bone; for this reason, osteoporosis is a common problem in estrogen-deficient postmenopausal women (see Chapter 44). In the liver, estrogens increase the synthesis of transport proteins for thyroxine, estrogen, testosterone, and other hormones. Estrogens also affect the composition of the plasma lipoproteins. They produce an increase in high-density lipoproteins (HDLs), a slight reduction in low-density lipoproteins (LDLs), and a reduction in cholesterol levels (see Chapter 18). Estrogens also increase plasma triglyceride levels, and they enhance the coagulability of blood by increasing the circulating levels of plasminogen and factors II, VII, IX, and X. Estrogens, which have a chemical structure similar to adrenal cortical hormones, can also cause sodium and water retention by the kidney. Most women retain sodium and water and gain weight just before menstruation. The actions of estrogens are summarized in Table 40-1.

Although the ovaries are the major source of estrogen, the biosynthesis of estrogens that occurs in adipose tissue may be a significant source of the hormone. There is evidence that a certain minimum body weight and fat content are necessary for menarche to occur and for the menstrual cycle to be maintained.[4] This is supported by the observation of amenorrhea in women with anorexia nervosa, chronic disease, and malnutrition and in those who are long-distance runners. In women with anorexia nervosa, gonadotropin and estradiol secretion, including LH release and responsiveness to the hypothalamic GnRH, can revert to prepubertal levels. With resumption of weight gain and attainment of sufficient body mass, the normal hormonal pattern usually is reinstated. Obesity or significant weight gain also is associated with oligomenorrhea or amenorrhea and infertility, although the mechanism is not well understood.

Progesterone. Although the word *progesterone* refers to a substance that maintains pregnancy, progesterone is secreted as part of the normal menstrual cycle.[3,4] The corpus luteum of the ovary secretes large amounts of progesterone after ovulation, and the adrenal cortex secretes small amounts. The hormone circulates in the blood attached to a specific plasma protein. It is metabolized in the liver and conjugated for excretion in the bile.

The local effects of progesterone on reproductive organs include the glandular development of the lobular and alveolar tissue of the breasts and the cyclic glandular development of the endometrium. Progesterone also can compete with aldosterone at the level of the renal tubule, causing a decrease in sodium reabsorption, with a resultant increase in secretion of aldosterone by the adrenal cortex (as occurs in pregnancy). Although the mechanism is uncertain, progesterone increases basal

TABLE 40-1 Actions of Estrogens

General Function	Specific Actions
Growth and development	
Reproductive organs	Stimulate development of vagina, uterus, and fallopian tubes in utero and of secondary sex characteristics during puberty
Skeleton	Accelerate growth of long bones and closure of epiphyses at puberty
Reproductive processes	
Ovulation	Promote growth of ovarian follicles
Fertilization	Alter the cervical secretions to favor survival and transport of sperm
	Promote motility of sperm within the fallopian tubes by decreasing mucus viscosity
Implantation	Promote development of endometrial lining in the event of pregnancy
Vagina	Proliferate and cornify vaginal mucosa
Cervix	Increase mucus consistency
Breasts	Stimulate stromal development and ductal growth
General metabolic effects	
Bone resorption	Decrease rate of bone resorption
Plasma proteins	Increase production of thyroid and other binding globulins
Lipoproteins	Increase high-density and slightly decrease low-density lipoproteins

body temperature and is responsible for the increase in body temperature that occurs with ovulation. Smooth muscle relaxation under the influence of progesterone plays an important role in maintaining pregnancy by decreasing uterine contractions and is responsible for many of the common discomforts of pregnancy, such as edema, nausea, constipation, flatulence, and headaches. The increased progesterone present during pregnancy and the luteal phase of the menstrual cycle enhances the ventilatory response to carbon dioxide, leading to a measurable change in arterial and alveolar carbon dioxide (PCO_2) levels.

Androgens. Ovarian cells also secrete androgens. In the female, androgens contribute to normal hair growth at puberty and may have other important metabolic effects. Androgen production takes place in the connective tissue (stroma) that surrounds the follicles.[4] During the reproductive years, the ovaries are directly responsible for one third of testosterone production. The remaining two thirds comes from the periphery and ovarian and adrenal precursors—mainly androstenedione, which is produced in equal proportions by the adrenal and ovary. The adrenal gland may directly secrete testosterone, but its main contribution is derived from its production of precursors.

Ovarian Follicle Development and Ovulation

Unlike the male gonads, which produce sperm throughout a man's reproductive life, the female gonads contain a fixed number of ova at birth that diminishes throughout a woman's life. The process of oogenesis (generation of ova by mitotic division) begins during the sixth week of fetal life and proceeds to the development of the primary oocytes, which become surrounded by a single layer of granulosa cells.[2–4] The primary oocytes with their surrounding granulosa cells are referred to as *primordial follicles*. These primitive germ cells provide the 1 to 2 million oocytes that are present in the ovaries at birth. Throughout childhood, the granulosa cells provide nourishment for the ovum and secrete an inhibiting factor that keeps the ovum suspended in a primordial state.

Beginning at puberty, a cyclic rise in the anterior pituitary hormones FSH and LH stimulates the development of several graafian, or mature, follicles. Follicles at all stages of development can be found in both ovaries, except in menopausal women (Fig. 40-7). Most follicles exist as primary follicles, each of which consists of a round oocyte surrounded by a single layer of flattened epithelial cells called *granulosa cells*. The primary follicles constitute an inactive pool of follicles from which all the ovulating follicles develop. Under the influence of endocrine stimulation, 6 to 12 primary follicles develop into secondary follicles once every ovulatory cycle. During the development of the secondary follicle, the primary oocyte increases in size, and the granulosa cells proliferate to form a multilayered wall around it. During this time, a membrane called the *zona pellucida* develops and surrounds the oocyte and small pockets of fluid begin to appear between the granulosa cells.

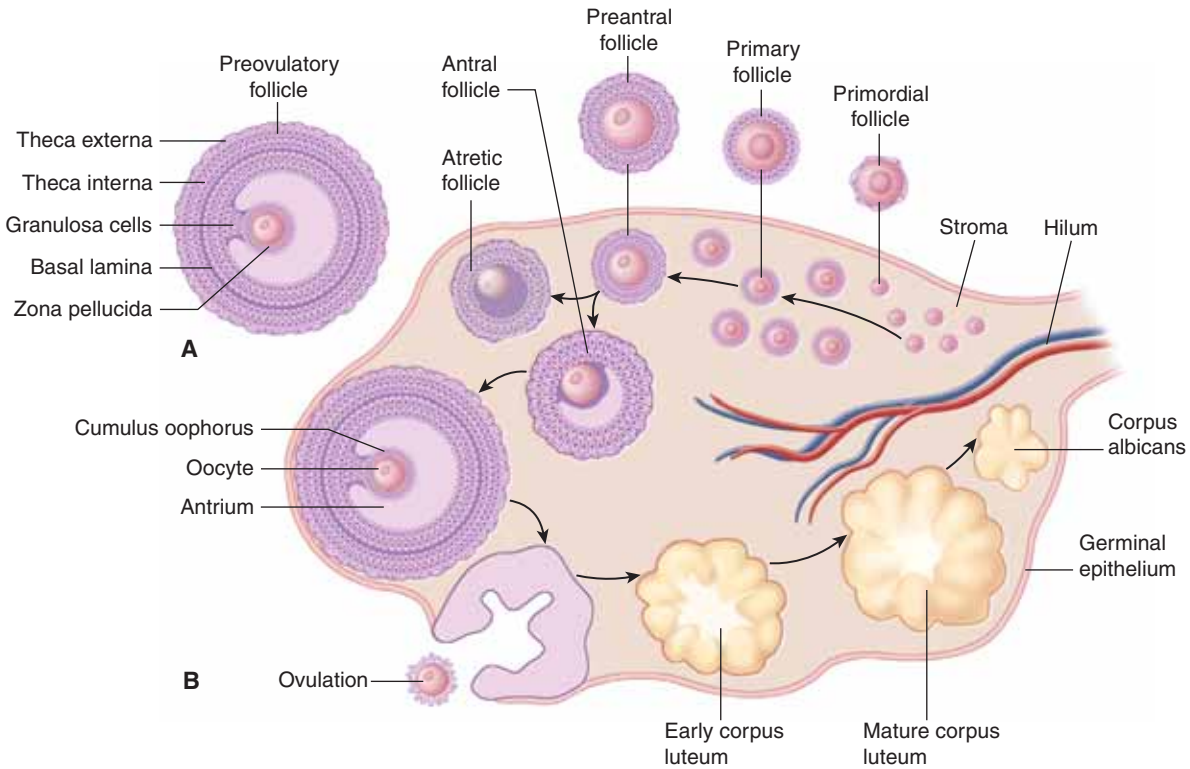

FIGURE 40-7. **(A)** Cross-section of preovulatory follicle. **(B)** Schematic diagram of an ovary, showing the sequence of events in the origin, growth, and rupture of an ovarian follicle and the formation and retrogression of a corpus luteum. The atretic follicles are those that show signs of degeneration and death.

As the follicles mature, FSH stimulates the development of the cell layers. Cells from the surrounding stromal tissue align themselves to form a sheath of connective tissue cells, known as the *theca folliculi*. The cells of the theca folliculi become differentiated into two layers: an inner layer of highly vascularized androgen-producing cells, called the *theca interna,* and an outer layer of connective tissue, called the *theca extern.* As the follicle enlarges, a single large cavity, or *antrum,* is formed, and a portion of the granulosa cells and the oocyte are displaced to one side of the follicle by the fluid that accumulates. The secondary oocyte remains surrounded by a crown of granulosa cells, the *corona radiata*. As the follicle matures, ovarian estrogen is produced by the granulosa cells. Selection of a dominant follicle occurs with the conversion to an estrogen microenvironment. The lesser follicles, although continuing to produce some estrogen, degenerate or become atretic. The dominant preovulatory follicle accumulates a greater mass of granulosa cells, and the theca becomes richly vascular, giving the follicle a hyperemic appearance. High levels of estrogen exert a negative feedback effect on FSH, inhibiting the development of multiple follicles and causing an increase in LH levels. This represents the follicular stage of the menstrual cycle. As estrogen suppresses FSH, the actions of LH predominate, and the mature follicle (measuring approximately 20 mm) bursts; the oocyte, along with the corona radiata, is ejected from the follicle. The ovum normally is then picked up and transported through the fallopian tube toward the uterus.

After ovulation, the follicle collapses, and the luteal stage of the menstrual cycle begins. The granulosa cells are invaded by blood vessels and yellow lipochrome-bearing cells from the theca layer. A rapid accumulation of blood and fluid forms a mass called the *corpus luteum.* Leakage of this blood onto the peritoneal surface that surrounds the ovary is thought to contribute to the *mittelschmerz* ("middle [or intermenstrual] pain") of ovulation. During the luteal stage, progesterone is secreted from the corpus luteum. If fertilization does not take place, the corpus luteum atrophies and is replaced by white scar tissue called the *corpus albicans;* the hormonal support of the endometrium is withdrawn and menstruation occurs. In the event of fertilization, a hormone called *human chorionic gonadotropin* is produced by the trophoblastic cells in the blastocyst. This hormone prevents luteal regression. The corpus luteum remains functional for 3 months and provides hormonal support for pregnancy until the placenta is fully functional.

Endometrial Changes

The endometrium consists of two distinct layers, or zones, that are responsive to hormonal stimulation: a basal layer and a functional layer. The *basal layer* lies adjacent to the myometrium and is not sloughed during menstruation.[2–4] The *functional layer* arises from the basal layer and undergoes proliferative changes and menstrual sloughing. It can be subdivided into two components: a thin, superficial, compact layer and a deeper spongiosa layer that makes up most of the secretory and fully developed endometrium. The endometrial cycle can be divided into three phases: proliferative, secretory, and menstrual (see Fig. 40-5). The proliferative, or preovulatory, phase is the period during which the glands and stroma of the superficial layer grow rapidly under the influence of estrogen. The secretory, or postovulatory, phase is the period during which progesterone produces glandular dilatation and active mucus secretion and the endometrium becomes highly vascular and edematous. The menstrual phase is the period during which the superficial layer degenerates and sloughs off.

In summary, the female reproductive system consists of external and internal genitalia. The external genitalia are situated in the anterior part of the perineum, and the internal structures (uterus, fallopian tubes, and ovaries) are located in the pelvic cavity. The uterus is a thick-walled, muscular organ. The wall of the uterus is composed of three layers: the outer perimetrium; the myometrium or muscle layer, which is continuous with the myometrium of the fallopian tubes and the vagina; and the inner lining or endometrium, which is continuous with the lining of the fallopian tubes and vagina. The paired gonads, or ovaries, have the dual function of steroidogenesis, or production of the female sex hormones, and gametogenesis, or production of female germ cells (ova). Unlike the male gonads, which produce sperm throughout a man's reproductive life, the female gonads contain a fixed number of ova at birth that diminishes throughout a woman's life.

Between menarche and menopause, the female reproductive system undergoes cyclic changes called the *menstrual cycle.* The normal menstrual cycle results from complex interactions among the hypothalamus, which produces GnRH; the anterior pituitary gland, which synthesizes and releases FSH, luteinizing hormone (LH), and prolactin; the ovaries, which synthesize and release estrogens, progesterone, and androgens; and the endometrium. Although each component of the system is essential for normal functioning, the ovarian hormones are largely responsible for controlling the cyclic changes and length of the menstrual cycle. Estrogens are necessary for normal female physical maturation, for growth of ovarian follicles, for generation of a climate that is favorable to fertilization and implantation of the ovum, and for promoting the development of the endometrium in the event of pregnancy. The functions of progesterone include the glandular development of the lobular and alveolar tissue of the breasts, the cyclic development of the glandular endometrium, and maintenance of pregnancy. Androgens, produced in the ovary, are derived from precursors produced by the ovary or adrenal gland, contribute to hair distribution in the female, and may have important metabolic effects.

Disorders of the Female Reproductive Organs

Disorders of the female reproductive system have widespread effects on physical, psychological, sexual, and reproductive function. The reproductive organs are located close to other pelvic structures, particularly those of the urinary system, and disorders of the reproductive system may affect urinary function. This section of the chapter focuses on infections and benign and malignant disorders of the external and internal genitalia.

Disorders of the External Genitalia

The external genitalia, which are covered with stratified squamous epithelium, are subject to dermatologic conditions that affect skin elsewhere in the body. The discussion in this section of the chapter focuses on Bartholin gland cysts and benign and malignant disorders of the vulva.

Bartholin Gland Cyst and Abscess

A Bartholin gland cyst is a fluid-filled sac located near the vaginal introitus that results from obstruction of the main duct of the gland.[6–8] It may become large, up to 3 to 5 cm in diameter, and produce pain and local discomfort. Infection of a Bartholin cyst produces acute inflammation within the gland and may result in an abscess. Acute symptoms are usually the result of infection and include pain, tenderness, and dyspareunia.

The treatment of symptomatic Bartholin gland cysts consists of the administration of appropriate antibiotics, local application of moist heat, and incision and drainage. Cysts that frequently are abscessed or are large enough to cause blockage of the introitus may require surgical intervention (i.e., marsupialization, a procedure that involves removal of a wedge of vulvar skin and the cyst wall).[8] Because the Bartholin glands usually shrink during menopause, a vulvar growth in postmenopausal women should be evaluated for malignancy.

Benign and Malignant Disorders of the Vulva

Disorders of the vulva often present as white lesions of the vulvar skin and mucosa that may produce pruritus (itching) and scaling. Although commonly referred to as *leukoplakia* because of their plaquelike appearance, these lesions can represent a number of disorders including inflammatory dermatoses (e.g., psoriasis or chronic dermatitis, discussed in Chapter 46), nonneoplastic epithelial disorders, and premalignant and malignant lesions of the vulva.[6]

Nonneoplastic Epithelial Disorders. The term *nonneoplastic epithelial disorders* refers to nonmalignant atrophic and hyperplastic changes of the vulvar skin and mucosa.[6,7,9] Depending on clinical and histologic characteristics, the lesions can be further categorized as lichen sclerosus and squamous cell hyperplasia (formerly known as *lichen simplex chronicus*).

Lichen sclerosus is an inflammatory disease of the vulva characterized by plaquelike areas that may progress to parchment-thin epithelium with focal areas of ecchymosis and superficial ulcerations secondary to scratching. Atrophy and contracture of the vulvar tissues with eventual stenosis of the introitus are common when this condition becomes chronic. Itching is common and dyspareunia (painful intercourse) is frequent. The condition develops insidiously and is progressive.

Squamous cell hyperplasia, which usually presents as thickened, gray-white plaques with an irregular surface, is a nonspecific condition resulting from rubbing or scratching on the skin to relieve pruritus. Presumed to be a response of the genital skin to some type of irritant, this diagnosis is used only when human papillomavirus (HPV) infection (see Chapter 41), fungal infections, or other known causative conditions have been excluded. Pruritus is the most common presenting complaint. Scaling is generally present, and excoriations due to recent scratching can often be seen. There is generally no increased predisposition to cancer, but similar lesions are often present at the margins of established cancer of the vulva.

Current treatment for lichen sclerosus includes the use of topical corticosteroids. Lichen sclerosus frequently recurs, and lifetime maintenance therapy may be required. Hyperplastic areas that occur in the field of lichen sclerosus may be sites of malignant change and warrant close follow-up and possible biopsy.

Premalignant and Malignant Neoplasms. Carcinoma of the vulva is a relatively rare cancer that accounts for approximately 3% to 5% of all cancers of the female reproductive system in the United States, occurring most often in women 60 years of age or older.[6] Approximately 90% of vulvar malignancies are squamous cell carcinomas.[10] Less common forms of vulvar cancer include malignant melanomas, adenocarcinoma, basal cell carcinoma, and metastatic cancers from various other sites.

In terms of etiology, pathogenesis, and clinical presentation, vulvar carcinoma can be divided into two general groups: (1) basaloid and warty carcinomas, related to infection with oncogenic strains of HPV (about 30% of cases), and (2) keratinizing squamous cell carcinoma, not related to HPV infection (about 70% of cases).[6,7]

Invasive basaloid and warty-type carcinomas develop from a precancerous in situ lesion called vulvar intraepithelial neoplasia (VIN). This type of lesion occurs in reproductive-age women, and risk factors are similar to those for cancer in situ of the cervix.[6] Spontaneous resolution of VIN lesions has occurred. The risk of progression to invasive cancer increases in older women and in women with suppressed immune function. The second form of vulvar cancer, which is seen more often in older women, is generally preceded by vulvar nonneoplastic disorders such as chronic vulvar irritation or lichen sclerosus. The etiology of this group of vulvar cancers is unclear, but they are not typically associated with HPV. Neoplastic changes may arise from lichen sclerosus lesions or hyperplasia, leading directly to invasion, or through an intermediate step involving cellular atypia.[6]

The initial lesion of squamous cell vulvar carcinoma may appear as an inconspicuous thickening of the skin, a small raised area or lump, or an ulceration that fails to heal. It may be single or multiple and vary in color from white to velvety red or black. The lesions may resemble eczema or dermatitis and may produce few symptoms other than pruritus, local discomfort, and exudation. The symptoms frequently are treated with various home remedies before medical treatment is sought. The lesion may become secondarily infected, causing pain and discomfort. The malignant lesion gradually spreads superficially or as a deep furrow involving all of one labial side. Because there are many lymph channels around the vulva, the cancer metastasizes freely to the regional lymph nodes, including those of the inguinal and femoral chains.[11]

Early diagnosis is important in the treatment of vulvar carcinoma. Because malignant lesions can vary in appearance and commonly are mistaken for other conditions, biopsy and treatment often are delayed. Any vulvar lesion that is increasing in size or has an unusual wartlike appearance should be biopsied.[11] Treatment is primarily wide surgical excision of the lesion for noninvasive cancer and radical excision or vulvectomy with node resection for invasive cancer.

Vulvodynia

Vulvodynia is a syndrome of unexplained vulvar pain, previously referred to as *vulvar pain syndrome* or *burning vulva syndrome*.[12,13] The terminology and diagnostic criteria used for this chronic disorder remain in flux, but the most recent classification system of the International Society for the Study of Vulvovaginal Disorders (ISSVD) defines it as a condition characterized by "burning, stinging, irritation, soreness or rawness in the absence of relevant visible findings or a specific, clinically identifiable, neurological disorder."[12] Vulvodynia is further classified as localized or generalized, and as to whether it is provoked, unprovoked, or of mixed origin.

Localized vulvodynia or *vestibulodynia,* formerly referred to as *vulvar vestibulitis syndrome,* is characterized by pain at onset of intercourse, localized point tenderness near the vaginal opening, and sensitivity to tampon placement, tight-fitting pants, bicycling, or prolonged sitting. It is the leading cause of dyspareunia in women younger than 50 years of age. The pain can be primary (present from first contact) or secondary (developing after a period of comfortable sexual relations). The etiology is unknown, but the problem may evolve from chronic vulvar inflammation or trauma. Nerve fibers that supply the vestibular epithelium may become highly sensitized, causing neurons in the dorsal horn of the spinal cord to respond abnormally, thus transforming the sensation of touch in the vestibule into pain.

Generalized vulvodynia, formerly called *vulvar dysesthesia* or *essential vulvodynia,* involves severe, constant, widespread burning that interferes with daily activities. No abnormalities are found on examination, but there is diffuse and variable hypersensitivity and altered sensation to light touch. The quality of this unprovoked pain shares many of the features of other neuropathic pain disorders, particularly complex regional pain syndrome (see Chapter 35) or pudendal neuralgia. Although the cause of the neuropathic pain is unknown, it has been suggested that it may result from myofascial restrictions affecting the sacral and pelvic floor nerves.[12,13]

There are many proposed triggers for vulvodynia, including chronic recurrent vaginal infections; chemical irritation or drug effects, especially prolonged use of topical steroid creams; the irritating effects of elevated urinary levels of calcium oxalate; and immunoglobulin A deficiency or other disorders of immune regulation. Often it is multifactorial in origin.

Careful history taking and physical assessment are essential for differential diagnosis and treatment. *Vulvodynia* is a diagnosis of exclusion after ruling out infections, such as candidiasis and genital herpes; inflammatory conditions, such as squamous cell hyperplasia and lichen sclerosus; vulvar cancer; or neurologic disorders, such as herpes neuralgia or spinal nerve compression, as causes for the pain.

Treatment of vulvodynia is aimed at symptom relief, is frequently long term, and often needs to be managed from a multidimensional, chronic pain perspective.[12,13] Local measures include avoidance of harsh soaps and perfumed products, use of sitz baths, and application of topical anesthetic agents (i.e., lidocaine ointment). Because dermatologic conditions such as atopic dermatitis and candidiasis are responsible for many of the symptoms of vulvodynia, some health care providers recommend treatment with antihistamines and antifungal medications, as well as avoidance of irritating contactants.[14] Biofeedback and physical therapy may be used to reverse the changes in pelvic floor musculature and help women control the muscles, regaining strength and improving relaxation. Oral medications, including tricyclic antidepressants and other antidepressants, are often used to treat the neuropathic pain associated with vulvodynia.

Disorders of the Vagina

The normal vaginal ecology depends on the delicate balance of hormones and bacterial flora. Normal estrogen levels maintain a thick, protective squamous epithelium that contains glycogen. Döderlein bacilli, part of the normal vaginal flora, metabolize glycogen, and in the process produce the lactic acid that normally maintains the vaginal pH of 3.8 to 4.5.[15] Disruptions in these normal environmental conditions predispose to infection.

Vaginitis

Vaginitis represents an inflammation of the vagina that is characterized by vaginal discharge and burning, itching, redness, and swelling of vaginal tissues. Pain often occurs with urination and sexual intercourse. Vaginitis may be caused by chemical irritants, foreign bodies, or infectious agents. The causes of vaginitis differ in various age groups. In premenarchal girls, most vaginal infections have nonspecific causes, such as poor hygiene, intestinal parasites, or the presence of foreign bodies. *Candida albicans, Trichomonas vaginalis,* and bacterial vaginosis are

the most common causes of vaginitis in the childbearing years, and some of these organisms can be transmitted sexually[15] (see Chapter 41).

The decrease in estrogen levels that occurs during perimenopause and after menopause can lead to an atrophic form of vaginitis.[16] Estrogen deficiency results in a lack of regenerative growth of the vaginal epithelium and changes in the vaginal pH and flora, rendering these tissues more susceptible to infection and irritation. Döderlein bacilli disappear, and the vaginal secretions become less acidic. The symptoms of atrophic vaginitis include itching, burning, and dyspareunia. These symptoms usually can be reversed by local application of estrogen.

Every woman normally experiences vaginal discharge during the menstrual cycle, but it should not cause burning or itching or have an unpleasant odor. These symptoms suggest inflammation or infection. Because these symptoms are common to the different types of vaginitis, precise identification of the organism is essential for proper treatment. A careful history should include information about systemic disease conditions, the use of drugs such as antibiotics that foster the growth of yeast, dietary habits, stress, and other factors that alter the resistance of vaginal tissue to infections. A physical examination usually is done to evaluate the nature of the discharge and its effects on the genital structures. Microscopic examination of a saline wet-mount smear is the primary means of identifying the organism responsible for the infection.[15,16] Culture methods and deoxyribonucleic acid (DNA) probe tests may be needed when the organism is not apparent on a wet-mount preparation.

Cancer of the Vagina

Primary cancers of the vagina are extremely rare, accounting for approximately 1% to 2% of all cancers of the female reproductive system.[6,7,10] Like vulvar carcinoma, cancer of the vagina is largely a disease of older women, with a peak incidence between 60 and 70 years of age.[7] The exception to that is the clear cell adenocarcinoma associated with diethylstilbestrol (DES) exposure in utero. DES is a hormonal drug that was given to some women to prevent miscarriage during the years between 1940 and 1971.[17] Vaginal cancers may also result from local extension of cervical cancer, from exposure to sexually transmitted HPV, or rarely from local irritation such as occurs with prolonged use of a pessary. Smoking and human immunodeficiency virus (HIV) infection also increase the risk of vaginal cancer.

Approximately 70% of vaginal cancers are squamous cell carcinomas, with other less common types being adenocarcinomas (15%), malignant melanomas (9%), and sarcomas (up to 4%).[17] Squamous cell carcinomas begin in the epithelium and progress over many years from precancerous lesions called *vaginal intraepithelial neoplasia* (VAIN). Not infrequently, squamous cell carcinoma develops some years after cervical or vulvar carcinoma, a sequence that supports the carcinogenic effect in the lower genital tract related to HPV infection.

The most common symptom of vaginal carcinoma is abnormal bleeding. Other signs or symptoms include an abnormal vaginal discharge, a palpable mass, or dyspareunia. Most women with preinvasive vaginal carcinoma are asymptomatic, with the cancer being discovered during a routine pelvic examination. The anatomic proximity of the vagina to other pelvic structures (urethra, bladder, and rectum) permits early spread to these areas. Pelvic pain, dysuria, and constipation can be associated symptoms.

Since most preinvasive and early invasive cancers are silent, the routine use of vaginal cytology (Papanicolaou [Pap] smear) is the most effective way to detect vaginal cancer. Diagnosis requires biopsy of suspect lesions or areas. Both radiation and surgical methods are used in treatment of vaginal cancer, with the treatment plan being determined by the cancer type, stage of the disease (i.e., size, location, and spread), and the woman's age. Radiation therapy is the mainstay for treatment of squamous cell carcinomas. Radical hysterectomy combined with upper vaginectomy and pelvic lymph node dissection may be used for selected cases.[11]

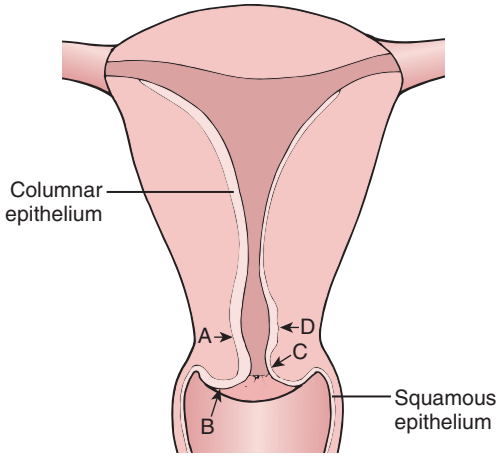
Disorders of the Uterine Cervix

The cervix is composed of two types of epithelial tissue: stratified squamous and columnar epithelium. The exocervix, or visible portion, is covered with stratified squamous epithelium, which also lines the vagina. The endocervix, which is the canal that leads to the endometrial cavity, is lined with columnar epithelium that contains large, branched mucus-secreting glands. The amount and properties of the mucus secreted by the gland cells vary during the menstrual cycle. Blockage of the mucosal glands results in trapping of mucus in the deeper glands, leading to the formation of dilated cysts in the cervix called *nabothian cysts*. These are benign cysts that require no treatment unless they become so numerous that they cause cervical enlargement.

The junction of the squamous epithelium of the exocervix and mucus-secreting columnar epithelium of the endocervix (i.e., squamocolumnar junction) appears at various locations on the cervix at different points in a woman's life (Fig. 40-8). During childhood, the squamocolumnar junction is located just inside the external os. The combination of hormones and the acidification of the vaginal environment that occurs during puberty lead to a gradual transformation from columnar to squamous epithelium—a process called *metaplasia* (see Chapter 2). The metaplasia in these cells causes the squamocolumnar junction to "roll out" or evert from its original position inside the external os to a position of enlarged cervical surface, where it is exposed to vaginal secretions, irritants, and a changing hormonal environment. The area of dynamic change where metaplasia takes place is called the *transformation zone*.[6,7] The transformation zone is a critical area for the development of cervical cancer.

Cervicitis

Cervicitis is an acute or chronic inflammation of the cervix. Acute cervicitis may result from the direct infection of the cervix or may be secondary to a vaginal or uterine infection. It may be caused by a variety of



A. Menarchial
B. Menstruating
C. Menopausal
D. Postmenopausal

FIGURE 40-8. Location of the squamocolumnar junction (transformation zone) in menarchial, menstruating, menopausal, and postmenopausal women.

infective agents, including *C. albicans, T. vaginalis, Neisseria gonorrhoeae, Gardnerella vaginalis, Chlamydia trachomatis, Ureaplasma urealyticum,* and herpes simplex virus. *C. trachomatis* is the organism most commonly associated with mucopurulent cervicitis. With acute cervicitis, the cervix becomes reddened and edematous. Irritation from the infection results in copious mucopurulent drainage. Depending on the causative agent, acute cervicitis is treated with appropriate antibiotic therapy.

Chronic cervicitis represents a low-grade inflammatory process. It is seen most commonly in parous women and may be sequelae to minute lacerations that occur during childbirth, instrumentation, or other trauma. The organisms usually are nonspecific—often staphylococcal, streptococcal, or coliform bacilli. The symptoms of chronic cervicitis are less well defined than those of acute cervicitis. The cervix may be ulcerated or normal in appearance; it may contain nabothian cysts; the cervical os may be distorted by old lacerations or everted to expose areas of columnar epithelium; and a mucopurulent drainage may be present.

Untreated cervicitis may extend to include the development of pelvic cellulitis, low back pain, dyspareunia, cervical stenosis, dysmenorrhea, and ascending infection of the uterus or fallopian tubes. Diagnosis of chronic cervicitis is based on vaginal examination, colposcopy, Pap smears, and occasionally biopsy to exclude malignant changes. Treatment usually involves cryosurgery or cauterization, which causes the tissues to slough and leads to eradication of the infection.

Premalignant Lesions and Cancer of the Cervix

Cervical cancer is one of the best-understood cancers and potentially one of the most preventable. In the 1950s cervical cancer was the leading cause of cancer deaths in women in the United States, but the death rate has declined steadily over the past several decades due to prevention and early detection by cancer screening.[6] Worldwide, however, cervical cancer continues to remain a commonly diagnosed cancer in women. More than 80% of these cases occur in developing countries, where cervical cancer kills more women than any other cancer.[18]

Pathogenesis and Risk Factors. The pathogenesis of cervical cancer has been linked to HPV infection by a series of epidemiologic, pathologic, and molecular genetic studies. Of the approximate 100 types of HPV, about 40 affect the anogenital tract. About 15 of these types are associated with cancer and are known as high-risk groups, with subtypes 16 and 18 being the most important in terms of cervical cancer pathology (see Chapter 41).[6] HPV 16 accounts for almost 60% of cervical cancer cases, and HPV 18 for another 10%.[7] By contrast, low-risk types 6 and 11 are associated with genital warts (condylomata acuminata).

Most cervical cancers begin their development in the transformation zone. The metaplastic cells within this zone represent the newest and least mature cells in the cervix, and it is thought that they are most vulnerable to oncogenic change. Even though HPV has been firmly established as a causative factor in cervical cancer, the evidence does not implicate HPV as the only risk factor. Most HPV infections are transient, indicating the host's defense system is able to eradicate the virus before it can cause neoplastic changes in cervical cells. Other factors such as cigarette smoking, dietary and nutritional factors, early age of first sexual intercourse, family history of cervical cancer, immunodeficiency (e.g., HIV infection), multiparity, use of oral contraceptive agents, and a history of

Gynecologic Cancers

- Cancers of the vulva, cervix, endometrium, and ovaries represent a spectrum of malignancies.
- Cancers of the vulva and cervix are mainly squamous cell carcinomas. Certain types of sexually transmitted human papillomaviruses are risk factors for cervical intraepithelial neoplasia, which can be a precursor lesion of invasive carcinoma.
- Endometrial cancers, which are seen most frequently in women 55 to 65 years of age, are strongly associated with conditions that produce excessive estrogen stimulation and endometrial hyperplasia.
- Ovarian cancer is the second most common female cancer and the most lethal. The most significant risk factors for ovarian cancer are the length of time that a woman's ovarian cycles are not suppressed by pregnancy, lactation, or oral contraceptive use, and family history.

chlamydial, *Trichomonas*, or herpes virus infection may play a contributing role in determining whether a woman with HPV infection develops cervical cancer.[6,19]

A quadrivalent vaccine (Gardasil) to prevent infection with the HPV subtypes 16, 18, 6, and 11 is now available.[20,21] The target population for the vaccine is females between the ages of 9 and 26 years, optimally before initiation of sexual activity. Clinical studies have confirmed that the vaccine appears safe and effective in inducing long-term immunity to HPV.[21] Although its use in males and older women or those who have already become sexually active has not been studied, it may offer some protection.

Premalignant and Malignant Lesions. One of the most important advances in the early diagnosis and treatment of cancer of the cervix was made possible by the observation that this cancer arises from precancerous lesions that begin with the development of atypical cervical cells. There are variations in cell size and shape and changes in the nuclear and cytoplasmic parts of the cell, commonly referred to as *dysplasia* (see Chapter 7). These precancerous changes represent a continuum of morphologic changes with indistinct boundaries that may gradually progress to cancer in situ and then to invasive cancer, or they may spontaneously regress.

The classification of cervical precancerous lesions has changed over time, and terms from different classification systems are currently used interchangeably. An initial system of grading described the dysplastic changes of cervical cancer precursors using the term *cervical intraepithelial neoplasia* (CIN).[6,7,11] This system, based on histology, divided the precursors into three categories of dysplasia severity: CIN I (mild dysplasia), CIN II (moderate dysplasia), and CIN III (severe dysplasia). This system has been largely replaced by the Bethesda system, which divides epithelial lesions into squamous and glandular lesions.[11,22] In both categories, lesions are either precancerous or cancerous. Precancerous cell precursor lesions are described as either atypical squamous cells (ASCs), low-grade intraepithelial lesions (LSILs), or high-grade intraepithelial lesions (HSILs), and cancerous lesions are termed invasive squamous carcinoma. ASC can be further divided into ASC of underdetermined significance (ASC-US) or ASC-cannot exclude HSIL. Precancerous glandular lesions are classified in a similar manner as atypical glandular carcinoma (AGC). Cancerous glandular lesions are classified as adenocarcinoma.[6,11,22]

Squamous cell carcinoma is the most common histologic subtype of cervical cancer, accounting for 80% of cases. Most LSILs regress spontaneously, with only a small percentage of lesions progressing to HSIL. In HSIL, there is progressive disruption of the cell cycle by HPV, resulting in increased cell proliferation and degree of dysplasia. Cancers of the cervix have a long latent period; untreated dysplasia gradually progresses to carcinoma in situ, which may remain static for 7 to 10 years before it becomes invasive. After the preinvasive period, growth may be rapid, and survival rates decline significantly depending on the extent of disease at the time of diagnosis.

The atypical cellular changes that precede frank neoplastic changes consistent with cancer of the cervix can be recognized by a number of direct and microscopic techniques, including the Pap smear, colposcopy, and cervicography. Currently, Pap smears are used for cervical cancer screening. The appropriate use of Pap smears in cervical screening programs has been controversial. The American Cancer Society (ACS), the American College of Obstetricians and Gynecologists (ACOG), and the U.S. Preventative Services Task Force (USPSTF) have developed evidence-based guidelines for cancer screening.[23–25] The ACOG guidelines recommend that screening begin at age 21 years regardless of sexual history and be done at every 2 years between the ages of 21 years and 29 years.[24] After age 30 women who have a normal Pap test results may be tested less often—every 2 to 3 years.[23] After age 65 or 70, screening may be discontinued if there have been no abnormalities on at least three cytologic examinations.[23,25]

Testing for the presence of high-risk HPV DNA is now being used as an adjunct to the Pap smear in women over age 30 and in women with abnormal Pap results. It is also being used as a triage tool for women with Pap test results reported as ASC-US and in the management of nonadolescent women with LSIL. HPV DNA can also identify women who have abnormal Pap results caused by other, non–HPV-associated phenomena, such as infection, thus eliminating the need for unnecessary colposcopic evaluations.[11]

Diagnosis and Treatment. In its early stages, cervical cancer often manifests as a poorly defined lesion of the endocervix. Frequently, women with cervical cancer present with abnormal vaginal bleeding, spotting, and discharge. Although bleeding may assume any course, it is reported most frequently after intercourse. Women with more advanced disease may present with pelvic or back pain that may radiate down the leg, hematuria, fistulas (rectovaginal or vesicovaginal), or evidence of metastatic disease to supraclavicular or inguinal lymph node areas.

Diagnosis of cervical cancer requires pathologic confirmation. Pap smear results demonstrating squamous intraepithelial lesions often require further evaluation by colposcopy, during which a biopsy sample may be obtained from suspect areas and examined microscopically.[26] An alternative diagnostic tool in areas where colposcopy is not readily available is a noninvasive photographic technique in which a cervicography camera is used to take photographs of the cervix. The projected cervicogram (a slide made from the film) is then sent for expert evaluation.[26,27]

Early treatment of cervical cancer involves removal of the lesion by one of various techniques. Biopsy or local destruction of the affected cervical tissue may be therapeutic in and of itself. Electrocautery, cryosurgery, or carbon dioxide laser therapy may be used to treat moderate to severe dysplasia that is limited to the exocervix (i.e., squamocolumnar junction clearly visible). Therapeutic conization becomes necessary if the lesion extends into the endocervical canal and can be done surgically or with a large loop electrocautery procedure (LEEP) in the physician's office.[26]

Depending on the stage of involvement of the cervix, invasive cancer is treated with surgery, radiation therapy, chemoradiation, or chemotherapy.[27] External-beam irradiation and intracavitary irradiation or *brachytherapy* (i.e., insertion of radioactive materials into the body) can be used in the treatment of cervical cancer (see Chapter 7). Intracavitary radiation provides direct access to the central lesion and increases the tolerance of the cervix and surrounding tissues, permitting curative levels of radiation to be used. External-beam radiation eliminates metastatic disease in pelvic lymph nodes and other structures, as well as shrinking the cervical lesion to optimize the effects of intracavitary radiation. Surgery can include extended hysterectomy (i.e., removal of the uterus, fallopian tubes, ovaries, and upper portion of the vagina) without pelvic lymph node dissection, and radical hysterectomy with pelvic lymph node dissection. The choice of treatment is influenced by the stage of the disease as well as the woman's age and health.

Disorders of the Uterus

Infectious Disorders of the Uterus and Pelvic Structures

The uterus and pelvic structures are subject to infections by a number of agents, including the sexually transmitted organisms *N. gonorrhoeae* and *C. trachomatis,* as well as endogenous microorganisms such as anaerobes, *Haemophilus influenzae,* enteric gram-negative rods, and streptococci. Tuberculosis salpingitis is rare in the United States but more common in developing countries.

Endometritis. The endometrium and myometrium are relatively resistant to infections, primarily because the endocervix normally forms a barrier to ascending infections. Acute endometritis is uncommon and usually occurs after the cervical barrier is compromised by abortion, delivery, or instrumentation.[6,7] Curettage is diagnostic and often curative because it removes the necrotic tissue that has served as a site for microbial growth.

Chronic inflammation of the endometrium is associated with intrauterine devices (IUDs), pelvic inflammatory disease, and retained products of conception after delivery or abortion. The presence of plasma cells (which are not present in the normal endometrium) is required for diagnosis. The clinical picture is variable, but often includes abnormal vaginal bleeding, mild to severe uterine tenderness, fever, malaise, and foul-smelling discharge. Treatment involves oral or intravenous antibiotic therapy, depending on the severity of the condition.

Pelvic Inflammatory Disease. Pelvic inflammatory disease (PID) is a polymicrobial infection of the upper reproductive tract (uterus, fallopian tubes, or ovaries) associated with the sexually transmitted organisms and with endogenous organisms.[28–30] The organisms ascend through the endocervical canal to the endometrial cavity, and then to the fallopian tubes and ovaries (Fig. 40-9). The endocervical canal is slightly dilated during menstruation, allowing bacteria to gain entrance to the uterus and other pelvic structures. After entering the upper reproductive tract, the organisms multiply rapidly in the favorable environment of the sloughing endometrium and ascend to the fallopian tube.

Factors that predispose women to the development of PID include an age of 16 to 24 years, nulliparity, history of multiple sexual partners, and previous history of PID. Although the use of an IUD has been associated with a three- to fivefold increased risk for development of pelvic

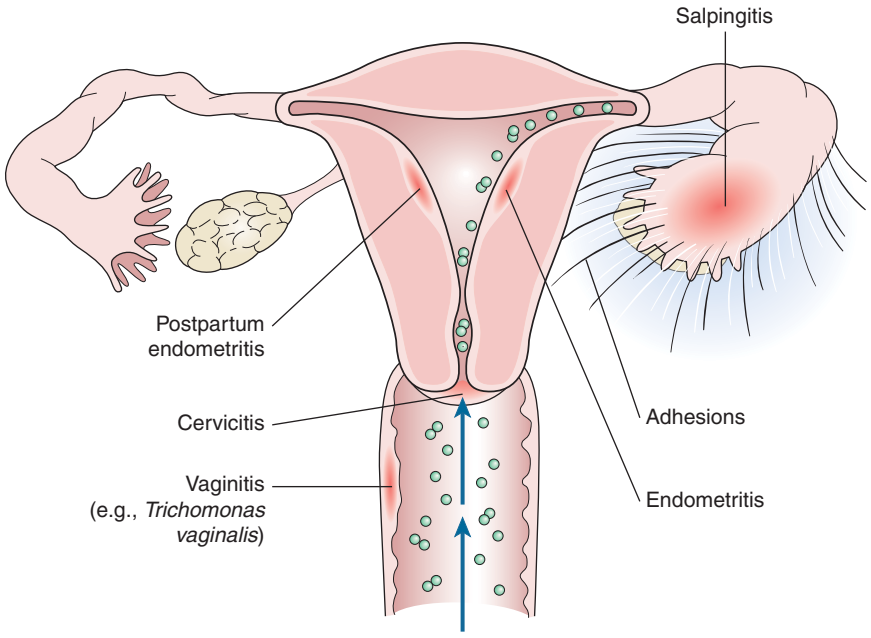


FIGURE 40-9. Pelvic inflammatory disease. Microbial agents enter through the vagina and ascend to involve the uterus, fallopian tubes, and pelvic structures.

inflammatory disease, studies have shown that women with only one sexual partner who are at low risk of acquiring sexually transmitted infections have no significant risk for development of PID from using an IUD.

Clinical Features. The symptoms of PID include lower abdominal pain, which may start just after a menstrual period; dyspareunia; back pain; purulent cervical discharge; and the presence of lower abdominal tenderness and exquisitely painful cervix on bimanual pelvic examination. New-onset breakthrough bleeding in women who are on oral contraceptives or medroxyprogesterone contraceptive injection (Depo-Provera) has been associated with PID. Fever (>101°F), increased erythrocyte sedimentation rate, and an elevated white blood cell count (>10,000 cells/mL) commonly are seen, even though the woman may not appear acutely ill. Elevated C-reactive protein (CRP) levels equate with inflammation and can be used as another diagnostic tool. Laparoscopy, which allows for direct visualization of the ovaries, fallopian tubes, and uterus, is one of the most specific procedures for diagnosing PID, but is costly and carries the inherent risks of surgery and anesthesia.[30] Minimal criteria for a presumptive diagnosis of PID require only the presence of lower abdominal pain, adnexal tenderness, and cervical motion tenderness on bimanual examination with no other apparent cause.

Treatment may involve hospitalization with intravenous administration of antibiotics. If the condition is diagnosed early, outpatient antibiotic therapy may be sufficient. Treatment is aimed at preventing complications, which can include pelvic adhesions, infertility, ectopic pregnancy, chronic abdominal pain, and tuboovarian abscesses. Accurate diagnosis and appropriate antibiotic therapy may decrease the severity and frequency of PID sequelae.

Endometriosis

Endometriosis is the condition in which functional endometrial tissue is found in ectopic sites outside the uterus.[11,31–33] The site may be the ovaries, posterior broad ligaments, uterosacral ligaments, pouch of Douglas (cul-de-sac), pelvis, vagina, vulva, perineum, or intestines (Fig. 40-10). Rarely, endometrial implants have been found in the nostrils, umbilicus, lungs, and limbs.

The cause of endometriosis is largely unknown. There appears to have been an increase in its incidence in the developed Western countries during the past four to five decades. Approximately 10% to 15% of premenopausal women have some degree of endometriosis. The incidence may be higher in women with infertility (15% to 70%) or women younger than 20 years of age with chronic pelvic pain (47% to 73%).[31] It is also more common in women who have postponed childbearing. Risk factors for endometriosis may include early menarche; regular periods with shorter cycles (<27 days), longer duration (>7 days), or heavier flow; increased menstrual pain; and other first-degree relatives with the condition.

Several theories attempt to explain the origin of the dispersed endometrial lesions that occur in women with endometriosis.[7,11,31] One theory, the *regurgitation/implantation theory,* suggests that menstrual blood containing fragments of endometrium is forced upward through the fallopian tubes into the peritoneal cavity. Retrograde menstruation is not an uncommon phenomenon, and it is unknown why endometrial cells implant and grow in some women but not in others. A second theory, the *vascular* or *lymphatic theory,* suggests that the endometrial tissue may metastasize through the lymphatics or vascular system. Another theory, the *metaplastic theory,* proposes that dormant, immature cellular elements, spread over a wide area during embryonic development, persist into adult life and then differentiate into endometrial tissue.

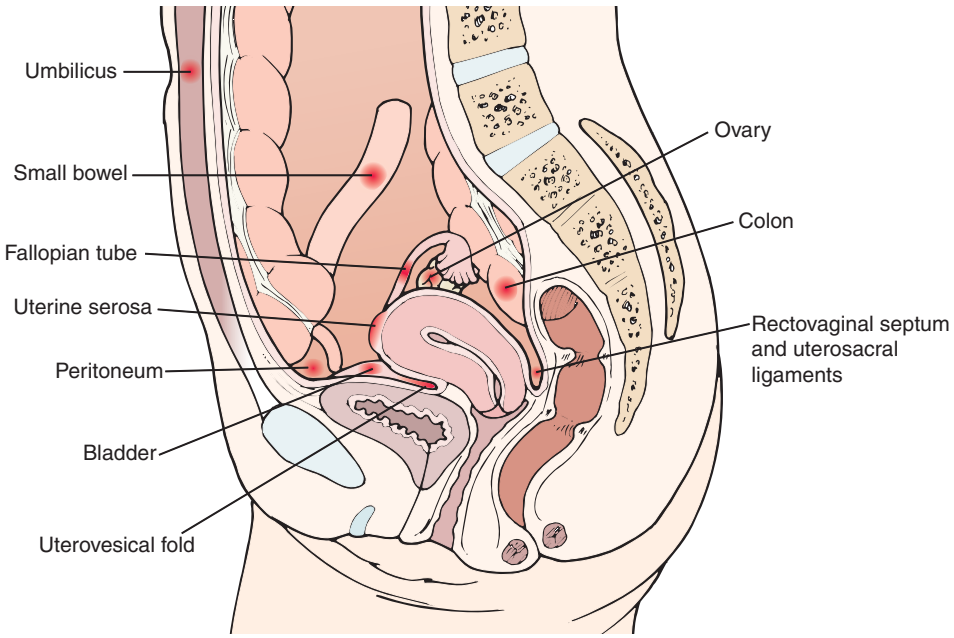

FIGURE 40-10. Common locations of endometriosis in the pelvis and abdomen.

Genetic and immune factors also have been studied as contributing factors to the development of endometriosis.

Endometriosis usually becomes apparent in the reproductive years when the lesions are stimulated by ovarian hormones in the same way as normal endometrium, becoming proliferative, then secretory, and finally undergoing menstrual breakdown. Bleeding into the surrounding structures can cause pain and the development of significant pelvic adhesions. Symptoms tend to be more severe premenstrually, subsiding after cessation of menstruation. Pelvic pain is the most common presenting symptom; other symptoms include back pain, dyspareunia, and pain on defecation and micturition. Endometriosis is associated with infertility because of adhesions that distort the pelvic anatomy and cause impaired ovum release and transport.

The gross pathologic changes that occur in endometriosis differ with location and duration. In the ovary, the endometrial tissue may form cysts (i.e., endometriomas filled with old blood that resembles chocolate syrup [chocolate cysts]). Rupture of these cysts can cause peritonitis and adhesions. Elsewhere in the pelvis, the tissue may take the form of small hemorrhagic lesions that may be black, bluish, red, clear, or opaque (Fig. 40-11). Some may be surrounded by scar tissue.

Endometriosis may be difficult to diagnose because its symptoms mimic those of other pelvic disorders and the severity of the symptoms does not always reflect the extent of the disease. Definitive diagnosis can be accomplished only through laparoscopy. This minimally invasive surgery allows direct visualization of pelvic organs to determine the presence and extent of endometrial lesions. Imaging techniques, including ultrasonography and magnetic resonance imaging (MRI), can be useful tools in evaluating endometriomas and deep endometriosis.[31,32] Serum cancer antigen 125 (CA-125), which is known for its use in diagnosis and monitoring of ovarian cancer, may be elevated in the presence of endometriosis. It has limitations as a screening tool, but can be useful in monitoring response to therapy and recurrence.

FIGURE 40-11. Endometriosis. Implants of endometrium on the ovary appear as red-blue nodules. (From Robboy S.J., Merino M.J., Mutter G.L. [2008]. The female reproductive system. In Rubin R., Strayer D.S. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 829]. Philadelphia: Lippincott Williams & Wilkins.)

Treatment modalities fall into three categories: pain relief, endometrial suppression, and surgery.[11,29,31,32] In young women, simple observation and analgesics (nonsteroidal anti-inflammatory drugs [NSAIDs]) may be sufficient treatment. The use of hormones to induce physiologic amenorrhea is based on the observation that pregnancy and menopause afford pain relief by inducing atrophy of the endometrial tissue. This can be accomplished through administration of oral contraceptives, continuous progestogen therapy, androgenic agents (danazol), or long-acting GnRH analogs that inhibit the pituitary gonadotropins and suppress ovulation.

Surgery may offer more definitive therapy for women with large or symptomatic endometriomas, or those who have failed medical therapy for endometriosis.[31,34,35] Laparoscopic surgical options include the use of cautery, laser ablation, and excision techniques. Definitive treatment involves total hysterectomy and bilateral salpingo-oophorectomy when the symptoms are unbearable or the woman's childbearing is completed. Continuous combined estrogen–progestogen therapy is recommended to manage menopausal symptoms and minimize the risk of endometriosis recurrence.[33]

Adenomyosis

Adenomyosis is the condition in which endometrial glands and stroma are found within the myometrium, interspersed between the smooth muscle fibers.[6,7] In contrast to endometriosis, which usually is a problem of young, infertile women, adenomyosis typically is found in multiparous women in their late fourth or fifth decade. It is thought that events associated with repeated pregnancies, deliveries, and uterine involution may cause the endometrium to be displaced throughout the myometrium. Adenomyosis frequently coexists with uterine myomas or endometrial hyperplasia. Heavy, painful periods with clots and dyspareunia are common complaints of women with adenomyosis. Adenomyosis resolves with menopause. Conservative therapy using oral contraceptives or GnRH agonists is usually the first choice of treatment. Hysterectomy (with preservation of the ovaries in premenopausal women) is considered when this approach fails.

Endometrial Cancer

Endometrial cancer is the most frequent invasive cancer of the female reproductive tract in the United States and Western countries of the world. Endometrial cancer is typically a disease of postmenopausal women. Between 15% and 25% of postmenopausal women with bleeding have endometrial cancer.[11]

Most primary endometrial cancers are adenocarcinomas that arise from the glandular elements of the endometrium. Endometrial hyperplasia, which is the most common precursor of endometrial cancer, can be divided into four types: simple hyperplasia, complex hyperplasia,

and hyperplasia (simple or complex) with cytologic atypia.[11] Simple hyperplasia is characterized by proliferation of both the glandular and stromal elements of the endometrium. It is not commonly associated with progression to endometrial carcinoma. Complex hyperplasia represents abnormal proliferation primarily of the glandular elements of the endometrium with concomitant proliferation of the stromal elements. It is thought to represent a true intraepithelial neoplastic process, and is occasionally found coexisting in areas of endometrial adenocarcinoma. Hyperplasia characterized by significant numbers of glandular cells that exhibit cytologic atypia and disordered maturation is considered a precursor lesion to endometrial carcinoma.

Epidemiology and Pathogenesis. Endometrial cancer occurs most frequently in postmenopausal women (peak age of 55 to 65 years) and is uncommon in women younger than 40 years of age.[6] Two groups in which endometrial cancers arise are perimenopausal women with estrogen excess and older women with endometrial atrophy. Endometrial cancers that arise in women with estrogen excess are described as type I or endometrioid carcinoma, and those that arise in women with endometrial atrophy as type II or serous carcinoma.[6,36–38]

Type I is the most common type of endometrial cancer, accounting for 80% of cases. Most of these tumors are well differentiated and mimic proliferative endometrial glands, and as such are referred to as *endometrioid carcinoma*. Endometrioid carcinoma is associated with prolonged estrogen stimulation and mutations in PTEN, a tumor-suppressor gene. In addition to unopposed estrogen therapy, other risks for endometrioid carcinoma are obesity, diabetes, nulliparity, early menarche, and late menopause. Many of these risk factors are the same as those for endometrial hyperplasia.[36] Obesity predisposes to insulin resistance, ovarian androgen excess, anovulation, and chronic progesterone deficiency. These hormonal changes stimulate endometrial cell proliferation, inhibit apoptosis, and promote angiogenesis. The degree of risk correlates with body weight: the risk increases 10-fold in women who are 25 kg (50 lb) overweight.[7] Progesterone counteracts the effects of estrogen. Pregnancy, with intense placental production of progestins, protects against endometrial cancer. Thus, multiparity protects against endometrial cancer, whereas nulliparity increases risk, especially when infertility is also present. Diabetes mellitus, hypertension, and polycystic ovary syndrome are conditions that alter estrogen metabolism and elevate estrogen levels.

Type II endometrial cancers occur in a small subset of women who do not exhibit increased estrogen levels. These women usually acquire the disease at an older age and in a setting of endometrial atrophy rather than hyperplasia. This type of endometrial cancer usually is associated with a poorer prognosis than type I carcinomas.[7,36]

Clinical Features. The major symptom of endometrial hyperplasia or overt endometrial cancer is abnormal, painless bleeding. Abnormal bleeding is an early warning sign of endometrial cancer in up to 90% of women, and because endometrial cancer tends to be slow growing in its early stages, the chances of cure are good if prompt medical care is sought.[36] In menstruating women, this takes the form of bleeding between periods or excessive, prolonged menstrual flow. In postmenopausal women, any bleeding is abnormal and warrants investigation. Later signs of uterine cancer may include cramping, pelvic discomfort, postcoital bleeding, lower abdominal discomfort, and enlarged lymph nodes.

Although the Pap smear can identify a small percentage of endometrial cancers, it is not a good screening tool for the tumor. Endometrial biopsy is far more accurate. Dilatation and curettage (D&C), which consists of dilating the cervix and scraping the uterine cavity, is the definitive procedure for diagnosis because it provides a more thorough evaluation. Transvaginal ultrasonography may be used to determine the endometrial thickness as an indicator of hypertrophy and possible neoplastic change.

The prognosis for endometrial cancer depends on the clinical stage of the disease when it is diagnosed and its histologic grade and type. Surgery and radiation therapy are the most successful methods of treatment for endometrial cancer. With early diagnosis and treatment, the 5-year survival rate is approximately 80% to 85%.[6,37]

Uterine Leiomyomas

Uterine leiomyomas (commonly called *fibroids*) are benign neoplasms of smooth muscle origin.[6,7,39] They are the most common female reproductive tumor. Leiomyomas usually develop in the corpus of the uterus as intramural, subserosal, or submucosal growths (Fig. 40-12). Intramural fibroids are embedded in the myometrium. They are the most common type of fibroid and present as a symmetric enlargement of the nonpregnant uterus. Subserosal tumors are located beneath the perimetrium of the uterus. These tumors are recognized as irregular projections on the uterine surface; they may become pedunculated, displacing or impinging on other genitourinary structures and causing hydroureter or bladder problems. Submucosal fibroids displace endometrial tissue and are more likely to cause bleeding, necrosis, and infection than either of the other types.

Leiomyomas are asymptomatic approximately half of the time and may be discovered during routine pelvic examination, or they may cause menorrhagia (excessive menstrual bleeding), anemia, urinary frequency, rectal pressure/constipation, abdominal distention, and infrequently pain. Their rate of growth is variable, but they may increase in size during pregnancy or with exogenous estrogen stimulation (i.e., oral contraceptives or menopausal estrogen replacement therapy). Interference with pregnancy is rare unless the tumor is submucosal and interferes with implantation or obstructs the cervical outlet. These tumors may outgrow their blood supply, become infarcted, and undergo degenerative changes.

Most leiomyomas regress with menopause, but if bleeding, pressure on the bladder, pain, or other problems persist, hysterectomy may be indicated. Myomectomy (removal of just the tumors) can be done to preserve the uterus for future childbearing. Cesarean section may be

(From Robboy S.J., Merino M.J., Mutter G.L. [2008]. The female reproductive system. In Rubin R., Strayer D.S. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 813]. Philadelphia: Lippincott Williams & Wilkins.)

recommended if the uterine cavity is entered during myomectomy. Hypothalamic GnRH agonists may be used to suppress leiomyoma growth before surgery. Uterine artery embolization is a nonsurgical therapy for management of heavy bleeding.[39]

Disorders of Uterine Support

The uterus and the pelvic structures are maintained in proper position by the uterosacral ligaments, round ligaments, broad ligament, and cardinal ligaments. The two cardinal ligaments maintain the cervix in its normal position (see Fig. 40-4A). The uterosacral ligaments hold the uterus in a forward position, and the broad ligaments suspend the uterus, fallopian tubes, and ovaries in the pelvis. The vagina is encased in the semirigid structure of the strong supporting fascia (Fig. 40-13A). The muscular floor of the pelvis is a strong, slinglike structure that supports the uterus, vagina, urinary bladder, and rectum (Fig. 40-14). In the female anatomy, nature is faced with the problems of supporting the pelvic viscera against the force of gravity and increases in intra-abdominal pressure associated with coughing, sneezing, defecation, and laughing while at the same time allowing for urination, defecation, and normal reproductive tract function, especially the delivery of an infant.

Relaxation of the pelvic outlet usually comes about because of overstretching of the perineal supporting tissues during pregnancy and childbirth. Although the tissues are stretched only during these times, there may be no difficulty until later in life, such as in the fifth or sixth decade, when further loss of elasticity and muscle tone occurs.[11] Even in a woman who has not borne children, the combination of aging and postmenopausal changes may give rise to problems related to relaxation of the pelvic support structures. The three most common conditions associated with this relaxation are cystocele, rectocele, and uterine prolapse.[11] These may occur separately or together.

Cystocele is a herniation of the bladder into the vagina. It occurs when the normal muscle support for the bladder is weakened, and the bladder sags below the uterus. This causes the anterior vaginal wall to stretch and bulge downward, allowing the bladder to herniate into the vagina due to the force of gravity and pressures from coughing, lifting, or straining at stool (see Fig. 40-13B). The symptoms of cystocele include an annoying bearing-down sensation, difficulty in emptying the bladder, frequency and urgency of urination, and cystitis. Stress incontinence may occur at times of increased abdominal pressure, such as during squatting, straining, coughing, sneezing, laughing, or lifting (see Chapter 27).

Rectocele is the herniation of the rectum into the vagina. It occurs when the posterior vaginal wall and underlying rectum bulge forward, ultimately protruding through the introitus as the pelvic floor and perineal muscles are weakened. The symptoms include discomfort because of the protrusion of the rectum and difficulty in defecation (see Fig. 40-13C). Digital pressure (i.e., splinting) on the bulging posterior wall of the vagina may become necessary for defecation. The area between the uterosacral ligaments just posterior to the cervix may weaken and form a hernial sac into which the small bowel protrudes when the woman is standing. This defect, called an *enterocele,* may extend into the rectovaginal septum. It may be congenital or acquired through birth trauma. Enterocele can be asymptomatic or cause a dull, dragging sensation and occasionally low backache.

Uterine prolapse is the bulging of the uterus into the vagina that occurs when the primary supportive ligaments (i.e., cardinal ligaments) are stretched (see Fig. 40-13D). Prolapse is ranked as first, second, or third degree, depending on how far the uterus protrudes through the introitus. First-degree prolapse shows some descent, but the cervix has not reached the introitus. In second-degree prolapse, the cervix or part of the uterus has passed through the introitus. The entire uterus protrudes through the vaginal opening in third-degree prolapse (i.e., procidentia). The symptoms associated with uterine prolapse result from

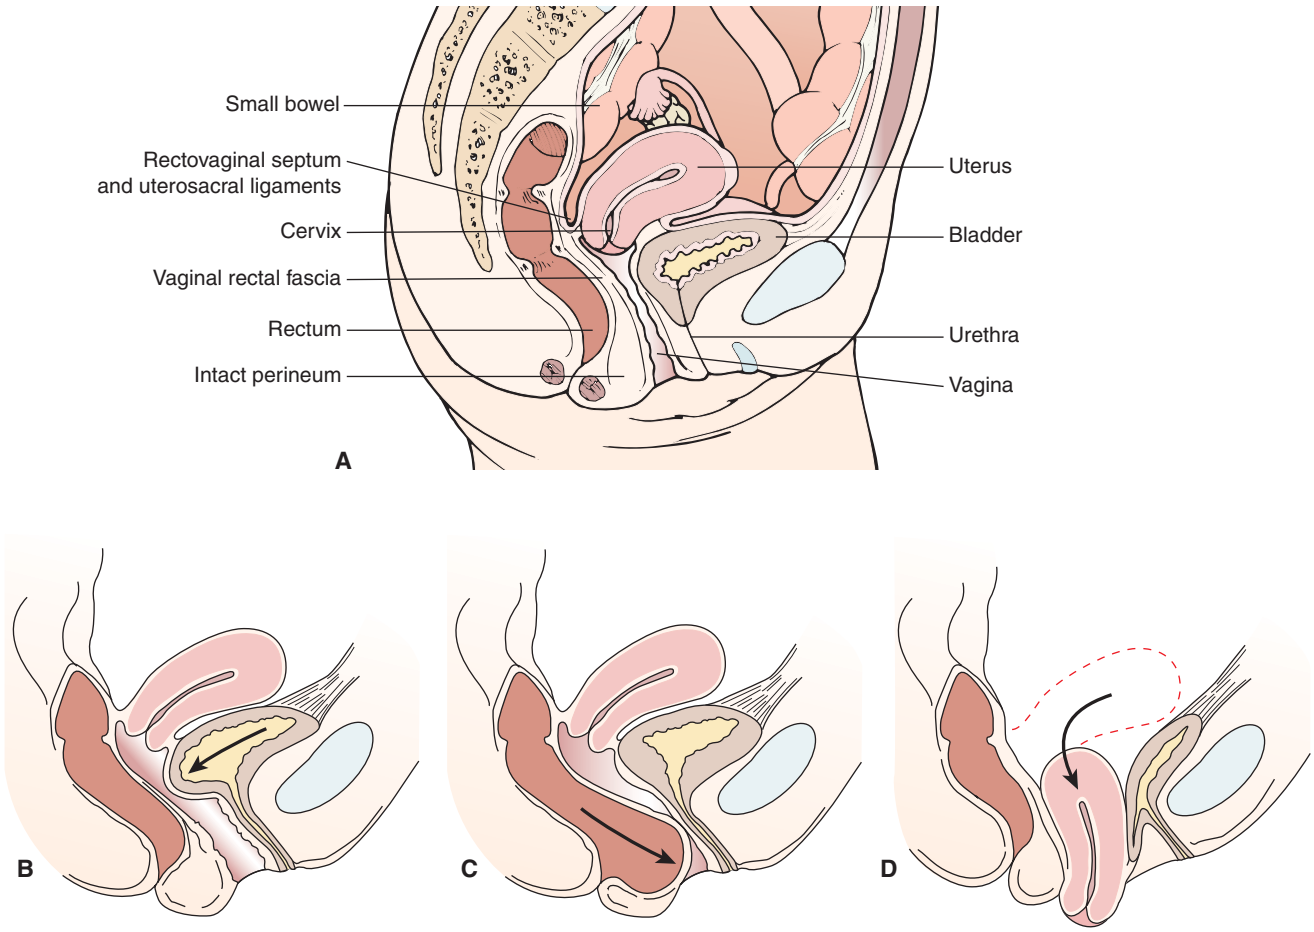

FIGURE 40-13. **(A)** Normal support of the uterus and vagina, **(B)** cystocele, **(C)** rectocele, and **(D)** uterine prolapse.

irritation of the exposed mucous membranes of the cervix and vagina and the discomfort of the protruding mass.

Most of the disorders of pelvic relaxation require surgical correction. These are elective surgeries and usually are deferred until after the childbearing years. The symptoms associated with the disorders often are not severe enough to warrant surgical correction. In other cases, the stress of surgery is contraindicated because of other physical disorders; this is particularly true of older women, in whom many of these disorders occur. Kegel exercises, which strengthen the pubococcygeus muscle, may be helpful in cases of mild cystocele or rectocele or after surgical repair to help maintain the improved function. In women with uterine prolapse, a pessary may be inserted to hold the uterus in place and may stave off surgical intervention in women who want to have children or in older women for whom the surgery may pose a significant health risk.

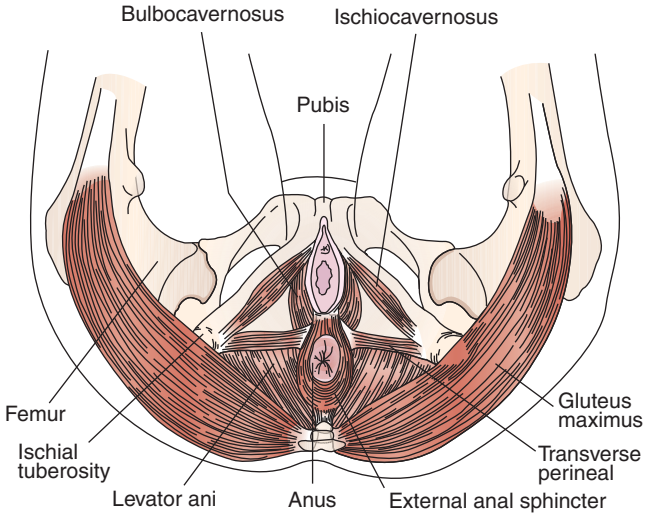

FIGURE 40-14. Muscles of the pelvic floor (female perineum).

Disorders of the Ovaries

Disorders of the ovaries frequently cause menstrual and fertility problems. Benign conditions can present as primary lesions of the ovarian structures or as secondary disorders related to hypothalamic, pituitary, or adrenal dysfunction.

Cystic Lesions of the Ovaries

Cysts are the most common cause of enlarged ovaries.[7] Many are benign. A follicular cyst is one that results from occlusion of the duct of the follicle. Each month,

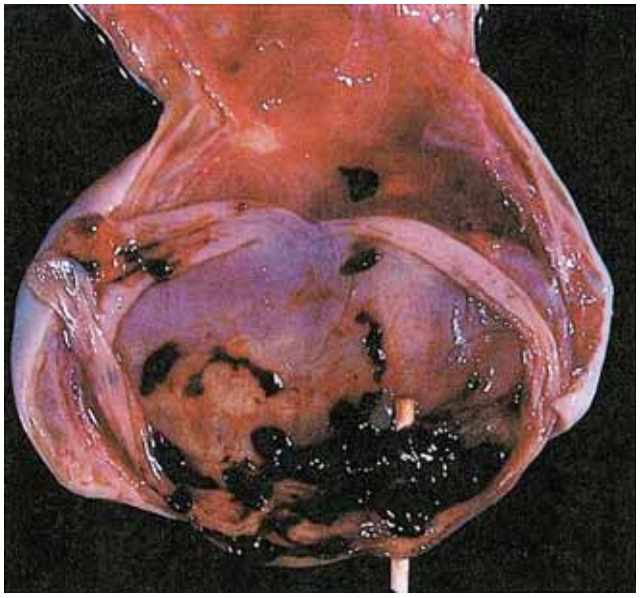

FIGURE 40-15. Follicular cyst of the ovary. The rupture of this thin-walled follicular cyst (dowel stick) led to intra-abdominal hemorrhage. (From Robboy S.J., Merino M.J., Mutter G.L. [2008]. The female reproductive system. In Rubin R., Strayer D.S. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 815]. Philadelphia: Lippincott Williams & Wilkins.)

several follicles begin to develop and are blighted at various stages of development. These follicles form cavities that fill with fluid, producing a cyst. The dominant follicle normally ruptures to release the egg (i.e., ovulation) but occasionally persists and continues growing. Likewise, a luteal cyst is a persistent cystic enlargement of the corpus luteum that is formed after ovulation and does not regress in the absence of pregnancy. Functional cysts are asymptomatic unless there is substantial enlargement or bleeding into the cyst. This can cause considerable discomfort or a dull, aching sensation on the affected side. However, these cysts usually regress spontaneously. Occasionally, a cyst may become twisted or may rupture into the intra-abdominal cavity (Fig. 40-15).

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is a common endocrine disorder affecting 5% to 10% of women of reproductive age, and is a frequent source of chronic anovulation. The disorder is characterized by varying degrees of menstrual irregularity, signs of hyperandrogenism (acne, excess body hair [hirsutism], male-pattern hair loss), and infertility, and is often associated with hyperinsulinemia or insulin resistance.[4,40–43] A substantial number of women who are diagnosed with PCOS are obese, and most have polycystic ovaries.

Chronic anovulation, causing amenorrhea or irregular menses, is now thought to be the underlying cause of the bilaterally enlarged "polycystic" ovaries. Hence, the appearance of the ovary is a sign, not the disease itself. There is increasing evidence that the disorder may begin before adolescence and that many of the manifestations of PCOS begin to make their appearance at that time. Because many of the symptoms common to PCOS, such as excess hair, acne, and obesity, can be detrimental to a teenage girl's health and self-esteem, early detection and treatment of PCOS in adolescents are essential.[44]

The underlying etiology of the disorder is unknown, although most women have altered gonadotropin levels.[4,43] This is manifested by increased release of LH in relation to FSH release, with a resultant increase in production of androstenedione and testosterone by the theca cells of the ovary. Androstenedione, in turn, is converted to estrone within adipocytes. Although estrone is a weak estrogen, it causes suppression of pituitary FSH release and stimulation of LH release. Although the presence of some FSH allows for new follicular development, full maturation is not attained, and ovulation does not occur. The elevated LH level results in increased androgen production, which in turn prevents normal follicular development and contributes to a vicious cycle of anovulation and multiple cyst formation. Increased androgen levels also lead to the development of acne and hirsutism.

The typical woman with PCOS has hyperinsulinemia and many of the signs of the metabolic syndrome (see Chapter 33).[4,11] It has been shown that the cause of hyperinsulinemia is insulin resistance. The frequency and degree of hyperinsulinemia in women with PCOS is often amplified by the presence of obesity. In addition to its clinical manifestations, long-term health problems including cardiovascular disease and type 2 diabetes have been linked to PCOS. Classic lipid abnormalities include elevated triglyceride levels, low HDL levels, and elevated LDL levels. Hypertension is also common in women with PCOS. There is also concern that women with PCOS who are anovulatory do not produce progesterone. This, in turn, may subject the endometrium to an unopposed estrogen environment, which is a significant risk factor for the development of endometrial cancer.[4,43]

The diagnosis of PCOS can be suspected from the clinical presentation. Although there is no consensus as to which tests should be used, laboratory evaluation to exclude hyperprolactinemia, late-onset adrenal hyperplasia, and androgen-secreting tumors of the ovary and adrenal gland is commonly done. Because of the high risk of insulin resistance, a fasting blood glucose, 2-hour oral glucose tolerance test, and insulin levels are done to evaluate for hyperinsulinemia. Confirmation with ultrasonography or laparoscopic visualization of the ovaries is often done, but not required.[41]

The overall goal of treatment should be directed toward symptom relief, prevention of potential malignant endometrial sequelae, and reduction in risk for development of diabetes and cardiovascular disease. The preferred and most effective treatment for PCOS is lifestyle modification. Weight loss may be beneficial in restoring normal ovulation when obesity is present. Combined oral contraceptive agents ameliorate menstrual irregularities and improve hirsutism and acne. The addition of spironolactone, a mineralocorticoid antagonist that inhibits the production of androgens by the adrenal gland, may be beneficial to women with severe hirsutism.[4]

Insulin-sensitizing agents (metformin or thiazolidinedione [rosiglitazone or pioglitazone]) alone or with ovulation-inducing medications are emerging as an important component of PCOS treatment.[43] In addition to expected improvements in insulin sensitivity and glucose metabolism, they have been associated with reductions in androgen and LH levels and are highly effective in restoring normal menstrual regularity and ovulatory cycles.

Benign Ovarian Tumors

Ovarian tumors can be benign, borderline, or malignant. About 80% are benign and occur mainly in young women between the ages of 20 and 45 years. Borderline tumors occur at a slightly older age. Malignant tumors are more common in older women, between the ages of 45 and 65 years.[6]

Ovarian neoplasms can arise from any of the ovarian tissue types—serosal surface epithelium (65% to 75%), germ cells layers (10% to 20%), or gonadal stroma tissue (5% to 10%)[6,7] (Fig. 40-16). Benign epithelial cell neoplasms are almost always serous (serous cystadenoma) or mucinous (mucinous cystadenoma) adenomas. These neoplasms are large, often 15 to 30 cm in diameter. Benign cystic teratomas, or dermoid cysts, are derived from primordial germ cells and are composed of various combinations of well-differentiated ectodermal, mesodermal, and endodermal elements. Not uncommonly, they contain sebaceous material, hair, or teeth. Approximately 80% of these tumors occur during the reproductive years, with a median age of 30 years.

Although most benign tumors are nonfunctional and tend to produce relatively few symptoms until they reach a large size, some are hormonally active.[6] One such tumor, the granulosa cell tumor, is associated with excess estrogen production.[11] When it develops during the reproductive period, the persistent and uncontrolled production of estrogen interferes with the normal menstrual cycle, causing irregular and excessive bleeding, endometrial hyperplasia, or amenorrhea and fertility problems. When it develops after menopause, it causes postmenopausal bleeding, stimulation of the glandular tissues of the breast, and other signs of renewed estrogen production. Androgen-secreting tumors (i.e., Sertoli-Leydig cell tumor or androblastoma) inhibit ovulation and estrogen production.[11] They tend to cause hirsutism and development of masculine characteristics, such as baldness, acne, oily skin, breast atrophy, and deepening of the voice.

Treatment for benign ovarian tumors is surgical excision. Ovarian tissue that is not affected by the tumor can be left intact if frozen-section analysis does not reveal malignancy. When ovarian tumors are very large, as is frequently the case with serous or mucinous cystadenomas, the entire ovary must be removed.

Approximately 10% of seemingly benign epithelial cell tumors may contain histologic evidence of intraepithelial

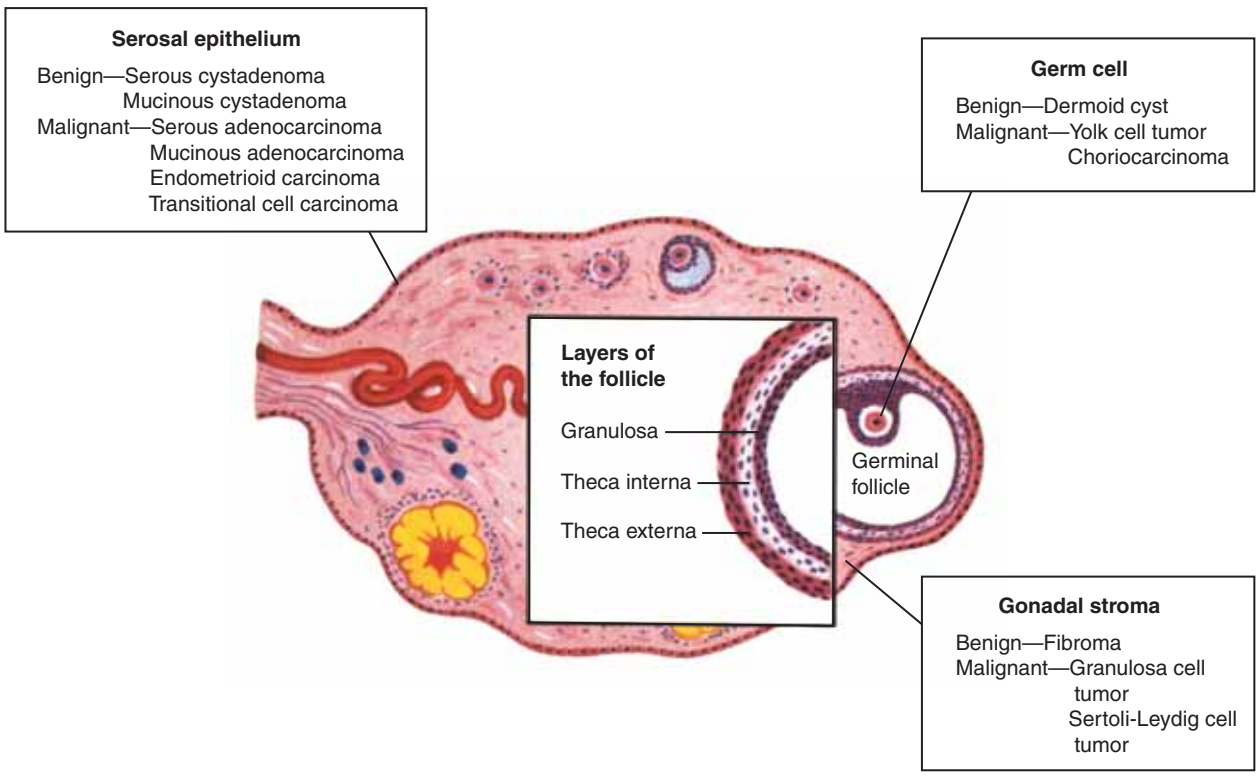

FIGURE 40-16. Classification of ovarian neoplasms based on cell type. (From Robboy S.J., Merino M.J., Mutter G.L. [2008]. The female reproductive system. In Rubin R., Strayer D.S. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 818]. Philadelphia: Lippincott Williams & Wilkins.)

neoplasia, commonly referred to as borderline malignancies.[11] These tumors generally remain confined to the ovary, are more common in premenopausal women (30 to 50 years of age), and have a good prognosis. They require careful frozen-section analysis and individualized therapy following the initial surgical removal of the tumor.

Ovarian Cancer

Ovarian cancer is the second most frequent gynecologic malignancy after endometrial cancer in the United States, and it carries the highest mortality rate of all genital cancers combined.[6,7,44,45] The incidence of ovarian cancer increases with age, being greatest between 45 and 60 years of age. Ovarian cancer is difficult to diagnose, and up to 75% of women are diagnosed at an advanced state when the 5-year survival rate is 20% to 30%.[11]

As with benign ovarian tumors, malignant ovarian tumors are categorized according to cell type of origin—epithelial cell tumors, germ cell tumors, and gonadal stromal cell tumors (see Fig. 46-16). Approximately 90% of ovarian cancers are of epithelial cell origin. These tumors tend to occur in older women, are usually discovered late in the disease, and have a high mortality rate. The nonepithelial ovarian cancers, which include germ cell tumors and stromal cell tumors, tend to occur in a younger population of women. They typically present with earlier signs of disease and excellent survival potential when detected early.

The most significant risk factor for ovarian cancer appears to be ovulatory age—the length of time during a woman's life when her ovarian cycle is not suppressed by pregnancy, lactation, or oral contraceptive use. The incidence of ovarian cancer is much lower in countries where women bear numerous children. Epithelial cancer of the ovaries derives from malignant transformation of the epithelium of the ovarian surface. When these epithelial cells are situated over developing follicles, they undergo metaplastic transformation whenever ovulation occurs.[11,44,46] It follows that repeated stimulation of the epithelium of the ovarian surface, which occurs with uninterrupted ovulation, may predispose the epithelium to malignant transformation. Family history also is a significant risk factor for ovarian cancer. The breast cancer susceptibility genes, *BRCA1* and *BRCA2* mutations, which are tumor-suppressor genes, increase the susceptibility to ovarian cancer (see Chapter 7). The estimated risk of ovarian cancer in women bearing the BRCA1 and BRCA2 mutations is 20% to 60% by the age of 70 years. A high-fat Western diet and use of powders containing talc in the genital area are other factors that have been linked to the development of ovarian cancer.

Clinical Features. Until recently it was believed that most cancers of the ovary produce no symptoms. Several studies have now established that symptoms are often present and reported by women before diagnosis, but are nonspecific and therefore difficult to interpret. Symptoms that are believed to have a strong correlation to ovarian cancer include increased abdominal size, dyspepsia, early satiety, or bloating as the result of increased pressure from ascites (i.e., fluid in the peritoneal cavity) or involvement of the omentum. Occasionally, women with early-onset disease present with abdominal or pelvic pain, due to ovarian torsion, although most women with early-stage disease are asymptomatic. Because the gastrointestinal manifestations can occur for a variety of reasons, many women self-treat with antacids and other remedies for a time before seeking treatment, and health care providers may dismiss the woman's complaints as being caused by other conditions, further delaying diagnosis and treatment. Recent onset (<12 months) and frequent occurrence (>12 times per month) of these symptoms should increase the index of suspicion for ovarian cancer and suggest the need for further evaluation.[47] It is not fully understood why the initial symptoms of ovarian cancer are manifested as gastrointestinal disturbances. It is thought that biochemical changes in peritoneal fluids may irritate the bowel or that pain originating in the ovary may be referred to the abdomen and be interpreted as a gastrointestinal disturbance. Clinically evident ascites is seen in approximately one fourth of women with malignant ovarian tumors and is associated with a worse prognosis.

At present, no good screening tests or other early methods of detection exist for ovarian cancer.[48,49] The serum tumor marker CA-125 is a cell surface antigen that can be used in monitoring therapy and recurrences when preoperative levels have been elevated. Despite its role in diagnostic evaluation and follow-up, CA-125 is not cancer or tissue specific for ovarian cancer. Levels also are elevated in the presence of endometriosis, uterine fibroids, pregnancy, liver disease, and other benign conditions and with cancers of the endometrium, cervix, fallopian tube, and pancreas. Transvaginal ultrasonography (TVS) has been used to evaluate ovarian masses for malignant potential. Although TVS has demonstrated high sensitivity and specificity as a screening tool, cost precludes its use as a universal screening method.

When ovarian cancer is suspected, surgical evaluation is required for diagnosis, complete and accurate staging, and cytoreduction and debulking procedures to reduce the size of the tumor. The most common surgery involves removal of the uterus, fallopian tubes, ovaries, and omentum. Recommendations regarding treatment beyond surgery and prognosis depend on the stage of the disease. Women with early-stage disease usually do not require adjuvant treatment; women with intermediate disease or advanced disease can often benefit from chemotherapy using a combination of a platinum compound (cisplatin or carboplatin) and a taxane (paclitaxel or docetaxel). When this combination therapy fails, salvage chemotherapy with newer drugs may prolong survival.

In summary, the external genitalia are affected by disorders that affect skin on other parts of the body. Bartholin cysts are the result of occluded ducts in Bartholin glands. They often are painful and can become infected. Vulvar dystrophies are characterized by thinning and hyperplastic thickening of vulvar tissues. Vulvodynia

is a chronic vulvar pain syndrome with several classifications and variable treatment results. Cancer of the vulva, which accounts for 3% of all female genitourinary cancers, is associated with HPV infections.

The normal vaginal ecology depends on the delicate balance of hormones and bacterial flora. Vaginitis or inflammation of the vagina is characterized by vaginal discharge and burning, itching, redness, and swelling of vaginal tissues. It may be caused by chemical irritants, foreign bodies, and infectious agents. Primary cancers of the vagina are uncommon, accounting for 1% of all cancers of the female reproductive system.

Disorders of the cervix and uterus include inflammatory conditions (i.e., cervicitis and endometritis), cancer (i.e., cervical and endometrial cancer), endometriosis, leiomyomas, and disorders of uterine support. Cervicitis, which may be caused by a number of agents, may result from the direct infection of the cervix or may be secondary to a vaginal or uterine infection. Cervical cancer is caused by HPV and arises from precursor lesions that can be detected on a Pap smear, and if detected early, is the most easily cured of all the cancers of the female reproductive system.

Pelvic inflammatory disease is an inflammation of the upper reproductive tract that involves the uterus (endometritis), fallopian tubes (salpingitis), or ovaries (oophoritis). It is most commonly caused by *N. gonorrhoeae* or *C. trachomatis*. Endometriosis is the condition in which functional endometrial tissue is found in ectopic sites outside the uterus. It causes dysmenorrhea, dyspareunia, and infertility.

Adenomyosis is the condition in which endometrial glands and stroma are found in the myometrium interspersed between the smooth muscle fibers. Leiomyomas are benign uterine wall neoplasms of smooth muscle origin. They can develop in the corpus of the uterus and can be submucosal, subserosal, or intramural. Submucosal fibroids displace endometrial tissue and are more likely to cause bleeding, necrosis, and infection than either of the other types. Endometrial cancer is the most common cancer found in the female pelvis; it occurs twice as frequently as cervical cancer. Prolonged estrogen stimulation with hyperplasia of the endometrium has been identified as a major risk factor for endometrial cancer.

Disorders of uterine support result from weakness and relaxation of the pelvic floor muscles. Cystocele and rectocele involve herniation of the bladder or rectum into the vagina. Uterine prolapse occurs when the uterus bulges into the vagina. Pelvic relaxation disorders typically result from overstretching of the supporting muscles during pregnancy and childbirth. The loss of elasticity in these structures that is a normal accompaniment of aging contributes to these problems.

Disorders of the ovaries include cystic disorders, PCOS, and benign and malignant tumors. Functional cysts usually are asymptomatic unless there is substantial enlargement or bleeding into the cyst or the cyst becomes twisted or ruptures. PCOS is a disorder characterized by various degrees of hirsutism, obesity, and infertility, and often is associated with hyperinsulinemia and insulin resistance. Ovarian tumors, benign, borderline, and malignant, can arise from any of the ovarian tissue types—serosal surface epithelium, germ cells, or gonadal stromal tissue. Cancer of the ovary is the second most common female genitourinary cancer and the most deadly. A family history of cancer, particularly breast and ovarian cancer, and nulliparity increase the risk of developing ovarian cancer, whereas oral contraceptive use, pregnancy, and lactation decrease the risk. Because there are no effective screening methods and the symptoms of early-stage ovarian cancer are often nonspecific, the disease is often far advanced at the time of diagnosis.

Menstrual Disorders

Between menarche (i.e., first menstrual bleeding) and menopause (i.e., last menstrual bleeding), the female reproductive system undergoes cyclic changes called the *menstrual cycle*. This includes the maturation and release of oocytes from the ovary during ovulation and periodic vaginal bleeding resulting from the shedding of the endometrial lining (Fig. 40-5). It is not necessary for a woman to ovulate to menstruate; anovulatory cycles do occur. The menstrual cycle produces changes in the breasts, uterus, skin, ovaries, and perhaps other unidentified tissues.

Dysfunctional Menstrual Cycles

Although unexplained uterine bleeding can occur for many reasons, such as pregnancy, abortion, bleeding disorders, and neoplasms, the most frequent cause in the nonpregnant woman is what is commonly called *dysfunctional menstrual cycles* or *bleeding*. Dysfunctional cycles may take the form of *amenorrhea* (absence of menstruation), *hypomenorrhea* (scanty menstruation), *oligomenorrhea* (infrequent menstruation, periods more than 35 days apart), *polymenorrhea* (frequent menstruation, periods less than 21 days apart), *menorrhagia* (excessive menstruation), or *metrorrhagia* (bleeding between periods). *Menometrorrhagia* is heavy bleeding during and between menstrual periods.

Dysfunctional Bleeding

Dysfunctional bleeding is related to alterations in the hormones that support normal cyclic endometrial changes. Estrogen deprivation causes retrogression of a previously built-up endometrium and bleeding. Such bleeding often is irregular in amount and duration, with the flow varying with the time and degree of estrogen stimulation and with the degree of estrogen withdrawal. A lack of progesterone can cause abnormal menstrual bleeding; in its absence, estrogen induces development of a much thicker endometrial layer with a richer blood supply. The absence of progesterone results from the

Dysfunctional Menstrual Cycles

- The pattern of menstrual bleeding tends to be fairly consistent in most healthy women with regard to frequency, duration, and amount of flow.
- Dysfunctional bleeding in postpubertal women can take the form of absent or scanty periods, infrequent periods, excessive and irregular periods, excessive bleeding during periods, and bleeding between periods.
- When the basic pattern of bleeding is changed, it is most often due to a lack of ovulation and disturbances in the pattern of hormone secretion.
- When the basic pattern is undisturbed and there are superimposed episodes of bleeding or spotting, the etiology is more likely to be related to organic lesions or hematologic disorders.

failure of any of the developing ovarian follicles to mature to the point of ovulation, with the subsequent formation of the corpus luteum and production and secretion of progesterone.

Periodic bleeding episodes alternating with amenorrhea are caused by variations in the number of functioning ovarian follicles present. If sufficient follicles are present and active and if new follicles assume functional capacity, high levels of estrogen develop, causing the endometrium to proliferate for weeks or even months. In time, estrogen withdrawal and bleeding develop. This can occur for two reasons: an absolute estrogen deficiency may develop when several follicles simultaneously degenerate, or a relative deficiency may develop as the needs of the enlarged endometrial tissue mass exceed the capabilities of the existing follicles, even though estrogen levels remain constant. Estrogen and progesterone deficiencies are associated with the absence of ovulation, hence the term *anovulatory bleeding*. Because the vasoconstriction and myometrial contractions that normally accompany menstruation are caused by progesterone, anovulatory bleeding seldom is accompanied by cramps, and the flow frequently is heavy. Anovulatory cycles are common among adolescents during the first several years after menarche, when ovarian function is becoming established, and among perimenopausal women, whose ovarian function is beginning to decline.

Dysfunctional bleeding can originate as a primary disorder of the ovaries or uterus or as a secondary defect in ovarian function related to hypothalamic-pituitary stimulation. The latter can be initiated by emotional stress, marked variation in weight (i.e., sudden gain or loss), or nonspecific endocrine or metabolic disturbances. Nonhormonal causes of irregular menstrual bleeding include endometrial polyps, submucosal myoma (i.e., fibroid), bleeding disorder (e.g., von Willebrand disease, platelet dysfunction), endometrial dysplasia, and cancer.

The treatment of dysfunctional bleeding depends on what is identified as the probable cause. The minimum evaluation should include a detailed history with emphasis on bleeding pattern and a physical examination. Endocrine studies (e.g., FSH/LH ratio, prolactin, androgen levels), β-hCG pregnancy test, ultrasonography of the endometrium, endometrial biopsy, D&C with or without hysteroscopy, and progesterone withdrawal tests may be needed for diagnosis. Nonhormonal causes generally require surgical intervention. D&C can be therapeutic as well as diagnostic. Endometrial ablation (destruction of the basal layer of the endometrium from which the monthly buildup generates) has become a primary treatment method for abnormal uterine bleeding.[11] Various ablation devices are available; some use heat, and others use cryotherapy. If nonhormonal problems have been excluded and alterations in hormone levels are the primary cause, treatment may include the use of oral contraceptives, cyclic progesterone therapy, or long-acting progesterone injections.

Amenorrhea

There are two types of amenorrhea: primary and secondary. Primary amenorrhea is the failure to menstruate by 15 years of age, or by 13 years of age if failure to menstruate is accompanied by absence of secondary sex characteristics.[50] Secondary amenorrhea is the cessation of menses for at least 6 months in a woman who has established normal menstrual cycles. Primary amenorrhea usually is caused by gonadal dysgenesis, congenital müllerian agenesis, testicular feminization, or a hypothalamic-pituitary-ovarian axis disorder. Causes of secondary amenorrhea include ovarian, pituitary, or hypothalamic dysfunction; intrauterine adhesions; infections (e.g., tuberculosis, syphilis); pituitary tumor; anorexia nervosa; or strenuous physical exercise, which can alter the critical body fat–to–muscle ratio needed for menses to occur.[50]

Diagnostic evaluation resembles that for dysfunctional uterine bleeding, with the possible addition of a computed tomographic scan or MRI to exclude a pituitary tumor. Treatment is based on correcting the underlying cause and inducing menstruation with cyclic progesterone or combined estrogen–progesterone regimens.

Dysmenorrhea

Dysmenorrhea is pain or discomfort with menstruation.[11] Although not usually a serious medical problem, it causes some degree of monthly disability for a significant number of women. There are two forms of dysmenorrhea: primary and secondary. Primary dysmenorrhea is caused by the effects of excess prostaglandin (i.e., prostaglandin F_{2a}) production in the endometrium. Prostaglandins are potent smooth muscle stimulants that cause intense uterine contractions. Prostaglandin production in the uterus normally increases under the influence of progesterone, reaching a peak at or soon after the onset of menstruation. With onset of menstruation, formed prostaglandins are released from the shedding endometrium. Prostaglandins also cause contraction of

smooth muscle elsewhere in the body. Severe dysmenorrhea may be associated with systemic symptoms such as headache, nausea, vomiting, and diarrhea. The pain of primary dysmenorrhea is often diffusely located in the lower abdomen or suprapubic area, often radiating to the lower back. The pain is often described as cramping and spasmodic, or similar to labor pains. Secondary dysmenorrhea is menstrual pain caused by structural abnormalities or disease processes such as endometriosis, uterine fibroids, adenomyosis, pelvic adhesions, IUDs, or PID. In women with secondary dysmenorrhea, the pain often lasts longer than the menstrual period; it may begin before menstrual bleeding begins; and it may become worse during menstruation.

Treatment for primary dysmenorrhea is directed at symptom control. Women with primary dysmenorrhea generally experience dramatic pain relief with the nonsteroidal anti-inflammatory drugs (e.g., ibuprofen, naproxen, mefenamic acid), which are prostaglandin synthetase inhibitors. Ovulation suppression and symptomatic relief of dysmenorrhea can be instituted simultaneously with the use of oral contraceptives. Relief of secondary dysmenorrhea depends on identifying the cause of the problem. Medical or surgical intervention may be needed to eliminate the problem.

Premenstrual Syndrome Disorders

Premenstrual syndrome disorders are a group of physical, emotional, and behavioral changes that occur in a regular, cyclic relationship to the luteal phase of the menstrual cycle and that interfere with some aspect of a woman's life.[11] The severity of this cyclic symptom complex can vary from *premenstrual molimina* on the mild end; through *premenstrual syndrome* (PMS), which is characterized by mild to moderate physical and psychological symptoms limited to 3 to 14 days preceding menstruation and relieved by onset of the menses; to *premenstrual dysphoric disorder* (PMDD), which is the most severe form of premenstrual distress and generally is associated with mood disorders.

According to recent surveys, 75% to 80% of women in the United States experience some emotional or physical premenstrual changes; in approximately 3% to 8% of these women, extreme or severe symptoms cause a negative impact on their life.[51,52] The incidence of PMS and PMDD seems to increase with age. It is less common in women in their teens and twenties, and most of the women seeking help for the problem are in their mid thirties. The disorder is not culturally distinct; it affects both Westerners and non-Westerners.

Physical symptoms of PMS include painful and swollen breasts, bloating, abdominal pain, headache, and backache. Psychologically, there may be depression, anxiety, irritability, and behavioral changes. In some cases, there are puzzling alterations in motor function, such as clumsiness and altered handwriting. Women with PMS may report one or several symptoms, with symptoms varying from woman to woman and from month to month in the same patient. PMS can significantly affect a woman's ability to perform at normal levels. Family responsibilities and relationships may suffer and she may lose time from or function ineffectively at work. Students have had lower grades during the premenstrual period. More crimes are committed by women during the premenstrual phase of the cycle, and more lives are lost to suicide during this period.

Although the causes of PMS are poorly documented, they probably are multifactorial. Like dysmenorrhea, it is only recently that PMS has been recognized as a bona fide disorder rather than merely a psychosomatic illness. Because there appear to be no measurable differences in hormone levels between women with and without PMS, it is presumed that normal cyclic variation in the hormones is the trigger for symptoms in vulnerable or predisposed women.[52] Currently, data suggest a relationship between normal gonadal fluctuations and central neurotransmitter activity, particularly serotonin. It is unclear whether decreased levels of serotonin are present during the luteal phase and only susceptible women respond with varying degrees of premenstrual symptoms, or if women with PMDD have a neurotransmitter abnormality.[51–54]

Diagnosis of PMS and PMDD focuses on documentation of the relationship of a woman's symptoms to the luteal phase of the menstrual cycle (Chart 40-1). Diagnosis focuses on identification of symptoms by means of a daily calendar on which the woman records her symptoms for 2 to 3 consecutive months.[51] A complete history and physical examination are necessary to exclude other physical causes of the symptoms. Depending on the symptom pattern, blood studies, including thyroid hormones, glucose, and prolactin assays, may be done. Psychosocial evaluation is helpful to exclude emotional illness that is merely exacerbated premenstrually.

PMDD is a psychiatric diagnosis that has been developed to distinguish those women whose symptoms are severe enough to interfere significantly with activities of daily living.[51–54] It requires prospective symptom charting, and a minimum of 5 of the 11 symptom groups as described in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) to establish a diagnosis of PMDD (Chart 40-1).

Management of PMS/PMDD has been largely symptomatic and includes education and support directed toward lifestyle changes for women with mild symptoms. An integrated program of personal assessment by diary, regular exercise, avoidance of caffeine, and a diet low in simple sugars and high in lean proteins is often beneficial. In addition to lifestyle changes, pharmacologic treatment includes the use of diuretics to reduce fluid retention, nonsteroidal anti-inflammatory agents for pain, and anxiolytic drugs to treat mood changes. Because symptoms are associated with ovulatory cycles, suppressing ovulation may be beneficial for some women with PMS and can be accomplished by using oral contraceptives, danazol (a synthetic androgen), or GnRH agonists.[51,52] Oral contraceptives can be used for women who also require contraception. However, some women find their symptoms worsen when taking contraceptives. The pharmacologic treatment of PMDD differs from that of PMS.

CHART 46-1 DSM-IV-TR Criteria for Premenstrual Dysphoric Disorder (PMDD)

Core Symptoms

Depressed mood
Moodiness
Anxiety, edginess, nervousness
Anger, irritability

Other Symptoms

Fatigue, lethargy
Insomnia, hypersomnia
Difficulty concentrating
Appetite changes or cravings
Diminished interest in usual activities
Feeling overwhelmed or out of control
Physical symptoms (headache, breast tenderness or swelling, bloating, joint and muscle pain)

PMDD = patient must exhibit five or more symptoms, including at least one core symptom during the premenstrual period, confirmed by prospective charting during at least two consecutive menstrual cycles. Symptoms must cause marked impairment in the woman's ability to carry out her usual activities, must abate within a few days of the onset of menses, and not recur during the week after menses.

From American Psychiatric Association. (2000). Premenstrual dysphoric disorder. In *Diagnostic and statistical manual of mental disorders, fourth edition, text revision* (pp. 771–774). Washington, DC: Author.

Ovulation suppression does not seem to help women with PMDD. Although many medications have been studied, only three antidepressants (fluoxetine, sertraline, and paroxetine controlled release) and an oral contraceptive that contains drospirenone (a spironolactone derivative) have been approved for treatment of the emotional and physical symptoms of PMDD.[51,52]

Menopause and Aging Changes

Menopause is the cessation of menstrual cycles. Like menarche, it is more of a process than a single event.[55,56] Most women stop menstruating between 48 and 55 years of age. *Perimenopause* (the years immediately surrounding menopause) precedes menopause by approximately 4 years and is characterized by menstrual irregularity and other menopausal symptoms. *Climacteric* is a more encompassing term that refers to the entire transition to the nonreproductive period of life. Premature ovarian failure describes the approximately 1% of women who experience menopause before the age of 40 years. A woman who has not menstruated for a full year or has an FSH level greater than 30 mIU/mL is considered menopausal.[11]

Menopause results from the gradual cessation of ovarian function and the resultant diminished levels of estrogen. Although estrogens derived from the adrenal cortex continue to circulate in a woman's body, they are insufficient to maintain the secondary sexual characteristics in the same manner as ovarian estrogens. As a result, breast tissue, body hair, skin elasticity, and subcutaneous fat decrease; the ovaries and uterus diminish in size; and the cervix and vagina become pale and friable. Problems that can arise as a result of this urogenital atrophy include vaginal dryness, urinary stress incontinence, urgency, nocturia, vaginitis, and urinary tract infection.[55,56] The woman may find intercourse painful and traumatic, although some type of vaginal lubrication may be helpful.

Systemically, a woman may experience significant vasomotor instability secondary to the decrease in estrogens and the relative increase in other hormones, including FSH, LH, GnRH, dehydroepiandrosterone, and androstenedione. This instability may give rise to "hot flashes," palpitations, dizziness, and headaches as the blood vessels dilate. Despite the association with these biochemical changes, the underlying cause of hot flashes is unknown. Tremendous variation exists in the onset, frequency, severity, and length of time that women experience hot flashes. When they occur at night and are accompanied by significant perspiration, they are referred to as *night sweats*. Insomnia as well as frequent awakening because of vasomotor symptoms can lead to sleep deprivation. A woman may experience irritability, anxiety, and depression as a result of these uncontrollable and unpredictable events.

Consequences of long-term estrogen deprivation include osteoporosis due to an imbalance in bone remodeling (see Chapter 44), and an increased risk for cardiovascular disease, which is the leading cause of death for women after menopause. With perimenopause, changes occur in the cardiovascular lipid profile: total cholesterol increases, HDL cholesterol decreases, and LDL cholesterol increases.

Menopausal hormonal therapy has come under scrutiny with the publication of the Women's Health Care Initiative.[57] Since the publication of these trials, there has been great interest in developing alternative doses, delivery systems, and medications for hormone therapy. Many products are now available, including transdermal delivery systems and lower-dose traditional hormone therapy. Vaginal estrogen preparations are available to treat symptoms related to vaginal atrophy. Selective estrogen receptor modulators (SERMs) may be used in place of estrogen to prevent osteoporosis.

In summary, menstrual disorders include dysfunctional menstrual cycles, dysmenorrhea, and premenstrual syndromes. Dysfunctional menstrual cycles produce amenorrhea, oligomenorrhea, metrorrhagia, or menorrhagia. Dysmenorrhea is characterized by pain or discomfort during menses. It can occur as a primary or secondary disorder. Primary dysmenorrhea is caused by excess prostaglandin F_{2a}, a potent smooth muscle stimulant that causes intense uterine contractions. Secondary dysmenorrhea is caused by structural abnormalities; disease processes such as endometriosis, uterine fibroids, pelvic adhesions, or PID; or IUDs. The terms

premenstrual syndrome and *premenstrual dysphoric disorder* represent an array of predictable physical, cognitive, affective, and behavioral symptoms that occur during the luteal phase of the menstrual cycle and that are resolved by menstruation or within a few days of the onset. Although the etiology of these disorders is currently unknown, it is probably the result of an interaction between the sex hormones and central neurotransmitters, particularly serotonin.

Menopause is the cessation of ovarian function and menstrual cycles. It is accompanied by a decline in secondary sexual characteristics, vasomotor instability, and long-term consequences, including osteoporosis and increased risk of heart disease.

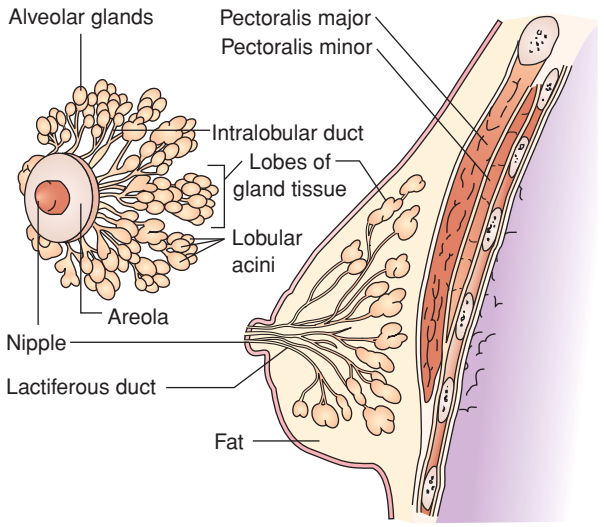

FIGURE 40-18. The breast, showing the glandular tissue and ducts of the mammary glands.

Disorders of the Breast

Although anatomically separate, the breasts are functionally related to the female reproductive system in that they respond to the cyclic changes in sex hormones and produce milk for infant nourishment. The breasts are composed of specialized epithelium and stroma that may give rise to both benign and malignant lesions.

Breast Structures

The breasts, or mammary glands, are located between the third and seventh ribs of the anterior chest wall and are supported by the pectoral muscles and superficial fascia. They are specialized glandular structures that have an abundant shared nervous, vascular, and lymphatic supply[1,2] (Fig. 40-17). Structurally the breast consists of fat, fibrous connective tissue, and glandular tissue. The superficial fibrous connective tissue is attached to the skin, a fact that is important in the visual observation of skin movement over the breast during breast self-examination. A nipple is located near the tip of the breast at about the level of the fourth intercostal space and is surrounded by an area of pigmented skin called the *areola* (Fig. 40-18). The areola contains sebaceous glands and modified sweat glands (glands of Montgomery). These glands have a structure intermediate between sweat glands and true mammary glands, and produce small elevations at the surface of the areola.

The breast mass is supported by the fascia of the pectoralis major and minor muscles and by the fibrous connective tissue of the breast. Fibrous tissue ligaments, called *Cooper ligaments*, extend from the outer boundaries of the breast to the nipple area in a radial manner, like the spokes on a wheel. These ligaments further support the breast and form septa that divide the breast into 15 to 20 lobes. Each lobe consists of grapelike clusters of glands (alveolar glands) and a duct (lactiferous duct) that lead to the nipple and opens to the outside (see Fig. 40-18). Two epithelial cell types line the ducts and alveolar glands of

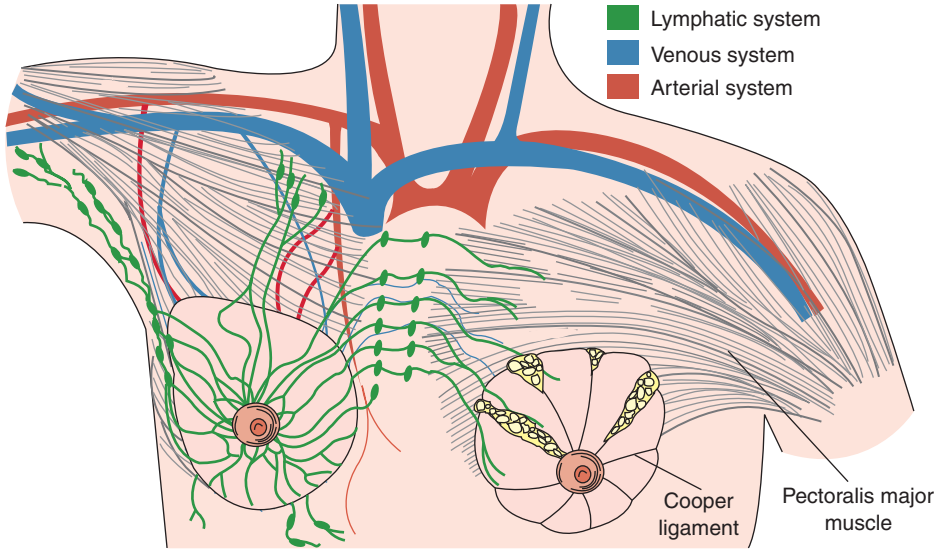

FIGURE 40-17. The breasts, showing the shared vascular and lymphatic supply as well as the pectoral muscles.

the lobules—myoepithelial and luminal epithelial cells. Contractile epithelial cells, which lie between the surface epithelium and the basement membrane, provide structural support for the lobules and assist in milk ejection during lactation. The luminal epithelial cells, which are the only cells capable of producing milk, overlie the myoepithelial cells.

The structure of the breast changes with the menstrual cycle and pregnancy. Estrogen stimulates the growth of the ductal system, whereas progesterone stimulates the growth and development of the ductile and glandular secretory epithelium. Early in the menstrual cycle, the ducts appear as cords with little or no lumen. Under estrogen stimulation, at the time of ovulation, the secretory cells increase in size, lumina appear in the ducts as small amounts of secretions accumulate, and fluid collects in the connective tissue. This causes a feeling of breast fullness and discomfort. During pregnancy, placental estrogen and progesterone produce further changes in the mammary glands. Beginning at about the fifth week of pregnancy, the anterior pituitary releases increasing amounts of the hormone *prolactin*. The alveolar glands are lined with secretory cells capable of producing milk under the influence of prolactin. However, milk production does not occur until after birth. This is because placental hormones inhibit milk production. Following childbirth and expulsion of the placenta, the maternal concentration of placental hormones declines rapidly and the action of prolactin is no longer inhibited.

Benign Disorders

Breast disease may be described as benign or cancerous.[7,11,58] Benign breast conditions are nonmalignant conditions of the breast. They include inflammatory disorders and benign epithelial disorders. Some benign disorders may increase the risk of malignant disease and others may present with signs that resemble malignant disease.

Inflammatory Disorders

Inflammatory diseases of the breast are uncommon, accounting for less than 1% of breast disorders.[11] They include mastitis, mammary duct ectasia, and fat necrosis.

Mastitis. Mastitis is inflammation of the breast.[11,59,60] It most frequently occurs during lactation but may also result from other conditions. In the lactating woman, inflammation results from an ascending infection that travels from the nipple to the ductal structures. The most common organisms isolated are *Staphylococcus aureus* and *Streptococcus*.[59] The offending organisms often originate from the suckling infant's nasopharynx or the mother's hands. During the early weeks of nursing, the breast is particularly vulnerable to bacterial invasion because of minor cracks and fissures that occur with vigorous suckling. Infection and inflammation cause obstruction of the ductal system. The breast area becomes hard, inflamed, and tender if not treated early. Without treatment, the area becomes walled off and may abscess, requiring incision and drainage. It is advisable for the mother to continue breast-feeding during antibiotic therapy to prevent this.

Mastitis is not confined to the postpartum period; it can occur as a result of hormonal fluctuations, tumors, trauma, or skin infection. Cyclic inflammation of the breast occurs most frequently in adolescents, who commonly have fluctuating hormone levels. Tumors may cause mastitis secondary to skin involvement or lymphatic obstruction. Local trauma or infection may develop into mastitis because of ductal blockage of trapped blood, cellular debris, or the extension of superficial inflammation. The treatment for mastitis symptoms may include application of heat or cold, excision, aspiration, mild analgesics, antibiotics, and a supportive brassiere or breast binder.

Mammary Duct Ectasia. Mammary duct ectasia refers to the presence of dilated breast ducts containing a thick pasty material, with accompanying periductal inflammation and fibrosis.[11,59] The dilated ducts may rupture, resulting in grayish-green nipple discharge. Palpation of the breast increases the discharge. The disorder is usually unilateral, occurring after menopause, most often in elderly multiparous women. Women typically present with a poorly defined perialveolar mass that is often associated with thick, white nipple secretions and sometimes with nipple retraction. Pain and erythema are uncommon. Duct ectasia may be difficult to distinguish clinically from carcinoma and may require biopsy.

Fat Necrosis. Fat necrosis is a distinct clinical and histologic entity, resulting in either a localized or diffuse mass lesion of the breast. The majority of women have a history of trauma, surgery, or radiation therapy.[11,58,59] Initially the lesion consists of necrotic adipocytes and hemorrhage, after which the inflammatory cells phagocytize the lipid debris. Macrophages may produce a granulomatous inflammatory response. Fibroblast proliferation and collagen deposition during healing may lead to scar tissue (fibrosis). As a result, an irregular fixed hard mass may form that clinically resembles breast cancer. Unlike a malignant mass, however, fat necrosis is typically very tender and has a specific mammographic appearance.

Benign Epithelial Disorders

A wide variety of benign alterations in ducts and lobules are observed in the breast. Most are detected by mammography or as incidental findings on surgical specimens. These lesions have been divided into three groups according to the subsequent risk of developing carcinoma: nonproliferative (fibrocystic) changes, proliferative breast disease without atypia, and proliferative breast disease with atypia.[11,59]

Nonproliferative (Fibrocystic) Breast Changes. Formerly called *fibrocystic disease*, fibrocystic changes are the most frequent lesion of the breast. They encompass a wide variety of lesions and breast changes. Microscopically, fibrocystic changes refer to a constellation of

morphologic changes manifested by (1) cystic dilation of terminal ducts, (2) relative increase in fibrous tissue, and (3) variable proliferation of terminal duct epithelial elements.[59] They are most common in women 30 to 50 years of age and are rare in postmenopausal women not receiving hormone replacement.[59,60]

Fibrocystic changes usually present as nodular (i.e., "shotty"), granular breast masses that are more prominent and painful during the luteal or progesterone-dominant portion of the menstrual cycle. Discomfort ranges from heaviness to exquisite tenderness, depending on the degree of vascular engorgement and cystic distention.

Although fibrocystic changes have been thought to increase the risk of breast cancer, only certain variants in which proliferation of the epithelial components is demonstrated represent a true risk. Fibrocystic changes with giant cysts and proliferative epithelial lesions with atypia are more common in women who are at increased risk for development of breast cancer. The nonproliferative form of fibrocystic changes that does not carry an increased risk for development of cancer is more common.

Diagnosis of fibrocystic changes is made by physical examination, mammography, ultrasonography, and biopsy (i.e., aspiration or tissue sample). Mammography may be helpful in establishing the diagnosis, but increased breast tissue density in women with fibrocystic changes may make an abnormal or cancerous mass difficult to discern among the other structures. Ultrasonography is useful in differentiating a cystic from a solid mass. Because a mass caused by fibrocystic changes may be indistinguishable from carcinoma on the basis of clinical findings, suspect lesions should undergo biopsy. Any discrete mass or lump on the breast should be viewed as possible carcinoma, and cancer should be excluded before instituting the conservative measures used to treat fibrocystic changes.

Treatment for fibrocystic changes is usually symptomatic. Mild analgesics (e.g., aspirin, acetaminophen, or NSAIDs), vitamin E, and local application of heat or cold may be used for pain relief. Prominent or persistent cysts may be aspirated and any fluid obtained sent to the laboratory for cytologic analysis. Women should be encouraged to wear a good supporting brassiere, and are advised to avoid foods that contain xanthines (e.g., coffee, cola, chocolate, and tea) in their daily diets, particularly premenstrually. Danazol, a synthetic androgen, may be used for women with severe pain.[11] While it suppresses pituitary gonadotropins, the androgenic effects (acne, edema, hirsutism) of danazol often make this treatment intolerable. Similarly, tamoxifen reduces some of the symptoms of the fibrocystic condition, but because of its side effects, it is not useful in young women unless it is given to reduce the risk of cancer.

Proliferative Lesions without Atypia. Proliferative lesions without atypia, which are commonly detected as mammographic densities or calcifications, include epithelial hyperplasia, sclerosing adenosis, and intraductal papillomas.[11,59] They are characterized by proliferation of ductile or lobular epithelial cells.

In a normal breast, only myoepithelial cells and a single layer of luminal cells rest on the basement membrane. If there are more than two cell layers, the abnormality is known as *epithelial hyperplasia*. If there is increased fibrosis within the expanded lobule, with distortion and compression of the epithelium, the lesion is termed *sclerosing adenosis*. Papillomas are intraductal growths composed of supporting tissue and lined with both myoepithelial and luminal cells. Solitary *intraductal papillomas* are found in the major lactiferous ducts of women, typically between the ages of 30 and 50. The papillomas, which can range in size from 2 mm to 5 cm, often present with serous or serosanguineous drainage.

Proliferative Lesions with Atypia. Proliferative disease with atypia includes atypical ductile hyperplasia and atypical lobular hyperplasia.[11,59] The hyperplasia is accompanied by replacement of the normal epithelial cells lining the ducts or lobules with atypical cells resembling those of carcinoma in situ. The basement membrane remains intact and, therefore, the cells cannot metastasize.[11]

There are two types of atypical hyperplasia: lobular and ductile.[59] Atypical ductile hyperplasia is recognized by its histologic resemblance to ductile carcinoma in situ (DCIS). It is distinguished from DCIS by its limited extent and partial filling of the ducts. Atypical lobar hyperplasia is defined by proliferation of cells identical to those of lobar carcinoma in situ (LCIS), but the cells do not fill or distend more than 50% of the acini within the lobule. Management of LCIS consists of excisional biopsy.[11] Women with DCIS are at increased risk for developing invasive cancer or recurrence of the DCIS lesion.[11] For this reason, DCIS is evaluated with core-needle biopsy (to be discussed) followed by surgical biopsy or excision. Women with both types of lesions require careful follow-up to prevent and detect the presence of invasive cancer.

Breast Cancer

Cancer of the breast is the most common female cancer. Currently, one in nine American women will have breast cancer in her lifetime.[60] Although the breast cancer mortality rate has shown a slight decline, it is second only to lung cancer as a cause of cancer-related deaths in women. Incidence rates for carcinoma in situ have increased dramatically since the mid-1970s because of recommendations regarding mammography screening. A 3.9% decrease in breast cancer incidence has been observed between 2001 and 2004, along with a 2.2% decrease in breast cancer mortality. The decline in the breast cancer mortality rate undoubtedly is due to earlier diagnosis through screening programs and increased awareness, as well as improvements in cancer treatments.

Risk factors for breast cancer include increasing age, personal or family history of breast cancer (i.e., at highest risk are those with multiple affected first-order relatives), history of benign breast disease (i.e., primary "atypical" hyperplasia), and hormonal influences that promote breast maturation and may increase the chance

of cell mutation (i.e., early menarche, late menopause, and no term pregnancies or first child after 30 years of age). Modifiable risk factors include obesity (particularly after menopause), physical inactivity, alcohol intake greater than one drink per day, and long-term use of postmenopausal hormone therapy (especially combined estrogen and progestin). Most women with breast cancer have no identifiable risk factors.

Approximately 5% to 10% of all breast cancers are hereditary, with genetic mutations causing up to 80% of breast cancers in women younger than 50 years of age.[61] Mutations in two breast cancer susceptibility genes—*BRCA1* on chromosome 17 and *BRCA2* on chromosome 13—may account for most inherited forms of breast cancer (see Chapter 7). *BRCA1* is known to be involved in tumor suppression. A woman with known mutations in *BRCA1* has a lifetime risk of 60% to 85% for breast cancer and an increased risk of ovarian cancer. *BRCA2* is another susceptibility gene that carries an elevated cancer risk similar to that with *BRCA1*.[61] Breast cancer risk reduction options available to known carriers of *BRCA1* and *BRCA2* mutations include surveillance and surgery. Breast evaluation using MRI is generally preferred over standard mammography for these women because of its enhanced sensitivity and lack of radiation exposure, which may be safer for them. Prophylactic surgery, in the form of bilateral mastectomy, bilateral oophorectomy, or both, has been shown to decrease the risk of developing cancer. These controversial surgeries can have physical and psychological side effects that warrant careful consideration before proceeding.

Detection

Cancer of the breast may manifest clinically as a mass, a puckering, nipple retraction, or unusual discharge. Many cancers are found by women themselves—sometimes when only a thickening or subtle change in breast contour is noticed. The variety of symptoms and potential for self-discovery underscore the need for all women to have an awareness of what their normal breast appearance and texture are like. In 2003, the American Cancer Society dropped its recommendation that all women perform regular, systematic self-examination.[62] Research has indicated that most women who discover their own cancer do so at times other than scheduled breast self-examination (BSE). American Cancer Society screening guidelines now place primary emphasis for breast cancer diagnosis on clinical breast examination and mammography, while encouraging women in the area of self-awarenenss.[62] Women should have a clinical examination by a trained health professional and mammography at least every 3 years between 20 and 40 years of age, and annually after 40 years of age.

Mammography is the only effective screening technique for the early detection of clinically inapparent breast lesions. A generally slow-growing form of cancer, breast cancer may have been present for 2 to 9 years before it reaches 1 cm, the smallest mass normally detected by palpation. Mammography can disclose lesions as small as 1 mm and the clustering of calcifications that may warrant biopsy to exclude cancer. Mammography has a sensitivity of 80% to 90% for the detection of breast cancer even when performed by the most capable institutions. Therefore, palpable masses need further evaluation and potentially biopsy even if the mammogram is negative. Approximately 40% of breast cancers can be detected only by palpation and another 40% only by mammography. The most comprehensive approach to screening is a combination of individual self-awareness, clinical breast evaluation by a health professional, and mammogram.

Diagnosis and Classification

Procedures used in the diagnosis of breast cancer include physical examination, mammography, ultrasonography, percutaneous needle aspiration, stereotactic needle biopsy (i.e., core biopsy), and excisional biopsy. Figure 46-19 illustrates the appearance of breast cancer on mammography. Breast cancer often manifests as a solitary, painless firm fixed lesion with poorly defined borders. It can be found anywhere in the breast but is most common in the upper outer quadrant. Because of the variability in presentation, any suspect change in breast tissue warrants further investigation. The diagnostic use of mammography enables additional definition of the clinically suspect area (e.g., appearance, character, calcification). Placement of a wire marker under radiographic guidance can ensure accurate surgical biopsy of nonpalpable suspect areas. Ultrasonography is useful as a diagnostic adjunct to differentiate cystic from solid tissue in women with nonspecific thickening.

Fine needle aspiration is a simple in-office procedure that can be performed repeatedly in multiple sites and with minimal discomfort. It can be accomplished by stabilizing a palpable mass between two fingers or in conjunction with handheld sonography to define cystic masses or fibrocystic changes and to provide specimens for cytologic examination. Fine needle aspiration can identify the presence of malignant cells, but it cannot differentiate in situ from infiltrating cancers. Stereotactic needle biopsy is an outpatient procedure done with the guidance of a mammography machine. After the lesion is localized radiologically, a large-bore needle is mechanically thrust quickly into the area, removing a core of tissue. Discomfort is similar to that with ear piercing, and even when multiple cores are obtained, healing occurs quite rapidly. Cells are available for histologic evaluation with 96% accuracy in detecting cancer. This procedure is less costly than excisional biopsy. Excisional biopsy to remove the entire lump provides the only definitive diagnosis of breast cancer, and often is therapeutic without additional surgery. MRI, positron emission tomography (PET), and computer-based or digital mammography are available as additional diagnostic modalities for breast cancer, and may be recommended to supplement conventional mammography in women with radiographically dense breasts or a strong family history of cancer, or who are known carriers of *BRCA1* or *BRCA2*.[63]

Tumors are classified histologically according to tissue characteristics and staged clinically according to tumor size, nodal involvement, and presence of metastasis.

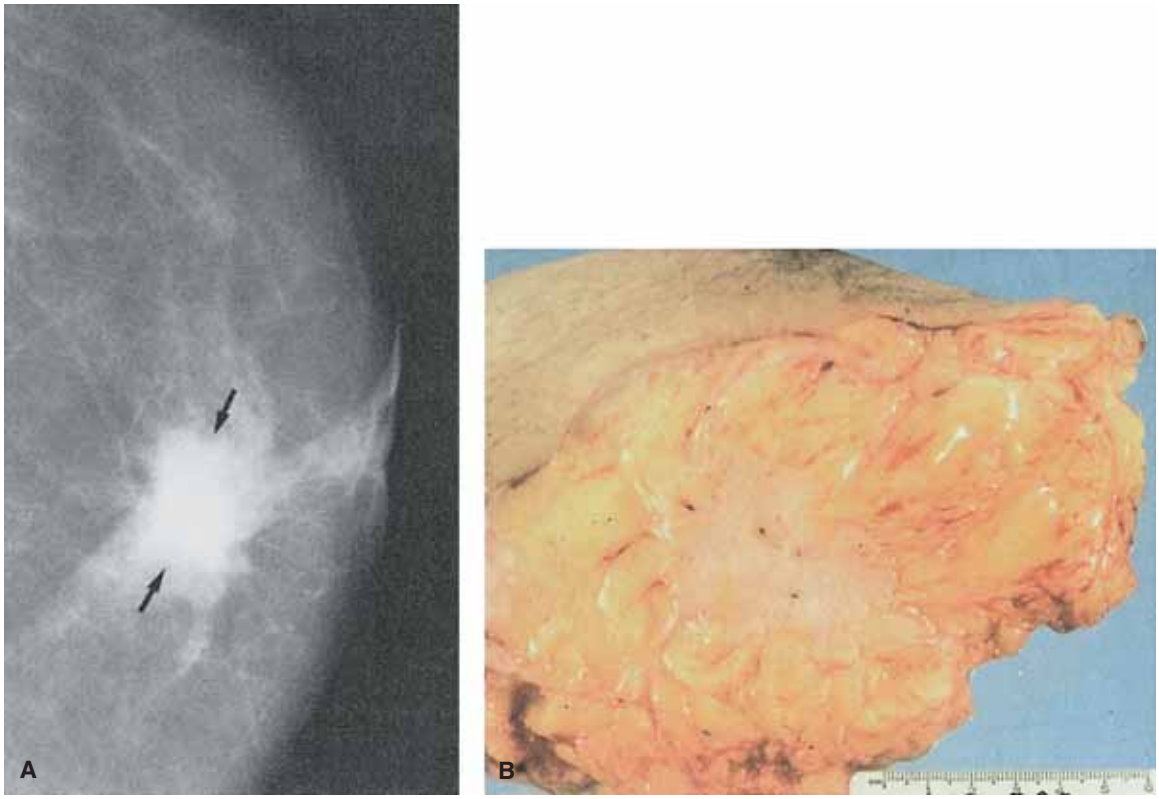

FIGURE 40-19. Carcinoma of the breast. **(A)** Mammogram. An irregularly shaped, dense mass (*arrows*) is seen in this otherwise fatty breast. **(B)** Mastectomy specimen. The irregular white, firm mass in the center is surrounded by fatty tissue. (From Thor A.D., Osunkoya A.O. [2008]. The breast. In Rubin R., Strayer D.S. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 851]. Philadelphia: Lippincott Williams & Wilkins.)

It is recommended that estrogen and progesterone receptor analysis be performed on surgical specimens. Information about the presence or absence of estrogen and progesterone receptors can be used in predicting tumor responsiveness to hormonal manipulation. High levels of both receptors improve the prognosis and increase the likelihood of remission.

Treatment

The treatment methods for breast cancer include surgery, chemotherapy, radiation therapy, and hormonal manipulation. Radical mastectomy (i.e., removal of the entire breast, underlying muscles, and all axillary nodes) rarely is used today as a primary surgical therapy unless breast cancer is advanced at the time of diagnosis. Modified surgical techniques (i.e., mastectomy plus axillary dissection or lumpectomy for breast conservation) accompanied by chemotherapy or radiation therapy have achieved outcomes comparable with those obtained with radical surgical methods and constitute the preferred treatment methods.

The prognosis for women with breast cancer is related more to the extent of nodal involvement than to the extent of breast involvement. Greater nodal involvement requires more aggressive postsurgical treatment, and many cancer specialists believe that a diagnosis of breast cancer is not complete until dissection and testing of the axillary lymph nodes have been accomplished. A newer technique for evaluating lymph node involvement is a sentinel lymph node (SLN) biopsy. A radioactive substance or dye is injected into the region of the tumor. In theory, the dye is carried to the first (sentinel) node to receive lymph from the tumor.[64] This would therefore be the node most likely to contain cancer cells if the cancer has spread. If the sentinel node biopsy is positive, more nodes are removed. If it is negative, further lymph node evaluation may not be needed.

Systemic therapy refers to the administration of chemotherapy, biologic therapy, or hormonal therapy. Neoadjuvant therapy is given before surgery to shrink the tumor and make surgical removal more effective. Adjuvant therapy is given after surgery to women with and without detectable metastatic disease. The goal of this therapy depends on nodal involvement, menopausal status, and hormone receptor status. Systemic adjuvant therapy has been widely studied and has demonstrated benefits in reducing rates of recurrence and death from breast cancer.[64] Biologic therapy, using the drug trastuzumab (Herceptin), is used to stop the growth of breast tumors that express the HER2/neu receptor on their cell surface. The HER2/neu receptor binds an epidermal growth factor that contributes to cancer cell growth. Trastuzumab is a recombinant DNA-derived

monoclonal antibody that binds to the HER2/neu receptor, thereby inhibiting proliferation of tumor cells that overexpress the receptor gene.[65]

Hormone therapy is used to block the effects of estrogen on the growth of breast cancer cells. Tamoxifen is a nonsteroidal antiestrogen that binds to estrogen receptors and blocks the effects of estrogens on the growth of malignant cells in the breast. Studies have shown decreased cancer recurrence, decreased mortality rates, and increased 5-year survival rates in women with estrogen receptor–positive tissue samples who have been treated with the drug. Aromatase inhibitors block the enzyme that converts androstenedione and testosterone to estrogen in the peripheral tissues. This reduces the circulating estrogen levels in postmenopausal women and is becoming the most effective adjuvant therapy for women with early-stage breast cancer.[66] Autologous bone marrow transplantation and peripheral stem cell transplantation are experimental therapies that may be used for treatment of advanced disease or in women at increased risk for recurrence.

Paget Disease

Paget disease accounts for 1% of all breast cancers.[59,60] The disease presents as an eczematoid lesion of the nipple and areola. Paget disease usually is associated with an infiltrating, intraductal carcinoma. When the lesion is limited to the nipple only, the rate of axillary metastasis is approximately 5%. Complete examination is required and includes a mammogram and biopsy. Treatment depends on the extent of spread.

In summary, the breast contains alveolar glands and ducts that are lined with epithelial tissue that may give rise to benign and malignant lesions. The benign conditions include inflammatory disorders (mastitis, mammary duct dysplasia, and fat necrosis) and benign epithelial lesions (nonproliferative lesions, proliferative lesions without atypia, and proliferative lesions with atypia). Some benign conditions, such as proliferative lesions, may predispose to malignant disease, and others, such as fibrocystic changes and fat necrosis, may present with a mass and signs that resemble malignant disease. By far the most important disease of the breast is breast cancer, which is a significant cause of death for women. Risk factors for breast cancer include increasing age, personal or family history of breast cancer, history of benign breast disease (i.e., proliferative lesions with atypia), and hormonal influences (e.g., early menarche and late menopause) that promote breast maturation and may increase the chance of cell mutation. Some inherited breast cancers are associated with mutations in breast cancer genes *BRCA1* and *BRCA2*. Both physical examination and mammography afford a woman the best protection against breast cancer. They provide the means for early detection of breast cancer and, in many cases, allow early treatment and cure. The choice of treatment, which includes surgical resection, radiation, and chemotherapy, depends on the stage of the disease.

REVIEW EXERCISES

1. Most oral contraceptive agents use low doses of estrogen and progestin to prevent conception.

- **A.** Use Figure 40-4 to explain how these oral agents prevent ovulation and pregnancy.

2. A 32-year-old woman has been told that the report of her annual Pap test revealed the presence of mild cervical dysplasia.

- **A.** What questions should this woman ask to become informed about the significance of these findings?
- **B.** In obtaining additional information about the results of her Pap test, the woman is informed that the dysplastic changes are consistent with a CIN1 classification.
  - **a.** Does this mean that the woman has cervical cancer?
  - **b.** Cervical cancer is often referred to as a sexually transmitted disease. Explain.
  - **c.** What type of follow-up care would be indicated?

3. A 30-year-old woman consults her gynecologist because of amenorrhea and inability to become pregnant. Physical examination reveals an obese woman with hirsutism. The physician tells her that she might have a condition known as *polycystic ovary syndrome* and that further laboratory tests are indicated.

- **A.** Among tests ordered were a fasting blood glucose and serum LH, FSH, and dehydroepiandrosterone levels. What information can these tests provide that would help in establishing a diagnosis of polycystic ovary syndrome?
- **B.** What is the probable cause of this woman's amenorrhea, hirsutism, and failure to become pregnant?
- **C.** What type of treatment might be used to help this woman become pregnant?

4. A 45-year-old woman makes an appointment to see her physician because of a painless lump in her breast that she has discovered.

- **A.** What tests should be done to confirm the presence or absence of breast cancer?
- **B.** During the removal of breast cancer, a sentinel node biopsy is often done to determine whether the cancer has spread to the lymph nodes. Explain how this procedure is done and its value in determining lymph node spread.
- **C.** After surgical removal of breast cancer, tamoxifen may be used as an adjuvant systemic therapy for women without detectable metastatic disease. The presence or absence of estrogen receptors in the cytoplasm of tumor cells is important in determining the selection of an agent for use in adjuvant therapy. Explain.

Chapter 41

Sexually Transmitted Infections

Sexually transmitted infections (STIs), previously referred to as sexually transmitted diseases (STDs), encompass a broad range of infectious diseases that are spread by sexual contact. Although the incidence of syphilis and gonorrhea as reported in the professional literature and public health statistics has decreased slightly, the incidence of other STIs is increasing. The actual figures are probably much higher than those reported because many STIs are not reportable or not reported. The agents of infection include bacteria, *Chlamydia,* viruses, fungi, and unidentified microorganisms (see Chapter 14). The initial site of an STI may be the urethra, genitalia, rectum, or oral pharynx. The organisms that cause these infections tend to be short lived outside the host, so they usually depend on person-to-person spread. The rates of many STIs are highest among adolescents; all STIs are more common in persons who have more than one sexual partner; and it is not uncommon for a person to be concurrently infected with more than one type of STI.

There are many factors that contribute to the increased prevalence and the continued spread of STIs, including the fact that STIs are frequently asymptomatic, which promotes the spread of infection by persons who are unaware that they are carrying the infection. Furthermore, partners of infected persons are often difficult to notify and treat. Condoms could prevent the spread of many STIs, but they often are not used or are used improperly. In addition, there currently are no cures for viral STIs (e.g., human immunodeficiency virus [HIV], herpes simplex virus); although there are drugs available that may help to manage the infections, they do not entirely control the spread. Also, drug-resistant microorganisms are rapidly emerging, making treatment of many STIs more difficult.

This chapter discusses the manifestations of STIs in men and women in terms of infections of the external genitalia, vaginal infections, and infections that have genitourinary as well as systemic manifestations. HIV infection is presented in Chapter 16.

Sexually Transmitted Infections

- Sexually transmitted infections (STIs) are spread by sexual contact and involve both male and female partners. Portals of entry include the mouth, genitalia, urinary meatus, rectum, and skin. All STIs are more common in persons who have more than one sexual partner, and it is not uncommon for a person to be concurrently infected with more than one type of STI.
- In general, STIs due to bacterial pathogens can be successfully treated and the pathogen eliminated by antimicrobial therapy. However, many of these pathogens are developing antibiotic resistance.
- STIs due to viral pathogens such as genital herpes simplex virus infections (HSV-1 and HSV-2) are not eliminated by current treatment modalities and persist with risk of recurrence.
- Untreated, STIs such as chlamydial infection and gonorrhea can spread to involve the internal genital organs with risk of complications and infertility.
- Intrauterine or perinatally transmitted STIs can have potentially fatal or severely debilitating effects on a fetus or an infant.

Infections of the External Genitalia

Sexually transmitted infections can selectively infect the mucocutaneous tissues of the external genitalia, cause vaginitis in women, or produce both genitourinary and systemic effects. Some STIs may be transmitted by an infected mother to a fetus or newborn, causing congenital defects or death of the child. The discussion in this section of the chapter focuses on STIs that affect the mucocutaneous tissues of the oropharynx and external genitalia, and anorectal tissues. These infections include condylomata acuminata, genital herpes, chancroid, and lymphogranuloma venereum.

Human Papillomavirus Infection and Genital Warts

Genital warts (condylomata acuminata) are caused by the human papillomavirus (HPV) that infects epithelial cells and can cause a number of benign and malignant growths.[1–7] Although recognized for centuries, HPV-induced genital warts have become one of the fastest-growing STIs of the past decade. The Centers for Disease Control and Prevention (CDC) estimates that 20 million Americans 15 to 49 years of age (approximately 15% of the population) are currently infected with the HPV.[1] Transmission of HPV is usually through skin-to-skin contact, most often through penetration (oral–genital, manual–genital, and genital–genital contact).[1,2] HPV can also be transmitted though nonsexual routes including mother to newborn (vertical transmission) and fomites. Prevention of HPV transmission through condom use has not been adequately demonstrated. Most HPV infections are asymptomatic and transient, and resolve without treatment.[1–4] However, in some cases, HPV infection results in genital warts, Papanicolaou (Pap) test abnormalities, or, rarely, cervical cancer.

HPVs are nonenveloped double-stranded deoxyribonucleic acid (DNA) viruses that cause proliferative lesions of the squamous epithelium.[1,2] More than 100 distinct HPV subtypes have been identified, over 40 of which affect the anogenital area. These subtypes are routinely classified into low-risk and high-risk categories. Low-risk types such as 6 and 11 are typically associated with genital warts. Types 16, 18, 31, 33, and 45 are considered to be high risk because of their association with cervical dysplasia and cervical cancer. Of the high-risk types, HPV 16 and 18 account for approximately two thirds of cervical cancer.[1,4] Only a subset of women infected with HPV go on to develop cervical cancer, however, suggesting that even the most virulent HPV strains may vary in terms of their oncogenic potential. Cofactors that may increase the risk for cancer include smoking, immunosuppression, and exposure to hormonal alteration (e.g., pregnancy, oral contraceptives).[1] The recent release of a quadrivalent vaccine to protect against HPV types 6, 11, 16, and 18 may eventually reduce the risk of cervical cancer associated with HPV.[1,2,8] Currently, however, there is no treatment to eradicate the virus once a person has become infected.

HPV infection begins with viral inoculation into a stratified squamous epithelium, where infection stimulates replication of the squamous epithelium, producing the various HPV-proliferative lesions.[5] The incubation period for HPV-induced genital warts ranges from 6 weeks to 8 months, with a mean of 2 to 3 months. Genital warts typically present as soft, raised, fleshy lesions on the external genitalia, including the penis (Fig. 41-1), vulva, scrotum, perineum, and perianal skin. External warts may appear as small bumps, or they may be flat, rough surfaced, or pedunculated. Less commonly, they can appear as smooth reddish or brown raised papules or as dome-shaped lesions on keratinized skin. Internal warts are cauliflower-shaped lesions that affect the mucous membranes of the vagina, urethra, anus, or mouth. They may cause discomfort, bleeding, or painful intercourse.[6]

Although warts can be a disturbing clinical feature of HPV infection, subclinical infection is common. Approximately 70% of women with HPV become HPV DNA negative within 1 year, and as many as 91% of them become negative within 2 years.[1] Many women with transient HPV infections develop atypical squamous cells of undetermined significance (ASC-US) or low-grade squamous intraepithelial lesions (LSILs) of the cervix as

FIGURE 41-1. Condylomata of the penis. Raised circumscribed lesions are seen on the shaft of the penis. (From Damjanov I. [2005]. The lower urinary tract and male reproductive system. In Rubin E., Gorstein F., Rubin R., et al. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [4th ed., p. 904]. Philadelphia: Lippincott Williams & Wilkins.)

detected on a Pap test, colposcopy, or biopsy (see Chapter 40). In men, transient HPV infection may be associated with intraepithelial neoplasia of the penis and anus.[1] Development of an effective immune response helps clear the infection, but the virus can remain dormant for years and reactivate at a later time.

Diagnosis of genital warts is usually made by visualization or palpation of nontender papillomatous genital lesions. A diagnosis of genital warts may be confirmed by biopsy. There are no approved serologic tests for HPV or routine methods for culturing the virus. The only test that is currently approved by the U.S. Food and Drug Administration (FDA) is a solution hybridization method to test for high-risk HPV DNA.[1] The HPV DNA test determines whether one or more of the high-risk types of HPV is present, but does not identify the individual HPV type. HPV DNA testing is warranted with equivocal (ASC-US) Pap test results, and is now recommended to determine which women older than 30 years of age need annual Pap smear screening (see Chapter 40). There is currently no FDA-approved HPV DNA test for men, nor is testing for men recommended.[1]

The choice of treatment for genital warts is based on the number, size, site, and morphology of the lesions, as well the person's preference. If left untreated, the warts may resolve spontaneously, so expectant management is acceptable if the person is comfortable with this approach. Evaluation and treatment of sexual partners may be suggested, although this may be difficult considering that warts often do not become clinically apparent for several years after exposure.

The CDC identifies several pharmacologic treatments for symptomatic removal of visible genital warts, including patient-applied (podofilox and imiquimod) and provider-administered (podophyllin and trichloroacetic acid) therapies.[9] Podofilox is a topical antimitotic agent that results in visible necrosis of wart tissue. The safety of podofilox during pregnancy has not been established. Imiquimod cream is a new type of therapeutic agent that stimulates the body's immune system (i.e., production of interferon-α and other cytokines). It is a category B drug and therefore potentially safe for use in pregnancy. Podophyllin, a topical cytotoxic agent, has long been used for treatment of visible external growths. Multiple applications may be required for resolution of lesions. The amount of drug used and the surface area treated should be limited with each treatment session to avoid systemic absorption and toxicity. This treatment is contraindicated in pregnancy for the same reason. An alternative therapy is the topical application of a solution of trichloroacetic acid. This weak destructive agent produces an initial burning in the affected area, followed in several days by a sloughing of the superficial tissue. Several applications at 1- to 2-week intervals may be necessary to eradicate the lesion. Sexual abstinence is suggested during any type of treatment to enhance healing.

Genital warts also may be removed using cryotherapy (i.e., freezing therapy), surgical excision, laser vaporization, or electrocautery. Because it can penetrate deeper than other forms of therapy, cryotherapy often is the treatment of choice for cervical HPV lesions. Laser surgery can be used to remove large or widespread lesions of the cervix, vagina, or vulva, or lesions that have failed to respond to other first-line methods of treatment. Electrosurgical treatment has become more widespread for these types of lesions because it is more readily available in outpatient settings and is much less expensive than laser.

Genital Herpes

Genital herpes is one of the most common causes of genital ulcers in the United States. Because herpesvirus infection is not reportable in all states, reliable data on its true incidence and prevalence are lacking. Recent estimates in the United States indicate 67 million people (1 in 4 adolescents or adults) are infected with genital herpes.[10] Women have a greater mucosal surface area exposed in the genital area and therefore are at greater risk of acquiring the infection.

Genital herpes is caused by the herpes simplex virus (HSV), a large double-stranded DNA virus.[11–15] Herpes simplex infections are highly contagious. There are eight types of HSV, including HSV-1 (usually associated with fever blisters and cold sores) and HSV-2 (usually associated with genital herpes).[11,12] HSV-1 and HSV-2 are genetically similar; both cause a similar set of primary and recurrent infections, and both can cause oropharyngeal and genital lesions. HSV-1 and HSV-2 are *neurotropic* viruses, meaning that they grow in neurons and share the biologic property of latency. Latency refers to the ability to

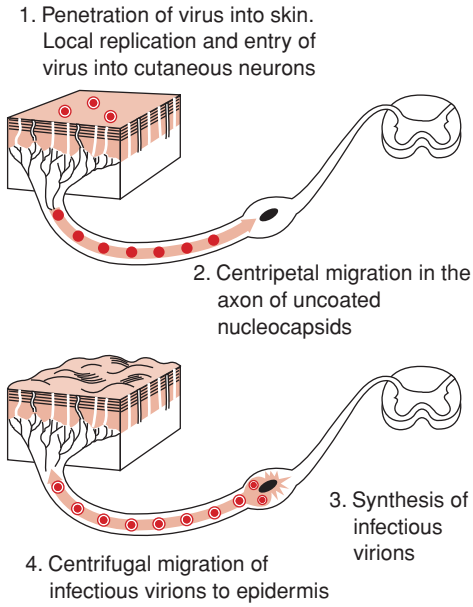

FIGURE 41-2. Pathogenesis of primary mucocutaneous herpes simplex virus infection. (From Corey L., Spear P.G. [1986]. Infections with herpes simplex viruses: Part 1. *New England Journal of Medicine* 314, 686.)

maintain disease potential in the absence of clinical signs and symptoms. In genital herpes, the virus ascends through the peripheral nerves to the sacral dorsal root ganglia (Fig. 41-2). The virus can remain dormant in the dorsal root ganglia, or it can reactivate, in which case the viral particles are transported back down the nerve root to the skin, where they multiply and cause a lesion to develop. During the dormant or latent period, the virus replicates in a different manner so that the immune system or available treatments have no effect on it. It is not known what reactivates the virus. It may be that the body's defense mechanisms are altered. Numerous studies have shown that host responses to infection influence initial development of the disease, severity of infection, development and maintenance of latency, and frequency of HSV recurrences.

HSV is transmitted by contact with infectious lesions or secretions. Most HSV genital infections are caused by HSV-2, but genital HSV-1 infections are becoming increasingly common, particularly among adolescents and young women. Women infected with HSV-1 remain at risk for acquiring HSV-2. Most cases of HSV-2 infection are subclinical, manifesting as truly asymptomatic or symptomatic but unrecognized infections. These subclinical infections can occur in people who have never had a symptomatic outbreak or they can occur between recognized clinical recurrences. Up to 70% of genital herpes is spread through asymptomatic shedding by people who do not realize they have the infection.[15] This "unknown" transmission of the virus to sex partners explains why this infection has reached epidemic proportions throughout the world.

The incubation period for HSV is 2 to 12 days.[14] Genital HSV infection may manifest as a first-episode or recurrent infection. The initial symptoms of primary genital herpes infections include tingling, itching, and pain in the genital area, followed by eruption of small pustules and vesicles. These lesions rupture on approximately the fifth day to form wet ulcers that are excruciatingly painful to touch and can be associated with dysuria, dyspareunia, and urine retention. This period is followed by a 10- to 12-day interval during which the lesions crust over and gradually heal. Involvement of the cervix, vagina, urethra, and inguinal lymph nodes is common in women with primary infections. In men, the infection can cause urethritis and lesions of the penis and scrotum. Rectal and perianal infections are possible with anal contact. Systemic symptoms associated with primary infections include fever, headache, malaise, muscle ache, and lymphadenopathy. Primary infections may be debilitating enough to require hospitalization, particularly in women. First episodes of nonprimary infections (acquisition of HSV-2 in persons with preexisting antibodies to HSV-1 or, more rarely, acquisition of HSV-1 in persons with preexisting HSV-2 antibodies) are associated with fewer lesions, a shorter duration of disease, and a lower rate of complications than primary infections.

Recurrent HSV episodes are usually milder than the initial episode—there typically are fewer lesions, and viral shedding occurs at a lower concentration and for a shorter duration (about 3 days). However, the prodromal symptoms of itching, burning, and tingling at the lesion site are similar. Except for the greater tendency of HSV-2 to recur, the clinical manifestations of genital HSV-2 and HSV-1 infections are similar. The frequency and severity of recurrence vary from person to person. Numerous factors, including emotional stress, lack of sleep, overexertion, other infections, vigorous or prolonged coitus, and premenstrual or menstrual distress, have been identified as triggering mechanisms.

Diagnosis of genital herpes is based on symptoms, appearance of the lesions, and identification of the virus taken from the lesions for cell culture. Viral culture can generally isolate the virus in 5 days, is relatively inexpensive, and is highly specific.[7] However, it is not very sensitive, with false-negative results of 25% with primary infections and as high as 50% with recurrent infections.[4] Polymerase chain reaction (PCR) testing for HSV DNA (see Chapter 14) may be used to confirm a diagnosis of genital HSV infection; however, it is more expensive than other methods and is not routinely used.[9,13,14] In addition to viral detection methods, the detection of type-specific antibodies to HSV-1 and HSV-2 also can help to establish the diagnosis. These tests yield false-negative results when used in the early stages of infection, since it takes approximately 22 days for the body to produce antibodies to the virus.[4] Approximately 20% of patients may remain seronegative for 3 months, particularly if they have received antiviral medications.[4] This type of testing may prove useful in confirming infection in persons with recurrent genital symptoms and negative HSV cultures, or in establishing a clinical diagnosis of genital herpes without laboratory confirmation or in a partner of a person with genital herpes.[9]

There is no known cure for genital herpes, and the methods of treatment are largely symptomatic. The oral

antiviral drugs acyclovir, valacyclovir, and famciclovir have become the cornerstone for management of genital herpes.[4,13–15] By interfering with viral DNA replication, these drugs decrease the frequency of recurrences, shorten the duration of active lesions, reduce the number of new lesions formed, and decrease viral shedding with primary infections. Valacyclovir, the active component of acyclovir, and famciclovir have greater bioavailability, which enables improved dosing schedules and increased compliance. Episodic intervention reduces the duration of viral shedding and the healing time for recurrent lesions. Continuous antiviral suppressive therapy may be advised when more than six outbreaks occur within 1 year.[9] These drugs are well tolerated, with few adverse effects. This long-term suppressive therapy does not limit latency, and reactivation of the disease frequently occurs after the drug is discontinued. In 2002, the FDA approved long-term suppressive therapy with valacyclovir for the prevention of HSV-2 transmission to an uninfected sexual partner.

Current information indicates that the risk of neonatal infection is very low when the mother has developed type-specific antibodies, which are then transmitted to the neonate. Newborns at highest risk are those born to women who shed the virus and have not developed antibodies from previous infections. Disseminated neonatal infection carries high mortality and morbidity rates. Active infection during labor may necessitate cesarean delivery, ideally before membranes rupture. Recommendations from the CDC direct health care providers to obtain cultures only when a woman has active lesions during the third trimester. Vaginal delivery is acceptable if visible lesions are not present at the onset of labor.[9]

Chancroid

Chancroid is a disease of the external genitalia and lymph nodes caused by the gram-negative bacterium *Haemophilus ducreyi*.[4] The disease is most common in tropical and subtropical regions. It is one of the most common causes of genital ulcers in less developed countries, especially in Africa and parts of Asia, where it probably serves as an important cofactor in the transmission of HIV infection.[11] This STI has become uncommon in the United States, with only 20 to 50 reported cases in the last several years.[11] However, recent evidence suggests that chancroid may be underdiagnosed because many STI clinics do not have the facilities to test for *H. ducreyi*.

Chancroid is highly infectious and is usually transmitted by sexual intercourse or through skin and mucous membrane abrasions. Autoinoculation may lead to multiple chancres. Lesions begin as macules, progress to pustules, and then rupture. This painful ulcer has a necrotic base and jagged edges. In contrast, the syphilitic chancre is nontender and indurated. Subsequent discharge can lead to further infection of self or others. On physical examination, lesions and regional lymphadenopathy (i.e., buboes) may be found. Secondary infection may cause significant tissue destruction.

Diagnosis usually is made clinically, but may be confirmed through culture. Gram stain rarely is used today because it is insensitive and nonspecific. PCR testing methods may soon be available commercially for definitive identification of *H. ducreyi*. The organism has shown resistance to treatment with sulfamethoxazole alone and to tetracycline. The CDC recommends treatment with azithromycin, erythromycin, or ceftriaxone.[9]

Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is an acute and chronic venereal disease caused by *Chlamydia trachomatis* types L1, L2, and L3. The disease, although found worldwide, has a low incidence outside the tropics. Most cases reported in the United States are in men. There appears to be a new variant of L2 that is causing a resurgence of LGV in Europe and the United States, particularly in men who have sex with men.[16]

The lesions of LGV can incubate for a few days to several weeks and thereafter cause small, painless papules or vesicles that may go undetected. An important characteristic of the infection is the early (1 to 4 weeks later) development of large, tender, and sometimes fluctuant inguinal lymph nodes called *buboes*. There may be flulike symptoms with joint pain, rash, weight loss, pneumonitis, tachycardia, splenomegaly, and proctitis. In later stages of the disease, a small percentage of affected persons develop elephantiasis of the external genitalia, caused by lymphatic obstruction or fibrous strictures of the rectum or urethra from inflammation and scarring. Urethral involvement may cause pyuria and dysuria. Cervicitis is a common manifestation of primary LGV in women, and could extend to perimetritis or salpingitis, which are known to occur in other chlamydial infections.[16] Anorectal structures may be compromised to the point of incontinence. Complications of LGV may be minor or extensive, involving compromise of whole systems or progression to a cancerous state.

Diagnosis usually is accomplished by a complement fixation test for LGV-specific *Chlamydia* antibodies. High titers for this antibody differentiate this group from other chlamydial subgroups. PCR techniques, when more widely available, will provide a more practical, cost-effective tool for diagnosis.[16] Treatment involves 3 weeks of doxycycline, tetracycline, or erythromycin.[9] Surgery may be required to correct sequelae such as strictures or fistulas or to drain fluctuant lymph nodes.

In summary, sexually transmitted infections that primarily affect the external genitalia include HPV-induced genital warts, genital HSV infections, chancroid, and lymphogranuloma venereum. The lesions of these infections occur on the external genitalia of male and female sexual partners. Of recent concern is the relation between HPV infections and the development of genital neoplasms. Over 100 types of HPV have been

identified, including subtypes 6 and 11, which are typically associated with genital warts, and subtypes 16 and 18, which account for approximately two thirds of cervical dysplasia and cervical cancer. Genital herpes is an ulcerative disorder caused by the highly contagious HSV. There are two types of HSV that can cause genital herpes—HSV-1, which is usually associated with cold sores of the mouth, but may also cause genital lesions, and HSV-2. Both HSV-1 and HSV-2 are neurotrophic viruses that produce acute primary infections and latent recurrent episodes. During the primary infection, the HSV ascends through peripheral nerves to a sacral dorsal root ganglia. Recurrences occur when the virus is reactivated and travels down the nerve root to the affected area. There is no permanent cure for herpes infections. Chancroid and LGV produce external genital lesions with various degrees of inguinal lymph node involvement. These diseases are uncommon in the United States.

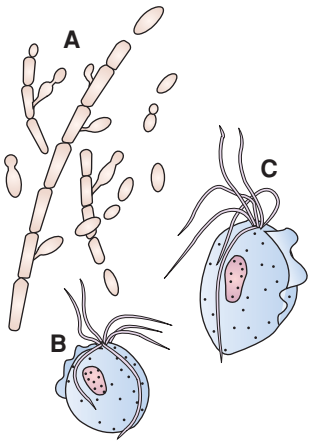

FIGURE 41-3. Organisms that cause vaginal infections. **(A)** *Candida albicans* (blastospores and pseudohyphae). **(B, C)** *Trichomonas vaginalis.*

Vaginal Infections

Candidiasis, trichomoniasis, and bacterial vaginosis are vaginal infections that can be associated with sexual activity. Trichomoniasis is the only form of vaginitis that is known to be sexually transmitted and requires partner treatment. The male partner usually is asymptomatic.

Candidiasis

Also called *yeast infection, thrush,* and *moniliasis, candidiasis* is the second leading cause of vulvovaginitis in the United States. Approximately 75% of reproductive-age women in the United States experience one episode in their lifetime; 40% to 45% experience two or more infections.[17]

Candida albicans is the most commonly identified organism in vaginal yeast infections, but other *Candida* species, such as *Candida glabrata* and *Candida tropicalis,* may also be present.[18] These organisms are present in 20% to 55% of healthy women without causing symptoms, and alteration of the host vaginal environment usually is necessary before the organism can cause pathologic effects.[17] Although vulvovaginal candidiasis usually is not transmitted sexually, it is included in the CDC STI treatment guidelines because it often is diagnosed in women being evaluated for STIs.[9] The possibility of sexual transmission has been recognized for many years; however, candidiasis requires a favorable environment for growth of the organism. The gastrointestinal tract also serves as a reservoir for this organism, and candidiasis can develop through autoinoculation in women who are not sexually active. Studies have documented the presence of *Candida* on the penis of male partners of women with vulvovaginal candidiasis, but few men develop balanoposthitis that requires treatment.

Reported risk factors for the overgrowth of *C. albicans* include recent antibiotic therapy, which suppresses the normal protective bacterial flora; high hormone levels owing to pregnancy or the use of oral contraceptives, which cause an increase in vaginal glycogen stores; and uncontrolled diabetes mellitus or HIV infection, which compromise the immune system.[19,20] Women with vulvovaginal candidiasis commonly complain of vulvovaginal pruritus accompanied by irritation, erythema, swelling, dysuria, and dyspareunia. The characteristic discharge, when present, is usually thick, white, and odorless. In obese persons, *Candida* may grow in skin folds underneath the breast tissue, the abdominal flap, and the inguinal folds.

Accurate diagnosis is made by identification of budding yeast filaments (i.e., hyphae) or spores on a wet-mount slide using 20% potassium hydroxide (Fig. 41-3A). The pH of the discharge, which is checked with litmus paper, typically is less than 4.5. When the wet-mount technique is negative but the clinical manifestations are suggestive of candidiasis, a culture may be necessary.

Antifungal agents such as clotrimazole, miconazole, butoconazole, and terconazole, in various forms, are effective in treating candidiasis. These drugs, with the exception of terconazole, are available without prescription for use by women who have had a previously confirmed diagnosis of candidiasis. Oral fluconazole has been shown to be as safe and effective as the standard intravaginal regimens.[9] Chronic vulvovaginal candidiasis, defined as four or more mycologically confirmed episodes within 1 year, affects approximately 5% of women and is difficult to manage. Subsequent prophylaxis (maintenance therapy) often is required for long-term management of this problem.[17]

Trichomoniasis

Trichomoniasis is credited with being a far more prevalent STI than either chlamydial infection or gonorrhea.[21–23]

Trichomonas vaginalis infections are commonly associated with other STIs and are therefore a marker for high-risk sexual behavior. The majority of women with trichomoniasis also have other STIs, particularly gonorrhea.[22] Although the infection is commonly transmitted by sexual contact, it can occur via fomites and the organism has been shown to survive in swimming pools and hot tubs.[4]

T. vaginalis is an anaerobic protozoan that is shaped like a turnip and has three or four anterior flagella (see Fig. 41-3B, C). Trichomonads can reside in the paraurethral glands of both sexes. Men harbor the organism in the urethra and prostate and are asymptomatic. Although 10% to 25% of women are asymptomatic, trichomoniasis is a common cause of vaginitis when some imbalance allows the protozoan to proliferate. This extracellular parasite feeds on the vaginal mucosa and ingests bacteria and leukocytes. The infection causes a copious, frothy, malodorous, green or yellow discharge. There commonly is erythema and edema of the affected mucosa, with occasional itching and irritation. Sometimes, small hemorrhagic areas, called *strawberry spots,* appear on the cervix.

Trichomoniasis can cause a number of complications.[21–23] It is a risk factor for HIV transmission and infectivity in both men and women.[23] In women, it increases the risk of tubal infertility and atypical pelvic inflammatory disease (PID; see Chapter 40), and it is associated with adverse outcomes such as premature birth in pregnant women. Trichomonads attach easily to mucous membranes. They may serve as vectors for the spread of other organisms, carrying pathogens attached to their surface into the fallopian tubes. In men, it is a common cause of nongonococcal urethritis and is a risk factor for infertility, altering sperm motility and viability. It has also been associated with chronic prostatitis.

Diagnosis is made microscopically by identification of the motile protozoan on a wet-mount slide preparation. The pH of the discharge usually is greater than 6.0. Newer point-of-care tests include an antigen-based diagnostic test (OSOM *Trichomonas* Rapid Test) and a DNA probe test (Affirm VP III). Both tests have greater sensitivity than a vaginal mount and results can be available in less than an hour.[9,23] PCR-based tests for *T. vaginalis* are currently under development.

Because the organism resides in other urogenital structures besides the vagina, systemic treatment is recommended. The treatment of choice is oral metronidazole or tinidazole, medications that are effective against anaerobic protozoans.[9] Both medications are chemically similar to disulfiram (Antabuse), a drug used in the treatment of alcohol addiction that causes nausea, vomiting, flushing of the skin, headache, palpitations, and lowering of the blood pressure when alcohol is ingested. Gastrointestinal disturbances and a metallic taste in the mouth are potential adverse effects of the drugs. Although metronidazole is considered safe for use during pregnancy, data on tinidazole use in pregnancy are limited. Sexual partners should be treated to avoid reinfection, and abstinence is recommended until the full course of therapy is completed.

Bacterial Vaginosis

Bacterial vaginosis is a polymicrobial infection characterized by lack of hydrogen peroxide–producing lactobacilli and an overgrowth of anaerobic organisms. It is the most prevalent vaginal disorder in women of reproductive age.[23] The disorder is associated with having multiple sex partners, a new sex partner, douching, and a lack of vaginal lactobacilli. Its relation to sexual activity is not clear. Sexual activity is believed to be a catalyst rather than a primary mode of transmission, and endogenous factors may play a role in the development of symptoms.

The predominant symptom of bacterial vaginosis is a thin, grayish-white discharge that has a foul, fishy odor. Burning, itching, and erythema usually are absent because the bacteria have only minimal inflammatory potential. Because of the lack of inflammation, the term *vaginosis* rather than *vaginitis* is used to describe the condition. The organisms associated with bacterial vaginosis may be carried asymptomatically by men and women.

The pathogenesis of bacterial vaginosis remains poorly understood. It is a complex disorder characterized by a shift in the vaginal flora from one dominated by hydrogen peroxide–producing lactobacilli to one with greatly reduced numbers of *Lactobacillus* species and an overgrowth of facultative anaerobic organisms, including *Gardnerella vaginalis, Mobiluncus* species, and *Mycoplasma hominis*.[4,23,24] The massive overgrowth of vaginal anaerobes is associated with the production of proteolytic enzymes that break down vaginal amines, which in a high pH become volatile and malodorous. The amines are associated with increased vaginal transudation and squamous epithelial cell exfoliation, creating the typical discharge.[24] In conditions of elevated pH, the vaginal anaerobes more efficiently adhere to the exfoliating epithelial cells, creating what are called *clue cells* (Fig. 41-4).

In addition to causing bothersome symptoms, bacterial vaginosis is associated with an increased risk of PID, preterm labor, premature rupture of membranes, and

FIGURE 41-4. Clue cells. Clue cells are epithelial cells with clumps of bacteria clustered to their surface. Clue cells indicate the presence of bacterial vaginosis. (Courtesy M. Rein, Centers for Disease Control and Prevention Public Health Image Library.)

postpartum endometritis linked to the organisms associated with bacterial vaginosis. Postoperative infections, including postabortion PID, posthysterectomy cuff cellulitis, and postcesarean endometritis, have been shown to be associated with asymptomatic bacterial vaginosis. It has also been associated with increased risk of acquisition of HIV and HSV infection.

The diagnosis of bacterial vaginosis is made when at least three of the following characteristics are present: abnormal gray discharge, vaginal pH above 4.5 (usually 5.0 to 6.0), positive whiff test on addition of 10% potassium hydroxide, and appearance of characteristic "clue cells" on wet-mount microscopic studies. Because *G. vaginalis* can be a part of the normal vaginal flora, cultures should not be done routinely.

Bacterial vaginosis may be treated with oral or topical metronidazole or oral or topical clindamycin. Symptomatic pregnant women can also be treated with these medications. Some studies have shown that screening for and treating bacterial vaginosis may reduce the incidence adverse pregnancy outcomes. However, studies do not confirm a benefit from universal testing of low- and medium-risk pregnant women.[25]

In summary, candidiasis, trichomoniasis, and bacterial vaginosis are common vaginal infections that become symptomatic because of changes in the vaginal ecosystem. Only trichomoniasis is spread through sexual contact. *Trichomoniasis*, which is caused by the anaerobic protozoan *T. vaginalis,* incites the production of a copious, frothy, yellow or green, malodorous discharge. It is a risk factor for HIV transmission and infectivity in both men and women. In women, it increases the risk of pelvic inflammatory disease, tubal infertility, and adverse outcomes such as premature birth in pregnant women. *Candidiasis*, also called a *yeast infection,* is a frequent cause of vulvovaginitis. Candida can be present without producing symptoms; usually some host factor, such as altered immune status, contributes to the development of vulvovaginitis. *Bacterial vaginosis* is a polymicrobial disorder characterized by a lack of hydrogen peroxide–producing lactobacilli and an overgrowth of anaerobic organisms, including *G. vaginalis, Mobiluncus* species, and *M. hominis*. It is the most prevalent vaginal disorder in women of reproductive age. The predominant symptom of bacterial vaginosis is a thin, grayish-white discharge that has a foul, fishy odor.

Vaginal-Urogenital-Systemic Infections

Some STIs infect male and female genital and extragenital structures. Among the infections of this type are chlamydial infections, gonorrhea, and syphilis. Many of these infections also pose a risk to infants born to infected mothers. Some infections, such as syphilis, may be spread to the infant while in utero, whereas others, such as chlamydial and gonorrheal infections, can be spread to the infant during the birth process.

Chlamydial Infections

Chlamydial infection is the most frequently reported bacterial STI in the United States, with an incidence estimated to be more than twice that of gonorrhea. Despite high numbers of reported cases, most cases of chlamydial infections go unreported. If untreated, up to 40% of women with chlamydial infection will develop pelvic inflammatory disease. It has been estimated that 20% of women become infertile, 18% experience chronic pelvic pain, and 9% have a tubal pregnancy.[26]

C. trachomatis is an obligate intracellular bacterial pathogen that is closely related to gram-negative bacteria.[11,12] It resembles a virus in that it requires tissue culture for isolation, but like bacteria, it has both DNA and ribonucleic acid (RNA) and is susceptible to some antimicrobial agents. Chlamydial infection exists in two morphologically distinct forms during its unique life—a small infectious elementary body and a large noninfectious reticulate body. Much like a spore, the *elementary body* is metabolically inactive and can survive outside the cell. It does not replicate. The *reticulate body* is metabolically active and cannot survive outside the cell. The 48-hour growth cycle starts with attachment of the elementary body to the susceptible host cell, after which it is ingested by a process that resembles phagocytosis (Fig. 41-5). Once inside the cell, the elementary body transforms in the larger *reticulate body*, which then commandeers the host cell's metabolic machinery to fuel its replication. The reticulate body divides repeatedly for up to 36 hours, forming new elementary bodies that are released when the infected cell bursts. Necrotic debris elicits inflammatory and immune processes that further damage infected tissue.

The signs and symptoms of chlamydial infection resemble those produced by gonorrhea. The most significant difference between chlamydial and gonococcal salpingitis is that chlamydial infections may be asymptomatic or clinically nonspecific. In women, chlamydial infections may cause urinary frequency, dysuria, and vaginal discharge.[27–29] The most common symptom is a mucopurulent cervical discharge. The cervix itself frequently hypertrophies and becomes erythematous, edematous, and extremely friable. This can lead to fallopian tube damage and increase the reservoir for further chlamydial infections. In men, chlamydial infections cause urethritis, including meatal erythema and tenderness, urethral discharge, dysuria, and urethral itching. Prostatitis and epididymitis with subsequent infertility may develop. The most serious complication of untreated chlamydial infection in men is the development of Reiter syndrome, a reactive arthritis that includes the triad of urethritis, conjunctivitis, and painless mucocutaneous lesions (see Chapter 44).[29]

Questions remain regarding screening for chlamydial infections.[25] At present, the CDC recommends annual

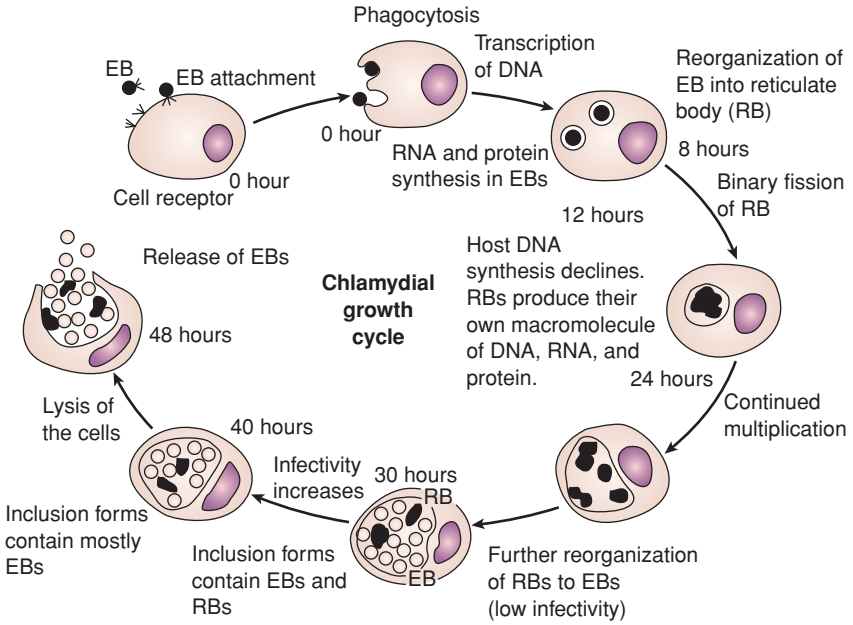

FIGURE 41-5. Chlamydial growth cycle. EB, elementary body; RB, reticulate body. (From Thompson S.E., Washington A.E. [1983]. Epidemiology of sexually transmitted *Chlamydia trachomatis* infections. *Epidemiologic Reviews* 5, 96–123.)

screening of women who are sexually active and younger than 25 years; women who are older than 25 years and having sex with more than one partner; women who are older than 25 years and having sex with a new partner; and women who are pregnant.[30]

Diagnosis of chlamydial infections takes several forms. The identification of polymorphonuclear leukocytes on Gram stain of penile discharge in the man or cervical discharge in the woman provides presumptive evidence. The direct fluorescent antibody test and the enzyme-linked immunosorbent assay, which use antibodies against an antigen in the *Chlamydia* cell wall, are rapid tests that are highly sensitive and specific. The positive predictive value of these tests is excellent among high-risk groups, but false-positive results occur more often in low-risk groups. The methodologic challenges of culturing this organism have led to the development of non–culture-based tests that amplify and detect *C. trachomatis*–specific DNA and RNA sequences.[29] One of the newest sets of nonculture techniques, the nucleic acid amplification tests (NAATs), do not require viable organisms for detection, and can produce a positive signal from as little as a single copy of the target DNA or RNA.[30] These amplification methods are highly sensitive and, if properly monitored, very specific. Because NAATs can be performed on urine and self-collected swab specimens from the distal vagina as well as the traditional endocervical and urethral specimens, this easy, convenient means of accurate detection has become the diagnostic method of choice.[9,28,29] Detection rates (specificity) for chlamydiae in urine and vaginal samples are nearly identical to those for cervical and urethral samples.[30]

The CDC recommends the use of azithromycin or doxycycline in the treatment of chlamydial infection; penicillin is ineffective. Azithromycin or amoxicillin is the preferred choice in pregnancy.[9] Simultaneous antibiotic treatment of both sexual partners is recommended. Abstinence from sexual activity is encouraged to facilitate cure. Retesting all women with chlamydial infection 3 to 4 months after treatment has been recommended to rule out recurrence.[9]

Gonorrhea

Gonorrhea is a reportable STI caused by the bacterium *Neisseria gonorrhoeae*. It is one of the oldest and still one of the most common STIs. Although the incidence of gonorrhea has declined steadily from its peak in 1975, rates in 2005 rose for the first time since 1999.[31] The emergence of antimicrobial-resistant strains and patterns of sexual behavior have contributed to a rise in its incidence. The highest rates are seen in adolescents and young adults.[4]

The gonococcus is a pyogenic (i.e., pus-forming), gram-negative diplococcus that evokes inflammatory reactions characterized by purulent exudates.[11,12] Humans are the only natural host for *N. gonorrhoeae*. The organism grows best in warm, mucus-secreting epithelia. The portal of entry can be the genitourinary tract, eyes, oropharynx, anorectum, or skin. Transmission usually is by heterosexual or homosexual intercourse. Autoinoculation of the organism to the conjunctiva is possible. Neonates born to infected mothers can acquire the infection during passage through the birth canal and are in danger of developing gonorrheal conjunctivitis, with resultant blindness, unless treated promptly. Genital gonorrhea in young children should raise the possibility of sexual abuse.

The infection commonly manifests 2 to 7 days after exposure. It typically begins in the anterior urethra, accessory urethral glands, Bartholin or Skene glands, and cervix. If untreated, gonorrhea spreads from its initial sites upward into the genital tract. In males, it spreads to the prostate and epididymis; in females, it commonly

FIGURE 41-6. Gonorrhea of the fallopian tube. Cross-section of a "pus tube" shows thickening of the wall and lumen swollen with pus. (From Schwartz D., Genta R.M., Conner D.H. [2005]. Infectious and parasitic diseases. In Rubin E., Gorstein F., Rubin R., et al. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [4th ed., p. 386]. Philadelphia: Lippincott Williams & Wilkins.)

FIGURE 41-7. Purulent penile discharge due to gonorrhea with overlying pyodermal lesions. (From the Centers for Disease Control and Prevention Public Health Image Library.

moves to the fallopian tubes[31] (Fig. 41-6). Pharyngitis may follow oral–genital contact. The organism also can invade the bloodstream (i.e., disseminated gonococcal infection), causing serious sequelae such as bacteremic involvement of joint spaces, heart valves, meninges, and other body organs and tissues.

Persons with gonorrhea may be asymptomatic and may unwittingly spread the disease to their sexual partners. Men are more likely to be symptomatic than women.[32] In men, the initial symptoms include urethral pain and a creamy yellow, sometimes bloody, discharge (Fig. 41-7). The disorder may become chronic and affect the prostate, epididymis, and periurethral glands. Rectal infections are common in homosexual men. In women, recognizable symptoms include unusual genital or urinary discharge, dysuria, dyspareunia, pelvic pain or tenderness, unusual vaginal bleeding (including bleeding after intercourse), fever, and proctitis. Symptoms may occur or increase during or immediately after menses because the bacterium is an intracellular diplococcus that thrives in menstrual blood but cannot survive long outside the human body. There may be infections of the uterus and development of acute or chronic infection of the fallopian tubes (i.e., salpingitis), with ultimate scarring and sterility.

Diagnosis is based on the history of sexual exposure and symptoms. It is confirmed by identification of the organism on Gram stain or culture. A Gram stain usually is an effective means of diagnosis in symptomatic men (i.e., those with discharge). In women and asymptomatic men, a culture usually is preferred because the Gram stain often is unreliable. Culture has been the gold standard, particularly when the Gram stain is negative. An enzyme immunoassay for detecting gonococcal antigens (Gonozyme) is available but has several requirements that limit its usefulness. Detection by NAATs is possible using urine and urethral swab specimens.[33] The sensitivity of these tests is similar to that of culture, and they may be cost effective in high-risk populations.

Updated recommendations from the U.S. Preventive Services Task Force (USPSTF) suggest that clinicians screen all sexually active men and women for gonorrhea who are at increased risk for infection (i.e., younger than 25 years of age, new or multiple sexual partners, inconsistent condom use, sex work, or drug use).[34] Testing for other STIs, particularly syphilis and chlamydial infection, is suggested at the time of examination. Pregnant women are routinely screened at the time of their first prenatal visit; high-risk populations should have repeat cultures during the third trimester. Neonates are routinely treated with various antibacterial agents applied to the conjunctiva within 1 hour of birth to protect against undiagnosed gonorrhea and other diseases.

Penicillin-resistant strains of *N. gonorrhoeae* are prevalent worldwide and strains with other kinds of antibiotic resistance continue to evolve and spread. The current treatment recommendation to combat tetracycline- and penicillin-resistant strains of *N. gonorrhoeae* is ceftriaxone in a single injection or cefixime, ciprofloxacin, ofloxacin, or levofloxacin in a single oral dose.[9] All are equally effective and should be followed with azithromycin or doxycycline for chlamydiae. Quinolone-resistant strains are now common in Asia, the Pacific islands (including Hawaii), and California, so the CDC recommends avoiding the use of fluoroquinolones in those areas for infections in men who have sex with men or for individuals with a history of recent foreign travel.

All sex partners within 60 days prior to discovery of the infection should be contacted, tested, and treated. Test of cure is not required with observed single-dose therapy. Patients are instructed to refrain from intercourse until therapy is completed and symptoms are no longer present.[9]

Syphilis

Syphilis is a reportable STI caused by a spirochete, *Treponema pallidum*. After declining every year from 1990 to 2000, the rate of primary and secondary syphilis increased every year since 2001. Increased rates were primarily in men, although in 2005 the rates in women increased as well.[11] In 2006, 9756 cases of syphilis were reported in the United States (3.3 per 100,000 population). This increase in syphilis incidence has been demonstrated worldwide. The epidemiology of syphilis in the United States and Europe has changed over the years, and currently men who have sex with men represent the primary group affected.[35]

T. pallidum is spread by direct contact with an infectious moist lesion, usually through sexual intercourse. Bacteria-laden secretions may transfer the organism during kissing or intimate contact. Skin abrasions provide another possible portal of entry. There is rapid transplacental transmission of the organism from the mother to the fetus after 16 weeks' gestation, so that active infection in the mother during pregnancy can produce congenital syphilis in the fetus. Untreated syphilis can cause prematurity, stillbirth, and congenital defects and active infection in the infant. Because the manifestations of maternal syphilis may be subtle, testing for syphilis is mandatory in all pregnancies. Once treated for syphilis, a pregnant woman usually is followed throughout pregnancy by repeat testing of serum titers.

The clinical disease is divided into three stages: primary, secondary, and tertiary. Primary syphilis is characterized by the appearance of a chancre at the site of exposure.[11,36–38] Chancres typically appear within 3 weeks of exposure but may incubate for 1 week to 3 months. The primary chancre begins as a single, indurated, buttonlike papule up to several centimeters in diameter that erodes to create a clean-based ulcerated lesion on an elevated base. These lesions usually are painless and located at the site of sexual contact. Primary syphilis is readily apparent in the male, where the lesion is on the scrotum or penis (Fig. 41-8). Although chancres can develop on the external genitalia in females, they are more common on the vagina or cervix, and primary syphilis therefore may go untreated. There usually is an accompanying regional lymphadenopathy. The infection is highly contagious at this stage, but because the symptoms are mild, it frequently goes unnoticed. The chancre usually heals within 3 to 12 weeks, with or without treatment.

The timing of the second stage of syphilis varies even more than that of the first, lasting from 1 week to 6 months. The symptoms of a rash (especially on the palms [Fig. 41-9] and soles), fever, sore throat, stomatitis, nausea, loss of appetite, and inflamed eyes may come and go for a year but usually last for 3 to 6 months. Secondary manifestations may include alopecia and genital

FIGURE 41-8. Syphilitic chancre of the penis shaft. (From the Centers for Disease Control and Prevention Public Health Image Library.

FIGURE 41-9. Secondary syphilis. A maculopapular rash is present on the palm. (From Schwartz D., Genta R.M., Conner D.H. [2005]. Infectious and parasitic diseases. In Rubin E., Gorstein F., Rubin R., et al. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [4th ed., p. 409]. Philadelphia: Lippincott Williams & Wilkins.)

condylomata lata.[35] Condylomata lata are elevated, red-brown lesions that may ulcerate and produce a foul discharge. They are 2 to 3 cm in diameter, contain many spirochetes, and are highly infectious.

After the second stage, syphilis frequently enters a latent phase that may last the lifetime of the person or progress to tertiary syphilis at some point. Persons can be infective during the first 1 to 2 years of latency.

Tertiary syphilis is a delayed response to the untreated disease. It can occur as long as 20 years after the initial infection. Only approximately one third of those with untreated syphilis progress to the tertiary stage of the disease, and symptoms develop in approximately one half of these. Approximately one third undergo spontaneous cure, and the remaining one third continue to have positive serologic tests but do not develop structural lesions.[31] When syphilis does progress to the symptomatic tertiary stage, it commonly takes one of three forms: development of localized destructive lesions called *gummas*, development of cardiovascular lesions, or development of central nervous system lesions. The syphilitic gumma is a peculiar, rubbery, necrotic lesion that is caused by noninflammatory tissue necrosis. Gummas can occur singly or multiply and vary in size from microscopic lesions to large, tumorous masses. They most commonly are found in the liver, testes, and bone. Central nervous system lesions can produce dementia, blindness, or injury to the spinal cord, with ataxia and sensory loss (i.e., tabes dorsalis). Cardiovascular manifestations usually result from scarring of the medial layer of the thoracic aorta with aneurysm formation. These aneurysms produce enlargement of the aortic valve ring with aortic valve insufficiency.

T. pallidum cannot be cultured. It does, however, evoke a humoral immune response and production of antibodies that provide the basis for serologic tests. Although PCR tests have been developed for syphilis, serology remains the mainstay for diagnosis.[11] Because the disease's incubation period may delay test sensitivity, serologic tests usually are repeated after 6 weeks if the initial test results were negative.

Two types of antibodies—nonspecific and specific—are produced.[11] Tests for nonspecific antibodies measure antibody to cardiolipin, a phospholipid that is present in both host cells and the *T. pallidum*. These antibodies are detected by flocculation tests such as the Venereal Disease Research Laboratory (VDRL) test or the rapid plasma reagin test. Because these tests are nonspecific, positive results can occur with diseases other than syphilis. The tests are easy to perform, rapid, and inexpensive and frequently are used as screening tests for syphilis. Results become positive 4 to 6 weeks after infection or 1 to 3 weeks after the appearance of the primary lesion. Because these tests are quantitative, they can be used to measure the degree of disease activity or treatment effectiveness. The VDRL titer usually is high during the secondary stage of the disease and becomes less so during the tertiary stage. A falling titer during treatment suggests a favorable response. The fluorescent treponemal antibody absorption test or microhemagglutinin test is used to detect specific antibodies to *T. pallidum*. These qualitative tests are used to determine whether a positive result on a nonspecific test such as the VDRL is attributable to syphilis. The test results remain positive for life.

The treatment of choice for syphilis is penicillin.[9,37] Because of the spirochetes' long generation time, effective tissue levels of penicillin must be maintained for several weeks. Long-acting injectable forms of penicillin are used. Tetracycline or doxycycline is used for treatment in persons who are sensitive to penicillin. Pregnant patients should be desensitized and treated with penicillin because erythromycin does not treat fetal infection. Sexual partners should be evaluated and treated prophylactically even though they may show no sign of infection. All treated individuals should be reexamined clinically and serologically at 6 and 12 months after completing therapy; more frequent monitoring (3-month intervals) is suggested for individuals with HIV infection.[9]

In summary, the vaginal-urogenital-systemic STIs—chlamydial infections, gonorrhea, and syphilis—can severely involve the genital structures and manifest as systemic infections. Gonorrheal and chlamydial infections can cause a wide variety of genitourinary complications in men and women, and both can cause ocular disease and blindness in neonates born to infected mothers. Syphilis is caused by a spirochete, *T. pallidum*. It can produce widespread systemic effects and is transferred to the fetus of infected mothers through the placenta.

REVIEW EXERCISES

1. A 25-year-old woman has been told that her Pap test indicates infection with HPV type 16.

- **A.** What are the possible implications of infection with HPV 16?
- **B.** How might she have acquired this infection?
- **C.** What treatments are currently available for treatment of this infection?

2. A 35-year-old woman presents with vulvar pruritus, dysuria, dyspareunia, and an odorless, thick, cheesy vaginal discharge. She has diabetes mellitus and has recently recovered from a respiratory tract infection, which required antibiotic treatment.

- **A.** Given that these manifestations are consistent with a Candida infection, what tests might be used to confirm the diagnosis?
- **B.** What risk factors does this woman have that predispose to this type of vaginitis?
- **C.** How might this infection be treated?

Chapter 42

Structure and Function of the Skeletal System

Without the skeletal system, movement in the external environment would not be possible. The bones of the skeletal system serve as a framework for skeletal muscle attachment and movement. The skeletal system protects and maintains vital structures in their proper position, provides stability for the body, and maintains the body's shape. Bones also serve as a reservoir for ions such as calcium, phosphorous, and magnesium, and it houses the hematopoietic connective tissue in which blood cells are formed.

Structures of the Skeletal System

The skeletal system can be divided into two functional parts—the axial and appendicular skeleton. The *axial skeleton* is composed of the bones of the skull, thorax, and vertebral column, and forms the axis of the body. The *appendicular skeleton* consists of the bones of the upper and lower extremities, including the shoulder and hip. In addition to bones, the skeletal system includes cartilage and ligaments that join bones together at joints. The joints give the body flexibility and allow movement to occur. Skeletal muscles, which are attached to bones by tendons, use bones as levers to move the body and its parts.

Two types of connective tissue are found in the skeletal system: cartilage and bone. They both have living cells that secrete the extracellular matrix in which the cells are housed. The extracellular matrix in cartilage is solid and

The Skeletal System

- The skeletal system consists of the bones of the skull, thorax, and vertebral column, which form the *axial skeleton,* and the bones of the upper and lower extremities, which form the *appendicular skeleton.*
- Two types of connective tissue are found in the skeletal system: (1) cartilage, a semirigid and slightly flexible structure that plays an essential role in prenatal and childhood development of the skeleton and as a surface for the articulating ends of skeletal joints; and (2) bone, which provides for the firm structure of the skeleton and serves as a reservoir for calcium and phosphate storage.
- Both bone and cartilage tissue are composed of living cells and a nonliving intercellular matrix that is secreted by the living cells.
- Bone matrix is maintained by four types of cells: osteoblasts, which synthesize and secrete the constituents of bone; osteoclasts, which resorb surplus bone and are required for bone remodeling; osteocytes, which make up the osteoid tissue of bone; and osteoprogenitor cells, which are the source of all bone cells, except osteoclasts.

firm but also somewhat pliable, which provides resilience for cushioning of bony structures. In contrast to cartilage, the extracellular matrix of bone is mineralized, producing a hard tissue capable of providing protection for body structures and rigid support for the extremities.

Cartilage

Cartilage is an avascular tissue that consists of cells, called *chondrocytes*, and an extensive extracellular matrix. More than 95% of cartilage volume is extracellular matrix, which is the functional element of this tissue. The chondrocytes are sparse, but are essential to the production and maintenance of the matrix. A connective tissue sheath, called the *perichondrium,* overlies the free surfaces of most cartilage. The perichondrium is vascular and its vessels supply nutrients to the cells of cartilage. In areas where the cartilage has no perichondrium, such as the articular surfaces of moving joints, the cartilage cells receive their nourishment from the synovial fluid that bathes the joint surfaces. The perichondrium also is the source of new cartilage cells.

Types of Cartilage

There are three types of cartilage, which differ in appearance and mechanical properties—hyaline cartilage, elastic cartilage, and fibrocartilage.

Hyaline Cartilage. Hyaline cartilage, a bluish-gray semitranslucent pliable substance, is the most abundant type of cartilage. It forms the costal cartilages that join the ribs to the sternum and vertebrae, many of the cartilages of the respiratory tract, and the articulating surfaces of movable joints of the body. It is also essential for growth before and after birth. In the embryo, most of the axial and appendicular skeleton is formed first as a cartilage model and then is replaced by bone. This process is known as *endochondral bone formation*. In postnatal life, cartilage continues to play an essential role in the growth of long bones and persists as articular cartilage in the adult.

The matrix of hyaline cartilage is composed of proteoglycans, multiadhesive glycoproteins, and collagen fibers. The collagen fibers of the cartilage matrix are embedded in a gel formed by the proteoglycans. Proteoglycans consist of polysaccharides, called *glycosaminoglycans,* linked to a core protein. Cartilage matrix contains three types of glycosaminoglycans: chondroitin sulfate, keratin sulfate, and hyaluronan. A proteoglycan may contain more than 100 glycosaminoglycans. Aggrecan, the most important proteoglycan in hyaline cartilage, contains 100 chondroitin sulfate chains and up to 50 keratin sulfate molecules. Hyaluronan is a single polypeptide chain, allowing it to associate with as many as 100 to 200 aggrecan molecules and form large proteoglycan aggregates. The negatively charged groups on the proteoglycans have a high affinity for water molecules. In this way, the cartilage matrix becomes hydrated to such an extent that up to 80% of the wet weight of cartilage is water. Both transient and regional changes occur in water content during joint movement and when the joint is subjected to pressure. This high degree of hydration and the movement of water in the matrix allow the cartilage matrix to respond to varying pressure loads and contribute to cartilage's weight-bearing properties.

The multiadhesive glycoproteins influence interactions between the chondrocytes and matrix molecules and have clinical value as markers of cartilage turnover and degeneration. Throughout life, cartilage undergoes continuous internal remodeling as the cells replace matrix molecules lost through degradation. Normal matrix turnover depends on the ability of the chondrocytes to detect changes in matrix composition. The chondrocytes then respond by synthesizing appropriate types of new molecules. In addition, the matrix acts as a signal transducer for the chondrocytes. Thus, pressure loads applied to the cartilage create mechanical and chemical signals that direct synthetic activity by the chondrocytes. As the body ages, however, the composition of the matrix changes and the chondrocytes lose their ability to respond to these signals.

Elastic Cartilage. Elastic cartilage resembles hyaline cartilage, except that it has a dense network of elastic fibers scattered throughout its matrix. It is found in areas where flexibility is important, such as in the auricle of the external ear, the auditory canal, the epiglottis, and the larynx. The cartilage in these locations is surrounded by a perichondrium.

Fibrocartilage. Fibrocartilage is a combination of dense connective tissue and cartilage. The chondrocytes are similar to those found in hyaline cartilage, but there is considerably less matrix associated with them, and there is no surrounding perichondrium. Fibrocartilage is typically present in intervertebral disks, the symphysis pubis, articular disks of the sternoclavicular and temporomandibular joints, menisci of the knee, and certain areas where tendons attach to bones. Fibrocartilage serves as a shock absorber, and its presence in these sites indicates that resistance to both compression and shearing forces is required.

Repair of Hyaline Cartilage

Hyaline cartilage can tolerate considerable amounts of intense and repetitive stress, but manifests a striking inability to heal from even the most minor injuries. This lack of response to injury is attributable to the avascular nature of cartilage, the immobility of chondrocytes, and the limited ability of chondrocytes to proliferate. Some repair can occur, but only if the defect involves the perichondrium, in which case chondrogenic cells from the perichondrium enter the defect and form new cartilage. If the defect is large, the cells form dense connective tissue to repair the scar. Hyaline cartilage is also subject to calcification, a process in which calcium phosphate crystals become embedded in the cartilage matrix. In most situations, given sufficient time, cartilage that calcifies will be replaced by bone. Chondrocytes normally derive all of their nutrients and dispose of waste materials through the matrix. When the matrix becomes heavily calcified, diffusion is impeded and the chondrocytes swell and die. The ultimate consequence of this event is removal of the calcified matrix and its replacement by bone.

Bones and Bone Structure

Bone is a connective tissue that, like other connective tissue, consists of cells and an extracellular matrix. The feature of bone that distinguishes it from other connective tissue is the mineralization of its matrix with calcium phosphate in the form of hydroxyapatite crystals, which produces an extremely hard tissue capable of providing support and protection. By virtue of its mineral content, bone also serves as a storage site for calcium and phosphorous, which can be mobilized and taken up by the blood to maintain appropriate levels throughout the body.

Types of Bone

There are two types of mature bones: cancellous and compact (Fig. 42-1B). Cancellous, or spongy, bone is found in the interior of bones and is composed of *trabeculae,* or *spicules,* of bone that form a latticelike pattern. These latticelike structures are lined with osteogenic cells and filled with red or yellow bone marrow. Cancellous bone is relatively light, but its structure is such that it has considerable tensile strength and weight-bearing

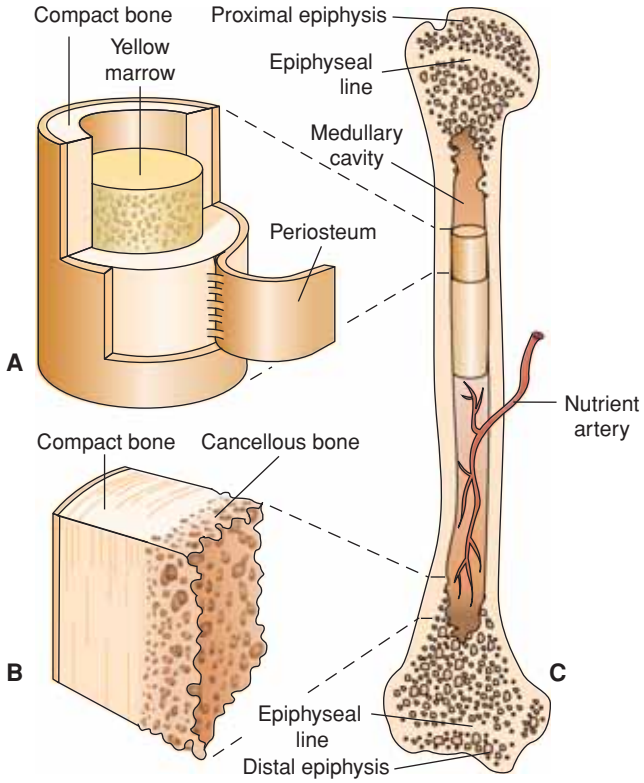

FIGURE 42-1. A long bone shown in longitudinal section. **(A)** Periosteum and bone marrow, **(B)** compact and cancellous bone, and **(C)** epiphysis and source of blood supply from epiphysial and nutrient arteries.

properties. Compact, or cortical, bone, which forms the outer shell of a bone, has a densely packed, calcified intercellular matrix that makes it more rigid than cancellous bone. Although bones contain both cancellous and compact elements, their proportions vary in different bones throughout the body and in different parts of the same bone, depending on the relative needs for strength and lightness. Compact bone, for example, is the major component of tubular bones and is also found along the lines of stress on long bones.

Bones are classified by shape as long, short, flat, and irregular. Long bones are found in the upper and lower extremities. Short bones are irregularly shaped bones located in the ankle and the wrist. Except for their surface, which is compact bone, these bones are spongy throughout. Flat bones are composed of a layer of cancellous bone between two layers of compact bone. They are found in areas such as the skull and rib cage, where extensive protection of underlying structures is needed, or, as in the scapula, where a broad surface for muscle attachment must be provided. Irregular bones, because of their shapes, cannot be classified in any of the previous groups. This group includes bones such as the vertebrae and the bones of the jaw.

A typical long bone has a shaft, or *diaphysis,* and two ends, called *epiphyses* (Fig. 42-2). Long bones usually are narrow in the midportion and broad at the ends so that the weight they bear can be distributed over a wider

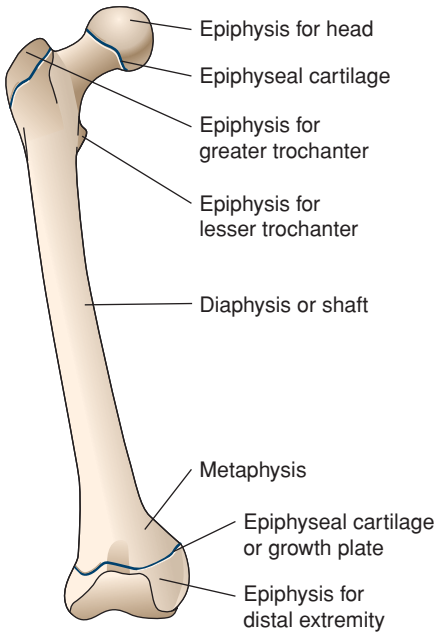

FIGURE 42-2. A femur, showing epiphyseal cartilages for the head, metaphysis, trochanters, and distal end of the bone.

surface. The shaft of a long bone is formed mainly of compact bone roughly hollowed out to form a marrow-filled medullary canal. The ends of long bones are covered with articular cartilage.

In growing bones, the part of the bone shaft that funnels out as it approaches the epiphysis is called the *metaphysis*. It is composed of bony trabeculae that have cores of cartilage. In the child, the epiphysis is separated from the metaphysis by the cartilaginous growth plate. After puberty, the metaphysis and epiphysis merge, and the growth plate is obliterated.

Periosteum and Endosteum

Bones are covered, except at their articular ends, by a membrane called the *periosteum* (see Fig. 42-1A). The periosteum has an outer fibrous layer and an inner layer that contains the osteoprogenitor cells needed for bone growth and development. The periosteum also contains blood vessels and acts as an anchorage point for vessels as they enter and leave the bone. The endosteum is the membrane that lines the spaces of spongy bone, the marrow cavities, and the haversian canals of compact bone. It is composed mainly of osteoprogenitor cells that contribute to the growth and remodeling of bone and are necessary for bone repair.

Bone Marrow

Bone marrow occupies the medullary cavities of the long bones throughout the skeleton and the cavities of cancellous bone in the vertebrae, ribs, sternum, and flat bones of the pelvis. The cellular composition of the bone marrow varies with age and skeletal location. Red bone marrow contains developing red blood cells and is the site of blood cell formation. Yellow bone marrow is composed largely of adipose cells. At birth, nearly all of the marrow is red and hematopoietically active. As the need for red blood cell production decreases during postnatal life, red marrow is gradually replaced with yellow bone marrow in most of the bones. In the adult, red marrow persists in the vertebrae, ribs, sternum, and ilia.

Blood Supply

The compact bone of long tubular bones is provided with blood supply from two sources, nutrient arteries and perforating arteries (Fig. 42-1C). The nutrient arteries enter the bone through a nutrient foramen and supply the marrow space and the internal one half of the cortex. The perforating arteries are small arteries that extend inward from the periosteal arteries on the external surface of the periosteum and anastomose in the cortex with branches of the nutrient arteries coming from the bone marrow. The distribution of blood in the cortex occurs through the haversian and Volkmann canals (Fig. 42-3). Haversian canals are spaces in the bone of the cortex that course parallel through the long axis of the bone for a short distance and then branch and communicate with other, similar canals. Each canal carries one or two blood vessels, lymphatics, and some nerve fibers. Volkmann canals, which also contain blood vessels, are spaces in the cortex that run perpendicular to the long axis of the cortex to connect adjacent haversian canals.

Cancellous bone is usually not penetrated by blood vessels. Instead, the bone cells of cancellous bone are nourished by diffusion from the endosteal surface through canaliculi, which interconnect their surrounding fluid-filled lacunae and extend to the bone surface.

Bone Tissue

Bone is connective tissue in which the intercellular matrix has been impregnated with inorganic calcium salts so that it has great tensile and compressive strength but is light enough to be moved by coordinated muscle contractions. The matrix is composed of two types of substances—organic matter and inorganic salts.

The organic matter, which constitutes approximately one-third the dry weight of bone, consists primarily of collagen fibers embedded in an amorphous ground substance. The inorganic matter consists of hydroxyapatite crystals and small amounts of calcium carbonate and calcium fluoride. Bone may also take up lead and other heavy metals, thereby removing these toxic substances from the circulation. This can be viewed as a protective mechanism. The antibiotic tetracycline is readily bound to calcium deposited in newly formed bones and teeth. When tetracycline is given during pregnancy, it can be deposited in the teeth of the fetus, causing discoloration and deformity. Similar changes can occur if the drug is given for long periods to children younger than 6 years of age.

Lamellar and Woven Bone

There are two types of bone tissue: lamellar and woven. Both forms of bone tissue can be mineralized or

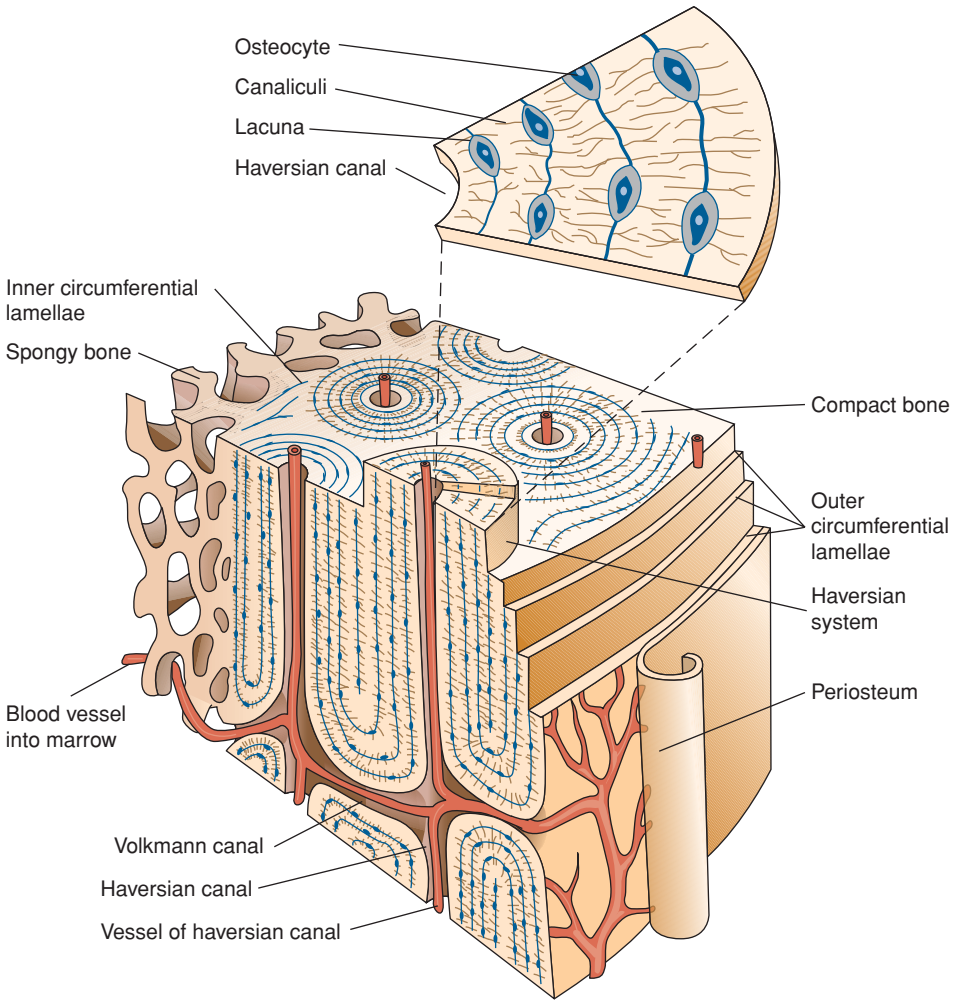

FIGURE 42-3. (Bottom) Haversian systems as seen in a wedge of compact bone tissue. The periosteum has been peeled back to show a blood vessel entering a Volkmann canal. **(Top)** Osteocytes lying within lacunae; canaliculi permit interstitial fluid to reach each lacuna.

unmineralized, the latter being referred to as *osteoid*. *Lamellar bone* is a strong, mature form of bone that is formed slowly and is highly organized. It is the mature bone found in the adult skeleton. Lamellar bone is composed largely of cylindrical units called *osteons* or *haversian systems*. The osteons consist of concentric lamellae of bone matrix, surrounding a central canal, called the *haversian canal*, that contains the blood vessels and nerve supply for the osteon (see Fig. 42-3). In compact bone, 4 to 20 lamellae are arranged concentrically around a central haversian canal, which runs essentially parallel to the long axis of the bone. Between the osteons are remnants of previous concentric lamellae, called the *interstitial lamella*. Circumferential lamellae follow the entire inner and outer shaft of a long bone, appearing much like the growth rings of a tree. Cancellous bone is also composed of lamellae, but, as mentioned previously, its trabeculae usually are not penetrated by blood vessels.

Woven bone is deposited more rapidly than lamellar bone. It is of low tensile strength, serving as temporary scaffolding for support. It is found in the developing fetus, in areas surrounding tumors and infections, and as part of a healing fracture.

Bone Cells

Four types of bone cells participate in the formation and maintenance of bone tissue: osteoprogenitor cells, osteoblasts, osteocytes, and osteoclasts (Table 42-1). With the exception of the osteoclast, each type of bone cell originates from the same basic cell type, undergoing transformation from a less mature to a more mature cell type.

Osteoprogenitor Cells. Osteoprogenitor cells are undifferentiated cells that are found in the periosteum, endosteum, and epiphyseal plate of growing bone. Derived from mesenchymal stem cells in the bone marrow, they have the potential to differentiate into many different cell types, including adipocytes, fibroblasts, muscle cells, and osteoblasts. When appropriately stimulated by bone morphogenic proteins (BMPs) and transforming growth factors, they undergo cell division and differentiate into osteoblasts.

Osteoblasts. Osteoblasts are bone-building cells that secrete bone matrix. Bone formation occurs in two stages: ossification and calcification. Ossification involves

TABLE 42-1 Function of Bone Cells

Type of Bone Cell	Function
Osteoprogenitor cells	Undifferentiated cells that differentiate into osteoblasts. They are found in the periosteum, endosteum, and epiphyseal growth plate of growing bones.
Osteoblasts	Bone-building cells that synthesize and secrete the organic matrix of bone. Osteoblasts also participate in the calcification of the organic matrix.
Osteocytes	Mature bone cells that function in the maintenance of bone matrix. Osteocytes also play an active role in releasing calcium into the blood.
Osteoclasts	Bone cells originating from mononuclear hematopoietic progenitor cells that are responsible for bone resorption.

the formation of the initial unmineralized bone, or osteoid. Osteoblasts secrete both type I collagen (which constitutes 90% of the protein of bone) and bone matrix proteins, forming the osteoid or prebone. They also are responsible for calcification of the bone matrix. The calcification process appears to be initiated by the osteoblast through the secretion of *alkaline phosphatase*, which is thought to act locally in bone tissue to raise calcium and phosphate levels to the point at which precipitation occurs. The activity of the osteoblasts undoubtedly contributes to the increase in serum levels of alkaline phosphatase that follows bone injury and fractures.

Osteocytes. Osteocytes are mature bone cells, derived from osteoblasts, that are housed in small lakes, or *lacunae*, within the calcified bony matrix (see Fig. 42-3). Extracellular fluid-filled passageways permeate the calcified matrix and connect with the lacunae of adjacent osteocytes. These passageways are called *canaliculi*. Because diffusion does not occur through the calcified matrix of bone, the canaliculi serve as communicating channels for the exchange of nutrients and metabolites between the osteocytes and the blood vessels on the surface of the bone layer.

Osteocytes are the cells responsible for maintaining the bone matrix. Osteocytes can synthesize new matrix, as well as participate in matrix degradation. Death of osteocytes, either through trauma, cell senescence, or apoptosis, results in resorption of the bone matrix by osteoclasts, followed by repair or remodeling of the bone tissue by osteoblasts.

Osteoclasts. Osteoclasts are large multinucleated "bone-chewing" cells that function in the resorption of bone, removing the mineral content and organic matrix. They are derived from the same mononuclear hematopoietic progenitor cells that give rise to blood monocytes and tissue macrophages. Osteoclast formation occurs in close association with the stromal cells of the bone marrow. These cells secrete essential cytokines that promote the differentiation of both osteoclasts and macrophages. These cytokines function either by stimulating osteoclast progenitor cells or by participating in a paracrine system in which osteoblasts and marrow stromal cells play a central role. Recent studies indicate that substances promoting osteoclast differentiation act through the RANK-RANKL signaling pathway (to be discussed).

Newly formed osteoclasts undergo activation to become a bone-resorbing cell. Once activated, they bind to the bone surface, where they form an underlying resorption pit. The cell membrane overlying the resorption pit is thrown into numerous folds, increasing its surface area, while the adjacent cell surface forms a tight seal with the bone that prevents leakage of digestion products. The osteoclast removes the bone mineral by generating an acidic environment utilizing a proton pump and digests the organic bone matrix by releasing proteolytic enzymes.

Bone Formation, Growth, and Remodeling

The development of skeletal structures begins in utero and continues to change throughout life. During childhood, skeletal structures grow in length and diameter and sustain a large increase in bone mass. The term *modeling* refers to the formation of the macroscopic skeleton resulting in a bone having adult form and shape. Once skeletal growth has ceased, the process of bone *remodeling* is responsible for skeletal maintenance. It involves both bone resorption and formation. With aging, bone resorption and formation are no longer perfectly coupled, and there is loss of bone.

Bone Growth in Childhood

During the first two decades of life, the skeleton undergoes general overall growth. The long bones of the skeleton, which grow at a relatively rapid rate, are provided with a specialized structure called the *epiphyseal growth plate*. As long bones grow in length, the deeper layers of cartilage cells in the growth plate multiply and enlarge, pushing the articular cartilage farther away from the metaphysis and diaphysis of the bone. As this occurs, the mature and enlarged cartilage cells at the metaphyseal end of the plate become metabolically inactive and are replaced by bone cells. This process allows bone growth to proceed without changing the shape of the bone or causing disruption of the articular cartilage. The cells in the growth plate stop dividing at puberty, at which time the epiphysis and metaphysis fuse.

Several factors can influence the growth of cells in the epiphyseal growth plate. Epiphyseal separation can occur in children as the result of trauma. The separation usually occurs in the zone of the mature enlarged cartilage cells, which is the weakest part of the growth plate. The blood vessels that nourish the epiphysis pass through the growth

plate. These vessels are ruptured when the growth plate separates. This can cause cessation of growth and a shortened extremity. The growth plate also is sensitive to nutritional and metabolic changes. Scurvy (i.e., vitamin C deficiency) impairs the formation of the organic matrix of bone, causing slowing of growth at the epiphyseal plate and cessation of diaphyseal growth. In rickets (i.e., vitamin D deficiency), calcification of the newly developed bone on the metaphyseal side of the growth plate is impaired. Thyroid and growth hormones are required for normal growth. Alterations in these and other hormones can also affect growth (see Chapter 32).

Growth in the diameter of bones occurs as new bone is added to the outer surface of existing bone along with an accompanying resorption of bone on the endosteal or inner surface. Such oppositional growth allows for widening of the marrow cavity while preventing the cortex from becoming too thick and heavy. In this way, the shape of the bone is maintained. As a bone grows in diameter, concentric rings are added to the bone surface, much as rings are added to a tree trunk; these rings form the lamellar structure of mature bone. Osteocytes, which develop from osteoblasts, become buried in the rings. Haversian channels form as periosteal vessels running along the long axis become surrounded by bone (see Fig 42-3).

Bone Remodeling

Peak bone mass is achieved during early adulthood after cessation of modeling. It is determined by a number of factors, including the type of vitamin D receptor inherited, nutrition, level of physical activity, age, and hormonal status. Once skeletal growth has attained its adult size, the breakdown and renewal of bone that is responsible for skeletal maintenance is initiated at sites that require replacement or repair. This process is called *bone remodeling*.

In bone remodeling, the processes of bone formation and resorption are tightly coupled, and their balance determines skeletal mass at any time. The sequence of bone resorption and bone formation begins with osteoclastic resorption of existing bone, during which the organic (protein matrix) and the inorganic (mineral) components are removed. The sequence proceeds to the formation of new bone by osteoblasts. In the adult, the length of one sequence (i.e., bone resorption and formation) is approximately 4 months. Ideally, the replaced bone should equal the absorbed bone. If it does not, there is a net loss of bone. In the elderly, for example, bone resorption and formation no longer are perfectly coupled, and bone mass is lost.

Recently, significant progress has been made in understanding the phenomenon of bone remodeling as it relates to the coupling of bone resorption with bone formation. The pivotal paracrine pathway linking these two processes consists of three factors: RANKL (for *r*eceptor *a*ctivator of *n*uclear factor-κB *l*igand); its receptor, RANK; and a soluble inhibitor receptor for RANKL called *osteoprotegerin* (OPG). RANKL is a member of the tumor necrosis factor (TNF) superfamily, and both RANK and OPG are members of the TNF receptor family. RANKL is expressed by osteoblasts and their immature precursors and is necessary for osteoclast differentiation and function. RANKL activates its receptor, RANK, which is expressed on osteoclasts and their precursors, thus promoting osteoclast differentiation and activation and prolonging osteoclast survival by suppressing apoptosis. The fact that RANKL is expressed on osteoblasts indicates that bone resorption and bone formation are linked through RANKL. The term *osteoprotegerin* was coined because of its protective effects against bone loss, detected in animal studies. The effects of RANKL are blocked by OPG, a soluble receptor protein, which acts as a decoy receptor that binds RANKL and prevents it from binding with RANK on osteoclasts.

It is now believed that dysregulation of the RANKL/RANK/OPG pathway plays a prominent role in the pathogenesis of bone diseases such as osteoporosis. For example, it has been shown that postmenopausal women express higher levels of RANKL on their marrow stromal cells and lymphocytes than premenopausal women or postmenopausal women taking estrogen. It has also been shown that estrogens and the selective estrogen receptor modulator, raloxifene, stimulate OPG production in osteoblasts. Glucocorticoid exposure, which can contribute to steroid osteoporosis, enhances RANKL expression and suppresses OPG levels, thus elevating the RANKL-to-OPG ratio. There is also evidence linking the pathogenesis of inflammatory conditions such as rheumatoid arthritis to dysregulation of the RANKL/OPG system. Based on animal models of rheumatoid arthritis, cytokines differentially regulate RANKL and OPG, producing an enhanced RANKL-to-OPG ratio that favors skeletal damage. There is also evidence that RANKL is expressed on T cells, and in vitro studies have shown that activated T cells can regulate the development and activation of osteoclasts through RANKL.

Hormonal Control of Bone Formation and Metabolism

The process of bone formation and mineral metabolism is complex. It involves the interplay among the actions of parathyroid hormone (PTH), calcitonin, and vitamin D (Table 42-2). Other hormones, such as cortisol, growth hormone, thyroid hormone, and the sex hormones, also influence bone formation directly or indirectly.

Parathyroid Hormone. Parathyroid hormone is one of the important regulators of calcium and phosphate levels in the blood. PTH prevents serum calcium levels from falling below and serum phosphate levels from rising above normal physiologic concentrations (see Chapter 8). The secretion of PTH is regulated through negative feedback related to serum levels of ionized calcium, with decreased levels of ionized calcium stimulating PTH release and increased levels inhibiting its release.

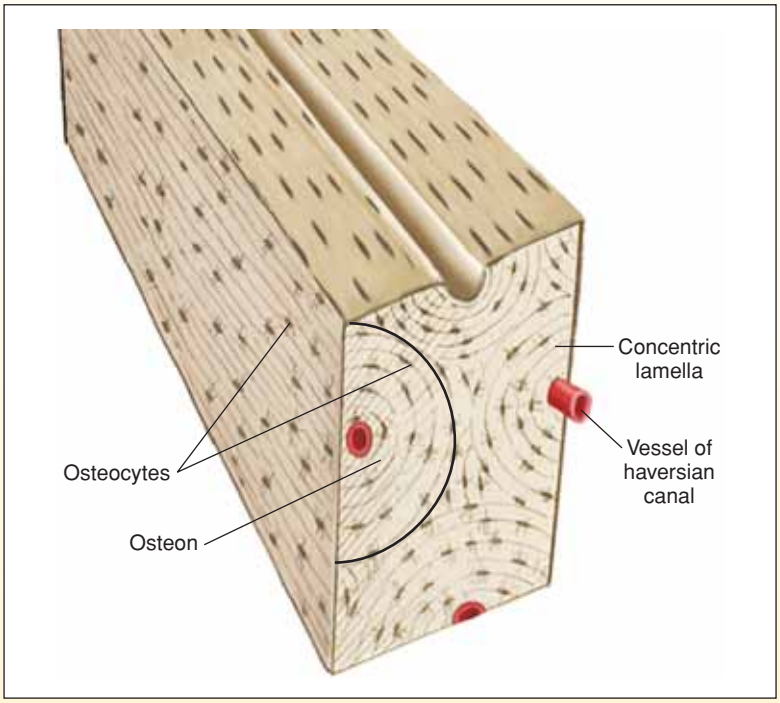
PTH maintains serum calcium levels by promoting bone resorption, by conserving calcium by the kidney, by enhancing intestinal absorption of calcium through

UNDERSTANDING → Bone Remodeling

Bone remodeling constitutes a process of skeletal maintenance once skeletal growth is complete. It takes place in the (1) osteons of mature bone and consists of a cycle of (2) bone resorption by osteoclasts, (3) followed by bone formation by osteoblasts. Bone remodeling is (4) controlled by cytokines and growth factors that interact with a paracrine system consisting of the RANK ligand (RANKL), the RANK receptor, and osteoprotegerin.

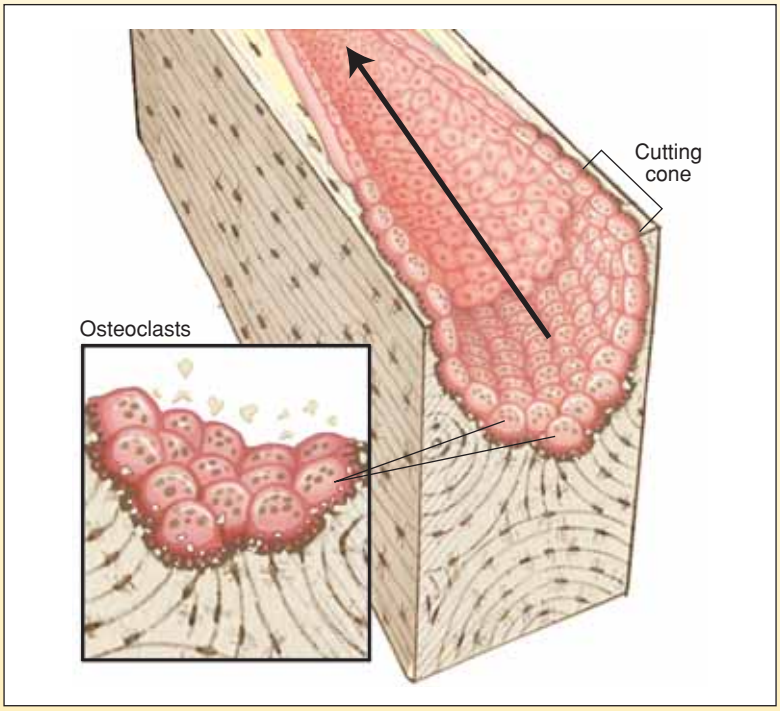
1

Bone Remodeling Cycle. Mature bone is made up of osteons or units of concentric lamellae (bone layers) and the haversian canal they surround. Bone remodeling consists of a sequence of bone resorption within an osteon by osteoclasts, followed by new bone formation by osteoblasts. In the adult, the length of one sequence (i.e., bone resorption and formation) is approximately 4 months. Ideally, the replaced bone should equal the resorbed bone. If it does not, there is net loss of bone. In the elderly, for example, bone resorption and formation no longer are perfectly coupled, and bone mass is lost.



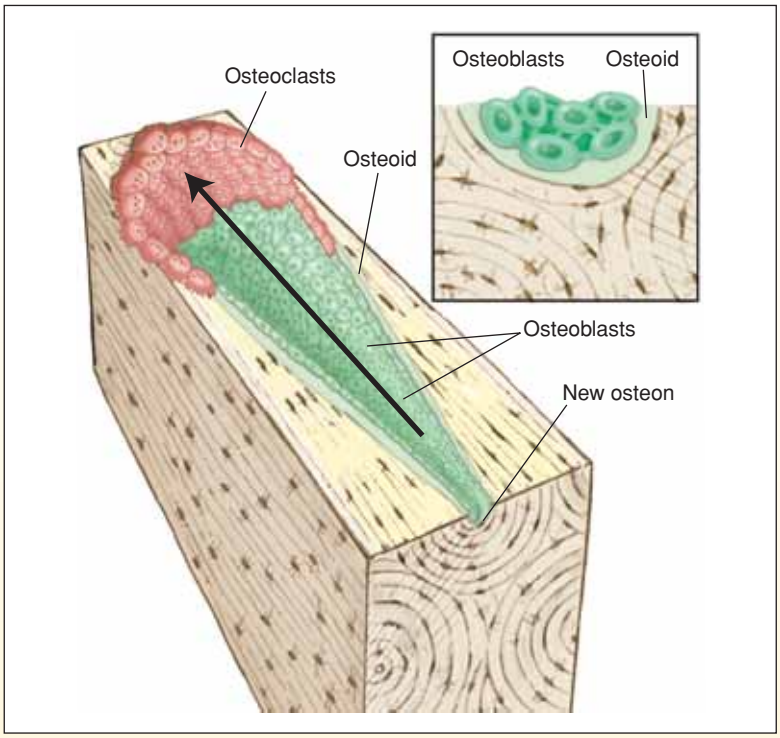
2

Bone Resorption. The osteoclasts, which are bone-resorbing cells derived from monocyte/macrophage precursors, are the cells involved in the initiation of bone remodeling. The sequence of bone resorption and bone formation is activated by many stimuli, including the action of parathyroid hormone and calcitonin. It begins with osteoclastic resorption of existing bone, during which the organic (protein matrix) and inorganic (mineral) components are removed, creating a tunnel-like space in the osteon. Soluble factors released during resorption aid in the recruitment of osteoblasts to the site, thereby linking bone resorption to bone formation.



3

Bone Formation. After osteoclastic activity has ceased, osteoblasts begin to deposit the organic matrix (osteoid) on the wall of the osteon canal. As successive lamellae of bone are deposited, the canal ultimately attains the relative proportions of the original osteon. In the formation and maintenance of bone, osteoblasts provide much of the local control because not only do they produce new bone matrix, they play an essential role in mediating osteoclast activity. Many of the primary stimulators of bone resorption, such as parathyroid hormone, have minimal or no direct effects on osteoclasts. Once the osteoblast, which has receptors for these substances, receives the appropriate signal, it releases a soluble mediator called *RANKL* that induces osteoclast activity.



4

Control of Bone Metabolism and Remodeling. The pivotal pathway linking osteoclast-mediated bone resorption with osteoblast-mediated bone formation consists of a paracrine system that includes RANKL, its receptor RANK, and a soluble protein called *osteoprotegerin* (OPG). RANKL, which is produced by osteoblasts and their precursors, binds to RANK, promoting osteoclast differentiation and proliferation. The soluble OPG molecule, which is produced by a number of tissues, acts as a decoy receptor to block the action of RANKL. This system ensures the tight coupling of bone formation and resorption, and provides a means whereby a wide variety of biologic mediators (e.g., hormones, cytokines, growth factors) influence the homeostasis of bone.

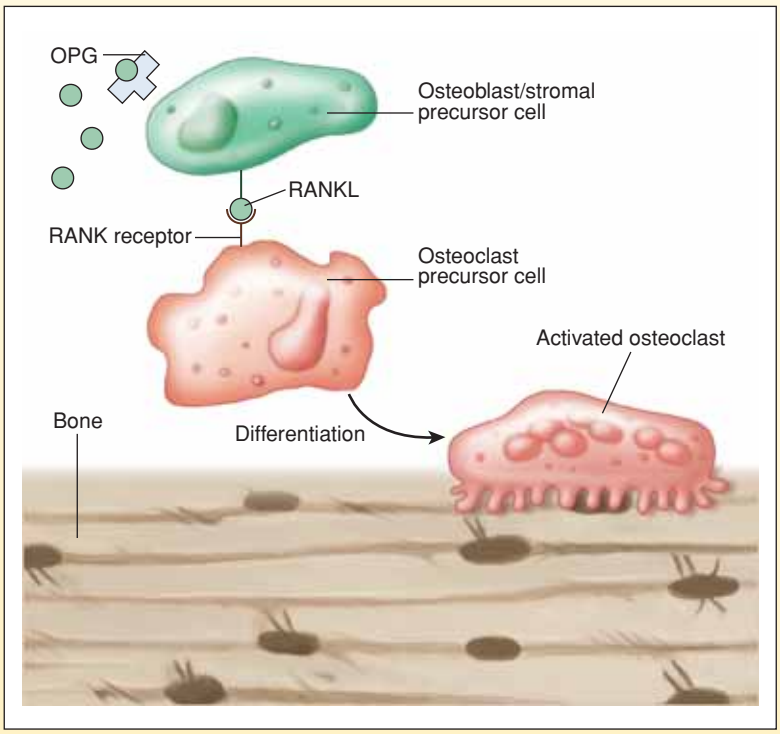


TABLE 42-2 Actions of Parathyroid Hormone, Calcitonin, and Vitamin D

Actions	Parathyroid Hormone	Calcitonin	Vitamin D
Intestinal absorption of calcium	Increases indirectly through increased activation of vitamin D	Probably not affected	Increases
Intestinal absorption of phosphate	Increases	Probably not affected	Increases
Renal excretion of calcium	Decreases	Minor effect	Probably increases, but less effect than PTH
Renal excretion of phosphate	Increases	Minor effect	Increases
Bone resorption	Increases	Decreases	$1,25\text{-}(OH)_2D_3$ increases
Bone formation	Decreases	Uncertain	$24,25\text{-}(OH)_2D_3$ increases (?)
Serum calcium levels	Produces a prompt increase	Decreases with pharmacologic doses	No effect
Serum phosphate levels	Prevents an increase	Decreases with pharmacologic doses	No effect

activation of vitamin D, and by reducing serum phosphate levels (Fig. 42-4). PTH also increases the movement of calcium and phosphate from bone into the extracellular fluid. Calcium is immediately released from the canaliculi and bone cells; a more prolonged release of calcium and phosphate is mediated by increased osteoclast activity. In the kidney, PTH stimulates tubular reabsorption of calcium while reducing the reabsorption of phosphate. The latter effect ensures that the increased release of phosphate from bone during mobilization of calcium does not produce an elevation in serum phosphate levels. This is important because an increase in calcium and phosphate levels could lead to crystallization in soft tissues. PTH also stimulates the activation of vitamin D by the kidney, thereby increasing the absorption of calcium from the intestine.

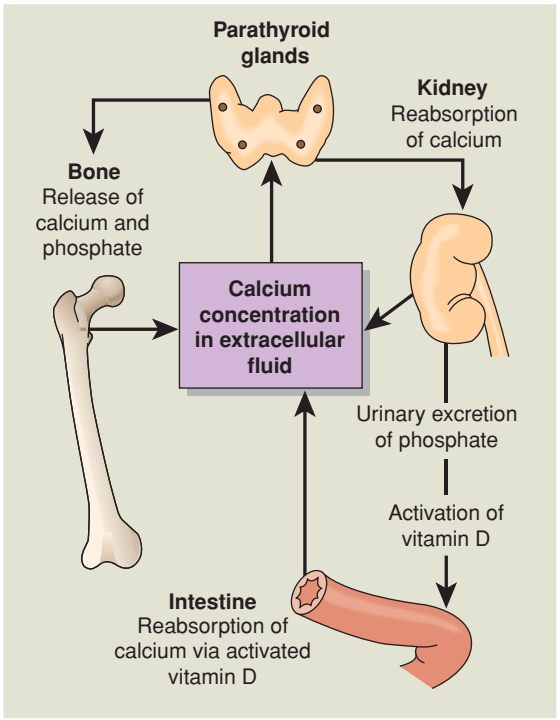

FIGURE 42-4. Regulation and actions of parathyroid hormone.

Calcitonin. Whereas PTH increases blood calcium levels, the hormone calcitonin lowers blood calcium levels. Calcitonin, sometimes called *thyrocalcitonin,* is secreted by the parafollicular, or C, cells of the thyroid gland. Calcitonin inhibits the release of calcium from bone into the extracellular fluid. It is thought to act by causing calcium to become sequestered in bone cells and by inhibiting osteoclast activity. Calcitonin also reduces the renal tubular reabsorption of calcium and phosphate; the decrease in serum calcium level that follows administration of pharmacologic doses of calcitonin may be related to this action.

The major stimulus for calcitonin synthesis and release is an increase in serum calcium. The role of calcitonin in overall mineral homeostasis is uncertain. There are no clearly definable syndromes of calcitonin deficiency or excess, which suggests that calcitonin does not directly alter calcium metabolism. It has been suggested that the physiologic actions of calcitonin are related to the postprandial handling and processing of dietary calcium. This theory proposes that after meals, calcitonin maintains PTH secretion at a time when it normally would be reduced by calcium entering the blood from the digestive tract. Although excess or deficiency states associated with alterations in physiologic levels of calcitonin have not been observed, it has been shown that pharmacologic doses of the hormone reduce osteoclast activity. Because of this action, calcitonin has proved effective in the treatment of Paget disease (see Chapter 44). The hormone is also used to reduce serum calcium levels during hypercalcemic crises.

Vitamin D. Vitamin D and its metabolites are not true vitamins but steroid hormones. There are two forms of vitamin D: vitamin D_2 (ergocalciferol) and vitamin D_3 (cholecalciferol). The two forms differ by the presence of a double bond, but they have identical biologic activity. The term *vitamin D* is used to indicate both forms.

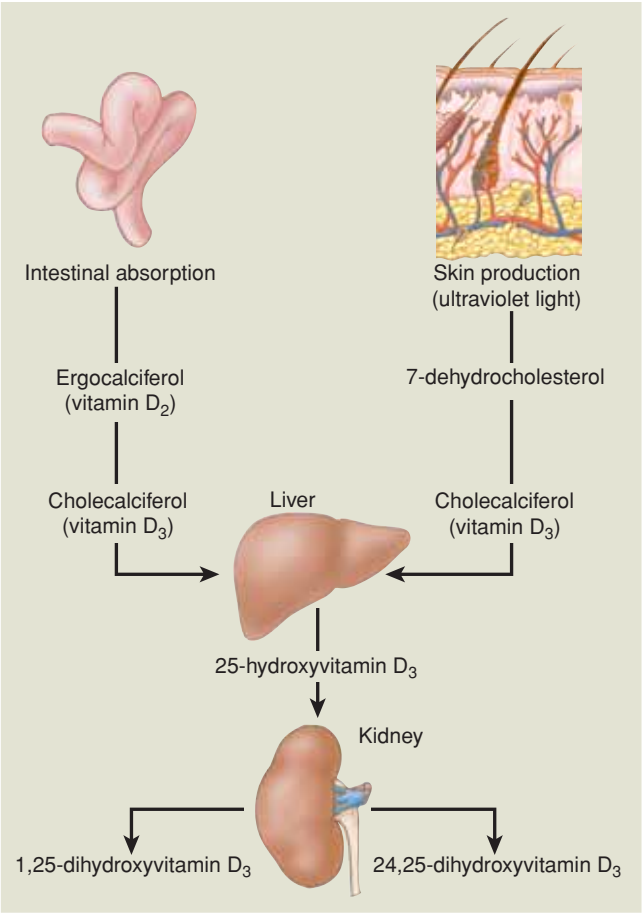

FIGURE 42-5. Sources and pathways for activation of vitamin D.

Vitamin D has little or no activity until it has been converted to physiologically active compounds. Figure 42-5 depicts sources of vitamin D and pathways for activation. The first step of the activation process occurs in the liver, where vitamin D is hydroxylated to form the metabolite 25-hydroxyvitamin D_3 [25-(OH)D_3]. From the liver, 25-(OH)D_3 is transported to the kidneys, where it undergoes conversion to 1,25-dihydroxyvitamin D_3 [1,25-$(OH)_2D_3$] or 24,25-dihydroxyvitamin D_3 [24,25-$(OH)_2D_3$]. Other metabolites of vitamin D have been and are still being discovered.

There are two sources of vitamin D: intestinal absorption and skin production. Intestinal absorption occurs mainly in the jejunum and includes vitamin D_2 and vitamin D_3. The most important dietary sources of vitamin D are fish, liver, and irradiated milk. Because vitamin D is fat soluble, its absorption is mediated by bile salts and occurs by means of the lymphatic vessels. In the skin, ultraviolet radiation from sunlight spontaneously converts 7-dehydrocholesterol D_3 to vitamin D_3. A circulating vitamin D–binding protein provides a mechanism to remove vitamin D from the skin and make it available to the rest of the body.

With adequate exposure to sunlight, the amount of vitamin D that can be produced by the skin is usually sufficient to meet physiologic requirements. Modern conditions of dress, lifestyle, and recommendations regarding sun screens and avoidance of sun exposure to reduce skin cancer risk may prevent a large proportion of the population from producing adequate amounts of vitamin D. Elderly persons who are housebound or institutionalized frequently have low vitamin D levels. The deficiency often goes undetected until there are problems such as pseudofractures or electrolyte imbalances. Seasonal variations in vitamin D levels probably reflect changes in sunlight exposure.

The most potent of the vitamin D metabolites is 1,25-$(OH)_2D_3$. This metabolite increases intestinal absorption of calcium and promotes the actions of PTH on resorption of calcium and phosphate from bone. Bone resorption by the osteoclasts is increased, and bone formation by the osteoblasts is decreased; there is also an increase in acid phosphatase and a decrease in alkaline phosphatase. Intestinal absorption and bone resorption increase the amount of calcium and phosphorus available to the mineralizing surface of the bone. The role of 24,25-$(OH)_2D_3$ is less clear. There is evidence that 24,25-$(OH)_2D_3$, in conjunction with 1,25-$(OH)_2D_3$, may be involved in normal bone mineralization.

The regulation of vitamin D activity is influenced by several hormones. PTH and prolactin stimulate 1,25-$(OH)_2D_3$ production by the kidney. States of hyperparathyroidism are associated with increased levels of 1,25-$(OH)_2D_3$, and hypoparathyroidism leads to lowered levels of this metabolite. Prolactin may have an ancillary role in regulating vitamin D metabolism during pregnancy and lactation. Calcitonin inhibits 1,25-$(OH)_2D_3$ production by the kidney. In addition to hormonal influences, changes in the concentration of ions such as calcium, phosphate, hydrogen, and potassium exert an effect on 1,25-$(OH)_2D_3$ and 24,25-$(OH)_2D_3$ production. Under conditions of phosphate and calcium deprivation, 1,25-$(OH)_2D_3$ levels are increased, whereas hyperphosphatemia and hypercalcemia decrease the levels of metabolite.

In summary, the skeletal system is made up of two types of connective tissue—cartilage and bone. Cartilage is a firm, flexible type of skeletal tissue that is essential for growth before and after birth. There are three types of cartilage: hyaline, elastic, and fibrocartilage. Hyaline cartilage is the most abundant type of cartilage. It forms the costal cartilages that join the ribs to the sternum and vertebrae, many of the cartilages of the respiratory tract, the articulating surfaces of movable joints of the body, and the epiphyseal plates in growing bones.

There are two types of bone: compact bone, which forms the outer shell of a bone, and cancellous or spongy bone, which forms the interior. The endosteum is the membrane that lines the spaces of spongy bone, the marrow cavities, and the haversian canals of compact bone. The periosteum, the membrane that covers bones, contains blood vessels and acts as an anchor point for

vessels as they enter and leave the bone. Mature bone is largely made up of cylindrical units called *osteons,* formed from concentric layers or lamellae of bone matrix and surrounding a central *haversian canal.* The haversian canals contain the blood vessels and nerve supply for the osteon. There are four types of bone cells: osteocytes, or mature bone cells; osteoblasts, or bone-building cells; osteoclasts, which function in bone resorption; and osteoprogenitor cells, which differentiate into osteoblasts.

The process of bone formation and mineral metabolism involves the interplay among the actions of PTH, calcitonin, and vitamin D. PTH acts to maintain serum levels of ionized calcium; it increases the release of calcium and phosphate from bone, the conservation of calcium and elimination of phosphate by the kidney, and the intestinal reabsorption of calcium through vitamin D. Calcitonin inhibits the release of calcium from bone and increases renal elimination of calcium and phosphate, thereby serving to lower serum calcium levels. Vitamin D functions as a hormone in regulating body calcium. It increases absorption of calcium from the intestine and promotes the actions of PTH on bone.

Joints

Joints, or articulations, are places where adjacent bones or cartilages meet. Joints exhibit a variety of movements. Some joints have no movement; others allow only slight movement; and some such as the shoulder joint are freely moveable. There are two classes of joints based on their movement and the presence or absence of a joint cavity: synarthroses and synovial joints.

Skeletal Joints

- Articulations, or joints, are sites where two or more bones meet to hold the skeleton together and give it mobility.
- There are two types of joints: synarthroses, which are immovable joints, and synovial joints, which are freely movable joints.
- All limb joints are synovial diarthroidal joints, which are enclosed in a joint cavity containing synovial fluid.
- The articulating surfaces of synovial joints are covered with a layer of avascular cartilage that relies on oxygen and nutrients contained in the synovial fluid.
- Regeneration of articular cartilage of synovial joints is slow, and healing of injuries often is slow and unsatisfactory.

Synarthroses

Synarthroses are joints that lack a joint cavity and move a little or not at all. There are three types of synarthroses: synostoses, synchondroses, and syndesmoses. *Synostoses* are nonmovable joints in which the surfaces of the bones are joined by dense connective tissue or bone. The bones of the skull are joined by synostoses. They are joined by dense connective tissue in children and young adults and by bone in older persons. *Synchondroses* are joints in which bones are connected by hyaline cartilage and have limited motion. The ribs are attached to the sternum by this type of joint. *Syndesmoses* permit a certain amount of movement; they are separated by a fibrous disk and joined by interosseous ligaments. The symphysis pubis of the pelvis and the vertebral bodies joined by intervertebral disks are examples of syndesmoses.

Synovial (Diarthrodial) Joints

Synovial or *diarthrodial joints* are freely moveable joints in which the articulating bone ends are separated by a joint cavity containing synovial fluid. Most joints in the body are of this type. Although they are classified as freely movable, their movements range from those of *planar joints* with almost no movement (e.g., vertebrocostal joint), to *hinge joints* with angular movement in one plane (e.g., interphalangeal, knee, and ankle joint), to the *ball and socket joints* with movement in all directions (e.g., shoulder or hip joint).

All synovial joints are covered with articular cartilage, a feature that allows the surfaces of these joints to slide freely past each other during movement. The articular cartilage, which is typically hyaline cartilage, is unique in that its free surface is not covered with perichondrium. It has only a peripheral rim of perichondrium, and calcification of the portion of cartilage abutting the bone may limit or preclude diffusion from blood vessels supplying the subchondral bone. Regeneration of most cartilage is slow; it is accomplished primarily by growth that requires the activity of perichondrium cells.

In synovial joints, the articulating ends of the bones are not connected directly but are indirectly linked by a strong fibrous capsule (i.e., joint capsule) that surrounds the joint and is continuous with the periosteum (Fig. 42-6). The joint capsule consists of two layers: an outer fibrous layer and an inner membrane, the *synovium*. The outer fibrous layer of the capsule supports the joint and helps to hold the bones in place. Additional support is provided by ligaments that extend between the bones and by tendons that attach to muscles supplying the joint. The synovium secretes a slippery fluid with the consistency of egg white called *synovial fluid*. In addition to supplying nutrients and oxygen to the chondrocytes in the articular cartilage, this fluid serves as a lubricant for the joint. Moreover, macrophages in the synovial fluid act to phagocytize debris in the joint space.

Ligaments and Tendons

Ligaments and tendons are dense connective tissue structures that connect muscles and bone and support joint

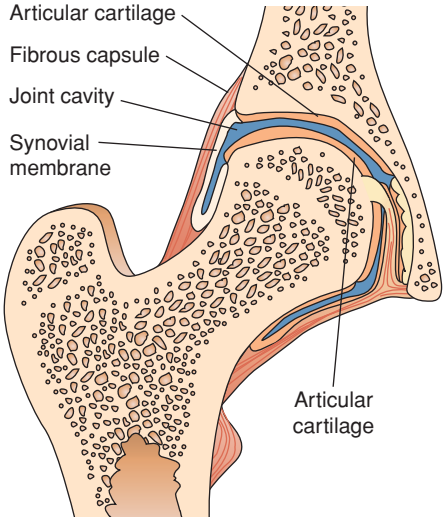

FIGURE 42-6. Synovial (diarthrodial) joint, showing the articular cartilage, fibrous joint capsule, joint cavity, and synovial membrane.

structures. The dense connective tissue found in tendons and ligaments has a limited blood supply and is composed largely of intercellular bundles of collagen fibers arranged in the same direction and plane. Collagen is an inelastic and insoluble fibrous protein. Because of its molecular configuration, collagen has great tensile strength; the breaking point of collagenous fibers found in human tendons is reached with a force of several hundred kilograms per square centimeter.

Ligaments are fibrous thickenings of the articular capsule that join one bone to its articulating mate. They vary in size and shape depending on their specific role. Although most ligaments are considered inelastic, they are pliable enough to permit movement at the joints. However, ligaments tear rather than stretch when exposed to excess stress. Torn ligaments are extremely painful and accompanied by local swelling.

Tendons, which attach skeletal muscles to bone, are relatively inextensible because of their richness in collagen fibers. The intercellular bands of collagen fibers aggregate into bundles that are enveloped by loose connective tissue, blood vessels, and nerves. Tendons that may rub against bone or other friction-generating surfaces are enclosed in double-layered sheaths. An outer connective tissue tube is attached to the structures surrounding the tendon, and an inner sheath encloses the tendon and is attached to it. The space between the inner and outer sheath is filled with a fluid similar to synovial fluid. Overuse can result in *tendonitis* or inflammation of the tendon.

Joint Vasculature and Innervation

All the tissues of synovial joints, except the surfaces of the articulating cartilage, receive nourishment either directly or indirectly from blood vessels. The articulating areas are nourished indirectly by the synovial fluid that is distributed over the surface of the articular cartilage.

The blood supply to a joint arises from blood vessels that enter the subchondral bone at or near the attachment of the joint capsule and form an arterial circle around the joint. The synovial membrane has a rich blood supply, and constituents of plasma diffuse rapidly between these vessels and the joint cavity. Because many of the capillaries are near the surface of the synovium, blood may escape into the synovial fluid after relatively minor injuries. Healing and repair of the synovial membrane usually are rapid and complete. This is important because synovial tissue is injured in many surgical procedures that involve the joint.

The nerve supply to joints is provided by the same nerve trunks that supply the muscles that move the joints. These nerve trunks also supply the skin over the joints. As a rule, each joint of an extremity is innervated by all the peripheral nerves that cross the articulation; this accounts for the referral of pain from one joint to another. For example, hip pain may be perceived as pain in the knee.

The synovial membrane is innervated only by autonomic fibers that control blood flow. It is relatively free of pain fibers, as evidenced by the fact that surgical procedures on the joint are often done under local anesthesia. The joint capsule and the ligaments have pain receptors; these receptors are more easily stimulated by stretching and twisting than are other joint structures. Pain arising from the capsule tends to be diffuse and poorly localized.

The tendons and ligaments of the joint capsule are sensitive to position and movement, particularly stretching and twisting. These structures are supplied by the large sensory nerve fibers that form proprioceptor endings for the deep tendon reflex (see Chapter 36). The proprioceptors function reflexively to adjust the tension of the muscles that support the joint and are particularly important in maintaining muscular support for the joint. For example, when a weight is lifted, there is a proprioceptor-mediated reflex contraction and relaxation of appropriate muscle groups to support the joint and protect the joint capsule and other joint structures. Loss of proprioception and reflex control of muscular support leads to destructive changes in the joint.

Bursae and Tendon Sheaths

In some diarthrotic joints, the synovial membrane forms closed sacs that are not part of the joint. These sacs, called *bursae,* contain synovial fluid. Their purpose is to prevent friction on a tendon. Bursae occur in areas where pressure is exerted because of close approximation of joint structures (Fig. 42-7). Such conditions occur when tendons are deflected over bone or where skin must move freely over bony tissue. Bursae may become injured or inflamed, causing discomfort, swelling, and limitation in movement of the involved area.

In addition to bursae, structures called tendon sheaths also reduce friction at joints. Tendon sheaths are tube-like bursae that wrap around tendons where there is considerable friction. This occurs where tendons pass through synovial cavities, such as the tendon of the

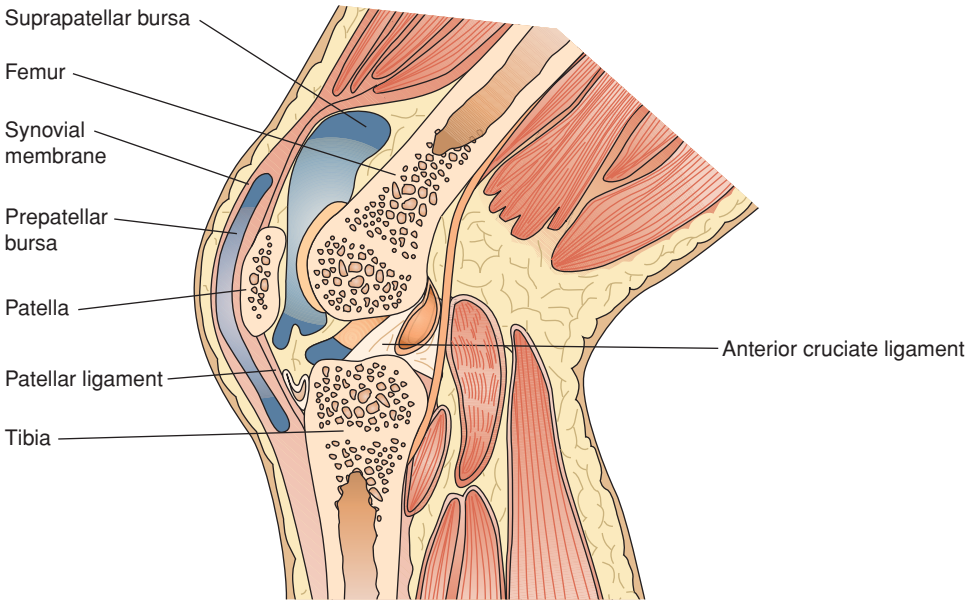

FIGURE 42-7. Sagittal section of knee joint, showing prepatellar and suprapatellar bursa.

biceps brachii muscle at the shoulder joint. Similar areas of friction are found at the wrist and ankle, where many tendons come together in a confined space.

Intra-Articular Menisci

Intra-articular menisci are fibrocartilage structures that develop from portions of the articular disk that occupied the space between articular cartilage surfaces during fetal development. Menisci may extend through the joint, separating it into two separate cavities, as in the sternoclavicular joint, or they may extend partway through the joint and have a free inner border, as at the lateral and medial articular surfaces of the knee. The menisci of the knee joint may be torn as the result of an injury (see Chapter 43).

In summary, joints or articulations are areas where two or more bones meet. Synarthroses are joints in which bones are joined together by fibrous tissue, cartilage, or bone; they lack a joint cavity and have little or no movement. Synovial or diarthrodial joints are freely movable. The surfaces of the articulating ends of bones in synovial joints are covered with a thin layer of articular cartilage, and they are enclosed in a fibrous joint capsule. The joint capsule consists of two layers: an outer fibrous layer and an inner membrane, the synovium. The synovial fluid, which is secreted by the synovium into the joint capsule, acts as a lubricant and facilitates movement of the joint's articulating surfaces. Tendons and ligaments are dense connective tissue structures that connect muscles and bones. Bursae, which are closed sacs containing synovial fluid, prevent friction in areas where tendons are deflected over bone or where skin must move freely over bony tissue. Menisci are fibrocartilaginous structures that develop from portions of the articular disk that occupied the space between articular cartilage surfaces during fetal development. The menisci may have a free inner border, or they may extend through the joint, separating it into two cavities.

REVIEW EXERCISES

1. Hyaline cartilage degenerates when the chondrocytes become metabolically inactive and die, causing the matrix to calcify and be replaced by bone.

A. Explain how this process can contribute to normal skeletal growth during childhood and adolescence, but cause joint pain and immobility when it occurs during adulthood.

2. Persons with end-stage kidney disease have a deficiency of activated vitamin D.

A. Explain why this occurs and what effect it would have on their bones.

3. Recent studies have revealed that estrogen deficiency as well as normal aging may produce a decrease in osteoblast activity.

A. Explain how this would contribute to a disruption in bone remodeling and the development of osteoporosis.

4. Often pain from injury to the knee is experienced as pain in the hip.

A. Explain why this might occur.

Chapter 43

Disorders of the Skeletal System: Trauma, Infections, Neoplasms, and Childhood Disorders

The musculoskeletal system includes the bones, joints, and muscles of the body together with associated structures such as ligaments and tendons. This system, which constitutes more than 70% of the body, is subject to a large number of disorders. These disorders affect persons in all age groups and walks of life and are a major cause of pain and disability. The main discussion in this chapter focuses on injuries, infections, necrosis, and neoplasms of the musculoskeletal system. At the end of the chapter, disorders of skeletal growth and development in children are discussed.

Injury and Trauma of Musculoskeletal Structures

A broad spectrum of musculoskeletal injuries results from numerous physical forces, including blunt tissue trauma, disruption of tendons and ligaments, and fractures of bony structures. Many of the forces that cause these injuries are typical for a particular age group, activity, or environmental setting.[1] The most common causes of childhood injuries are falls, bicycle-related injuries, and sports injuries. Trauma resulting from high-speed motor vehicle accidents is ranked as the number one killer of adults younger than 45 years of age. Falls are the most common cause of injury in people 65 years of age and older, with fractures of the hip and proximal humerus particularly common in this age group.

Sports-Related Injuries

Sports and athletic activities are particularly common causes of acute and overuse injuries of the musculoskeletal system. Acute injuries are caused by sudden trauma and include injuries to soft tissues (contusion, strains, and sprains) and to bone (fractures). Overuse injuries have been described as chronic injuries, including tendinopathies, stress fractures, compartment syndrome, and shin splints, that result from constant high levels of physiologic stress without sufficient recovery time.[2–4] They commonly occur in the elbow ("little league elbow" or "tennis elbow") and in tissue where tendons attach to the bone, such as the heel, knee, hip, and shoulder. Contact sports pose a greater threat for injury to the neck, spine, and growth plates in children and adolescents, who have not yet reached maturity. Injuries can often be prevented by proper training, use of safety equipment, and limiting the level of competition according to skill and size rather than chronologic age. Adequate warm-up time, hydration, and proper nutrition are also key factors in injury prevention.

Soft Tissue Injuries

Most skeletal injuries are accompanied by soft tissue (muscle, tendon, or ligament) injuries. These injuries include contusions and hematomas. They are discussed here because of their association with musculoskeletal injuries.

A contusion is an injury, or *bruise,* that results from direct trauma and is usually caused by striking a body part against a hard object.[5] Although the resulting disability is usually minor, some contusions can be quite painful. Muscle bruises are common in all athletic events, even the so-called noncontact sports. The thigh and upper portion of the arm are the most commonly involved. In contusions, the skin overlying the injury remains intact while the injured tissue undergoes a well-defined sequence of events including microscopic rupture of blood vessels and damage to muscle cells, swelling, and inflammation. The area often becomes ecchymotic (i.e., black and blue) because of local hemorrhage; later, the discoloration gradually changes to brown and then to yellow as the blood is reabsorbed. A large area of local hemorrhage is called a *hematoma*. Hematomas cause pain as blood accumulates and exerts pressure on nerve endings. The pain increases with movement or when pressure is applied to the area. The pain and swelling of a hematoma take longer to subside than those accompanying a contusion.

The treatment for a contusion and a hematoma consists of elevating the affected part and applying cold for the first 24 hours to reduce the bleeding into the area. A compression wrapping is sometimes helpful in the early stages. Reinjury is avoided by appropriately protecting the area and allowing for complete healing to occur before returning to activities.

Joint Injuries

- Joints are the weakest part of the skeletal system and common sites for injury due to mechanical overloading or forcible twisting or stretching.
- Injury can include damage to the tendons, which connect muscle to bone; ligaments, which hold bones together; or the cartilage that covers the articular surface.
- Healing of the dense connective tissue involved in joint injuries requires time to restore the structures so that they are strong enough to withstand the forces imposed on the joint. Ligamentous injuries may require surgical intervention with approximation of many fibrous strands to facilitate healing.
- Injuries involving the articular cartilage may predispose to later joint disease.

Joint (Musculotendinous) Injuries

Joints, or articulations, are sites where two or more bones meet. Joints (i.e., diarthrodial) are supported by tough bundles of collagenous fibers called *ligaments* that attach to the joint capsule and hold the articular ends of bones together, and by *tendons* that join muscles to the periosteum of the articulating bones (see Chapter 42). Joint injuries usually involve mechanical overloading or forcible twisting or stretching.

Strains and Sprains

Strains and sprains are both musculoskeletal injuries, but they differ in terms of the tissue that is affected.[5] Strains involve muscles, or more precisely the muscle–tendon unit. Sprains involve the supporting ligaments of a joint.

A *strain* is a stretching or partial tear in a muscle or a muscle–tendon unit. Strains commonly result from sudden stretch of a muscle that is actively contracting. Although there usually is no external evidence of a specific injury, an inflammatory response develops at the injured site, followed by fibrous tissue replacement of the damaged muscle fibers. Muscle strains are usually characterized by pain, stiffness, swelling, and local tenderness. Pain is increased with stretching of the muscle group. Strains can occur at any age, but are more common in middle-aged and older adults. With aging, the collagen fibers in the muscle–tendon unit change; as result, muscles have decreased elasticity and are more susceptible to injury. Common sites of muscle strains are the lower back and the cervical region of the spine. The elbow and the shoulder are also supported by muscle–tendon units that are subject to strains. Strains of muscle units around the hip, hamstring, and quadriceps are commonly associated with athletic activities. Proper warm-up exercises increase the flexibility of muscle–tendon units and help prevent these types of injuries.

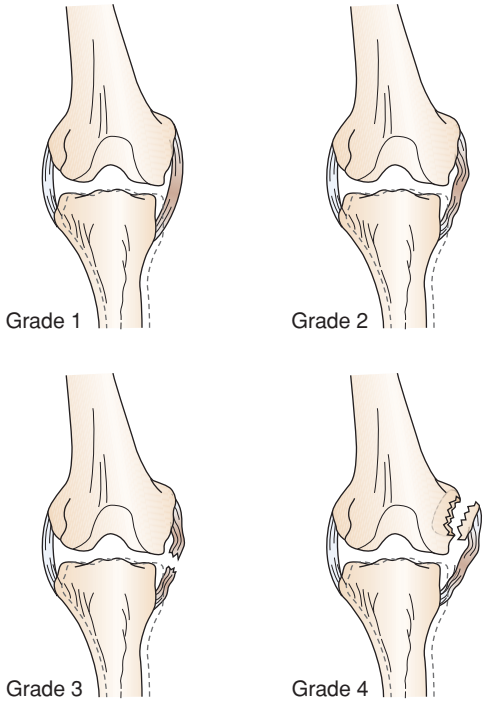

FIGURE 43-1. Degrees of sprain on the medial side of the right knee: grade 1, mild sprain of the medial collateral ligament; grade 2, moderate sprain with hematoma formation; grade 3, severe sprain with total disruption of the ligament; and grade 4, severe sprain with avulsion of the medial femoral condyle at the insertion of the medial collateral ligament.

A *sprain,* which involves the joint ligaments or capsule surrounding the joint, resembles a strain, but the pain and swelling subside more slowly. It usually is caused by abnormal or excessive movement of a joint. With a sprain, the ligaments may be incompletely torn or, as in a severe sprain, completely torn or ruptured (Fig. 43-1). The signs of sprain are pain, rapid swelling, discoloration, and limitation of function. Any joint may be sprained, but the ankle joint is most commonly involved, especially in high-risk sports such as basketball. Most ankle sprains occur in the lateral ankle when the foot is turned inward under a person, forcing the ankle into inversion beyond its structural limits. Other common sites of sprain are the knee (the collateral ligament and anterior cruciate ligament) and elbow (the ulnar side). As with a strain, the soft tissue injury that occurs with a sprain is not evident on the radiograph. However, occasionally a chip of bone is evident when the entire ligament, including part of its bony attachment, has been ruptured or torn from the bone.

The treatment of muscle strains and ligamentous sprains involves rest, ice, compression, and elevation (RICE).[5] For an injured extremity, such as the ankle, elevation of the part followed by local application of cold may be sufficient. Compression, accomplished through the use of adhesive wraps, helps to reduce swelling and provide support. Immobilization may be required for severe sprains, especially those severe enough to warrant surgical repair. Immobilization for a muscle strain is continued until the pain and swelling have subsided. In a sprain, the affected joint is immobilized for several weeks. Immobilization may be followed by graded active exercises. Early diagnosis, treatment, and rehabilitation are essential in preventing chronic ligamentous instability.

Healing of the dense connective tissues in tendons and ligaments is similar to that of other soft tissues. If properly treated, injuries usually heal with the restoration of the original tensile strength. Repair is accomplished by fibroblasts from the inner tendon sheath or, if the tendon has no sheath, from the loose connective tissue that surrounds the tendon.[6,7] Capillaries infiltrate the injured area during the initial healing process and supply the fibroblasts with the materials they need to produce large amounts of collagen. Formation of the long collagen bundles occurs within the first 2 weeks, and although tensile strength increases steadily thereafter, it is not sufficient to permit strong tendon pulls for 6 to 8 weeks.[6] During the healing process, there is a danger that muscle contraction will pull the injured ends apart, causing the tendon to heal in the lengthened position. There is also a danger that adhesions will develop in areas where tendons pass through fibrous channels, such as in the distal palm of the hands, rendering the tendon useless.

Dislocations

A dislocation is the abnormal displacement of the articulating surfaces of a joint such that surfaces are not in contact. It usually follows a severe trauma that disrupts the holding ligaments. Dislocations are seen most often in the shoulder and acromioclavicular joints. A *subluxation* is a partial dislocation in which the bone ends in the joint are still in partial contact with each other.

Dislocations can be congenital, traumatic, or pathologic. Congenital dislocations occur in the hip or knee. Traumatic dislocations occur after falls, blows, or rotational injuries. For example, auto accidents often cause dislocations of the hip and accompanying acetabular fractures because of the direction of impact. In the shoulder and patella, dislocations may become recurrent, especially in athletes. They recur with the same motion but require less and less force each time. Less common sites of dislocation, seen mainly in young adults, are the wrist and midtarsal region. They usually are the result of direct force, such as a fall on an outstretched hand. Pathologic dislocation in the hip is a late complication of infection, rheumatoid arthritis, paralysis, and neuromuscular diseases.

Diagnosis of a dislocation is based on history, physical examination, and radiologic findings. The symptoms are pain, deformity, and limited movement. The treatment depends on the site, mechanism of injury, and associated injuries such as fractures. Dislocations that do not reduce spontaneously usually require manipulation or surgical repair. Immobilization is necessary for several weeks after reduction of a dislocation to allow healing of the joint structures. In dislocations affecting the knee, alternatives to surgery are isometric quadriceps-strengthening exercises and a temporary brace.

Shoulder and Rotator Cuff Injuries

The shoulder is a complex series of joints that produce extraordinary range of motion. The extreme mobility is accomplished at the expense of instability. This instability, combined with its relatively exposed position, makes the shoulder extremely vulnerable to injuries including fractures, dislocations, and degenerative processes such as rotator cuff disorders.[5,8,9]

The shoulder is composed of three bones: the scapula, the clavicle, and the humerus (Fig. 43-2). The scapula is a thin bone that articulates widely and closely with the chest wall. It also articulates with the humerus by way of its small, shallow glenoid cavity and with the clavicle at the acromion process. The clavicle, which is held firmly in place by ligaments at the sternum and acromion, forms the only bony connection between the axial skeleton and the upper extremity. Clavicle fractures are among the most common fractures of childhood.[9] The typical mechanism of fracture is a fall on the lateral shoulder, or less commonly by a direct blow or by falling on an outstretched arm. Most clavicle fractures are treated nonoperatively, with either a simple arm sling or figure-of-eight clavicle strap.[5,8]

Three articulations form the shoulder joint—the acromioclavicular joint, which joins the clavicle to the acromion of the scapula; the glenohumeral joint, which connects the head of the humerus to the relatively shallow glenoid cavity in the scapula; and the sternoclavicular joint, which joins the sternum to the clavicle. The stability of these joints is provided by a series of muscles and tendons. The acromioclavicular joint is a common site of sprains in athletes and physically active persons. The classic cause of an acromioclavicular joint injury is a direct blow to the acromion with the humerus in an adducted position. This force drives the acromion medially and inferiorly. Acromioclavicular joint injuries also may be caused by indirect trauma, such as falling on an outstretched arm or elbow. The glenohumeral joint is one of the most commonly dislocated joints. It is also the joint most likely to develop problems with instability. Most acute dislocations involve anterior displacement of the humeral head with respect to the glenoid cavity, the result of the shoulder being abducted and forcefully extended and rotated. Other mechanisms include a fall on an outstretched arm or a blow to the posterior shoulder.

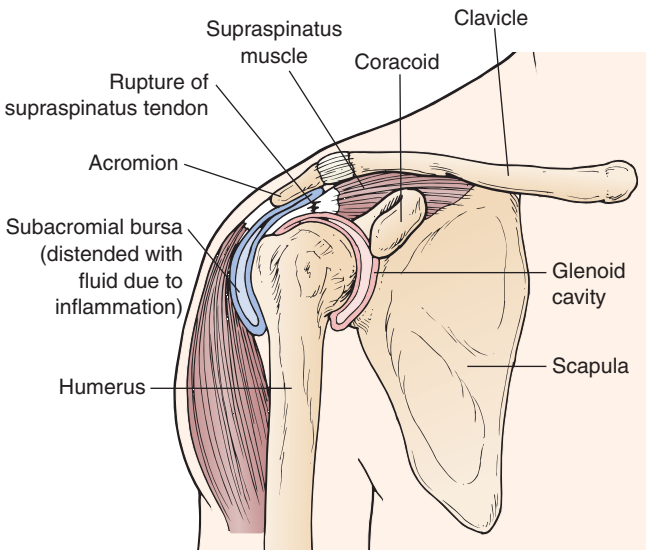

FIGURE 43-2. Structures of the glenohumeral shoulder joint, showing the location of common rotator cuff injuries. The supraspinatus muscle is the most commonly injured part of the rotator cuff. (Adapted from Moore K.L., Dalley A.F. (2006). *Clinically oriented anatomy* [5th ed., p. 763]. Philadelphia: Lippincott Williams & Wilkins.)

Movement of the shoulder results from the coordinated efforts the muscles of the rotator cuff: the supraspinous, teres minor, infraspinatus, and subscapularis.[5,8,9] These muscle and their musculotendinous attachments form a cover around the head of the humerus and function to rotate the arm and stabilize the humoral head against the glenoid. The rotator cuff muscles are separated from the overlying "coracoacromial arch" by the subdeltoid and subcoracoid bursae. Disorders of the rotator cuff, such as tendinitis, subacromial bursitis, and partial and complete tears, account for a substantial majority of shoulder problems (Fig. 43-2). Rotator cuff injuries can result from excessive use, a direct blow, or stretch injury, usually involving throwing or swinging, as with baseball pitchers or tennis players. While rotator cuff injuries sometimes occur with acute injury, most are the result of a combination of factors, including altered blood supply to the tendons, repeated mechanical insult as the tendon passes under the coracoacromial arch, and age-related degeneration. Repetitive overhead throwing, which produces significant stress on the glenohumeral complex of the rotator cuff, is a common cause of rotator cuff tendinitis. Full-thickness tears are more common in persons older than 40 years of age, although they can occur in athletes.[5,8] Tears generally originate in the supraspinous tendon and may progress posteriorly and anteriorly. Inflammation of the subacromial bursa and underlying rotator cuff tendons is a common cause of impingement and shoulder pain in middle-aged persons. The major clinical features of rotator cuff disorders are pain (especially at night), tenderness, and occasionally muscle atrophy. Pain and impingement may be noted when motions of the arm squeeze and pinch cuff tendons between the humerus and the overlying arch. With rotator cuff tears there may be difficulty abducting and rotating the arm.

Several physical examination maneuvers, including assessment of active and passive range of motion, are used to define shoulder pathology. The history and mechanism of injury are important. In addition to standard radiographs, an arthrogram or magnetic resonance imaging (MRI) scan may be obtained. Arthroscopic examination under anesthesia may be done for diagnostic purposes. Conservative treatment with anti-inflammatory agents, corticosteroid injections, and physical therapy often is used. A period of rest is followed by a customized exercise and rehabilitation program to improve strength, flexibility, and endurance. Surgical repair may be considered for persons with an acute traumatic rotator

cuff tear or those with significant symptoms and failed rehabilitation.

Knee Injuries

The knee is a common site of injury, particularly sports-related injuries in which the knee is subjected to abnormal twisting and compression forces.[10] These forces can result in injury to the ligaments and menisci, patellar subluxation and dislocation, and the patellofemoral pain syndrome. Many knee injuries can predispose to osteoarthritis in later life.

The knee joint consists of medial and lateral, femoral and tibial condyles, and the patella (Fig. 43-3). It is essentially a round bone (femoral condyles) sitting on a flat bone (tibial condyles) with no intrinsic bony stability, and depends on its ligaments and menisci for support.[8] The most important ligaments are the medial and lateral collateral ligament along with their associated posterior capsular structures and the anterior cruciate ligament (ACL) and posterior cruciate ligament (PCL).

Ligamentous Injuries. Ligamentous injuries of the knee are among the most serious of all knee injuries. The mechanism is usually one of forceful stress against the knee when the extremity is bearing weight. A "pop" or tearing sensation along with sudden pain is often described, especially with ACL ruptures. After injury, the ability to bear weight on the extremity is often lost, and the knee becomes swollen because of hemorrhaging into the joint.

Initial treatment includes rest, ice, and use of crutches until the person is able to ambulate without a limp. A knee immobilizer or range-of-motion brace may be used for comfort until the acute pain subsides. Range-of-motion exercises are important. Definitive treatment depends on the ligaments that are involved, the person's age and activity level, and any associated injuries. Most isolated lateral ligament injuries are treated nonsurgically. Isolated ACL and PCL ruptures are generally treated nonsurgically, at least initially. Surgical reconstruction is usually required in young, active persons. Older and less active individuals may be treated with physical therapy aimed at controlling the instability. A well-constructed brace may provide an option in some persons.

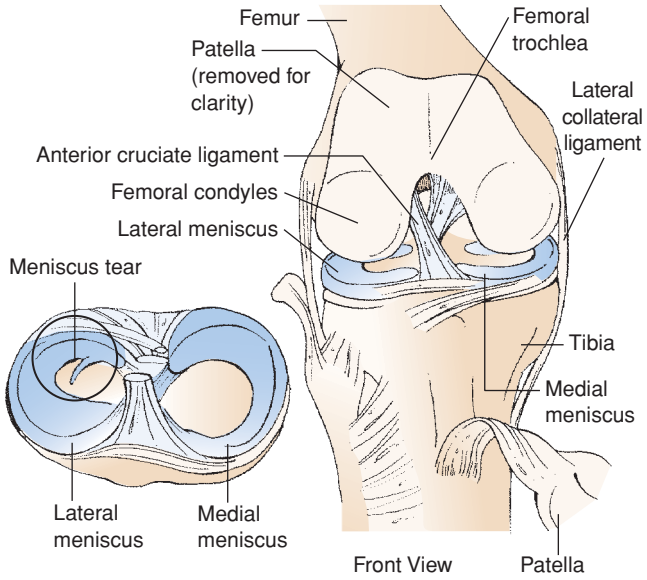

FIGURE 43-3. The knee, showing the lateral and medial meniscus (with the patella removed for clarity). *Inset* (*lower left*) shows meniscus tear.

Meniscus Injuries. The menisci are C-shaped plates of fibrocartilage that are superimposed between the condyles of the femur and tibia. There are two menisci in each knee, a lateral and medial meniscus[5,8] (see Fig. 44-3). The menisci are thicker at their external margins and taper to thin, unattached edges at their interior margin. They are firmly attached at their ends to the intercondylar area of the tibia and are supported by the coronary and transverse ligaments of the knee. The menisci play a major role in load bearing and shock absorption. They also help to stabilize the knee by deepening the tibial socket and maintaining the femur and tibia in proper position. In addition, the meniscus assists in joint lubrication and serves as a source of nutrition for articular cartilage in the knee.

Meniscus injury commonly occurs as the result of a rotational injury from a sudden or sharp pivot or a direct blow to the knee, as in hockey, basketball, or football. It is often associated with other injuries, such as a torn ACL. The type and location of the meniscal tear are determined by the magnitude and direction of the force that acts on the knee and the position of the knee at the time of injury. Meniscus tears can be described by their appearance (e.g., parrot-beak, bucket handle) or their location (e.g., posterior horn, anterior horn). The injured knee is edematous and painful, especially with hyperflexion and hyperextension. A loose fragment may cause knee instability and locking.

Diagnosis is made by examination and confirmed by MRI. A regular radiograph may be needed to rule out osteoarthritis. Initial treatment of meniscal injuries may be conservative. The knee may be placed in a removable knee immobilizer. Isometric quadriceps exercises may be prescribed. Activity usually is restricted until complete motion is recovered. Arthroscopic meniscectomy may be performed when there is recurrent or persistent locking, recurrent effusion, or disabling pain.

There is evidence that loss of meniscal function is associated with progressive deterioration of knee function and osteoarthritic changes.[11] Damaged articular cartilage has a limited capacity to heal because of its avascular nature and inadequate mobilization of regenerative cells. Meniscal reconstruction procedures have been developed to preserve these functions before significant degenerative changes develop, thus preventing the need for a total joint replacement later in life.

Patellar Subluxation and Dislocations. Recurrent subluxation and dislocation of the patella are common injuries in young adults.[5,8] Sports such as skiing or tennis may cause stress on the patella. These sports involve

external rotation of the foot and lower leg with knee flexion, a position that exerts rotational stresses on the knee. Congenital knee variations are also a predisposing factor. There is often a sensation of the patella "popping out" when the dislocation occurs. Other complaints include the knee giving out, swelling, crepitus, stiffness, and loss of range of motion. Treatment measures include immobilization with the knee extended, bracing, administration of anti-inflammatory agents, and isometric quadriceps-strengthening exercises. Surgical intervention often is necessary.

Patellofemoral Pain Syndrome. Patellofemoral pain syndrome is the most common cause of anterior knee pain.[5,12] It is caused by imbalances in the forces controlling movement of the patella during knee flexion and extension, particularly with overloading of the joint. The patellofemoral joint is composed of the patella and central groove (trochlea) in the proximal femur (see Fig. 43-3). Stability of the joint involves dynamic and static stabilizers, which control the movement of the patella within the trochlea, referred to as *patellar tracking*.[12] The disorder, also called "runner's knee," occurs most frequently in young adults, and is often associated with jogging, volleyball, and basketball. Persons with this disorder typically complain of pain, particularly when climbing stairs or sitting with the knees bent. The pain is usually difficult to localize and swelling of the knee is not characteristic of the disorder. Occasionally, the person experiences weakness of the knee.

Diagnosis is usually based on history and physical examination. Radiography may be used as an adjunct to the history and physical. Treatment consists of relative rest and physical therapy.[12] Reduction of loading of the patellofemoral joint and surrounding tissues is the first step to reduce pain. Inappropriate or excessively worn footwear may contribute to the problem and need to be replaced. Although a variety of braces, sleeves, and straps have been used in treatment of the disorder, studies have found no significant benefit from their use.[12]

Hip Injuries

The hip is a ball-and-socket joint in which the femoral head articulates deeply in the acetabulum.[8] The proximal part of the femur consists of a head, neck, and greater trochanter. The vascular anatomy of the femoral head, which receives its main blood supply from the lateral and medial circumflex femoral arteries and the obturator artery, is of critical importance in any disorder of the hip (Fig. 43-4). Disease or injuries that compromise blood flow may damage the viability of the femoral head and lead to avascular necrosis or osteonecrosis.

Dislocations of the Hip. Dislocations of the hip in which the femoral head is displaced from the acetabulum are commonly the result of severe trauma and are usually posterior in direction. They typically result from the knee being struck while the hip and knee are in a flexed position.[8] This force drives the femoral head out of the acetabulum posteriorly. Anterior dislocations are less common and usually result from a force on the knee with the thigh abducted.

Hip dislocation is an emergency.[5,8] The disorder is typically accompanied by severe pain and inability to move the lower extremity. In the dislocated position, great tension is placed on the blood supply to the femoral head and avascular necrosis may result. To prevent this complication, early reduction is indicated. Weight bearing is usually limited after reduction to prevent the dislocation from reoccurring and allow healing to occur.

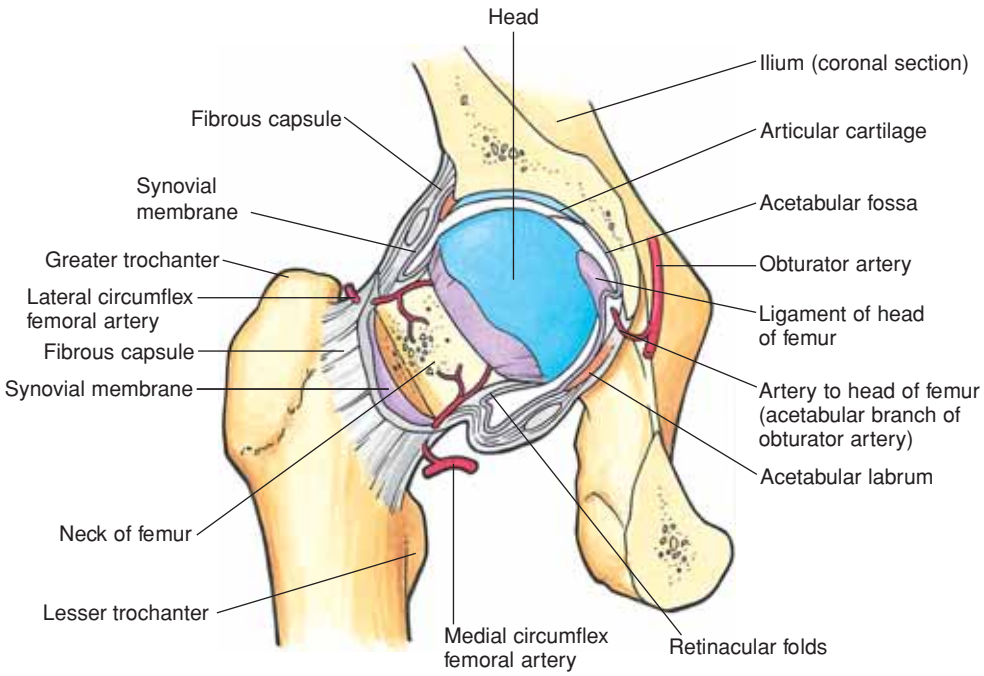

FIGURE 43-4. Blood supply of the head and neck of the femur (anterior view). A section of the bone has been removed from the femoral neck. (Modified from Moore K., Agur A.M.R. [2002]. *Essential clinical anatomy* [2nd ed., p. 381]. Philadelphia: Lippincott Williams & Wilkins.)

Fractures of the Hip. Hip fracture is a major public health problem in the Western world, particularly among the elderly. It results in hospitalization, disability, and loss of independence. The incidence of hip fractures increases with age, doubling for each decade after 50 years of age, and is two to three times higher in women than men.[13] Risk factors for hip fracture include physical inactivity, excessive consumption of alcohol, use of certain psychotropic drugs, residence in an institution, visual impairment, and dementia.[13] Osteoporosis is an important contributing factor.

Most hip fractures result from falls. Occasionally, the person may actually fracture the hip before falling, the fracture representing the completion of an incomplete fracture. The characteristics of the fall (the direction, site of impact, and protective response) and environmental factors are recognized as important influences for the risk of hip fracture from a fall.

A hip fracture is usually a fracture of the proximal femur. Such fractures are commonly categorized according to the anatomic site in which they occur.[13,14] Femoral neck fractures are located in the area distal to the femoral head but proximal to the greater and lesser trochanters and are considered intracapsular because they are located within the capsule of the hip joint. Intertrochanteric fractures occur in the metaphyseal region between the greater and lesser trochanter. Subtrochanteric fractures are those that occur just below the greater trochanter. Femoral neck and intertrochanteric fractures account for over 90% of hip fractures.[14]

The location of a hip fracture is important in terms of blood flow to the femoral head, which receives its blood supply from vessels that course proximally up the femoral neck (see Fig. 43-4). Subtrochanteric and intertrochanteric fractures that occur distal to these vessels do not usually disturb the blood supply to the femoral head, whereas femoral neck fractures, particularly those involving marked displacement, often disrupt the blood supply to the femoral head and are therefore associated with an increased incidence of complications (nonunion and avascular necrosis).

Most hip fractures are diagnosed based on clinical findings and standard radiographs. A bone scan or MRI may be done when the radiograph is negative but the clinical findings support the diagnosis of hip fracture.

The primary goal of treatment for a hip fracture is a return to the preinjury level of function as soon as possible.[8] Undisplaced or impacted fractures have a better prognosis in terms of healing and are often treated nonoperatively or by simple internal fixation to provide stability. Displaced intracapsular fractures in the elderly are usually best treated by surgical hip replacement and early mobilization. Young, healthy people are treated by reduction of the fracture (if needed) and internal fixation. This method allows for preservation of the femoral head, which in this age group is desirable because the long-term results are better than with prosthetic replacement. Intertrochanteric fractures are usually treated with open reduction and internal fixation. This allows for early ambulation by eliminating pain at the fracture site.

Fractures

A fracture represents a disruption in the continuity of a bone.[8,15,16] Normal bone can withstand considerable compression and shearing forces and, to a lesser extent, tension forces. A fracture occurs when more stress is placed on the bone than it is able to absorb. Grouped according to cause, fractures can be divided into three major categories: (1) fractures caused by sudden injury, (2) fatigue stress fractures, and (3) pathologic stress fractures. The most common fractures are those resulting from sudden injury. The force causing the fracture may be direct, such as a fall or blow, or indirect, such as a massive muscle contraction or trauma transmitted along the bone. For example, the head of the radius or clavicle can be fractured by the indirect forces that result from falling on an outstretched hand.

Stress fractures are incomplete fractures.[8] They may be described as either fatigue or pathologic fractures. *Fatigue stress fractures* occur when excess stress is applied to normal bone. They may occur in any weight-bearing bone, but they are most common in the metatarsal, neck of the femur, calcaneus, tibia, fibula, and pelvis. Fatigue stress fractures typically occur in unconditioned athletes. Clinically, a history of unusual stress with subsequent pain over a bone is common in fatigue fractures. *Stress fractures* in the tibia may be confused with "shin splints," a nonspecific term for pain in the lower leg from overuse in walking and running, because they frequently are not apparent on x-ray films until 2 weeks after the onset of symptoms.[3,4]

Pathologic stress fractures occur when normal stress is applied to bones that have been weakened by disease or tumors.[8] Fractures of this type may occur spontaneously with little or no stress. The underlying disease state can be local, as with infections, cysts, or tumors, or it can be generalized, as in osteoporosis, Paget disease, or disseminated tumors.

Classification

Fractures usually are classified according to location, type, and direction or pattern of the fracture line[14–16] (Fig. 43-5). A fracture of the long bone is described in relation to its position in the bone—proximal, midshaft, and distal. Other descriptions are used when the fracture affects the head or neck of a bone, involves a joint, or is near a prominence such as a condyle or malleolus.

The type of fracture is determined by its communication with the external environment, the degree of break in continuity of the bone, and the character of the fracture pieces. A fracture can be classified as open or closed. When the bone fragments have broken through the skin, the fracture is called an *open* or *compound fracture*. In a closed fracture, there is no communication with the outside skin.

The degree of a fracture is described in terms of a complete or incomplete break in the continuity of bone.[5,8] A *greenstick fracture,* which is seen in children, is an example of a partial break in bone continuity and resembles that seen when a young sapling is broken. This kind of break occurs because children's bones, especially

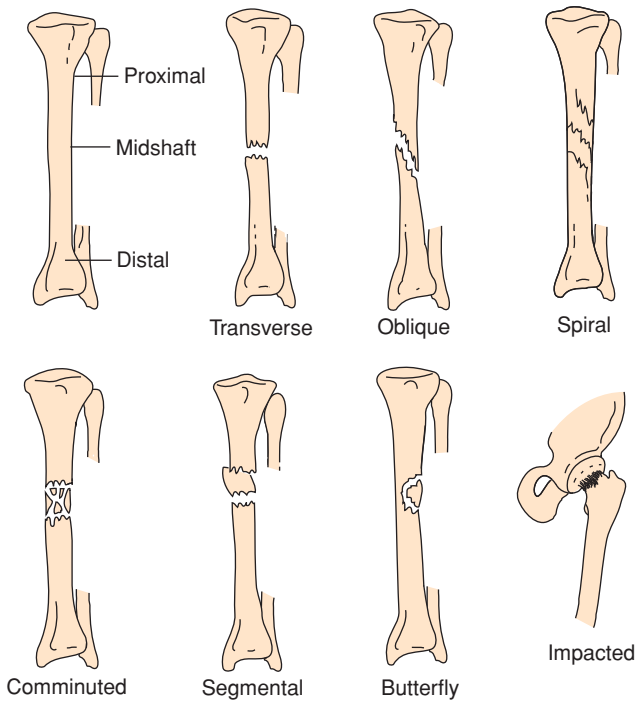

FIGURE 43-5. Classification of fractures. Fractures are classified according to location (proximal, midshaft, or distal), the direction of fracture line (transverse, oblique, spiral), and type (comminuted, segmental, butterfly, or impacted).

until approximately 10 years of age, are more resilient than the bones of adults.

The character of the fracture pieces may also be used to describe a fracture. A *comminuted fracture* has more than two pieces. A *compression fracture,* as occurs in the vertebral body, involves two bones that are crushed or squeezed together. A fracture is called *impacted* when the fracture fragments are wedged together. This type usually occurs in the humerus, often is less serious, and usually is treated without surgery.

The direction of the trauma or mechanism of injury produces a certain configuration or pattern of fracture. *Reduction* is the restoration of a fractured bone to its normal anatomic position. The pattern of a fracture indicates the nature of the trauma and provides information about the easiest method for reduction. *Transverse fractures* are caused by simple angulatory forces. A *spiral fracture* results from a twisting motion, or torque. A transverse fracture is not likely to become displaced or lose its position after it is reduced. On the other hand, spiral, oblique, and comminuted fractures often are unstable and may change position after reduction.

Manifestations

The signs and symptoms of a fracture include pain, tenderness at the site of bone disruption, swelling, loss of function, deformity of the affected part, and abnormal mobility. The deformity varies according to the type of force applied, the area of the bone involved, the type of fracture produced, and the strength and balance of the surrounding muscles.

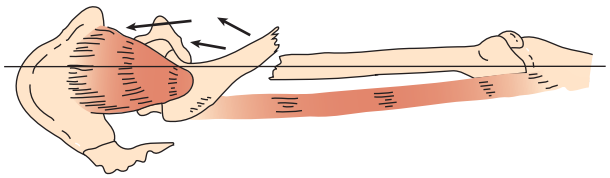

FIGURE 43-6. Displacement and overriding of fracture fragments of a long bone (femur) caused by severe muscle spasm.

In long bones, three types of deformities—angulation, shortening, and rotation—are seen. Severely angulated fracture fragments may be felt at the fracture site and often push up against the soft tissue to cause a tenting effect on the skin. Bending forces and unequal muscle pulls cause angulation. Shortening of the extremity occurs as the bone fragments slide and override each other because of the pull of the muscles on the long axis of the extremity (Fig. 43-6). Rotational deformity occurs when the fracture fragments rotate out of their normal longitudinal axis; this can result from rotational strain produced by the fracture or unequal pull by the muscles that are attached to the fracture fragments. A crepitus, or grating sound, may be heard as the bone fragments rub against each other. In the case of an open fracture, there is bleeding from the wound where the bone protrudes. Blood loss from a pelvic fracture or multiple long bone fractures can cause hypovolemic shock in a trauma victim.

Shortly after the fracture has occurred, nerve function at the fracture site may be temporarily lost. The area may become numb, and the surrounding muscles may become flaccid. This condition has been called *local shock*. During this period, which may last for a few minutes to half an hour, fractured bones may be reduced with little or no pain. After this brief period, the pain sensation returns and, with it, muscle spasms and contractions of the surrounding muscles.

Diagnosis and Treatment

Diagnosis is the first step in the care of fractures and is based on history and physical manifestations. X-ray examination is used to confirm the diagnosis and direct the treatment. The ease of diagnosis varies with the location and severity of the fracture. In the trauma patient, the presence of other, more serious injuries may make diagnosis more difficult.

Treatment depends on the general condition of the person, the presence of associated injuries, the location of the fracture and its displacement, and whether the fracture is open or closed. A *splint* is a device for immobilizing the movable fragments of a fracture. When a fracture is suspected, the injured part always should be splinted before it is moved. This is essential for preventing further injury.[8]

There are three objectives for treatment of fractures: (1) reduction of the fracture, (2) immobilization, and (3) preservation and restoration of the function of the injured part.[8] Reduction of a fracture is directed toward replacing the bone fragments to as near-normal an anatomic position as possible. This can be accomplished

by closed manipulation or surgical (open) reduction. Closed manipulation uses methods such as manual pressure and traction. Fractures are held in reduction by external or internal fixation devices. Surgical reduction involves the use of various types of hardware to accomplish internal fixation of the fracture fragments.

Immobilization prevents movement of the injured parts and is the single most important element in obtaining union of the fracture fragments. Immobilization can be accomplished through the use of external devices, such as splints, casts, external fixation devices, or traction, or by means of internal fixation devices inserted during surgical reduction of the fracture. Preservation and restoration of the function of muscles and joints is an ongoing process in the unaffected and affected extremities during the period of immobilization required for fracture healing. Exercises designed to preserve function, maintain muscle strength, and reduce joint stiffness should be started early.

Bone Healing

Bone healing occurs in a manner similar to soft tissue healing. However, it is a more complex process and takes longer. There are essentially four stages involved in bone healing: hematoma formation, fibrocartilaginous callus development, ossification, and remodeling.[15–17] The degree of response during each of these stages is in direct proportion to the extent of trauma.

Hematoma formation occurs during the first 1 to 2 days after fracture. It develops from torn blood vessels in the periosteum and adjacent muscles and soft tissue. Disruption of blood vessels also leads to death of bone cells at the fracture site. In 2 to 5 days, the hemorrhage forms a large blood clot. Neovascularization begins to occur peripheral to the blood clot. By the end of the first week, most of the clot is organized by invasion of blood vessels and early fibrosis. Hematoma formation is thought to be necessary for the initiation of the cellular events essential to bone healing.[15] As the result of hematoma formation, clotting factors remain in the injured area to initiate the formation of a fibrin meshwork, which serves as a framework for the ingrowth of fibroblasts and new capillary buds. At the same time, degranulated platelets and migrating inflammatory cells release growth factors, which stimulate osteoclast and osteoblast proliferation.[15]

The next event in fracture healing is formation of granulation tissue or *soft tissue callus*. During this stage of bone healing, fibroblasts and osteoblasts migrate into the fracture site from the nearby periosteal and endosteal membranes and begin reconstruction of bone. The fibroblasts produce collagen that spans the break and connects the broken bone ends, and some differentiate into chondrocytes that secrete collagen matrix. At about the same time, osteoblasts begin depositing bone into this matrix. After a few days, a fibrocartilage "collar" becomes evident around the fracture site. The collar edges on either side of the fracture eventually unite to form a bridge, which connects the bone fragments. The earliest bone, in the form of woven bone, begins its formation sometime after the first week. In an uncomplicated fracture, the repair tissue reaches its maximum girth at the end of the second to third week, which helps stabilize the fracture, but it is not yet strong enough for weight bearing.

Ossification represents the deposition of mineral salts into the callus. This stage usually begins during the third to fourth week of fracture healing. During this stage, mature bone gradually replaces the fibrocartilaginous callus, and the excess callus is gradually resorbed by the osteoclasts. The fracture site feels firm and immovable and appears united on the radiograph. At this point, it is usually safe to remove the cast.

Remodeling involves resorption of the excess bony callus that develops in the marrow space and encircles the external aspect of the fracture site. As the callus matures and transmits weight-bearing forces, the portions that are not stressed are resorbed. It is in this manner that the callus is reduced in size until the shape and outline of the bone have been reestablished. The medullary cavity of the bone is also restored. After this is completed, the bone usually appears as it did before the injury.

Healing Time. Healing time depends on the site of the fracture, the condition of the fracture fragments, hematoma formation, and other local and host factors. In children, fractures usually heal within 4 to 6 weeks; in adolescents, they heal within 6 to 8 weeks; and in adults, they heal within 10 to 18 weeks. The increased rate of healing among children compared with adults may be related to the increased cellularity and vascularity of the child's periosteum.[15] In general, fractures of long bones, displaced fractures, and fractures with less surface area heal more slowly. Function usually returns within 6 months after union is complete. However, return to complete function may take longer.

Impaired Bone Healing. Factors that influence bone healing are specific to the person, the type of injury sustained, and local factors that disrupt healing. Individual factors that may delay bone healing are the patient's age; current medications; debilitating diseases, such as diabetes and rheumatoid arthritis; local stress around the fracture site; circulatory problems and coagulation disorders; and poor nutrition.

Malunion is healing with deformity, angulation, or rotation that is visible on x-ray films.[18] Early and aggressive treatment, especially of the hand, can help prevent malunion and result in earlier alignment and return of function. *Delayed union* is the failure of a fracture to unite within the normal period (e.g., 20 weeks for a fracture of the tibia or femur in an adult). Intra-articular fractures (i.e., those through a joint) may heal more slowly and may eventually produce arthritis. *Nonunion* is failure to produce union and cessation of the processes of bone repair. It is seen most often in the tibia, especially with open fractures or crushing injuries. It is characterized by mobility of the fracture site and pain on weight bearing. Muscle atrophy and loss of range of motion may occur. Nonunion usually is established

TABLE 43-1 Complications of Fracture Healing

Complication	Manifestations	Contributing Factors
Delayed union	Failure of fracture to heal within predicted time as determined by x-ray	Large displaced fracture Inadequate immobilization Large hematoma Infection at fracture site Excessive loss of bone Inadequate circulation
Malunion	Deformity at fracture site Deformity or angulation on x-ray	Inadequate reduction Malalignment of fracture at time of immobilization
Nonunion	Failure of bone to heal before the process of bone repair stops Evidence on x-ray Motion at fracture site Pain on weight bearing	Inadequate reduction Mobility at fracture site Severe trauma Bone fragment separation Soft tissue between bone fragments Infection Extensive loss of bone Inadequate circulation Malignancy Bone necrosis Noncompliance with restrictions

6 to 12 months after the time of the fracture.[18] The complications of fracture healing are summarized in Table 43-1.

Treatment methods for impaired bone healing encompass surgical interventions, including bone grafts, bracing, external fixation, or electrical stimulation of the bone ends. Electrical stimulation is thought to stimulate the osteoblasts to lay down a network of bone. Three types of commercial bone growth stimulators are available: a noninvasive model, which is placed outside the cast; a semi-invasive model, in which pins are inserted around the fracture site; and a totally implantable type, in which a cathode coil is wound around the bone at the fracture site and operated by a battery pack implanted under the skin.[8]

Complications of Fractures and Other Injuries

The complications of fractures and other orthopedic injuries are associated with loss of skeletal continuity, injury from bone fragments, pressure from swelling and hemorrhage (e.g., fracture blisters, compartment syndrome), or development of fat emboli. The complex regional pain syndrome or reflex sympathetic dystrophy, caused by involvement of nerve fibers, is discussed in Chapter 35.

Fracture Blisters. Fracture blisters are skin bullae and blisters representing areas of epidermal necrosis with separation of the epidermis from the underlying dermis by edema fluid. They are seen with more severe, twisting types of injuries (e.g., motor vehicle accidents and falls from heights) but can also occur after excessive joint manipulation, dependent positioning, and heat application, or from peripheral vascular disease. They can be solitary, multiple, or massive, depending on the extent of injury. Most fracture blisters occur in the ankle, elbow, foot, knee, or areas where there is little soft tissue between the bone and the skin. The development of fracture blisters reportedly is reduced by early surgical intervention in persons requiring operative repair.[19] This probably reflects the early operative release of the fracture hematoma, reapproximation of the disrupted soft tissues, ligation of bleeding vessels, and fixation of bleeding fracture surfaces. Prevention of fracture blisters is important because they pose an additional risk of infection.

Compartment Syndrome. The compartment syndrome has been described as a condition of increased pressure within a limited space (e.g., abdominal and limb compartments) that compromises the circulation and function of the tissues within the space.[20–23] The abdominal compartment syndrome alters cardiovascular hemodynamics, respiratory mechanics, and renal function. The discussion in this chapter is limited to a discussion of the limb compartment syndromes.

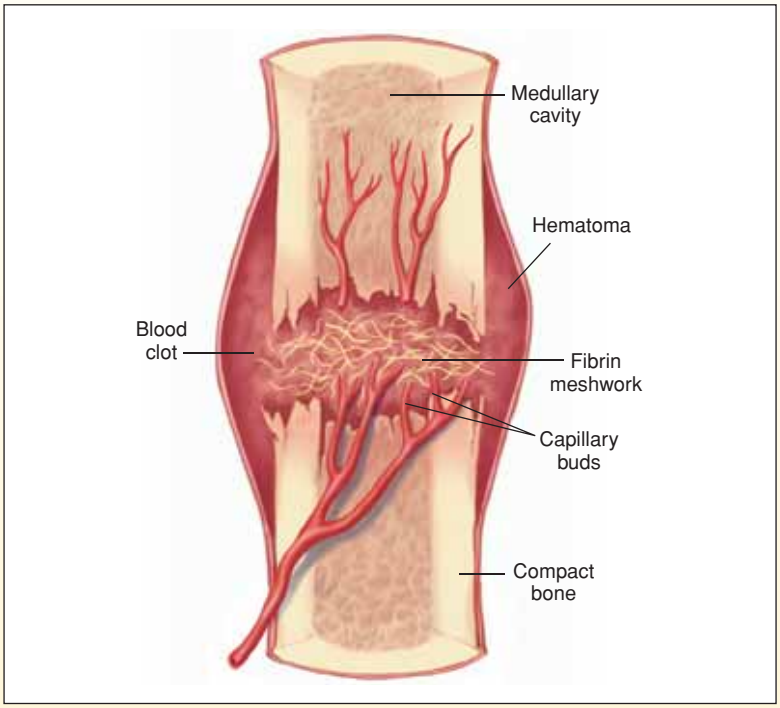
The muscles and nerves of an extremity are enclosed in a tough, inelastic fascial envelope called a *muscle compartment* (Fig. 43-7). If the pressure in the compartment is sufficiently high, tissue circulation is compromised, causing death of nerve and muscle cells. Permanent loss of function may occur. The amount of pressure required to produce a compartment syndrome depends on many factors, including the duration of the pressure elevation, the metabolic rate of the tissues, vascular tone, and local blood pressure. Less tissue pressure is required to impair circulation when hypotension or vasoconstriction is present. Intracompartmental pressures greater than 30 mm Hg (normal is approximately 6 mm Hg) are considered sufficient to impair capillary blood flow.[5]

UNDERSTANDING → Fracture Healing

A fracture, which is any break in a bone, undergoes a healing process to reestablish bone continuity and strength. The repair of simple fractures is commonly divided into four phases: (1) hematoma formation, (2) fibrocartilaginous callus formation, (3) bony callus formation, and (4) remodeling.

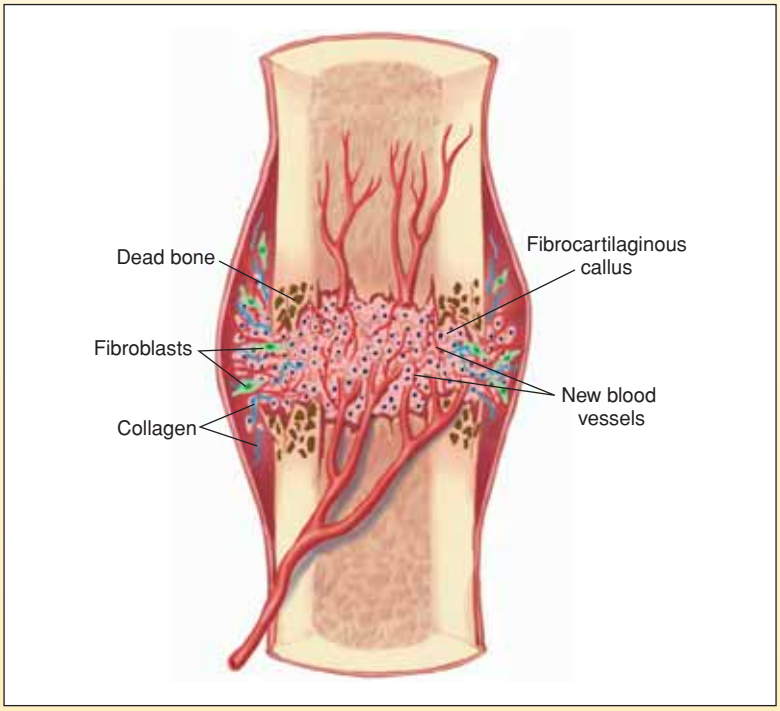
1

Hematoma Formation. When a bone breaks, blood vessels in the bone and surrounding tissues are torn and bleed into and around the fragments of the fractured bone, forming a blood clot, or hematoma. The hematoma facilitates the formation of the fibrin meshwork that seals off the fracture site and serves as a framework for the influx of inflammatory cells, the ingrowth of fibroblasts, and the development of new capillary buds (vessels). It is also the source of signaling molecules that initiate the cellular events that are critical to the healing process.



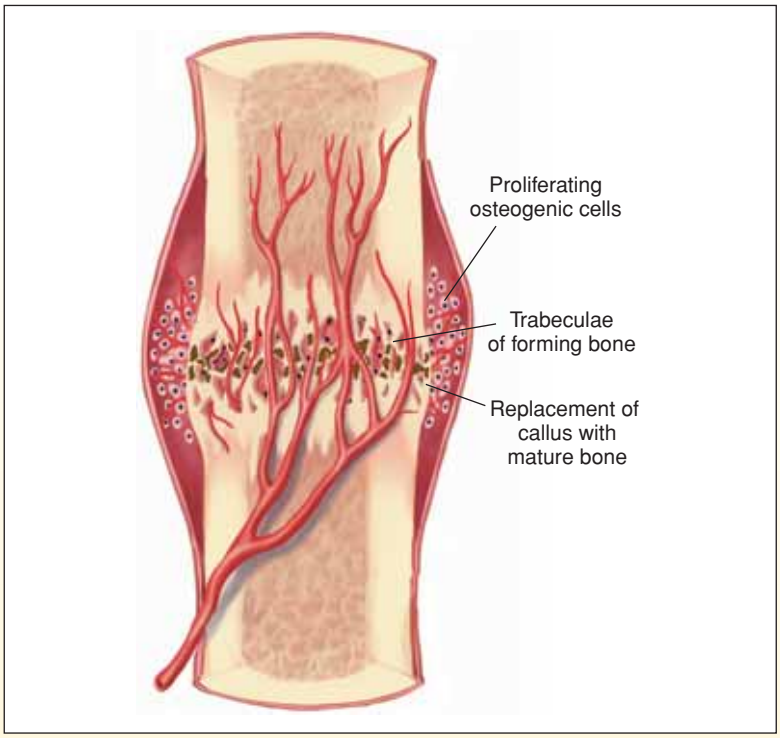
2

Fibrocartilaginous Callus Formation. As new capillaries infiltrate the hematoma at the fracture site, it becomes organized into a form of granulation tissue, called *procallus*. Fibroblasts from the periosteum, endosteum, and red bone marrow proliferate and invade the procallus. The fibroblasts produce a fibrocartilaginous soft callus bridge that connects the bone fragments. Although this repair tissue usually reaches its maximum girth at the end of the second or third week, it is not strong enough for weight bearing.



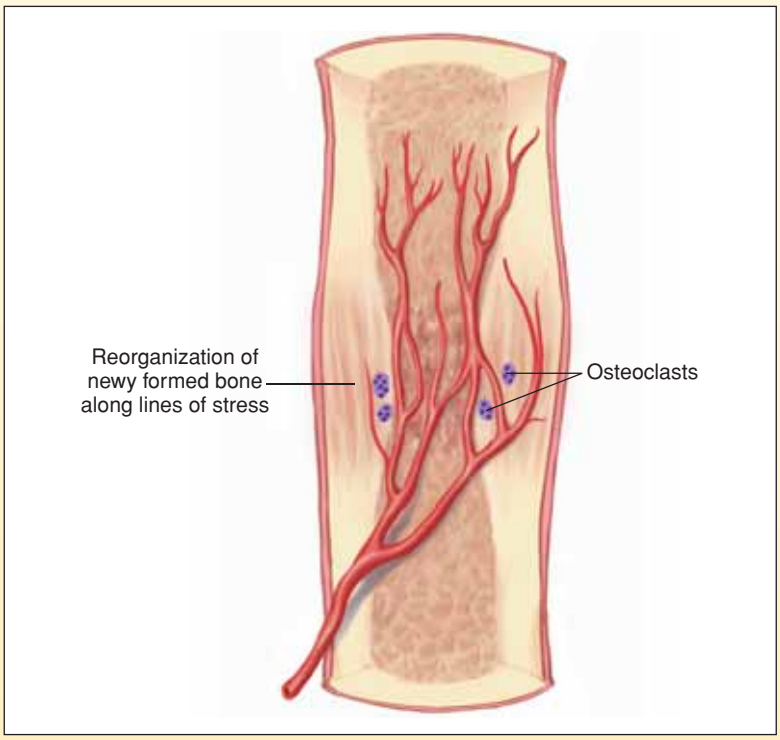
3

Bony Callus Formation. Ossification represents the conversion of the fibrocartilaginous cartilage to bony callus. In areas close to well-vascularized bone tissue, osteogenic cells develop into osteoblasts, or bone-building cells, which produce spongy bone trabeculae. The newly formed osteoblasts first deposit bone on the outer surface of the bone some distance from the fracture site. The formation of bone progresses toward the fracture site until a new bony sheath covers the fibrocartilaginous callus. In time, the fibrocartilage is converted to spongy bone, and the callus is then referred to as bony callus. Gradually, the bony callus calcifies and is replaced by mature bone. Bony callus formation begins 3 to 4 weeks after injury and continues until a firm bony union is formed months later.



4

Remodeling. During remodeling of the bony callus, dead portions of the bone are gradually removed by osteoclasts. Compact bone replaces spongy bone around the periphery of the fracture, and there is reorganization of mineralized bone along the lines of mechanical stress. During this period, the excess material on the outside of the bone shaft and within the medullary cavity is removed and compact bone is laid down to reconstruct the shaft. The final structure of the remodeled area resembles that of the original unbroken bone; however, a thickened area on the surface of the bone may remain as evidence of a healed fracture.



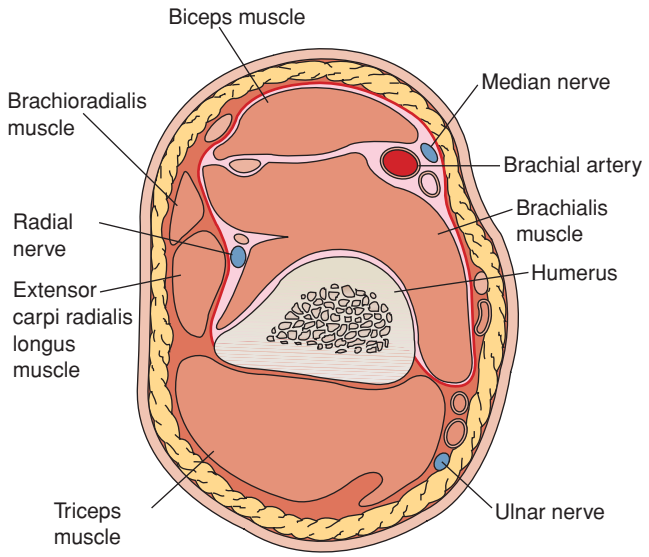


FIGURE 43-7. The proximal muscle compartment of the arm, showing the location of fascia, muscles, nerves, and blood vessels.

Compartment syndrome can result from a decrease in compartment size, an increase in the volume of its contents, or a combination of the two factors. Among the causes of decreased compartment size are constrictive dressings and casts, closure of fascial defects, and burns. In persons with circumferential third-degree burns, the inelastic and constricting eschar decreases the size of the underlying compartments.

An increase in compartment volume can be caused by trauma, swelling, vascular injury and bleeding, and venous obstruction. One of the most important causes of compartment syndrome is bleeding and edema caused by fractures and bone surgery. Contusions and soft tissue injury also are common causes of compartment syndrome. Increased compartment volume may also follow ischemic events, such as arterial occlusion, that are of sufficient duration to produce capillary damage, causing increased capillary permeability and edema. Infiltration of intravenous fluids or bleeding from an arterial puncture can also cause compartment swelling and ischemia. During unattended coma caused by drug overdose or carbon monoxide poisoning, high compartment pressures are produced when an extremity is compressed by the weight of the overlying head or torso.

Compartment syndrome can be acute or chronic. Acute compartment syndrome can occur after a fracture or crushing injury, when excessive swelling around the site of injury results in increased pressure in a closed compartment. Chronic compartment syndrome may develop in long-distance runners and others involved in a major change in activity level. In this case, the symptoms are less severe and tend to improve with rest. Several factors are thought to contribute to an increase in compartmental pressure during exercise including an inelastic facial sheath, an increase in volume of the skeleton muscles due to increased blood flow and edema, and muscle hypertrophy.[2]

The hallmark symptom of an acute compartment syndrome is severe pain that is out of proportion to the original injury or physical findings. Nerve compression may cause changes in sensation (e.g., paresthesias such as burning or tingling or loss of sensation), diminished reflexes, and eventually the loss of motor function. Symptoms usually begin within a few hours but can be delayed as long as 64 hours.[21]

Because muscle necrosis can occur in as little as 4 to 8 hours, it is important that persons at risk for compartment syndrome be identified and proper treatment methods instituted.[5] Assessment should include pain assessment, examination of sensory (i.e., light touch and two-point discrimination) and motor function (i.e., movement and muscle strength), tests of passive stretch, and palpation of the muscle compartments. Peripheral pulses frequently are normal in the presence of compartment syndrome because the major arteries are located outside the muscle compartments. Although edema may make it difficult to palpate the pulse, the increased compartment pressure seldom is sufficient to occlude flow in a major artery. Doppler methods usually confirm the existence of a pulse. Direct measurements of tissue pressure can be obtained using a needle or wick catheter inserted into the muscle compartment. This method is particularly useful in persons who are unresponsive and in those with nerve deficits.

Treatment consists of reducing compartmental pressures. This entails cast splitting or removal of restrictive dressings. These procedures often are sufficient to relieve most of the underlying pressure and symptoms. Elevating the extremity on pillows can help to reduce edema. However, excessive elevation should be avoided because the effects of gravity can lower the arterial pressure in the limb, thereby decreasing compartment perfusion.[5] When compartment syndrome cannot be relieved by conservative measures, a fasciotomy may become necessary. During this procedure, the fascia is incised longitudinally and separated so that the compartment volume can expand and blood flow can be reestablished. Because of potential problems with wound infection and closure, this procedure is usually performed as a last resort.

Fat Embolism Syndrome. The fat embolism syndrome (FES) refers to a constellation of clinical manifestations resulting from the presence of fat droplets in the small blood vessels of the lung or other organs after a long bone fracture or other major trauma.[20,24–26] The fat emboli are thought to be released from the bone marrow or adipose tissue at the fracture site into the venous system through torn veins. It is important to point out that FES is not synonymous with fat embolization, which involves the presence of fat particles in the circulation.[25] Although fat embolization occurs in many persons with fractures or operative fixation of fractures, FES occurs in only a small percentage of cases, supporting the hypothesis that factors other than fat embolization may be necessary in the development of FES.

The main clinical features of FES are respiratory failure, cerebral dysfunction, and skin and mucosal petechiae.[20,26] Cerebral manifestations include encephalopathy, seizures, and focal neurologic deficits unrelated to head injury. Initial symptoms begin within a few hours to 3 to 4 days after injury and do not appear beyond 1 week after the injury. The first symptoms include a subtle change in

behavior and signs of disorientation resulting from emboli in the cerebral circulation combined with respiratory depression. There may be complaints of substernal chest pain and dyspnea accompanied by tachycardia and a low-grade fever. Diaphoresis, pallor, and cyanosis become evident as respiratory function deteriorates. A petechial rash that does not blanch with pressure often occurs 2 to 3 days after the onset of symptoms. This rash usually is found on the anterior chest, axillae, neck, and shoulders. It also may appear on the soft palate and conjunctiva. The rash is thought to be related to embolization of the skin capillaries or thrombocytopenia.

Three degrees of severity are seen: subclinical, overt clinical, and fulminating. Although the subclinical and overt clinical forms of FES respond well to treatment, the fulminating form often is fatal. An important part of the treatment of FES is early diagnosis. Arterial blood gases should be assayed immediately after recognition of clinical manifestations. Treatment is directed toward correcting hypoxemia and maintaining adequate fluid balance. Mechanical ventilation may be required. Corticosteroid drugs are administered to decrease the inflammatory response of lung tissues, decrease edema, stabilize the lipid membranes to reduce lipolysis, and combat bronchospasm. Corticosteroids are also given prophylactically to high-risk persons. The only preventive approach to FES is early stabilization of the fracture.

In summary, many external physical agents can cause trauma to the musculoskeletal system. Particular factors, such as environment, activity, or age, can place a person at greater risk for injury. Some soft tissue injuries such as contusions, hematomas, and lacerations are relatively minor and easily treated. Muscle strains and ligamentous sprains are caused by mechanical overload on the connective tissue. They heal more slowly than the minor soft tissue injuries and require some degree of immobilization. Healing of soft tissue begins within 4 to 5 days of the injury and is primarily the function of fibroblasts, which produce collagen. Joint dislocation is caused by trauma to the supporting structures. The knee and shoulder are common sites for injuries in athletes. The rotator cuff is a common site for shoulder injuries. Knee injuries include injury to the ligaments and menisci, anterior cruciate ligament tears, patellar subluxation and dislocation, and patellofemoral pain syndrome. Hip injuries include dislocations and fractures. The blood supply to the head of the femur travels through the femoral neck. Thus, dislocations and hip fractures affecting the femoral neck often disrupt blood flow to the femoral head, predisposing to fracture malunion and avascular necrosis.

Fractures occur when more stress is placed on a bone than the bone can absorb. The nature of the stress determines the type of fracture and the character of the resulting bone fragments. Healing of fractures is a complex process that takes place in four stages: hematoma formation, fibrocartilaginous callus formation, ossification, and remodeling. For satisfactory healing to take place, the affected bone has to be reduced and immobilized. This is accomplished with external fixation devices (e.g., splints, casts, or traction) or surgically implanted internal fixation devices.

The complications of fractures include a loss of skeletal continuity (malunion or nonunion), pressure from swelling and hemorrhage (fracture blisters and compartment syndrome), and development of fat emboli. Compartment syndrome is a condition of increased pressure in a muscle compartment that compromises blood flow and potentially leads to death of nerve and muscle tissue. The fat embolism syndrome refers to a constellation of symptoms including a petechial skin rash, respiratory failure, and cerebral dysfunction due to the presence of fat droplets in small blood vessels after a fracture.

Bone Infections and Osteonecrosis

Infections—Osteomyelitis

Osteomyelitis represents an acute or chronic infection of the bone and marrow.[15,16] Despite the common use of antibiotics, these infections remain difficult to treat and eradicate. All types of organisms, including parasites, viruses, bacteria, and fungi, can cause osteomyelitis, but certain pyogenic bacteria and mycobacteria are the most common.[16]

Pyogenic Osteomyelitis

Pyogenic osteomyelitis is almost always caused by bacteria. Organisms may reach the bone by seeding through the bloodstream (hematogenous spread), direct penetration or contamination of an open fracture or wound (exogenous origin), or extension from a contiguous site.

The specific agents isolated in pyogenic bacterial osteomyelitis are often associated with the age of the person or the inciting condition (e.g., trauma or surgery).

Bone Infections

- Bone infections may be caused by a wide variety of microorganisms introduced during injury, during operative procedures, or from the bloodstream.
- Once established in bone, the microorganisms proliferate, produce cell death, and spread within the bone shaft, inciting a chronic inflammatory response with further destruction of bone.
- Bone infections are difficult to treat and eradicate. Measures to prevent infection include careful cleaning and debridement of skeletal injuries and strict operating room protocols.

Staphylococcus aureus is the most common cause, but organisms such as *Escherichia coli, Neisseria gonorrhoeae, Haemophilus influenzae,* and *Salmonella* species are also seen. *S. aureus* has two characteristics that favor its ability to produce osteomyelitis: (1) it has the ability to produce a collagen-binding adhesion molecule that allows it to adhere to the connective tissue elements of bone, and (2) it has the ability to evade host defenses, attack host cells, and colonize bone persistently. Also, infection caused by methicillin-resistant *S. aureus* is becoming an increasingly common problem.[27]

Hematogenous Osteomyelitis. Hematogenous osteomyelitis originates with infectious organisms that reach the bone through the bloodstream.[8,15,16,27–29] Acute hematogenous osteomyelitis occurs predominantly in children. In adults, it is seen most commonly in debilitated persons and in those with a history of chronic skin infections, chronic urinary tract infections, and intravenous drug use and in those who are immunologically suppressed. Intravenous drug users are especially at risk for infections with *Streptococcus* and *Pseudomonas*.

The pathogenesis of hematogenous osteomyelitis differs in children and adults.[27,29] In children, the infection usually affects the long bones of the appendicular skeleton. It starts in the metaphyseal region close to the growth plate, where termination of nutrient blood vessels and sluggish blood flow favor the attachment of bloodborne bacteria (Fig. 43-8). With advancement of the infection, purulent exudate collects in the rigidly enclosed bony tissue. Because of the bone's rigid structure, there is little room for swelling and the purulent exudate finds its way beneath the periosteum, shearing off the perforating arteries that supply the cortex with blood, thereby leading to necrosis of cortical bone. The necrotic bone that is formed may separate from the viable surrounding bone to form devascularized fragments, called *sequestra*.[15,16] Eventually, the purulent drainage may penetrate the periosteum and skin to form a draining sinus. In children 1 year of age and younger, the adjacent joint is often involved because the periosteum is not firmly attached to the cortex.[15,16] From 1 year of age to puberty, subperiosteal abscesses are more common. As the process continues, periosteal new bone formation and reactive bone formation in the marrow tend to wall in the infection.

In adults, the long bone microvasculature no longer favors seeding, and hematogenous infection rarely affects the appendicular skeleton. Instead, vertebrae, sternoclavicular and sacroiliac joints, and the symphysis pubis are involved. Infection typically first involves subchondral bone, then spreads to the joint space. With vertebral osteomyelitis, this causes sequential destruction of the endplate, adjoining disk, and contiguous vertebral body. Infection less commonly begins in the joint and spreads to the adjacent bone.

The signs and symptoms of acute hematogenous osteomyelitis are those of bacteremia accompanied by symptoms referable to the site of the bone lesion. Bacteremia is characterized by chills, fever, and malaise. There often is pain on movement of the affected extremity, loss of movement, and local tenderness followed by redness and swelling. X-ray studies may appear normal initially, but they show evidence of periosteal elevation and increased osteoclast activity after an abscess has formed. Radiographic bone scans and MRI can usually detect subtle changes at an earlier stage.

The treatment of hematogenous osteomyelitis begins with identification of the causative organism through blood and bone aspiration cultures. Antimicrobial agents are given first parenterally and then orally. The length of time the affected limb needs to be rested and the pain control measures used are based on the person's symptoms. Débridement and surgical drainage also may be necessary.

Chronic Osteomyelitis. Chronic osteomyelitis usually occurs in adults. Generally, these infections occur secondary to an open wound, most often to the bone or surrounding tissue. It may be the result of delayed or inadequate treatment of acute hematogenous osteomyelitis or osteomyelitis caused by direct contamination of bone by exogenous organisms. Chronic osteomyelitis can persist for years; it may appear spontaneously following a minor trauma, or when resistance is lowered.

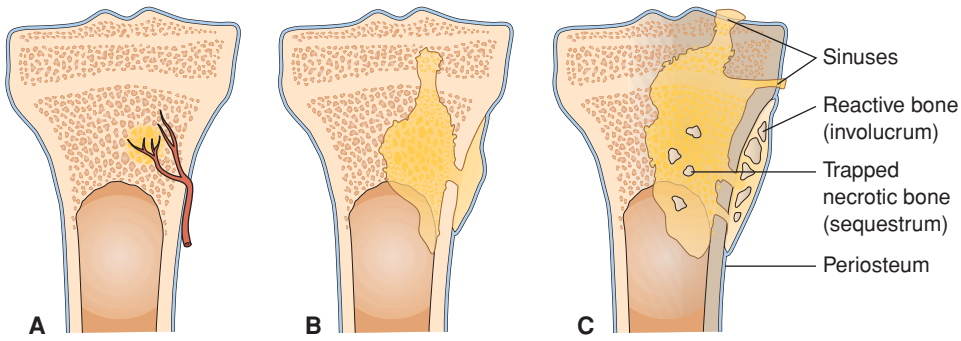

FIGURE 43-8. Hematogenous osteomyelitis. **(A)** Infectious organisms reach the metaphysis through a nutrient blood vessel. **(B)** Bacterial growth results in bone destruction and abscess formation. From the abscess cavity, the infection spreads between the trabeculae into the medullary cavity of compact bone and then through the cortex to the outside. **(C)** The purulent exudate finds its way beneath the periosteum, shearing off the perforating arteries that supply the cortex with blood, thereby leading to necrosis of cortical bone and formation of devascularized fragments, called *sequestra.*

The hallmark feature of chronic osteomyelitis is the presence of infected dead bone, a *sequestrum,* that has separated from the living bone.[8,15,16] A sheath of new bone, called the *involucrum,* forms around the dead bone. Radiologic techniques such as x-ray films, bone scans, and sinograms are used to identify the infected site. Chronic osteomyelitis or infection around a total joint prosthesis can be difficult to diagnose because the classic signs of infection are not apparent and the blood leukocyte count may not be elevated. A subclinical infection may exist for years. Bone scans are used with bone biopsy for a definitive diagnosis.

The treatment of chronic bone infections begins with wound cultures to identify the microorganism and its sensitivity to antibiotic therapy.[28] Initial antibiotic therapy is often followed by surgery to remove foreign bodies (e.g., metal plates, screws) or sequestra and by long-term antibiotic therapy. Immobilization of the affected part usually is necessary, with restriction of weight bearing on a lower extremity. External fixation devices are sometimes used.

Direct Penetration and Contiguous Spread Osteomyelitis. Direct penetration or extension of bacteria from an outside (exogenous) source is now the most common cause of osteomyelitis in the United States.[15] Bacteria may be introduced directly into the bone by a penetrating wound, an open fracture, or surgery. Iatrogenic bone infections are those inadvertently brought about by surgery or other treatments. These complications include pin tract infection in skeletal traction, septic (infected) joints in joint replacement surgery, and wound infections after surgery. In persons with vascular insufficiency, osteomyelitis may develop from a skin lesion. It is most commonly associated with chronic or ischemic foot ulcers in persons with long-standing diabetes.

The pathogenesis of osteomyelitis resulting from direct penetration or contiguous spread differs from hematogenous infection in that virtually any traumatized bone may be involved. Although healthy bone is highly resistant to infection, injury from local inflammation and trauma may devitalize bone and surrounding tissue, providing an inert matrix on which microorganisms introduced during trauma thrive.

Osteomyelitis after trauma or bone surgery usually is associated with persistent or recurrent fever, increased pain at the operative or trauma site, and poor incisional healing, which often is accompanied by continued wound drainage and wound separation. Prosthetic joint infections often present with joint pain, fever, and cutaneous drainage.

Treatment includes the use of antibiotics and selective use of surgical interventions. The choice of agents and method of administration depend on the microorganisms causing the infection. In acute osteomyelitis that does not respond to antibiotic therapy, surgical decompression is used to release intramedullary pressure and remove drainage from the periosteal area. Prosthesis removal may be necessary in cases of an infected prosthetic joint. The joint is left out while a 2- to 6-week course of therapy is given, after which another joint is implanted.[29]

Tuberculosis Osteomyelitis

A resurgence of tuberculosis osteomyelitis is occurring in industrialized countries of the world, attributed to the influx of immigrants from developing countries and the greater numbers of immunocompromised people.[30] Tuberculosis can spread from one part of the body, such as the lungs or the lymph nodes, to the musculoskeletal system. Any bone, joint, or bursa may be affected, but the spine is the most common site, followed by the knees and hips.[16,30] Tubercular osteomyelitis tends to be more destructive and difficult to control than pyogenic osteomyelitis. The infection spreads through large areas of the medullary cavity and causes extensive necrosis. In tuberculosis of the spine, also known as *Pott disease,* the infection spreads through the intervertebral disks to involve multiple vertebrae and extends into the soft tissue, forming abscesses.

Local symptoms include pain, immobility, and muscle atrophy; joint swelling, mild fever, and leukocytosis also may occur. The most feared complication of spinal tuberculosis is neurologic compromise due to spinal deformity and epidural abscess formation. Because there are no specific radiographic findings in tubercular osteomyelitis, the diagnosis is usually made by tissue biopsy or culture findings. In spinal tuberculosis, a computed tomography (CT)-guided biopsy is often used. The mainstay of treatment for tubercular osteomyelitis remains the appropriate three- or four-drug antimicrobial therapy based on current guidelines.[30] Conservative treatment is usually as effective as surgery, especially for earlier and milder cases.

Osteonecrosis

Osteonecrosis is an aseptic destruction of a segment of bone that is due to an interruption in blood flow rather than an infection.[15,16,31,32] It is a relatively common disorder and can occur in the medullary cavity of the metaphysis and the subchondral region of the epiphysis, especially in the proximal femur, distal femur, and proximal humerus. Destruction of bone frequently is severe enough to require joint replacement surgery.

Bone has a rich blood supply that varies from site to site. The flow in the medullary portion of bone originates in nutrient vessels from an interconnecting plexus that supplies the marrow, trabecular bone, and endosteal half of the cortex. The outer cortex receives its blood supply from periosteal, muscular, metaphyseal, and epiphyseal vessels that surround the bone. Some bony sites, such as the head of the femur, have only limited collateral circulation so that interruption of the flow, such as with a hip fracture, can cause necrosis and irreversible damage to a substantial portion of medullary and cortical bone.

Although bone necrosis results from ischemia, the mechanisms producing the ischemia are varied and include mechanical interruption such as occurs with a fracture; thrombosis and embolism (e.g., sickle cell

disease, nitrogen bubbles caused by inadequate decompression during deep sea diving); vessel injury (e.g., vasculitis, radiation therapy); and increased intraosseous pressure with vascular compression. Chart 43-1 lists some of the conditions associated with osteonecrosis. Other than vessel injury and obstruction, the most common causes of bone necrosis are idiopathic (i.e., those of unknown cause) and prior steroid therapy. Despite numerous studies, the mechanism of steroid-induced osteonecrosis remains unclear. The condition may develop after the administration of very high, short-term doses; during long-term treatment; or even from intra-articular injection. Although the risk increases with the dose and duration of treatment, it is difficult to predict who will be affected. Of recent concern is the development of osteonecrosis of the jaw with long-term use of bisphosphonates, drugs that are widely used for the treatment of postmenopausal osteoporosis, Paget disease of the bone, and cancer-related conditions.[33] The pathogenesis of bisphosphonate-associated osteonecrosis of the jaw remains largely unknown. The complication has mainly been reported in patients receiving the drugs intravenously for treatment of malignancies.

The pathologic features of bone necrosis are the same, regardless of cause. The site of the lesion is related to the vessels involved. There is necrosis of cancellous bone and marrow. The cortex usually is not involved because of collateral blood flow. In persons with subchondral infarcts (i.e., ischemia below the cartilage), a triangular or wedge-shaped segment of tissue that has the subchondral bone plate as its base and the center of the epiphysis as its apex undergoes necrosis (Fig. 43-9). In cases where medullary infarcts occur in fatty marrow, death of bone results in calcium release and necrosis of fat cells with the formation of free fatty acids. Released calcium forms an insoluble "soap" with free fatty acids. Because bone lacks mechanisms for resolving the infarct, the lesions remain for life.

The symptoms associated with osteonecrosis are varied and depend on the site and extent of infarction. Typically, subchondral infarcts cause chronic pain that is initially associated with activity but that gradually becomes more progressive until it is experienced at rest. Subchondral infarcts often collapse and predispose the patient to severe secondary osteoarthritis.

Diagnosis of osteonecrosis is based on history, physical findings, radiographic findings, and the results of special imaging studies, including CT scans and technetium-99m bone scans. Treatment depends on the underlying pathologic process. In some cases, only short-term immobilization, nonsteroidal anti-inflammatory drugs, exercises, and limitation in weight bearing are used. Osteonecrosis of the hip is particularly difficult to treat. In persons with early disease, limitation of weight bearing through the use of crutches may allow the condition to stabilize. Although several surgical approaches have been used, the most definitive treatment of advanced osteonecrosis of the knee or hip is total joint replacement.

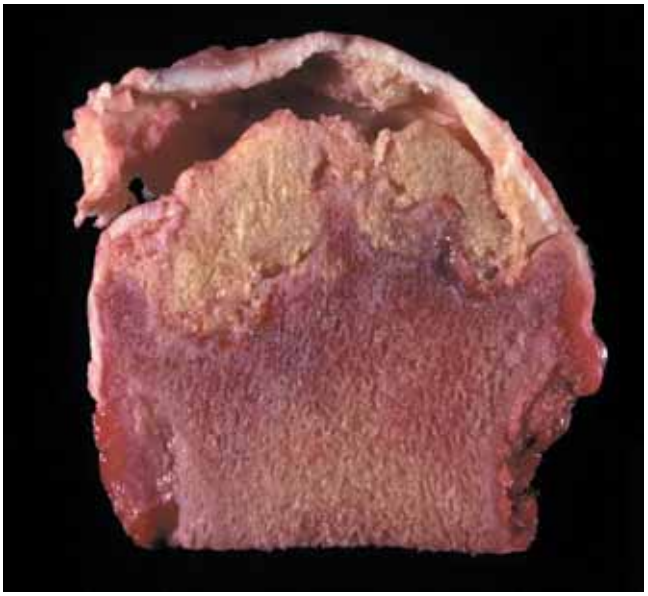

FIGURE 43-9. Osteonecrosis of the head of the femur. A coronal section shows a circumscribed area of subchondral infarction with partial detachment of the overlying articular cartilage and subarticular bone. (From Hoch B.L., Klein M.J., Schiller A.L. [2008]. Bones and joints. In Rubin R., Strayer D.E. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1100]. Philadelphia: Lippincott Williams & Wilkins.)

CHART 43-1 Causes of Osteonecrosis

- Mechanical disruption of blood vessels
  - Fractures
  - Legg-Calvé-Perthes disease
  - Blount disease
- Thrombosis and embolism
  - Sickle cell disease
  - Nitrogen bubbles in decompression sickness
- Vessel injury
  - Vasculitis
  - Connective tissue disease
    - Systemic lupus erythematosus
    - Rheumatoid arthritis
  - Radiation therapy
  - Gaucher disease
- Corticosteroid therapy
- Biphosphonate therapy (jaw osteonecrosis)

In summary, bone infections occur because of the direct or indirect invasion of the musculoskeletal system by microorganisms, most commonly *S. aureus*. Osteomyelitis, or infection of the bone and marrow, can be an acute or chronic disease. Acute osteomyelitis is seen most often as a result of the direct contamination of bone by a foreign object. Chronic osteomyelitis represents an infection that continues beyond 6 to 8 weeks and may persist for years. The incidence of all types of bone infection has been dramatically reduced since the

advent of antibiotic therapy. Iatrogenic infections are those inadvertently brought about by surgery or other treatments. Tuberculosis osteomyelitis, which is characterized by bone destruction and abscess formation, is caused by spread of the infection from the lungs or lymph nodes.

Osteonecrosis, or death of a segment of bone, is due to an interruption in blood flow rather than an infection. The mechanisms producing interruption of blood flow are varied and include mechanical interruption such as occurs with a fracture, vessel injury, increased intraosseous pressure with vascular compression, and steroid therapy. Sites with poor collateral circulation, such as the femoral head, are most commonly affected. Of recent concern is the development of osteonecrosis of the jaw in persons receiving long-term treatment with bisphosphonate drugs. Symptoms include pain that varies in severity, depending on the extent of infarction. Total joint replacement is the most frequently used treatment for advanced osteonecrosis.

Neoplasms

Neoplasms of the skeletal system, often referred to as *bone tumors*, may be benign or malignant, and in the case of malignant neoplasms, may represent a primary tumor or secondary metastatic lesion.[5,8,15,16,34] Benign tumors greatly outnumber their malignant counterparts and occur with the greatest frequency in the first three decades of life, whereas in the elderly, a bone tumor is more likely to be malignant.

Both benign and malignant tumors can develop from the cartilage (chondrogenic), bone (osteogenic), and supporting (fibrogenic) elements of bone, and bone tumors are generally classified according to their tissue counterpart. As a group, these tumors affect all age groups and arise in virtually every bone. Most develop during the first several decades of life and have a propensity to originate in the long bones of the extremities; however, certain types of tumors target specific age groups and anatomic sites. Thus, the location of the tumor provides important diagnostic information.

There are three major manifestations of bone tumors: pain, presence of a mass, and impairment of function.[5,8] Although benign tumors are frequently asymptomatic and are detected as an incidental finding, many tumors produce pain. Malignant tumors are associated with constant, deep aching pain that does not go away with rest and is present at night. However, certain benign tumors also cause night pain. A mass or hard lump may be the first sign of a bone tumor. A malignant tumor is suspected when a painful mass exists that is enlarging or eroding the cortex of the bone. The ease of discovery of a mass depends on the location of the tumor; a small lump arising on the surface of the tibia is easy to detect, whereas a tumor that is deep in the medial portion of the femur may grow to a considerable size before it is noticed. Benign and malignant tumors may cause the bone to erode to the point where it cannot withstand the strain of ordinary use. A sudden increase in pain followed by trivial trauma that is preceded by a history of mild, dull aching pain is suggestive of a pathologic fracture. A tumor also may produce pressure on a peripheral nerve, causing a decreased sensation, numbness, a limp, or limitation in movement.

The diagnosis of bone tumors relies on the history and physical examination, as well radiography, CT, and MRI.[35] Radiographs give the most general diagnostic information, such as malignant versus benign and primary versus metastatic status. The radiograph demonstrates the region of bone involvement, extent of destruction, and amount of reactive bone formed. CT scans further aid diagnosis and anatomic localization and can identify small pulmonary metastases not seen by conventional radiographs. MRI is the most accurate method of evaluating the intramedullary extent of bone tumor and can demarcate the soft structures in relation to neurovascular structures without the use of contrast media. It is best used in conjunction with a CT scan. Radionuclide bone scans are used to assess for metastasis. A biopsy may be done to determine the histologic characteristics of the tumor.

Bone Tumors

- Bone tumors include both primary neoplasms that arise from the cartilage, osseous, or fibrous tissue elements of bone and metastatic tumors that arise from other primary sites.
- Most primary bone tumors, both benign and malignant, develop during the first several decades of life and have a propensity to originate in the long bones of the extremities.
- The more common benign tumors are often asymptomatic and are detected as an incidental finding.
- Malignant tumors tend to grow rapidly and extend beyond the confines of the bone, and typically present as painful enlarging masses.

Benign Bone Tumors

Benign bone tumors usually are limited to the confines of the bone, have well-demarcated edges, and are surrounded by a thin rim of sclerotic bone. The most common benign tumors are of either fibrous or cartilaginous tissue origin. Benign fibrous tumors of the bone are common in growing bones. They are usually asymptomatic, resolve in 2 to 3 years, and do not require treatment.[8] Common cartilaginous tumors include chondromas and osteochondromas. Giant cell tumors, which contain mononuclear and osteoclast-type giant cells, are often classified

as "intermediate" in nature between malignant and benign.

Chondromas are benign tumors of hyaline cartilage that usually occur in bones of endochondral origin. They can arise within the medullary cavity, where they are known as *endochondromas*, or on the surface of bone, where they are called *subperiosteal* or *juxtacortical chondromas*. The endochondromas are the most common of the intraosseous cartilage tumors and are usually diagnosed in persons between the ages of 20 and 40 years.[16] They are usually solitary lesions of tubular bone, and are most commonly found in short tubular bones of hands and feet. Most endochondromas are asymptomatic and detected incidentally. Occasionally they are painful and cause fractures. Treatment is usually simple observation, with surgical intervention reserved for cases in which pain or danger of fracture is present.

An *osteochondroma,* also known as an *exostosis,* is a benign cartilage-capped tumor that is attached to the underlying bone by a bony stalk. It is the most common benign bone tumor, about 85% of which occur as solitary tumors.[16] The remaining tumors are seen as part of a multiple hereditary exostosis syndrome, which is inherited as an autosomal dominant disorder. Solitary exostoses are usually first diagnosed in late adolescence or early adulthood, but multiple exostoses become apparent in childhood. Exostoses develop only in bones of endochondral origin, arising from the metaphysis near the growth plate of tubular bones, especially about the knee. Clinically, osteochondromas present as slow-growing masses, which can be painful if they impinge on a nerve or if the stalk is fractured. In many cases they are discovered incidentally. In multiple hereditary exostosis, the underlying bone may be bowed and shortened, reflecting an associated disturbance in epiphyseal growth. Osteochondromas usually stop growing at the time of growth plate closure. Malignant changes are rare, and excision of the tumor is done only when necessary.

A *giant cell tumor,* or *osteoclastoma,* is an aggressive tumor that often behaves like a malignant tumor, metastasizing through the bloodstream and recurring locally after excision.[16,36] The tumor is a mixture of mononuclear and multinucleated osteoclast-type giant cells. The mononuclear cells in the tumor express RANKL, and the giant osteoclast-like cells are believed to form via the RANK/RANKL signaling pathway (see Chapter 42).

Giant cell tumors usually arise in people in their twenties to forties.[16] The majority of tumors arise around the knee (distal femur and proximal tibia), but virtually any bone can be involved. The tumor begins in the metaphyseal region, grows into the epiphysis, and may extend into the joint surface. Pathologic fractures are common because the tumor destroys the bone substance. Clinically, pain may occur at the tumor site, with gradually increasing swelling. X-ray films show destruction of the bone with expansion of the cortex. The biologic unpredictability of these tumors complicates their management. Conservative surgery such as curettage is associated with a 40% to 60% recurrence rate; up to 4% metastasize to the lung.[16]

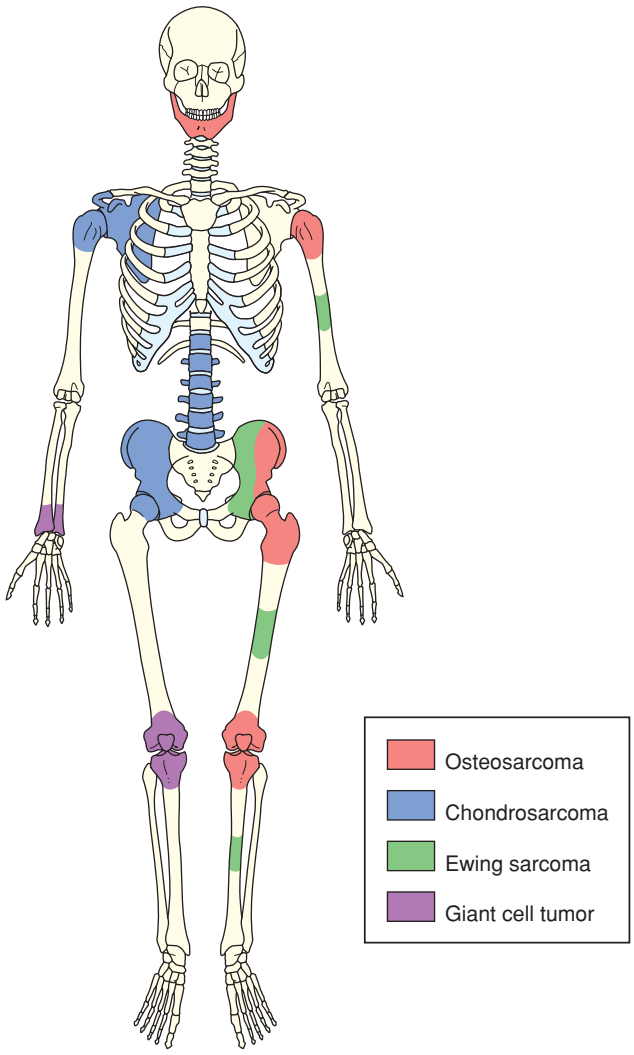

FIGURE 43-10. Common sites of primary malignant bone tumors (chondrosarcoma, osteosarcoma, and Ewing sarcoma) and giant cell tumor, a locally aggressive benign tumor.

Malignant Bone Tumors

In contrast to benign tumors, primary malignant tumors tend to be ill defined, lack sharp borders, and extend beyond the confines of the bone. Primary malignant bone tumors occur in all age groups and may arise in any part of the skeleton. However, certain types of tumors tend to target certain age groups and anatomic sites (Fig. 43-10). For example, most osteogenic sarcomas occur in adolescents and are particularly common around the knee joint. Also, people with certain conditions such as Paget disease are at increased risk for development of bone cancer.

Osteosarcoma

Osteosarcoma is an aggressive and highly malignant bone tumor. It is the most common malignant bone tumor, representing one fifth of all primary bone tumors.[16] The tumor has a bimodal distribution, with

75% occurring in persons younger than 20 years of age.[15] A second peak occurs in the elderly with predisposing factors such as Paget disease, bone infarcts, or prior irradiation. Overall, men are more commonly affected than women.

The cause of osteosarcoma is unknown. The correlation of age and location of most of the tumors with the period of maximum growth suggests some relation to increased osteoblastic activity. In younger persons, the primary tumor most often is located at the anatomic sites associated with maximum growth velocity—the distal femur, proximal tibia, and proximal humerus. Bone tumors in the elderly are more common in the humerus, pelvis, and proximal femur. There are known genetic factors associated with osteosarcoma. Mutations in two genes are reported to increase the susceptibility to the development of osteosarcoma: the retinoblastoma gene (*RB*), a critical cell cycle generator, and the p53 gene, which regulates deoxyribonucleic acid (DNA) repair and certain aspects of cellular metabolism[16] (see Chapter 7).

Osteosarcomas are aggressive tumors that grow rapidly in a circular, ball-like mass in the bone tissue. They often are eccentrically placed in the bone and move from the metaphysis of the bone out into the periosteal surface, with subsequent spread to adjacent soft tissues (Fig. 43-11). These tumors spread through the blood stream; most often, the tumor cells exit the primary tumor through the venous end of the capillary, and early metastasis to the lung is common. Lung metastases, even if massive, usually are relatively asymptomatic. The prognosis for a person with osteosarcoma depends on the aggressiveness of the disease, presence or absence of pathologic fractures, size of the tumor, and rapidity of tumor growth.

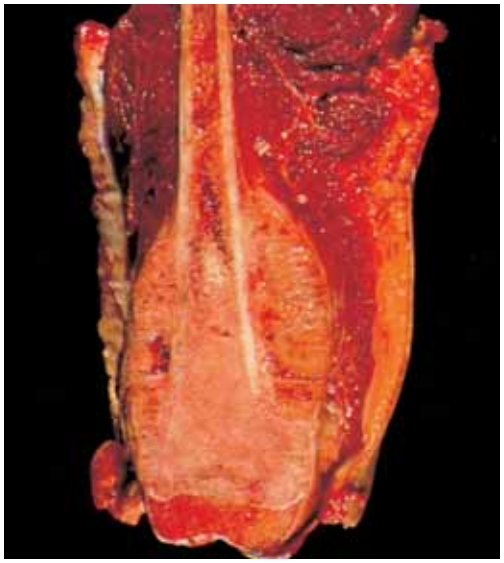

FIGURE 43-11. Osteosarcoma. The distal femur contains a dense osteoblastic malignant tumor that extends through the center in the soft tissue and epiphysis. (From Hoch B.L., Klein M.J., Schiller A.L. [2008]. Bones and joints. In Rubin R., Strayer D.E. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1126]. Philadelphia: Lippincott Williams & Wilkins.)

The primary clinical feature of osteosarcoma is deep, localized pain with nighttime awakening and swelling in the affected bone. Because the pain is often of sudden onset, patients and their families often associate the symptoms with recent trauma.[34] The skin overlying the tumor may be warm, shiny, and stretched, with prominent superficial veins. The range of motion of the adjacent joint may be restricted.

The treatment of osteosarcoma is surgery in combination with multiagent chemotherapy, both before and after surgery.[35,37] In the past, treatment usually entailed amputation above the level of the tumor. Limb salvage surgical procedures, using a metal prosthesis or cadaver allograft, are now a standard alternative. In younger children who undergo arthroplasty, an expandable internal prosthesis is used to allow for bone growth. Amputation is another surgical option. It involves either the removal of expendable bones such as the fibula, toes, or ulna, or the complete removal of the tumor and the affected limb.

Chondrosarcoma

Chondrosarcoma consists of malignant tumors of cartilaginous lineage and is commonly subclassified according to site of origin as central (intramedullary) or peripheral (juxtacortical and surface). Chondrosarcomas can arise as a primary tumor from preexisting benign cartilage tumors such as osteochondroma or chondroblastoma.[38] They commonly arise in the central portions of the skeleton, including the pelvis, shoulder, and ribs.

Chondrosarcomas develop about half as frequently as osteosarcomas. They occur primarily in middle or later life; however, there are chondromas that occur in younger persons. Chondrosarcomas are slow growing and metastasize late, and often are painless. They can remain hidden in an area such as the pelvis for a long period of time. This type of tumor, like many primary malignancies, tends to destroy bone and extend into the soft tissues beyond the confines of the bone of origin.

Early diagnosis is important because chondrosarcomas responds well to early radical surgical excision. It usually is resistant to radiation therapy and available chemotherapeutic agents. Not infrequently, these tumors transform into a highly malignant tumor, mesenchymal chondrosarcoma, which requires a more aggressive treatment, including combination chemotherapy.

Ewing Sarcoma

Ewing sarcoma is a member of a family of tumors that includes Ewing sarcoma and primitive neuroectodermal tumor (PNET). Both tumors are characterized by densely packed, regularly shaped, small cells with round or oval nuclei; and both share a specific reciprocal translocation of chromosomes 11 and 31, or variants thereof.[16,39]

Ewing sarcoma is primarily a disease of children and young adults and is rarely seen in older adults.[39] Males are affected slightly more frequently than females, and white children have an approximately ninefold higher incidence rate than black children.[39] The most frequent

site of Ewing sarcoma is the femur, usually in the diaphysis. The pelvis represents the second most common site; other sites include the pubis, sacrum, humerus, vertebrae, ribs, skull, and other flat bones. Manifestations of Ewing tumor include bone pain, limitation of movement, and tenderness over the involved bone or soft tissue. It often is accompanied by systemic manifestations such as fever or weight loss, which may serve to confuse the diagnosis. There may be a delay in diagnosis when the pain and swelling associated with the tumor are attributed to a sports injury or when the tumor is located in the pelvis and the pain is not localized and the mass is not apparent. Pathologic fractures are common because of bone destruction. The most common sites of metastasis are the lungs, bone marrow, and other bones. Because Ewing sarcoma is a difficult diagnosis to establish, the diagnostic biopsy is very important.

Treatment methods incorporate a combination of multiagent chemotherapy, surgery, and radiation therapy.[39] Multiagent chemotherapy can shrink the tumor rapidly, and is generally given before local control measures are initiated. Ewing sarcoma is considered to be a radiosensitive tumor, and local control may be achieved through radiation or surgery. Patients with small, nonmetastatic, distally located tumors generally have the best prognosis.

Metastatic Bone Disease

Skeletal metastases are the most common malignancy of osseous tissue.[40,41] Approximately half of all people with cancer have bone metastasis at some point in their disease. Metastatic lesions are seen most often in the spine, femur, pelvis, ribs, sternum, proximal humerus, and skull, and are less common in anatomic sites more distant from the trunk of the body. Tumors that frequently spread to the skeletal system are those of the breast, lung, prostate, kidney, and thyroid, although any cancer can ultimately involve the skeleton.

The major symptom of bone metastasis is pain with evidence of an impending pathologic fracture. It usually develops gradually, over weeks, and is more severe at night. Pain is caused by stretching of the periosteum of the involved bone or by nerve entrapment, as when the nerve roots of the spinal cord are compressed by the vertebral body. Symptoms of hypercalcemia may occur in cases of bony destruction.

Radiographic examinations are used along with CT or bone scans to detect, diagnose, and localize metastatic bone lesions. A bone biopsy usually is done when there is a question regarding the diagnosis or treatment. Serum levels of alkaline phosphatase and calcium often are elevated in persons with metastatic bone disease.

The primary goals in treatment of metastatic bone disease are to prevent pathologic fractures and promote survival with maximum functioning, allowing the person to maintain as much mobility and pain control as possible. Standard treatment methods include chemotherapy, irradiation, and surgical stabilization. Radiation therapy is primarily used as a palliative treatment to alleviate pain and prevent pathologic fractures. After a pathologic fracture has occurred, bracing, intramedullary nailing of the femur, or spine stabilization may be done. Because adequate fixation often is difficult, bone cement often is used with internal fixation devices to stabilize the bone.

Recent research has focused on the role of osteoclastic and osteoblastic activity in the pathogenesis of metastatic bone disease and on the use of the bisphosphonates (e.g., pamidronate disodium, zoledronic acid) for its treatment.[40,41] The bisphosphonates, which are now well-established agents for the prevention and treatment of osteoporosis, have recently been shown to decrease symptoms associated with bone metastasis secondary to breast and prostate cancer. These agents bind preferentially to bone at sites of active bone metabolism, are released from the bone matrix during bone resorption, and potentially inhibit osteoclast activity and survival, thereby reducing osteoclast-mediated bone resorption. Recent studies suggest that besides their strong antiosteoclastic activity, these agents may also have some direct antitumor effects.[42]

In summary, bone tumors, like any other type of neoplasm, may be benign or malignant. Both benign and malignant tumors can develop from the cartilage (chondrogenic), bone (osteogenic), and supporting (fibrogenic) elements of bone, and bone tumors are generally classified according to their tissue counterpart. Benign bone tumors grow slowly and usually do not destroy the surrounding tissues. Malignant tumors can be primary or metastatic. Primary bone tumors are rare, grow rapidly, metastasize to the lungs and other parts of the body through the bloodstream, and have a high mortality rate. They include osteosarcoma, which begins in osteogenic cells of the bone and is the most common type of bone cancer; chondrosarcoma, which has its origin in the cartilaginous elements of bone; and Ewing sarcoma, which is characterized by small round cell tumors of bone and soft tissue origin. Advances in chemotherapy, radiation therapy, and surgical procedures have substantially increased the survival and cure rates for many types of bone cancers. Metastatic bone tumors usually are multiple in occurrence, originating primarily from cancers of the breast, lung, and prostate. A primary goal in metastatic bone disease is the prevention of pathologic fractures.

Skeletal Disorders in Children

During childhood, skeletal structures grow in length and diameter and sustain a large increase in bone mass. Alterations in musculoskeletal structure and function may develop as a result of normal growth and developmental processes or as a result of impairment of skeletal development caused by hereditary or congenital influences.

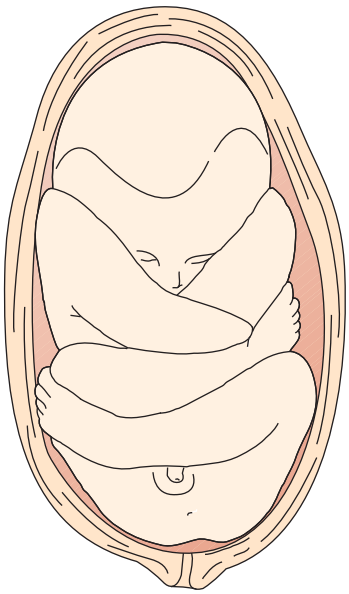

FIGURE 43-12. Position of fetus in utero, with tibial bowing and legs folded. (From Dunne K.B., Clarren S.K. [1986]. The origin of prenatal and postnatal deformities. *Pediatric Clinics of North America* 33, 1282; with permission from Elsevier Science.)

Variations of Normal Growth and Development

Infants and children undergo changes in muscle tone and joint motion during growth and development. Intoeing, outtoeing, bowlegs, and knock-knees occur frequently in infancy and childhood. They usually cause few problems and are corrected during normal growth processes. The normal folded position of the fetus in utero causes physiologic flexion contractures of the hips and a froglike appearance of the lower extremities[43] (Fig. 43-12). The hips are externally rotated and the patellae point outward, whereas the feet appear to point forward because of the internal pulling force of the tibiae. During the first year of life, the lower extremities begin to straighten out in preparation for walking. Internal and external rotations become equal, and the hips extend.

Musculoskeletal assessment of the newborn is important to identify abnormalities that require early intervention, facilitate treatment, establish baselines for future reference, and educate and counsel parents.[44–47] There are many clinical deviations that are easily correctable in a newborn. Many others correct spontaneously as the child grows.

Torsional and Angular Deformities

All infants and toddlers have lax ligaments that become tighter with age and assumption of the weight-bearing posture. The hypermobility that accompanies joint laxity coupled with the torsional, or twisting, forces exerted on the limbs during growth are responsible for a number of variants seen in young children. Torsional forces caused by intrauterine positions or sleeping and sitting patterns twist the growing bones and can produce deformities as a child grows and develops.

Developmental Skeletal Disorders

- Many disorders of early infancy are caused by intrauterine positions and resolve as the child grows.
- All infants and toddlers have lax ligaments that predispose to skeletal disorders caused by twisting or torsional forces.
- Bone growth in infants and children occurs at the epiphysis. Separation of the epiphyseal growth plate ruptures the blood vessels that nourish the epiphysis, causing cessation of growth and shortened extremity length.

In infants, the femur normally is rotated to an anteverted or forward position with the femoral head and neck rotated anteriorly with respect to the femoral condyles. Normally this angle is approximately 30 degrees at birth and declines to 15 degrees by age 10.[48] A second source of rotation is found in the tibia. The normal tibia is externally rotated approximately 5 degrees at birth and 15 degrees at maturity. The abnormalities may be excessive adduction (turning in or toward the body) or abduction (turning out or away from the body).

Intoeing and Outtoeing. The foot progression angle describes the angle between the axis of the foot and the line of progression.[45] It is determined by watching the child walking and running, although it is usually less noticeable when the child is running or barefoot. Figure 43-13 illustrates the position of the foot in intoeing and outtoeing. Inward rotation of the foot is assigned a negative value and outward rotation is assigned a positive value. The normal value in children and adolescents is 10 degrees (range –3 to 20 degrees). The foot progression value serves only to define whether there is an intoeing or outtoeing gait.

Intoeing may be secondary to foot deformities or may be due to inward rotation of the femur or tibia, or a combination of the two.[45] Increased internal torsion of the femur (femoral anteversion) is the most common finding. In many cases intoeing is a variation of normal development. Outtoeing is a common problem in children and is caused by external femoral torsion.[45] Because the femoral torsion persists when a child habitually sleeps in the prone position, an external tibial torsion also may develop. External tibial torsion rarely causes outtoeing; it only intensifies the condition. Outtoeing usually corrects itself as the child becomes proficient in walking.

Intoeing due to a condition called *metatarsus adductus* is a common congenital deformity characterized by forefoot adduction with a normal hindfoot, giving the foot a kidney-shaped appearance[49–51] (Fig. 43-14). It may occur in one foot or both feet. Diagnostic methods

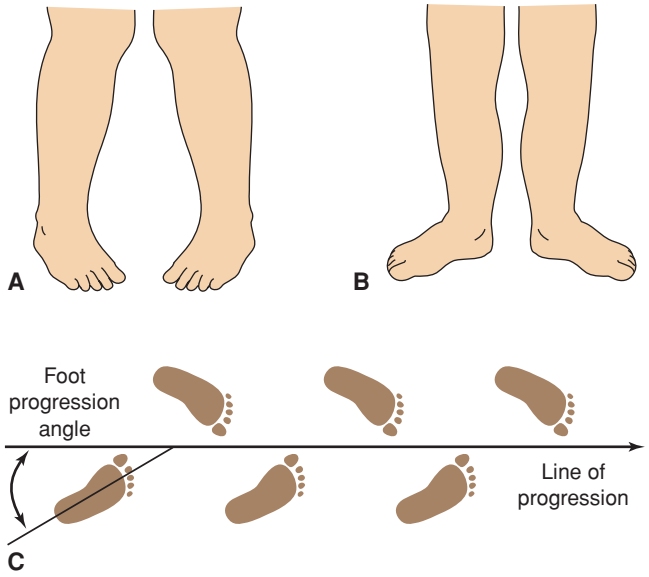

FIGURE 43-13. **(A)** Toeing-in. **(B)** Toeing-out. **(C)** Toeing-in and toeing-out can be determined by watching a child walk and comparing the long axis of the foot with the direction in which the child is walking. If the foot is directed inward, the angle is negative and indicative of in toeing; if it is positive, it is indicative of out toeing.

include examination of the plantar aspect of the foot, noting the overall shape of the foot and the presence or absence of an arch. The severity of the deformity can be determined by assessing the flexibility of the foot and using a heel bisection line. Normally, a line bisecting the heel crosses the forefoot between the second and third toes. In mild metatarsus adductus, the foot is flexible and can be passively manipulated and the line crosses the third toe; in a moderate deformity, the foot is less flexible and the line falls between the third and fourth toes; and in a severe deformity, the foot is more rigid and the line crosses between the fourth and fifth toes. Most infants do not require treatment, although parents are advised to avoid positioning the infant in the prone position with the feet turned in, a position that accentuates metatarsus adductus. Because the condition often corrects itself spontaneously, treatment is usually not instituted until the infant is 6 months of age.[50] When needed, treatment consists of serial long leg casting or a brace that pushes the metatarsals (not the hindfoot) into abduction.

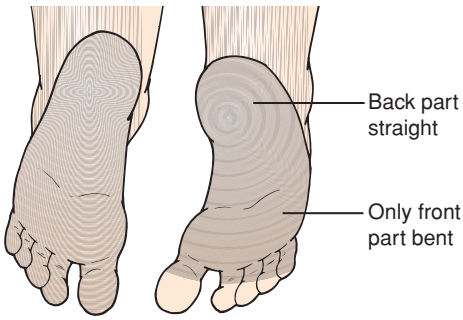

FIGURE 43-14. Shape of foot. The left foot is normal, whereas the right foot has metatarsus adductus.

Femoral Torsion. *Femoral torsion* refers to abnormal variations in hip rotation.[45,48] Hip rotation is measured at the pelvic level with the child in the prone position and the knees flexed at a 90-degree angle (Fig. 43-15A). In this position, the hip is in a neutral position. Rotating the lower leg outward produces internal or medial femoral rotation; rotating it inward produces external or lateral rotation. During measurement of hip rotation, the legs are allowed to fall to full internal rotation by gravity alone; lateral rotation is measured by allowing the legs to fall inward and cross. Hip rotation in flexion and extension also can be measured with CT.

Excessive *internal femoral anteversion* is a normal variant commonly seen during the first 6 years of life, especially in 3- and 4-year-old girls.[45] Characteristically, there is 80 to 90 degrees of internal rotation of the hip in the prone position.[46] The condition is thought to be related to increased laxity of the anterior capsule of the

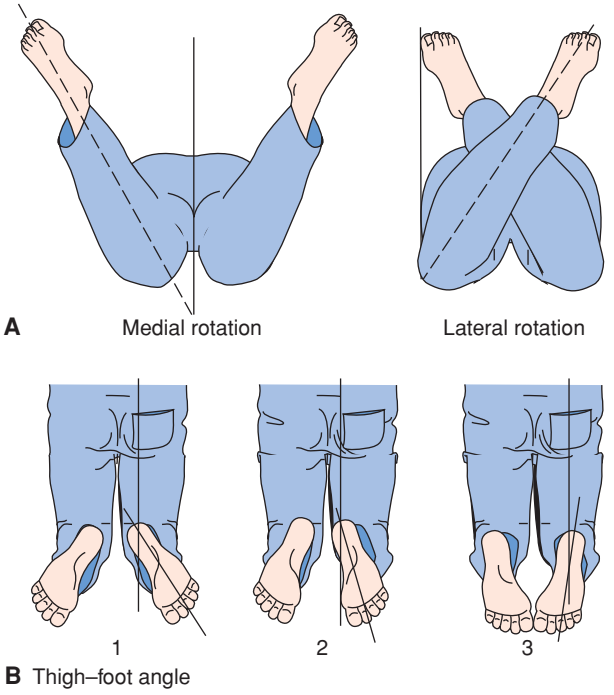

FIGURE 43-15. **(A)** Hip rotation is measured with the child prone and knees flexed at a 90-degree angle. On outward rotation the leg produces internal (medial) hip and femoral rotation; on inward rotation the leg produces external hip and femoral rotation. **(B)** Assessment for tibial torsion using thigh–foot angle. When the child is in the prone position with the knee flexed, with normal alignment there is slight external rotation (2); internal tibial torsion produces inward rotation (3); external tibial torsion produces outward rotation (1). (Adapted from Staheli L.T. [1986]. Torsional deformity. *Pediatric Clinics of North America* 33, 1378; and Kliegman R.M., Neider M.I., Super D.M. [Eds.]. [1996]. *Practical strategies in pediatric diagnosis and therapy.* Philadelphia: W.B. Saunders.)

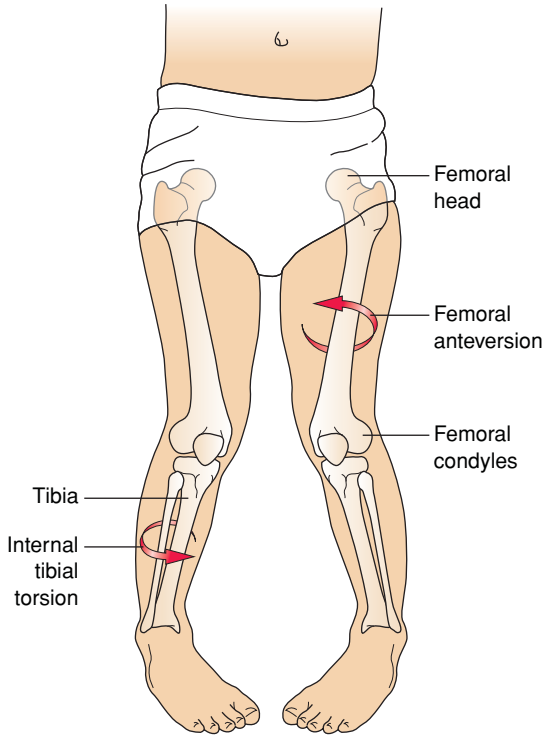

FIGURE 43-16. Femoral anteversion and internal tibial rotation. Femoral anteversion normally decreases from about 40 degrees at birth to 15 degrees at maturity, and internal tibial rotation from 5 degrees at birth to 15 degrees at maturity.

hip such that it does not provide the stable pressure needed to correct the anteversion that is present at birth. Children are most comfortable sitting in the "W" position, with their hips between their knees. It is believed that this position allows the lower leg to act as a lever, producing torsional changes in the femur. When the child stands, the knees turn in and the feet appear to point straight ahead, and when the child walks, the knees and toes point in (Fig. 43-16). Children with this problem are encouraged to sit cross-legged or in the so-called *tailor position* (with the knees touching and the legs folded under). If left untreated, the tibiae compensate by becoming externally rotated so that by 8 to 12 years of age, the knees may turn in but the feet no longer do so. This can result in patellofemoral malalignment with patellar subluxation or dislocation and pain.[48] A derotational osteotomy may be done in severe cases or if there is functional disability.

External femoral torsion is an uncommon disorder characterized by excessive external rotation of the hip. Bilateral external torsion is usually a benign condition, and treatment is observational. When the disorder is unilateral, slipped capital femoral epiphysis should be excluded (to be discussed).[45]

Tibial Torsion. Tibial rotation is determined by measuring the thigh–foot angle, which is done with the ankle and knee positioned at 90 degrees (see Fig. 43-15B). The angle is formed between the longitudinal axis of the femur and the longitudinal axis of the foot. Inward rotation, which is assigned a negative value, indicates internal tibial torsion, and outward rotation, which is given a positive value, represents external tibial rotation. Infants normally have a mean angle of –5 degrees as a consequence of normal in utero position.[45] In midchildhood through adult life the mean angle increases to about 10 degrees.

Internal or medial tibial torsion (i.e., bowing of the tibia) is a rotation of the tibia that makes the feet appear to turn inward. It is the most common cause of intoeing in children younger than 2 years of age.[45] It is present at birth and may fail to correct itself if children sleep on their knees with the feet turned in, or sit on in-turned feet. It is thought to be caused by genetic factors and intrauterine compression, such as an unstretched uterus during a first pregnancy or intrauterine crowding with twins or multiple fetuses. Tibial torsion improves naturally with growth, but this may take several years.[46]

External or *lateral tibial torsion* is a much less common disorder. It is usually seen between 4 and 7 years of age, and is often unilateral.[46] The natural growth rotates the tibia externally, and hence external tibial rotation can become worse with time.[45,46] Clinically, the patella faces outward when the foot is straight. There may be associated patellofemoral instability with knee pain. Although some correction may occur with growth, extremely symptomatic children may require surgical correction, which is usually done after 10 years of age.

Genu Varum and Genu Valgum

Genu varum and genu valgus are common pediatric deformities of the knee. As children grow, lower limb alignment usually follows a predicable pattern (Fig. 43-17). *Genu varum,* or *bowlegs,* is an outward bowing of the knees greater than 1 inch when the medial malleoli of the ankles are touching. Most infants and toddlers have some bowing of their legs up to 18 months of age. If there is a large separation between the knees (>15 degrees) after 2 years of age, the child may require bracing. The child also should be evaluated for diseases such as rickets or tibia vara (i.e., Blount disease, to be discussed).[48]

Genu valgum, or *knock-knees,* is a deformity in which there is decreased space between the knees.[52,53] The medial malleoli in the ankles cannot be brought in contact with each other when the knees are touching. Valgus gradually develops after age 24 months and is most apparent between 3 and 4 years of age (see Fig. 43-17). By 7 years of age, the lower limb is in slight valgus and changes very little thereafter. Genu valgum can be ignored up to 7 years of age, unless it is more than 15 degrees, unilateral, or associated with short stature. It usually resolves spontaneously and rarely requires treatment. Genu varum can cause gait awkwardness and increased risk for sprains and fractures. Uncorrected genu valgum may cause subluxation and recurrent dislocation of the patella, with a predisposition to chondromalacia and joint pain and fatigue. If genu varum or genu valgum persists and is uncorrected, osteoarthritis

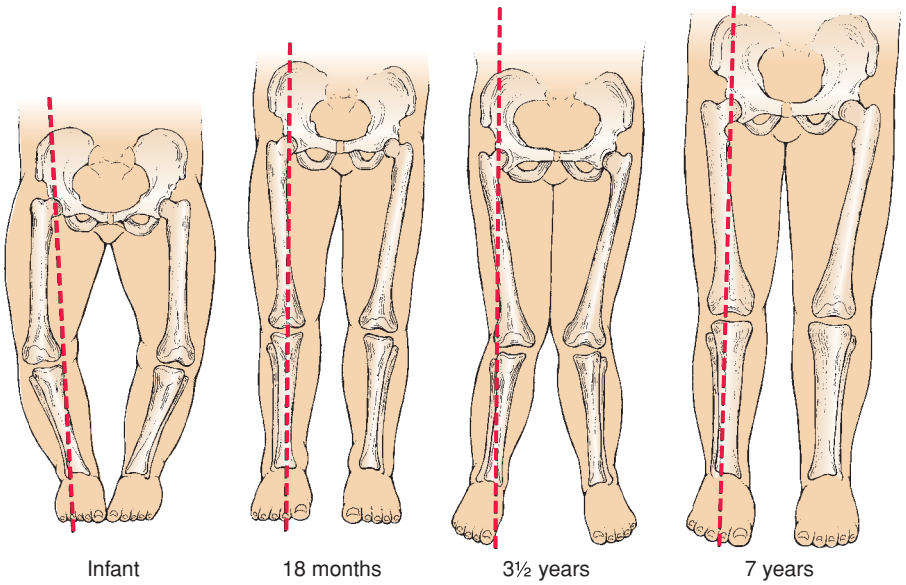

FIGURE 43-17. Lower limb alignment follows a predictable pattern. Infants typically have a gentle varus bow throughout the femur and tibia. By 18 to 24 months, the lower leg is nearly straight, with a neutral mechanical axis. Valgus gradually develops and is most apparent between 3 and 4 years of age. By 7 years of age, the lower limb is in slight valgus and changes very little thereafter. Varus should not recur, nor should valgus increase. (From Schoeneker P.L., Rich M.M. [2006]. The lower extremity. In Morissy R.T., Weinstein S.L. [Eds.], *Lovell & Winter's pediatric orthopaedics* [6th ed., pp. 1158–1213]. Philadelphia: Lippincott Williams & Wilkins.)

may develop in adulthood as a result of abnormal intra-articular stress.

Idiopathic tibia vara, or *Blount disease,* is an abnormal pathologic, developmental bowing that results from altered growth of the upper medial epiphysis[45,48,52] (Fig. 43-18). Although the cause of tibia vara remains unknown, it may occur secondary to growth suppression from increased compression forces across the medial aspect of the knee. Blount disease is more common in obese children who are early walkers. It is also more common in black children. It may be unilateral, in contrast to physiologic bowing, which is almost always bilateral. It has been classified into three types, dependent on the age of onset: infantile (1 to 3 years of age), juvenile (4 to 10 years of age), and adolescent (11 years or older). The juvenile and adolescent forms are commonly combined as late-onset tibia vara.

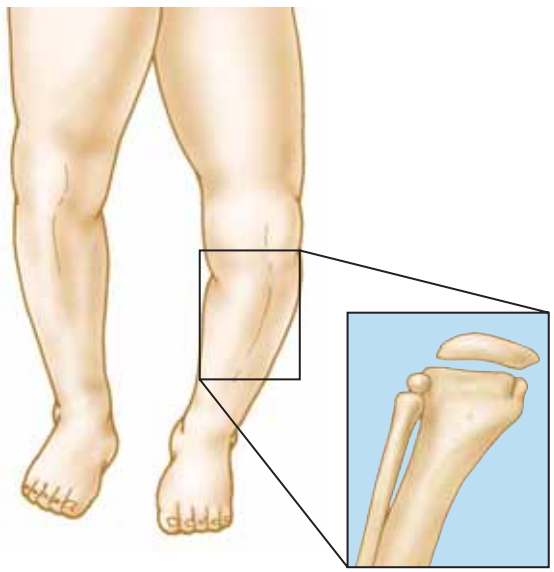

FIGURE 43-18. Rotational deformity of the proximal tibia, especially when unilateral, suggests tibia vera (Blount disease).

The infantile form of tibia vara, which is commonly bilateral, is the most common. Untreated infantile tibia vara is almost always progressive, with evidence of outward angulation, flexion, internal rotation, and abnormal lateral knee laxity. There is radiographic evidence of progressive depression of the medial metaphysis, the growth plate, and the epiphysis. Fusion of the metaphysis to the epiphysis may occur in severe cases. Night-brace treatment is used for mild early-onset disease. Valgus rotational osteotomy of the tibia is usually indicated if angulation persists beyond 3 years of age. Persistent tibia vara leads to early degenerative changes of the knee.

Late-onset Blount disease is more common in obese boys, who are of normal or greater-than-normal height. The condition may be bilateral or unilateral and is often characterized by pain rather than deformity as the primary initial complaint.[44] Radiography shows medial femoral and tibial bowing. Bracing is not practical in obese adolescents. Treatment includes osteotomy to realign the limb or lateral growth plate closure to allow growth to "catch up" medially.[48]

Hereditary and Congenital Disorders

Congenital skeletal deformities can be caused by many factors, including hereditary influences, external agents that injure the fetus (e.g., radiation, alcohol, drugs, viruses), and intrauterine environmental factors. They range in severity from mild limb deformities, which are relatively common, to major limb malformations, which are relatively rare. The most common anomaly of the toes or fingers is *polydactyly,* or the presence of an extra digit on the hand or foot. There may also be a simple webbing of the fingers or toes (syndactyly) or the absence of a bone such as the phalanx, rib, or clavicle. Joint contractures and dislocations produce more severe deformity, as does the absence of entire bones, joints, or limbs.

Osteogenesis Imperfecta

Osteogenesis imperfecta, or brittle bone disease, is a hereditary disorder caused by deficiencies in the synthesis of type I collagen.[15,16,54] It is one of the most common hereditary bone diseases, with an occurrence rate of approximately 1 case in 20,000 births.[54] Although it is usually transmitted as an autosomal trait, a distinctive form of the disorder with multiple lethal defects is thought to be transmitted as an autosomal recessive trait.[16,54] In some cases, the disorder is caused by a spontaneous mutation.

The clinical manifestations of osteogenesis imperfecta include a spectrum of disorders marked by extreme skeletal fragility. Four major subtypes of the disorder have been identified[16] (Table 43-2). The disorder is characterized by thin and poorly developed bones that are prone to multiple fractures. These children have short limbs and a soft, thin cranium with bifrontal prominences that give a triangular appearance to the face. Other problems associated with defective connective tissue synthesis include thin skin, blue or gray sclera, abnormal tooth development, hypotonic muscles, loose-jointedness, scoliosis, and a tendency toward hernia formation. Hearing loss due to otosclerosis of the tiny bones in the middle ear is common in affected adults.

The most serious defects occur when the disorder is inherited as a recessive trait (type II). Severely affected fetuses have multiple intrauterine fractures and bowing and shortening of the extremities. Many of these infants are stillborn or die during infancy. Less severe forms occur when the disorder is inherited as a dominant trait. The skeletal system is not as weakened, and fractures often do not appear until the child becomes active and starts to walk, or even later in childhood. These fractures heal rapidly, although with a poor-quality callus. In some cases, parents may be suspected of child abuse when the child is admitted to the health care facility with multiple fractures. There also is an increased incidence of complications such as hernias and congenital heart abnormalities.

There is no definitive treatment for correction of the defective collagen synthesis that is characteristic of osteogenesis imperfecta. However, a short course of treatment with bisphosphonates has been shown to produce an increase in cortical bone width and cancellous bone volume, as well as increased bone strength and mineral content. In children treated with intravenous pamidronate, this has led to a decrease in fractures, improvements in mobility, and less pain.[54,55] Prevention and treatment of fractures is important. Precise alignment is necessary to prevent deformities. Nonunion is common, especially with repeated fractures. Surgical intervention often is needed to stabilize fractures and correct deformities (e.g., internal fixation of long bones may be done with an intramedullary rod that "grows" with the child).

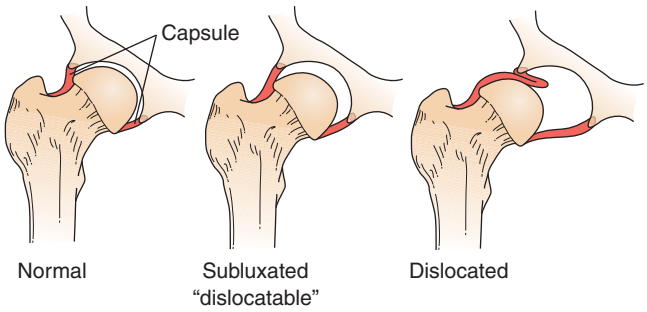

FIGURE 43-19. Normal **(left)** and abnormal relationships of hip joint structure in subluxation **(middle)** and dislocation **(right)**.

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH), formerly known as *congenital dislocation of the hip*, is an abnormality in hip development that leads to a wide spectrum of hip problems in infants and children, including hips that are unstable, malformed, subluxated, or dislocated.[48,56,57] In less severe cases, the hip joint may be unstable, with excessive laxity of the joint capsule, or subluxated, so that the joint surfaces are separated and there is a partial dislocation (Fig. 43-19). With dislocated hips, the head of the femur is located outside of the acetabulum.

TABLE 43-2 Types of Osteogenesis Imperfecta

Type	Subtype	Inheritance	Major Features
I	Postnatal fractures, blue sclera	Autosomal dominant	Normal stature, skeletal fragility, hearing impairment, joint laxity, blue sclera
II	Perinatal, lethal	Autosomal recessive	Death in utero, or in days after birth Skeletal deformity with excessive fragility, multiple fractures, blue sclera
III	Progressive deformity	Autosomal dominant (75%) Autosomal recessive (25%)	Growth retardation, multiple fractures, progressive kyphoscoliosis, hearing impairment, blue sclera at birth
IV	Postnatal fractures, normal sclera	Autosomal dominant	Moderate skeletal fragility, short stature

Developed from Kumar V., Abbas A. K., Fausto N., Aster V. C. (2010). *Robbins pathologic basis of disease* (8th ed., p. 1212). Philadelphia: Elsevier Saunders.

The results of newborn screening programs have shown that up to 1 of 250 infants have some evidence of hip instability, whereas actual dislocation of the hip is less common, being found in 1 to 1.5 of every 1000 live births.[56] The left hip is involved more frequently than the right hip because of the left occipital intrauterine positioning of most infants. The disorder occurs most frequently in first-born children and is six times more common in female than in male infants.[48] The cause of DDH is multifactorial, with heredity, environmental, and mechanical factors playing a role. A positive family history and generalized laxity of the ligaments are related. The increased frequency in girls is thought to result from their susceptibility to maternal estrogens and other hormones associated with pelvic relaxation. Dislocation also may result from environmental factors such as fetal position, a tight uterus that prevents fetal movement, and breech delivery. The presence of other congenital abnormalities is associated with an increased incidence of DDH. Thus, the hips of children presenting with congenital abnormalities should be examined carefully.

Early diagnosis of DDH is important because treatment is easiest and most effective if begun during the first 6 months of life. Also, repeated dislocations cause damage to the femoral head and the acetabulum. In infants, signs of DDH include asymmetry of the hip or gluteal folds, shortening of the thigh so that one knee (on the affected side) is higher than the other hip, and limited abduction of the affected hip[56,57] (Fig. 43-20). The asymmetry of gluteal folds is not definitive but indicates the need for further evaluation. Physical examination remains the key to the diagnosis of DDH. However, the U.S. Preventive Services Task Force (USPSTF) recently concluded that evidence was insufficient to recommend routine screening of asymptomatic infants as a means of preventing adverse outcomes.[58] This recommendation applies only to infants who do not have obvious hip dislocation or other abnormalities evident without screening.

Several examination techniques can be used to screen for a dislocatable hip. Two provocative dynamic tests for assessing hip stability in the newborn are the Ortolani maneuver (for reducible dislocation) and the Barlow maneuver (for the dislocatable hip)[8,56,57] (Fig. 43-21). The Galeazzi test is a measurement of the length of the femurs that is done by comparing the height at the knees while they are flexed at 90 degrees. An inequality in the height of the knees is a positive Galeazzi sign and is usually caused by hip dislocation or congenital femoral shortening. This test is not useful in detecting bilateral DDH because both leg lengths will be equal. In an older child, instability of the hip may produce a delay in standing or walking and eventually cause a characteristic waddling gait. When the thumbs are placed over the anterior iliac crest and the hands are placed over the lateral pelvis in examination, the levels of the thumbs are not even; the child is unable to elevate the opposite side of the pelvis (positive Trendelenburg test).

Diagnosis of DDH is confirmed by ultrasonography or radiography. Ultrasonography is used in infants with high-risk factors (e.g., female infants born in the breech position) or an abnormal result on examination.[48,56,57] Radiographs of newborns with suspected DDH are of limited value because the femoral heads do not ossify until 4 to 6 months of age. After 6 months of age, the

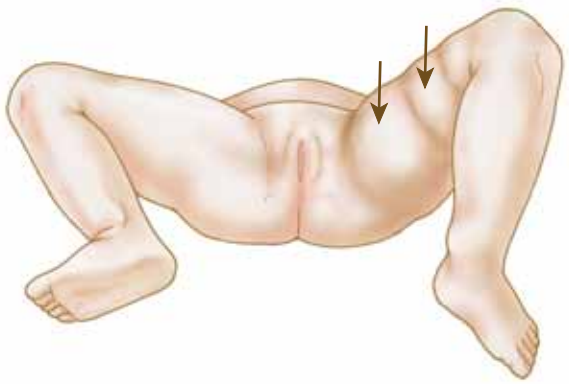

FIGURE 43-20. Congenital dysplasia of the left hip with shortening of the femur, as indicated by legs in abduction and asymmetric gluteal and thigh folds (*arrows*).

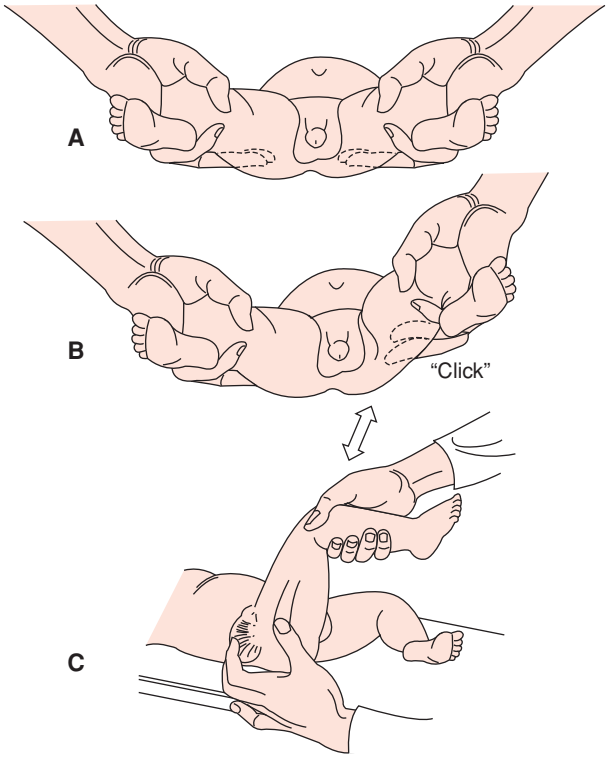

FIGURE 43-21. Examination for developmental dysplasia of the hip. **(A)** In the newborn, both hips can be equally flexed, abducted, and externally rotated without producing a "click." **(B)** A diagnosis of congenital dislocation of the hip may be confirmed by the Ortolani "click" test. The involved hip cannot be abducted as far as the opposite one, and there is a "click" as the hip reduces. **(C)** Telescoping of the femur to aid in the diagnosis of a congenitally dislocated hip. (From Hoppenfeld S. [1976]. *Physical examination of the spine and extremities.* New York: Appleton-Century-Crofts.)

increasing ossification of the femur renders ultrasonography less reliable, and radiographs are preferred.

Treatment of DDH should be individualized and depends on whether the hip is subluxated or dislocated. Subluxation of the hip at birth often resolves without treatment and should be observed for 2 weeks. When subluxation persists beyond this time, treatment may be indicated and referral is recommended. The best results are obtained if the treatment is begun before changes in the hip structure (e.g., 2 to 3 months) prevent it from being reduced by gentle manipulation or abduction devices. The Pavlik harness is used on newborns (up to 6 months) to maintain the femoral head in the acetabulum.[8,48,56,57] The principal goals for treatment of children 6 months to 2 years of age are to obtain and maintain reduction of the hip without damaging the femoral head. Closed reduction is often performed under general anesthesia, followed by several months of immobilization in a hip spica cast, plaster splints, or an abduction splint. Surgical treatment may be required for children who fail to maintain a stable hip with closed reduction methods. The most serious complication of any treatment is avascular necrosis of the femoral head as a result of the forced abduction.[56] This most often occurs as a complication of a closed or open reduction in an older child. In addition, hyperflexion has the potential to cause femoral nerve palsies.

Congenital Clubfoot

Clubfoot, or talipes, is one of the most common pediatric orthopedic conditions. The clubfoot deformity may be positional, congenital, or associated with a variety of other underlying congenital conditions. The positional clubfoot is a normal foot that has been held in a deformed position in utero and is found to be flexible on examination in the nursery. The congenital clubfoot involves a spectrum of severity, while the clubfoot associated with other congenital conditions is typically rigid and difficult to treat.

Congenital clubfoot has an incidence of approximately 1 to 2 cases per 1000 live births, is bilateral in about 50% of cases, and affects boys more often than girls.[50–52] Like congenital dislocation of the hip, its occurrence follows a multifactorial inheritance pattern. Clubfoot may be associated with chromosomal abnormalities or congenital syndromes that are transmitted by mendelian inheritance patterns. However, it is most commonly idiopathic and found in normal infants in whom no genetic or chromosomal abnormality or other extrinsic cause can be found.

In forefoot adduction, which accounts for approximately 95% of idiopathic cases, the foot is plantar flexed and inverted or twisted toward the midline of the leg. This is the so-called *equinovarus type* of clubfoot (Fig. 43-22). The other 5% of cases are of the equinovalgus type, or reverse clubfoot, in which the foot is dorsiflexed and everted. The reverse clubfoot can occur as an isolated condition or in association with multiple congenital defects. At birth, the feet of many infants assume one of these two positions, but they can be passively

FIGURE 43-22. Newborn with clubbing of the left foot. (From the Centers for Disease Control and Prevention Public Health Images Library. ID#: 2632. [Online] Available: http://phil.cdc.gov/phil/detail.asp.)

overcorrected or brought back into the opposite position. If the foot cannot be overcorrected, some type of correction may be necessary.

Treatment of clubfoot is begun as soon as the diagnosis is made. When treatment is initiated during the first few weeks of life, a nonoperative procedure may be effective. Serial manipulations and casting are used gently to correct each component of the deformity. One method, called the *Ponseti method*, involves weekly gentle stretching and manipulation of the misaligned bones followed by application of a well-molded long leg plaster cast with the knee held at a right angle.[59] The cast maintains the correction and allows for further relaxation of tight structures in anticipation of the next week's casting. Correction of the deformity is usually obtained within 6 to 8 weeks. Frequently, a percutaneous Achilles tendon lengthening is performed using a topical anesthetic cream before application of the final cast to allow for complete correction of the equinus deformity. The correction is maintained by full-time wear of a Denis Browne splint for 3 months and part-time wear during napping and at night for approximately 2 to 3 years.[59] Surgery may be required for severe deformities or when nonoperative treatment methods are unsuccessful. It is performed most commonly between 6 and 12 months of age.[48,50]

Juvenile Osteochondroses

The term *juvenile osteochondroses* is used to describe a group of children's diseases in which one or more growth ossification centers undergo a period of degeneration, necrosis, or inactivity that is followed by regeneration and usually deformity. The osteochondroses are separated

into two groups according to their causes. The first group consists of the true osteonecrotic osteochondroses, so called because the diseases are caused by localized osteonecrosis of an apophyseal or epiphyseal center (e.g., Legg-Calvé-Perthes disease, Freiberg infraction, Panner disease, Kienböck disease). The second group of juvenile osteochondroses is caused by abnormalities in ossification of cartilaginous tissue resulting from a genetically determined normal variation or from trauma (e.g., Osgood-Schlatter disease, Blount disease, Sever disease, Scheuermann disease). The discussion in this section focuses on Legg-Calvé-Perthes disease from the first group and Osgood-Schlatter disease from the second group. Slipped capital femoral epiphysis is a disorder of the growth plate.

Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes disease is an idiopathic osteonecrotic disease of the proximal (capital) femoral epiphysis with later reabsorption.[48,56,60,61] The disorder usually, but not exclusively, affects children between the ages of 4 and 8 years. Boys are affected four to five times as often as girls and 10% to 5% of all cases are bilateral. Although no definite genetic pattern has been established, it occasionally affects more than one family member.

The cause of Legg-Calvé-Perthes disease is unknown. The disorder usually is insidious in onset and occurs in otherwise healthy children. It may, however, be associated with acute trauma. Affected children usually have a shorter stature. Recent evidence indicates that some cases may be caused by a subclinical hypercoagulable state such as deficiency in antithrombotic factors S or C or a decrease in fibrinolysis.[48,56] When girls are affected, they usually have a poorer prognosis than boys because they are skeletally more mature and have a shorter period for growth and remodeling than boys of the same age.

The primary pathologic feature of Legg-Calvé-Perthes disease is an avascular necrosis of the bone and marrow involving the epiphyseal growth center in the femoral head. The disorder may be confined to part of the epiphysis, or it may involve the entire epiphysis. In severe cases, there is a disturbance in the growth pattern that leads to a broad, short femoral neck. The necrosis is followed by slow absorption of the dead bone over 2 to 3 years. Although the necrotic trabeculae eventually are replaced by healthy new bone, the epiphysis rarely regains its normal shape.

The main symptoms of Legg-Calvé-Perthes disease are pain in the groin, thigh, or knee and difficulty in walking. The child may have a painless limp with limited abduction and internal rotation and a flexion contracture of the affected hip. The age of onset is important because young children have a greater capability for remodeling of the femoral head and acetabulum, and thus less flattening of the femoral head occurs. Early diagnosis is important and is based on correlating physical symptoms with radiographic findings that are related to the stage of the disease.

The goal of treatment is to reduce deformity and preserve the integrity of the femoral head. Conservative and surgical interventions are used in the treatment of Legg-Calvé-Perthes disease. Children younger than 4 years of age with little or no involvement of the femoral head may require only periodic observation. In all other children, some intervention is needed to relieve the force of weight bearing, muscular tension, and subluxation of the femoral head. It is important to maintain the femur in a well-seated position in the concave acetabulum to prevent deformity. This is done by keeping the hip in abduction and mild internal rotation. Treatment involves periods of rest, use of assistive devices for walking, non–weight bearing, and abduction braces to keep the legs separated in abduction with mild internal rotation. The Atlanta Scottish Rite brace, which does not extend below the knee, is the most widely used orthosis because it provides containment while allowing free knee motion and ambulation without crutches or external support[48,56] (Fig. 43-23). Surgery may be done to contain the femoral head in the acetabulum. This treatment usually is reserved for children older than 6 years of age who at the time of diagnosis have more serious involvement of the femoral head. The best surgical results are obtained when surgery is done early, before the epiphysis becomes necrotic.

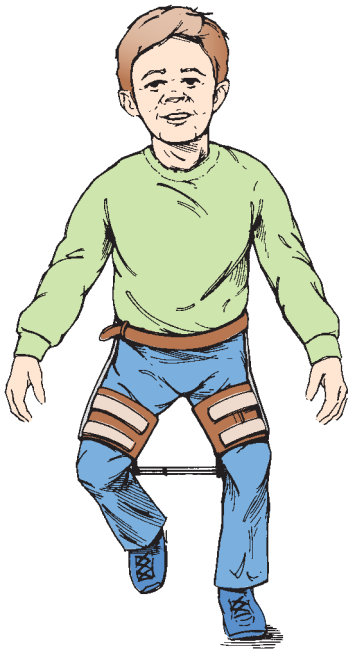

FIGURE 43-23. Scottish Rite brace for Legg-Calvé-Perthes disease produces containment for abduction and allows free knee motion. (From Crocetti M., Barone M.A. [2004]. *Oski's essential pediatrics* [2nd ed., p. 679]. Philadelphia: Lippincott Williams & Wilkins.)

Osgood-Schlatter Disease

Osgood-Schlatter disease involves microfractures in the area where the patellar tendon inserts into the tibial tubercle.[48,53] This area, which is an extension of the proximal tibial epiphysis, is particularly vulnerable to injury caused by sudden or continued strain from the patellar tendon during periods of growth. It occurs most

frequently in boys between the ages of 10 and 15 years and in girls about 2 years before that in boys.[53]

The disorder is characterized by pain in the front of the knee that is associated with inflammation and thickening of the patellar tendon. The pain usually is associated with specific activities such as kneeling, running, bicycle riding, or stair climbing. There is swelling, tenderness, and increased prominence of the tibial tubercle. The symptoms usually are self-limiting. They may recur during growth periods, but usually resolve after closure of the tibial growth plate.

Treatment consists of rest, restriction of activities, and occasionally a knee immobilizer. Complete resolution of symptoms through healing (physical closure) of the tibial tubercle usually requires 12 to 24 months.[53] Occasionally, minor symptoms or an increased prominence of the tibial tubercle may continue into adulthood.

Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis, or coxa vara, is a disorder of the growth plate that occurs near the age of skeletal maturity.[48,56] It involves a three-dimensional displacement of the epiphysis (posteriorly, medially, inferiorly), meaning that the femur is rotated externally from under the epiphysis. It is considered the most common hip disorder of adolescence with an increased prevalence among males, most often between 12 and 15 years of age.[56]

The cause of slipped capital femoral epiphysis is obscure, but it may be related to the child's susceptibility to stress on the femoral neck as a result of genetics or structural abnormalities. Affected children often are overweight with poorly developed secondary sex characteristics, or, in some instances, are extremely tall and thin. In many cases, there is a history of rapid skeletal growth preceding displacement of the epiphysis. The condition also may be affected by nutritional deficiencies or endocrine disorders such as hypothyroidism, hypopituitarism, and hypogonadism. Rapid growth after administration of growth hormone has been associated with displacement of the epiphysis.

Children with the condition often complain of referred knee pain accompanied by difficulty in walking, fatigue, and stiffness. The diagnosis is confirmed by radiographic studies in which the degree of slipping is determined and graded according to severity (mild, <33%; moderate, 33% to 50%; and severe, >50%).[48] Early treatment is imperative to prevent further slippage and permanent deformity. Avoidance of weight bearing on the femur and bed rest are essential parts of the treatment. Traction or gentle manipulation under anesthesia is used to reduce the slip. Surgical insertion of pins to keep the femoral neck and head of the femur aligned is a common method of treatment for children with moderate or severe slips. Crutches are used for several months after surgical correction to prevent full weight bearing until the growth plate closes.

Children with the disorder must be followed closely until the epiphyseal plate closes. Long-term prognosis depends on the amount of displacement that occurs. Complications include avascular necrosis, leg shortening, malunion, and problems with internal fixation. Degenerative arthritis may develop, requiring joint replacement later in life.

Scoliosis

Scoliosis is a lateral curvature of the spine in the upright position. Scoliosis is classified as postural or structural. With postural scoliosis, there is a small curve that corrects with bending. It can be corrected with passive and active exercises. Structural scoliosis does not correct with bending. It is a fixed deformity classified according to the cause: congenital, neuromuscular, or idiopathic. The majority of scoliotic deformities are idiopathic. Others can be congenital, associated with neuromuscular disorders or intraspinal deformities, or are caused by compensation for leg-length discrepancy.[62]

Congenital Scoliosis

Congenital scoliosis is caused by disturbances in vertebral development during the sixth to eighth weeks of embryologic development.[63,64] Congenital scoliosis may be divided into failures of formation and failures of segmentation. Failures of formation indicate the absence of a portion of the vertebra, such as hemivertebra (absence of a whole side of the vertebra) and wedge vertebra (missing only a portion of the vertebra). Failure of segmentation is the absence of the normal separation between the vertebrae. The child may have other anomalies and neurologic complications if the spine is involved. Early diagnosis and treatment of progressive curves are essential for children with congenital scoliosis. Surgical intervention is the treatment of choice for progressive congenital scoliosis.

Neuromuscular Scoliosis

Neuromuscular scoliosis develops from neuropathic or myopathic diseases. It is seen with cerebral palsy, myelodysplasia, and poliomyelitis. There is often a long, C-shaped curve from the cervical to the sacral region. In children with cerebral palsy, severe deformity may make treatment difficult. Myopathic neuromuscular scoliosis develops with Duchenne muscular dystrophy and usually is not severe.

Idiopathic Scoliosis

Idiopathic scoliosis is a structural spinal curvature for which no cause has been established. It occurs in healthy, neurologically normal children. Although the incidence is only slightly greater in girls than boys, it is more likely to progress and require treatment in girls.[8,62–64] The cause is most likely complex and multifactorial. It seems likely that heredity is involved because mother–daughter pairings are common, but identical twins are not uniformly affected. The magnitude of the curvature in an affected individual is not related to magnitude of curvature in relatives. A recent study of the melatonin receptor 1B (*MTNR1B*) gene in persons with adolescent idiopathic scoliosis suggests that the

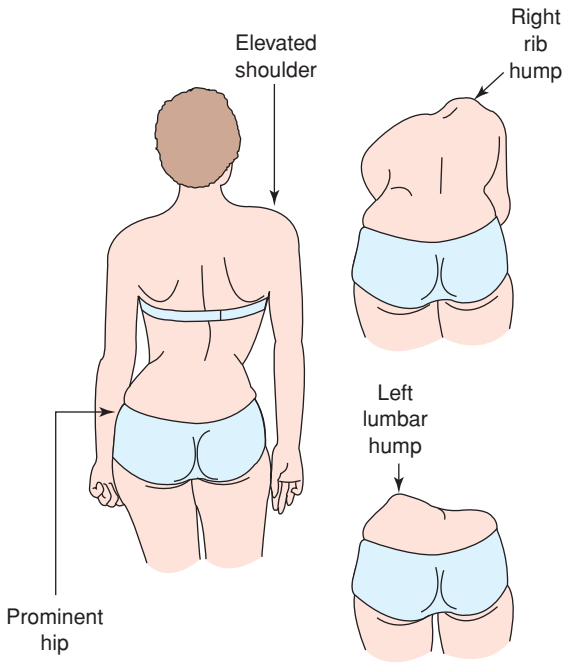

FIGURE 43-24. Scoliosis: abnormalities to be determined at initial screening examination. (From Gore D.R., Passehl R., Sepic S., et al. [1981]. Scoliosis screening: Results of a community project. *Pediatrics* 67, 196–200. Copyright © 1981 by the American Academy of Pediatrics.)

MTNR1B gene may serve as a susceptibility gene for adolescent idiopathic scoliosis.[65]

Idiopathic scoliosis usually appears clinically between the age of 10 and skeletal maturity, but may be seen at any age. By definition, the curve must be greater than 10 degrees. (This has been used historically because 10 degrees is the limit that can be detected by physical examination.)[8] Although a scoliotic curve may be present in any area of the spine, the most common curve is a right thoracic curve.

Manifestations. Scoliosis usually is first noticed because of the deformity it causes. A high shoulder, prominent hip, or projecting scapula may be noticed by a parent or in a school-based screening program (Fig. 43-24). In girls, difficulty in hemming or fitting a dress may call attention to the deformity. Idiopathic scoliosis usually is a painless process, although pain may be present in severe cases, usually in the lumbar region. The pain may be caused by pressure on the ribs or on the crest of the ilium. There may be shortness of breath as a result of diminished chest expansion and gastrointestinal disturbances from crowding of the abdominal organs. Adults with less severe deformity may experience mild backache. If scoliosis is left untreated, the curve may progress to an extent that compromises cardiopulmonary function and creates a risk for neurologic complications.

Diagnosis and Treatment. Early diagnosis of scoliosis can be important in the prevention of severe spinal deformity. The cardinal signs of scoliosis are uneven shoulders or iliac crest, prominent scapula on the convex side of the curve, malalignment of spinous processes, asymmetry of the flanks, asymmetry of the thoracic cage, and rib hump or paraspinal muscle prominence when bending forward (see Fig. 43-24). A complete physical examination is necessary for children with scoliosis because the defect may be indicative of other, underlying pathologic processes.

Diagnosis of scoliosis is made by physical examination and confirmed by radiography. A scoliometer should be used at the apex of the curvature to quantify a prominence; a scoliometer reading of greater than 10 degrees requires referral to a physician. The curve is measured by determining the amount of lateral deviation present on radiographs and is labeled "right" or "left" for the convex portion of the curve. Other radiographic procedures may be done, including CT scanning, MRI, and myelography.

Although school screening continues to be mandated in a number of states, the USPSTF recommends against the routine screening of asymptomatic adolescents for idiopathic scoliosis, indicating that the potential harms from screening include unnecessary follow-up visits and evaluations due to false-positive results, and adverse psychological effects, especially related to brace wear.[66] It is recommended, however, that health care professionals be prepared to evaluate idiopathic scoliosis when it is discovered incidentally or when an adolescent or parent expresses concern about scoliosis.

The treatment of scoliosis depends on the severity of the deformity and the likelihood of curve progression. The three determinants of progression are gender, the curve magnitude at the time of diagnosis, and skeletal growth potential.[62] In all cases, girls have a risk progression of 10 times greater than boys. Larger curves are more likely to progress. Age of presentation also is important. Curves that are detected before menarche are more likely to progress than those detected after menarche. For persons with lesser degrees of curvature (10 to 20 degrees), the trend has been away from aggressive treatment and toward a "wait and see" approach, taking advantage of the more sophisticated diagnostic methods that now are available. Treatment is considered for physically immature patients with curves between 20 and 30 degrees. Curves between 20 and 40 degrees usually are considered for bracing, and those greater than 40 to 45 degrees are considered for surgery.

A brace may be used to control the progression of the curvature during growth and can provide some correction. In an effort to improve compliance, a number of new bracing techniques have been developed. These orthoses consist of easily more concealed, prefabricated forms that are modified to suit the patient. The goals of surgery are to arrest progression of the deformity, improve appearance, and achieve a balanced spine, while limiting the number of vertebral segments that are stabilized. Instrumentation helps correct the curve and balance, and spinal fusion maintains the spine in the corrected position.[62–64] Several methods of instrumentation (i.e., rods that attach to the vertebral column and posterior fusion) are used. Combined anterior and posterior surgery is used for more severe curvatures. The newer systems provide better sagittal control and more stable fixation, which allow earlier mobility. Despite

great advances in spinal surgery, no one method seems to be the best for all cases. There is recent interest in growth modulation approaches using minimally invasive techniques, which will result in curve correction while preserving spinal motion and intervertebral disk viability.[67]

In summary, skeletal disorders can result from congenital or hereditary influences or from factors that occur during normal periods of skeletal growth and development. Newborn infants undergo normal changes in muscle tone and joint motion, causing torsional conditions of the femur or tibia. Many of these conditions are corrected as skeletal growth and development take place. Osteogenesis imperfecta is a rare autosomal hereditary disorder characterized by defective synthesis of connective tissue, including bone matrix. It results in poorly developed bones that fracture easily. Disorders such as developmental dysplasia of the hip and congenital clubfoot are present at birth. Both of these disorders are best treated during infancy. Regular examinations during the first year of life are recommended as a means of achieving early diagnosis of such disorders. Other childhood skeletal disorders, such as the osteochondroses, slipped capital femoral epiphysis, and scoliosis, are not corrected by the growth process. These disorders are progressive, can cause permanent disability, and require treatment.

Scoliosis is a lateral curvature of the spine. Scoliosis is classified as congenital, which results from defects in vertebral development; neuromuscular, which is caused by diseases such as cerebral palsy; and idiopathic, which is the most common form. Idiopathic scoliosis affects girls more often than boys and usually becomes evident between age 10 years and skeletal maturity. The treatment of scoliosis depends on the severity of the deformity and the likelihood of curve progression. Curves between 30 and 40 degrees usually are considered for bracing, and those greater than 40 to 45 degrees are considered for surgery.

REVIEW EXERCISES

1. A 34-year-old football player dislocates his hip during one of the season's games.

- **A.** Explain the need for immediate reduction of the dislocation based on the vascular anatomy of the hip.

2. A 39-year-old man is in intensive care after a motorcycle accident in which he skidded across the pavement on his right side. He has fractures of his right femur, pelvis, and several ribs on the right side. His right leg was crushed beneath the motorcycle, and he is beginning to lose movement in that leg.

- **A.** What are the priorities in treating his orthopedic injuries? What are the available options for stabilizing his leg?
- **B.** What risk factors for complications of fractures are present?
- **C.** What are the symptoms of compartment syndrome, and how is it treated?

3. A 73-year-old woman with a history of breast cancer sustained a comminuted fracture in the middiaphysis of her left humerus when her husband lifted her up in bed. She has multiple lucent lesions scattered throughout her proximal humerus, radius, and ulna. She was recently hospitalized for confusion and found to have diffuse bone metastases.

- **A.** What would you consider to be the most likely cause of her fracture?
- **B.** What are the most common sites for bone metastasis?
- **C.** Explain the treatment goals for persons with pathologic fractures.

4. A 14-year-old boy complains of recent pain and swelling of the knee, with some restriction in movement. Although he thinks he may have injured his knee playing football, his mother insists that he be seen by an orthopedic specialist and raises the possibility that the boy may have an osteosarcoma.

- **A.** Use the information that osteosarcoma originates in sites of maximal growth velocity to explain the site of this boy's possible tumor.
- **B.** What diagnostic tests could be used to establish a diagnosis of osteosarcoma?
- **C.** The boy and his family are concerned that the boy will require radical surgery with amputation of the leg. How would you go about explaining possible treatment options to him?

5. A newborn girl was found to have developmental dysplasia of the hip during a routine screening examination.

- **A.** Describe the anatomic abnormalities that are present in the disorder.
- **B.** Explain the need for early treatment of developmental dysplasia of the hip.

Disorders of the Skeletal System: Metabolic and Rheumatic Disorders

The skeletal system plays an essential role in mineral homeostasis and mobility. The bones of the skeletal system provide the basic framework that supports the body, protects its organs, and provides for movement. Joints hold the bones of the skeleton together, making movement possible. Bone is also one of the few tissues that normally undergo mineralization. It is a storehouse for 99% of the body's calcium and 85% of its phosphorus. This chapter focuses on two types of skeletal disorders: metabolic bone disorders, which produce a decrease in bone mass and mineralization, and joint disorders, which disrupt mobility.

Metabolic Bone Disease

Metabolic bone disease represents disorders of bone metabolism that result in structural effects on the skeleton, including decreased bone density and diminished bone strength. The strength of bone is determined by its composition and structure.[1] Bone must be both rigid and flexible. It must be rigid enough to support the body, yet flexible enough to absorb energy by deforming, to shorten and widen when compressed, and to lengthen and narrow under tension without cracking.

There are two types of bone: cortical and trabecular. Cortical or compact bone is composed of densely packed layers of mineralized collagen; it provides rigidity and is the major component of tubular bones (see Chapter 42, Fig. 42-1). Trabecular or cancellous bone is spongy on cross-section; it provides strength and elasticity, and constitutes the major part of axial skeletal structures such as the vertebrae. Disorders in which cortical bone is defective or reduced in mass lead to fractures of the long bones, whereas those of cancellous bone lead preferentially to vertebral fractures.

Metabolic Bone Disorders

- Metabolic bone disorders have their origin in the bone remodeling process that involves an orderly sequence of osteoclastic bone reabsorption, the formation of new bone by the osteoblasts, and mineralization of the newly formed osteoid tissue.
- Osteoporosis represents an increased loss of total bone mass due to an imbalance between bone absorption and bone formation, most often related to the aging process and decreased estrogen levels in postmenopausal women.
- Osteomalacia and rickets represent a softening of bone due to inadequate mineralization of the bone matrix caused by a deficiency of calcium or phosphate.
- Paget disease is a disorder involving excessive bone destruction and repair, resulting in structural deformities of the long bones, spine, pelvis, and cranium.

Osteopenia

Osteopenia is a condition that is common to all metabolic bone diseases. It is characterized by a reduction in bone mineral density greater than expected for age, race, or gender, and occurs because of a decrease in bone formation, inadequate bone mineralization, or excessive bone deossification.[2] *Osteopenia* is not a diagnosis but a term used to describe an apparent lack of bone density seen on x-ray studies. Approximately 60% of bone is mineral content, approximately 30% is organic matrix, and the remainder is living bone cells. Osteopenia can involve a decrease in bone matrix due to an imbalance between bone formation and destruction, or a decrease in mineralization. The major causes of osteopenia are osteoporosis, osteomalacia, malignancies such as multiple myeloma, and endocrine disorders such as hyperparathyroidism and hyperthyroidism.

Osteoporosis

Osteoporosis is a metabolic bone disease characterized by decreased bone density (i.e., increased porosity) and strength in which both the bone matrix and mineralization are decreased.[3–8] The World Health Organization has defined osteoporosis as a bone mineral density (BMD) value greater than 2.5 standard deviations below the mean for normal young white women.[7] The exact value is difficult to determine because bone loss varies in the different parts of the skeleton where bone mass is measured, and definitions of osteoporosis have not been developed for all subpopulations. Osteoporosis can occur as the result of a number of disorders, but is most often associated with the aging process. In the United States alone, osteoporosis affects approximately 10 million persons aged 50 years or older, and an additional 34 million have low bone mass (osteopenia) and are potentially at risk for development of osteoporosis and its complications.[8]

Etiology and Pathogenesis

The cause of osteoporosis remains largely unknown, but most data suggest an imbalance between bone resorption and formation such that bone resorption exceeds bone formation. Although both of these factors play a role in most cases of osteoporosis, their relative contribution to bone loss may vary depending on age, gender, genetic predisposition, activity level, and nutritional status.

Under normal conditions, bone mass increases steadily during childhood, reaching a peak in the young adult years. The peak bone mass, or BMD, is an important determinant of the subsequent risk for osteoporosis. It is determined in part by genetic factors, hormone (estrogen) levels, exercise, calcium intake and absorption, and environmental factors (Chart 44-1). Genetic factors are linked, in largest part, to the maximal amount of bone in a given person, referred to as *peak bone mass*. Race is a

key determinant of BMD and the risk of fractures. Incidence rates obtained from studies among racial and ethnic groups demonstrate that although women have higher fracture rates compared with men overall, these differences vary by race and age. White and Asian women had higher rates for all age groups older than 50 years.[9] The highest BMD values and lowest fracture rates have been reported for black women.[9] Body size is another factor affecting the risk of osteoporosis and risk of fractures. Women with smaller body builds are at increased risk of hip fracture because of lower hip BMD.

Hormonal factors play a significant role in the development of osteoporosis, particularly in postmenopausal women.[10] Postmenopausal osteoporosis, which is caused by an estrogen deficiency, is manifested by a loss of cancellous bone and a predisposition to fractures of the vertebrae and distal radius. The loss of bone mass is greatest during early menopause, when estrogen levels are withdrawing. Several factors appear to influence the increased loss of bone mass associated with an estrogen deficiency, including an increased secretion of cytokines by monocytes and bone marrow cells. These cytokines stimulate osteoclast recruitment and activity by increasing the levels of RANK ligand (RANKL) while diminishing the expression of osteoprotegerin (OPG)[3] (see Chapter 42, Understanding Bone Remodeling). Compensatory osteoblastic activity and new bone formation occurs, but does not keep pace with the bone that is lost.

Male sex hormone deficiency may contribute to age-related bone loss in men, although the effect is not of the same magnitude as that caused by estrogen deficiency. Unlike women, men do not have a midlife loss of sex hormone production.[11] Another factor that provides relative protection for men is the fact that they achieve 8% to 10% more peak bone mass than women. Although androgens have long been assumed to be critical for growth and maintenance of the male skeleton, it has recently been suggested that estrogens obtained from peripheral conversion of testicular and adrenal hormone precursors may be even more important than androgens in the maintenance of bone mass in men.

Age-related changes in bone density occur in all individuals and contribute to the development of osteoporosis in both sexes. Age-related changes in bone cells and matrix have a strong impact on bone metabolism. Osteoblasts from elderly persons have reduced replicative and biosynthetic potential compared with those of younger persons. Growth factors that stimulate osteoblastic activity also lose their potential over time. The end result is a skeleton that has decreased ability to make bone. Reduced physical activity increases the rate of bone loss because mechanical forces are important stimuli for normal bone remodeling. Thus, the decreased physical activity that often accompanies aging may also contribute to the loss of bone mass in the elderly.

Secondary osteoporosis is associated with many conditions, including endocrine disorders, malabsorption disorders, malignancies, alcoholism, and certain medications.[12] Persons with endocrine disorders such as hyperthyroidism, hyperparathyroidism, Cushing syndrome, or diabetes mellitus are at high risk for development of osteoporosis. Hyperthyroidism causes an acceleration of bone turnover. Some malignancies (e.g., multiple myeloma) secrete osteoclast-activating factor, causing significant bone loss. Alcohol is a direct inhibitor of osteoblasts and may also inhibit calcium absorption. Corticosteroid use is the most common cause of drug-related osteoporosis, and long-term corticosteroid use in the treatment of disorders such as rheumatoid arthritis and chronic obstructive lung disease is associated with a high rate of fractures. The prolonged use of aluminum-containing antacids, which increase calcium excretion, and anticonvulsants, which impair vitamin D production, may also contribute to bone loss. Persons with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS) who are being treated with antiretroviral therapy may develop a decrease in bone density and signs of osteopenia and osteoporosis.[13]

Several groups of children and adolescents are at particular risk for decreased bone mass, including premature infants and those with low birth weight who have lower-than-expected bone mass in the early weeks of life, children who require treatment with corticosteroid drugs (e.g., those with childhood inflammatory diseases and transplant recipients), children with cystic fibrosis, and those with hypogonadal states (e.g., anorexia nervosa and the female athlete triad). Children with cystic fibrosis often have impaired gastrointestinal function that reduces the absorption of calcium and other nutrients, and many also require the frequent use of corticosteroid drugs.

Premature osteoporosis is increasingly being seen in female athletes owing to an increased prevalence of eating disorders and amenorrhea.[14] It most frequently affects women engaged in endurance sports, such as running and swimming; in activities where appearance is important, such as figure skating, diving, and gymnastics; or in sports with weight categories, such as horse racing, martial arts, and rowing. The *female athlete triad* refers to a pattern of disordered eating that leads to amenorrhea and eventually osteoporosis. Poor nutrition, combined with intense training, can decrease the critical body fat–to–muscle ratio needed for normal menses and estrogen production by the ovary. The decreased levels of estrogen combined with the lack of calcium and vitamin D from dietary deficiencies result in a loss of bone density and increased risk for fractures. There is a concern that athletes with low BMD will be at increased risk for fractures during their competitive years. It is unclear whether osteoporosis induced by amenorrhea is reversible. Data are emerging that even having only one or two elements of the triad greatly increases the risk of these women for long-term morbidity.[14]

Clinical Features

Osteoporotic changes occur in the diaphysis and metaphysis of bone. There is loss of trabeculae from cancellous bone and thinning of the cortex to such an extent that minimal stress causes fractures. The changes that occur with osteoporosis have been explained by two distinct disease processes: postmenopausal and senile, or age-related, osteoporosis. In postmenopausal women, the

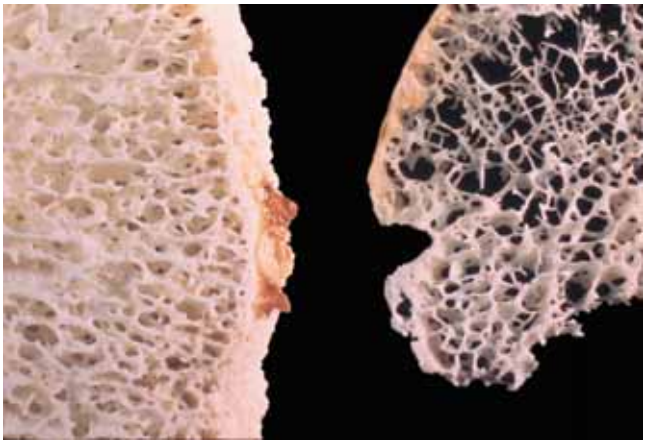

FIGURE 44-1. Osteoporosis. Femoral head of an 82-year-old woman with osteoporosis and femoral neck fracture **(right)**, compared with a normal control bone cut to the same thickness **(left)**. (From Hoch B.J., Klein M.J., Schiller A.L. [2008]. Bones and joints. In Rubin R., Strayer D.S. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1109]. Philadelphia: Lippincott Williams & Wilkins.)

increase in osteoclastic activity affects mainly bones or portions of bone that have increased surface area, such as the cancellous compartment of the vertebral bodies. The osteoporotic trabeculae become thinned and lose their interconnections, leading to microfractures and eventual vertebral collapse. In senile osteoporosis, the osteoporotic cortex is thinned by subperiosteal and endosteal resorption and the haversian systems are widened. In severe cases, the haversian systems are so enlarged that the cortex resembles cancellous bone (Fig. 44-1). Hip fractures, which are seen later in life, are more commonly associated with senile osteoporosis.

Clinical Manifestations. Osteoporosis is usually a silent disorder. Often, the first manifestations of the disorder are those that accompany a skeletal fracture—a vertebral compression fracture or fracture of the hip, pelvis, humerus, or other bones (Fig. 44-2). Fractures are typically sudden in onset and may be caused by a fall, sudden movement, lifting, jumping, or even coughing. Hip fractures occur mainly in persons over age 65. Wedging and collapse of vertebrae cause a loss of height in the vertebral column and kyphosis, a condition commonly referred to as *dowager hump*. Usually, there is no generalized bone tenderness. When pain occurs, it usually is related to fractures. Systemic symptoms such as weakness and weight loss suggest that the osteoporosis may be caused by underlying disease.

Diagnosis and Treatment. An important advance in diagnostic methods used for the identification of osteoporosis has been the use of BMD assessment. The clinical method of choice for BMD studies is dual-energy x-ray absorptiometry (DEXA) of the spine and hip.[15,16] Measurement of serial heights in older adults is another simple way to screen for osteoporosis. A further advance in the diagnosis of osteoporosis is the refinement of risk

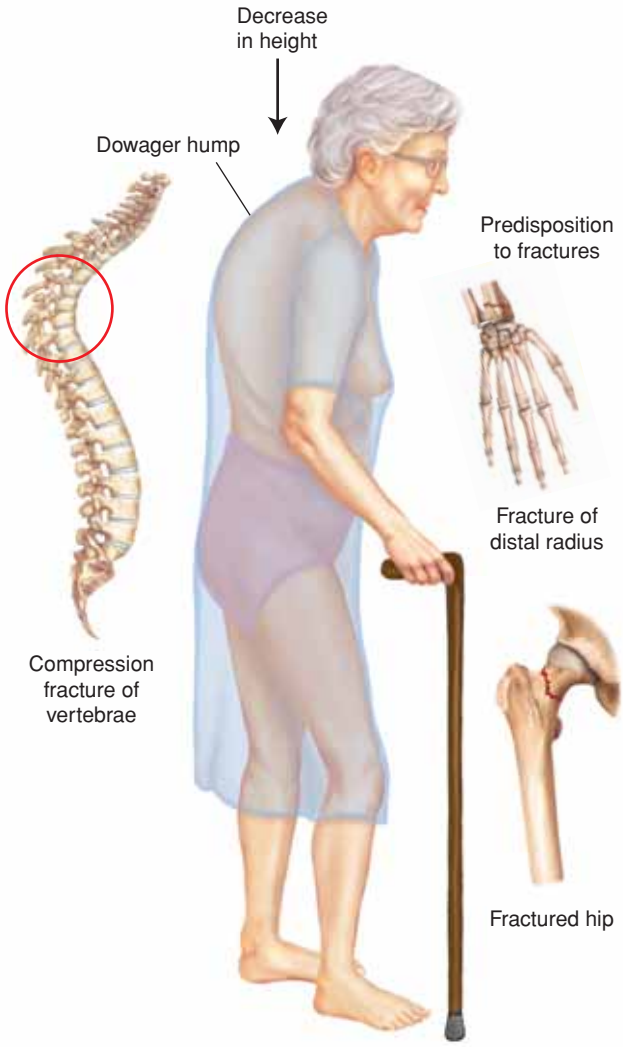

FIGURE 44-2. Clinical manifestations of osteoporosis.

factors, permitting better analysis of risk pertaining to particular persons. The U.S. Preventive Services Task Force (USPSTF) recommends a screening DEXA of all women 65 years of age and older, as well as women 60 to 64 years of age who have an increased fracture risk.[17] Although there are no USPSTF guidelines for BMD testing in men, the National Osteoporosis Foundation (NOF) recommends screening for all men 70 years of age and older and men 50 to 69 years of age with risk factors.[18]

Prevention and early detection of osteoporosis are essential to the prevention of associated deformities and fractures. It is important to identify persons in high-risk groups so that preventive measures can begin early (see Chart 44-1). Regular exercise and adequate calcium and vitamin D intake are important factors in preventing osteoporosis. Weight-bearing exercises such as walking, jogging, rowing, and weight lifting are important in the maintenance of bone mass. Studies have indicated that premenopausal women need more than 1000 mg/day of calcium, and postmenopausal women need at least 1200 mg of calcium daily.[15,18] Because most older American women do not consume a sufficient quantity of dairy

products to meet their calcium needs, calcium supplementation is recommended. A daily intake of 800 to 1000 IU of vitamin D is recommended for adults age 50 years and older. Many elderly persons are at high risk for vitamin D deficiency, especially those with chronic illness, malabsorption disorders (e.g., celiac disease), and limited exposure to sunlight. It is recommended that serum vitamin D levels be obtained for persons at risk of a deficiency and that supplemental vitamin D be prescribed for persons with low serum levels.[18]

There are four main types of drugs used in the treatment of osteoporosis: bisphosphonates, selective estrogen receptor modulators, calcitonin, and recombinant parathyroid hormone. Bisphosphonates are effective inhibitors of bone resorption and the most effective agents for prevention and treatment of osteoporosis.[15,18] The bisphosphonates (e.g., alendronate, risedronate, ibandronate) are analogs of endogenous inorganic pyrophosphate that the body cannot break down. In bone, they bind to hydroxyapatite and prevent bone resorption by inhibiting osteoclast activity. The most dramatic impact has been in the reduction of multiple spine fractures, showing that treatment can decrease progression of the disease.

Raloxifene, a selective estrogen receptor modulator (SERM) that acts only on specific estrogen receptors, has been approved by the U.S. Food and Drug Administration (FDA) for prevention and treatment of osteoporosis in postmenopausal women. Although hormone therapy (i.e., estrogen with or without progesterone) has been shown to slightly reduce the risk of hip and vertebral fractures in postmenopausal women, the use of hormone therapy has come under scrutiny after the recent release of data from the Women's Health Initiative, which linked hormone replacement therapy to an increased risk of stroke, venous thromboembolism, coronary heart disease, and breast cancer.[19]

Calcitonin is an endogenous peptide that partially inhibits osteoclastic activity. Nasal calcitonin has been approved for the treatment of postmenopausal osteoporosis. It has been shown to decrease the occurrence of vertebral fractures, but not nonvertebral or hip fractures. Because more effective drugs are available, it is not usually considered first-line treatment for osteoporosis. Teriparatide, a recombinant human parathyroid hormone, was recently approved by the FDA for the treatment of osteoporosis.[15] Unlike the antiresorptive drugs, parathyroid hormone is a potent anabolic agent that stimulates bone remodeling by increasing osteoblast-mediated bone formation.

Persons with osteoporosis have many special needs. Walking and swimming are encouraged. Unsafe conditions that predispose persons to falls and fractures should be corrected or avoided. In treating fractures, it is important to minimize immobility. Surgical interventions are used to provide stable fixation of lower extremity fractures and allow for early weight bearing and restoration of mobility and function. Vertebral fractures are treated symptomatically. Conservative treatment with bracing is most often seen, especially in fractures of the thoracic vertebra. Vertebroplasty and kyphoplasty are minimally invasive spinal procedures that use bone cement to restore vertebral height and relieve pain.[20] Bone cement is instilled directly into the fractured vertebral body to restore height and shape. Kyphoplasty involves the use of a balloon as a tamp to create a void for the cement, and seems to be associated with less cement extravasation and better restoration of vertebral height than vertebroplasty.[20]

Osteomalacia and Rickets

In contrast to osteoporosis, which causes a loss of total bone mass and results in brittle bones, osteomalacia and rickets produce a softening of the bones resulting from an inadequate mineralization of newly formed bone matrix.[4] The term *rickets* refers to the disorder in children in which changes in bone growth produce characteristic skeletal abnormalities, and *osteomalacia* is used in adults because the bone that forms during the remodeling process is undermineralized.[4]

Osteomalacia

Osteomalacia is a generalized bone condition in which there is inadequate mineralization of bone. There are two main causes of osteomalacia: (1) insufficient calcium absorption from the intestine because of a lack of dietary calcium or a deficiency of or resistance to the action of vitamin D and (2) phosphate deficiency caused by increased renal losses or decreased intestinal absorption. Vitamin D is ingested in the diet and synthesized in the skin from 7-dehydrocholesterol under the influence of ultraviolet B (UVB) sunlight. The vitamin is first hydroxylated in the liver to form its major metabolite, 25-hydroxyvitamin D. It is then hydroxylated in the kidney to produce the active hormone $1,25(OH)_2D$ (see Chapter 42). There are many causes of vitamin D deficiency including reduced skin synthesis, inadequate dietary intake, diminished intestinal absorption, and heritable and acquired disorders of vitamin D metabolism and responsiveness.[21,22]

The incidence of osteomalacia is high among the elderly because of diets deficient in calcium and vitamin D, a problem often compounded by the intestinal malabsorption that accompanies aging. Melanin is extremely efficient in absorbing UVB radiation; thus, decreased skin pigmentation markedly reduces vitamin D synthesis, as does the use of sunscreens. Osteomalacia also may occur in persons on long-term treatment with medications such as anticonvulsants (e.g., phenytoin, carbamazepine, valproate) that decrease the activation of vitamin D in the liver. There also is a greater incidence of osteomalacia in the colder regions of the world, particularly during the winter months, probably because of lessened exposure to sunlight.

A form of osteomalacia called *renal rickets* occurs in persons with chronic renal failure. It is caused by the inability of the kidney to activate vitamin D and excrete phosphate and is accompanied by hyperparathyroidism, increased bone turnover, and increased bone resorption (see Chapter 26). Another form of osteomalacia results

from renal tubular defects that cause excessive phosphate losses. This form of osteomalacia is commonly referred to as *vitamin D–resistant rickets,* and often is a familial disorder.[4] It is inherited as an X-linked dominant gene passed by mothers to one half of their children and by fathers to their daughters only. This form of osteomalacia affects boys more severely than girls. Long-standing primary hyperparathyroidism causes increased calcium resorption from bone and hypophosphatemia, which can lead to rickets in children and osteomalacia in adults.

The clinical manifestations of osteomalacia are bone pain, tenderness, and fractures as the disease progresses. In severe cases, muscle weakness often is an early sign. Osteomalacia predisposes a person to pathologic fractures in the weakened bones, especially those in the distal radius and the proximal femur. In contrast to osteoporosis, it is not a significant cause of hip fractures. There may be delayed healing and poor retention of internal fixation devices. Osteomalacia usually is accompanied by a compensatory or secondary hyperparathyroidism stimulated by low serum calcium levels. Parathyroid hormone reduces renal absorption of phosphate and removes calcium from the bone. Serum calcium levels are only slightly reduced in osteomalacia.

Diagnostic measures are directed toward identifying osteomalacia and establishing its cause. Diagnostic methods include x-ray studies, laboratory tests, bone scan, and bone biopsy. X-ray findings typical of osteomalacia are the development of transverse lines or pseudofractures called *Looser zones*. These apparently are caused by stress fractures that are inadequately healed or by the mechanical inadequacy of penetrating nutrient vessels.[4] A bone biopsy may be done to confirm the diagnosis of osteomalacia in a person with nonspecific osteopenia who shows no improvement after treatment with exercise, vitamin D, and calcium.

The treatment of osteomalacia is directed at the underlying cause. If the problem is nutritional, restoring adequate amounts of calcium and vitamin D to the diet may be sufficient. The elderly and persons with an inadequate dietary intake or sunlight exposure may require supplemental vitamin D. Supplemental vitamin D is specific for vitamin D–resistant rickets, but large doses usually are needed to overcome the resistance to calcium absorption action and to prevent renal loss of phosphate. The biologically active forms of vitamin D, 25-OH vitamin D (calciferol) or 1,25-$(OH)_2$ vitamin D (calcitriol), are available for use in the treatment of osteomalacia resistant to vitamin D (i.e., osteomalacia resulting from chronic liver disease and kidney failure). If osteomalacia is caused by malabsorption, the treatment is directed toward correcting the primary disease. For example, adequate replacement of pancreatic enzymes is of paramount importance in pancreatic insufficiency. In renal tubular disorders, the treatment is directed at the altered renal physiology.

Rickets

Rickets is a metabolic bone disorder characterized by a failure or delay in calcification of the cartilaginous growth plate in children whose epiphyses have not yet fused.[23–25] It is also manifested by widening and deformation of the metaphyseal regions of long bones and a delay in the mineralization of trabecular, endosteal, and periosteal bone surfaces. There are several forms of rickets, including nutritional rickets, vitamin D–dependent rickets, and vitamin D–resistant rickets. As with osteomalacia in the adult, rickets can result from kidney failure; malabsorptive syndromes such as celiac disease and cystic fibrosis; and medications such as anticonvulsants, which impair the activation of vitamin D in the liver, and aluminum-containing antacids, which bind phosphorus and prevent its absorption.

Nutritional rickets results from inadequate sunlight exposure or inadequate intake of vitamin D, calcium, or phosphate. Although uncommon in developed countries of the world, rickets still can occur, particularly when an infant is solely breast fed, is dark skinned, or has limited exposure to sunlight. Modern conditions of dress, lifestyle, and recommendations regarding sun avoidance to reduce skin cancer risk may prevent a large proportion of the population from producing adequate amounts of vitamin D. Because rickets is not a reportable disease, the only current prevalence estimates have been obtained mainly from case reports and hospital records. According to reported and published cases in the United States, nutritional rickets increased from 65 cases between 1975 and 1985 to 166 cases between 1986 and 2003.[25] Since then, 3 reports added another 62 cases to the American literature. In 2003, the American Academy of Pediatrics recommended a vitamin D supplement for breast-fed infants who do not consume at least 500 mL of vitamin D–fortified formula/beverages and non–breast-fed infants who do not consume greater than 500 mL of vitamin D—fortified beverages.[25] The supplementation should start during the first 2 months of life and continue throughout childhood and adolescence.

Vitamin D–dependent rickets can result from abnormalities in the gene coding for the enzyme that converts inactive vitamin D to the active form of vitamin D, or from an autosomal disorder caused by mutations in the vitamin D receptor.[24] Vitamin D–resistant rickets involves hypophosphatemia or a decrease in serum phosphate levels, the most common form being caused by mutations of the phosphate-regulating gene on the X chromosome.[24] The gene mutation causes renal wasting of phosphate at the proximal tubular level of the kidney.

Clinical Features. Rickets is characterized by changes in the growing bones of children with overgrowth of the epiphyseal cartilage due to inadequate provisional calcification and failure of the cartilage cells to disintegrate. Bones become deformed; ossification at the epiphyseal plates is delayed and disordered, resulting in widening of the epiphyseal cartilage plate. Any new bone that does grow is unmineralized. The conformation of the gross skeletal changes depends on the severity and duration of the rachitic process, and in particular on the stresses to which the individual bones are subjected. During the nonmobile stage of infancy, the head and chest undergo

FIGURE 44-3. A child suffering from nutritional rickets. Note the bowed legs, protruding abdomen, and enlarged left wrist. (From Centers for Disease Control and Prevention Public Health Images Library.)

the greatest stresses. The skull is enlarged and soft, and closure of the fontanels is delayed. Teeth are slow to develop, and the child may have difficulty standing. When an ambulating child develops rickets, deformities are likely to affect the spine, pelvis, and long bones (i.e., tibia), causing, most notably, lumbar lordosis and bowing of the legs (Fig. 44-3). The ends of long bones and ribs are enlarged. The thorax may be abnormally shaped, with prominent rib cartilage (i.e., rachitic rosary). The child usually has stunted growth, with a height sometimes far below the normal range. Weight often is not affected so that the children, many of whom present with a protruding abdomen (i.e., rachitic potbelly), have been described as presenting a Buddha-like appearance when sitting.

Nutritional rickets is treated with a balanced diet sufficient in calcium, phosphorus, and vitamin D. Exposure to sunlight also is important, especially for premature infants and those on artificial milk feedings. Supplemental vitamin D in excess of normal requirements is given for several months. Children with vitamin D–dependent rickets caused by lack of the enzyme needed to convert vitamin D to its active form are treated with calcitriol, the active form of vitamin D.[24] Vitamin D–resistant forms of rickets are treated with oral phosphorus or oral phosphorus and calcitriol. Maintenance of good posture, positioning, and bracing in older children are used to prevent deformities. After the disease is controlled, deformities may have to be surgically corrected as the child grows.

Paget Disease

Paget disease (i.e., osteitis deformans) is the second most common bone disease after osteoporosis.[3,4,26–28] The disease, which has been described as a "collage of matrix madness," is characterized by focal areas of excessive osteoclast-mediated bone reabsorption preceding disorganized osteoblast-mediated bone repair. Paget disease usually begins during midadulthood and becomes progressively more common with increasing age. It is more common in people of Northern European heritage. Men are about twice as likely as women to have the disease.[28]

Etiology and Pathogenesis

Although the pathogenesis of Paget disease remains unclear, there is evidence of both genetic and environmental influences. It has been reported that 15% to 40% of persons with the disease have a first-degree relative with Paget disease, and numerous studies have described extended family members with the disease.[28] There is increasing evidence that Paget disease and some related diseases are caused by mutations in genes encoding proteins in the RANK signaling pathways.[3,4] Other evidence presents a probable association with a virus, possibly a paramyxovirus, suggesting that a viral infection may serve as a trigger for development of Paget disease in genetically predisposed individuals.[4,28]

Paget disease is a focal process with considerable variation in its stage of development in separate skeletal sites. At the onset, the disease is marked by regions of furious osteoclastic bone resorption, followed by a period of hectic bone formation with increased numbers of osteoblasts rapidly depositing bone in a chaotic fashion such that the newly formed bone is of poor quality and is disorganized rather than lamellar. The poor quality of bone accounts for the bowing and fractures that occur in bones affected by the disease. The bone marrow adjacent to the bone-forming surface is replaced by loose connective tissue that contains osteoprogenitor cells and numerous blood vessels, which transport blood to and from these metabolically active sites. The lesions of Paget disease may be solitary or may occur in multiple sites. They tend to localize to the bones of the axial skeleton, including the skull, spine, and pelvis. The proximal femur and tibia may be involved in more widespread forms of the disease. Histologically, Paget lesions show increased vascularity and bone marrow fibrosis with intense cellular activity. The bone has a somewhat mosaic-like pattern caused by areas of density outlined by heavy blue lines, called *cement lines* (Fig. 44-4).

Clinical Features

The clinical manifestations of Paget disease are extremely variable and depend on the extent and site of the disease (see Fig. 44-4). The disease is usually asymptomatic and discovered as an incidental radiograph finding.[27] Skeletal expansion and distortion may be obvious if the disease

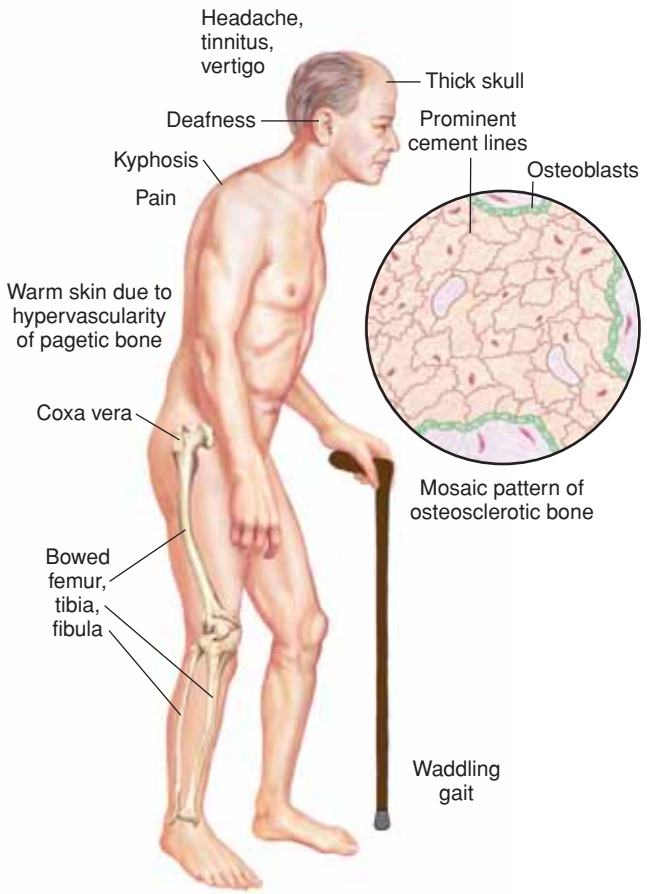

FIGURE 44-4. Clinical manifestations of Paget disease.

affects the skull, jaw, clavicle, or long bones of the leg. Involvement of the skull causes headaches, intermittent tinnitus, vertigo, and eventual hearing loss. The vertebrae of the spine may enlarge, weaken, and collapse, causing kyphosis of the thoracic spine and nerve compression. Weight bearing may cause anterior bowings of the femur and tibia. Softening of the femoral neck can cause coxa vara (i.e., reduced angle of the femoral neck), which in combination with involvement of the pelvis can cause a waddling gait and secondary osteoarthritis. Mild to moderate deep, aching pain characteristically begins late in the course of the disease, persists throughout the day and at rest, and becomes worse at night. In some persons, the early hypervascularity of the pagetic bone produces warmth of the overlying skin and subcutaneous tissue. In persons with extensive disease, blood flow to the bones and subcutaneous tissue can increase remarkably, leading to high-output heart failure or exacerbation of underlying cardiac disease.[3]

A variety of tumor and tumorlike conditions develop in pagetic bone, the most dreaded of which is sarcoma. Osteogenic sarcomas occur in 5% to 10% of persons with extensive disease.[3] The bones most often affected, in order of frequency, are the femur, pelvis, and humerus.[4]

Diagnosis and Treatment. Diagnosis of Paget disease is based on characteristic bone deformities and x-ray changes. Elevated levels of serum alkaline phosphatase and urinary hydroxyproline support the diagnosis, and continued surveillance of these levels may be used to monitor the effectiveness of treatment. Bone scans are used to detect the rapid bone turnover indicative of active disease and to monitor the response to treatment. The scan cannot identify bone activity resulting from malignant lesions. Bone biopsy may be done to differentiate the lesion from osteomyelitis or a primary or metastatic bone tumor.

The treatment of Paget disease is based on the degree of pain and the extent of the disease. Pain can be reduced with nonsteroidal or other anti-inflammatory agents. Suppressive agents such as the bisphosphonates and calcitonin are used to manage pain and prevent further spread of the disease and neurologic defects. Persons with Paget disease should receive adequate doses of calcium and vitamin D.

In summary, metabolic bone disease represents disorders of the skeletal system that result from an imbalance between bone formation and destruction or a decrease in mineralization. Osteopenia is a condition that is common to all metabolic bone diseases. It is characterized by a reduction in bone mineral density greater than expected for age, race, or gender, and it occurs because of a decrease in bone formation, inadequate bone mineralization, or excessive bone deossification.

Osteoporosis, the most common of the metabolic bone diseases, is a disorder of bone remodeling that is characterized by increased bone porosity (decreased bone mass density) and diminished bone strength. It is associated with an increase in bone fragility and susceptibility to fractures. The cause of osteoporosis remains largely unknown, but most data suggest an imbalance between bone resorption and formation such that bone resorption exceeds bone formation. Although the disease can occur as the result of a number of disorders, the most common causes are age-related changes in bone metabolism and a relative absence of estrogen in postmenopausal women.

Osteomalacia and rickets are caused by inadequate mineralization of bone matrix, primarily because of a deficiency of vitamin D. In contrast to osteoporosis, which causes bones to become brittle, osteomalacia and rickets produce bone softening. Osteomalacia is a disorder of adults and is caused by insufficient calcium absorption from the intestine because of lack of dietary vitamin D, resistance to the action of the vitamin, or a phosphate deficiency. Rickets, which affects children, is characterized by failure or delay in calcification of the cartilaginous growth plate, widening and deformation of the metaphyseal regions in long bones, and a delay in mineralization of trabecular, endosteal, and periosteal bone surfaces. Rickets is beginning to reemerge as a problem in developed countries due to a number of factors including modern

conditions of dress, diet, lifestyle, and avoidance of sun exposure to prevent skin cancer.

Paget disease results from excessive osteoclastic activity and is characterized by focal areas of excessive osteoclast-mediated bone resorption, disorganized osteoblast bone formation, and increased blood flow due to hypervascularity in the bone marrow adjacent to the lesions. The disease is often asymptomatic and discovered as an incidental radiographic finding. Symptomatic disease may be manifest as skeletal changes and symptoms related to expansion of the skull, jaw, clavicle, spine, and long bones of the leg. Involvement of the skull may cause headache, intermittent tinnitus, vertigo, and hearing loss; involvement of the spine may cause the vertebrae to collapse, leading to kyphosis of the thoracic spine and nerve compression. Hypervascularity may produce warmth of the overlying pagetic bone and, in extensive disease, high-output heart failure or exacerbation of underlying heart disease.

Systemic Autoimmune Rheumatic Disorders

- Systemic autoimmune rheumatic disorders are immune-mediated inflammatory connective tissue disorders that have similar clinical features and may affect many of the same organs.
- Rheumatoid arthritis is an autoimmune disorder that affects many tissues but principally attacks joints by producing a proliferative synovitis that progresses to produce a disabling form of arthritis by destroying the articular joint cartilage and underlying bone.
- Systemic lupus erythematosus is an autoimmune disorder that can affect almost any organ system, including the joints of the musculoskeletal system, skin, kidneys, lungs, nervous system, and heart.
- Systemic sclerosis is another autoimmune disorder that produces progressive disability by producing extensive fibrosis of many body organs and systems, including structures of the musculoskeletal system.

Rheumatic Disorders

Arthritis is a descriptive term applied to more than 100 rheumatic disorders, ranging from localized, self-limiting conditions to those that are systemic immune-mediated processes. The term, which is used to describe any disorder that affects the joints, oversimplifies the nature of the varied disease processes, the difficulty in differentiating one form of arthritis from another, and the complexity of treatment of these usually chronic conditions. These diverse rheumatic conditions share inflammation of the joint as a prominent or accompanying symptom. In the systemic rheumatic diseases, such as rheumatoid arthritis, the inflammation is primary, resulting from an immune response, probably autoimmune in origin. In rheumatic conditions limited to a single or few diarthrodial joints, such as osteoarthritis, the inflammation is secondary, resulting from the degenerative process and joint irregularities.

Systemic Autoimmune Rheumatic Diseases

Systemic autoimmune rheumatic diseases are a group of chronic disorders characterized by diffuse inflammatory vascular lesions and degenerative changes in connective tissue that share clinical features and may affect many of the same tissues and organs. They include rheumatoid arthritis, systemic lupus erythematosus, and systemic sclerosis, all of which share an immune-mediated pathogenesis.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic autoimmune systemic disease that affects all ethnic groups throughout the world, with women affected 2.5 times more frequently than men.[29] The onset of the disease can occur at any age, but its peak incidence is between 40 and 50 years of age. Although the cause of RA remains uncertain, evidence points to a genetic predisposition and the development of joint inflammation that is immunologically mediated.[3,4] It has been suggested that the disease is initiated in a genetically predisposed individual by the activation of a T-cell–mediated response to an immunologic trigger, such as a microbial agent (Fig. 44-5). The importance of genetic factors in the pathogenesis of RA is supported by the increased frequency of the disease among first-degree relatives and monozygotic twins.[4] In addition, specific major histocompatibility complex (MHC) alleles or human leukocyte antigen (HLA) types have been associated with RA (see Chapter 15). An increased prevalence of RA has been associated with specific HLA DR alleles that share a sequence of amino acids located in the antigen-binding site of the DR molecule. This location is presumably the specific binding site of the immunologic trigger.[3]

The pathogenesis of RA can be viewed as an aberrant immune response that leads to synovial inflammation and destruction of the joint architecture. It has been suggested that the disease is initiated by the activation of $CD4^+$ helper T cells, the local release of inflammatory mediators and cytokines (e.g., tumor necrosis factor [TNF], interleukin [IL]-1) that destroy the joint, and formation of antibodies directed against joint-specific and systemic autoantigens. Approximately 70% to 80% of persons with the disease have a substance called the *rheumatoid factor* (RF), which is an antibody that reacts with a fragment of immunoglobulin G (IgG) to form immune complexes.[3,30] Although persons with RA may

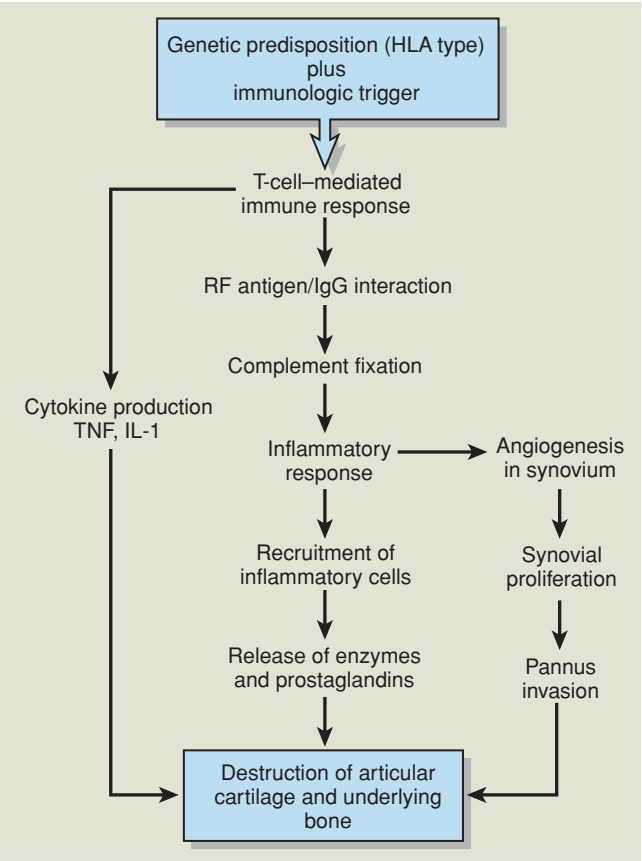

FIGURE 44-5. Disease process in rheumatoid arthritis. IL, interleukin; TNF, tumor necrosis factor.

be seronegative (not have Ig RF in their serum), the presence of a high RF titer is frequently associated with severe and unremitting disease, mainly systemic complications. Anticyclic citrullinated peptide (anti-CCP) antibodies are another key antibody system in RA.[29] Citrulline is a nonnaturally occurring amino acid that is generated by the enzymatic digestion of arginine on proteins. Recent research suggests that citrulline-containing proteins may serve as specific targets for the IgG antibody response in RA.

The role of the autoimmune process in the joint destruction of RA remains obscure. At the cellular level, neutrophils, macrophages, and lymphocytes are attracted to the area. The neutrophils and macrophages phagocytize the immune complexes and, in the process, release lysosomal enzymes capable of causing destructive changes in the joint cartilage (see Fig. 44-5). The inflammatory response that follows attracts additional inflammatory cells, setting into motion a chain of events that perpetuates the process. As the inflammatory process progresses, synovial cells and subsynovial tissues undergo reactive hyperplasia. The joint swelling that occurs is the result increased blood flow and capillary permeability that accompanies the inflammatory process.

Characteristic of RA is the development of an extensive network of new blood vessels in the synovial membrane that contributes to the advancement of the rheumatoid synovitis. This destructive vascular granulation tissue, which is called *pannus,* extends from the synovium to involve the "bare area," a region of unprotected bone at the junction between cartilage and subchondral bone (Fig. 44-6B). Pannus is a feature of RA that differentiates it from other forms of inflammatory arthritis.[3,4] The inflammatory cells found in the pannus have a destructive effect on the adjacent cartilage and bone. Eventually, pannus develops between the joint margins, leading to reduced joint motion and the possibility of eventual ankylosis (joint fusion). With progression of the disease, joint inflammation and the resulting structural changes lead to joint instability, muscle atrophy from disuse, stretching of the ligaments, and involvement of the tendons and muscles. The effect of the pathologic changes on joint structure and function is related to the degree of disease activity, which can change at any time. Unfortunately, the destructive changes are irreversible.

Rheumatoid arthritis often is associated with articular as well as extra-articular (i.e., systemic) manifestations (see Fig. 44-6). It usually has an insidious onset marked by systemic manifestations such as fatigue, weakness, and generalized aching and stiffness.[29,31] The disease, which is characterized by exacerbations and remissions, may involve only a few joints for brief durations, or it may become relentlessly progressive and debilitating.

Articular Manifestations. Joint involvement usually is symmetric and polyarticular. Any diarthrodial joint can be involved. The person may complain of joint pain and stiffness that lasts for 30 minutes and frequently for several hours. The limitation of joint motion that occurs early in the disease usually is because of pain; later, it is because of fibrosis. In early disease, the wrists, metacarpophalangeal (MCP) joints, proximal interphalangeal (PIP) joints of the fingers, interphalangeal joints of the thumb, and metatarsophalangeal (MTP) joints are most commonly affected. Pain in the ball of the foot upon arising from bed and widening of the forefoot necessitating an increase in shoe size are frequently reported due to inflammation of the metatarsophalangeal joints.[29] Pain with turning door knobs, opening jars, and buttoning shirts is commonly reported due to swelling of the wrists and small joints of the hand. As the disease progresses, larger joints such as the ankles, knees, elbows, and shoulders become affected. Spinal involvement usually is limited to the cervical region.

Progressive joint destruction may lead to subluxation (i.e., dislocation of the joint resulting in misalignment of the bone ends) and instability of the joint and limitation of movement. Swelling and thickening of the synovium can result in stretching of the joint capsule and ligaments. When this occurs, muscle and tendon imbalances develop, and mechanical forces applied to the joints through daily activities produce joint deformities. In the MCP joints, the extensor tendons can slip to the ulnar side of the metacarpal head, causing ulnar deviation of the fingers (see Fig. 44-6A). Hyperextension of the PIP joint and partial flexion of the distal interphalangeal (DIP) joint is called a *swan neck deformity.* After this

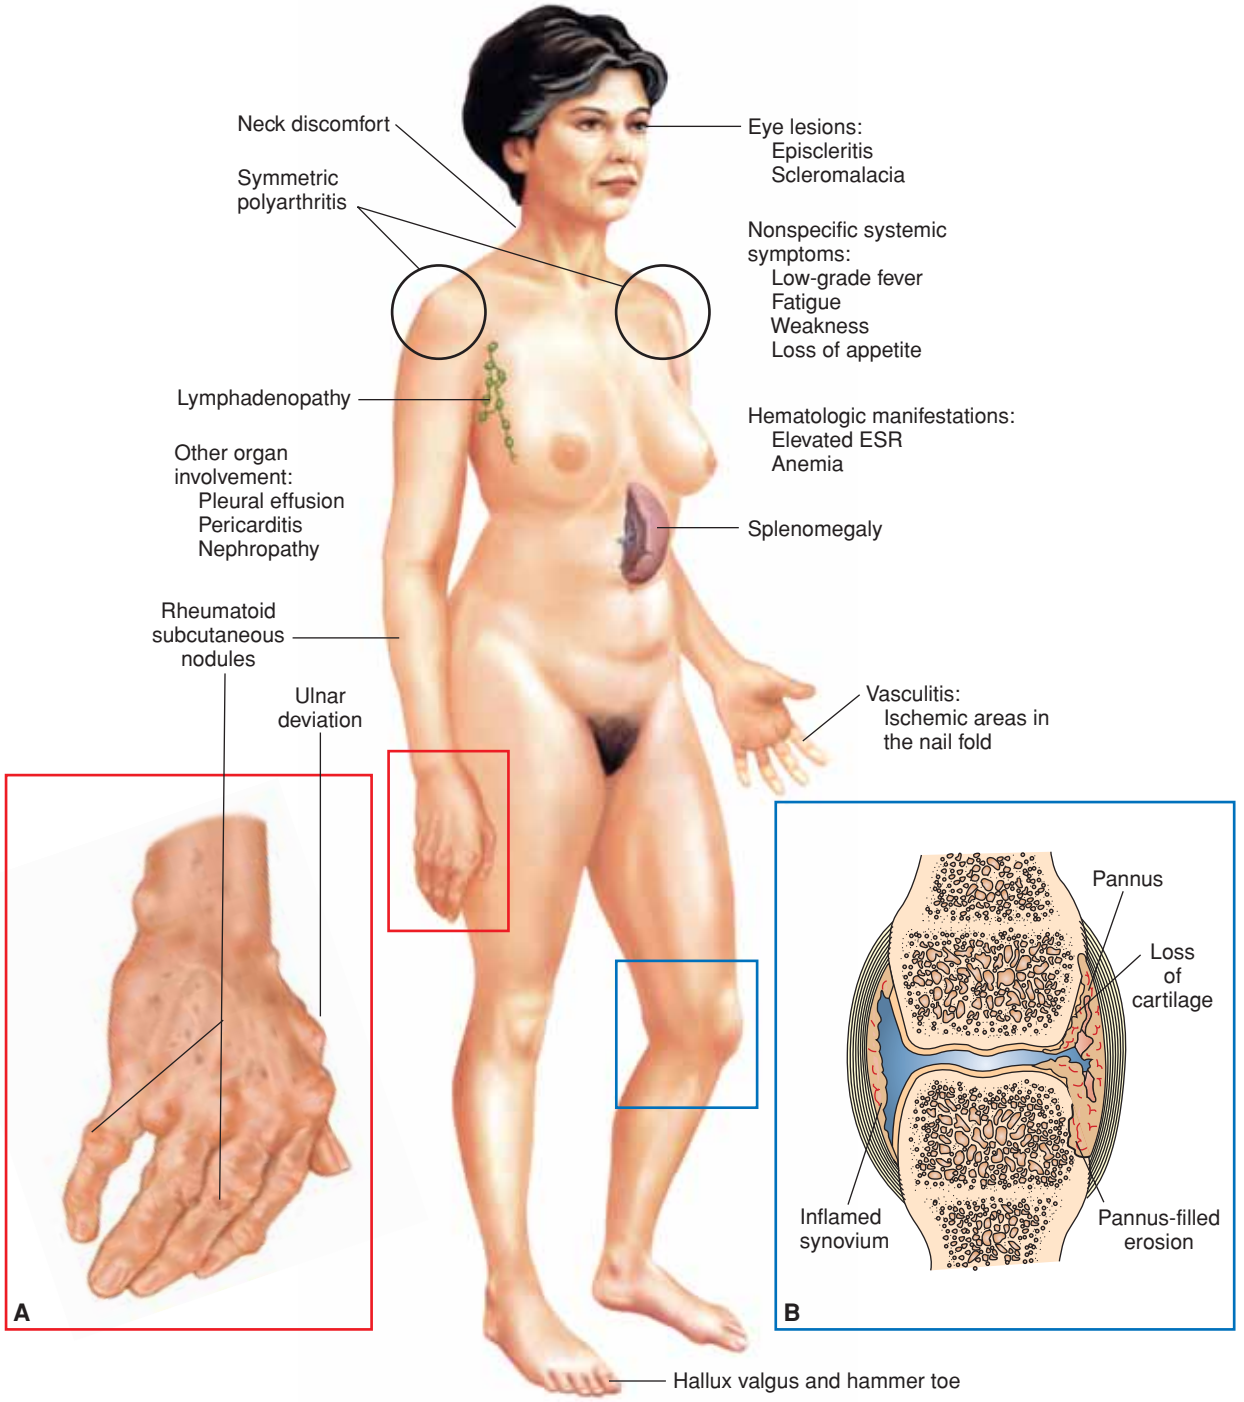

FIGURE 44-6. Clinical manifestations of rheumatoid arthritis featuring **(A)** hand and finger manifestations and **(B)** destructive joint changes. ESR, erythrocyte sedimentation rate.

condition becomes fixed, severe loss of function occurs because the person can no longer make a fist.

The knee is one of the most commonly affected joints and is responsible for much of the disability associated with the disease. Active synovitis may be apparent as visible swelling that obliterates the normal contour over the medial and lateral aspects of the patella. Joint contractures, instability, and genu valgus (knock-knee) deformity are other possible manifestations. Severe quadriceps atrophy can contribute to the disability. A *Baker cyst* may develop in the popliteal area behind the knee. This is caused by enlargement of the bursa but does not usually cause symptoms unless the cyst ruptures, in which case symptoms mimicking thrombophlebitis appear. Ankle involvement can limit flexion and extension, which can create difficulty in walking. Involvement of

the metatarsophalangeal joints can cause subluxation, hallux valgus, and hammertoe deformities. Neck pain and stiffness occur later in the disease.

Extra-Articular Manifestations. In addition to articular manifestations, persons with early RA frequently have constitutional symptoms such as fatigue, weakness, anorexia, and weight loss that are due to systemic inflammation.[29,31,32] The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), which commonly are elevated during inflammatory processes, have been found to correlate with the amount of disease activity. A moderate hypochromic anemia is common.

Extra-articular involvement tends to occur in long-standing disease and includes rheumatic nodules (Fig. 44-6A). Rheumatoid nodules are granulomatous lesions that have a central core of fibrinoid necrosis that is made up of a mixture of fibrin and other proteins such as degraded collagen.[4] The nodules may be tender or nontender, movable or immovable, and small or large. Typically, they are found over pressure points such as the extensor surfaces of the ulna. The nodules may remain unless surgically removed, or they may resolve spontaneously.

Vasculitis, or inflammation of small and medium-sized arteries, is an uncommon manifestation of RA in persons with a long history of active arthritis and high titers of RF (see Chapter 18). Manifestations include ischemic areas in the nail fold and digital pulp that appear as brown spots. Ulcerations may occur in the lower extremities, particularly around the malleolar areas. In some cases, neuropathy may be the only symptom of vasculitis. The visceral organs, such as the heart, lungs, and gastrointestinal tract, also may be affected.

Dryness of the eyes, mouth, and other mucous membranes may occur, especially in advanced disease. Ocular manifestations include episcleritis, scleritis, and scleromalacia, which is due to scleral nodules. Additional extra-articular manifestations of RA include pulmonary fibrosis and pericarditis. A small number of persons have splenomegaly and lymph node enlargement.

Diagnosis and Treatment. The diagnosis of RA is based on findings of the history, physical examination, and laboratory tests. The criteria for RA developed by the American Rheumatism Association are useful in establishing the diagnosis[32] (Chart 44-2). At least four of the criteria must be present to make a diagnosis of RA. Although these criteria were developed for classification purposes and for use in epidemiologic studies, they can be used as guidelines for diagnosing the illness in individual patients.

Because changes in joint structure usually are not visible early in the disease, diagnosis is often difficult. On physical examination, the affected joints show signs of inflammation, swelling, tenderness, and possibly warmth and reduced motion. The joints have a soft, spongy feeling because of the synovial thickening and inflammation. Body movements may be guarded to prevent pain.

The combined presence of the RF and anti-CCP antibodies in laboratory tests are findings that are sensitive and fairly specific for RA.[3,4,29] The presence of anti-CCP antibodies, which have been detected very early in RA, appear to be a good prognostic marker for the disease and discriminate between erosive and nonerosive forms of the disease. Disease severity and activity tend to correlate with RF levels; patients with high RF levels tend to have a significantly higher frequency of extra-articular involvement (e.g., rheumatoid nodules, vasculitis, neuropathy). Synovial fluid analysis can be helpful in the diagnostic process. The synovial fluid has a cloudy appearance, the white blood cell count is elevated as a result of inflammation, and the complement components are decreased. Radiologic findings provide the most specific evidence of joint changes in RA, but are often normal during the early stages of the disorder.

The treatment goals for a person with RA are to reduce pain, minimize stiffness and swelling, maintain mobility, and become an informed health care consumer. The treatment plan includes education about the disease and its treatment, physical rest, therapeutic exercises, and medications. Because of the chronicity of the disease and the need for continuous, long-term adherence to the prescribed treatment modalities, it is important that the treatment be integrated with the person's lifestyle.

Both physical rest and therapeutic exercises are important aspects of care.[32] Physical rest reduces joint stress. Rest of specific joints is recommended to relieve pain. For example, sitting reduces the weight on an inflamed knee, and the use of lightweight splints reduces undue movement of the hand or wrist. Although rest is essential, therapeutic exercises also are important in maintaining joint motion and muscle strength.[33] Proper posture, positioning, body mechanics, and the use of supportive shoes can provide further comfort. There often is a need for information about the principles of joint protection and work simplification. Some persons need assistive devices to reduce pain and improve their ability to perform activities

CHART 44-2 Criteria for Classification of Rheumatoid Arthritis

Four or more of the following conditions must be present to establish a diagnosis of rheumatoid arthritis:

1. Morning stiffness for at least 1 hour and present for at least 6 weeks
2. Simultaneous swelling of three or more joints for at least 6 weeks
3. Swelling of wrist, metacarpophalangeal, or proximal interphalangeal joints for 6 or more weeks
4. Symmetric joint swelling for 6 or more weeks
5. Rheumatoid nodules
6. Serum rheumatoid factor identified by a method that is positive in less than 5% of normal subjects
7. Radiographic changes typical of rheumatoid arthritis on hand or wrist radiographs.

Adapted from Arnett F.C., Edworthy S.M., Block D.L., et al. (1988). The American Rheumatism Association 1987 revised criteria for the clarification of rheumatoid arthritis. *Arthritis and Rheumatism* 31, 315–324.

of daily living. Instruction in the safe use of heat and cold modalities to relieve discomfort and in the use of relaxation techniques also is important.

The classes of drugs used in the treatment of RA include salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs), and selective cyclooxygenase (COX)-2 inhibitors; disease-modifying antirheumatic drugs (DMARDs); corticosteroids; and biologic agents.[34]

The NSAIDs, including salicylates, inhibit COX-mediated synthesis of prostaglandins, which have a damaging effect on joint structures (see Chapter 3, Fig. 3-4). There are two COX isomers—COX-1 and COX-2. COX-1 is continuously expressed in many cells and is responsible for the general effects of prostaglandins, including protection of the gastric mucosa, whereas COX-2 is induced by cytokines and mainly expressed in inflammatory tissues. The selective COX-2 inhibitors (e.g., celecoxib) were developed with the goal of decreasing the gastrointestinal adverse effects seen with the traditional NSAIDs.

The DMARDs are a diverse group of therapeutic drugs that reduce the signs and symptoms of RA as well as retard radiographic progression of the disease. The DMARDs include gold salts, hydroxychloroquine, sulfasalazine, methotrexate, and azathioprine. Methotrexate has become the drug of choice because of its potency, and it is relatively fast acting (i.e., improvement is seen in 1 month) compared with the slower-acting DMARDs, which can take 3 to 4 months to work. Methotrexate is thought to interfere with purine metabolism, leading to the release of adenosine, a potent anti-inflammatory compound. All of the DMARDs can be toxic and require close monitoring for adverse effects, especially those related to bone marrow suppression.

Corticosteroid drugs interrupt the inflammatory and immune cascade at several levels, such as interfering with inflammatory cell adhesion and migration, impairing prostaglandin synthesis, and inhibiting neutrophil superoxide production. To avoid long-term side effects, they are used only in specific situations for short-term therapy at a low dose level. The corticosteroids do not modify the disease and are unable to prevent joint destruction. Intra-articular corticosteroid injections can provide rapid relief of acute or subacute inflammatory synovitis (after infection is excluded) in a few joints. They should not be repeated more than a few times each year.

The biologic agents are structurally engineered versions of natural molecules (e.g., monoclonal antibodies) designed to target specific pathogenic mediators of joint inflammation and damage. Leflunomide is a pyrimidine synthesis inhibitor that blocks the proliferation of T cells. Etanercept, infliximab, and adalimumab are biologic response–modifying agents that block TNF-α, one of the key proinflammatory cytokines in RA. Abatacept and rituximab are among the most recent biologic agents available for treatment of moderate to severe RA. Abatacept is a recombinant protein that prevents the costimulatory signal that results in full T-cell activation. Rituximab is a chimeric antibody that causes B-cell depletion.

Surgery also may be a part of the treatment of RA.[32] Synovectomy may be indicated to reduce pain and joint damage when synovitis does not respond to medical treatment. The most common soft tissue surgery is tenosynovectomy (i.e., repair of damaged tendons) of the hand to release nerve entrapments. Total joint replacements (i.e., arthroplasty) may be indicated to reduce pain and increase motion. Arthrodesis (i.e., joint fusion) is indicated only in extreme cases when there is so much soft tissue damage and scarring or infection that a replacement is impossible.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic inflammatory disease that can affect virtually any organ system, including the musculoskeletal system. It is a major rheumatic disease, with a prevalence of approximately 1 case per 2000 persons. SLE is primarily a disease of young women, with a peak incidence between the ages of 15 and 40 years.[35] It is more common in African Americans, Hispanics, and Asians than whites, and the incidence in some families is higher than in others.

Etiology and Pathogenesis. The cause of SLE is unknown. It is characterized by the formation of autoantibodies and immune complexes (type III hypersensitivity; see Chapter 16). Persons with SLE appear to have defective elimination of self-reactive B cells with a resultant increase in production of antibodies that can directly damage tissues or combine with corresponding antigens to form tissue-damaging immune complexes. Autoantibodies have been identified against an array of self-molecules found in the nucleus, in the cytoplasm, or on the surface of cells. Among the autoantibodies found in the serum of persons with SLE, those directed against components of the cell nucleus (antinuclear antibodies [ANAs]) are the most characteristic. These antibodies bind deoxyribonucleic acid (DNA), ribonucleic acid (RNA), nuclear proteins, and protein nuclear complexes. Antibodies to double-stranded DNA and a nuclear antigen called *Sm* are essentially found in all persons with SLE and are included as a serologic classification of the disease. In addition to ANAs, persons with lupus have a host of other self-autoantibodies including those directed against elements of the blood (red cells, platelets, lymphocytes) and plasma proteins (clotting and complement factors).

The development of autoantibodies can result from a combination of factors, including genetic, hormonal, and environmental factors.[36,37] Genetic predisposition is evidenced by the occurrence of familial cases of SLE, especially among identical twins. The increased incidence among African Americans compared with whites also suggests genetic factors. As many as four genes may be involved in the expression of SLE in humans. Genes linked to the HLA-DQ loci in the MHC class II molecules provide strong support for a genetic link in the development of SLE.[37] Studies also suggest that an imbalance in sex hormone levels may play a role in the development of the disease, especially because the disease is so prevalent among women.

Possible environmental triggers include ultraviolet (UV) light, chemicals (e.g., drugs, hair dyes), some foods,

and infectious agents.[36,37] UV light, specifically UVB associated with exposure to the sun or unshielded fluorescent bulbs, may trigger exacerbations. Photosensitivity occurs in approximately one third of patients with SLE. Certain drugs may also provoke a lupus-like disorder in susceptible persons, particularly in the elderly. The most common of these drugs are hydralazine and procainamide.[37,38] Other drugs, such as quinidine, chlorpromazine, methyldopa, isoniazid, minocycline, and phenytoin, also have been known to produce this syndrome. The disorder usually recedes when the drug is discontinued.

Clinical Manifestations. Systemic lupus erythematosus can manifest in a variety of ways. The disease has been called the *great imitator* because it has the capacity for affecting many different body systems, including the musculoskeletal system, the skin, the cardiovascular system, the lungs, the kidneys, the central nervous system (CNS), and the red blood cells and platelets[36,38] (Fig. 44-7). The onset may be acute or insidious, and the course of the disease is characterized by exacerbations and remissions. Rare cases result in death within weeks or months.

Arthralgias and arthritis are among the most commonly occurring early symptoms of SLE; approximately 90% of all persons with the disease complain of joint pain at some point during the course of their disease.[36] The polyarthritis of SLE initially can be confused with other forms of arthritis, especially RA. However, articular destruction rarely is found on radiologic examination. Although arthritis can affect any joint, it is most often symmetric with involvement of the small joints of the hands, wrists, and knees, but sparing the spine. Ligaments, tendons, and the joint capsule may be involved, causing varied deformities. Flexion contractures, hyperextension of the interphalangeal joints, and subluxation of the carpometacarpal joints contribute to the deformity and subsequent loss of function in the hands. Other musculoskeletal manifestations of SLE include tenosynovitis, rupture of the intrapatellar and Achilles tendons, and avascular necrosis, frequently of the femoral head.

Skin manifestations can vary greatly and may be classified as acute, subacute, or chronic. The acute skin lesions include the classic malar or "butterfly" rash on the nose and cheeks (see Fig. 44-7). This rash is seen in SLE but may be associated with other skin lesions, such as hives or livedo reticularis (i.e., reticular cyanotic discoloration of the skin, often precipitated by cold), and fingertip lesions, such as periungual erythema, nail fold infarcts, and splinter hemorrhages. Hair loss is common. Mucous membrane lesions tend to occur during periods of exacerbation. Sun sensitivity may occur in SLE even after mild sun exposure.

Renal involvement occurs in approximately one half to two thirds of persons with SLE.[38] Several forms of glomerulonephritis may occur, including mesangial, focal proliferative, diffuse proliferative, and membranous (see Chapter 25). Interstitial nephritis also may occur. Nephrotic syndrome causes proteinuria with resultant edema in the legs and abdomen, and around the eyes. Renal failure may or may not be preceded by the nephrotic syndrome. Kidney biopsy is the best determinant of renal damage and the extent of treatment needed.

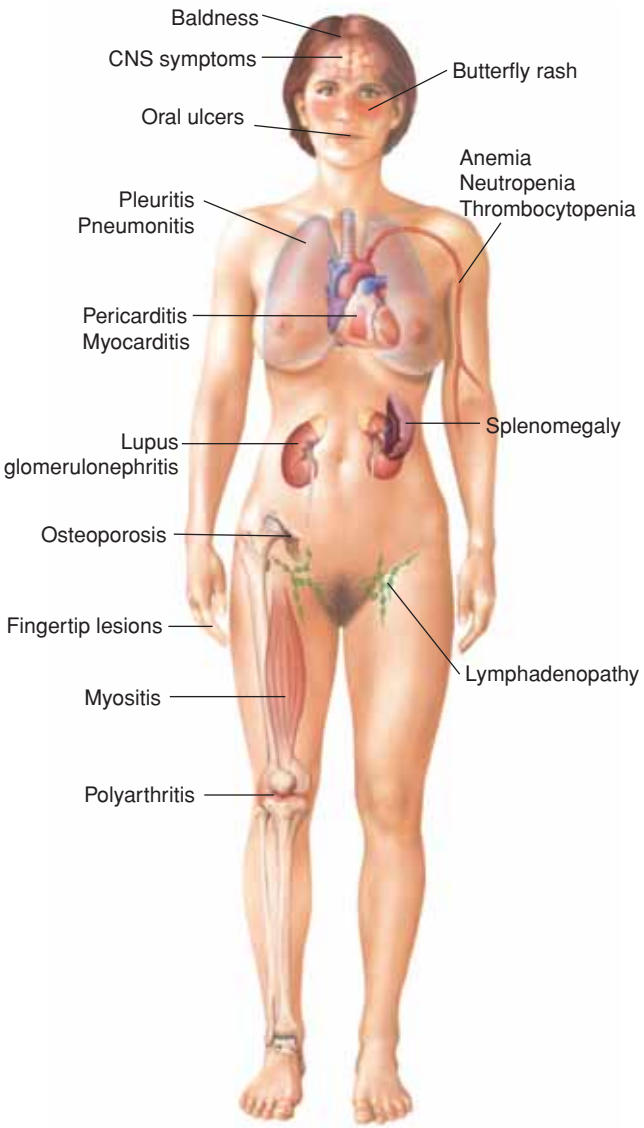

FIGURE 44-7. Clinical manifestations of systemic lupus erythematosus.

Pulmonary involvement occurs in 30% of persons with SLE and is manifested primarily by pleural effusions or pleuritis.[38] Less frequently occurring pulmonary problems include acute pneumonitis, pulmonary hemorrhage, chronic interstitial lung disease, and pulmonary embolism. Pericarditis is the most common of the cardiac manifestations, occurring in up to 45% of persons with SLE and often accompanied by pleural effusions.[38] Myocarditis affects as many as 25% of those with SLE. Congenital heart block can occur in infants of mothers with SLE who have a specific type of ANA (anti-Ro) in their serum. Secondary heart disease also is a problem in those with SLE. Hypertension may be associated with lupus nephritis and long-term corticosteroid use. Ischemic heart disease can occur in older persons with longer-duration SLE. Infective endocarditis is rare but

can occur with valvular lesions.[36] Hematologic disorders may manifest as hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia.

The CNS is involved in approximately two thirds of persons with SLE.[38] The pathologic basis for the CNS symptoms is not well understood, probably because of the inaccessibility of the tissue involved. It has been ascribed to an acute vasculitis that impedes blood flow, causing strokes or hemorrhage; an immune response involving antineuronal antibodies that attack nerve cells; or production of antiphospholipid antibodies that damage blood vessels and cause blood clots in the brain. Seizures can occur and are more frequent when renal failure is present. Psychotic symptoms, including depression and unnatural euphoria, as well as decreased cognitive functioning, confusion, and altered levels of consciousness, may develop.

Chronic discoid cutaneous lupus is a disease in which the skin manifestations may mimic SLE, but systemic manifestations are rare. It is characterized by plaquelike lesions on the head, scalp, and neck. These lesions first appear as red, swollen patches of skin, and later there can be scarring, depigmentation, and plugging of hair follicles. The disease is usually confined to the skin, but 5% to 10% of persons with the disorder may go on to develop multisystem manifestations after many years.

Subacute cutaneous lupus erythematosus is a less severe form of lupus that presents with predominant skin involvement that may resemble psoriasis. These lesions are found in sun-exposed areas such as the face, chest, upper back, and arms. Most persons have mild systemic manifestations of SLE, which usually are limited to joint and muscle pains. There is also a low incidence of lupus nephritis.

Diagnosis and Treatment. The diagnosis of SLE is based on a complete history, physical examination, and analysis of blood work. The most common laboratory test performed is the immunofluorescence test for ANA. Ninety-five percent of persons with untreated SLE have high ANA levels. The ANA test is not specific for SLE, and positive ANA results may be found in healthy persons or may be associated with other disorders. Antibodies to double-stranded DNA are more specific, but are not as sensitive since they present in only about 60% of persons with SLE.[39,40] Other serum tests may reveal moderate to severe anemia, thrombocytopenia, and leukocytosis or leukopenia. Additional immunologic tests may be done to give support to the diagnosis or to differentiate SLE from other connective tissue diseases.

Treatment of SLE focuses on managing the acute and chronic symptoms of the disease. The goals of treatment include preventing progressive loss of organ function, reducing the possibility of exacerbations, minimizing disability from the disease process, and preventing complications from medication therapy. Persons with photosensitivity should be cautioned against sun exposure and should apply a protective lotion when out of doors. Skin lesions often respond to local application of corticosteroids and minor joint symptoms are usually relieved by rest and NSAIDs.

An antimalarial drug (e.g., hydroxychloroquine) may be helpful in treating lupus rashes or musculoskeletal manifestations not relieved by NSAIDs. Corticosteroids are used to treat more significant symptoms of SLE, such as renal and CNS disorders. High-dose corticosteroid treatment is used for acute symptoms, and the drug is tapered to the lowest therapeutic dose as soon as possible to minimize the adverse effects. Immunosuppressive drugs, such as cyclophosphamide, may be used in cases resistant to corticosteroids.

Systemic Sclerosis/Scleroderma

Systemic sclerosis, commonly called *scleroderma,* is an autoimmune disease of connective tissues that causes extensive fibrosis throughout the body.[37,41,42] The disease affects women four times as frequently as men, with a peak incidence in the 35- to 50-year-old age group.[42]

The cause of systemic sclerosis is poorly understood, although there is evidence of both humoral and cellular immune system abnormalities. Fibroblast activation with excessive fibrosis is a hallmark of the disease. Skin involvement is the usual presenting symptom, but it is the involvement of organs such as the lungs, gastrointestinal tract, heart, lungs, and kidneys that produce the major morbidity and mortality. Microvascular disease is also consistently present early in the disease, with repeated cycles of endothelial damage followed by platelet activation and release of platelet factors that lead to fibrosis and narrowing of the microvasculature and tissue ischemia.

Clinical Manifestations. Scleroderma presents as two distinct clinical subsets: limited and diffuse scleroderma. The most common subset, which accounts for approximately 60% of cases, is limited cutaneous scleroderma in which the skin changes are limited to the fingers, forearms, and face.[42] Some persons with limited involvement also develop a condition called the *CREST* syndrome, characterized by a combination of *c*alcinosis (i.e., calcium deposits in the subcutaneous tissue that erupt through the skin), *R*aynaud phenomenon (a vascular disorder characterized by reversible vasospasm of the arteries supplying the fingers [see Chapter 18]), *e*sophageal dysmotility, *s*clerodactyly (localized scleroderma of the fingers), and *t*elangiectasia (dilated skin capillaries).[42]

Diffuse scleroderma, which accounts for approximately 35% of persons with scleroderma, is characterized by severe widespread and progressive skin involvement and early onset of organ involvement.[42] The typical person has a "stone facies" due to tightening of the facial skin with restricted motion of the mouth. Other cutaneous manifestations include hair loss on the involved skin and telangiectasis on the face, buccal mucosa, chest, and hands. Almost all persons with diffuse scleroderma develop Raynaud phenomenon. Musculoskeletal involvement is common in early systemic sclerosis and often prompts persons to seek medical attention. Puffy hands with arthralgia and myalgia may lead to difficulty forming a fist. There are palpable or audible friction rubs over the extensor and flexor tendons

of the hands, knees, and ankles. Involvement of the esophagus that leads to difficulty swallowing is common in persons with early systemic sclerosis. Malabsorption may develop if the disease affects the intestine. Pulmonary involvement leads to dyspnea and eventually respiratory failure. Vascular involvement of the kidneys is responsible for malignant hypertension and progressive renal insufficiency. Cardiac problems include pericarditis, heart block, and myocardial fibrosis.

Treatment. Treatment of systemic sclerosis is largely symptomatic and supportive.[42,43] Advances in treatment, primarily the use of angiotensin-converting enzyme (ACE) inhibitors in renal involvement, have led to a substantial decrease in the mortality from hypertensive renal disease. Cardiopulmonary manifestations of scleroderma, specifically pulmonary hypertension, can be treated with prostanoids (or endothelial receptor antagonists [bosentan]).

Seronegative Spondyloarthropathies

The *spondyloarthropathies* are an interrelated group of multisystem inflammatory disorders that primarily affect the axial skeleton, particularly the spine.[3,4,44] Sacroiliitis is a pathologic hallmark of the disorders. Typically, the inflammation begins at sites, called *entheses*, where tendon and ligament insert into bone rather than in the synovium. There may also be inflammation and involvement of the peripheral joints, in which case the signs and symptoms overlap with other inflammatory types of arthritis. Because there is an absence of the RF, these disorders often are referred to as *seronegative spondyloarthropathies*.

The seronegative spondyloarthropathies include ankylosing spondylitis, reactive arthritis, and psoriatic arthritis. Although they differ in terms of factors such as age and type of onset and extent of joint involvement, there is clinical evidence of overlap between the various disorders.

Ankylosing Spondylitis

Ankylosing spondylitis is a chronic, systemic inflammatory disease of the joints of the axial skeleton manifested by pain and progressive stiffening of the spine.[44] The disease usually begins in late adolescence or early adulthood. The incidence is greater in men than in women, and symptoms are generally more prominent in men.

Although the pathogenesis of ankylosing spondylitis has not been established, the presence of mononuclear cells in the acutely involved tissue suggests an immune response. Epidemiologic findings indicate that genetic and environmental factors play a role in the pathogenesis of the disease. The HLA-B27 antigen remains one of the best-known examples of an association between a disease and a hereditary marker. Although approximately 90% of those with ankylosing spondylitis possess the HLA-B27 antigen, the HLA-B27 antigen also is present in approximately 5% to 15% of the normal population.[45] Several theories have been advanced to account for the association between the HLA-B27 antigen and ankylosing spondylitis. One possibility is that the gene that determines the HLA-B27 antigen may be linked to other genes that determine the pathologic autoimmune phenomena or lead to increased susceptibility to infections or environmental agents that trigger the response.

Clinical Manifestations. The typical musculoskeletal lesion associated with ankylosing spondylitis is inflammation, or *enthesitis*, at sites where tendons and ligaments attach to bones. Typically, the disease process begins with bilateral involvement of the sacroiliac joints and then moves to the smaller joints of the posterior elements of the spine (Fig. 44-8). The result is ultimate destruction of these joints with ankylosis or posterior fusion of the spine. The vertebrae take on a squared appearance and bone bridges fuse one vertebral body to the next across the intervertebral disks. Progressive spinal changes usually follow an ascending pattern beginning with the sacroiliac area and then moving up the spine to involve the costovertebral joints and cervical spine. Occasionally, large synovial joints (i.e., hips, knees, and shoulders) may be involved. The small peripheral joints usually are not affected. The disease spectrum ranges from an asymptomatic sacroiliitis to a progressive disease that can affect many body systems.

The usual presenting symptom is back pain that may be persistent or intermittent.[44,46] The pain, which becomes worse when resting, particularly when lying in bed, initially may be blamed on muscle strain or spasm from physical activity. Lumbosacral pain also may be present, with discomfort in the buttocks and hip areas. Sometimes, pain can radiate to the thigh in a manner similar to that of sciatic pain. Prolonged stiffness is present in the morning and after periods of rest. Mild physical activity or a hot shower helps reduce pain and stiffness. Sleep patterns frequently are interrupted because of these manifestations. Walking or exercise may be needed to provide the comfort needed to return to sleep.[46] The most common extraskeletal involvement is acute anterior uveitis (iritis), which occurs in approximately 30% of persons sometime in the course of their disease.[44] Systemic features of weight loss, fever, and fatigue may be apparent. Sometimes, the fatigue is a greater problem than pain or stiffness. Osteoporosis

Seronegative Spondyloarthropathies

- The seronegative spondyloarthropathies represent a group of related multisystem disorders that lack the RF.
- The inflammatory process associated with the disorders commonly affects the axial skeleton, involving areas where ligaments and tendons attach to bone.
- Although the cause of the disorders is unknown, there is a striking association between the HLA-B27 antigen and development of the spondyloarthropathies.

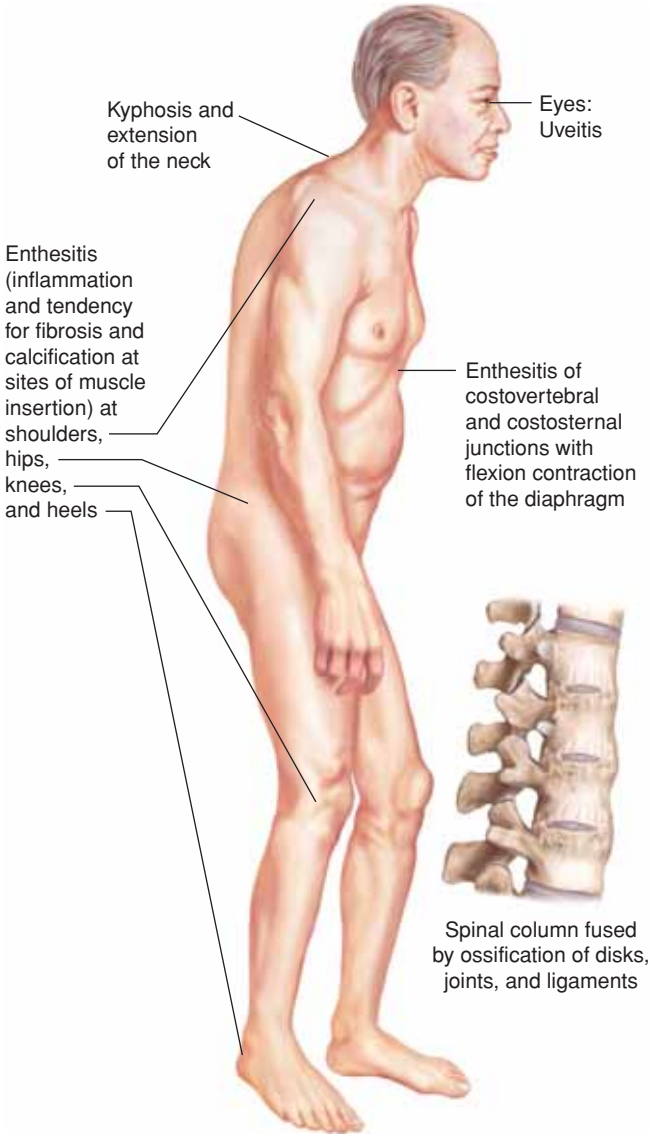

FIGURE 44-8. Clinical manifestations of ankylosing spondylitis.

may occur, especially in the spine, which contributes to the risk of spinal fracture. Loss of motion in the spinal column is characteristic of the disease (see Fig. 44-8). The severity and duration of disease activity influence the degree of mobility. Loss of lumbar lordosis occurs as the disease progresses, and this is followed by kyphosis of the thoracic spine and extension of the neck. A spine fused in the flexed position is the end result in severe ankylosing spondylitis. A kyphotic spine makes it difficult for the patient to look ahead and to maintain balance while walking. The image is one of a person bent over looking at the floor and unable to straighten up. X-ray films show a rigid, bamboolike spine. The heart and lungs are constricted in the chest cavity. Abnormal weight bearing can lead to degeneration and destruction of the hips, necessitating joint replacement procedures. Peripheral arthritis is more common in the hips and shoulders.

Diagnosis and Treatment. The diagnosis of ankylosing spondylitis is based on history, physical examination, and x-ray examination. The history and physical examination should include measures of physical function, pain, spinal mobility, duration of morning stiffness, involvement of peripheral joints and entheses, and fatigue. Laboratory findings frequently include an elevated ESR. The person also may have a mild normocytic normochromic anemia. HLA typing is not diagnostic of the disease and should not be used as a routine screening procedure. Radiologic evaluations help differentiate ankylosing spondylitis from sacroiliitis due to other diseases. However, x-ray images may be negative in early disease.

Treatment of ankylosing spondylitis is directed at controlling pain and maintaining mobility by suppressing inflammation. Proper posture and positioning are important. This includes sleeping in a supine position on a firm mattress and using one small pillow or no pillow. A bed board may be used to supply additional firmness. Therapeutic exercises are important to assist in maintaining motion in peripheral joints and in the spine. Muscle-strengthening exercises for extensor muscle groups also are prescribed. Heat applications or a shower or bath may be beneficial before exercise to improve ease of movement. Swimming is an excellent general conditioning exercise that avoids joint stress and enhances muscle tone. Immobilizing joints is not recommended. Maintaining ideal weight reduces the stress on weight-bearing joints. Deep breathing exercises and avoidance or discontinuation of smoking should be emphasized. Pharmacologic treatment includes the use of NSAIDs to reduce inflammation, relieve pain, and reduce muscle spasm. DMARDs are potential second-line therapies, but their efficacy in ankylosing spondylitis is unproven. Sulfasalazine and methotrexate have not shown benefit for spondylitis-associated back pain, but have shown efficacy for the peripheral joint involvement. Anti–TNF-α therapies, including etanercept, infliximab, and adalimumab, have demonstrated rapid effectiveness in reducing both the axial and peripheral symptoms of ankylosing spondylitis, as well as improving quality-of-life measures.[47]

The disease process in ankylosing spondylitis varies considerably among individuals. Exacerbations and remissions are common; almost all persons have persistent symptoms over decades. Fortunately, most of those affected are able to lead productive lives. Progression during the first decade of the disease tends to predict the prognosis.

Reactive Arthritis

Reactive arthritis is an inflammatory joint disorder that arises after certain inciting gastrointestinal or genitourinary tract infections and manifests as a sterile oligoarthritis, typically of the lower extremities.[48] Most cases of reactive arthritis develop after either a gastrointestinal infection (*Salmonella, Shigella, Campyobacter,* or *Yersinia*) or sexually transmitted infection (*Chlamydia trachomatis*). The infecting agents cannot be cultured and are not viable once having reached the joints. A clinically

indistinguishable syndrome can occur without antecedent infection, suggesting that subclinical infection or some other unrecognized agent can precipitate reactive arthritis. *Reiter syndrome* is a form of reactive arthritis defined by a triad of arthritis, nongonococcal urethritis or cervicitis, and conjunctivitis.[3] *Enteropathic arthritis* is a reactive arthritis that is associated with inflammatory bowel disease (i.e., Crohn disease and ulcerative colitis) or triggered by enterogenic bacteria.

Clinical Manifestations. Reactive arthritis is most commonly asymmetric and frequently involves the lower extremities. Symptoms typically start within 1 to 4 weeks of the initial infection. Hip disease is uncommon and involvement of the upper extremities is rare. The joints are typically warm, swollen, and tender. Systemic manifestations including fever and weight loss are common at the onset. Enthesitis is a common feature of reactive arthritis. The Achilles tendon and plantar fascia are the most common sites of involvement, but pain in the iliac crests, ischial tuberosities, and back may occur. This aspect of the disease can be disabling, with marked restriction in weight bearing and ambulation. Extra-articular lesions are common and include circinate balanitis (shallow ulcers on the glans or shaft of the penis), stomatitis (e.g., painless oral ulcers on the hard palate or tongue), and keratoderma blennorrhagicum (a papulosquamous rash most commonly affecting the palms of the hands and soles of the feet [Fig. 44-9]). While most of the signs and symptoms disappear within days or weeks, the arthritis may persist for several months, and in a small number of cases, it may follow a continuous and unremitting course.

Treatment. The treatment is largely symptomatic. NSAIDs are used in treating the arthritic symptoms. Vigorous treatment of possible triggering infections is thought to prevent relapses of reactive arthritis, but in many cases the triggering infection passes unnoticed or is mild, and the person seeks medical care only with the onset of definite arthritis. Short antibiotic courses at this time are not effective.

Psoriatic Arthritis

Psoriatic arthritis is a seronegative inflammatory arthropathy that occurs in 6% to 11% of people with psoriasis.[49,50] It is a disease with various and similar features of the spondyloarthropathies in some persons, of RA in others, and of both coexisting in yet others. Although the arthritis can antedate a detectable skin rash, the definitive diagnosis of psoriatic arthritis cannot be made without evidence of skin or nail changes typical of psoriasis (see Chapter 46).

The etiology of psoriasis and psoriatic arthritis is unknown. Genetic, environmental, and immunologic factors appear to affect susceptibility and play a role in expression of the psoriatic skin disease and the arthritis. Environmental factors that may play a role in the pathogenesis of the disorder include infectious agents and physical trauma. T-cell–mediated immune responses seem to play an important role in the skin and joint manifestations of the disease, as indicated by the observation that there is improvement in disease status after treatment with immunosuppressant agents such as cyclosporine.

Psoriatic arthritis falls into five subgroups: (1) an oligoarticular form affecting four or fewer joints; (2) a spondylitis form in which sacroiliitis and spinal involvement predominate; (3) a polyarticular, or symmetric, form that resembles RA; (4) a form in which the distal interphalangeal joints are primarily affected; and (5) arthritis mutilans, a very destructive form of arthritis.[49,50] The joint involvement of peripheral psoriatic arthritis is inflammatory in nature, presenting with swelling and stiffness of the affected joints. Early in the disease, the arthritis tends to be oligoarticular, but may become polyarticular over time. The affected joints of persons with psoriatic arthritis are often less tender than those of persons with RA. Thus, persons with psoriatic arthritis may present with deformity and joint damage, not having perceived any pain during the inflammatory phase of the disease.[49] Sacroiliac involvement, when it occurs, tends to be asymmetric, involving only one sacroiliac joint and sparing the other or with different degrees of radiologic involvement. Likewise, spinal involvement tends to be asymmetric, with skip lesions. *Dactylitis*, or *sausage digit*, is a typical feature of distal interphalangeal joint disease and reflects inflammation of the entire digit.[49]

Basic management is similar to the treatment of RA. Suppression of the skin disease may be important in helping control the arthritis. Often, affected joints are surprisingly functional and only minimally symptomatic. The biologic response modifiers, specifically the TNF inhibitors (e.g., etanercept, infliximab, and adalimumab), have been found to be beneficial in controlling the arthritis as well as the psoriasis in patients with psoriatic arthritis.[50]

Osteoarthritis

Osteoarthritis (OA), also called *degenerative joint disease*, is the most prevalent type of joint disease and is one

Osteoarthritis

- Often referred to as "wear-and-tear" arthritis, osteoarthritis, often is a slowly destructive disorder of the articular cartilage.
- It can present as a primary disease of unknown etiology or as a secondary disorder related to congenital or acquired defects that affect the distribution of joint stress.
- The pathogenesis of osteoarthritis includes the progressive disruption of the smooth surface of the articular cartilage with development of surface cracks that deepen to involve the subchondral bone, followed by complete erosion of the articular cartilage with exposure of ivory-like polished subchondral bone, dislodgment of fragments of free-floating osteocartilaginous bodies, development of bone cysts, and formation of abnormal bony spurs at the joint margins.

of the 10 most disabling conditions in developing nations.[3,4] The disorder, which is characterized by degenerative changes of the articular cartilage, can affect any one of 200 or so synovial joints in the body, and can occur as a primary idiopathic disorder or as a secondary disorder. In most instances, OA appears insidiously, without an apparent initiating cause, as an aging phenomenon (idiopathic or primary OA).[3,4] In these cases the disorder is usually oligoarticular, but may be generalized. Secondary OA has a known underlying cause such as congenital or acquired defects of joint structures, trauma, metabolic disorders, or inflammatory diseases.

Joint changes associated with OA include a gradual loss of articular cartilage, combined with thickening of the subchondral bone, bony outgrowths (osteophytes) at joint margins, and mild synovial inflammation.[51] These changes are accompanied by joint pain, stiffness, and limitation of motion, and in some cases by joint instability and deformity.

Etiology and Pathogenesis

Osteoarthritis is a multifactorial disease that has genetic and environmental risk factors. Studies of families and twins suggest that the risk of OA is related to the net impact of multiple genes, each with a small effect.[3] Age, gender, and race interact to influence the time of onset and the pattern of joint involvement in OA.[52] Age is one of the strongest risk factors for OA of all joints. The increase in incidence and prevalence with age probably is the consequence of cumulative exposure to the various risk factors and biologic changes that occur with aging. Women are more likely to have OA than men, and they tend to have more severe OA as well. The prevalence of OA and pattern of joint involvement varies among racial and ethnic groups. Hand OA is more likely to affect white women, whereas knee OA is more common in black women. The incidence of hip OA is lower among the Chinese than Europeans, perhaps representing the influence of other factors such as occupation, obesity, or heredity. Bone mass may also influence the risk of developing OA. In theory, thinner subchondral bone mass may provide a greater shock-absorbing function than denser bone, allowing less direct trauma to the cartilage. Obesity is a particular risk factor for OA of the knee in women and a contributory biomechanical factor in the pathogenesis of the disease.[53] Excess fat may have a direct metabolic effect on cartilage beyond the effects of excess joint stress. Weight loss reduces the risk of developing symptomatic arthritis of the knee.

The pathogenesis of OA resides in the homeostatic mechanisms that maintain the articular cartilage.[3,4] Articular cartilage plays two essential mechanical roles in joint physiology. First, the articular cartilage serves as a remarkably smooth weight-bearing surface. In combination with synovial fluid, the articular cartilage provides extremely low friction during movement of the joint. Second, the cartilage transmits the load down to the bone, dissipating the mechanical stress.[3] Thus, the subchondral bone protects the overlying articular cartilage, providing it with a pliable bed and absorbing the energy of the force (Fig. 44-10). Articular cartilage has two major components: an extracellular matrix, which is rich in proteoglycan and collagen fibers, and a limited number of chondrocytes, which produce the matrix.

Popularly known as *wear-and-tear* arthritis, OA is characterized by significant changes in both the composition and mechanical properties of cartilage.[3,4,51,54] The articular cartilage injury that occurs in OA is thought to result from chondrocyte injury and release of cytokines such as IL-1 and TNF (Fig. 44-11). These chemical messengers stimulate the production and release of proteases (enzymes) that are destructive to joint structures. The resulting damage predisposes the chondrocytes to additional injury and impairs their ability to maintain cartilage synthesis and repair the damage. The combined

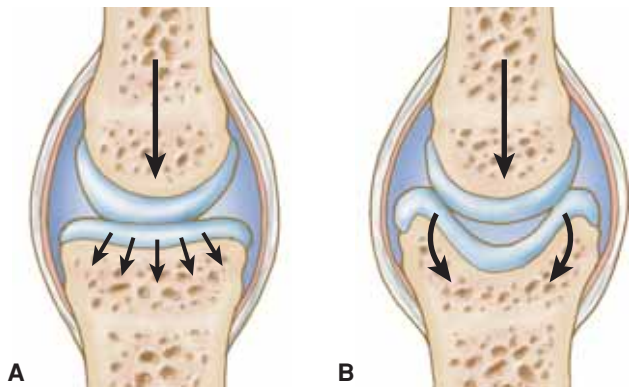

FIGURE 44-10. **(A)** A joint normally undergoes deformation of the articular cartilage and the subchondral bone when carrying a load. This maximizes the contact area and spreads the force of the load. **(B)** If the joint does not deform with a load, the stresses are concentrated and the joint breaks down.

effects of inadequate repair mechanisms and imbalances between the proteases and their inhibitors contribute further to disease progression.

The earliest structural changes in OA include enlargement and reorganization of the chondrocytes in the superficial part of the articular cartilage.[3,4] This is accompanied by edematous changes in the cartilaginous matrix, principally the intermediate layer. The cartilage loses its smooth aspect and surface cracks or microfractures occur, allowing synovial fluid to enter and widen the crack. As the crack deepens, vertical clefts form and eventually extend through the full thickness of the articular surface and into the subchondral bone. Portions of the articular cartilage eventually become completely eroded and the exposed surface of the subchondral bone becomes thickened and polished to an ivory-like consistency (eburnation). Fragments of cartilage and bone often become dislodged, creating free-floating osteocartilaginous bodies ("joint mice") that enter the joint cavity. Synovial fluid may leak though the defects in the residual cartilage to form cysts within the bone (Fig. 44-12). As the disease progresses, the underlying subchondral bone becomes sclerotic and thickened in response to increased pressure on the surface of the joint, rendering it less effective as a shock absorber. Sclerosis, or formation of new bone and cysts, usually occurs at the joint margins, forming abnormal bony outgrowths called *osteophytes,* or *spurs* (Fig. 44-12). As the joint begins to lose its integrity, there is trauma to the synovial membrane, which results in nonspecific inflammation. Compared with RA, however, the inflammatory changes in the synovium that occur in OA are not as pronounced, nor do they occur as early (Fig. 44-12).

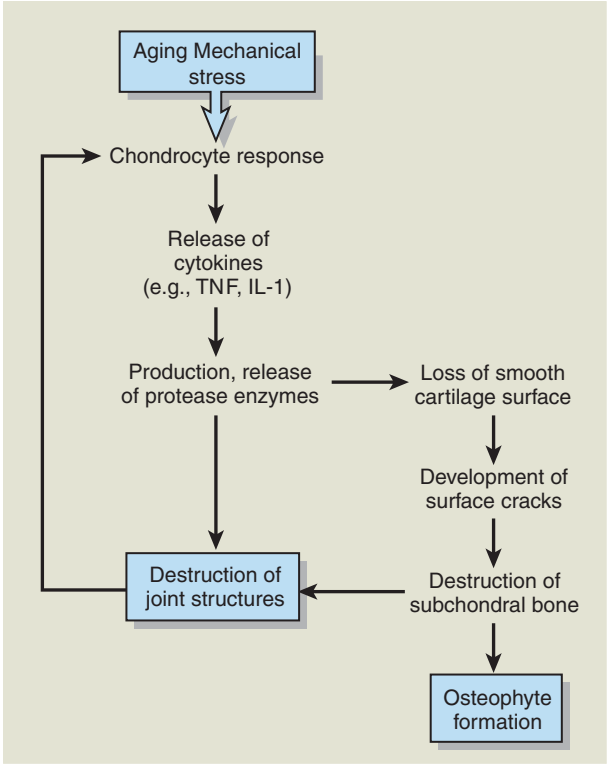

FIGURE 44-11. Disease process in osteoarthritis.

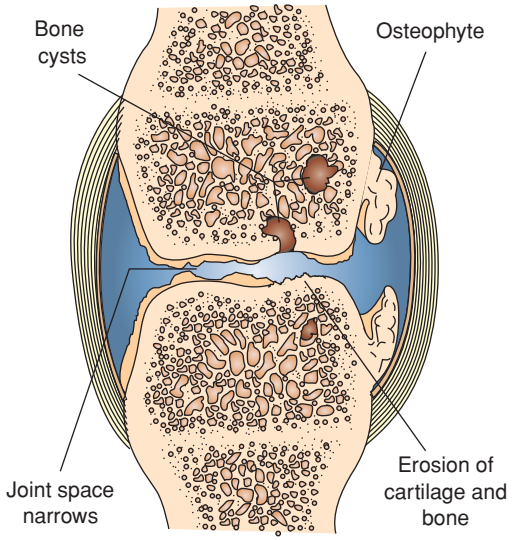

FIGURE 44-12. Joint changes in osteoarthritis. The left side denotes early changes and joint space narrowing with cartilage breakdown. The right side shows more severe disease progression with lost cartilage and osteophyte formation.

In secondary forms of OA, repetitive impact loading contributes to joint failure, accounting for the high prevalence of OA specific to vocational or avocational sites, such as the shoulders and elbows of baseball pitchers, ankles of ballet dancers, and knees of basketball players. Immobilization also can produce degenerative changes in articular cartilage. Cartilage degeneration due to immobility may result from loss of the pumping action of lubrication that occurs with joint movement. These changes are more marked and appear earlier in areas of contact but occur also in areas not subject to mechanical compression. Although cartilage atrophy is rapidly reversible with activity after a period of immobilization, impact exercise during the period of remobilization can prevent reversal of the atrophy. Therefore, slow and gradual remobilization may be important in preventing cartilage injury. Clinically, this has implications for instructions concerning the recommended level of physical activity after removal of a cast.

Clinical Features

Clinical Manifestations. Typically, OA presents with joint pain.[51,55] Initially, pain may be described as aching and may be somewhat difficult to localize. It usually worsens with use or activity and is relieved by rest. A common phenomenon, often referred to as "gelling," involves difficulty initiating joint movement after inactivity, epitomized by the problems older people with OA have in "getting started" after sitting down for a while. In later stages of disease activity, night pain may be experienced during rest. Cracking of joints (audible crepitus) and joint locking may occur when the joint is moved. As the disease advances, even minimal activity may cause pain.

TABLE 44-1 Clinical Features of Osteoarthritis

Joint	Clinical Features
Cervical spine	Localized stiffness; radicular or nonradicular pain; posterior osteophyte formation may cause vascular compression
Lumbar spine	Low back pain and stiffness; muscle spasm; decreased back motion; nerve root compression causing radicular pain; spinal stenosis
Hip	Most common in older men; characterized by insidious onset of pain, localized to groin region or inner aspect of the thigh; may be referred to buttocks, sciatic region, or knee; reduced hip motion; leg may be held in external rotation with hip flexed and adducted; limp or shuffling gait; difficulty getting in and out of chairs
Knee	Localized discomfort with pain on motion; limitation of motion; crepitus; quadriceps atrophy due to lack of use; joint instability; genu varus or valgus; joint effusion
First carpometacarpal joint	Tenderness at base of thumb; squared appearance to joint
Proximal interphalangeal joint—Bouchard nodes	Same as for distal interphalangeal joint disease
Distal interphalangeal joint—Heberden nodes	Occurs more frequently in women; usually involves multiple DIPs, lateral flexor deviation of joint, spur formation at joint margins, pain and discomfort after joint use
First metatarsophalangeal joint	Insidious onset; irregular joint contour; pain and swelling aggravated by tight shoes

The most frequently affected joints are the hips, knees, lumbar and cervical vertebrae, proximal and distal joints of the hands, the first carpometacarpal joint, and the first metatarsophalangeal joints of the feet. Table 44-1 identifies the joints that commonly are affected by OA and the common clinical features correlated with the disease activity of each particular joint. A single joint or several may be affected. Although a single weight-bearing joint may be involved initially, other joints often become affected because of the additional stress placed on them while trying to protect the initial joint. It is not unusual for a person having a knee replacement to discover soon after the surgery is done that the second knee also needs to be replaced. Other clinical features are limitations of joint motion and joint instability. Joint enlargement usually results from new bone formation; the joint feels hard, in contrast to the soft, spongy feeling characteristic of the joint in RA. Sometimes, mild synovitis or increased synovial fluid can cause joint enlargement.

Diagnosis and Treatment. The diagnosis of OA usually is determined by history and physical examination, x-ray studies, and laboratory findings that exclude other diseases. Although OA often is contrasted with RA for diagnostic purposes, the differences are not always readily apparent. Other rheumatic diseases may be superimposed on OA. Psychological factors, severity of joint disease, and educational level affect the expression of symptoms.

Because there is no cure, the treatment of OA is symptomatic and includes physical rehabilitative, pharmacologic, and surgical measures. Physical measures are aimed at improving the supporting structures of the joint and strengthening opposing muscle groups involved in cushioning weight-bearing forces.[55,56] This includes a balance of rest and exercise, use of splints to protect and rest the joint, use of heat and cold to relieve pain and muscle spasm, and adjusting the activities of daily living. Weight reduction is helpful when the knee is involved. The involved joint should not be further abused, and steps should be taken to protect and rest it. These include weight reduction (when weight-bearing surfaces are involved) and the use of a cane or walker if the hips and knees are involved. Muscle-strengthening exercises may help protect the joint and decrease pain.

Several nutritional products are available and advertised as beneficial for OA, but few have undergone rigorous testing. Among these, glucosamine and chondroitin sulfate have been evaluated in clinical trials, some of which demonstrated greater pain relief with treatment with either compound than with placebo, and others finding little or no difference.[56] A recent multicenter trial funded by the National Institutes of Health found that glucosamine and chondroitin (alone or in combination) were no better than placebo in reducing pain in the total group of persons with knee pain, but that the combination may be effective in those with moderate to severe pain.[57]

Oral medications are aimed at reducing inflammation or providing analgesia. Popular medications used in the treatment of OA are the NSAIDs, many of which are available without a prescription. For many persons, acetaminophen may be as effective and less toxic than NSAIDs. The American College of Rheumatology (ACR) recommends the use of acetaminophen as the initial systemic treatment for OA.[58]

Intra-articular corticosteroid injections may be used when other treatment measures have been unsuccessful in adequately relieving symptoms. They are especially helpful in persons who have an effusion of the joint. Injections usually are limited to no more than three times a year in the same joint because their use is thought to accelerate joint destruction.[56] Viscosupplementation is a newer concept in treatment and is based on the hypothesis that joint lubrication is abnormal in OA. Hyaluronate is injected into the joint weekly for 3 to 5 weeks. Topical capsaicin may have some pain-relieving effect in osteoarthritic knees and hands.[59]

Surgery is considered when the person is having severe pain and joint function is severely reduced.[56] Procedures include arthroscopic lavage and débridement, bunion resections, osteotomies to change alignment of the knee and hip joints, and decompression of the spinal roots in osteoarthritic vertebral stenosis. Total hip replacements have provided effective relief of symptoms and improved range of motion for many persons, as have total knee replacements, although the latter procedure has produced less consistent results. Joint replacement is available for the first carpometacarpal joint. Arthrodesis (surgical stiffening of a joint) is used in advanced disease to reduce pain; however, this results in loss of motion.

Crystal-Induced Arthropathies

Musculoskeletal disorders result from biochemical and metabolic disorders that affect the joints. Metabolic and endocrine diseases associated with joint symptoms include amyloidosis, osteogenesis imperfecta, diabetes mellitus, hyperparathyroidism, thyroid disease, AIDS, and hypermobility syndromes. The discussion in this chapter is limited to the crystal-induced arthropathy caused by monosodium urate deposition, or gout.

Crystal deposition in joints produces arthritis. In gout, monosodium urate or uric acid crystals are found in the joint cavity. Another condition in which calcium pyrophosphate dihydrate crystals are found in the joints sometimes is referred to as *pseudogout* or *chondrocalcinosis*. A brief discussion of pseudogout is found in the section on rheumatic diseases in the elderly.

Gout

Gout is actually a group of diseases known as the *gout syndrome*.[60,61] It includes acute gouty arthritis with recurrent attacks of severe articular and periarticular inflammation; tophi or the accumulation of crystalline deposits in articular surfaces, bones, soft tissue, and cartilage; gouty nephropathy or renal impairment; and uric acid kidney stones.

The term *primary gout* is used to designate cases in which the cause of the disorder is unknown or an inborn error in metabolism and is characterized primarily by hyperuricemia and gout. Primary gout is predominantly a disease of men, with a peak incidence in the fourth to sixth decade. In secondary gout, the cause of the hyperuricemia is known but the gout is not the main disorder. Asymptomatic hyperuricemia is a laboratory finding and not a disease. Most persons with hyperuricemia do not develop gout.

Pathogenesis. The pathogenesis of gout resides in an elevation of serum uric acid levels. Uric acid is the end product of purine (adenine and guanine from DNA and RNA) metabolism.[3,4] The elevation of uric acid and the subsequent development of gout can result from overproduction of purines, decreased salvage of free purine bases, augmented breakdown of nucleic acids as a result of increased cell turnover, or decreased urinary excretion of uric acid. Primary gout, which constitutes 90% of cases,[3] may be a consequence of enzyme defects that result in an overproduction of uric acid; inadequate elimination of uric acid by the kidney; or a combination of the two. In most cases, the reason is unknown. In secondary gout, the hyperuricemia may be caused by the increased breakdown of nucleic acids, as occurs with rapid tumor cell lysis during treatment for lymphoma or leukemia. Other cases of secondary gout result from chronic kidney disease. Some of the diuretics, including the thiazides, can interfere with the excretion of uric acid.

An attack of gout occurs when monosodium urate crystals precipitate in the joint and initiate an inflammatory response. Synovial fluid is a poorer solvent for uric acid than plasma, and uric acid crystals are even less soluble at temperatures below 37°C. Crystal deposition usually occurs in peripheral areas of the body, such as the great toe, where the temperatures are cooler than other parts of the body. With prolonged hyperuricemia, crystals and microtophi (i.e., small, hard nodules with irregular surfaces that contain crystalline deposits of monosodium urate) accumulate in the synovial lining cells and in the joint cartilage. The released crystals are chemotactic to leukocytes and also activate complement. Phagocytosis of urate crystals by polymorphonuclear leukocytes occurs and leads to polymorphonuclear cell death with the release of lysosomal enzymes. As this process continues, the inflammation causes destruction of the cartilage and subchondral bone.

Repeated attacks of acute arthritis eventually lead to chronic arthritis and the formation of the large, hard nodules called *tophi*[3,4] (Fig. 44-13). They are found most commonly in the synovium, olecranon bursa, Achilles tendon, subchondral bone, and extensor surface of the forearm and may be mistaken for rheumatoid nodules. Tophi usually do not appear until 10 years or more after the first gout attack. This stage of gout, called *chronic tophaceous gout,* is characterized by more frequent and prolonged attacks, which often are polyarticular.[61]

Clinical Manifestations. The typical acute attack of gout is monoarticular and usually affects the first metatarsophalangeal joint.[61] The tarsal joints, insteps, ankles, heels, knees, wrists, fingers, and elbows also may be initial sites of involvement. Acute gout often begins at night and may be precipitated by excessive exercise, certain medications or foods, alcohol, or dieting. The onset of pain typically is abrupt, and redness and swelling are observed. The attack may last for days or weeks. Pain may be severe enough to be aggravated even by the weight of a bed sheet covering the affected area.

In the early stages of gout after the initial attack has subsided, the person is asymptomatic, and joint abnormalities are not evident. This is referred to as *intercritical gout*. After the first attack, it may be months or years before another attack. As attacks recur with increased frequency, joint changes occur and become permanent.

Diagnosis and Treatment. Although hyperuricemia is the biochemical hallmark of gout, the presence of hyperuricemia cannot be equated with gout because many persons with this condition never develop gout. A definitive

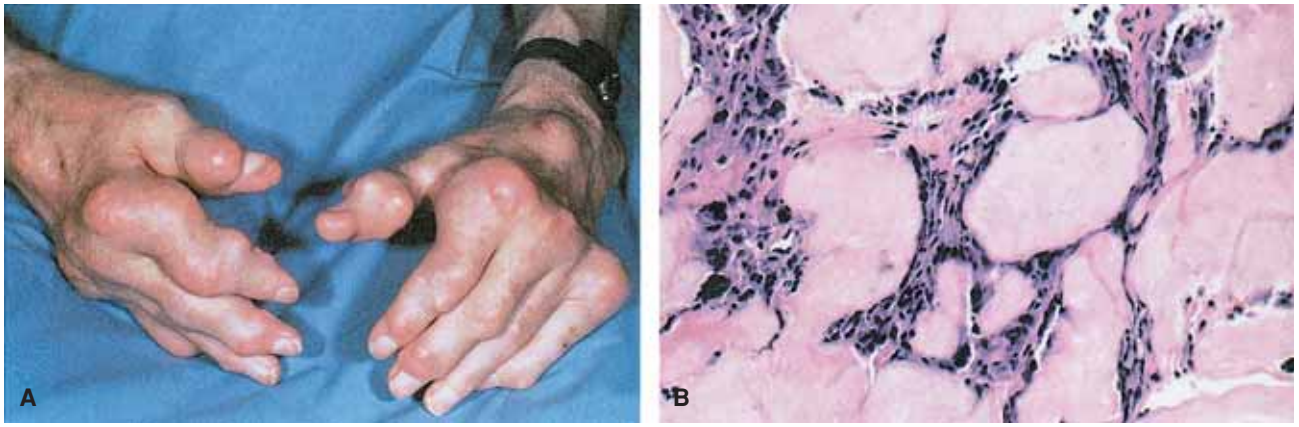

FIGURE 44-13. Gout. **(A)** Gouty tophi project from the fingers as rubbery nodules. **(B)** A section from a tophus shows extracellular masses of urate crystals with accompanying foreign body giant cells. (From Rubin E., Farber J.L. [Eds.]. [1999]. *Pathology* [3rd ed., p. 1404]. Philadelphia: Lippincott Williams & Wilkins.)

diagnosis of gout can be made only when monosodium urate crystals are present in the synovial fluid or in tissue sections of tophaceous deposits.[61] Synovial fluid analysis is useful in excluding other conditions, such as septic arthritis, pseudogout, and RA. Diagnostic methods also include measures to determine if the disorder is related to overproduction or to underexcretion of uric acid. This is done through measurement of serum uric acid levels and collection of a 24-hour urine sample for determination of urate excretion in the urine.

The objectives for treatment of gout include the termination and prevention of the acute attacks of gouty arthritis and the correction of hyperuricemia, with consequent inhibition of further precipitation of sodium urate and absorption of urate crystal deposits already in the tissues.

Pharmacologic management of acute gout is directed toward reducing joint inflammation. Hyperuricemia and related problems of tophi, joint destruction, and renal problems are treated after the acute inflammatory process has subsided. NSAIDs, particularly indomethacin and ibuprofen, are used for treating acute gouty arthritis.[61] Alternative therapies include colchicine and intra-articular deposition of corticosteroids. Colchicine produces its anti-inflammatory effects by inhibition of leukocyte migration and phagocytosis. Although the drug usually is given orally, a more rapid response is obtained when colchicine is given intravenously. The acute symptoms of gout usually subside within 48 hours after treatment with oral colchicine has been instituted and within 12 hours after intravenous administration of the drug. The corticosteroid drugs have not been systemically studied, but can be useful in the treatment of acute gout limited to a single joint or bursa.

Between acute attacks nonpharmacologic and pharmacologic measures are used to normalize uric acid levels as a means of reducing or preventing the frequency and severity of recurrence. Nonpharmacologic methods include maintenance of ideal weight, moderation in alcohol consumption, and avoidance of purine-rich foods (e.g., liver, kidney, sardines, anchovies, and sweetbreads). Avoidance of medications that inhibit renal excretion of uric acid (e.g., loop and thiazide diuretics, low-dose aspirin, and niacin) is also needed. Two classes of drugs may be used to lower the serum uric acid—allopurinol and the uricosuric agents.[61] Allopurinol inhibits xanthine oxidase, an enzyme needed for the conversion of hypoxanthine to xanthine and xanthine to uric acid. The uricosuric drugs (e.g., probenecid) prevent the tubular reabsorption of urate and increase its excretion in the urine. The serum urate concentrations are monitored to determine efficacy and dosage. Prophylactic colchicine or NSAIDs may be used between gout attacks.

In summary, the systemic autoimmune rheumatic disorders are a group of chronic disorders with overlapping symptoms that are characterized by diffuse inflammatory lesions and progressive changes in connective tissue. Rheumatoid arthritis (RA) is a chronic systemic inflammatory disorder affecting multiple joints. Joint involvement, which is symmetric, begins with inflammatory changes of the synovium and formation of a destructive granulation tissue called *pannus* that leads to joint instability and eventual deformity. Systemic lupus erythematosus is a chronic autoimmune disorder that affects multiple body systems, including the musculoskeletal system, skin, kidneys, cardiovascular system, hematologic system, and CNS. There is an exaggerated production of autoantibodies, which interact with antigens to produce an immune complex. These immune complexes produce an inflammatory response in affected tissues. Systemic sclerosis, often prefixed by the term *progressive,* is sometimes called *scleroderma.* In this disorder, the skin is thickened through fibrosis with an accompanying fixation to the subdermal structures, including the sheaths or fascia covering tendons and muscles.

The spondyloarthropathies affect the axial skeleton, particularly the spine. Inflammation develops at sites where ligaments insert into bone. Because they lack the rheumatoid factor (RF), they are referred to as *seronegative spondyloarthropathies*. They include ankylosing spondylitis, reactive arthropathies, and psoriatic arthritis. Ankylosing spondylitis, which is characterized by bilateral sacroiliitis and loss of motion in the spinal column, is considered a prototype of this classification category. The cause remains unknown; however, a strong association between the HLA-B27 antigen and ankylosing spondylitis has been identified.

Osteoarthritis (OA), the most common form of arthritis, is a localized condition affecting primarily the weight-bearing joints. It can occur as a primary idiopathic disorder or as a secondary disorder due to congenital or acquired defects in joint structures. Risk factors for OA progression include older age, multiple joint involvement, neuropathy, and, for knees, obesity. The joint changes associated with OA, which include progressive loss of articular cartilage and subchondral bone, result from inflammatory changes that occur when cartilage tries to repair itself.

Gout is a crystal-induced arthropathy caused by the presence of monosodium urate crystals in the joint cavity. It includes acute gouty arthritis with recurrent attacks of auricular and periauricular inflammation, and tophi or the accumulation of crystalline deposits in articular surfaces, bones, and soft tissue surrounding joints. The disorder is accompanied by hyperuricemia, which results from overproduction of uric acid or from the reduced ability of the kidney to rid the body of excess uric acid.

Rheumatic Diseases in Children and the Elderly

Rheumatic Diseases in Children

Children can be affected with almost all of the rheumatic diseases that occur in adults. In addition to disease-specific differences, these conditions affect not only the child but also the family. Growth and development require special attention. Rheumatic disorders of children include juvenile RA, juvenile dermatomyositis, and juvenile spondyloarthropathies.

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) is the most common form of childhood arthritis and one of the most common chronic childhood illnesses.[62] It is characterized by synovitis and can influence epiphyseal growth by stimulating growth of the affected side. Generalized stunted growth also may occur. The initial symptoms of JIA may be subtle or acute, and often include morning stiffness and gelling; easy fatigability, particularly after school; and joint swelling. The involved joints are often warm, resist full range of motion, and are painful on motion, but not erythematous.[63] JIA can be regarded not as a single disease, but as a category of diseases with three principal types of onset: (1) oligoarticular or pauciarticular arthritis (affecting four or fewer joints), (2) polyarthritis (affecting five or more joints), and (3) systemic-onset disease.[62,63]

Oligoarthritis (pauciarticular disease), which is the most common type of JIA, predominantly affects joints of the lower extremities, usually the knees or ankle. Involvement of upper extremity large joints and the hip is rarely a presenting sign. Often a single joint is affected at onset. The severity of joint symptoms is usually mild and it is not uncommon for children to present with normal or near-normal overall function. Children with this form of JIA are usually younger (1 to 5 years at onset), more likely to be girls (girls outnumber boys by 4 to 1), often RF positive, and at greater risk for developing chronic eye inflammation.[62] The inflammation primarily involves the anterior chamber of the eye and is associated with minimal, if any, symptoms in about 80% of cases. Because severe eye changes can occur, these children should be screened at regular intervals and treated by an experienced eye specialist.

Polyarthritis (polyarticular disease) is generally characterized by involvement of both large and small joints. This form of JIA may develop at any age up to 16 years of age, with girls outnumbering boys by 3 to 1.[62] This form of arthritis more closely resembles the adult form of the disease than the other two subgroups. RF sometimes is present and may indicate a more active disease process. Clinical manifestations are highly variable and include fatigue, low-grade fever, weight loss, malaise, anemia, stunted growth, slight organomegaly (e.g., hepatosplenomegaly), and lymphadenopathy.

Systemic-onset disease, which affects approximately 2% to 17% of children with JIA, is characterized by arthritis and prominent visceral involvement that include hepatosplenomegaly, lymphadenopathy, and serositis, such as pericardial effusion.[62] The symptoms of systemic JIA include a daily intermittent high fever, which usually is accompanied by a characteristic faint erythematous, macular rash. The salmon-colored lesions of the rash may be linear or circular, from 2 to 5 mm in size, and appear in groups with a linear distribution on the trunk and proximal extremities. The rash is not pruritic. The most prominent diagnostic feature is its transient nature, with a group of lesions lasting less than an hour. Systemic symptoms usually subside in 6 to 12 months.

The prognosis for most children with JIA is good. NSAIDs are the first-line drugs used in treating JIA. Most children with polyarticular or systemic JIA, however, need additional anti-inflammatory therapy.[63] Glucocorticoids are recommended only for overwhelming inflammation of systemic disease. Careful attention to growth and development and nutritional issues are additional aspects of treatment of children with JIA. Children are encouraged to lead as normal a life as possible.

Juvenile Dermatomyositis

Juvenile dermatomyositis (JDMS) is an inflammatory myopathy primarily involving skin and muscle and associated with a characteristic rash. JDMS can affect children

of all ages, with an average age at onset of 7 years.[64] There is an increased incidence among girls. The cause is unknown, but there is a history of infection in the 3 months before disease onset in most affected children. Symmetric proximal muscle weakness, elevated muscle enzymes, evidence of vasculitis, and electromyographic changes confirming an inflammatory myopathy are diagnostic for JDMS. Generalized vasculitis is not seen in the adult form of the disease. The rash may precede or follow the onset of proximal muscle weakness. Periorbital edema, erythema, and eyelid telangiectasia are common.

Calcifications can occur in 30% to 50% of children with JDMS and are by far the most debilitating symptom. The calcifications appear at pressure points or sites of previous trauma. JDMS is treated primarily with corticosteroids to reduce inflammation. Occasionally, immunosuppressives are used in cases of refractory disease. All children with JDMS should avoid exposure to sun and also use a sunscreen with a sun protection factor (SPF) greater than 36, a calcium-sufficient diet, and vitamin D therapy.[64]

Juvenile Spondyloarthropathies

Ankylosing spondylitis, reactive arthritis, psoriatic arthritis, and spondyloarthropathies associated with ulcerative colitis and regional enteritis can affect children as well as adults. Psoriatic arthritis is particularly common in young girls. The arthropathies of inflammatory bowel disease and reactive arthritis are much less common in childhood. They can affect children of any age.[65]

In children, spondyloarthropathy manifests in peripheral joints first, mimicking pauciarticular JIA, with no evidence of sacroiliac or spine involvement for months to years after onset. The spondyloarthropathies are more common in boys and commonly occur in children who have a positive family history. HLA-B27 typing is helpful in diagnosing children because of the unusual presentation of the disease.

Management of the disease involves physical therapy, education, and attention to growth and developmental issues. Medication includes the use of salicylates or other NSAIDs. In children who are not responsive to these medications, methotrexate may be considered. Exercises to maintain range of motion of the back, thorax, and affected joints should be instituted early in the disease. Custom-fitted shoes are particularly useful in managing painful entheses of the feet.[65]

Rheumatic Diseases in the Elderly

Rheumatic disorders are common causes for complaint among elderly persons.[66] The pain, stiffness, and muscle weakness affect daily life, often threatening independence and quality of life. Symptoms of the rheumatic diseases can also have an indirect effect on and even threaten the duration of life for the elderly. The weakness and gait disturbance that often accompany the rheumatic diseases can contribute to the likelihood of falls and fracture, causing suffering, increased health care costs, further loss of independence, and the potential for a decreased life span.

Arthritic complaints in the elderly are most frequently associated with degenerative forms of arthritis, such as osteoarthritis, but forms of inflammatory arthritis such as RA and gouty arthritis are also seen. One form of rheumatic disease that has a predilection for the elderly is polymyalgia rheumatica.

Osteoarthritis

Osteoarthritis is by far the most common form of arthritis among the elderly.[56,66] It is the greatest cause of disability and limitation of activity in older populations. Knee OA, which affects 13% of adults over age 55, can be particularly disabling.[56] It has been suggested that OA begins at a very young age, expressing itself in the elderly only after a long period of latency. Management of OA in older persons focuses on education about both the disease process and its management, pain control, improving function and preventing disability, and altering the disease and its consequences. Because of their side effects, pharmacologic therapy is used only when conservative efforts fail to improve function and surgical interventions are usually used as a last resort.[56] Nonpharmacologic approaches include weight loss in persons who are obese, exercise, physical therapy, and use of braces and walking aids. Attention to environmental hazards to prevent falls is essential. For persons with knee OA, bracing and orthotics provide a shift in the medial knee compartment and, in so doing, may provide considerable relief of pain and improvement in function.[66] A cane reduces the loading force on a joint, and persons with hip or knee OA should consider using a cane in the hand contralateral to the painful joint. All persons with knee and hip OA should also receive appropriate advice concerning footwear.

Rheumatoid Arthritis

The prevalence of RA increases with advancing age, at least until 75 years of age.[66] Seropositive patients are more likely to have an acute onset with systemic features and higher disease activity. Patients with seronegative, elderly-onset RA have a disease that usually follows a mild course. The close resemblance of the manifestations of seronegative RA in the elderly to those of polymyalgia rheumatica has led to speculation concerning the relationship of these syndromes. It may be that RA in the elderly is a broad disorder that includes a number of distinct subsets with characteristic manifestations, courses, and outcomes.

Crystal-Induced Arthropathies

The two best-recognized forms of crystal-induced joint disease are caused by the deposition of monosodium urate (gout) and calcium pyrophosphate (pseudogout).[67] Gout typically has its onset in middle-aged adults, whereas, pseudogout has an increasing prevalence in older adults and is often associated with unique and atypical features.

Gout. The incidence of clinical gout increases with advancing age, in part because of the increased involvement of joints after years of continued hyperuricemia. High serum urate levels rarely occur in women before menopause; initial attacks of clinical gout occur around the age of 70 years, or 20 years after menopause. The treatment of gout is often more difficult in the elderly. Although colchicine may be effective in controlling the symptoms of chronic gout, it may cause diarrhea in some patients, limiting its effectiveness in maintenance therapy.

Pseudogout. As part of the tissue aging process, OA develops with associated cartilage degeneration and the shedding of calcium pyrophosphate crystals into the joint cavity. These crystals may produce a low-grade chronic inflammation—the chronic pseudogout syndrome. The accumulation of calcium pyrophosphate and related crystalline deposits in articular cartilage is common in the elderly. There are no medications that can remove the crystals from the joints. Although it may be asymptomatic, presence of the crystals may contribute to more rapid cartilage deterioration. This condition may coexist with severe OA. Calcium pyrophosphate deposition disease may also present with proximal muscle pain mimicking polymyalgia rheumatica.

Polymyalgia Rheumatica

Polymyalgia rheumatica is an inflammatory condition of unknown origin characterized by aching and morning stiffness in the cervical regions and shoulder and pelvic girdle areas.[68,69] Of the forms of arthritis affecting the elderly, it is one of the more difficult to diagnose and one of the most important to identify. Elderly women are especially at risk. Polymyalgia rheumatica is a common syndrome of older patients, rarely occurring before 50 years and usually after 60 years of age. The onset can be abrupt, with the patient going to bed feeling well and awakening with pain and stiffness in the neck, shoulders, and hips.

Diagnosis is based on the pain and stiffness persisting for at least 1 month and an elevated ESR. The diagnosis is confirmed when the symptoms respond dramatically to a small dose of prednisone, a corticosteroid. Biopsies have shown that the muscles are normal, despite the name, but that a nonspecific inflammation affecting the synovial tissue is present. It is possible that a number of patients are erroneously diagnosed as having RA or OA. For patients with an elevated ESR, the diagnosis usually is based on a 3-day trial of prednisone treatment.[69] Patients with polymyalgia rheumatica typically exhibit striking clinical improvement on approximately the second day. Patients with RA also show improvement, although usually days later.

Treatment with NSAIDs provides relief for some patients, but most require continuing therapy with prednisone, with gradual reduction of the dose over the course of 1.5 to 2 years, using the person's symptoms as the primary guide. Patients need close monitoring during the maintenance phase with prednisone therapy. Because their symptoms are relieved, they often quit taking the prednisone and their symptoms recur, or doses are missed and the decreased dosage leads to an increase in symptoms. Unless careful assessment reveals the frequency of missed doses, the physician may be misled into increasing the dosage when it is not needed. Because of the side effects of the corticosteroids, the goal is to use the lowest dose of the drug necessary to control the symptoms. Weaning patients off low-dose prednisone therapy after this length of time can be a difficult and extended process.

A certain percentage of patients with polymyalgia rheumatica also develop *giant cell arteritis* (i.e., temporal arteritis) with involvement of the ophthalmic arteries. The two conditions are considered to represent different manifestations of the same disease. Giant cell arteritis, a form of systemic vasculitis, is a systemic inflammatory disease of large and medium-sized arteries. The inflammatory response seems to be a T-cell response to an antigen.

Clinical manifestations of giant cell arteritis usually begin insidiously and may exist for some time before being recognized.[68] It is potentially dangerous if missed or mistreated, especially if the temporal artery or other vessels supplying the eye are involved, in which case blindness can ensue quickly without treatment. The condition is responsive to appropriate therapy. For those patients at risk, adherence to the medication program is critical, with preservation of sight being the goal. Because this complication can occur so quickly and is relatively asymptomatic, it is vital that the patient understand the importance of taking the correct dose regularly as prescribed. Initial treatment consists of large doses of prednisone. This dosage is continued for 4 to 6 weeks and then decreased gradually.

Management of Rheumatic Diseases in the Elderly

In addition to diagnosis-specific treatment, the elderly require special considerations. Management techniques that rely on modalities other than drugs are particularly important for the elderly. These include splints, walking aids, muscle-building exercise, and local heat. Muscle-strengthening and stretching exercises are particularly effective in the elderly person with age-related losses in muscle function and should be instituted early. Rest, the cornerstone of conservative therapy, is hazardous in the elderly, who can rapidly lose muscle strength.

In terms of medications, the selection of drugs used in the treatment of arthritic disorders and their dosages may need to be considered when prescribing for the elderly. For example, the NSAIDs may be less well tolerated by the elderly, and their side effects are more likely to be serious. In addition to bleeding from the gastrointestinal tract and renal insufficiency, there may be cognitive dysfunction manifested by forgetfulness, inability to concentrate, sleeplessness, paranoid ideation, and depression.

Joint arthroplasty can also be used for pain relief and increased function. Chronologic age is not a contraindication to surgical treatment of arthritis. In appropriately selected elderly candidates, survival and functional

outcome after surgery are equivalent to those in younger age groups. The more sedentary activity level of the elderly makes them even better candidates for joint replacement because they put less stress and demand on the new joint.

In summary, rheumatic diseases that affect children include juvenile idiopathic arthritis, juvenile dermatomyositis, and juvenile-onset spondyloarthropathies. Although the childhood form of the arthritis may be similar to that seen in the adult, there are manifestations and treatment issues that are unique to the younger population. Managing rheumatic diseases in children requires a team approach to address issues related to the family, school, growth and development, and coping strategies, with development of a comprehensive disease management program.

Arthritis is the most common complaint of the elderly population. There is a difference in the manifestations, diagnosis, and treatment of some of the rheumatic diseases in the elderly compared with those in the younger population. OA is the most common form of arthritis among the elderly. The prevalence of RA and gout increases with advancing age. One form of rheumatic disease that has a predilection for the elderly is polymyalgia rheumatica. A certain percentage of patients with polymyalgia rheumatica also develop giant cell arteritis, a condition that can potentially cause blindness if not recognized and treated.

REVIEW EXERCISES

1. A 60-year-old postmenopausal woman presents with a compression fracture of the vertebrae. She has also noticed increased backache and loss of height over the last few years.

- **A.** Explain how the lack of estrogen and aging contribute to the development of osteoporosis.
- **B.** What other factors should be considered when assessing the risk for developing osteoporosis?
- **C.** What is the best way to measure bone density?
- **D.** Name the two most important factors in preventing osteoporosis.
- **E.** What medications might be used to treat this woman's condition?

2. A 30-year-old woman, recently diagnosed with rheumatoid arthritis (RA), complains of general fatigue and weight loss along with symmetric joint swelling, stiffness, and pain. The stiffness is more prominent in the morning and subsides during the day. Laboratory measures reveal an RF of 120 IU/mL (nonreactive, 0 to 39 IU/mL; weakly reactive, 40 to 79 IU/mL; reactive, >80 IU/mL).

- **A.** Describe the immunopathogenesis of the joint changes that occur with RA.
- **B.** How do these changes relate to this woman's symptoms?
- **C.** What is the significance of her RF test results?
- **D.** How do her complaints of general fatigue and weight loss relate to the RA disease process?

3. A 65-year-old obese woman with a diagnosis of Osteoarthritis (OA) has been having increased pain in her right knee that is made worse with movement and weight bearing and is relieved by rest. Physical examination reveals an enlarged joint with a varus deformity; coarse crepitus is felt over the joint on passive movement.

- **A.** Compare the pathogenesis and articular structures involved in OA with those of RA.
- **B.** What is the origin of the enlargement of the affected joint, the varus deformity, and the crepitus that is felt on movement of the affected knee?
- **C.** Explain the predilection for involvement of the knee in persons such as this woman.
- **D.** What types of treatment are available for this woman?

4. A 75-year-old woman is seen by a health care provider because of complaints of fever, malaise, and weight loss. She is having trouble combing her hair, putting on a coat, and getting out of a chair because of the stiffness and pain in her shoulders, hip, and lower back. Because of her age and symptoms, the health care provider suspects the woman has polymyalgia rheumatica.

- **A.** What laboratory test can be used to substantiate the diagnosis?
- **B.** What other diagnostic strategies are used to confirm the diagnosis?
- **C.** How is the disease treated?

Chapter 45

Structure and Function of the Skin

The skin, also called the *integumentum*, is one of the largest and most versatile organs in the body. It has a surface area of 1.5 to 2 square meters, weighs approximately 4 kg (9 pounds), and forms the major interface between the internal organs and the external environment. Besides providing a covering for the entire body surface, the skin performs may other functions, including protection against physical injury, sunlight, and microorganisms; prevention of loss of fluids from the internal environment; regulation of body temperature; reception of continual sensations from the environment, such as touch, temperature, and pain; and synthesis of vitamin D through the action of sunlight on the skin.

Structure and Function of the Skin

The skin and its appendages (sweat glands, hair follicles, and nails) constitute a complex organ with many cell types. The properties of the skin, such as the thickness of skin layers, the distribution of sweat glands, and the number and size of hair follicles, vary in different parts of the body. Nevertheless, certain properties are common to the skin on all areas of the body. Structurally, the skin consists of two main layers: a superficial and thinner epithelial tissue layer, called the *epidermis*, and a deeper and thicker connective tissue layer, called the *dermis*. The basement membrane zone is an interface between the dermis and epidermis (Fig. 45-1). A layer

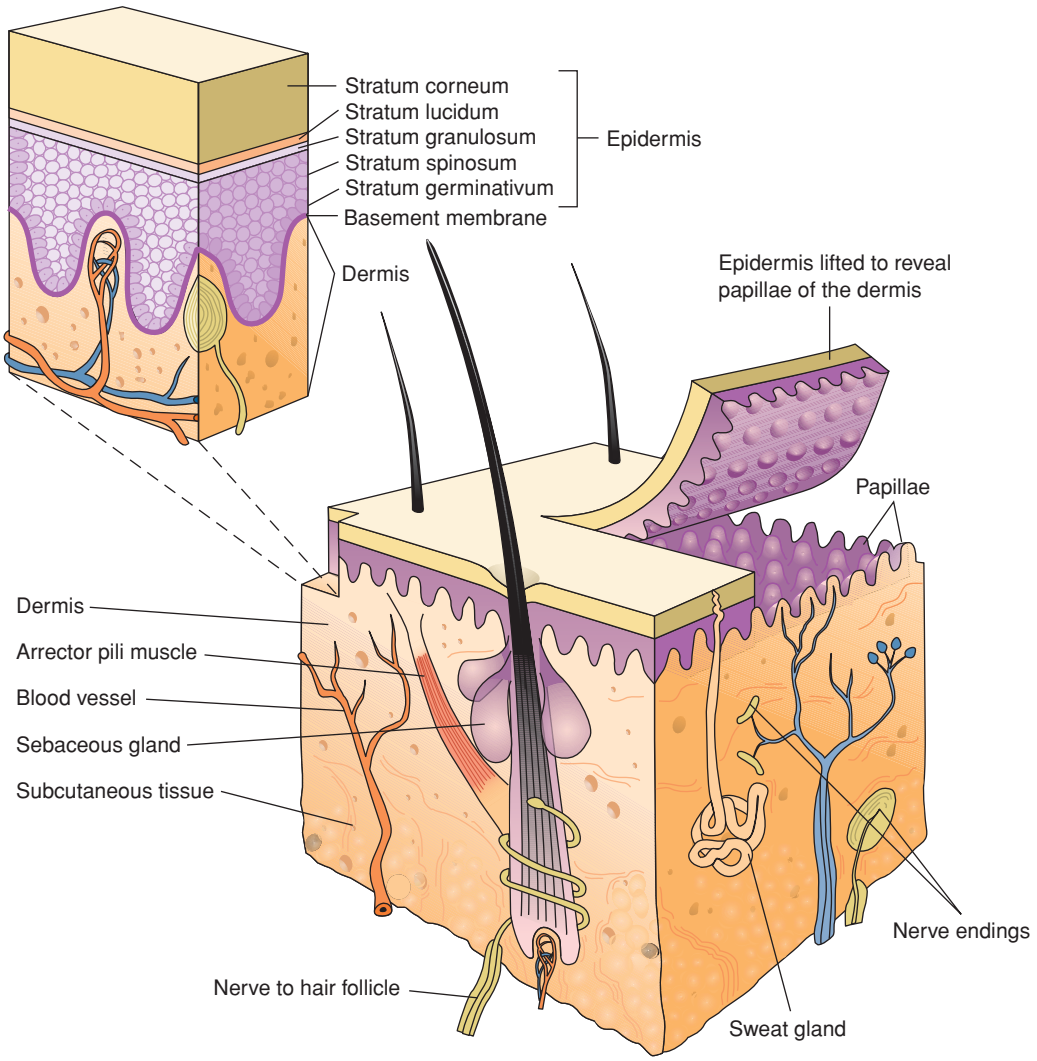

FIGURE 45-1. Three-dimensional view of the skin.

of subcutaneous tissue, sometimes called the *hypodermis*, serves as a storage site for fat and contains large blood vessels that supply the skin.

Epidermis

The functions of the skin depend largely on the properties of its epidermis, which is composed of stratified keratinized epithelium. The epidermis is composed of four types of cells: keratinocytes, melanocytes, Langerhans cells, and Merkel cells. The keratinocytes produce a fibrous protein called *keratin*, which is essential to the protective function of skin; the melanocytes produce a pigment called *melanin*, which is responsible for skin color, tanning, and protecting against ultraviolet radiation; the Langerhans cells link the epidermis to the immune system; and the Merkel cells provide sensory information.

Keratinocytes

The keratinocytes are the predominate cell type of the epidermis. These keratin-producing cells form five distinct

Organization of Skin Structures

- The skin has two layers, an outer epidermis and an inner dermis, separated by a basement membrane.
- The epidermis, which is avascular, is composed of four to five layers of stratified squamous keratinized epithelial cells that are formed in the deepest layer of the epidermis and migrate to the skin surface to replace cells that are lost during normal skin shedding.
- The basement membrane is a thin adhesive layer that cements the epidermis to the dermis. This is the layer involved in blister formation.
- The dermis is a connective tissue layer that separates the epidermis from the underlying subcutaneous fat layer. It contains the blood vessels and nerve fibers that supply the epidermis.

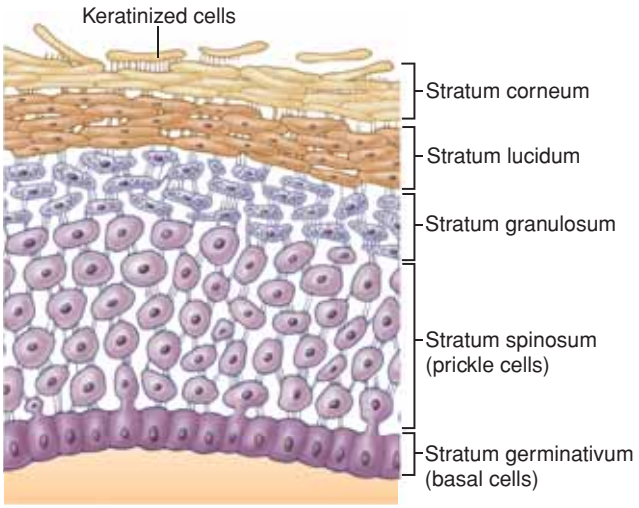

FIGURE 45-2. Epidermal cells. The basal cells undergo mitosis, producing keratinocytes that change their size and shape as they move upward, replacing cells that are lost during normal cell shedding.

layers, or *strata*, as they divide and mature: the stratum germinativum, the stratum spinosum, the stratum granulosum, the stratum lucidum, and the stratum corneum.

The deepest layer, the *stratum germinativum* or *stratum basale,* consists of a single layer of basal cells that are attached to the basal lamina in the basement membrane. The basal cells are the only epidermal cells that are mitotically active. All cells of the epidermis arise from this layer. As new cells form in the basal layer, the older cells change shape and are pushed upward toward the skin surface (Fig. 45-2). As these cells approach the surface, their cytoplasm is converted to keratin and they form flattened plates of dead cells on the skin surface. It normally takes 3 to 4 weeks for the epidermis to replicate itself. The rate of cell division in the stratum basale is greatly accelerated when the outer layers of the epidermis are stripped away as occurs in abrasions and burns.

The second layer, the *stratum spinosum,* is formed as cells from the basal cell layer move upward toward the skin surface. The stratum spinosum is two to four layers thick. The cells of this layer are commonly referred to as *prickle cells* because they develop a spiny appearance as their cell borders interact. The third layer, the *stratum granulosum,* consists of three to five layers of flattened keratinocytes. The nuclei and organelles of these cells begin to degenerate and keratin filaments become more apparent. A distinctive feature of cells in this layer is the appearance of dark staining granules of a protein called *keratohyalin,* which serve as a support for the keratin filaments. The *stratum lucidum,* the fourth layer, which lies just superficial to the stratum granulosum, is a thin, transparent layer mostly confined to the palms of the hands and soles of the feet. It consists of transitional cells that retain some of the functions of living skin cells from the layers below but otherwise resemble the cells of the stratum corneum.

The top or surface layer of the epidermis is the *stratum corneum*. The cells in the stratum corneum are made up of numerous layers of dead keratinized cells. The interior of the cells contain mostly keratin and keratohyalin. These cells are continuously shed and replaced by cells from the deeper strata. The stratum corneum is the layer that varies most in cell layers and thickness. It ranges from 15 layers of cells in areas such as the face to 25 or more layers on the arm. Specialized areas, such as the palms of the hand and soles of the feet, have 100 layers or more.

Melanocytes

Melanocytes are dendritic cells found scattered among the basal cells in the stratum basale. They function to produce pigment granules called *melanin,* the substance that gives skin its color. During embryonic life, melanocyte precursor cells migrate from the neural crest and enter the developing epidermis. A specific functional association is then established in which one melanocyte maintains an association with a given number of keratinocytes. This association is called the *dermal melanin unit*. The ratio of melanocytes to keratinocytes varies in different parts of the body and is constant in all races.

As dendritic cells, melanocytes are round to columnar cells with long undulating processes that extend between the keratinocytes of the stratum spinosum (Fig. 45-3). Melanocytes synthesize melanin from the amino acid tyrosine in the presence of an enzyme called *tyrosinase* that is activated by ultraviolet light. Synthesis of melanin occurs in membrane-bound structures called *premelanosomes,* which are derived from the Golgi complex. As melanin accumulates in the premelanosomes, they are transformed into mature melanin granules, called *melanosomes*. Premelanosomes are concentrated near the Golgi apparatus, nearly mature melanosomes near the base of the cell processes, and fully mature melanocytes

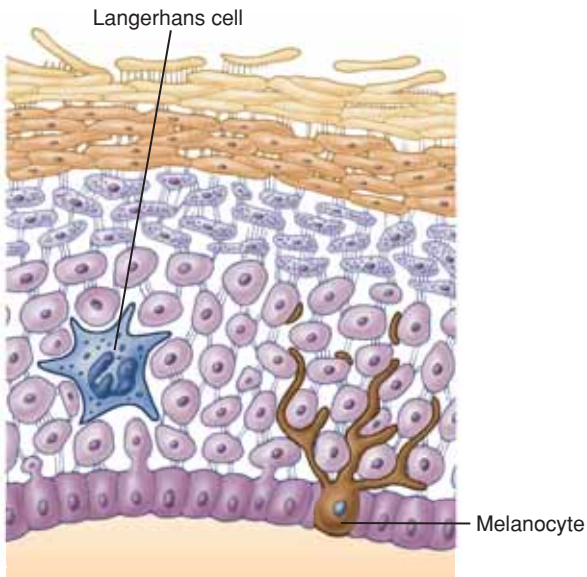

FIGURE 45-3. The melanocytes, which are located in the basal layer of the skin, produce melanin pigment granules that give skin its color. The melanocytes have threadlike, cytoplasm-filled extensions that are used in passing the pigment granules to the keratinocytes.

at the ends of the processes. Melanosomes and their melanin content are transferred to neighboring keratinocytes by pigment donation. This process involves the phagocytosis of the tips of the melanocyte process by keratinocytes. After pigment donation, the melanocyte process elongates and receives more melanosomes, and the process is repeated. Thus, a single melanocyte is able to provide melanin to all of the associated keratinocytes in its epidermal melanin unit.

Skin color is determined by the type, number, and size of the melanosomes transferred into the surrounding keratinocytes. Dark-skinned and light-skinned people have approximately the same number of melanocytes, but the production and packaging of pigment are different. In dark-skinned people, *larger* melanin-containing melanosomes are produced and transferred individually to the keratinocyte, whereas in light-skinned people, *smaller* melanosomes are produced and then packaged together in a membrane before being transferred to the keratinocyte.

There are two major forms of melanin: *eumelanin* and *pheomelanin*. Exposure to the sun's ultraviolet rays increases the production of eumelanin, a brownish-black pigment, which causes tanning to occur. The primary function of such melanin is to protect the skin by absorbing and scattering harmful ultraviolet rays, which are implicated in skin cancers. Localized concentrations of eumelanin are also responsible for the formation of freckles and moles. Pheomelanin, a reddish-yellow pigment, is particularly concentrated in the lips, nipples, glans penis, and vagina. Besides the skin, it is found in hair, particularly red hair. It has been suggested that the reason fair-haired individuals are more susceptible to skin cancers may be due to the enhanced photoreactivity of pheomelanin, as compared with eumelanin.

Langerhans Cells

Langerhans cells are a subtype of dendritic cells that reside in the epidermis (Fig. 45-4). They are antigen-presenting cells that originate in the bone marrow and are part of the mononuclear phagocytic system. Langerhans cells play a major role in functioning of the skin's immune system. Like macrophages, Langerhans cells express both major histocompatibility class (MHC) I and II molecules as well as receptors for immunoglobulins (see Chapter 15). It is postulated that the major function of the Langerhans cells found in the skin is to phagocytose and process foreign antigens, after which they migrate into regional lymph nodes, where they present the processed antigens to T cells (Fig. 45-4). As antigen-presenting cells, the Langerhans cells are involved in delayed-type hypersensitivity reactions such as contact dermatitis and other cell-mediated immune responses in the skin.

Merkel Cells

Merkel cells are epidermal cells that function in cutaneous sensation. They are interspersed among the keratinocytes of the stratum basale of the epidermis, and are particularly abundant in areas of the skin where sensory

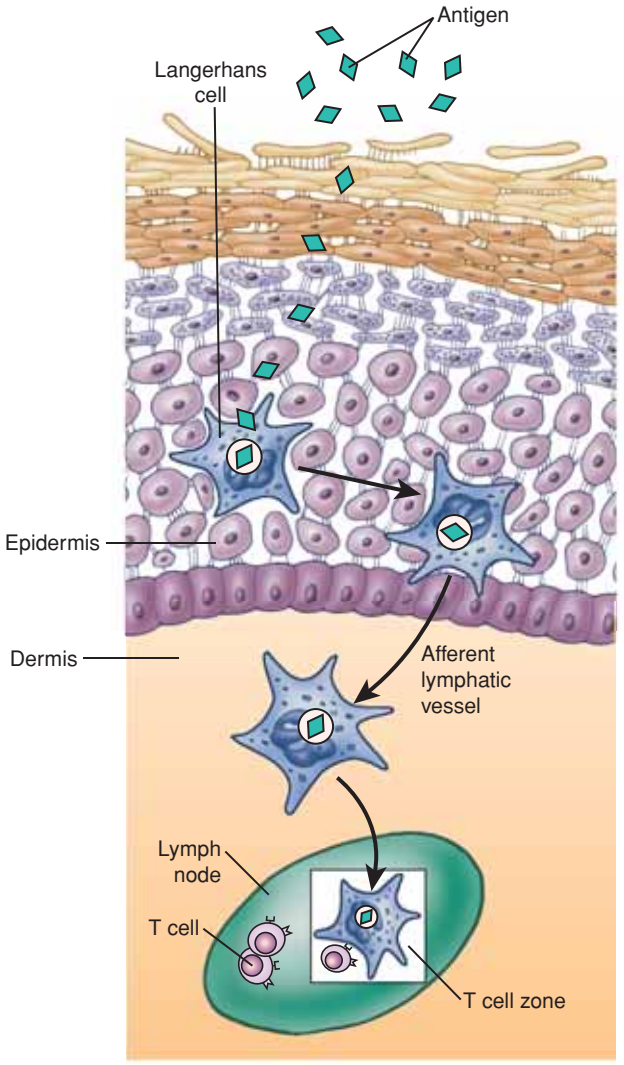

FIGURE 45-4. Langerhans cells.

perception is acute, such as the fingertips. They are usually found as single cells located parallel to the basement. Myelinated sensory neurons traverse the basement membrane to approximate the Merkel cell and form a Merkel cell–neuron complex. These complexes may function as tactile mechanoreceptors. Merkel cells display distinctive organelle and membrane-bound dense granules, suggesting that they possess neurosecretory function. These functions may include metabolic support of their associated neurons, neuron development, and regeneration after injury.

Dermis

The dermis is the connective tissue layer that separates the epidermis from the subcutaneous fat layer (see Fig. 45-1). It supports the epidermis and serves as its primary source of nutrition. The main component of the dermis is collagen, a group of fibrous proteins. Collagen represents 70% of dry skin weight and serves as the major stress-resistant material of the skin. Collagen is

rich in amino acids. Collagen fibers are loosely arranged in the papillary dermis, but are tightly bundled in the reticular dermis. The hair follicles and glandular structures are embedded in this layer and continue through the epidermis.

Based on its tissue structure, the dermis can be divided into both a superficial papillary dermis and a deeper reticular dermis. The two layers of the dermis contain immune cells and fibroblasts, blood vessels, and nerves.

Papillary Dermis

The papillary layer of the dermis is a thin superficial layer that interdigitates directly with the epidermis, but is separated from it by the basement membrane. It consists of collagen fibers and ground substance. This layer is densely covered with conical projections called *dermal papillae* (see Fig. 45-1). The basal cells of the epidermis project into the papillary dermis, forming *rete ridges*. It is believed that the dense structure of the dermal papillae serves to minimize the separation of the dermis and the epidermis. This layer of the dermis is richly vascularized. It contains capillaries, end arterioles, and venules that nourish the epidermal layers of the skin. Lymph vessels and nerve tissue also are found in this layer.

Reticular Dermis

The reticular layer of the dermis is the thicker area of the dermis and forms the bulk of the dermal layer. This is the tough layer in animal hides from which leather is made. The reticular dermis is characterized by a complex meshwork of three-dimensional collagen bundles interconnected with large elastic fibers and ground substance, a viscid gel that is rich in mucopolysaccharides. The collagen fibers are oriented parallel to the body's surface in any given area. Collagen bundles may be organized lengthwise, as on the abdomen, or in round clusters, as on the heel. The direction of surgical incisions is often determined by this organizational pattern.

Immune Cells

Once thought to be composed primarily of fibroblasts, it is now believed that one of the main cells of the dermis are dendritic cells, called *dermal dendrocytes*. Dermal dendrocytes are spindle-shaped cells that have both phagocytic and dendritic properties. They are believed to possess antigen-presenting functions and play an important part in the immunobiology of the dermis. In addition, it is possible that dermal dendrocytes may be able either to initiate or respond to immunologic events in the epidermis. Dermal dendrocytes also are thought to be involved in processes such as wound healing, blood clotting, and inflammation.

The dermis also contains macrophages, T cells and mast cells, and fibroblasts. Dermal macrophages and venular epithelial cells may present antigen to T cells in the dermis. Most of these T cells are previously activated or memory T cells. T-cell responses to macrophage- or endothelium-associated antigens in the dermis are probably more important in generating an immune response to antigen challenge in previously exposed persons than in initiating a response to a new antigen. The major type of T-cell–mediated immune response in the skin is delayed-type hypersensitivity (see Chapter 16).

Mast cells, which have a prominent role in immunoglobulin E–mediated immediate hypersensitivity, also are present in the dermis. These cells are strategically located at body interfaces such as the skin and mucous membranes and are thought to interact with antigens that come in contact with the skin.

Blood Vessels

The arterial vessels that nourish the skin form two plexuses (i.e., collections of blood vessels), one located between the dermis and the subcutaneous tissue and the other between the papillary and reticular layers of the dermis. The pink color of light skin results primarily from blood in the vessels of this latter plexus. Capillary flow that arises from vessels in this plexus also extends up and nourishes the overlying epidermis by diffusion. Blood leaves the skin through small veins that accompany the subcutaneous arteries. The lymphatic system of the skin, which aids in combating certain skin infections, also is limited to the dermis.

The skin is richly supplied with arteriovenous anastomoses in which blood flows directly between an artery and a vein, bypassing the capillary circulation. These anastomoses are important for temperature regulation. They can open up, letting blood flow through the skin vessels when there is a need to dissipate body heat, and close off, conserving body heat if the environmental temperature is cold.

Innervation

The innervation of the skin is complex. The dermis is well supplied with sensory receptors for temperature, pain, and tactile sensation (see Chapter 35), as well as nerves that supply the blood vessels, sweat glands, and arrector pili muscles.

The papillary layer of the dermis is supplied with free nerve endings that serve as nociceptors (i.e., pain receptors) and thermoreceptors. The dermis also contains encapsulated pressure-sensitive receptors that detect pressure and touch. The largest of these are the *pacinian corpuscles,* which are widely distributed in the dermis and subcutaneous tissue in the digits of the hands and breasts. These mechanoreceptors are specialized to perceive pressure, touch, and vibration. *Meissner corpuscles* are encapsulated mechanoreceptors specialized for tactile discrimination. They are concentrated on the fingertips and palms of the hands, where they account for about half of the tactile receptors. They are also located on the eyelids, lips, tongue, nipples, and skin of the foot and forearm. The deep dermis is supplied with small, oval mechanoreceptors called *Ruffini corpuscles*. They are slowly adapting receptors, responding to heavy pressure and joint movement. They are also believed to detect cold. The skin is also supplied by *Krause end bulbs*, nerve endings contained in a cylindrical or oval capsule. They are found most frequently in the oral cavity,

conjunctiva, and genitalia. Although their function is uncertain, they are thought to function as mechanoreceptors and heat detectors.

Most of the skin's blood vessels are innervated by the sympathetic nervous system. The sweat glands are innervated by cholinergic fibers but controlled by the sympathetic nervous system. Likewise, the sympathetic nervous system controls the arrector pili (pilomotor) muscles that cause elevation of hairs on the skin. Contraction of these muscles tends to cause the skin to dimple, producing "goose bumps."

Basement Membrane Zone

The basement membrane zone is a layer of intercellular and extracellular matrices that serves as an interface between the dermis and the epidermis. It separates the epithelium from the underlying connective tissue, anchors the epithelium to the loose connective tissue underneath, and serves as a selective filter for molecules moving between the two layers. It is also a major site of immunoglobulin and complement deposition in skin disease.

Most of the structures of the basal membrane zone are produced by cells of the epidermis. The basal lamina is the primary organizational structure of the basement membrane and is responsible for epithelial cell polarity as well as keratin gene expression. The ultrastructures of the basal lamina include the lamina lucida, lamina densa, hemidesmosomes, anchoring filaments, and microfilaments (Fig. 45-5). The *lamina lucida* is an electron-lucent layer where adherence proteins are located. It consists of fine anchoring filaments and a cell adhesion glycoprotein, called *laminin*, which plays a role in the organization of the macromolecules in the basement membrane zone and promotes attachment of cells to the extracellular matrix. The *lamina densa* contains an adhesive called *type IV collagen* as well as laminin. It is important in dermal–epidermal attachment. The tonofibril is a fiber similar to the keratin filament. Bundles of tonofibrils converge and terminate in the hemidesmosomes that serve as attachment sites for the dermis and epidermis. Because they form a continuous link between the intracellular tonofibrils of the epidermis and the extracellular basement membrane, the hemidesmosomes are also thought to be involved in relaying signals between the skin systems.

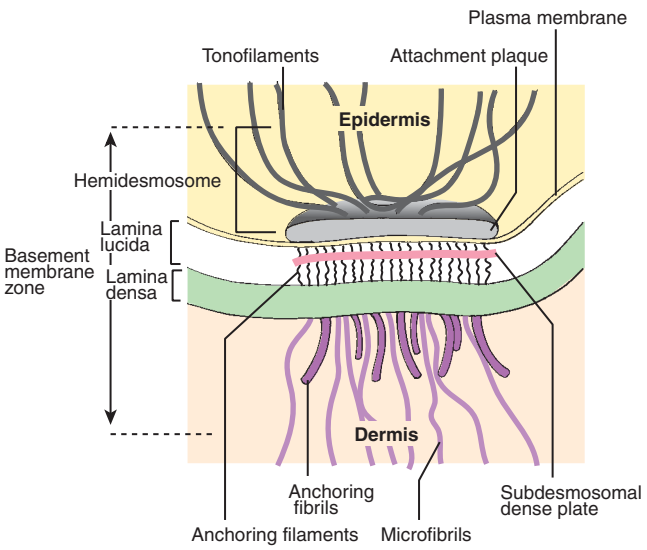

FIGURE 45-5. The dermal–epidermal interface and basement membrane layers. (Adapted from Rubin R., Strayer D.E. [Eds.]. [2008]. *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1004]. Philadelphia: Lippincott Williams & Wilkins.)

The basement membrane zone is often involved in skin disorders that cause bullae or blister formation. One of these disorders, bullous pemphigoid, is a blistering disease caused by antibodies against basement membrane proteins (Fig. 45-6). The blisters of bullous pemphigoid are large and tense and may appear on normal-appearing skin. The thighs and flexor tendons are most commonly affected. The disease is self-limited but chronic, and the person's general health is unaffected.

Skin Appendages

Skin appendages are derived from outgrowths of epidermal epithelium during development. They include the eccrine and apocrine sweat glands, sebaceous glands, hair follicles, and nails.

Eccrine and Apocrine Sweat Glands

There are two types of sweat glands: eccrine and apocrine. *Eccrine sweat glands* are simple tubular structures that originate in the dermis and open directly to the skin surface. They are numerous (several million), vary in density, and are located over the entire body surface. Their purpose is to transport sweat to the outer skin surface to regulate body temperature. *Apocrine sweat glands* are less numerous than eccrine sweat glands. They are larger and located deep in the dermal layer. They open through a hair follicle, even though a hair may not be present, and are found primarily in the axillae and groin. The major difference between these glands and the eccrine glands is that apocrine glands secrete an oily substance. In animals, apocrine secretions give rise to distinctive odors that enable animals to recognize the presence of others. In humans, apocrine secretions are sterile until mixed with the bacteria on the skin surface; they then produce what is commonly known as "body odor."

Sebaceous Glands

The sebaceous glands are located over the entire skin surface except for the palms, soles, and sides of the feet. They secrete a waxlike mixture of triglycerides, cholesterol, and secretory debris, called *sebum*. Sebum lubricates the hair and skin, prevents undue evaporation of moisture from the stratum corneum during cold weather, and helps to conserve body heat. The sebaceous glands are part of what is called the *pilosebaceous*

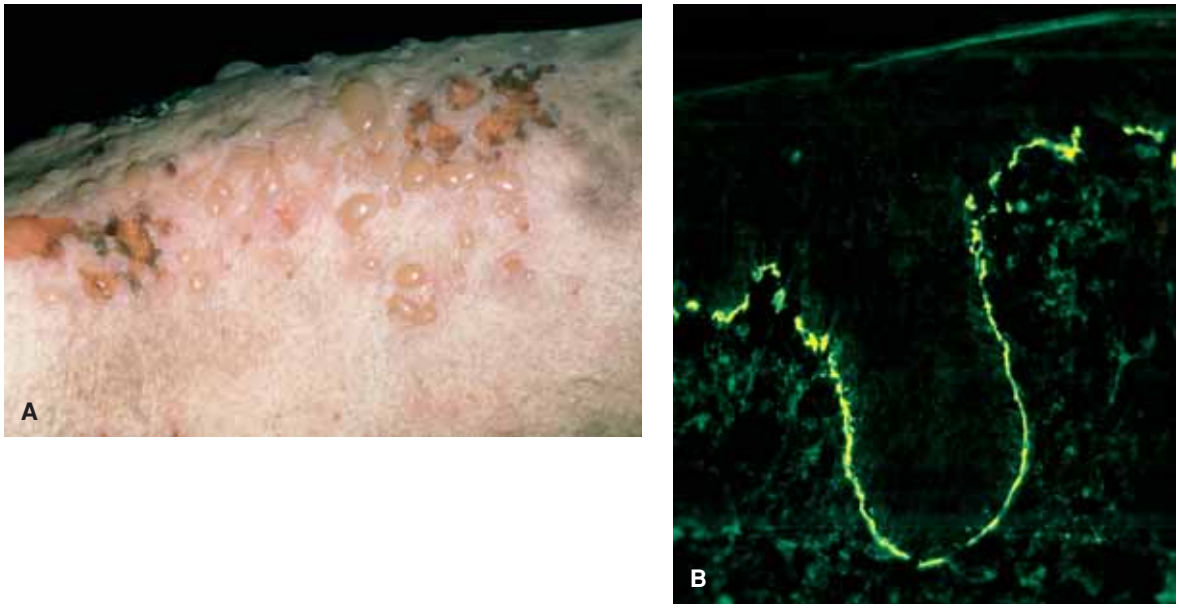

FIGURE 45-6. Bullous pemphigoid. **(A)** The skin shows multiple tense bullae on an erythematous base and erosions, distributed primarily on the medial thighs and trunk. **(B)** Direct immunofluorescence study discloses linear deposition of immunoglobulin G (and complement 3) along the dermal–epidermal junction. Ultrastructurally, these antibodies and complement are present in the lamina lucida. (From Storm C.A., Elder D.E. [2008]. The skin. In Rubin R., Strayer D.S. [Eds.], *Rubin's pathology: Clinicopathologic foundations of medicine* [5th ed., p. 1020]. Philadelphia: Lippincott Williams & Wilkins.)

unit, with their ducts opening into the upper third of the hair follicle. The sebum produced by the sebaceous gland is the product of holocrine secretion. The entire cell produces and becomes filled with the fatty product while it simultaneously undergoes cell death as the product fills the cell. Both the secretory product and the cell are then discharged from the gland into the hair follicle. New cells are produced by mitosis of the basal cells in the gland.

Sebum production is under the control of genetic and hormonal influences. Sebaceous glands are relatively small and inactive until individuals approach adolescence. The glands then enlarge, stimulated by the rise in sex hormones. Gland size directly influences the amount of sebum produced, and the level of androgens influences gland size. The sebaceous glands are the structures that become inflamed in acne (see Chapter 46).

Hair Follicles

Hair is a filamentous, keratinized structure that originates from hair follicles in the dermis. Coloration of hair is attributable to the content and type of melanin that the hair contains. The entire hair structure consists of the hair follicle, sebaceous gland, hair muscle (arrector pili), and, in some instances, apocrine gland (Fig. 45-7). Most hair follicles are associated with sebaceous glands, and these structures combine to form the pilosebaceous unit. The arrector pili muscle, located under the sebaceous gland, provides a thermoregulatory function by contracting to cause goose bumps, thereby reducing the skin surface area that is available for the dissipation of body heat.

The hair follicle is divided into three parts: the infundibulum, which extends from the surface opening to the level of the opening for the sebaceous gland; the isthmus, which extends from the infundibulum to the level of the arrector pili muscle; and the expanded inferior

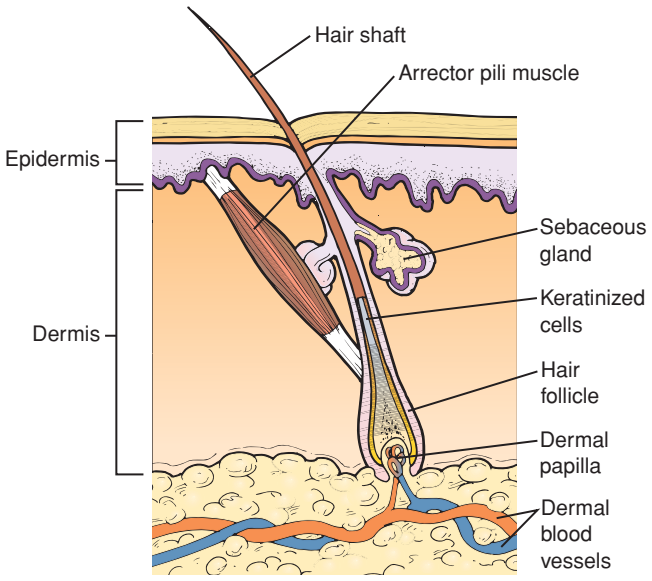

FIGURE 45-7. Parts of a hair follicle.

hair bulb, which is indented to conform to the shape of the dermal papillae occupying it. The dermal papillae contains a rich supply of nutrients and oxygen for the cells in the hair follicle.

Growth of the hair is centered in the bulb (i.e., base) of the hair follicle, and the hair undergoes changes as it is pushed outward. Hair growth goes through three cyclic phases: the anagen (growth), catagen (atrophy), and telogen (resting) phases. Anagen hair has long inner roots and outer root sheaths, is deeply rooted in the dermis, and is difficult to detach and does not come out with regular brushing. *Anagen* follicles are actively replicating and therefore especially susceptible to nutritional deficiencies and metabolic insults. The *catagen* phase represents degeneration of the root structure and migration of dermal papillae and the follicular unit toward the more superficial layers of the dermis. Catagen hair usually represents approximately 1% of all scalp hairs. *Telogen* hair has short, white, club-shaped roots. With formation of new anagen hair below the club, the developing follicle will eventually replace the telogen hair, leading to the shedding of approximately 50 to 100 hairs a day.

Nails

The nails are hardened keratinized plates, called *fingernails* and *toenails*, that protect the fingers and toes and enhance dexterity. The nails grow out from a curved transverse groove called the *nail groove*. The floor of this groove, called the *nail matrix*, is the germinal region of the nail plate (Fig. 45-8). The underlying epidermis, attached to the nail plate, is called the *nail bed*. Like hair, nails are the end product of dead matrix cells that are pushed outward from the nail matrix. Unlike hair, nails grow continuously rather than cyclically, unless permanently damaged or diseased. The epithelium of the fold of skin that surrounds the nail consists of the usual layers of skin. The stratum corneum forms the *eponychium* or cuticle. The nearly transparent nail plate provides a useful window for viewing the amount of oxygen in the blood, providing a view of the color of the blood in the dermal vessels. Changes or abnormalities of the nail can also serve to help diagnose skin or systemic diseases.

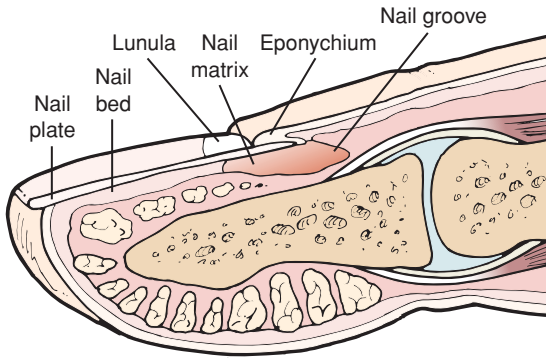

FIGURE 45-8. Parts of a fingernail.

In summary, the skin is primarily an organ of protection. It is the largest organ of the body and forms the major barrier between the internal organs and the external environment. The skin is richly innervated with pain, temperature, and touch receptors; it synthesizes vitamin D and plays an essential role in fluid and electrolyte balance. The skin is composed of two layers, the epidermis and the dermis, separated by a basement membrane.

The epidermis, the outermost layer of the skin, contains four to five layers, or strata. The major cells of the epidermis are the keratinocytes, Langerhans cells, Merkel cells, and melanocytes. The stratum germinativum, or basal layer, is the source of the cells in all five layers of the epidermis. The keratinocytes, which are the major cells of the epidermis, are transformed from viable keratinocytes to dead keratin as they move from the innermost layer of the epidermis (i.e., stratum germinativum) to the outermost layer (i.e., stratum corneum). The melanocytes are pigment-synthesizing cells that give skin its color; Langerhans cells are antigen-presenting cells that link the epidermis to the immune system; and Merkel cells are epidermal cells that function in cutaneous sensation.

The two layers of the dermis, the papillary dermis and the reticular dermis, provide the epidermis with support and nutrition and are the source of blood vessels, innervation, and skin appendages (i.e., sweat glands, sebaceous glands, hair follicles, and nails). The hypodermis, a layer of subcutaneous tissue, binds the dermis to the underlying organs and tissues of the body.

Manifestations of Skin Disorders

No two skin disorders look exactly alike, nor are they necessarily caused by the same agents. The appearance of many skin disorders may be further influenced by excessive itching, infection, or the effects of self-treatment. Skin color also may influence the appearance. Nevertheless, most skin disorders have some common characteristics that can be used to describe them. This section of the chapter covers lesions and rashes, pigmentary skin disorder, pruritus, dry skin, and variations in dark skin.

Lesions and Rashes

Rashes are temporary eruptions of the skin, such as those associated with childhood diseases, heat, diaper irritation, or drug-induced reactions. The term *lesion* refers to a traumatic or pathologic loss of normal tissue continuity, structure, or function. The components of a rash often are referred to as *lesions*. Skin lesions may occur as primary lesions arising in previously normal skin, or they may develop as secondary lesions resulting from other

disease conditions. Figure 45-9 illustrates various types of skin lesions.

Rashes and lesions may range in size from a fraction of a millimeter (e.g., the pinpoint spots of petechiae) to many centimeters (e.g., pressure ulcer). They may be blanched (white), erythematous (reddened), hemorrhagic or purpuric (containing blood), or pigmented (colored). A *macule* is a small (≤1.0 cm in diameter) flat spot, such as a freckle; a *papule* is an elevated (≥1.0 cm) superficial lesion. *Plaques* are elevated lesions (≥1 cm), often formed by the coalescence of papules. *Nodules* are solid marblelike lesions (>0.5 cm) that are deeper and firmer than a papule. A *wheal* is a somewhat irregular, relatively transient area of localized skin edema, such as a mosquito bite. *Lichenification* is a thickened and leathery roughening of the skin with increased visibility of the normal skin furrows and excoriations caused by scratching.

Blisters are circumscribed elevations of the skin caused by fluid under or within the epidermis. *Pustules* are circumscribed pus-filled elevations of the skin. *Vesicles* are small (<1.0 cm in diameter) and *bullae* are large (1.0 cm or larger in diameter) fluid-filled blisters (see Fig. 45-9). Friction blisters most commonly occur on the palmar and plantar surfaces of the hands and feet where the skin is constantly exposed to mechanical trauma, such as from shoes and household tools and appliances.

An *erosion* is a loss of the superficial epidermis, the surface of which is moist but does not bleed. An *ulcer* is a skin defect in which there has been loss of the epidermis and papillary layer of dermis. It may extend into the subcutaneous tissue, and often occurs in pathologically damaged tissue.

A *callus* is a hyperkeratotic plaque of skin due to chronic pressure or friction. It represents hyperplasia of the dead, keratinized cells that make up the cornified or horny layer of the skin. Increased cohesion between cells results in hyperkeratosis and decreased skin shedding. A callus may be filed down but is likely to recur if pressure continues in the localized area.

Corns (helomas) are small, well-circumscribed, conical, keratinous thickenings of the skin. They usually appear on the toes from rubbing or ill-fitting shoes. The corn may be either hard (heloma durum) with a central hard, horny core, or soft (heloma molle), as commonly seen between the toes. They may appear on the hands as an occupational hazard. The hard tissue at the center of the corn looks like a funnel with a broad top and a pointed bottom, hence the name "corn." Corns on the feet often are painful, whereas corns on the hands may be asymptomatic. Corns may be abraded or surgically removed, but they recur if the causative agent is not removed.

Pigmentary Skin Disorders

Pigmentary skin disorders involve the melanocytes. In some cases, there is an absence of melanin production, as in vitiligo or albinism. In other cases, there is an increase

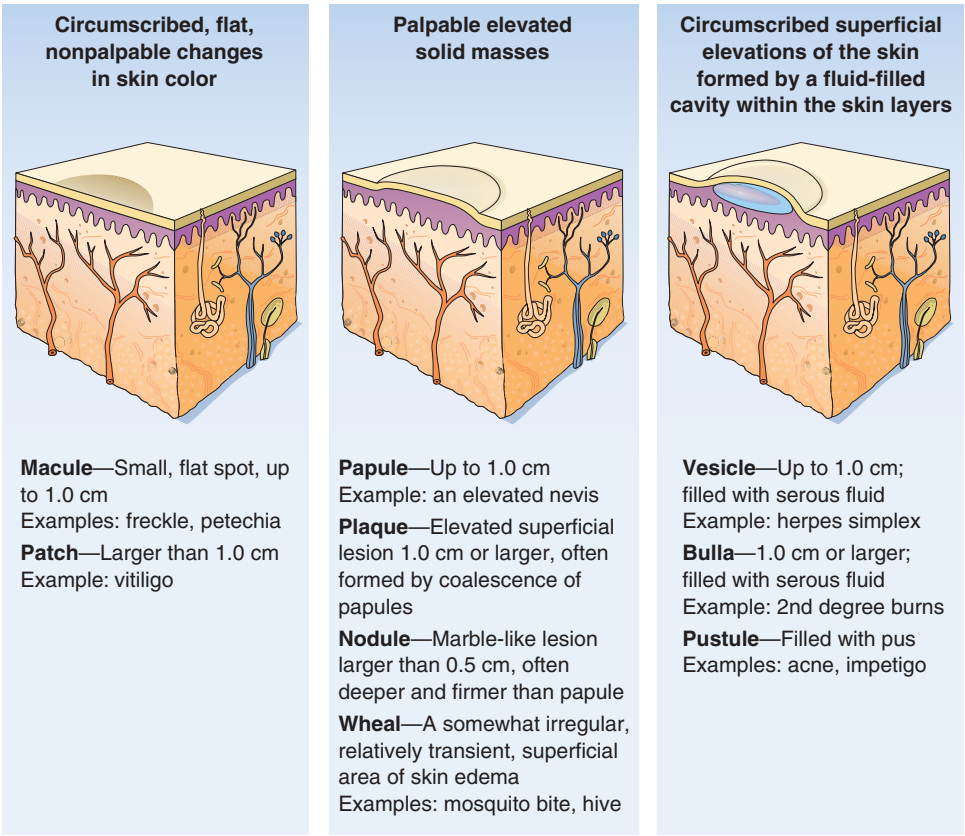

FIGURE 45-9. Primary lesions may arise in previously normal skin. Authorities vary somewhat on their definition of skin lesions by size. (Adapted from Bickley L.S., Szilagyi P.C. [2003]. *Bates' guide to physical assessment and history taking* [8th ed., p. 103]. Philadelphia: Lippincott Williams & Wilkins.)

in melanin or some other pigment, as in melasma. In either case, the emotional impact can be devastating.

Albinism, a genetic disorder in which there is complete or partial congenital absence of pigment in the skin, hair, and eyes, is found in all races. Although there are over 10 different types of albinism, the most common type is recessively inherited oculocutaneous albinism, in which there is a normal number of melanocytes but they lack tyrosinase, the enzyme needed for synthesis of melanin. It affects the skin, hair, and eyes. Individuals have pale or pink skin, white or yellow hair, and light-colored or sometimes pink eyes. Persons with albinism have ocular problems, such as extreme sensitivity to light and refractive problems. Treatment efforts for people with albinism are aimed at reducing their risk for skin cancer through protection from solar radiation and screening for malignant changes. Efforts to reduce the visual impact are important, such as glasses, preferential seating in classrooms, and large-print books.

Vitiligo is a pigmentary problem of concern to darkly pigmented persons of all races. It also affects white-skinned persons, but not as often, and the effects usually are not as socially problematic. The classic sign of vitiligo is the sudden appearance of white patches on the skin. The lesion is a depigmented macule with definite smooth borders on the face, axillae, neck, or extremities (Fig. 45-10). The patches vary in size from small macules to ones involving large skin surfaces. The large macular type is more common. Depigmented areas appear white, pale colored, or sometimes grayish-blue. Histologically, the depigmented areas may contain no melanocytes, greatly altered or decreased amounts of melanocytes, or, in some cases, melanocytes that no longer produce melanin. Although there are many treatment regimens for vitiligo, none is curative. Self-tanning lotions, skin stains, and cosmetics are used for camouflage. Micropigmentation (tattooing) has been done on smaller, recalcitrant areas, but it is often difficult to attain a correct color match. If extensive skin surfaces are involved, the treatment may be reversed and the pigmented areas bleached to match the remainder of the skin color. A melanocytotoxic agent is used to remove remaining melanocytes from skin areas.

FIGURE 45-10. Vitiligo of the forearm of a black person. (Neutrogena Skin Care Institute.) (From Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

Melasma is a disorder characterized by darkened macules on the face. It is common in all skin types, but most prominent in brown-skinned people from Asia, India, and South America. It occurs in men but is more common in women, particularly during pregnancy or while using oral contraceptives. It may or may not resolve after giving birth or discontinuing hormonal birth control. Melasma is exacerbated by sun exposure. Treatment measures are palliative, mostly consisting of limiting exposure to the sun and using sunscreens. Bleaching agents, containing 2% to 4% hydroquinone, are standard treatments.

Pruritus

Pruritus is an unpleasant sensation of itch leading to the desire to scratch. Symptoms of pruritus range from mild to severe. In some persons, the condition may be so severe that it interrupts sleep and the general quality of life. While pruritus most commonly occurs in skin disorders, it may also occur with systemic disorders, such as chronic kidney disease, diabetes, and biliary disease.

Pruritus originates within the skin's free nerve endings, is carried by small myelinated type C nerve fibers to the dorsal horn of the spinal cord, and is then transmitted to the somatosensory cortex through the spinothalamic tract (see Chapter 35). Many chemicals have been found to produce the itch sensation, including histamine, serotonin, and cytokines. Substances such as bradykinin and bile salts act locally to stimulate the itch sensation. Prostaglandins are modulators of the itch response, lowering the threshold for other mediators. Opioids produce pruritus in a number of patients who receive them and narcotic antagonists have been used successfully to relieve pruritus. Regardless of cause, pruritus is often exacerbated by skin inflammation, dry or hot ambient temperatures, skin vasodilation, and psychological stressors. Pruritus can also have a neuropathic cause. The pruritus that occurs with herpes zoster (shingles) is an example of a pruritus with a neuropathic origin. Certain idiopathic types of pruritus have been attributed to peripheral neuropathies.

Scratching, the well-known response to itch, is a spinal reflex response that to varying degrees can be controlled by the individual. While providing momentary relief, scratching increases inflammation and stimulates nerve endings, leading to more itching and scratching. Repeated scratching also causes undesirable changes in the skin such as lichenification. Successful treatment of pruritus requires interruption of this cycle.

The focus of treatment measures for pruritus can be grouped into two categories: specific and nonspecific. Specific treatment involves finding and correcting the underlying disorder, thereby eliminating the itch sensation. Nonspecific measures involve the use of measures to relieve the itch sensation and prevent complications that arise from intense and persistent scratching.

Measures such as using the entire hand to rub over large areas and keeping the fingernails trimmed often can

relieve itch and prevent skin damage. Self-limited or seasonal cases of pruritus may respond to treatment measures such as moisturizing lotions, bath oils, and the use of humidifiers. Because vasodilation tends to increase itching, cold applications may provide relief. Cool showers before bed, light sleepwear, and cool home temperatures also may be helpful. Cooling over-the-counter anti-itch agents contain menthol, camphor, or phenol. These substances stimulate nerve fibers that transmit the sensation of cold, thereby masking the itch sensation. Mild cutaneous disorders, such as bug bites, are mediated by histamine; therefore, topical antihistamines tend to be the treatment of choice. Topical corticosteroids are effective as antipruritics, particularly when used for urticaria (hives) or insect bites.

However, because most cases of pruritus are not histamine related, their management should be directed at the underlying cause. For example, systemic antihistamines and corticosteroids may be indicated for persons with severe pruritus or atopic dermatitis. Topical capsaicin cream and topical aspirin have been used for localized chronic pruritic disorders. Other modalities that have been used for all cases of pruritus with varying degrees of success are phototherapy, acupuncture, antidepressant medications, behavior modification, and alternative therapies (herbal, nutritional, and reflex therapies). In persons with pruritus due to a systemic cause, itching gradually recedes as the primary condition improves.

Dry Skin

Dry skin, also called *xerosis,* may be a natural occurrence, as in the drying of skin associated with aging, or it may be symptomatic of an underlying systemic disease or skin disorder such as contact dermatitis. Most cases of dry skin are caused by dehydration of the stratum corneum. The effects of aging on skin dryness include a change in the composition of sebaceous gland secretions and a decrease in the secretion of moisture from the sweat glands. Aging is also accompanied by a decrease in skin capillaries as well as a flattening of the dermal rete ridges, resulting in less surface area for exchange of fluids between the dermis, epidermis, and skin surface.

Persons with dry skin often experience severe pruritus and discomfort, most commonly of the extremities. Other commonly involved areas include the back, abdomen, and waist. Dry skin appears rough and scaly; there may be increased wrinkles or lines. Skin drying also predisposes the skin to scratching, resulting in cracking, fissuring, and a number of other skin maladies.

Moisturizing agents are the cornerstone of treatment for dry skin. These agents exert their effects by repairing the skin barrier, increasing the water content of the skin, reducing transepidermal water loss, and restoring the lipid barrier's ability to attract, hold, and redistribute water. Moisturizing agents can be classified as emollients, humectants, and occlusives. *Emollients* are fatty acid–containing lotions that replenish the oils on the skin surface, but usually do not leave a residue on the skin. They have a short duration of action and need to be applied frequently. *Humectants* are the additives in lotions, such as α-hydroxy acids and urea, that draw out water from the deeper skin layers and hold it on the skin surface. However, the water that is drawn to the skin is transepidermal water, not atmospheric water; thus, continued evaporation from the skin can actually exacerbate dryness. α-Hydroxy acids are derived from fruits, hence the abundance of fruit additives in shampoos and lotions in over-the-counter preparations. Urea is a nitrogenous substance that has been quite effective in reducing xerosis when combined with lotions. It is a humectant at lower concentrations (10%), but in higher concentrations (20% to 30%) it is mildly keratolytic. Clinical trials of urea have indicated its utility compared with ammonium lactate (lactic acid) lotion and glycerin. *Occlusives* are thick creams that contain petroleum or some other moisture-proof material. They prevent water loss from the skin. They are the most effective agents for relieving skin dryness, but because of their greasiness and lack of cosmetic appeal, some people do not wish to use them.

Lotion or cream additives include corticosteroids or mild anesthetics, such as camphor, menthol, lidocaine, or benzocaine. These agents work by suppressing itching while moisturizing the skin. Using room humidifiers and keeping room temperatures as low as possible to prevent water loss from the skin also may be helpful. Soaps with moisturizers may be helpful. Glycerine soaps, although popular and visually appealing, are drying and can exacerbate the symptoms.

Variations in Dark-Skinned People

Some skin disorders common to people of African, Hispanic, or East Indian descent are not commonly found in those of European descent. Similarly, some skin disorders, such as skin cancers, affect light-skinned persons more commonly than dark-skinned persons. Because of these differences, serious skin disorders may be overlooked, and normal variations in darker skin may be mistaken for anomalies.

Skin color is determined by the melanin produced by the melanocytes. Although the number of melanosomes in dark and white skin is the same, black skin produces more melanin, and more quickly, than white skin. Because of their skin color, dark-skinned persons are better protected against skin cancer, premature wrinkling, and aging of the skin that occurs with sun exposure.

A condition common in people with dark skin is too much or too little color. Areas of the skin may darken after injury, such as a cut or scrape, or after disease conditions such as acne. These darkened areas may take many months or years to fade. Dry or "ashy" skin also can be a problem for people with dark skin. It often is uncomfortable, and it also is easily noticed because it gives the skin an ashen or grayish appearance. Although using a moisturizer may help relieve the discomfort, it may cause a worsening of acne in predisposed persons.

Normal variations in skin structure and skin tones often make evaluation of dark skin difficult. The darker pigmentation can make skin pallor, cyanosis, and

TABLE 45-1 Common Normal Variations in Dark Skin

Variation	Appearance
Futcher (Voigt) line	Demarcation between darkly pigmented and lightly pigmented skin in upper arm; follows spinal nerve distribution; common in black and Japanese populations
Midline hypopigmentation	Line or band of hypopigmentation over the sternum, dark or faint, lessens with age; common in Latin American and black populations
Nail pigmentation	Linear dark bands down nails or diffuse nail pigmentation, brown, blue, or blue-black
Oral pigmentation	Blue to blue-gray pigmentation of oral mucosa; gingivae also affected
Palmar changes	Hyperpigmented creases, small hyperkeratotic papules, and tiny pits in creases
Plantar changes	Hyperpigmented macules, can be multiple with patchy distribution, irregular borders, and variance in color

Developed from information in Rosen T., Martin S. (1981). *Atlas of black dermatology.* Boston: Little, Brown.

erythema more difficult to observe. Therefore, verbal histories must be relied on to assess skin changes. The verbal history should include the client's description of her or his normal skin tones. Changes in skin color, in particular hypopigmentation and hyperpigmentation, often accompany disorders of dark skin and are very important signs to observe when diagnosing skin conditions. Common variations in dark skin and nails are described in Table 45-1.

In summary, skin lesions and rashes are the most common manifestations of skin disorders. Rashes are temporary skin eruptions. Lesions result from traumatic or pathologic loss of the normal continuity, structure, or function of the skin. Rashes and lesions may vary in size and color; they may be flat (macule or patch), palpable (papule, plaque, or nodule), or fluid-filled elevations (vesicle or bullae). Erosions involve a loss of the superficial epidermis, and an ulcer a loss of the epidermis and papillary layer of dermis. Pigmentary skin disorders involve the melanocytes. In some cases, there is an absence of melanin production, as in vitiligo or albinism. In other cases, there is an increase in melanin or some other pigment, as in melasma.

Pruritus and dry skin are symptoms common to many skin disorders. Pruritus is an unpleasant sensation of itch leading to the desire to scratch that occurs as the result of skin disorders or systemic diseases such chronic kidney disease, diabetes, and biliary disease. Pruritus is a complex process that has its origin in free nerve endings and is transmitted via the spinothalamic tract to the cerebral cortex. Pruritus, or the sensation of itch, can result from stimulation of the peripheral itch receptors or by neuropathic mechanisms that alter transmission of the itch response. Dry skin, also called *xerosis,* may be a natural occurrence, as in the drying of skin associated with aging, or it may be symptomatic of an underlying systemic disease or skin disorder such as contact dermatitis. Normal variations in dark skin often make evaluation difficult and result in some disorders being overlooked.

REVIEW EXERCISES

1. Bullous pemphigoid is an autoimmune blistering disease caused by autoantibodies to constituents of the dermal–epidermal junction.

A. Explain how antibodies, which attack glycoproteins in the lamina lucida and their attachment to the hemidesmosomes, can cause blisters to form (hint: see Fig. 45-5).

2. "Allergy tests" involve the application of an antigen to the skin, either through a small scratch or intradermal injection.

A. Explain how the body's immune system is able to detect and react to these antigens.

Chapter 46

Disorders of Skin Integrity and Function

The skin is a unique organ in that numerous signs of disease or injury are immediately observable on the skin. The skin serves as the interface between the body's internal organs and the external environment. Therefore, skin disorders represent the culmination of environmental forces and the internal functioning of the body. Sunlight, infectious organisms, chemicals, and physical agents all play a role in the pathogenesis of skin diseases. Although most disorders are intrinsic to skin, many are external manifestations of systemic disease. Thus, skin provides a valuable window for the recognition of many systemic disorders.

Primary Disorders of the Skin

Primary skin disorders are those originating in the skin. They include infectious processes, acne, rosacea, papulosquamous dermatoses, allergic disorders, and drug reactions. Although most of these disorders are not life-threatening, they can affect the quality of life.

Infectious Processes

Normally, the skin flora, sebum, immune responses, and other protective mechanisms defend against serious systemic infections. However, the skin frequently succumbs to attack by microorganisms, including fungi, bacteria, and viruses, whose primary clinical manifestations are in the skin.

Superficial Fungal Infections

Fungi are free-living, saprophytic, plantlike organisms, certain strains of which are considered part of the normal skin flora (see Chapter 14). There are two types of fungi, yeasts and molds. Yeasts, such as *Candida albicans,* grow as single cells and reproduce asexually. Molds grow in long filaments, called *hyphae*. Fungal infections of the skin or mycoses are commonly classified as deep fungal infection and superficial mycoses, more commonly known as *tinea*.[1,2] As opposed to deep fungal infections

Primary Skin Disorders

- Primary skin disorders are condition that have their origin in the skin.
- Infectious skin disorders are caused by viruses, bacteria, and fungi that invade the skin, incite inflammatory responses, and otherwise cause rashes and lesions that disrupt the skin surface.
- Disorders of the pilosebaceous unit include acne vulgaris, which occurs most frequently in adolescence and manifests as comedones, papulopustules, nodules, or in severe cases, cysts and scarring; and rosacea, which is a chronic acneform disorder of middle-aged and older persons.
- Allergic and hypersensitivity responses are caused by antigen-antibody responses resulting from sensitization to topical or systemic antigens.
- The papulosquamous dermatoses constitute a group of disorders characterized by scaling papules and plaques that result from uncontrolled keratinocyte proliferation.

of the skin, where the dermis, subcutaneous, and deeper tissues are primarily involved, superficial fungal infections are confined to the epidermis and its integuments, the hair and nails.

Most of the superficial mycoses, or *dermatophytoses*, are caused by the dermatophytes, a group of closely related fungi classified into three genera: *Microsporum* (*M. audouinii, M. canis, M. gypseum*), *Epidermophyton* (*E. floccosum*), and *Trichophyton* (*T. schoenleinii, T. violaceum, T. tonsurans, T. rubrum*).[1–3] Another way of classifying the dermatophytes is according to their ecologic origin—human, animal, or soil. *Anthropophilic* species (*M. audouinii, M. tonsurans, T. violaceum*) are parasitic in humans and are spread by other infected humans. *Zoophilic* species (*M. canis* and *T. mentagrophytes*) cause parasitic infections in animals, some of which can be spread to humans. *Geophilic* species originate in the soil, but may infect animals, which in turn serve to infect humans. The clinical purpose of identifying species of dermatophytes is to determine the possible cause of infection. There is also some consideration of prognostic value. The anthropophilic species tend to cause chronic infections that are difficult to treat, whereas the Zoophilic and Geophilic species tend to cause inflammatory lesions that respond well to therapy or occasionally resolve spontaneously.[1]

The fungi that cause superficial mycoses live on the dead keratinized cells of the epidermis. They emit an enzyme that enables them to digest keratin, which results in superficial skin scaling, nail disintegration, or hair breakage, depending on the location of the infection. Deeper reactions involving vesicles, erythema, and infiltration are caused by the inflammation that results from exotoxins liberated by the fungus. The superficial mycoses, more commonly known as *tinea* or *ringworm,* can affect various parts of the body, with lesions varying according to site and fungal species.

Diagnosis of superficial fungal infections is primarily done by microscopic examination of skin scrapings for fungal spores, the reproducing bodies of fungi.[2] Potassium hydroxide (KOH) preparations are used to prepare slides of skin scrapings. KOH disintegrates human tissue and leaves behind the threadlike filaments, or hyphae, that grow from the fungal spores. Cultures also may be done using a dermatophyte test medium or a microculture slide that produces color changes and allows for direct microscopic identification. The Wood light (ultraviolet [UV] light) is another method that can assist with the diagnosis of tinea. Some types of fungi (e.g., *M. canis* and *M. audouinii*) fluoresce yellow-green when the light is directed onto the affected area.

Treatment usually follows diagnosis confirmed by KOH preparation or culture, particularly if a systemic agent is to be used. Topical agents are commonly used in the treatment of tinea infections; however, success often is limited because of the lengthy duration of treatment, poor compliance, and high rates of relapse at specific body sites.

The topical fungal agents can be grouped by structure and function. The principal pharmacologic groups are the azoles and allylamines. The azoles are a group of synthetic antifungal drugs that act by inhibiting the fungal enzymes needed for the synthesis of ergosterol, which is an essential part of fungal cell membranes. In contrast to the azoles, the allylamines act by interrupting ergosterol synthesis, causing the accumulation of a metabolite that is toxic to the fungus. Many of the topical azoles are available as either over-the-counter or prescription preparations.[4] Members of this class include ketoconazole, miconazole, clotrimazole, econazole, miconazole, and oxiconazole. Two allylamines, naftifine and terbinafine, are available as topical preparations. Topical corticosteroids may be used in conjunction with topical antifungal agents to relieve itching and erythema secondary to inflammation.

The systemic (i.e., oral) antifungal agents include griseofulvin, the azoles, and the allylamines.[2,3] Griseofulvin is an antifungal agent derived from a species of penicillium, whose only use is in the systemic treatment of dermatophytosis. It acts by binding to the keratin of newly formed skin, protecting the skin from new infection. Because its action is to prevent new infections, it must be administered for 2 to 6 weeks to allow for skin and hair replacement. Nail infections often require months to allow for nail regrowth. Terbinafine is a synthetic allylamine that is used in the treatment of dermatophytosis. In contrast to griseofulvin, the synthetic agents are fungicidal (i.e., kill the fungus) and therefore are more effective over shorter treatment periods.

Some of the oral agents can produce serious side effects, such as hepatic toxicity, or interact adversely with other medications.

Tinea of the Body or Face. *Tinea corporis* (ringworm of the body) can be caused by any of the dermatophyte species, but is most frequently caused by *M. canis* and less commonly by *T. rubrum*. There has been an increase in *T. tonsurans* as the causative agent of tinea corporis as well. Although tinea corporis affects all ages, children seem most prone to infection. Transmission is most commonly from kittens, puppies, and other children who have infections.

The lesions vary, depending on the fungal agent. The most common types of lesions are oval or circular patches on exposed skin surfaces and the trunk, back, or buttocks (Fig. 46-1). Less common are foot and groin infections. The lesion begins as a red papule and enlarges, often with a central clearing. Patches have raised red borders consisting of vesicles, papules, or pustules. The borders are sharply defined, but lesions may coalesce. Pruritus, a mild burning sensation, and erythema frequently accompany the skin lesion.

Tinea faciale, or ringworm of the face, is an infection caused by *T. mentagrophytes* or *T. rubrum*. Tinea faciale may mimic the annular, erythematous, scaling, pruritic lesions characteristic of tinea corporis. It also may appear as flat erythematous patches. Topical antifungal agents usually are effective in treating tinea corporis and tinea faciale. Oral antifungal agents may be used in resistant cases.

Tinea of the Scalp. *Tinea capitis*, the most common type of fungal infection in children, is an infection of the scalp and hairshaft. Tina capitis can be divided into two types: primary (noninflammatory) and secondary (inflammatory). The noninflammatory type is caused primarily by *T. tonsurans*. Children between the ages of 3 and 14 years are primarily affected, with a higher incidence among people of African American or Hispanic descent.[5] The lower incidence among adults has been attributed to the higher content of fatty acids in the sebum after puberty. The primary lesions vary from grayish, round, hairless patches to balding spots. The lesions vary in size and are most commonly seen on the back of the head (Fig. 46-2). Mild erythema, crust, or scale may be present. The individual usually is asymptomatic, although pruritus may exist.

FIGURE 46-1. Tinea of the arm due to the dermatophytic fungus trichophyton rubrum. (From Centers for Disease Control and Prevention Public Health Image Library. [Online] Available: http://phil.cdc.gov/Phil/home.asp.)

FIGURE 46-2. Ringworm or tinea of the scalp (tinea capitis) caused by the *Microsporum* species. (From Centers for Disease Control and Prevention Public Health Image Library. [Online] Available: http://phil.cdc.gov/Phil/home.asp.)

The inflammatory type of tinea capitis is caused by virulent strains of *T. mentagrophytes, T. verrucosum,* and *M. gypseum*. The onset is rapid, and inflamed lesions usually are localized to one area of the head. The inflammation is believed to be a delayed hypersensitivity reaction to the invading fungus. The initial lesion consists of a pustular, scaly, round patch with broken hairs. A secondary bacterial infection is common and may lead to a painful, circumscribed, boggy, and an indurated lesion called a *kerion*. The highest incidence is among children and farmers who work with infected animals.

Both the noninflammatory and inflammatory forms of tinea capitis are treated with oral griseofulvin or synthetic antifungal agents that penetrate the hair shafts. Topical ointments or shampoos are sometimes indicated in addition to oral medications, both to decrease the spore population and to protect household members. Because of the lower fatty acid content in the sebum of young children, several of the topical antifungal agents are prepared with fatty acid bases. Wet packs, medicated shampoos, steroids, and antibiotics may be prescribed for secondary infections that occur.

Tinea of the Foot and Hand. *Tinea pedis* (athlete's foot) is the most common fungal dermatosis, primarily affecting the spaces between the toes, the soles, or the sides of the feet (Fig. 46-3). It is caused by *T. mentagrophytes* and *T. rubrum*. The lesions vary from a mildly scaling lesion to a painful, exudative, erosive, inflamed lesion with fissuring. Lesions often are accompanied by pruritus, pain, and foul odor. Some persons are prone

FIGURE 46-3. Chronic tinea of the sole caused by *Trichophyton rubrum.* (Schering Corp.) (From Hall J.C. [2006]. *Sauer's manual of skin diseases* [9th ed., p. 248]. Philadelphia: Lippincott Williams & Wilkins.)

FIGURE 46-4. Onychomycosis due to *Trichophyton rubrum,* right and left great toes. (Courtesy Dr. Edwin P. Ewing, Centers for Disease Control and Prevention Public Health Image Library. [Online] Available: http://phil.cdc.gov/Phil/home.asp.)

to chronic tinea pedis. Mild forms are more common during dry environmental conditions. Exacerbations occur as a result of hot weather, sweating, and exercise or when the feet are exposed to moisture, occlusive shoes, and communal swimming.

Tinea of the hand (*Tinea manus*) is usually a secondary infection with tinea pedis as the primary infection. In contrast to other skin disorders, such as contact dermatitis and psoriasis, which affect both hands, tinea manus usually occurs only on one hand. The characteristic lesion is a blister on the palm or finger surrounded by erythema. Chronic lesions are scaly and dry. Cracking and fissuring may occur. The lesions may spread to the plantar surfaces of the hand. If chronic, tinea manus may lead to tinea of the fingernails.

Simple forms of tinea pedis and tinea manus are treated with topical applications of antifungals. Complex cases are treated with oral griseofulvin, ketoconazole, or terbinafine. Other treatment and preventive measures include careful cleaning and drying of affected areas.

Tinea of the Nails. *Tinea unguium* is a dermatophyte infection of the nails.[6] It is a subset of a condition called *onychomycosis,* which includes dermatophyte, nondermatophyte, and candidal infections of the nails. There is an increased incidence of fungal nail infections in recent years, probably reflecting better diagnostics, increased numbers of immunocompromised patients who have greater susceptibility, increased use of immunosuppressive drugs, increasing numbers of elderly people, worldwide travel, and increased use of communal bathing facilities.

Distal and lateral subungual onychomycosis, the most common form of tinea unguium, usually is caused by *T. rubrum* or *T. mentagrophytes.* Toenails are involved more commonly than fingernails because fingernails are more exposed to air. The infection often begins at the tip of the nail, where the fungus digests the nail keratin (Fig. 46-4). In some cases, the infection may begin from a crushing injury to a toenail or from the spread of tinea pedis. Initially, the nail appears opaque, white, or silver. The nail then turns yellow or brown. The condition often remains unchanged for years. During this time it may involve only one or two nails and may produce little or no discomfort. Gradually, the nail thickens and cracks as the infection spreads and includes the nail plate. Permanent discoloration and distortion result as the nail plate separates from the nail bed.

The standard for the diagnosis of fungal nail disease is a positive result on microscopic examination and culture of nail clippings with subungual debris. Treatment considerations include efficiency, cost, and possible side effects of the treatment. Treatment of tinea unguium usually requires oral antifungal therapy administered over a period of months. Persons with minimal toenail involvement and no associated symptoms may not require treatment. All of the oral agents require careful monitoring for side effects. A nail lacquer containing the antifungal agent ciclopirox is available for use in the topical management of mild to moderate infections of the fingernails and toenails caused by *T. rubrum.* A new nail may require 3 to 12 months to grow. Thus, people being treated with antifungal agents need to be reminded that the resolution of the infection requires 4 to 6 months for fingernails and longer for toenails.

Dermatophytid Reaction. A secondary skin eruption may occur in persons allergic to the fungus responsible for the dermatophytosis. This dermatophytid or allergic reaction may occur during an acute episode of a fungal infection. The most common reaction occurs on the hands in response to tinea pedis. The lesions are vesicles with erythema extending over the palms and fingers, sometimes extending to other areas (Fig. 46-5). Less commonly, a more generalized reaction occurs in which papules or vesicles erupt on the trunk or extremities. These eruptions may resemble tinea corporis. Lesions may become excoriated and infected with bacteria. Treatment is directed at the primary site of infection. The intradermal reaction resolves in most cases without intervention if the primary site is cleared.

FIGURE 46-5. Dermatophytid or id reaction on the fingers due to a tinea infection. An id immunologic reaction, also known as *autoeczematization,* is an itchy, vesicular rash produced in response to an intense inflammatory process that can be located in another region of the body. (From Centers for Disease Control and Prevention Public Health Image Library. [Online] Available: http://phil.cdc.gov/Phil/home.asp.)

Candidal Infections. Candidiasis (moniliasis) is a fungal infection caused by *C. albicans*. This yeastlike fungus is a normal inhabitant of the gastrointestinal tract, mouth, and vagina (see Chapter 41). The skin problems result from the release of irritating toxins on the skin surface. *C. albicans* is found almost always on the surface of the skin; it rarely penetrates to the deeper layers of the skin. Some persons are predisposed to candidal infections by conditions such as diabetes mellitus, antibiotic therapy, pregnancy, oral contraceptive use, poor nutrition, and immunosuppressive diseases.[7] Oral candidiasis may be the first sign of infection with human immunodeficiency virus (HIV).

C. albicans thrives on warm, moist, intertriginous areas (i.e., between folds or adjacent surfaces) of the body. The rash is red with well-defined borders. Patches erode the epidermis, and there is scaling. Mild to severe itching and burning often accompany the infection. Severe forms of infection may involve pustules or vesiculopustules. In addition to microscopy, a candidal infection often can be differentiated from a tinea infection by the presence of satellite lesions. These satellite lesions are maculopapular and are found outside the clearly demarcated borders of the candidal infection. Satellite lesions often are diagnostic of diaper rash complicated by *Candida*. The appearance of candidal infections varies according to the site (see Chapter 41 for a discussion of vaginal candidiasis).

Diagnosis usually is based on microscopic examination of skin or mucous membrane scrapings placed in a KOH solution. Treatment measures vary according to the location. Preventive measures such as wearing rubber gloves are encouraged for persons with infections of the hands. Intertriginous areas often are separated with clean cotton cloth and allowed to air dry as a means of decreasing the macerating effects of heat and moisture. Topical and oral antifungal agents, such as clotrimazole, econazole, ketoconazole, and miconazole, are used in treatment depending on the site and extent of involvement.

Bacterial Infections

Bacteria are considered normal flora of the skin. Most bacteria are not pathogenic, but when pathogenic bacteria invade the skin, superficial or systemic infections may develop. Bacterial skin infections are commonly classified as primary or secondary infections. Primary infections are superficial skin infections such as impetigo. Secondary infections consist of deeper cutaneous infections, such as infected ulcers. Diagnosis usually is based on cultures taken from the infected site. Treatment methods include antibiotic therapy and measures to promote comfort and prevent the spread of infection.

Impetigo. Impetigo is a common, superficial bacterial infection caused by staphylococci or group A β-hemolytic streptococci, or both.[8,9] Impetigo is common among infants and young children, although older children and adults occasionally contract the disease. Impetigo initially appears as a small vesicle or pustule or as a large bulla on the face or elsewhere on the body. As the primary lesion ruptures, it leaves a denuded area that discharges a honey-colored serous liquid that hardens on the skin surface and dries as a honey-colored crust with a "stuck-on" appearance (Fig. 46-6). New vesicles erupt within hours. Pruritus often accompanies the lesions, and skin excoriations that result from scratching multiply the

FIGURE 46-6. Impetigo of the face. The lesions vary from small vesicles to large bullae that rupture and discharge a honey-colored serous liquid that hardens on the skin surface and dries as a honey-colored crust. (Abner Kurten, *Folia Dermatologica.* No. 2. Geigy Pharmaceuticals.) (From Hall J.C. [2006]. *Sauer's manual of skin diseases* [9th ed., p. 187]. Philadelphia: Lippincott Williams & Wilkins.)

infection sites. Although a very low risk, a possible complication of untreated streptococcal impetigo is poststreptococcal glomerulonephritis (see Chapter 25). Topical mupirocin (Bactroban), which has few side effects, may be effective for limited infections. If the area is large or if there is concern about complications, systemic antibiotics are used.

Another form of impetigo exists, *bullous impetigo,* which is usually caused by *Staphylococcus aureus*.[9] Bullous impetigo is more common among children and occurs intermittently, with some cases transmitted among family members, but most often found among the institutionalized. Thin bullae erupt that appear clear to cloudy and coalesce. The bullae open, leaving the original bullous rim with central thin, flat, honey-colored crusts, or in some cases denuded areas. The face is often affected, but bullous impetigo may occur anywhere on the body. The treatment measures are the same as for nonbullous impetigo.

Cellulitis. Cellulitis is a deeper infection affecting the dermis and subcutaneous tissues.[8] It is usually caused by group A β-hemolytic streptococci or *S. aureus,* but can be caused by bacteria specific to certain activities, such as fish handling, swimming in fresh water, or swimming in salt water, or from animal bites or scratches. Preexisting wounds (e.g., ulcers, erosions) and tinea pedis are often portals of entry. Legs are the most common sites, followed by the hands and pinnae of the ears, but cellulitis may occur on many body sites. The lesion consists of an expanding red, swollen, tender plaque with an indefinite border, covering a small to wide area (Fig. 46-7). Cellulitis is frequently accompanied by fever, erythema, heat, edema, and pain. Cellulitis often involves the lymph system and, once compromised, repeat infections may impair lymphatic drainage, leading to chronically swollen legs, and eventually dermal fibrosis and lymphedema. Incorrectly treated, it may result in septicemia, nephritis, or death. Treatment measures (oral and intravenous antibiotics) are aimed at the invasive organisms and the extent of the infection.

FIGURE 46-7. Cellulitis on leg infected with *Staphylococcus aureus* and *Pseudomonas.*

Viral Infections

Viruses are intracellular pathogens that rely on live cells of the host for reproduction. They have no organized cell structure but consist of a deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) core surrounded by a protein coat. The viruses seen in skin lesion disorders tend to be DNA-containing viruses. Viruses invade the keratinocyte, begin to reproduce, and cause cellular proliferation or cellular death. The rapid increase in viral skin diseases has been attributed to the use of corticosteroid drugs, which have immunosuppressive properties, and the use of antibiotics, which alter the bacterial flora of the skin. As the number of bacterial infections has decreased, there has been a proportional rise in viral skin diseases.

Verrucae. Verrucae, or warts, are common benign papillomas caused by the DNA-containing human papillomavirus (HPV).[10–13] Transmission of HPV infection is largely by direct contact between individuals or by autoinoculation. As benign papillomas, warts represent an exaggeration of the normal skin structures. There is an irregular thickening of the stratum spinosum and greatly increased thickening of the stratum corneum. The classification of warts is based largely on morphology and location.

Although warts vary in appearance depending on their location, it is now recognized that the clinically distinct types of warts result not simply because of the anatomic sites in which they arise, but also because of the distinct type of HPV. There are more than 80 types of HPV found on the skin and mucous membranes of humans that cause several different kinds of warts, including skin warts and genital warts. Many of the HPV types that cause genital warts are sexually transmitted, some of which (types 6, 11, 16, and 18) may increase the risk of cervical cancer (discussed in Chapter 41).

Nongenital warts often occur on the hands and feet. They are commonly caused by HPV types 1, 2, 3, 4, 27, and 57, and are not considered precancerous lesions. They are classified as common warts, flat warts, and plantar or palmar warts. Common warts, or verrucae vulgaris, are the most common type. The lesions can occur anywhere, but most frequently occur on dorsal surfaces of the hands, especially the periungual area, where they appear as small, grayish-white to tan, flat to convex papules with a rough, pebblelike surface (Fig. 46-8). Verrucae plana, or flat warts, are common on the face or dorsal surfaces of the hands. These warts are slightly elevated, flat, smooth, tan papules that are slightly larger than verrucae vulgaris. Verrucae plantaris and verrucae palmaris (i.e., plantar and palmar warts, respectively) occur on the soles of the feet and palms of the hands, respectively. They appear as rough, scaly lesions that may reach 1 to 2 cm in diameter, coalesce, and be confused with ordinary calluses. HPV transmission usually occurs through breaks in skin integrity. For example, plantar warts, which occur on the soles of the feet, frequently are transmitted to the abraded, softened heels of children in swimming areas. Common hand warts can be transmitted by biting the cuticles surrounding the nail.

FIGURE 46-8. Common and periungual warts. (Reed & Carnrick Pharmaceuticals.) (From Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

FIGURE 46-9. Recurrent herpes simplex of the face. (Dermik Laboratories, Inc.) (From Hall J.C. [2006]. *Sauer's manual of skin diseases* [9th ed., p. 228]. Philadelphia: Lippincott Williams & Wilkins.)

Treatment is usually directed at inducing a "wart-free" period without producing scarring. Warts resolve spontaneously when immunity to the virus develops.[13] The immune response, however, may be delayed for years. Because of their appearance or discomfort, people usually desire their removal, rather than waiting for immunity to develop. Removal is usually done by applying a keratolytic agent, such as salicylic acid gel or plaster that breaks down the wart tissue, or by freezing with liquid nitrogen. Salicylic acid works by dissolving intercellular cement and producing desquamation of the horny layer of skin without affecting normal epidermal cells. Intralesional bleomycin injections have been effective for recalcitrant warts. Various types of laser surgery, electrosurgery, cryotherapy, immunotherapy (e.g., oral zinc sulfate), and antiviral therapy (e.g., cidofovir) also have been successful in wart eradication.

Herpes Simplex. Herpes simplex virus (HSV) infections of the skin and mucous membrane (i.e., cold sore or fever blister) are common.[14,15] Two types of HSV infect humans: type 1 and type 2. HSV-1 is usually associated with oropharynx infections (labial herpes), and the organism is spread by respiratory droplets or by direct contact with infected saliva. HSV-1 may also be transmitted to other parts of the body through occupational hazards, such as skin contact athletics, dentistry, and medicine. Genital herpes usually is caused by HSV-2 (see Chapter 41). HSV-1 genital infections and HSV-2 oral infections are becoming more common, perhaps because of oral–genital sex.

Infection with HSV-1 may present as a primary or recurrent infection. Primary HSV-1 symptoms include fever, sore throat, painful vesicles, and ulcers of the lips, tongue, palate, and buccal mucosa. Primary infection results in the production of antibodies to the virus so that recurrent infections are more localized and less severe. After an initial infection, the herpesvirus persists in the trigeminal and other dorsal root ganglia in the latent state, periodically reactivating in recurrent infections. The symptoms of a primary HSV-1 infection most often occur in young children (1 to 5 years of age). It is likely that many adults were exposed to HSV-1 during childhood and therefore have antibodies to the virus.

The recurrent lesions of HSV-1 usually begin with a burning or tingling sensation. Umbilicated vesicles and erythema follow and progress to pustules, ulcers, and crusts before healing (Fig. 46-9). Lesions are most common on the lips, face, mouth, nasal septum, and nose. When a lesion is active, HSV-1 is shed and there is risk of transmitting the virus to others. Pain is common, and healing takes place within 10 to 14 days. Precipitating factors may be stress, menses, or injury. In particular, UVB exposure seems to be a trigger for recurrence. Individuals who are immunocompromised may have severe attacks.

There is no cure for oropharyngeal herpes; most treatment measures are palliative.[14,15] Application of over-the-counter topical preparations containing antihistamines, antipruritics, and anesthetic agents along with aspirin or acetaminophen may be used to relieve pain. Topical medications are best applied gently with a cotton-tipped applicator to prevent increased viral shedding and viral inoculation to another anatomic site. Oral acyclovir, an antiviral drug that inhibits herpesvirus replication, may be used prophylactically to prevent recurrences. The antiviral drugs valacyclovir and famciclovir also may be used for prophylaxis. Sunscreen preparations applied to the lips can prevent sun-induced herpes simplex. Efforts to develop vaccines to prevent HSV infections are in process.[14]

Herpes Zoster. Herpes zoster (shingles) is an acute, localized vesicular eruption distributed over a dermatomal segment of the skin.[7,16,17] It is caused by the same herpesvirus, varicella-zoster, that causes chickenpox. It is believed to be the result of reactivation of a latent varicella-zoster virus infection that was dormant in the sensory dorsal root ganglia since a primary childhood infection. During an episode of herpes zoster, the reactivated virus travels from the ganglia to the skin of the corresponding dermatome. Although herpes zoster is not as contagious as chickenpox, the reactivated virus can be transmitted to nonimmune contacts.

The incidence of herpes zoster increases with age; it occurs most frequently in persons older that 60 years of age. The normal age-related decrease in cell-mediated immunity is thought to account for the increased viral activation in this age group. Other persons at increased risk because of impaired cell-mediated immunity are persons with conditions such as HIV infection and certain malignancies, and those receiving long-term corticosteroid treatment, cancer chemotherapy, and radiation therapy.

The lesions of herpes zoster typically are preceded by a prodrome consisting of a burning pain, a tingling sensation, extreme sensitivity of the skin to touch, and pruritus along the affected dermatome (see Chapter 35). Among the dermatomes, the most frequently involved are the thoracic (53%), the cervical (20%), the trigeminal (15%), and the lumbosacral (11%).[17] Prodromal symptoms may be present for 1 to 3 days or longer before the appearance of the rash. During this time, the pain may be mistaken for a number of other conditions, such as heart disease, pleurisy, musculoskeletal disorders, or gastrointestinal disorders.

The lesions appear as an eruption of vesicles with erythematous bases that are restricted to skin areas supplied by sensory neurons of a single or associated group of dorsal root ganglia (Fig. 46-10). In immunosuppressed persons, the lesions may extend beyond the dermatome. Eruptions usually are unilateral in the thoracic region, trunk, or face. New crops of vesicles erupt for 3 to 5 days along the nerve pathway. The vesicles dry, form crusts, and eventually fall off. The lesions usually clear in 2 to 3 weeks, although they can persist up to 6 weeks in some elderly persons.

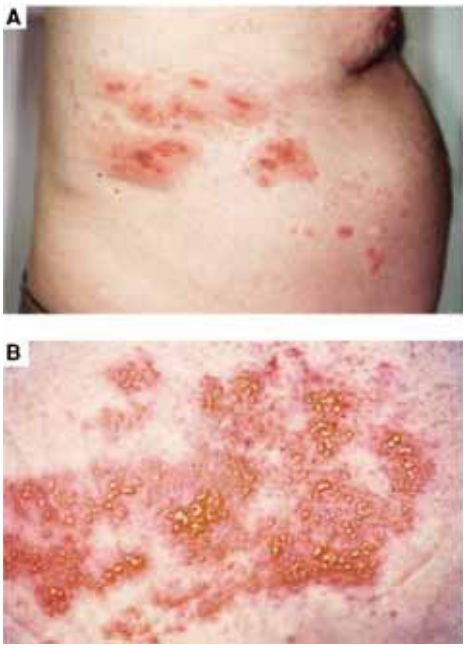

FIGURE 46-10. Acute herpes zoster. Panel **(A)** shows a cutaneous eruption in the right T7 dermatome. Panel **(B)** shows a close-up of fresh vesicular lesions. (From Gnann J.W., Whitley R.J. [2002]. Herpes zoster. *New England Journal of Medicine* 347, 341.)

Serious complications can accompany eruptions. Eye involvement can result in permanent blindness and occurs in a large percentage of cases involving the ophthalmic division of the trigeminal nerve (see Chapter 38). *Postherpetic neuralgia,* which is pain that persists longer than 1 to 3 months after the resolution of the rash, is an important complication of herpes zoster (discussed in Chapter 35). It is seen most commonly in persons older than 60 years of age, increasing age being the greatest risk factor. Affected persons complain of sharp, burning pain that often occurs in response to nonnoxious stimuli. Even the slightest pressure of clothing and bed sheets may elicit pain. It usually is a self-limited condition that persists for months, with symptoms abating over time.

The treatment of choice for herpes zoster is the administration of an antiviral agent (e.g., acyclovir, valacyclovir, famciclovir).[7] The treatment is most effective when started within 72 hours of rash development. When given in the acute vesicular stage, the antiviral drugs have been shown to decrease the amount of lesion development and pain. Narcotic analgesics, tricyclic antidepressants, gabapentin, anticonvulsant drugs, and nerve blocks have been used for management of postherpetic neuralgia. Local application of capsaicin cream or lidocaine patches may be used in selected cases. Palliative treatments, such as heat and gentle pressure, may also be helpful.

An effective live herpes zoster vaccine is available to prevent both herpes zoster and postherpetic neuralgia. The vaccine is recommended for use in people 60 years of age and older.[18]

Pustular Disorders

Acne Vulgaris

Acne vulgaris is a disorder of the pilosebaceous unit (see Chapter 45, Fig. 45-7) that results in formation of discrete papular or pustular lesions and may lead to scarring.[11,12,19–22] It can be cosmetically disfiguring and often psychologically disabling. Scarring can lead to lifelong problems in regard to self-esteem. Acne typically begins around puberty, as a result of increased androgen production. It may begin earlier and persist longer in females; however, overall the incidence and severity are greater in males. The disorder, which affects more than 85% of teenagers, is so common that many regard it as a "rite of passage" through adolescence.[12] Although acne is frequently considered a disorder of adolescence, a large percentage of young adults continue to show signs of the disorder.

Acne vulgaris is characterized by both noninflammatory and inflammatory lesions. The lesions are typically located on the face and neck and, to a lesser extent, on the back, chest, and shoulders. Noninflammatory lesions consist of *comedones* (whiteheads and blackheads). *Blackheads* are plugs of material that accumulate in sebaceous glands that open to the skin surface. The color of blackheads results from melanin that has moved

into the sebaceous glands from adjoining epidermal cells. *Whiteheads* are pale, slightly elevated papules with no visible orifice. Inflammatory lesions consist of papules, pustules, nodules, and, in severe cases, cysts. *Papules* are raised areas less than 5 mm in diameter. *Pustules* have a central core of purulent material. *Nodules* are larger than 5 mm in diameter and may become suppurative or hemorrhagic. Suppurative nodules often are referred to as *cysts* because of their resemblance to inflamed epidermal cysts. The inflammatory lesions are believed to develop from the escape of sebum into the dermis and the irritating effects of the fatty acids contained in the sebum.

The cause of acne vulgaris is largely unknown. It is considered a chronic inflammatory disease of the pilosebaceous unit. There is a hereditary factor; multiple generations of family members often experience it. Several factors are believed to contribute to acne, including (1) the influence of androgens on sebaceous gland activity; (2) increased proliferation of the keratinizing epidermal cells that form the sebaceous cells; (3) increased sebum production in relation to the severity of the disease; and (4) the presence of *Propionibacterium acnes,* the microorganism responsible for the inflammatory stage of the disorder. These factors are probably interrelated. Increased androgen production results in increased sebaceous cell activity, with resultant plugging of the pilosebaceous ducts. The excessive sebum provides a medium for *P. acnes* growth, and the organism contains lipases that break down the free fatty acids that produce the acne inflammation. *P. acnes* is also thought to form a biofilm (an extracellular polysaccharide lining in which the bacteria are encased) that acts as a protective barrier to antibiotic treatment (see Chapter 14), explaining why prolonged antibiotic treatments are necessary.[23] Acne may be triggered or worsened by external factors such as obstructions (e.g., head bands, collars), manipulation of the lesions, cosmetics, and occupational exposures.

The diagnosis of acne is based on history and physical examination. The severity of the acne is generally assessed by the number, type, and distribution of lesions.[19] Mild acne is usually characterized by the presence of a small number (generally <10) of open and closed comedones, with a few inflammatory papules; moderate acne by the presence of a moderate number (10 to 40) of erythematous papules and pustules (Fig. 46-11), usually limited to the face; and moderately severe acne by the presence of numerous papules and pustules (40 to 100) and occasionally larger, deeper, nodular inflamed lesions involving the face, chest, and back. Acne conglobata (to be discussed) is a severe chronic form of acne.

Treatment of acne focuses on clearing up existing lesions, preventing new lesions, and limiting scar formation.[19–22] Treatment measures include the use of topical antimicrobials, oral antibiotics, topical retinoids, and isotretinoin. Soaps are usually not effective in treating acne, and unless the skin is exceptionally oily, a mild soap should be used to avoid additional irritation that will limit the effectiveness of other topical treatments.

FIGURE 46-11. Moderate acne. Erythematous papules and pustules are the predominant lesions, and lesions are limited to the face. (From James W.D. [2005]. Acne. *New England Journal of Medicine* 352, 1464.)

Mild acne is usually treated with a topical preparation containing a combination of erythromycin or clindamycin and benzoyl peroxide. Topical antibiotics do not affect existing lesions but decrease the *P. acnes* on the skin, thereby reducing subsequent inflammation resulting from free fatty acid release and breakdown. Benzoyl peroxide, which is a bactericide, does not induce resistance, and when used with topical and oral antibiotics it protects against the development of this problem. Azelaic acid, products containing sodium sulfacetamide and sulfur, and salicylic acid preparations are also available. These agents are usually not considered as first-line therapies, but may be used in persons who cannot tolerate other topical agents.

Moderate to severe cases of acne may be managed with systemic antibiotics (e.g., tetracycline), topical vitamin A derivatives (retinoids), or oral retinoids (isotretinoin). Systemic antibiotics decrease *P. acnes* colonization and have intrinsic anti-inflammatory effects. The action of topical vitamin A (e.g., tretinoin) has been attributed to decreased cohesiveness of epidermal cells and increased epidermal cell turnover. This is thought to result in increased extrusion of open comedones and transformation of closed comedones into open ones. Isotretinoin is approved for treatment of recalcitrant cases of acne and cystic acnes. Although the exact mode of action is unknown, isotretinoin decreases sebaceous gland activity, prevents new comedones from forming, reduces the *P. acnes* count through sebum reduction, and has an anti-inflammatory effect. Because of its many side effects, it is used only in persons with severe acne. The oral retinoids are known teratogens and must not be used in women who are pregnant or may become pregnant.

Acne Conglobata

Acne conglobata occurs later in life as a chronic form of acne. Comedones, papules, pustules, nodules, abscesses, cysts, and scars occur on the back, buttocks,

and chest. Lesions occur to a lesser extent on the abdomen, shoulders, neck, face, upper arms, and thighs. The comedones or cysts have multiple openings, large abscesses, and interconnecting sinuses. Inflammatory nodules are not uncommon. Their discharge is odoriferous, serous or mucoid, and purulent. Healing often leaves deep keloidal lesions. Affected persons have anemia with elevated white blood cell counts, erythrocyte sedimentation rates, and neutrophil counts. The treatment is difficult and stringent. It often includes débridement, systemic corticosteroid therapy, oral retinoids, and systemic antibiotics.

Rosacea

Rosacea is a chronic skin disorder of middle-aged and older persons. The disease has a variety of clinical manifestations (blushing, presence of telangiectatic vessels, eruption of inflammatory papules and pustules) that primarily affect the central areas of the face. In the early stage of rosacea development, there are repeated episodes of blushing.[24–26] The blush eventually becomes a permanent dark red erythema on the nose and cheeks that sometimes extends to the forehead and chin (Fig. 46-12). This stage often occurs before 20 years of age. Ocular problems occur in at least 50% of persons with rosacea. Prominent symptoms include eyes that are itchy, burning, or dry; a gritty or foreign body sensation; and erythema and swelling of the eyelid. As the person ages, the erythema persists, and telangiectasia with or without acne components (e.g., comedones, papules, pustules, nodules, erythema, and edema) develops. After years of affliction, acne rosacea may develop into an irregular bullous hyperplasia (thickening of the skin) of the nose, known as *rhinophyma* (Fig. 46-13). Although rosacea is more common in women, rhinophyma is more common in men.

FIGURE 46-12. Papulopustular and ocular rosacea of moderate severity. The pustules are seen over the central portion of the face with sparing of the periocular area. Erythema and edema of the upper eyelids are also present. (From Powell F.C. [2005]. Rosacea. *New England Journal of Medicine* 352, 793–803.)

FIGURE 46-13. Chronic rosacea with rhinophyma. (Hoechst Marion Roussel Pharmaceuticals, Inc.) (From Hall J.C. [2006]. *Sauer's manual of skin diseases* [9th ed., p. 149]. Philadelphia: Lippincott Williams & Wilkins.)

The cause of rosacea is unknown; however, it is believed to be a chronic inflammatory process involving the area surrounding the pilosebaceous units, accompanied by vascular instability with leakage of fluid and inflammatory mediators into the dermis. The lesions are accompanied by nonspecific perifollicular infiltrate of lymphocytes surrounded by dermal edema and dilated capillaries and terminal arterioles (telangiectases).[24] In the pustular phase, neutrophils may colonize the follicles, and follicular rupture may produce a granulomatous response. Rhinophyma is associated with hypertrophy of the sebaceous glands.

Rosacea is distinguished from acne vulgaris by the presence of the neurovascular component and absence of comedones. Treatment measures are similar to those used for acne vulgaris. Persons with rosacea are heat sensitive. They are instructed to avoid vascular stimulating agents such as heat, sunlight, hot liquids, foods, and alcohol. Topical metronidazole and azelaic acid creams have been effective. Topical antibiotics (e.g., clindamycin, erythromycin) have been useful, as well as systemic antibiotics (e.g., tetracycline and its derivatives). Pulsed dye laser therapy may be used for ablation of vessels in persons with prominent telangiectases. Rhinophyma can be treated by a number of surgical methods, including electrosurgery, laser ablation, dermabrasion, cryosurgery, and excision.

Allergic and Hypersensitivity Dermatoses

Allergic and hypersensitivity dermatoses involve the inflammatory response to multiple exogenous and endogenous agents. The disorders, which are usually characterized by epidermal edema with separation of epidermal cells, include atopic dermatitis, urticaria, drug-induced skin eruptions, and allergic contact dermatitis (discussed in Chapter 16).

Atopic Dermatitis

Atopic dermatitis (atopic eczema) is a highly pruritic chronic inflammatory skin disease. It usually begins early in life and often occurs in children with a personal or family history of other atopic disorders, such as allergic rhinitis and asthma.[27–29] A total of 45% of cases begin within the first 6 months of life, 60% begin during the first year, and 85% occur before the fifth year of life.[27] Up to 70% of these children have a spontaneous remission before adolescence. The hallmarks of atopic dermatitis are a chronic, relapsing form of skin inflammation; a disturbance in the epidermal barrier function that leads to increased transepidermal water loss and dry skin; and immunoglobulin E (IgE)-mediated sensitization to food and environmental antigens.[27–29] Whether the primary defect resides in an immunologic disturbance or a disorder of the epidermal barrier is uncertain. It has been suggested that an abnormal skin barrier allows increased antigen absorption and contributes to the hyperreactivity characteristic of atopic dermatitis.[27]

The lesions of atopic dermatitis are usually characterized by vesicle formation, oozing, and crusting with excoriations. Scratching causes crusted erosions. The clinical manifestations of the disorder can be divided into three stages that often vary with age.[27] In infancy the eczematous lesion usually appear on the checks and scalp (Fig. 46-14).

FIGURE 46-14. Atopic eczema on an infant's face and on a wrist. (Dome Chemicals.) (From Hall J.C. [2006]. *Sauer's manual of skin diseases* [9th ed., p. 84]. Philadelphia: Lippincott Williams & Wilkins.)

The skin of the cheeks may be paler, with extra creases under the eyes, called *Dennie-Morgan folds*. During childhood, lesions involve flexures, the nape of the neck, and the dorsal aspects of the limbs.

Adolescents and adults usually have dry, red patches affecting the face, neck, and upper trunk, but without the thickening and discrete demarcation associated with psoriasis. The bends of the elbows and knees are usually involved. In chronic cases, the skin is dry, leathery, and lichenified. Persons with dark skin may have a papular eruption and poorly demarcated hypopigmentation patches on the cheeks and extremities. In persons with black skin, pigmentation may be lost from lichenified skin. Acute flares may present with red patches that are weepy, shiny, or lichenified (i.e., thickened, with prominent markings), and with plaques and papules. Itching may be severe and prolonged with both childhood and adult forms of atopic dermatitis. Secondary infections are common.

Treatment of atopic eczema is designed to target the underlying abnormalities: dryness, pruritus, infection, and inflammation.[28–30] Basic therapy begins with optimal skin care, addressing the skin barrier defect with continuous use of emollients and skin hydration, along with avoiding exposure to environmental irritants and foods that cause exacerbations of the symptoms. Nonspecific irritants include contact with clothing made from irritating synthetic or wool materials. Further irritants are soaps and hot water temperature during bathing or showering. Although there is no evidence that emollients improve atopic dermatitis directly, they are widely used to relieve the problem of dry skin and pruritus. A key feature of atopic dermatitis is severe dryness of the skin caused by dysfunction of the skin barrier with transepidermal water loss. This is accompanied by intense pruritus and inflammation.

Topical corticosteroids remain an important treatment for acute flare-ups but can cause local and systemic side effects. Potency of topical corticosteroids is classified by the potential for vasoconstriction. In general, only preparations that have weak or moderate potency are used on the face and genital areas, whereas those that have moderate or high potency are used on other areas of the body. Lower-potency corticosteroids may be sufficient on all areas of the body in younger children. One of the main concerns of topical corticosteroid use is skin thinning. Another concern is secondary adrenal suppression and the suppression of growth in children resulting from systemic absorption. Wet-wrap therapy, in which a wet dressing is applied over emollients in combination with topical antiseptics or topical corticosteroids, has been shown to be beneficial in some cases of severe atopic dermatitis.[30]

Systemic or adjuvant therapy is usually reserved for severe acute exacerbations. Short-term corticosteroids are also used during acute flare-ups with adult patients. Antihistamines may be used to relieve itching. Secondary infection with *S. aureus* is common and may be treated with systemic antimicrobial therapy. Phototherapy can be an important adjunct for severely affected adults and adolescents older than 12 years of age.[30]

Urticaria

Urticaria, or hives, is a common skin disorder characterized by the development of edematous wheals accompanied by intense itching.[31–33] The lesions typically appear as raised pink or red areas surrounded by a paler halo. They blanch with pressure and vary in size from a few millimeters to centimeters. Angioedema, which can occur alone or with urticaria, is characterized by nonpitting, nonpruritic, well-defined edematous swelling that involves subcutaneous tissues of the face, hands, feet, or genitals. It is more likely than urticaria to produce life-threatening swelling of the tongue and upper airways.

Urticaria can be acute or chronic and due to known or unknown causes. Numerous factors, both immunologic and nonimmunologic, can be involved in its pathogenesis. The urticarial wheal results from liberation of histamine from mast cells and basophils. Histamine causes hyperpermeability of the microvessels of the skin and surrounding tissue, allowing fluid to leak into the tissues, causing edema and wheal formation.

Acute immunologic urticaria is commonly the result of an IgE-mediated immune reaction that usually occurs within 1 hour of exposure to an antigen. The most common causes of acute urticaria are foods or drinks, medications (most notably penicillin and cephalosporin), insect stings, and exposure to pollens or chemicals. Although nonsteroidal anti-inflammatory drugs, including aspirin, do not normally cause urticaria, they may exacerbate the preexisting disease. In rare cases, urticaria is a manifestation of underlying disease, such as certain cancers, collagen diseases, and hepatitis. There is an association between chronic urticaria and autoimmune thyroid disease (e.g., Hashimoto thyroiditis, Graves disease, toxic multinodular thyroiditis).[33] A hereditary deficiency of a C1 (complement 1) inhibitor also can cause a condition called *hereditary angioneurotic edema*.

The physical urticarias are a specific form of chronic urticaria, in which specific physical stimuli reproducibly elicit wheals.[33] Physical urticarias are intermittent, usually last less than 2 hours, are produced by appropriate stimuli, have distinctive appearances and locations, and are seen most frequently in young adults. Dermographism, or skin writing, is one form of physical urticaria in which wheals appear in response to simple rubbing of the skin (Fig. 46-15). The wheals follow the pattern of the scratch or rubbing, appearing within 10 minutes and dissolving completely within 20 minutes. Other types of physical urticaria are induced by exercise (cholinergic), cold, delayed pressure, sunlight (solar), water (aquagenic), vibration, and heat (external localized). Appropriate challenge tests (e.g., application of an ice cube to the skin to initiate development of cold urticaria) are used to differentiate physical urticaria from chronic urticaria due to other causes.

Most types of urticaria are treated with antihistamines: drugs that block histamine type 1 (H_1) receptors and, less frequently, H_1 receptor blockers in combination with H_2 receptor blockers. They control urticaria by inhibiting vasodilation and the escape of fluid into the surrounding tissues. Usually nonsedating antihistamines that alleviate pruritus and decrease the incidence of hives, without producing drowsiness, are used. Leukotriene antagonists (zafirlukast and montelukast) may also be used. Oral corticosteroids may be used in the treatment of refractory urticaria. Tricyclic antidepressant drugs, particularly those with antihistamine actions, also may be used. Persons who have experienced angioedema of the larynx and pharynx should be counseled to carry a prescription of epinephrine in an autoinjectable instrument (e.g., EpiPen).[32]

Drug-Induced Skin Eruptions

Most drugs can cause a localized or generalized skin eruption. Topical drugs are usually responsible for localized contact dermatitis types of rashes, whereas systemic drugs cause generalized skin lesions. Although many drug-induced skin eruptions are morbilliform (i.e., measleslike) or exanthematous, they may mimic most of the skin disorders described in this chapter. Because the

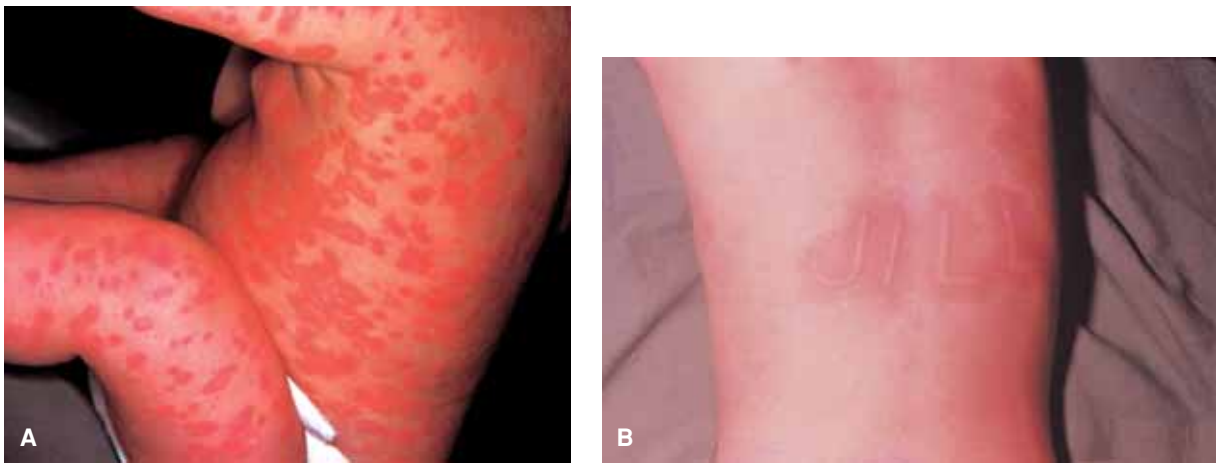

FIGURE 46-15. **(A)** Acute urticaria from penicillin in a 6-month-old-child. **(B)** Dermographism on flexor wrist. (Dermik Laboratories, Inc.) (From Hall J.C. [2006]. *Sauer's manual of skin diseases* [9th ed., p. 126]. Philadelphia: Lippincott Williams & Wilkins.)

lesions vary greatly, the diagnosis depends almost entirely on an accurate patient report, including a full drug history. Early recognition and discontinuation of the drug are essential. Management of mild cases is aimed at eliminating the offending drug while treating the symptoms. Severe cases require prompt medical attention.

Some drug reactions result in epidermal cell detachment and bullae (fluid-filled blisters) formation. The skin detachment seen with bullous skin lesions is different from the desquamation (i.e., peeling) that occurs with other skin disorders. In the bullous disorders, there is full-thickness detachment of the entire epidermis from the dermis. This leaves the person vulnerable to multiple problems, including loss of body fluids and electrolytes, impaired body temperature control, and a greatly increased risk of infection. Three types of drug reactions that result in bullous skin lesions are erythema multiforme minor, Stevens-Johnson syndrome, and toxic epidermal necrolysis.[7,34,35] *Erythema multiforme minor* is usually self-limiting. Cases involving less than 10% of the body surface area are called *Stevens-Johnson syndrome,* and detachment of more than 30% of the epidermis is labeled *toxic epidermal necrolysis,* with a 10% to 30% overlap of Stevens-Johnson syndrome and toxic epidermal necrolysis.[7,35]

Although the cause of erythema multiforme minor may be drug induced or unknown, it frequently occurs after infections, especially HSV infection. It is self-limiting, with a small amount of skin detachment at the lesion sites. Stevens-Johnson syndrome and toxic epidermal necrolysis are caused by a hypersensitivity reaction to drugs, the most common being sulfonamides, anticonvulsants, nonsteroidal anti-inflammatory drugs, antimalarial agents, and allopurinol. Although rare, Stevens-Johnson syndrome and toxic epidermal necrolysis have an annual incidence rate of 0.4 to 7 per 1 million people and a high mortality rate.[35] Recovery is based on the severity and quick, aggressive treatment.

The lesions of erythema multiforme minor and Stevens-Johnson syndrome are similar. The primary lesion of both is a round, erythematous papule, resembling an insect bite. Within hours to days, these lesions change into several different patterns. The individual lesions may enlarge and coalesce, producing small plaques, or they may change to concentric zones of color appearing as "target" or "iris" lesions (Fig. 46-16). The outermost rings of the target lesions usually are erythematous; the central portion usually is opaque white, yellow, or gray (dusky). In the center, small blisters on the dusky purpuric macules may form, giving them their characteristic targetlike appearance. Although there is wide distribution of lesions over the body surface area, there is a propensity for them to occur on the face and trunk.

Toxic epidermal necrolysis is the most serious type of drug reaction, with mortality rates of 25% to 35%.[35] The person experiences a prodromal period of malaise, low-grade fever, and sore throat. Within a few days, widespread erythema and large, flaccid bullae appear, followed by the loss of the epidermis, leaving a denuded and painful dermis. The skin surrounding the large denuded areas may have the typical targetlike lesions seen with Stevens-Johnson syndrome. Lateral pressure causes the surrounding skin to separate easily from the dermis (*Nikolsky sign*). The tracheobronchial mucosa and conjunctiva may be involved in severe cases with resultant scarring.[7] Ophthalmologic consultation is required when ocular involvement in present.

FIGURE 46-16. Erythema multiforme–like eruption on a patient's arm. Note the dusky, targetlike appearance. (Dermik Laboratories, Inc.) (From Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

Treatment of erythema multiforme minor and less severe cases of Stevens-Johnson syndrome includes relief of symptoms using compresses, antipruritic drugs, and topical anesthetics. Corticosteroid therapy may be indicated in moderate cases, although its use is controversial. For severe cases of Stevens-Johnson syndrome and toxic epidermal necrolysis, hospitalization is required for fluid replacement, respiratory care, administration of antibiotics and analgesics, and application of moist dressings. When large areas of skin are detached, the care is similar to that of thermal burn patients. Intravenous immunoglobulin may hasten the healing response of the skin. Generally, healing is a slow process, taking 6 weeks or more to regenerate skin. The mucous membranes heal slowly and follow-up treatment is often needed for ophthalmologic and mucous membrane sequelae. Discontinuation of the responsible drug and chemically related compounds is imperative, as are measures to prevent future exposures to the drug.

Papulosquamous Dermatoses

Papulosquamous dermatoses are a group of skin disorders characterized by scaling papules and plaques. Among the major papulosquamous diseases are psoriasis, pityriasis rosea, and lichen planus.

Psoriasis

Psoriasis is a common, chronic inflammatory skin disease, affecting approximately 2% of the population. Psoriasis

occurs worldwide, although the incidence is lower in warmer, sunnier climates. The average age of onset is in the third decade; its prevalence increases with age. Approximately one third of patients have a genetic history, indicating a hereditary factor. Childhood onset of the disease is more strongly associated with a family history than psoriasis occurring in adults older than 30 years of age. In rare cases, psoriasis is associated with arthritis (see Chapter 44).

The disease is usually manifested by raised, well-demarcated, erythematous plaques with adherent silvery scales.[11,12,36–38] Although the primary cause of psoriasis is uncertain, it is thought to be an immunologic disease with contributions from a genetic predisposition and environmental factors. It is not known if the inciting antigen is self or environmental. A genetic component is supported by population studies indicating a greater incidence of psoriasis among relatives of persons with the disease than among the general population. There is a strong association between psoriasis and the human leukocyte antigen (HLA)-C, particularly the HLA-Cw6 allele.[11] Immunologically, T lymphocytes may be the key to the pathogenesis of psoriasis.[39] Eruption of psoriatic lesions coincide with T-cell infiltration into the epidermis, and resolution of the lesions follows disappearance or reduction in epidermal T cells, suggesting a T-cell–mediated release of cytokines and growth factors that stimulate abnormal growth of keratinocytes and dermal blood vessels. Accompanying inflammatory changes are caused by infiltration of neutrophils and monocytes. Environmental stimuli may trigger the release of cytokines and growth factors from keratinocytes and other cells, with ensuing immune and inflammatory responses that lead to the full development of psoriatic lesions. For example, psoriatic lesions can be induced in susceptible individuals by trauma, a process known as the *Köbner phenomenon*.

Histologically, psoriasis is characterized by increased epidermal cell turnover with marked epidermal thickening, a process called *hyperkeratosis*. The granular layer (stratum granulosum) of the epidermis is thinned or absent, and neutrophils are found in the stratum corneum. There also is an accompanying thinning of the epidermal cell layer that overlies the tips of the dermal papillae, and the blood vessels in the dermal papillae become tortuous and dilated. These capillary beds show permanent damage even when the disease is in remission or resolved. The close proximity of the vessels in the dermal papillae to the hyperkeratotic scale accounts for multiple, minute bleeding points that are seen when the scale is lifted.

Psoriasis most frequently affects the elbows, knees, scalp, lumbosacral area, and intragluteal cleft. The primary lesions are sharply demarcated, thick, red plaques with a silvery scale that vary in size and shape (Fig. 46-17). In darker-skinned persons, the plaques may appear purple. There may be excoriation, thickening, or oozing from the lesions. A differential diagnostic finding is that the plaques bleed from minute points when removed, which is known as the *Auspitz sign*.

Treatment. The goals for psoriasis treatment focus on suppressing the hyperkeratosis, epidermal inflammation, and abnormal keratinocyte differentiation that are characteristic of the disease. Treatment measures are divided into topical and systemic approaches, the selection of which is dependent upon disease severity, as well as the person's age, sex, treatment history, and level of compliance. Usually, topical agents are used first in any treatment regimen

FIGURE 46-17. Psoriasis on the elbows of a 17-year-old girl. (Roche Laboratories.) (From Sauer G.C., Hall J.C. [1996]. *Manual of skin diseases* [7th ed.]. Philadelphia: Lippincott-Raven.)

and when less than 20% of the body surface is involved. Combination therapies tailored to the needs of the client are most effective.

Topical agents include emollients, keratolytic agents, coal tar products, corticosteroids, and calcipotriene.[38] Emollients hydrate and soften the psoriatic plaques. Petroleum-based products are more effective than water-based, but they are often less acceptable cosmetically to persons with psoriasis. Keratolytic agents are peeling agents. Salicylic acid is the most widely used. It softens and removes plaques. It has been used alone or in conjunction with other topical agents. Coal tar, the by-product of the processing of coke and gas from coal, is one of the oldest yet more effective forms of treatment. The exact mechanism of action of tar products is unknown, but side effects of the treatment are few. Newer preparations of coal tar lotions and shampoos are more aesthetically pleasing, but the odor remains a problem. *Calcipotriene* (a vitamin D derivative) *ointment* has been effective for the treatment of psoriasis. It inhibits epidermal cell proliferation and enhances cell differentiation. *Tazarotene,* a synthetic retinoid, also has been effective, but it is teratogenic and should be avoided in women of childbearing age.

Topical corticosteroids are widely used and relatively effective. They are generally more acceptable because they do not stain and are easy to use. Topical corticosteroids are available as low-, medium-, and high-potency preparations. Treatment usually is started with a medium-potency agent. Low-potency drugs usually are used on the face and areas of the body, such as the groin and axillary areas, where the skin tends to be thinner. High-potency preparations are reserved for treatment of thick chronic plaques that do not respond to less potent preparations. Although the corticosteroids are rapidly effective in the treatment of psoriasis, they are associated with flare-ups after discontinuation and they have many potential side effects. Their effectiveness is increased when used under occlusive dressings, but there is an increase in side effects.

Systemic treatments include phototherapy, photochemotherapy, methotrexate, corticosteroids, and cyclosporine. The positive effects of sunlight have long been established. Phototherapy with UVB is a widely used treatment. Newly developed narrow-band UVB radiation is reportedly more effective that broad-band UVB.[38] Photochemotherapy involves using a light-activated form of the drug methoxsalen. Methoxsalen, a psoralen or phototoxic drug, exerts its actions when exposed to UVA radiation in 320- to 400-nm wavelengths. The combination treatment regimen of psoralen and UVA is known by the acronym *PUVA*. Methoxsalen is given orally before UVA exposure. Activated by the UVA energy, methoxsalen inhibits DNA synthesis, thereby preventing cell mitosis and decreasing the hyperkeratosis that occurs with psoriasis. Although viewed as one of the safest therapies since its introduction in the 1970s, PUVA increases the risk for squamous cell carcinoma, and it may increase the risk for development of melanoma.

Methotrexate, which is used for cancer treatment, is an antimetabolite that inhibits DNA synthesis and prevents cell mitosis. Oral methotrexate has been effective in treating psoriasis when other approaches have failed. The drug has many side effects, including nausea, malaise, leukopenia, thrombocytopenia, and liver function abnormalities. Cyclosporine is a potent immunosuppressive drug used to prevent rejection of organ transplants. It suppresses inflammation and the proliferation of T cells in persons with psoriasis. Its use is limited to severe psoriasis because of serious side effects, including nephrotoxicity, hypertension, and increased risk of cancers. Intralesional cyclosporine also has been effective. Biologic agents (e.g., infliximab, etanercept, efalizumab, and alefacept) that target the activity of T lymphocytes and cytokines responsible for the inflammatory nature of psoriasis have proven effective.[7,38]

Pityriasis Rosea

Pityriasis rosea is a rash that primarily affects children and young adults. The origin of the rash is unknown, but is thought to be caused by an infective agent.[11,12,40] Numerous viruses have been investigated, thus far with no conclusive evidence. The incidence is highest in winter. Cases occur in clusters and among persons who are in close contact, indicating an infectious spread. However, there are no data to support communicability, suggesting it may be an immune response to any number of agents.

The characteristic lesion is an oval macule or papule with surrounding erythema (Fig. 46-18). The lesion spreads with central clearing, much like tinea corporis. This initial lesion is a solitary lesion called the *herald patch* and is usually on the trunk or neck. As the lesion enlarges and begins to fade (2 to 10 days), successive crops of lesions appear on the trunk and neck. The lesions on the back have a characteristic "Christmas tree" pattern. The extremities, face, and scalp may be involved. Mild to severe pruritus may occur. The disease is self-limited and usually disappears within 6 to 8 weeks. Treatment measures are palliative and include topical steroids, antihistamines, and colloid baths. Systemic corticosteroids may be indicated in severe cases.

FIGURE 46-18. Pityriasis rosea. Note oval herald patch (*arrow*) on the abdomen as well as a more generalized rash. (From Centers for Disease Control and Prevention Public Health Image Library. [Online] Available: http://phil.cdc.gov/Phil/home.asp.)

Lichen Planus

The term *lichen* (Greek, "tree moss") refers to skin disorders characterized by small (2 to 10 mm), flat-topped papules with irregular, angulated borders. *Lichen planus* is a relatively common chronic pruritic disease.[7,41] It involves inflammation and papular eruption of the skin and mucous membranes. There are variations in the pattern of lesions (e.g., annular, linear) and differences in the sites (e.g., mucous membranes, genitalia, nails, scalp). The characteristic lesion is a purple, polygonal papule covered with a shiny, white, lacelike pattern (Fig. 46-19). The lesions appear on the wrist, ankles, and trunk of the body. Most persons who have skin lesions also have oral lesions, appearing as milky white lacework on the buccal mucosa or tongue. Other mucosal surfaces, such as the genital, nasal, laryngeal, otic, gastric, and anal areas, may also be affected. As with psoriasis, lichen planus lesions can develop on scratches or skin injuries (Köbner phenomenon).

The etiology of lichen planus is unknown, but it is believed to be an abnormal immune response in which epithelial cells are recognized as foreign. The disorder involves the epidermal–dermal junction with damage to the basal cell layer. Some cases of lichen planus have been linked to hepatitis C virus infections or medication use. The most common medication agents include gold, antimalarial agents, thiazide diuretics, beta blockers, nonsteroidal anti-inflammatory agents, quinidine, and angiotensin-converting enzyme inhibitors. Some persons with oral lichen planus have reacted to the mercury in dental amalgams to the extent that when the dental fillings were replaced, the lesions healed.[41]

Diagnosis is based on the clinical appearance of the lesions and the histopathologic findings from a punch biopsy. For most persons, lichen planus is a self-limited disease. Treatment measures include discontinuation of all medications, followed by treatment with topical corticosteroids and occlusive dressings. Antipruritic agents are helpful in reducing itch. Systemic corticosteroids may be indicated in severe cases. Photochemotherapy (i.e., PUVA) may also be used. Acitretin, an orally administered retinoid agent, also may be effective. Because retinoids are teratogenic, they should be avoided in women of childbearing age.

FIGURE 46-19. Lichen planus affecting both wrists. (From Centers for Disease Control and Prevention Public Health Image Library. [Online] Available: http://phil.cdc.gov/Phil/home.asp.)

FIGURE 46-20. Localized lichen simplex chronicus of the leg. (Duke Laboratories, Inc.) (From Hall J.C. [2006]. *Sauer's manual of skin diseases* [9th ed., p. 119]. Philadelphia: Lippincott Williams & Wilkins.)

Lichen Simplex

Lichen simplex chronicus is a localized lichenoid pruritic dermatitis resulting from repeated rubbing and scratching.[7] It is characterized by the occurrence of itchy, reddened, thickened, and scaly patches of dry skin (Fig. 46-20). Persons with the condition may have a single or, less frequently, multiple lesions. The lesions are seen most commonly at the nape of the neck, wrists, ankles, or anal area. The condition usually begins as a small pruritic patch, which after a repetitive cycle of itching and scratching develops into a chronic dermatitis. Because of the chronic itching and scratching, excoriations and lichenification with thickening of the skin develops, often giving the appearance of tree bark.

In summary, primary skin disorders are those originating in the skin. They include infectious processes, acne and rosacea, allergic and hypersensitivity disorders, and papulosquamous dermatoses. The skin is subject to invasion by a number of microorganisms, including fungi, bacteria, and viruses. Superficial fungal infections or *dermatophytoses* are commonly known as *tinea* or

ringworm. Tinea can affect the whole body (tinea corporis), scalp (tinea capitis), feet or hands (tinea pedis or manus), or nails (tinea unguium). Candidal skin infection due *C. albicans* occurs most often in persons with diabetes mellitus, those who are immunosuppressed, or those have been treated with broad-spectrum antibiotics. Impetigo, which is caused by staphylococci or β-hemolytic streptococci, is the most common superficial bacterial infection. Viruses are responsible for verrucae (warts), herpes simplex type 1 lesions (cold sores or fever blisters), and herpes zoster (shingles).

Noninfectious inflammatory skin conditions include acne and rosacea and the papulosquamous dermatoses. Acne is a disorder of the pilosebaceous unit. Acne vulgaris, which is a common skin disorder of adolescents and young adults, is thought to reflect increased sebum production and the presence of *P. acnes.* Allergic skin responses involve the body's immune system and are caused by hypersensitivity reactions to allergens such as environmental agents, drugs, and other substances. They include atopic dermatitis, urticaria, and drug-induced skin eruptions (erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis).

The papulosquamous dermatoses, which are characterized by scaling papules and plaques, include psoriasis, pityriasis rosea, lichen simplex, and lichen planus. Psoriasis is a chronic proliferative skin disease characterized by epidermal hyperplasia. Lichen planus is a hypersensitivity reaction with lymphocytic infiltration at the dermal–epithelial junction.

Ultraviolet Radiation, Thermal, and Pressure Injury

- Because the skin covers the body, it is exposed to a number of potentially damaging agents in the external environment.
- The ultraviolet rays of sunlight have the potential for directly damaging skin cells, accelerating the effect of aging on the skin, and predisposing to the development of skin cancer.
- Prolonged pressure can interrupt blood flow, causing pressure ulcers.
- Thermal injury can damage skin and subcutaneous tissue and destroy the barrier function of the skin in terms of preventing the loss of body fluids and protecting against the entry of infectious organisms.

Ultraviolet Radiation, Thermal, and Pressure Injury

Ultraviolet Radiation

Sunlight is composed of a continuous spectrum of electromagnetic radiation that is divided into three main parts or wavelengths: ultraviolet (UV), visible, and infrared. The UV light region occurs between 200 and 400 nm (nm: one billionth of a meter).[42,43] The UV light region is divided into three categories depending on the wavelength: long-wave UVA (320 to 400 nm), medium-wave UVB (280 to 320 nm), and short-wave UVC (100 to 280 nm). The ozone layer effectively absorbs UV radiation up to 310 nm, absorbing all of UVC and much of UVB (95%) radiation. However, due to damage to the protective ozone layer, an increased amount of UVB is reaching the earth. The ozone layer does not absorb UVA.

Ultraviolet Radiation Skin Damage

UVA makes up more than 95% of the solar radiation that reaches us. Compared to UVB, this long-wave radiation penetrates deep into the dermis of the skin and is more effective in producing an immediate tan. UVB radiation is a minor, but more active constituent of sunlight. It is more genotoxic and about 1000 times more capable of causing sunburn than UVA light.[42] UVB acts mainly on the cells in the basal layer of the epidermis. It produces direct damage to the DNA and other nuclear proteins. It also provokes free radical production and induces a significant reduction in skin antioxidants, impairing the ability of the skin to protect itself against damage by the free radicals that are generated.

The acute effects of UVA and UVB are short lived and reversible. They include erythema, pigmentation, and injury to Langerhans cells and keratinocytes in the epidermis. These reactions differ depending on whether the inciting agent is UVA or UVB. For example, UVA-induced erythema occurs immediately, fades within hours, and is believed to be due to the "heat load." UVB-induced erythema has a delayed response, peaking within 6 to 24 hours after exposure to sunlight and fading over 1 or 2 days. Pigmentation or tanning induced by UVA and UVB is due to increased synthesis of melanin by melanocytes, along with increased transfer of the melanin to keratinocytes (see Chapter 45). Small doses of UVA produce transient, immediate darkening of the skin that fades within 2 hours, whereas higher doses of UVA can produce pigmentary changes lasting for several hours to days.[44] Tanning induced by UVB is protective against subsequent exposures, whereas tanning induced by UVA provides limited protection.

Skin damage induced by UVB is believed to be caused by the generation of reactive oxygen species and by damage to melanocytes.[43,44] Cellular proteins and DNA are primarily damaged because of their abundance and ability to absorb UVB radiation. Both UVA and UVB also deplete Langerhans cells and immune cells. It is believed that these effects prevent immune cells from detecting and removing sun-damaged cells with malignant potential. Both UVA and UVB are now considered causes of skin cancer. UVA may actually be more carcinogenic than UVB. Although it causes less sunburn, UVA is present during all daylight hours, year-round. Artificial sources of UVA, such as tanning beds and therapeutic solar

interventions (PUVA) for certain skin conditions, also produce the same effects as solar UVA in terms of skin cancer. This is of particular concern because of the increased use of indoor tanning, particularly among adolescents and young adults who are at greatest risk of melanoma.[45]

The UV rays of sunlight or other sources can be completely or partially blocked from the skin surface by sunscreens. There are two primary types of sunscreens available on the market—chemical (soluble) agents and physical (insoluble) agents.[46] Chemical agents (e.g., para-aminobenzoic acid [PABA] derivatives) protect the skin from absorbing sunlight, and physical agents (e.g., micronized titanium dioxide and microfine zinc) work by reflecting sunlight. The *sun protection factor* (SPF) rating of the various sunscreen products is based on their ability to obstruct UV radiation (UVR) absorption. The ratings usually are on a scale of 1 to 30+, with the higher ratings indicating greater blocking of UVR.[46] Products with a higher SPF screen out more UVB rays, which are primarily responsible for acute sun damage. Shielding the skin with protective clothing and hats or head coverings helps decrease UVR exposure.

Sunburn. Sunburn is caused by excessive exposure of the epidermal and dermal layers of the skin to UV radiation, resulting in an erythematous inflammatory reaction.[47] Sunburn ranges from mild to severe. Mild sunburn consists of various degrees of skin redness. The burn continues to develop for 24 to 72 hours, occasionally followed by peeling skin in 3 to 8 days. Some peeling and itching may continue for several weeks. Inflammation, blistering, weakness, chills, fever, malaise, and pain often accompany severe forms of sunburn. Scaling and peeling follow any overexposure to sunlight. Dark skin also burns and may appear grayish or gray-black. Severe sunburns are those that cover large portions of the body with blisters or are accompanied by a high fever or intense pain.

Mild to moderate sunburns are treated with anti-inflammatory medications, such as aspirin or ibuprofen, until redness and pain subside. Cold compresses, cool baths, and applying a moisturizing cream, such as aloe, to affected skin help treat the symptoms. Steroid and nonsteroidal agents are used depending on the severity of the burn. Blisters should not be broken to preserve the protective layer of the skin, hasten the healing process, and decrease the risk of infection. Extensive second- and third-degree sunburns may require hospitalization and specialized burn care techniques, as described in the section on thermal injury.

Drug-Induced Photosensitivity. Some drugs are classified as photosensitive drugs because they produce an exaggerated response to UVR when the drug is taken in combination with sun exposure.[48] Examples include some of the anti-infective agents (sulfonamides, tetracyclines, nalidixic acid), antihistamines (cyproheptadine, diphenhydramine), antipsychotic agents (phenothiazines, haloperidol), diuretics (thiazides, acetazolamide, amiloride), hypoglycemic agents (sulfonylureas), and nonsteroidal anti-inflammatory drugs (phenylbutazone, ketoprofen, naproxen).

Thermal Injury

About 1.2 million people in the United States require medical care for burns each year, with 51,000 requiring hospitalization. Between 30% and 40% of these are children younger than 15 years of age, with an average age of 32 months.[49] Thermal burns are caused by a number of sources. Flame burns occur because of exposure to direct fire. Scald burns result from hot liquids spilled or poured on the skin surface.

The effects and complications of burns fully illustrate the essential function that the skin performs in protecting the body from the many damaging elements in the environment while serving to maintain the constancy of the body's internal environment. The massive loss of skin tissue not only predisposes to attack by microorganisms that are present in the environment, but also allows for the massive loss of body fluids and their contents, interferes with temperature regulation, challenges the immune system, and imposes excessive demands on the metabolic and reparative processes that are needed to restore the body's interface with the environment.

Classification of Burns

Burns are typically classified according to the depth of involvement as first-degree, second-degree, and third-degree burns.[49–51] The depth of a burn is largely influenced by the duration of exposure to the heat source and the temperature of the heating agent. *First-degree burns* (superficial partial-thickness burns) involve only the outer layers of the epidermis. They are red or pink, dry, and painful. There usually is no blister formation. A mild sunburn is an example. The skin maintains its ability to function as a water vapor and bacterial barrier and heals in 3 to 10 days. First-degree burns usually require only palliative treatment, such as pain relief measures and adequate fluid intake. Extensive first-degree burns on infants, the elderly, and persons who receive radiation therapy for cancer may require more care.

Second-degree burns involve both the epidermis and dermis. *Second-degree partial-thickness burns* involve the epidermis and various degrees of the dermis. They are painful, moist, red, and blistered. Underneath the blisters is weeping, bright pink or red skin that is sensitive to temperature changes, air exposure, and touch. The blisters prevent the loss of body water and superficial dermal cells. Excluding excision of large burn areas, it is important to maintain intact blisters after injury because they serve as a good bandage and may promote wound healing. These burns heal in approximately 1 to 2 weeks.

Second-degree full-thickness burns involve the entire epidermis and dermis. Structures that originate in the subcutaneous layer, such as hair follicles and sweat glands, remain intact. These burns can be very painful because the pain sensors remain intact. Tactile sensation may be absent or greatly diminished in the areas of deepest destruction. These burns appear as mottled pink, red,

TABLE 46-1 American Burn Association Grading System for Burn Severity and Disposition

	Type of Burn		
	Minor	***Moderate***	***Major***
Criteria	<10% TBSA in adult <5% TBSA in young (<10 years) or old (>50 years) <2% Full-thickness burn	10%–20% TBSA in adult 5%–10% TBSA in young or old 2%–5% Full-thickness burn High-voltage injury Suspected inhalation injury Circumferential burn Concomitant medical problem predisposing to infection (e.g., diabetes, sickle cell disease)	>20% TBSA in adult >10% TBSA in young or old >5% Full-thickness burn High-voltage burn Known inhalation injury Any significant burn to face, eyes, ears, genitalia, hands, feet, or major joints Significant associated injuries (e.g., major trauma)
Disposition	Outpatient management	Hospital admission	Referral to burn center

TBSA, total body surface area.

From American Burn Association. (1990). Hospital and prehospital resources for optimal care of patients with burn injury: Guidelines for development and operation of burn centers. *Journal of Burn Care and Rehabilitation* 11, 98–104.

or waxy white areas with blisters and edema. The blisters resemble flat, dry tissue paper, rather than the bullous blisters seen with superficial partial-thickness injury. After healing, in approximately 1 month, these burns maintain their softness and elasticity, but there may be the loss of some sensation. Scar formation is usual. These burns heal with supportive medical care aimed at preventing further tissue damage, providing adequate hydration, and ensuring that the granular bed is adequate to support reepithelialization.

Third-degree full-thickness burns extend into the subcutaneous tissue and may involve muscle and bone. Thrombosed vessels can be seen under the burned skin, indicating that the underlying vasculature is involved. Third-degree burns vary in color from waxy white or yellow to tan, brown, deep red, or black. These burns are hard, dry, and leathery. Edema is extensive in the burn area and surrounding tissues. There is no pain because the nerve sensors have been destroyed. However, there is no such thing as a "pure" third-degree burn. Third-degree burns are almost always surrounded by second-degree burns, which are surrounded by an area of first-degree burns. The injury sometimes has an almost targetlike appearance because of the various degrees of burn. Full-thickness burns wider than 1.5 inches usually require skin grafts because all the regenerative (i.e., dermal) elements have been destroyed. Smaller injuries usually heal from the margins inward toward the center, the dermal elements regenerating from the healthier margins. However, regeneration may take many weeks and leave a permanent scar, even in smaller burns.

In addition to the depth of the wound, the extent of the burn also is important. Extent is measured by estimating the amount of total body surface area (TBSA) involved.[49–51] Several tools exist for estimating the TBSA. For example, the *rule of nines* counts anatomic body parts as multiples of 9% (the head and neck is 9%, each arm 9%, each leg 18%, anterior trunk 18%, posterior trunk 18%), with the perineum 1%. The Lund and Browder chart includes a body diagram table that estimates the TBSA by age and anatomic part. Children are more accurately assessed using this method because it takes into account the difference in relative size of body parts. The estimates of TBSA are then converted to the American Burn Association Classification of Extent of Injury (Table 46-1).

Other factors, such as age, location, other injuries, and preexisting conditions, are taken into consideration for a full assessment of burn injury.[51–55] These factors can increase the assessed severity of the burn and the length of treatment. For example, a first-degree burn is reclassified as a more severe burn if other factors are present, such as burns to the hands, face, and feet; inhalation injury; other trauma; or existence of psychosocial problems. Genital burns almost always require hospitalization because edema may cause difficulty urinating and the location complicates maintenance of a bacteria-free environment.

Systemic Complications

Burn victims often are confronted with hemodynamic instability, impaired respiratory function, a hypermetabolic response, and sepsis.[52–54] The magnitude of the response is proportional to the extent of injury, usually reaching a plateau when approximately 60% of the body is burned. In addition to loss of skin, burn victims often have associated injuries or illnesses. The treatment challenge is to provide immediate resuscitation efforts and long-term maintenance of physiologic function. Pain and emotional problems are additional challenges faced by persons with burns.

Hemodynamic Instability. Hemodynamic instability begins almost immediately with injury to capillaries in

the burned area and surrounding tissue. Fluid is lost from the vascular, interstitial, and cellular compartments. Because of a loss of vascular volume, major burn victims often present in the emergency department in a form of hypovolemic shock (Chapter 20) known as *burn shock*. Because proteins from the blood are lost into the interstitial compartment, generalized edema, including pulmonary edema, can be severe.

Respiratory System Dysfunction. Another injury commonly associated with burns is smoke inhalation and postburn lung injury. Victims often are trapped in a burning structure and inhale significant amounts of smoke, carbon monoxide, and other toxic fumes. Water-soluble gases, such as ammonia, sulfur dioxide, and chlorine, that are found in smoke from burning plastics and rubber react with mucous membranes to form strong acids and alkalis that induce ulceration of the mucous membrane, bronchospasm, and edema. Lipid-soluble gases, such as nitrous oxide and hydrogen chloride, are transported to the lower airways, where they damage lung tissue. There also may be thermal injury to the respiratory passages. Manifestations of inhalation injury include hoarseness, drooling and inability to handle secretions, hacking cough, and labored and shallow breathing. Serial blood gases show a fall in the partial pressure of arterial oxygen (PO_2). Signs of mucosal injury and airway obstruction often are delayed for 24 to 48 hours after a burn. Other pulmonary conditions, such as pneumonia, pulmonary embolism, or pneumothorax, may occur secondarily to the burn.

Hypermetabolic Response. The stress of burn injury increases metabolic and nutritional requirements. Secretion of stress-related hormones such as catecholamines and cortisol is increased in an effort to maintain homeostasis. Heat production is increased in an effort to balance heat losses from the burned area. Hypermetabolism, characterized by increased oxygen consumption, increased glucose use, and protein and fat wasting, is a characteristic response to burn trauma and infection. The hypermetabolic state peaks at approximately 7 to 17 days after the burn, and tissue breakdown diminishes as the wounds heal. Nutritional support is essential to recovery from burn injury. Enteral and parenteral hyperalimentation may be used during this time to deliver sufficient nutrients to prevent tissue breakdown and postburn weight loss.

Sepsis. A significant complication of the acute phase of burn injury is sepsis. It may arise from the burn wound, pneumonia, urinary tract infection, infection elsewhere in the body, or the use of invasive procedures or monitoring devices. The burn site is an ideal growth area for microorganisms; the serum and debris provide nutrients, and the burn injury compromises blood flow. Immunologically, the skin is the body's first line of defense. When the skin is no longer intact, the body is open to bacterial infection. Destruction of the skin also prevents the delivery of cellular components of the immune system to the site of injury. There also is loss of normal protective skin flora and a shift to colonization by more pathogenic flora.

Emergency and Long-Term Treatment

Regardless of the type of burn, the first step in any burn situation is to stop the burning process, cool the burn, provide pain relief, and cover the burn.[53,54] Active cooling removes the heat and prevents progression of the burn. Immersion or irrigation with lukewarm water for at least 20 minutes can be extremely helpful. Immediate submersion is more important than removal of clothing, which may delay cooling the involved areas. The application of ice or cold water is not recommended because it can further limit blood flow to an area, turning a partial-thickness into a full-thickness burn.

Depending on the depth and extent of the burn, medical treatment is necessary. Emergency care consists of resuscitation and stabilization with intravenous fluids while maintaining cardiac and respiratory function. Once hospitalized, the immediate treatment regimen focuses on continued maintenance of cardiorespiratory function, pain alleviation, wound care, and emotional support. After hemodynamic and pulmonary stability have been established, treatment is directed toward initial care of the wound. Treatment of the burn wound focuses on protection from desiccation and further injury of those burn areas that reepithelialize in 7 to 10 days (superficial second-degree burns). "Nature's own blister" is the best protection for these burns. Topical antimicrobial preparations (e.g., silver sulfadiazine) and dressings are used to cover the wound when the blister has been broken. Wounds that will not heal spontaneously in 7 to 10 days (deep second-degree and third-degree burns) are usually treated by excision and skin grafts. The sloughed tissue, or *eschar,* produced by the burn is excised as soon as possible. This decreases the chance of infection and allows the skin to regenerate faster.

Burns that encircle the entire surface of the body or a body part (e.g., arms, legs, torso) act like tourniquets and can cause major tissue damage to the muscles, tendons, and vasculature under the area of the leathery eschar skin. These burns are called *circumferential burns*. The eschar is incised longitudinally (escharotomy), and sometimes a fasciotomy (surgical incision through the fascia of the muscle) is performed.

Systemic infection remains a leading cause of morbidity among persons with extensive burns. Continuous microbiologic surveillance is necessary; protective isolation measures are often instituted. There is an increasing trend toward use of prophylactic antibiotic treatment in persons with major burns.

Skin grafts are surgically implanted as soon as possible, often at the same time the burn tissue is excised, to promote new skin growth, limit fluid loss, and act as a dressing.[56] Skin grafts can be permanent or temporary, and split thickness or full thickness. Permanent skin grafts are used over newly excised tissue. Temporary skin grafts are used to cover a burned area until the tissue underneath it has healed. Various sources of skin grafts exist: *autograft* (skin obtained from the person's own

body), *homograft* (skin obtained from another human being, alive or recently dead), and *heterograft* (skin obtained from another species, such as pigs). The best choice is autografting when there is enough uninterrupted skin on the person's body. The thickness of these grafts depends on the donor site and the needs of the burn patient. A *split-thickness skin graft* is one that includes the epidermis and part of the dermis. A split-thickness skin graft can be sent through a skin mesher that cuts tiny slits into the skin, allowing it to expand up to nine times its original size. These grafts are used frequently because they can cover large surface areas and there is less autorejection. *Full-thickness skin grafts* include the entire thickness of the dermal layer. They are used primarily for reconstructive surgery or for small deep areas. The donor site of a full-thickness skin graft requires a split-thickness skin graft to help it heal.

Two-layered synthetic skin grafts (*Apligraf, Integra*) are now available.[57] Synthetic skin grafts generally are composed of a layer of silicone, mimicking the properties of the epidermis, and a layer or matrix of fibers. Skin cells attach to the fibers, enabling dermal skin growth. Once the dermal skin has regenerated, the silicone layer is removed and a thin epidermal skin graft is applied, thus requiring less skin grafting overall.

Other treatment measures include positioning, splinting, and physical therapy to prevent contractures and maintain muscle tone. Because the normal body response to disuse is flexion, the contractures that occur with a burn are disfiguring and cause loss of limb or appendage use. Once the wounds have healed sufficiently, elastic pressure garments, sometimes for the full body, often are used to prevent hypertrophic scarring.

Pressure Ulcers

Pressure ulcers are ischemic lesions of the skin and underlying structures caused by unrelieved pressure that impairs the flow of blood and lymph. Pressure ulcers often are referred to as *decubitus ulcers* or *bedsores*. The word *decubitus* comes from the Latin term meaning "lying down." However, a pressure ulcer may result from pressure exerted in the seated or the lying position. Pressure ulcers are most likely to develop over a bony prominence, but they may occur on any part of the body that is subjected to external pressure, friction, or shearing forces. Several subpopulations are at particular risk, including persons with quadriplegia, elderly persons with restricted activity and hip fractures, and persons in the critical care setting.

Mechanisms of Development

Four factors contribute to the development of pressure ulcers: (1) pressure, (2) shearing forces, (3) friction, and (4) moisture.[58–60] External pressures that exceed capillary pressure interrupt blood flow in the capillary beds. When the pressure between a bony prominence and a support surface exceeds the normal capillary filling pressure, capillary flow essentially is obstructed. If this pressure is applied constantly for 2 hours, oxygen deprivation coupled with an accumulation of metabolic end products leads to irreversible tissue damage. Although 32 mm Hg has been traditionally accepted as the amount of pressure necessary to compress capillaries and interrupt blood flow, this is highly variable among individuals.[58] Persons with impaired circulation require less pressure to interrupt circulation. The same amount of pressure causes more damage when it is distributed over a small area than over a larger area.

Whether a person is sitting or lying down, the weight of the body is borne by tissues covering the bony prominences. More than 95% of pressure ulcers are located on the lower part of the body, most often over the sacrum, the coccygeal area, the ischial tuberosities, and the greater trochanters.[59] Pressure over a bony area is transmitted from the surface to the underlying dense bone, compressing all of the intervening tissue. As a result, the greatest pressure occurs at the surface of the bone and dissipates outward in a conelike manner toward the surface of the skin (Fig. 46-21). Thus, extensive underlying tissue damage can be present when a small superficial skin lesion is first noticed.

Altering the distribution of pressure from one skin area to another prevents tissue injury. Pressure ulcers most commonly occur in persons with conditions such as spinal cord injury in which normal sensation and movement to effect redistribution of body weight are impaired. Normally, persons unconsciously shift their

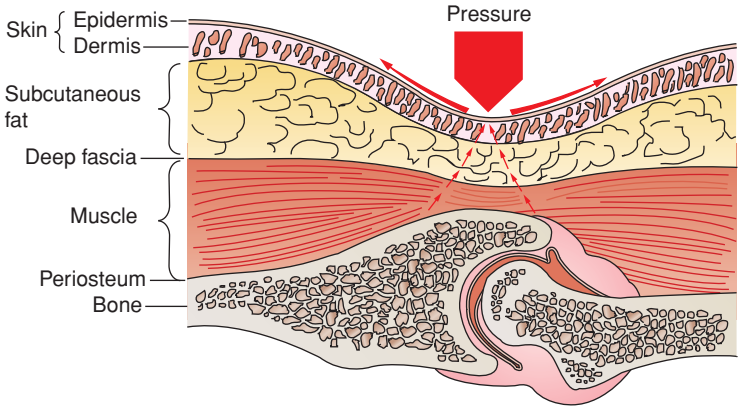

FIGURE 46-21. Pressure over a bony prominence compresses all intervening soft tissue, with a resulting wide, three-dimensional pressure gradient that causes various degrees of tissue damage. (From Shea J.D. [1975]. Pressure sores: Classification and management. *Clinical Orthopedics and Related Research* 112, 90.)

weight to redistribute pressure on the skin and underlying tissues. For example, during the night, people turn in their sleep, preventing ischemic injury of tissues that overlie the bony prominences that support the weight of the body; the same is true for sitting for any length of time. The movements needed to shift the body weight are made unconsciously, and only when movement is restricted do people become aware of discomfort.

Shearing forces are caused by the sliding of one tissue layer over another with stretching and angulation of blood vessels, causing injury and thrombosis. Shear occurs when the skeleton moves, but the skin remains fixed to an external surface, such as occurs with transfer from a stretcher to a bed or pulling a person up in bed. The same thing happens when the head of the bed is elevated, causing the torso to move toward the foot of the bed while friction and moisture cause the skin to remain fixed to the bed linens. *Friction* contributes to pressure ulceration by damaging the skin at the epidermal–dermal interface. It occurs as persons who are bedridden use their elbows and heels to aid in movement. *Moisture* contributes to pressure ulcer formation by weakening the cell wall of individual skin cells and by changing the protective pH of the skin. This makes the skin more susceptible to pressure, shear, and friction injury.

Prevention and Treatment

The prevention of pressure ulcers is preferable to their treatment.[60] Preventative measures include identifying at-risk persons who need preventive measures and the specific factors placing them at risk, maintaining and improving tissue tolerance to prevent injury, and protecting the skin and underlying tissue against the adverse effects of external mechanical forces (i.e., pressure, friction, shear). Risk factors contributing to the development of pressure ulcers are those related to sensory perception and the ability to respond meaningfully to pressure-related discomfort, level of skin moisture, urine and fecal continence, nutrition and hydration status, mobility, and circulatory status.

Prevention Methods. Methods for preventing pressure ulcers include frequent position changes, meticulous skin care, and frequent and careful observation to detect early signs of skin breakdown. Moisture macerates and injures skin. Sources of moisture include sweat, wound drainage, urine, and feces. Both urinary and fecal incontinence increase the risk of pressure ulcers. Food crumbs, intravenous tubing, and other debris in the bed can greatly increase local skin pressure points. Adequate hydration of the stratum corneum appears to protect the skin against mechanical insult. The prevention of dehydration improves the circulation. It also decreases the concentration of urine, thereby minimizing skin irritation in persons who are incontinent, and it reduces urinary problems that contribute to incontinence. Maintenance of adequate nutrition is important. Anemia and malnutrition contribute to tissue breakdown and delay healing after tissue injury has occurred.

Staging and Treatment. Pressure ulcers can be staged using four categories.[61] *Stage I ulcers* are characterized by a defined area of persistent redness in lightly pigmented skin or an area of persistent redness with blue or purple hues in darker skin. *Stage II ulcers* represent a partial-thickness loss of skin involving the epidermis or dermis, or both. The ulcer is superficial and presents clinically as an abrasion, a blister, or a shallow crater. *Stage III ulcers* represent a full-thickness skin loss involving damage and necrosis of subcutaneous tissue that may extend down to but not through underlying fascia. The ulcer manifests as a deep crater with or without undermining of adjacent tissue. *Stage IV ulcers* involve full-thickness skin loss and necrosis with extensive destruction or damage to the underlying subcutaneous tissues that may extend to involve muscle, bone, and supporting structures (e.g., tendon or joint capsule).

After skin breakdown has occurred, special treatment measures are needed to prevent further ischemic damage, reduce bacterial contamination and infection, and promote healing. Treatment methods are selected based on the stage of the ulcer.[60–62] Stage I ulcers usually are treated with frequent turning and measures to remove pressure. Stage II or III ulcers with little exudate are treated with semipermeable or occlusive dressings. Occlusive dressings are credited with preventing the loss of wound fluid and maintaining a moist environment that is necessary for epithelial cell migration. Wound fluid is thought to contain a variety of growth factors that enhance wound healing. Occlusive dressings may also relieve wound pain and prevent bacterial contamination. There are several types of occlusive dressings available, including polymer films, hydrogels, hydrocolloids, biomembranes, and absorbing granules. The available products differ in their permeability to water vapor and wound protection, and each has advantages and disadvantages.

Necrotic debris increases the possibility of bacterial infection and delays wound healing. Stage III ulcers with exudate and necrotic debris and stage IV ulcers usually require débridement (i.e., removal of necrotic tissue and eschar). This can be done surgically, with wet-to-dry dressings, or through the use of proteolytic enzymes. Stage IV wounds often require packing to obliterate dead space and are covered with nonadherent dressings. Stage IV ulcers may require surgical interventions, such as skin grafts or myocutaneous flaps.

In summary, repeated exposure to the UV rays of the sun predisposes to sunburn, premature aging of the skin (wrinkling, degenerative changes, and irregularities in pigmentation), and skin cancer. Solar and artificial sources of UV radiation, such as from a tanning bed, contribute to the amount of radiation to which human beings are exposed. Sunburn, which is caused by excessive exposure to UV radiation, is an erythematous inflammatory reaction, ranging from mild to severe. Photosensitive drugs can also produce an exaggerated response to UV radiation when they are taken in combination with sun

exposure. Sunscreens are protective agents that work by either reflecting sunlight or preventing its absorption.

Burns cause damage to skin structures, ranging from first-degree burns, which damage the epidermis, to third-degree full-thickness burns, which extend into the subcutaneous tissue and may involve muscle and bone. The extent of injury is determined by the thickness of the burn and the total body surface area involved. In addition to skin involvement, burn injury can cause hemodynamic instability with hypovolemic shock, inhalation injury with respiratory involvement, a hypermetabolic state, and sepsis. Treatment methods vary with the severity of injury and include immediate resuscitation and maintenance of physiologic function, wound cleaning and débridement, application of antimicrobial agents and dressings, and skin grafting.

Pressure ulcers are caused by ischemia of the skin and underlying tissues. They result from external pressure, which disrupts blood flow, or shearing forces, which cause stretching and injury to blood vessels. Pressure ulcers are divided into four stages, according to the depth of tissue involvement. The prevention of pressure ulcers is preferable to their treatment. The goals of prevention should include identifying at-risk persons who need prevention along with the specific factors placing them at risk, maintaining and improving tissue tolerance to pressure to prevent injury, and protecting against the adverse effects of external mechanical forces (i.e., pressure, friction, and shear).

Nevi and Skin Cancers

Nevi

Nevi, or moles, are common congenital or acquired tumors of the skin that are benign. Almost all adults have nevi, some in greater numbers than others. Nevi can be pigmented or nonpigmented, flat or elevated, and hairy or nonhairy.

Melanocytic nevi are pigmented skin lesions resulting from proliferation of melanocytes in the epidermis or dermis.[11,12] Melanocytic nevi are tan to deep brown, uniformly pigmented, small papules with well-defined, rounded borders (Fig. 46-22A). They are formed initially by melanocytes with their long dendritic extensions that are normally interspersed among the basal keratinocytes (see Chapter 45, Fig. 45-3). The melanocytes are transformed into round or oval melanin-containing cells that grow in nests or clusters along the dermal–epidermal junction. Because of their location, these lesions are called *junctional nevi* (see Fig. 46-22B). Most junctional nevi eventually grow into the surrounding dermis as nests or cords of cells. *Compound nevi* contain epidermal and dermal components. In older lesions, the epidermal nests may disappear entirely, leaving *dermal nevi.* Compound and dermal nevi usually are more elevated than junctional nevi.

Another form of nevus, the *dysplastic nevus,* is important because of its capacity to transform into malignant melanoma.[11,12,63] Although the association between nevi and malignant melanoma was made over 175 years ago, it was not until 1978 that the role of dysplastic nevi as precursors to malignant melanoma was described in detail.[11] Dysplastic nevi are usually larger than other nevi (often >5 mm in diameter). Their appearance is a flat, slightly raised plaque with a pebbly surface, or a targetlike lesion with a darker, raised center and irregular border (Fig. 46-23). They vary in shade from brown and red to flesh tones. A person may have hundreds of these lesions. Although dysplastic nevi can give rise to melanoma, the vast majority are stable and never progress, suggesting that they are best viewed as markers for melonoma risk. Dysplastic nevi have been documented in multiple members of families prone to development of malignant melanoma.

[Online] Available: http://phil.cdc.gov/Phil/home.asp.) **(B)** Junctional nevi on the back of a 16-year-old patient. (Owen Laboratories, Inc.) (From Hall J.C. [2006]. *Sauer's manual of skin diseases* [9th ed., p. 397]. Philadelphia: Lippincott Williams & Wilkins.)

FIGURE 46-23. Dysplastic nevi. Lesion has a dark brown "pebbly" elevated surface against a lighter tan, macular background. The irregular, indistinct margin helps to distinguish it from the small congenital pattern nevus, which some dysplastic nevi closely resemble. Its distinct morphology, rather than its size (6 × 6 mm), identifies it as a dysplastic nevus. (From National Cancer Institute Visuals. [Online] Available: http://visualsonline.cancer.gov/browseaction.cfm?topicid=g11.)

Skin Cancers

- Increased and unprotected exposure to the ultraviolet rays of sunlight produces sunburn and increases the risk for development of skin cancer.
- The melanocytes, which protect against sunburn through increased production of melanin and suntanning, are particularly vulnerable to the adverse effects of unprotected exposure to ultraviolet light. Malignant melanoma, which is a malignant tumor of melanocytes, is a rapidly progressive and metastatic form of skin cancer.
- Basal cell carcinoma and squamous cell carcinoma, which also reflect the effects of increased sun exposure, are less aggressive forms of skin cancer and are more easily cured.

Because of the possibility of malignant transformation, any mole that undergoes a change warrants immediate medical attention. The changes to observe and report are changes in size, thickness, or color; itching; and bleeding.

Skin Cancer

Skin cancer represents the most common malignancy in white-skinned people in the Western world.[64] The majority of skin cancers are nonmelanomas, either basal cell or squamous cell carcinoma. Although melanoma represents a small subset of skin cancers, it is the most deadly. Not only is melanoma more deadly, but also its incidence is increasing faster than any other malignancy.[65] The rising incidence of melanoma and other skin cancer has been attributed to increased sun exposure associated with social and lifestyle changes.

The factors linking sun exposure to skin cancer are not completely understood, but both total cumulative exposure and altered patterns of exposure are strongly implicated. Basal cell and squamous cell carcinomas are often associated with total cumulative exposure to UV radiation. Thus, basal cell and squamous cell carcinomas occur more commonly on maximally sun-exposed parts of the body, such as the face and back of the hands and forearms. Melanomas occur most commonly on areas of the body that are exposed to the sun intermittently, such as the back in men and the lower legs in women.[64] They are more common in persons with indoor occupations whose exposure to sun is limited to weekends and vacations. Excessive childhood sun exposure is an important risk factor for melanoma, particularly blistering sunburns.

Malignant Melanoma

Malignant melanoma is a malignant tumor of the melanocytes.[11,12,64–68] It is a rapidly progressing, metastatic form of cancer. The dramatic increase in the incidence of malignant melanoma over the past several decades has been credited to increased UV light exposure, including tanning salons. Other risk factors include a family history of malignant melanoma, fair hair and skin, tendency to freckle, and a history of blistering sunburns as a child. Still other significant risk factors for melanoma are atypical moles/dysplastic nevus syndrome, immunosuppression, and prior PUVA therapy.

Roughly 90% of malignant melanomas in whites occur on sun-exposed skin. However, in darker-skinned people melanomas often occur on non–sun-exposed areas, such as the mucous membranes and subungual, palmar, and plantar surfaces. Malignant melanomas differ in size and shape. Usually, they are slightly raised and black or brown. Borders are irregular and surfaces are uneven. Most appear to arise from preexisting nevi or new molelike growths (Fig. 46-24). There may be surrounding erythema, inflammation, and tenderness. Periodically, melanomas ulcerate and bleed. Dark melanomas are often mottled with shades of red, blue, and white. These three colors represent three concurrent processes: melanoma growth (blue), inflammation and the body's attempt to localize and destroy the tumor (red), and scar tissue formation (white).

Four types of melanomas have been identified based on their radial and vertical growth progression: lentigo maligna, superficial spreading, acral lentiginous, and nodular.[11] Radial growth describes the horizontal spread of the melanoma within the epidermis and superficial

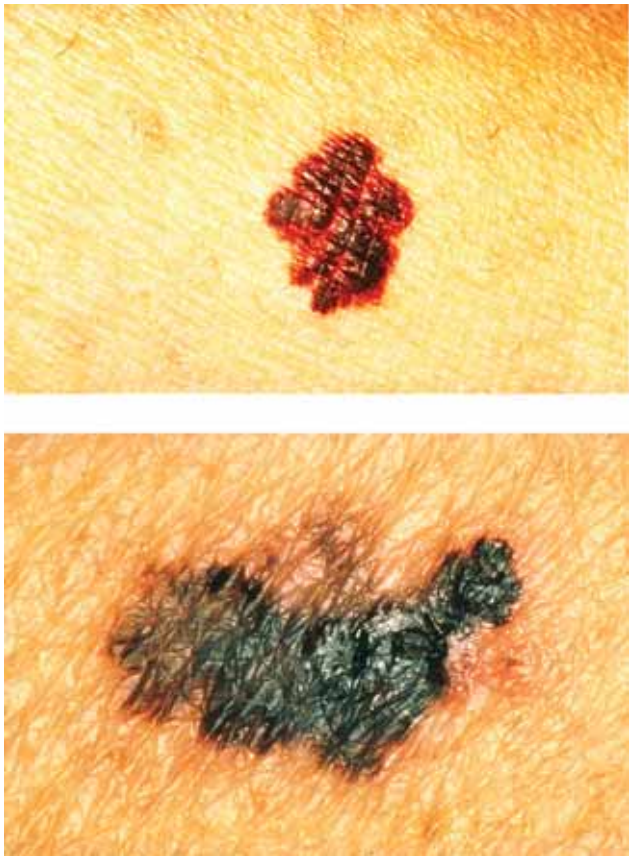

FIGURE 46-24. Melanoma lesions, demonstrating the ABCD rule: A (asymmetry), B (irregular borders), C (different colors), and D (diameter change in size). (From National Cancer Institute Visuals. [Online] Available: http://visualsonline.cancer.gov/browseaction.cfm?topicid=g11.)

dermis. During this initial stage, the tumor seems to lack the ability to metastasize. Lentigo maligna melanomas, superficial spreading melanomas, and acral lentiginous melanomas are tumors that are in the radial growth phase. *Lentigo maligna melanomas* are flat slow-growing nevi that may remain in the radial growth phase for several decades. They are seen primarily on sun-exposed skin of elderly persons. *Superficial spreading melanoma,* the most common type of melanoma, is seen most commonly in persons who sunburn easily and have intermittent sun exposure. It is characterized by a raised-edged nevus with lateral growth and a disorderly appearance in color and outline. It typically ulcerates and bleeds with growth. *Acral lentiginous melanoma* has an appearance similar to that of lentigo maligna, and is seen primarily on the palms, soles, nail beds, and mucous membranes. It occurrence is unrelated to sun exposure.

After a variable and unpredictable period of time, melanomas shift from a radial to vertical growth phase, during which the tumor cells invade downward into the deeper dermis layers.[11] This growth phase is heralded by the nodular phase and correlates with the emergence of a clone of cells with metastatic potential. *Nodular melanomas* are raised, dome-shaped lesions that can occur anywhere on the body. They are commonly a uniform blue-black color and tend to look like blood blisters. Nodular melanomas tend to rapidly invade the dermis from the start, with no apparent horizontal growth phase.

Early detection is critical with malignant melanoma. Regular self-examination of the total skin surface in front of a well-lighted mirror provides a method for early detection. It requires that a person undress completely and examine all areas of the body using a full mirror, handheld mirror, and handheld hair dryer (to examine the scalp). An *ABCD* rule has been developed to aid in early diagnosis and timely treatment of malignant melanoma.[68] The acronym stands for *a*symmetry, *b*order irregularity, *c*olor variegation, and *d*iameter greater than 6 mm (1/4 inch or pencil eraser size). People should be taught to watch for these changes in existing nevi or the development of new nevi, as well as other alterations such as bleeding or itching. Because of the existence of small-diameter melanomas (i.e., <6 mm in diameter), it has been suggested that people routinely screen their skin for all possible manifestations of skin cancer. Since their description over 20 years ago, evidence has accumulated to add an E for "evolving" to the ABCD rule.[68] The E for evolving is intended to encourage the recognition of melanomas at an earlier stage by emphasizing the dynamic nature of their growth.

Diagnosis of melanoma is based on biopsy findings from a lesion.[11,64,65,67] Because most melanomas initially metastasize to regional lymph nodes, additional information may be obtained through lymph node biopsy. Consistent with other cancerous tumors, melanoma is commonly staged using the TNM (tumor, lymph node, and metastasis) staging system (see Chapter 7) or the American Joint Committee on Cancer Staging System for Cutaneous Melanoma, in which the tumor is rated 0 to 4, depending on numerous factors, including extent of tumor invasion, ulceration, and metastasis.[11] Ulceration and invasion of the tumor into the deeper skin tissue result in a poorer prognosis. The degree and number of lymph nodes involved correlate well with overall survival.

Treatment of melanoma is usually surgical excision, the extent of which is determined by the thickness of the lesion, invasion into the deeper skin layers, and spread to the regional lymph nodes.[64,65,67] Deep, wide excisions with elective removal of lymph tissue and the use of skin grafts were once the hallmarks of treatment. When diagnosed in a premetastatic phase, melanoma is now treated in ambulatory settings, lessening the cost and inconvenience of care. Current capability allows for mapping lymph flow to a regional lymph node that receives lymphatic drainage from tumor sites on the skin. This lymph node, which is called the *sentinel lymph node,* is then sampled for biopsy. If tumor cells have spread from the primary tumor to the regional lymph nodes, the sentinel node will be the first node in which tumor cells appear. Therefore, sentinel node biopsy can be used to test for the presence of melanoma cells and determine if radical lymph node dissection is necessary. When nodes are positive, consideration is also given to systemic adjuvant

therapy. Although no effective chemotherapy is available for melanoma, interferon alfa-2b is a biologic therapy available for adjuvant treatment of melanoma. At this time, however, the use of interferon is controversial. Clinical trials with other therapies, including combination chemotherapies, vaccines, and hyperthermic isolation limb perfusion, are ongoing.[64,65,67]

Basal Cell Carcinoma

Basal cell carcinoma is a neoplasm of the nonkeratinizing cells of the basal layer of the epidermis.[11,69] It is the most common invasive cancer in humans, with nearly 1 million estimated new cases each year in the United States.[11] Basal cell carcinomas have a tendency to occur in fair-skinned persons with a history of significant long-term sun exposure. They are most frequently seen on the head and neck, most often occurring on skin that has hair.

Basal cell carcinomas are slow-growing tumors that extend wide and deep if left untreated, but rarely metastasize. Advanced lesions are often present as invasive and ulcerative lesions. Risk factors for extensive spread include a tumor diameter greater than 2 cm, location on the central part of the face or ears, long-standing duration, incomplete excision, and perineural or perivascular involvement.

Histologically, the tumor cells resemble those in the normal basal layer from the epidermis or follicular epithelium and do not occur on mucosal surfaces.[11,69] There are two types of basal cell carcinoma, determined by their pattern of growth: superficial basal cell carcinomas originating from the epidermis and extending upward, and nodular basal cell carcinomas in which the tumor grows downward into the dermis. *Nodular basal cell carcinoma,* the classic type, presents as a small, flesh-colored or pink, smooth, translucent nodule that enlarges over time (Fig. 46-25). Telangiectatic vessels frequently are seen beneath the surface. Over the years, there is a central depression that forms and develops into an ulcer surrounded by the original shiny, waxy border. *Superficial basal cell carcinoma* presents as a scaly erythematous patch or plaque. Both nodular and superficial forms may contain melanin, imparting a brown, blue, or black color to the lesions.

Since basal cell carcinoma is highly curable if detected and treated early, all suspected lesions should undergo biopsy for diagnosis. The treatment depends on the site and extent of the lesion. The most important treatment goal is complete elimination of the lesion. Also important is the maintenance of function and optimal cosmetic effect. Curettage with electrodesiccation, surgical excision, irradiation, laser, cryosurgery, and chemosurgery are effective in removing all cancerous cells. Immune therapy, gene therapy, and photodynamic therapy are emerging treatments. Persons should be checked at regular intervals for recurrences.

FIGURE 46-25. Nodular basal cell carcinoma, which presents as a reddish-brown papule, often with telangiectatic blood vessels, and a central depression with rolled borders. (From National Cancer Institute Visuals. [Online]

Squamous Cell Carcinoma

Squamous cell carcinomas are the second most common malignant tumors arising on sun-exposed sites in older people, exceeded only by basal cell carcinoma. The increase in the incidence of squamous cell carcinomas is consistent with increased UV exposure. There is also a strong occupational hazard link to the development of squamous cell carcinoma: persons exposed to arsenic (i.e., Bowen disease), industrial tars, coal, and paraffin have an increased likelihood of contracting squamous cell carcinoma. Men are twice as likely as women to have squamous cell carcinoma. Black persons are rarely affected.

Squamous cell cancers are composed of tumor cells that resemble the epidermal cells of the stratum spinosum to varying degrees and extend into the adjacent dermis.[11,70] There are two types of squamous cell carcinoma: intraepidermal (termed in situ carcinoma) and invasive carcinoma. *Intraepidermal squamous cell carcinoma* remains confined to the epidermis for a long time. However, at some unpredictable time, it penetrates the basement membrane to the dermis and metastasizes to the regional lymph nodes. It then converts to *invasive squamous cell carcinoma.* The invasive type of squamous cell carcinoma can develop from intraepidermal carcinoma or from a premalignant lesion (e.g., actinic keratoses). It may be slow growing or fast growing with metastasis.

Squamous cell carcinoma is a red-scaling, keratotic, slightly elevated lesion with an irregular border, usually

FIGURE 46-26. Squamous cell carcinoma of the right ear. This lesion is 1.2 × 0.7 in diameter. It was treated with micrographic surgery because of its location at a site associated with high risk and its history of rapid growth. (From Alam M., Ratner D. [2001]. Cutaneous squamous-cell carcinoma. *New England Journal of Medicine* 344[15], 980.)

with a shallow chronic ulcer (Fig. 46-26). The lesions usually lack the pearly rolled border and superficial telangiectases found on basal cell carcinomas. Later, lesions grow outward, show large ulcerations, and have persistent crusts and raised erythematous borders. The lesions occur on sun-exposed areas of the skin, particularly the nose, forehead, helix of the ear, lower lip, and back of the hand. Invasive squamous cell carcinoma has the potential to recur and metastasize. Chief among the risk factors for tumor recurrence and metastasis are the size and location of the tumor.[70] Large lesions (>2 cm in diameter), tumors of the lip and ear, tumors arising in injured or chronically diseased skin, and rapidly growing lesions are at particular risk.

Treatment measures are aimed at the removal of all cancerous tissue using methods such as electrosurgery, excision surgery, chemosurgery, or radiation therapy. After treatment, the person is observed for the remainder of his or her life for signs of recurrence.

In summary, nevi or moles usually are benign neoplasms of the skin. Because they may undergo cancerous transformation, any mole that undergoes a change warrants immediate medical attention. There has been an alarming increase in skin cancers over the past few decades. Repeated exposure to the UV rays of the sun has been implicated as the principal cause of skin cancer.

Malignant neoplasms of the skin include melanoma, basal cell carcinoma, and squamous cell carcinoma. Malignant melanoma is a malignant tumor of the melanocytes. It is a rapidly progressing, metastatic form of cancer. Clinically, malignant melanoma of the skin usually is asymptomatic. The most important clinical sign is the change in size, shape, and color of pigmented skin lesions, such as moles. As the result of increased public awareness, melanomas are being diagnosed at an earlier stage, when they can be cured surgically. Squamous cell carcinoma and basal cell carcinoma are of epidermal origin.

Basal cell carcinoma, which is a neoplasm of the nonkeratinizing cells of the basal layer of the epidermis, is the most common skin cancer in light-skinned people. They are slow-growing tumors that rarely metastasize. Squamous cell cancers are composed of tumor cells that resemble the epidermal cells of the stratum spinosum to varying degrees and extend into the adjacent dermis. Squamous cell carcinoma may remain confined to the epidermis for a period of time, but at some unpredictable time, it becomes invasive and metastasizes to the regional lymph nodes. Chief among the risk factors for tumor invasion and metastasis are the size and location of the tumor. Large lesions (>2 cm in diameter), tumors of the lip and ear, tumors arising in injured or chronically diseased skin, and rapidly growing lesions are at particular risk.

Age-Related Skin Manifestations

Skin Manifestations of Infancy and Childhood

Skin Disorders of Infancy

Infancy connotes the image of perfect, unblemished skin. For the most part, this is true. However, several congenital skin lesions, such as mongolian spots, hemangiomas, and nevi, are associated with the early neonatal period. There are also several acquired skin conditions, including diaper dermatitis, prickly heat, and cradle cap, that are relatively common in infants.

Diaper Dermatitis. Irritant diaper dermatitis, or *diaper rash,* is a form of contact dermatitis caused by the interaction of several factors, including prolonged contact of the skin with a mixture of urine and feces.[49,71] The appearance of diaper rash ranges from simple (i.e., widely distributed macules on the buttocks and anogenital areas) to severe (i.e., beefy, red, excoriated skin surfaces in the diaper area). Secondary infections with bacteria and yeasts are common; discomfort may be marked because of intense inflammation. Such conditions as contact dermatitis, seborrheic dermatitis, candidiasis, and atopic dermatitis should be considered when the eruption is persistent and recalcitrant to simple therapeutic measures.

Diaper dermatitis often responds to simple measures, including frequent diaper changes with careful cleansing of the irritated area to remove all waste products. Feces in particular should be removed from the skin as soon as possible after the diaper has been soiled. Because soap and lipid solvents remove protective lipids from the stratum corneum, using water or an alcohol-free baby wipe is recommended. Exposing the irritated area to air is helpful. It has been shown that application of a barrier ointment after each diaper change is a valuable component of therapy. Topical corticosteroid therapy is usually effective, but should be used cautiously because infants absorb proportionately greater quantities through their skin than adults. Antifungal therapy should not be used routinely, only when *Candida* infection is established or suspected. Antibacterial agents should not be used because it is known that bacterial infections are usually not involved in diaper dermatitis, and the normal microflora should be preserved.

Intractable and severe cases of diaper dermatitis should be seen by a health care provider for treatment of any secondary infections. Secondary candidal or other skin manifestations discussed in this chapter may occur in the diaper area. It is important to differentiate between normal diaper dermatitis and more serious skin problems.

Prickly Heat. Prickly heat (heat rash) results from constant maceration of the skin because of prolonged exposure to a warm, humid environment. Maceration leads to midepidermal obstruction and rupture of the sweat glands (Fig. 46-27). Although commonly seen during infancy, prickly heat may occur at any age. The treatment includes removing excessive clothing, cooling the skin with warm water baths, drying the skin with powders, and avoiding hot, humid environments.

Cradle Cap. Cradle cap is a greasy crust or scale formation on the scalp. It usually is attributed to infrequent and inadequate washing of the scalp. Cradle cap is treated using mild shampoo and gentle combing to remove the scales. Sometimes oil can be left on the head for minutes to several hours, softening the scales before scrubbing. Other emulsifying ointments or creams may be helpful in difficult cases. The scalp may need to be rubbed firmly to remove the buildup of keratinized cells. Recalcitrant cases need to be seen by a health care practitioner; serious or chronic forms of seborrheic dermatitis may exist.

FIGURE 46-27. Prickly heat in a 6-week-old infant. (From Hall J.C. [2006]. *Sauer's manual of skin diseases* [9th ed., p. 441]. Philadelphia: Lippincott Williams & Wilkins.)

Pigmented and Vascular Birthmarks

Pigmented birthmarks represent abnormal migration or proliferation of melanocytes. For example, *mongolian spots* are caused by selective pigmentation. They usually occur on the buttocks or sacral area and are seen commonly in Asian and black persons. *Nevi* or moles are small, tan to brown, uniformly pigmented solid macules. *Melanocytic nevi* are formed initially from aggregates of melanocytes and keratinocytes along the dermal–epidermal border. *Congenital melanocytic nevi* are collections of melanocytes that are present at birth or develop within the first year of life. They present as macular, papular, or plaquelike pigmented lesions of various shades of brown, with a black or blue focus. The texture of the lesions varies and they may be with or without hair. They usually are found on the hands, shoulders, buttocks, entire arm, or trunk of the body. Some involve large areas of the body in garmentlike fashion. They usually grow proportionately with the child. Congenital melanocytic nevi are clinically significant because of their association with malignant melanoma.

Vascular birthmarks are cutaneous anomalies of angiogenesis and vascular development.[72,73] Two types of vascular birthmarks commonly are seen in infants and small children: bright red, raised hemangiomas of infancy and flat, reddish-purple port-wine stains.

Hemangiomas of infancy (formerly called *strawberry hemangiomas*) are small, red lesions that are noticed shortly after birth.[49,72] Hemangiomas of infancy are generally benign vascular tumors produced by proliferation of endothelial cells. They are seen in approximately 10% of children in the first year of life, with about 60% being located on the head and neck.[72] Although they can occur anywhere on the body, they can be life-threatening when they occur in the airway. Approximately 30% of these lesions are present at birth, and the remainder develop within a few weeks after birth.[72] Hemangiomas of infancy typically undergo an early period of proliferation during which they enlarge, followed by a period of slow involution during which the growth is reversed until complete resolution. Most hemangiomas of infancy disappear before 5 to 9 years of age without leaving an appreciable scar. A small percentage of hemangiomas develop complications. Ulceration, the most frequent complication, can be painful and carries the risk of infection, hemorrhage, and scarring. Some are located in anatomic regions associated with other anomalies requiring careful monitoring and early intervention.

FIGURE 46-28. Port-wine stain on the face of a boy. (Ortho Dermatology Corp.) (From Hall J.C. [2006]. *Sauer's manual of skin diseases* [9th ed., p. 280]. Philadelphia: Lippincott Williams & Wilkins.)

Port-wine stains are pink or red patches that can occur anywhere on the body and are very noticeable (Fig. 46-28). They represent slow-growing capillary malformations that grow proportionately with the child and persist throughout life.[49] There is progressive dilation of the dermal capillaries, which initially is confined to the immediate epidermis, with gradual involvement of deeper dermal blood vessels, although the greater number is always in the upper dermis. Distribution of lesions on the face roughly corresponds to the sensory branches of the trigeminal nerve. The development of a port-wine stain may follow trauma. Port-wine stains usually are confined to the skin, but may be associated with vascular malformations of the eye, resulting primarily in glaucoma, or leptomeningeal involvement, leading to cognitive disorders, seizures, and other neurologic deficits (Sturge-Weber syndrome). Cover-up cosmetics are used in an attempt to conceal the disfiguring effects. Laser surgery has revolutionized the treatment of port-wine stains.

Skin Manifestations of Common Infectious Diseases

Infectious childhood diseases that produce rashes include exanthem subitum, rubella, rubeola, varicella, and scarlet fever.[49,74] Although these diseases are seen less frequently because of successful immunization programs and the use of antibiotics, they still occur. Because they are seen less frequently than in the past, they may be misdiagnosed or their diagnosis may be delayed.

Roseola Infantum. Roseola infantum (exanthem subitum or sixth disease) is a contagious disease caused by human herpes virus type 6 (HHV-6), and less frequently HHV-7. Because HHV-6 is the etiologic agent, the condition is often referred to as *sixth disease*. Primary HHV-6 infection occurs early in life. More than 95% of roseola cases occur in children younger than 3 years of age, with a peak at 6 to 15 months of age.[75] Transplacental antibodies likely protect most infants until 6 months of age. Roseola produces a characteristic maculopapular rash covering the trunk and spreading to the appendages. The rash is preceded by an abrupt onset of high fever (≤105°F), inflamed tympanic membranes, and coldlike symptoms usually lasting 3 to 4 days. These symptoms improve at approximately the same time the rash appears. Because infants with roseola exhibit a unique constellation of symptoms over a short time, the infection may be confused with other childhood exanthems. Blood antibody titers may be taken to determine the actual diagnosis. In most cases, there are no long-term effects from this disease. Infants who spike high temperatures should be seen by their health care providers.

Rubella. Rubella (i.e., 3-day measles or German measles) is a childhood disease caused by the rubella virus.[49,74] It is characterized by a diffuse, punctate, macular rash that begins on the trunk and spreads to the arms and legs (Fig. 46-29). Mild febrile states occur (usually <100°F). Postauricular, suboccipital, and cervical lymph node adenopathy is common. Coldlike symptoms usually accompany the disease in the form of cough, congestion, and coryza (i.e., nasal discharge).

Rubella usually has no long-lasting sequelae; however, the transmission of the disease to pregnant women early in their gestation periods may result in congenital rubella syndrome. Among the clinical signs of congenital

FIGURE 46-29. Rash of rubella on a child's back. Distribution is similar to measles (rubeola), but not as intense. (From Centers for Disease Control and Prevention Public Health Image Library. [Online] Available: http://phil.cdc.gov/Phil/home.asp.)

rubella syndrome are cataracts, microcephaly, mental retardation, deafness, patent ductus arteriosus, glaucoma, purpura, and bone defects. Most states have laws requiring immunization to prevent transmission of rubella. Immunization is accomplished by live-virus injection. Rubella vaccination has close to a 100% immunity response in treated children. Many states require a second preschool or later dose of rubella vaccine to increase immunity. Cases and outbreaks of rubella occur in the United States, especially among foreign-born unvaccinated adults.

Rubeola. Rubeola (measles, 7-day measles) is an acute, highly communicable viral disease caused by a morbillivirus.[49,74] The characteristic rash is macular and blotchy; sometimes the macules become confluent (Fig. 46-30). The rubeola rash usually begins on the face and spreads to the appendages. There are several accompanying symptoms: a fever of 100°F or greater, *Koplik spots* (i.e., small, irregular red spots with a bluish-white speck in the center) on the buccal mucosa, and mild to severe photosensitivity. The patient commonly has coldlike symptoms, general malaise, and myalgia. In severe cases, the macules may hemorrhage into the skin tissue or onto the outer body surface. This form is called *hemorrhagic measles*. The course of measles is more severe in infants, adults, and malnourished children. The World Health Organization recommends vitamin A treatment for measles in developing countries to reduce morbidity and mortality. There may be severe complications, including otitis media, pneumonia, and encephalitis. Antibody titers are determined for a conclusive diagnosis of rubeola. Measles is a disease preventable by vaccine, and immunization is required by law in the United States.

FIGURE 46-30. Child with measles (rubeola) showing the characteristic conjunctivitis, coryza, and red, blotchy rash that appear around day 3 of illness, first on the face and then becoming more generalized. (From Centers for Disease Control and Prevention Public Health Image Library.

FIGURE 46-31. Blisterlike lesions of varicella (i.e., chickenpox) on the face of a young child. (From Centers for Disease Control and Prevention Public Health Image Library.

Varicella. Varicella (chickenpox) is a common communicable childhood disease. It is caused by the varicella-zoster virus, which also is the agent in herpes zoster (shingles). The characteristic skin lesion occurs in three stages: macule, vesicle, and granular scab.[49,74] The macular stage is characterized by development within hours of macules over the trunk, spreading to the limbs, buccal mucosa, scalp, axillae, upper respiratory tract, and conjunctiva (Fig. 46-31). During the second stage, the macules form vesicles with depressed centers. The vesicles break open and a scab forms during the third stage. Crops of lesions occur successively, so that all three forms of the lesion usually are visible by the third day of the illness.

Mild to extreme pruritus accompanies the lesions, which can lead to scratching and subsequent development of secondary bacterial infections. Chickenpox also is accompanied by coldlike symptoms, including cough, coryza, and sometimes photosensitivity. Mild febrile states usually occur, typically beginning 24 hours before lesion outbreak. Side effects, such as pneumonia, septic complications, and encephalitis, are rare.

Varicella in adults may be more severe, with a prolonged recovery rate and greater chances for development of varicella pneumonitis or encephalitis. Immunocompromised persons may experience a chronic, painful form of the infection.

Live attenuated varicella vaccine has been demonstrated to have a lower efficacy than vaccines for rubella and rubeola in preventing the disease. There has been a dramatic decrease in varicella morbidity and mortality since 1995, when the varicella vaccine was introduced in the United States. However, outbreaks of mild cases of varicella, called *breakthrough varicella,* have occurred in vaccinated populations. The breakthrough infection is difficult to diagnose because the maculopapular rash does not have the classic sign of vesicles. One dose of the vaccine is required by law in the United States; however, a second dose is now recommended to address what is called *primary vaccine failure*. It is believed that a single dose of varicella vaccine

may only prime the host response, without inducing protective immunity.[76]

Skin Manifestations and Disorders in the Elderly

Elderly persons experience a variety of age-related skin disorders and exacerbations of earlier skin problems. Aging skin is believed to involve a complex process of actinic (solar) damage, normal aging, and hormonal influences. Actinic changes primarily involve increased occurrence of lesions on sun-exposed surfaces of the body.

Normal Age-Related Changes

Normal skin changes associated with aging are seen on areas of the body that have not been exposed to the sun.[77,78] They include thinning of the dermis and the epidermis, diminution in subcutaneous tissue, a decrease and thickening of blood vessels, and a decrease in the number of melanocytes, Langerhans cells, and Merkel cells. The keratinocytes shrink, but the number of dead keratinized cells at the surface increases. This results in less padding and thinner skin, with color and elasticity changes. The skin also loses its resistance to environmental and mechanical trauma. Tissue repair takes longer.

With aging, there is also less hair and nail growth, and there is permanent hair pigment loss. Hormonally, there is less sebaceous gland activity, although the glands in the facial skin may increase in size. Hair growth reduction also may be hormonally influenced. Although the reason is poorly understood, the skin in most elderly persons older than 70 years of age becomes dry, rough, scaly, and itchy. When there is no underlying pathologic process, it is called *senile pruritus*. Itching and dryness become worse during the winter, when the need for home heating lowers the humidity.

The aging of skin, however, is not just a manifestation of age itself. Most skin changes associated with the elderly are the result of cumulative actinic or environmental damage. For example, the wrinkled, leathery look of aged skin, as well as odd scars and ecchymotic spots, are due to solar elastotic degenerative change.

Skin Lesions Common Among the Elderly

Among the most common benign skin lesions in the elderly are skin tags, seborrheic keratoses, solar lentigines, and vascular lesions.[78] Most are actinic manifestations; they occur as a result of exposure to sun and weather over the years.

Skin Tags. *Skin tags* are soft, brown or flesh-colored papules. They occur on any skin surface, but most frequently the neck, axilla, and intertriginous areas. They range in size from a pinhead to the size of a pea. Skin tags have the normal texture of the skin. They are benign and can be removed with scissors or electrodesiccation for cosmetic purposes.

FIGURE 46-32. Large seborrheic keratoses on the hand of an 84-year-old woman. (From Hall J.C. [2006]. *Sauer's manual of skin diseases* [9th ed., p. 409]. Philadelphia: Lippincott Williams & Wilkins.)

Seborrheic Keratosis. A keratosis is a circumscribed overgrowth of the horny layer of keratinocytes. *Seborrheic keratoses* are common benign tumors that arise spontaneously and are particularly numerous on the trunk, although they can also occur on the extremities, head, and neck. In people of color, multiple small lesions on the face are termed dermatoses papulosa nigra. The lesions characteristically appear as round, flat, coin-shaped waxy plaques that vary in diameter from a few millimeters to several centimeters in diameter (Fig. 46-32). Seborrheic keratoses are benign, but they must be watched for changes in color, texture, or size, which may indicate malignant transformation.

Actinic Keratosis. *Actinic keratoses* are the most common premalignant skin lesions that develop on sun-exposed areas. The lesions usually are less than 1 cm in diameter and appear as dry, brown, scaly areas, often with a reddish tinge. Actinic keratoses often are multiple and more easily felt than seen (Fig. 46-33). They often are indistinguishable from squamous cell carcinoma without biopsy. Actinic keratoses may accumulate dense scale on the surface of the skin and become hyperkeratotic (i.e., developing cutaneous growths of fingernail-type tissue that grow into hornlike appendages). This form is more prominent and palpable. Often, there is a weathered appearance to the surrounding skin. Slight changes, such as enlargement or ulceration, may indicate malignant transformation. Roughly 20% of actinic keratoses convert to squamous cell carcinomas. There is controversy regarding the classification of actinic keratoses. Some believe them to be capable of converting to cancerous growths,[79] some believe them to be on a continuum of cancerous growth,[80] and still others believe that actinic keratoses do not convert or progress to cancerous cells, but that they are actual early malignancies.[81]

Actinic keratoses are removed with cryosurgery, electrodesiccation, or lasers. When surgery is not indicated,

FIGURE 46-33. Multiple actinic keratoses of the face of an 80-year-old man. (Dermik Laboratories, Inc.) (From Hall J.C. [2006]. *Sauer's manual of skin diseases* [9th ed., p. 277]. Philadelphia: Lippincott Williams & Wilkins.)

they are treated with topical chemotherapy agents, such as 5-fluorouracil or imiquimod creams, which erode the lesions.

Solar Lentigines. Lentigines are small (5- to 10-mm), benign, oval or round, tan-brown macules or patches resulting from localized hyperplasia of melanocytes. *Solar lentigines,* also referred to as *liver spots,* are tan to brown, benign spots that gradually appear on sun-exposed areas, particularly the dorsum of the hand. They do not fade with cessation of sun exposure. Like all pigmented lesions, they should be evaluated. If the pigmentation is homogenous and they are symmetric and flat, they are most likely benign. Solar lentigines can be treated with a topical bleaching agent such as hydroquinone (e.g., Eldoquin, Solaquin), laser therapy, or cryotherapy.

Lentigo maligna (i.e., Hutchinson freckle) is a slowly progressive (≤20 years) preneoplastic disorder of melanocytes. It occurs on sun-exposed areas, particularly the face. The lesion is a pigmented macule with a well-defined border and grows to 5 cm or sometimes larger. As it grows over the years, it may become slightly raised and wartlike. If untreated, a true malignant melanoma often develops. Surgery, curettage, and cryotherapy have been effective at removing the lentigines. Careful monitoring for conversion to melanoma is important.

Vascular Lesions. Vascular lesions include angiomas, telangiectases, and venous lakes. *Cherry angiomas* are smooth, cherry-red or purple, dome-shaped papules that occur in nearly all people older than 30 years of age. They usually are found on the trunk and are generally benign unless there is a sudden appearance of many cherry angiomas. *Telangiectases* are single dilated blood vessels, capillaries, or terminal arteries that appear on areas exposed to sun or harsh weather, such as the cheeks and the nose. They occur individually or in clusters, measure 1 cm or less, are nonpalpable, and easily blanch. They can become large and disfiguring. Pulsed dye lasers have been effective in removing them. *Venous lakes* are small, dark blue, slightly raised papules that have a lake-like appearance. They occur on exposed body parts, particularly the backs of the hands, ears, and lips. They are smooth and compressible. Venous lakes can be removed by electrosurgery, laser therapy, or surgical excision if a person desires.

In summary, some skin problems occur in specific age groups. Common in infants are diaper rash, prickly heat, and cradle cap. Infectious childhood diseases that are characterized by rashes include roseola infantum, rubella, rubeola, and varicella. Vaccines are available to protect against rubella, rubeola, and varicella.

With aging, there is thinning of the dermis and the epidermis, diminution in subcutaneous tissue, loss and thickening of blood vessels, and slowing of hair and nail growth. Dry skin is common among the elderly, becoming worse during the winter months. Among the skin lesions seen in the elderly are skin tags, keratoses, lentigines, and vascular lesions.

REVIEW EXERCISES

1. The mother of a 7-year-old boy notices that he is scratching his head frequently. On close examination she notices a grayish, round, and roughened area, where the hair has broken off. Examination by the child's pediatrician produces a diagnosis of tinea capitis.

- **A.** Explain the cause of the infection and propose possible mechanisms for spread of this infection in school-age children, particularly during winter months.
- **B.** Referring to Chapter 14, explain the preference of the superficial mycoses (dermatophytoses) for the skin-covered areas of the body.
- **C.** What methods are commonly used in the diagnosis of superficial fungal infections?

2. A 75-year-old woman presents with severe burning pain and a vesicular rash covering a strip over the rib cage on one side of the chest. She is diagnosed with herpes zoster or shingles.

- **A.** What is the source of this woman's rash and pain?
- **B.** Explain the dermatomal distribution of the lesions.

3. Psoriasis is a chronically recurring papulosquamous skin disorder, characterized by circumscribed red, thickened plaques with an overlying silvery-white scale.

A. Explain the development of the plaques in terms of epidermal cell turnover.
B. Persons with psoriasis are instructed to refrain from rubbing or scratching the lesions. Explain the rationale for these instructions.
C. Among the methods used in the treatment of psoriasis are the use of topical keratolytic agents and corticosteroid skin preparations. Explain how these two different types of agents exert their effect on the plaque lesions.

4. During the past several decades there has been an alarming increase in the incidence of skin cancers, including malignant melanoma, that has been attributed to increased sun exposure.

A. Explain the possible mechanisms whereby ultraviolet radiation promotes the development of malignant skin lesions.
B. Cite two important clinical signs that aid in distinguishing a dysplastic nevus from a malignant melanoma.

Glossary

Abduction The act of abducting (moving or spreading away from a position near the midline of the body or the axial line of a limb) or the state of being abducted.
Abrasion The wearing or scraping away of a substance or structure, such as the skin, through an unusual or abnormal mechanical process.
Abscess A collection of pus that is restricted to a specific area in tissues, organs, or confined spaces.
Accommodation The adjustment of the lens (eye) to variations in distance.
Acromion The lateral extension of the spine of the scapula, forming the highest point of the shoulder. (Adjective: acromial)
Acuity The clearness or sharpness of perception, especially of vision.
Adaptation The adjustment of an organism to its environment, physical or psychological, through changes and responses to stress of any kind.
Adduction The act of adducting (moving or drawing toward a position near the midline of the body or the axial line of a limb) or the state of being adducted.
Adhesin The molecular components of the bacterial cell wall that are involved in adhesion processes.
Adrenergic Activated by or characteristic of the sympathetic nervous system or its neurotransmitters (i.e., epinephrine and norepinephrine).
Aerobic Growing, living, or occurring only in the presence of air or oxygen.
Afferent Bearing or conducting inward or toward a center, as an afferent neuron.
Agglutination The clumping together of particles, microorganisms, or blood cells in response to an antigen–antibody reaction.
Agonist A muscle whose action is opposed by another muscle (antagonist) with which it is paired; or a drug or other chemical substance that has affinity for or stimulates a predictable physiologic function.
Akinesia An abnormal state in which there is an absence or poverty of movement.
Allele One of two or more different forms of a gene that can occupy a particular locus on a chromosome.
Alveolus A small saclike structure, as in the alveolus of the lung.
Amblyopia A condition of vision impairment without a detectable organic lesion of the eye.
Amine An organic compound containing nitrogen.
Amorphous Without a definite form; shapeless.
Amphoteric Capable of reacting chemically as an acid or a base.
Ampulla A saclike dilatation of a duct, canal, or any other tubular structure.
Anabolism A constructive metabolic process characterized by the conversion of simple substances into larger, complex molecules.
Anaerobic Growing, living, or occurring only in the absence of air or oxygen.
Analog A part, organ, or chemical having the same function or appearance but differing in respect to a certain component, such as origin or development.
Anaplasia A change in the structure of cells and in their orientation to each other that is characterized by a loss of cell differentiation, as in cancerous cell growth.
Anastomosis The connection or joining between two vessels; or an opening created by surgical, traumatic, or pathologic means.
Androgen Any substance, such as a male sex hormone, that increases male characteristics.
Anergy A state of absent or diminished reaction to an antigen or group of antigens.
Aneuploidy A variation in the number of chromosomes within a cell involving one or more missing chromosomes rather than entire sets.
Aneurysm An outpouching or dilation in the wall of a blood vessel or the heart.
Ankylosis Stiffness or fixation of separate bones of a joint, resulting from disease, injury, or surgical procedure. (Verb: ankylose)
Anorexia Lack or loss of appetite for food. (Adjective: anorexic)
Anoxia An abnormal condition characterized by the total lack of oxygen.
Antagonist A muscle whose action directly opposes that of another muscle (agonist) with which it is paired, or a drug or other chemical substance that can diminish or nullify the action of a neuromediator or body function.
Anterior Pertaining to a surface or part that is situated near or toward the front.
Antigen A substance that generates an immune response by causing the formation of an antibody or reacting with antibodies or T-cell receptors.
Apex The uppermost point, the narrowed or pointed end, or the highest point of a structure, such as an organ.
Aphagia A condition characterized by the refusal or the loss of ability to swallow.
Aplasia The absence of an organ or tissue due to a developmental failure.
Apnea The absence of spontaneous respiration.
Apoptosis A mechanism of programmed cell death, marked by shrinkage of the cell, condensation of chromatin, formation of cytoplasmic blebs, and fragmentation of the cell into membrane-bound bodies eliminated by phagocytosis.
Apraxia Loss of the ability to carry out familiar, purposeful acts or to manipulate objects in the absence of paralysis or other motor or sensory impairment.
Articulation The place of connection or junction between two or more bones of a skeletal joint.
Ascites An abnormal accumulation of serous fluid in the peritoneal cavity.
Asepsis The condition of being free or freed from pathogenic microorganisms.

Astereognosis A neurologic disorder characterized by an inability to identify objects by touch.
Asterixis A motor disturbance characterized by a hand-flapping tremor, which results when the prolonged contraction of groups of muscles lapses intermittently.
Ataxia An abnormal condition characterized by an inability to coordinate voluntary muscular movement.
Athetosis A neuromuscular condition characterized by the continuous occurrence of slow, sinuous, writhing movements that are performed involuntarily. (Adjective: athetoid)
Atopy Genetic predisposition toward the development of a hypersensitivity or an allergic reaction to common environmental allergens.
Atresia The absence or closure of a normal body orifice or tubular organ, such as the esophagus.
Atrophy A wasting or diminution of size, often accompanied by a decrease in function, of a cell, tissue, or organ.
Autocrine A mode of hormone action in which a chemical messenger acts on the same cell that secretes it.
Autophagy Segregation of part of the cell's own damaged cytoplasmic material within a vacuole and its disposal.
Autosome Any chromosome other than a sex chromosome.
Axillary Of or pertaining to the axilla, or armpit.
Bacteremia The presence of bacteria in the blood.
Bactericide An agent that destroys bacteria. (Adjective: bactericidal)
Bacteriostat An agent that inhibits bacterial growth. (Adjective: bacteriostatic)
Ballismus An abnormal condition characterized by violent flailing motions of the arms and, occasionally, the head, resulting from injury to or destruction of the subthalamic nucleus or its fiber connections.
Baroreceptor A type of sensory nerve ending such as those found in the aorta and the carotid sinus that is stimulated by changes in pressure.
Basal Pertaining to, situated at, or forming the base; or the fundamental or the basic.
Benign Not malignant; or of the character that does not threaten health or life.
Bipolar neuron A nerve cell that has a process at each end—an afferent process and an efferent process.
Bolus A rounded mass of food ready to swallow or such a mass passing through the gastrointestinal tract; or a concentrated mass of medicinal material or other pharmaceutical preparation injected all at once intravenously for diagnostic purposes.
Borborygmus The rumbling, gurgling, or tinkling noise produced by the propulsion of gas through the intestine.
Bruit A sound or murmur heard while auscultating an organ or blood vessel, especially an abnormal one.
Buccal Pertaining to or directed toward the inside of the cheek.
Buffer A substance or group of substances that prevents change in the concentration of another chemical substance.
Bulla A thin-walled blister of the skin or mucous membranes greater than 5 mm in diameter containing serous or seropurulent fluid.
Bursa A fluid-filled sac or saclike cavity situated in places in the tissues at which friction would otherwise develop, such as between certain tendons and the bones beneath them.
Cachexia A condition of general ill health and malnutrition, marked by weakness and emaciation.
Calculus A stony mass formed within body tissues, usually composed of mineral salts.
Capsid The protein shell that envelops and protects the nucleic acid of a virus.
Carcinogen Any substance or agent that causes the development or increases the incidence of cancer.
Carpal Of or pertaining to the carpus, or wrist.
Caseation A form of tissue necrosis in which the tissue is changed into a dry, amorphous mass resembling crumbly cheese.
Catabolism A metabolic process through which living organisms break down complex substances to simple compounds, liberating energy for use in work, energy storage, or heat production.
Catalyst A substance that increases the velocity of a chemical reaction without being consumed by the process.
Catecholamines Any one of a group of biogenic amines having a sympathomimetic action and composed of a catechol molecule and the aliphatic portion of an amine.
Caudal Signifying an inferior position, toward the distal end of the spine.
Cellulitis An acute, diffuse, spreading, edematous inflammation of the deep subcutaneous tissues and sometimes muscle, characterized most commonly by an area of heat, redness, pain, and swelling, and occasionally by fever, malaise, chills, and headache.
Cephalic Of or pertaining to the head, or to the head end of the body.
Cerumen The waxlike secretion produced by vestigial apocrine sweat glands in the external ear canal.
Cheilosis A noninflammatory disorder of the lips and mouth characterized by chapping and fissuring.
Chelate A chemical compound composed of a central metal ion and an organic molecule with multiple bonds, arranged in ring formation, used especially in treatment of metal poisoning.
Chemoreceptor A sensory nerve cell activated by chemical stimuli, as a chemoreceptor in the carotid artery that is sensitive to changes in the oxygen content in the blood and reflexly increases or decreases respiration and blood pressure.
Chemotaxis A response involving cell orientation or cell movement that is either toward (positive chemotaxis) or away from (negative chemotaxis) a chemical stimulus.
Chimeric Relating to, derived from, or being an individual possessing one's own immunologic characteristics and that of another individual; a phenomenon that can occur as the result of procedures such as a bone marrow graft.
Chondrocyte Any one of the mature polymorphic cells that form the cartilage of the body.
Chromatid One of the paired threadlike chromosome filaments, joined at the centromere, that make up a metaphase chromosome.

Chromosome Any one of the structures in the nucleus of a cell containing a linear thread of DNA, which functions in the transmission of genetic information.
Chyme The creamy, viscous, semifluid material produced during digestion of a meal that is expelled by the stomach into the duodenum.
Cilia A minute, hairlike process projecting from a cell, composed of nine microtubules arrayed around a single pair. Cilia beat rhythmically to move the cell around in its environment or they move mucus or fluids over the surface.
Circadian Being, having, pertaining to, or occurring in a period or cycle of approximately 24 hours.
Circumduction The active or passive circular movement of a limb or of the eye.
Cisterna An enclosed space, such as a cavity, that serves as a reservoir for lymph or other body fluids.
Clone One or a group of genetically identical cells or organisms derived from a single parent.
Coagulation The process of transforming a liquid into a semisolid mass, especially of blood clot formation.
Coarctation A condition of stricture or contraction of the walls of a vessel.
Cofactor A substance that must unite with another substance in order to function.
Colic Sharp, intermittent abdominal pain localized in a hollow or tubular organ, resulting from torsion, obstruction, or smooth muscle spasm. (Adjective: colicky)
Collagen The protein substance of the white, glistening, inelastic fibers of the skin, tendons, bone, cartilage, and all other connective tissue.
Collateral Secondary or accessory rather than direct or immediate; or a small branch, as of a blood vessel or nerve.
Complement Any one of the complex, enzymatic serum proteins that are involved in physiologic reactions, including antigen–antibody reaction and anaphylaxis.
Confluent Flowing or coming together; not discrete.
Congenital Present at, and usually before, birth.
Conjugate To pair and fuse in conjugation; or a form of sexual reproduction seen in unicellular organisms in which genetic material is exchanged during the temporary fusion of two cells.
Contiguous In contact or nearly so in an unbroken sequence along a boundary or at a point.
Contralateral Affecting, pertaining to, or originating in the opposite side of a point or reference.
Contusion An injury of a part without a break in the skin, characterized by swelling, discoloration, and pain.
Convolution An elevation or tortuous winding, such as one of the irregular ridges on the surface of the brain, formed by a structure being infolded upon itself.
Corpuscle Any small mass, cell, or body, such as a red or white blood cell.
Costal Pertaining to a rib or ribs.
Crepitus A sound or sensation that resembles a crackling or grating noise.
Cutaneous Pertaining to the skin.
Cyanosis A bluish discoloration, especially of the skin and mucous membranes, caused by an excess of deoxygenated hemoglobin in the blood.
Cytokine Any of a class of polypeptide immunoregulatory substances that are secreted by cells, usually of the immune system, that affect other cells.
Cytology The study of cells, including their origin, structure, function, and pathology.
Cytosol Cytoplasm exclusive of membranous components (e.g., mitochondria, endoplasmic reticulum) and nonmembranous insoluble components.
Decibel A unit for expressing the relative power intensity of electric or acoustic signal power that is equal to one tenth of a bel.
Defecation The evacuation of feces from the digestive tract through the rectum.
Deformation The process of adapting in form or shape; also the product of such alteration.
Degeneration The deterioration of a normal cell, tissue, or organ to a less functionally active form. (Adjective: degenerative)
Deglutition The act or process of swallowing.
Degradation The reduction of a chemical compound to a compound less complex, usually by splitting off one or more groups.
Dehydration The condition that results from excessive loss of water from the body tissues.
Delirium An acute, reversible organic mental syndrome characterized by confusion, disorientation, restlessness, incoherence, fear, and often illusions.
Dendrite One of the branching processes that extends and transmits impulses toward a cell body of a neuron. (Adjective: dendritic)
Depolarization The reduction of a cell membrane potential to a less negative value than that of the potential outside the cell.
Dermatome The area of the skin supplied with afferent nerve fibers of a single dorsal root of a spinal nerve.
Desmosome A small, circular, dense area within the intercellular bridge that forms the site of adhesion between intermediate filaments and cell membranes.
Desquamation A normal process in which the cornified layer of the epidermis is shed in fine scales or sheets.
Dialysis The process of separating colloids and crystalline substances in solution, which involves the two distinct physical processes of diffusion and ultrafiltration; or a medical procedure for the removal of urea and other elements from the blood or lymph.
Diapedesis The outward passage of red or white blood corpuscles through the intact walls of the vessels.
Diaphoresis Perspiration, especially the profuse perspiration associated with an elevated body temperature, physical exertion, exposure to heat, and mental or emotional stress.
Diarthrosis A specialized articulation that permits, to some extent, free joint movement. (Adjective: diarthrodial)
Diastole The dilatation of the heart; or the period of dilatation, which is the interval between the second and the first heart sound and is the time during which blood enters the relaxed chambers of the heart from the systemic circulation and the lungs.
Differentiation The act or process in development in which unspecialized cells or tissues acquire more

specialized characteristics, including those of physical form, physiologic function, and chemical properties.

Diffusion The process of becoming widely spread, as in the spontaneous movement of molecules or other particles in solution from an area of higher concentration to an area of lower concentration, resulting in an even distribution of the particles in the fluid.

Dimer A compound or unit formed by the combination of two identical molecules or radicals of a simpler compound. (Adjective: dimeric)

Diopter A unit of measurement of the refractive power of lenses equal to the reciprocal of the focal length in meters.

Diploid Pertaining to an individual, organism, strain, or cell that has two full sets of homologous chromosomes.

Disseminate To scatter or distribute over a considerable area.

Distal Away from or being the farthest from a point of reference.

Diurnal Of, relating to, or occurring in the daytime.

Diverticulum A pouch or sac of variable size occurring naturally or through herniation of the muscular wall of a tubular organ.

Dorsum The back or posterior. (Adjective: dorsal)

Dysgenesis Defective or abnormal development of an organ or part, typically occurring during embryonic development. (Also called dysgenesia.)

Dyslexia A disturbance in the ability to read, spell, and write words.

Dyspepsia The impairment of the power or function of digestion, especially epigastric discomfort following eating.

Dysphagia A difficulty in swallowing.

Dysphonia Any impairment of the voice that is experienced as a difficulty in speaking.

Dysplasia The alteration in size, shape, and organization of adult cell types.

Eburnation The conversion of bone or cartilage, through thinning or loss, into a hard and dense mass with a worn, polished, ivorylike surface.

Ecchymosis A small hemorrhagic spot, larger than a petechia, in the skin or mucous membrane caused by the extravasation of blood into the subcutaneous tissues.

Ectoderm The outermost of the three primary germ layers of the embryo, and from which the epidermis and epidermal tissues, such as nails, hair, and glands of the skin, develop.

Ectopic Relating to or characterized by an object or organ being situated in an unusual place, away from its normal location.

Edema The presence of an abnormal accumulation of fluid in interstitial spaces of tissues. (Adjective: edematous)

Efferent Conveyed or directed away from a center.

Effusion The escape of fluid from blood vessels into a part or tissue, as an exudation or a transudation.

Embolus A mass of clotted blood or other formed elements, such as bubbles of air, calcium fragments, or a bit of tissue or tumor, that circulates in the bloodstream until it becomes lodged in a vessel, obstructing the circulation. (Plural: emboli)

Empyema An accumulation of pus in a cavity of the body, especially the pleural space.

Emulsify To disperse one liquid throughout the body of another liquid, making a colloidal suspension, or emulsion.

Endocytosis The uptake or incorporation of substances into a cell by invagination of its plasma membrane, as in the processes of phagocytosis and pinocytosis.

Endoderm The innermost of the three primary germ layers of the embryo, and from which epithelium arises.

Endogenous Growing within the body; or developing or originating from within the body or produced from internal causes.

Endoscopy The visualization of any cavity of the body with an endoscope.

Enteropathic Relating to any disease of the intestinal tract.

Enzyme A protein molecule produced by living cells that catalyzes chemical reactions of other organic substances without itself being destroyed or altered.

Epiphysis The expanded articular end of a long bone (head) that is separated from the shaft of the bone by the epiphyseal plate until the bone stops growing, the plate is obliterated, and the shaft and the head become united.

Epithelium The covering of the internal and the external surfaces of the body, including the lining of vessels and other small cavities.

Epitope The simplest form of an antigenic determinant that combines with an antibody or a T-cell receptor to cause a specific reaction by an immunoglobulin.

Erectile Capable of being erected or raised to an erect position.

Erythema The redness or inflammation of the skin or mucous membranes produced by the congestion of superficial capillaries. (Adjective: erythematous)

Etiology The study or theory of all factors that may be involved in the development of a disease, including susceptibility of an individual, the nature of the disease agent, and the way in which an individual's body is invaded by the agent; or the cause of a disease.

Eukaryotic Pertaining to an organism with cells having a true nucleus; that is, a highly complex, organized nucleus surrounded by a nuclear membrane containing organelles and exhibiting mitosis.

Euploid Pertaining to an individual, organism, strain, or cell with a balanced set or sets of chromosomes, in any number, that is an exact multiple of the normal, basic haploid number characteristic of the species; or such an individual, organism, strain, or cell.

Evisceration The removal of the viscera from the abdominal cavity, or disembowelment; or the extrusion of an internal organ through a wound or surgical incision.

Exacerbation An increase in the severity of a disease as marked by greater intensity in any of its signs and symptoms.

Exfoliation Peeling and sloughing off of tissue cells in scales or layers. (Adjective: exfoliative)

Exocytosis The discharge of cell particles, which are packaged in membrane-bound vesicles, by fusion of the vesicular membrane with the plasma membrane and subsequent release of the particles to the exterior of the cell.
Exogenous Developed or originating outside the body, as a disease caused by a bacterial or viral agent foreign to the body.
Exophthalmos A marked or abnormal protrusion of the eyeball.
Extension A movement that allows the two elements of any jointed part to be drawn apart, increasing the angle between them, as extending the leg increases the angle between the femur and the tibia.
Extrapyramidal Pertaining to motor systems supplied by fibers outside the corticospinal or pyramidal tracts.
Extravasation A discharge or escape, usually of blood, serum, or lymph, from a vessel into the tissues.
Extubation The process of withdrawing a previously inserted tube from an orifice or cavity of the body.
Exudate Fluid, cells, or other substances that have been slowly exuded or have escaped from blood vessels and have been deposited in tissues or on tissue surfaces.
Fascia A sheet or band of fibrous connective tissue that may be separated from other specifically organized structures, as the tendons, the aponeuroses, and the ligaments.
Febrile Pertaining to or characterized by an elevated body temperature, or fever.
Fibrillation A small, local, involuntary contraction of muscle, resulting from spontaneous activation of a single muscle fiber or of an isolated bundle of nerve fibers.
Fibrin A stringy, insoluble protein formed by the action of thrombin on fibrinogen during the clotting process.
Fibrosis The formation of fibrous connective tissue, as in the repair or replacement of parenchymatous elements.
Filtration The process of passing a liquid through or as if through a filter, which is accomplished by gravity, pressure, or vacuum.
Fimbria Any structure that forms a fringe, border, or edge or the processes that resemble such a structure.
Fissure A cleft or a groove, normal or otherwise, on the surface of an organ or a bony structure.
Fistula An abnormal passage or communication from an internal organ to the body surface or between two internal organs.
Flaccid Weak, soft, and lax; lacking normal muscle tone.
Flatus Air or gas in the intestinal tract that is expelled through the anus. (Adjective: flatulent)
Flexion A movement that allows the two elements of any jointed part to be brought together, decreasing the angle between them, as bending the elbow.
Flora The microorganisms, such as bacteria and fungi, both normally occurring and pathologic, found in or on an organ.
Focal Relating to, having, or occupying a focus.
Follicle A sac or pouchlike depression or cavity.
Fontanel A membrane-covered opening in bones or between bones, such as the soft spot covered by tough membranes between the bones of an infant's incompletely ossified skull.
Foramen A natural opening or aperture in a membranous structure or bone.
Fossa A hollow or depressed area, especially on the surface of the end of a bone.
Fovea A small pit or depression in the surface of a structure or an organ.
Fundus The base or bottom of an organ or the portion farthest from the mouth of an organ.
Ganglion One of the nerve cell bodies, chiefly collected in groups outside the central nervous system. (Plural: ganglia)
Genotype The entire genetic constitution of an individual, as determined by the particular combination and location of the genes on the chromosomes; or the alleles present at one or more sites on homologous chromosomes.
Glia The neuroglia, or supporting structure of nervous tissue.
Globulin One of a broad group of proteins classified by solubility, electrophoretic mobility, and size.
Gluconeogenesis The formation of glucose from any of the substances of glycolysis other than carbohydrates.
Glycolysis A series of enzymatically catalyzed reactions, occurring within cells, by which glucose is converted to adenosine triphosphate (ATP) and pyruvic acid during aerobic metabolism.
Gonad A gamete-producing gland, as an ovary or a testis.
Gradient The rate of increase or decrease of a measurable phenomenon expressed as a function of a second; or the visual representation of such a change.
Granuloma A small mass of nodular granulation tissue resulting from chronic inflammation, injury, or infection. (Adjective: granulomatous)
Hapten A small, nonproteinaceous substance that is not antigenic by itself but that can act as an antigen when combined with a larger molecule.
Haustrum A structure resembling a recess or sacculation. (Plural: haustra)
Hematoma A localized collection of extravasated blood trapped in an organ, space, or tissue, resulting from a break in the wall of a blood vessel.
Hematopoiesis The normal formation and development of blood cells.
Hemianopia Defective vision or blindness in half of the visual field of one or both eyes.
Heterogeneous Consisting of or composed of dissimilar elements or parts; or not having a uniform quality throughout. (Noun: heterogeneity)
Heterophagy The taking into the cell of an exogenous substance by phagocytosis or pinocytosis and the subsequent digestion of the newly formed vacuole by a lysosome.
Heterozygous Having two different alleles at corresponding loci on homologous chromosomes.
Histology The branch of anatomy that deals with the minute (microscopic) structure, composition, and function of cells and tissue. (Adjective: histologic)
Homolog Any organ or part corresponding in function, position, origin, and structure to another organ or part, as the flippers of a seal that correspond to human hands. (Adjective: homologous)

Homozygous Having two identical alleles at corresponding loci on homologous chromosomes.
Humoral Relating to elements dissolved in the blood or body fluids.
Hybridoma A tumor of hybrid cells produced by fusion of normal lymphocytes and tumor cells.
Hydrolysis The chemical alteration or decomposition of a compound into fragments by the addition of water.
Hypercapnia Excess amounts of carbon dioxide in the blood.
Hyperemia An excess or engorgement of blood in a part of the body.
Hyperesthesia An unusual or pathologic increase in sensitivity of a part, especially the skin, or of a particular sense.
Hyperplasia An abnormal multiplication or increase in the number of normal cells of a body part.
Hypertonic A solution having a greater concentration of solute than another solution with which it is compared, hence exerting more osmotic pressure than that solution.
Hypertrophy The enlargement or overgrowth of an organ that is due to an increase in the size of its cells rather than the number of its cells.
Hypesthesia An abnormal decrease of sensation in response to stimulation of the sensory nerves. (Also called hypoesthesia.)
Hypocapnia A deficiency of carbon dioxide in the blood.
Hypotonic A solution having a lesser concentration of solute than another solution with which it is compared, hence exerting less osmotic pressure than that solution.
Hypoxia An inadequate supply of oxygen to tissue that is below physiologic levels despite adequate perfusion of the tissue by blood.
Iatrogenic Induced inadvertently through the activity of a physician or by medical treatment or diagnostic procedures.
Idiopathic Arising spontaneously or from an unknown cause.
Idiosyncrasy A physical or behavioral characteristic or manner that is unique to an individual or to a group. (Adjective: idiosyncratic)
Incidence The rate at which a certain event occurs (e.g., the number of new cases of a specific disease during a particular period of time in a population at risk).
Inclusion The act of enclosing or the condition of being enclosed; or anything that is enclosed.
Indigenous Native, or natural, to the particular country or region where found.
Infarction Necrosis or death of tissues due to local ischemia resulting from obstruction of blood flow.
Inotropic Influencing the force or energy of muscular contractions.
In situ In the natural or normal place; or something, such as cancer, that is confined to its place of origin and has not invaded neighboring tissues.
Interferon Any one of a group of small glycoproteins (cytokines) produced in response to viral infection and which inhibit viral replication.
Interleukin Any of several multifunctional cytokines produced by a variety of lymphoid and nonlymphoid cells, including immune cells, that stimulate or otherwise affect the function of lymphopoietic and other cells and systems in the body.
Interstitial Relating to or situated between parts or in the interspaces of a tissue.
Intramural Situated or occurring within the wall of an organ.
Intrinsic Pertaining exclusively to a part or situated entirely within an organ or tissue.
In vitro A biologic reaction occurring in an artificial environment, such as a test tube.
In vivo A biologic reaction occurring within the living body.
Involution The act or instance of enfolding, entangling, or turning inward.
Ionize To separate or change into ions.
Ipsilateral Situated on, pertaining to, or affecting the same side of the body.
Ischemia Decreased blood supply to a body organ or part, usually due to functional constriction or actual obstruction of a blood vessel.
Juxta-articular Situated near a joint or in the region of a joint.
Juxtaglomerular Near to or adjoining a glomerulus of the kidney.
Karyotype The total chromosomal characteristics of a cell; or the micrograph of chromosomes arranged in pairs in descending order of size.
Keratin A fibrous, sulfur-containing protein that is the primary component of the epidermis, hair, and horny tissues. (Adjective: keratinous)
Keratosis Any skin condition in which there is overgrowth and thickening of the cornified epithelium.
Ketosis A condition characterized by the abnormal accumulation of ketones (organic compounds with a carboxyl group attached to two carbon atoms) in the body tissues and fluid.
Kinesthesia The sense of movement, weight, tension, and position of body parts mediated by input from joint and muscle receptors and hair cells. (Adjective: kinesthetic)
Kyphosis An abnormal condition of the vertebral column, characterized by increased convexity in the curvature of the thoracic spine as viewed from the side.
Lacuna A small pit or cavity within a structure, especially bony tissue; or a defect or gap, as in the field of vision.
Lateral A position farther from the median plane or midline of the body or a structure; or situated on, coming from, or directed towards the side.
Lesion Any wound, injury, or pathologic change in body tissue.
Lethargy The lowered level of consciousness characterized by listlessness, drowsiness, and apathy; or a state of indifference.
Ligament One of many predominantly white, shiny, flexible bands of fibrous tissue that binds joints together and connects bones or cartilages.
Ligand A group, ion, or molecule that binds to the central atom or molecule in a chemical complex.

Lipid Any of the group of fats and fatlike substances characterized by being insoluble in water and soluble in nonpolar organic solvents, such as chloroform and ether.
Lipoprotein Any one of the conjugated proteins that is a complex of protein and lipid.
Lobule A small lobe.
Lordosis The anterior concavity in the curvature of the lumbar and cervical spine as observed from the side.
Lumen A cavity or the channel within a tube or tubular organ of the body.
Luteal Of or pertaining to or having the properties of the corpus luteum.
Lysis Destruction or dissolution of a cell or molecule through the action of a specific agent.
Maceration Softening of tissue by soaking, especially in acidic solutions.
Macroscopic Large enough to be visible with the unaided eye or without the microscope.
Macula A small, flat blemish, thickening, or discoloration that is flush with the skin surface. (Adjective: macular)
Malaise A vague feeling of bodily fatigue and discomfort.
Manometry The measurement of tension or pressure of a liquid or gas using a device called a manometer.
Marasmus A condition of extreme protein-calorie malnutrition that is characterized by growth retardation and progressive wasting of subcutaneous tissue and muscle and occurs chiefly during the first year of life.
Matrix The intracellular substance of a tissue or the basic substance from which a specific organ or kind of tissue develops.
Meatus An opening or passage through any body part.
Medial Pertaining to the middle; or situated or oriented toward the midline of the body.
Mediastinum The mass of tissues and organs in the middle of the thorax, separating the pleural sacs containing the two lungs.
Meiosis The division of a sex cell as it matures, so that each daughter nucleus receives one half of the number of chromosomes characteristic of the somatic cells of the species.
Mesoderm The middle layer of the three primary germ layers of the developing embryo, lying between the ectoderm and the endoderm.
Metabolism The sum of all the physical and chemical processes by which living organisms are produced and maintained, and also the transformation by which energy is provided for vital processes and activities.
Metaplasia Change in type of adult cells in a tissue to a form that is not normal for that tissue.
Metastasis The transfer of disease (e.g., cancer) from one organ or part to another not directly connected with it. (Adjective: metastatic)
Miosis Contraction of the pupil of the eye.
Mitosis A type of indirect cell division that occurs in somatic cells and results in the formation of two daughter nuclei containing the identical complements of the number of chromosomes characteristic of the somatic cells of the species.
Molecule The smallest mass of matter that exhibits the properties of an element or compound.
Morbidity A diseased condition or state; the relative incidence of a disease or of all diseases in a population.
Morphology The study of the physical form and structure of an organism; or the form and structure of a particular organism. (Adjective: morphologic)
Mosaicism In genetics, the presence in an individual or in an organism of cell cultures having two or more cell lines that differ in genetic constitution but are derived from a single zygote.
Mutagen Any chemical or physical agent that induces a genetic mutation (an unusual change in form, quality, or some other characteristic) or increases the mutation rate by causing changes in DNA.
Mydriasis Physiologic dilatation of the pupil of the eye.
Myoclonus A spasm of a portion of a muscle, an entire muscle, or a group of muscles.
Myoglobin The oxygen-transporting pigment of muscle consisting of one heme molecule containing one iron molecule attached to a single globin chain.
Myopathy Any disease or abnormal condition of skeletal muscle, usually characterized by muscle weakness, wasting, and histologic changes within muscle tissue.
Myotome The muscle plate or portion of an embryonic somite that develops into a voluntary muscle; or a group of muscles innervated by a single spinal segment.
Necrosis Localized tissue death that occurs in groups of cells or part of a structure or an organ in response to disease or injury.
Neutropenia An abnormal decrease in the number of neutrophilic leukocytes in the blood.
Nidus The point where a morbid process originates, develops, or is located.
Nociception The reception of painful stimuli from the physical or mechanical injury to body tissues by nociceptors (receptors usually found in either the skin or the walls of the viscera).
Nosocomial Pertaining to or originating in a hospital, such as a nosocomial infection; an infection acquired during hospitalization.
Nystagmus Involuntary, rapid, rhythmic movements of the eyeball.
Oncogene A gene that is capable of causing the initial and continuing conversion of normal cells into cancer cells.
Oncotic Relating to, caused by, or marked by edema or any swelling.
Oocyte A primordial or incompletely developed ovum.
Oogenesis The process of the growth and maturation of the female gametes, or ova.
Opsonization The process of making cells, such as bacteria, more susceptible to the action of phagocytes.
Organelle Any one of the various membrane-bound particles of distinctive morphology and function present within most cells, as the mitochondria, the Golgi complex, and the lysosomes.
Orthopnea An abnormal condition in which a person must be in an upright position in order to breathe deeply or comfortably.

Orthosis An external orthopedic appliance or apparatus, as a brace or splint, used to support, align, prevent, or correct deformities, or to improve the function of movable parts of the body.
Osmolality The concentration of osmotically active particles in solution expressed in osmols or milliosmols per kilogram of solvent.
Osmolarity The concentration of osmotically active particles in solution expressed in osmols or milliosmols per liter of solution.
Osmosis The movement or passage of a pure solvent, such as water, through a semipermeable membrane from a solution that has a lower solute concentration to one that has a higher solute concentration.
Osteophyte A bony project or outgrowth.
Palpable Perceptible by touch.
Papilla A small nipple-shaped projection, elevation, or structure, as the conoid papillae of the tongue.
Papule A small, circumscribed, solid elevation of the skin less than one centimeter in diameter. (Adjective: papular)
Paracrine A mode of hormone action in which a chemical messenger that is synthesized and released from a cell acts on nearby cells of a different type and affects their function.
Paralysis An abnormal condition characterized by the impairment or loss of motor function due to a lesion of the neural or muscular mechanism.
Paraneoplastic Relating to alterations produced in tissue remote from a tumor or its metastases.
Parenchyma The basic tissue or elements of an organ as distinguished from supporting or connective tissue or elements. (Adjective: parenchymal)
Paresis Slight or partial paralysis.
Paresthesia Any abnormal touch sensation, which can be experienced as numbness, tingling, or a "pins and needles" feeling, often in the absence of external stimuli.
Parietal Pertaining to the outer wall of a cavity or organ; or pertaining to the parietal bone of the skull or the parietal lobe of the brain.
Parous Having borne one or more viable offspring.
Pathogen Any microorganism capable of producing disease.
Pedigree A systematic presentation, such as in a table, chart, or list, of an individual's ancestors that is used in human genetics in the analysis of inheritance.
Peptide Any of a class of molecular chain compounds composed of two or more amino acids joined by peptide bonds.
Perfusion The process or act of pouring over or through, especially the passage of a fluid through a specific organ or an area of the body.
Peripheral Pertaining to the outside, surface, or surrounding area of an organ or other structure; or located away from a center or central structure.
Permeable A condition of being pervious, or permitting passage, so that fluids and certain other substances can pass through, as a permeable membrane.
Pervasive Pertaining to something that becomes diffused throughout every part.
Petechia A tiny, perfectly round, purplish red spot that appears on the skin as a result of minute intradermal or submucous hemorrhage. (Plural: petechiae)
Phagocytosis The process by which certain cells engulf and consume foreign material and cell debris.
Phalanx Any one of the bones composing the fingers of each hand and the toes of each foot.
Phenotype The complete physical, biochemical, and physiologic makeup of an individual, as determined by the interaction of both genetic makeup and environmental factors.
Pheresis A procedure in which blood is withdrawn from a donor, a portion (plasma, leukocytes, etc.) is separated and retained, and the remainder is reperfused into the donor. It includes plasmapheresis and leukophoresis.
Pili Hair; or in microbiology, the minute filamentous appendages of certain bacteria. (Singular: pilus)
Plethoric Relating to an excess of any of the body fluids, especially blood; the term used to describe the beefy red coloration of a newborn.
Plexus A network of intersecting nerves, blood vessels, or lymphatic vessels.
Polygene Any of a group of nonallelic genes that interact to influence the same character in the same way so that the effect is cumulative, usually of a quantitative nature, as size, weight, or skin pigmentation. (Adjective: polygenic)
Polymorph One of several, or many, forms of an organism or cell. (Adjective: polymorphic)
Polyp A small, tumor-like growth that protrudes from a mucous membrane surface.
Polypeptide A molecular chain of more than two amino acids joined by peptide bonds.
Presbyopia A visual condition (farsightedness) that commonly develops with advancing years or old age in which the lens loses elasticity causing defective accommodation and inability to focus sharply for near vision.
Prevalence The number of new and old cases of a disease that are present in a population at a given time or occurrences of an event during a particular period of time.
Prodrome An early symptom indicating the onset of a condition or disease. (Adjective: prodromal)
Prokaryotic Pertaining to an organism, such as bacterium, with cells lacking a true nucleus and nuclear membrane that reproduces through simple fission.
Prolapse The falling down, sinking, or sliding of an organ from its normal position or location in the body.
Proliferation The reproduction or multiplication of similar forms, especially cells.
Pronation Assumption of a position in which the ventral, or front, surface of the body or part of the body faces downward. (Adjective: prone)
Propagation The act or action of reproduction.
Proprioception The reception of stimuli originating from within the body regarding body position and muscular activity by proprioceptors (sensory nerve endings found in muscles, tendons, joints).
Prosthesis An artificial replacement for a missing body part; or a device designed and applied to improve function, such as a hearing aid.

Proteoglycans Any one of a group of polysaccharide-protein conjugates occurring primarily in the matrix of connective tissue and cartilage.
Proto-oncogene A normal cellular gene that with alteration, such as by mutation, becomes an active oncogene.
Proximal Closer to a point of reference, usually the trunk of the body, than other parts of the body.
Pruritus The symptom of itching, an uncomfortable sensation leading to the urge to rub or scratch the skin to obtain relief. (Adjective: pruritic)
Purpura A small hemorrhage, up to about 1 cm in diameter, in the skin, mucous membrane, or serosal surface; or any of several bleeding disorders characterized by the presence of purpuric lesions.
Purulent Producing or containing pus.
Quiescent Quiet, causing no disturbance, activity, or symptoms.
Reflux An abnormal backward or return flow of a fluid, such as stomach contents, blood, or urine.
Regurgitation A flow of material that is in the opposite direction from normal, as in the return of swallowed food into the mouth or the backward flow of blood through a defective heart valve.
Remission The partial or complete disappearance of the symptoms of a chronic or malignant disease; or the period of time during which the abatement of symptoms occurs.
Resorption The loss of substance or bone by physiologic or pathologic means, for example, the loss of dentin and cementum of a tooth.
Retrograde Moving backward or against the usual direction of flow; reverting to an earlier state or worse condition (degenerating); catabolic.
Retroversion A condition in which an entire organ is tipped backward or in a posterior direction, usually without flexion or other distortion.
Rhabdomyolysis Destruction or degeneration of muscle, associated with myoglobinuria (excretion of myoglobin in the urine).
Rostral Situated near a beak (oral or nasal region).
Sacroiliitis Inflammation in the sacroiliac joint.
Sclerosis A condition characterized by induration or hardening of tissue resulting from any of several causes, including inflammation, diseases of the interstitial substance, and increased formation of connective tissues.
Scotopic vision Describes vision, especially night vision, when the eye is dark adapted.
Semipermeable Partially but not wholly permeable, especially a membrane that permits the passage of some (usually small) molecules but not of other (usually larger) particles.
Senescence The process or condition of aging or growing old.
Sepsis The presence in the blood or other tissues of pathogenic microorganisms or their toxins; or the condition resulting from the spread of microorganisms or their products. (Adjective: septic)
Serous Relating to or resembling serum; or containing or producing serum, such as a serous gland.
Shunt To divert or bypass bodily fluid from one channel, path, or part to another; a passage or anastomosis between two natural channels, especially between blood vessels, established by surgery or occurring as an abnormality.
Soma The body of an organism as distinguished from the mind; all of an organism, excluding germ cells; the body of a cell.
Spasticity The condition characterized by spasms or other uncontrolled contractions of the skeletal muscles. (Adjective: spastic)
Spatial Relating to, having the character of, or occupying space.
Sphincter A ringlike band of muscle fibers that constricts a passage or closes a natural orifice of the body.
Stenosis An abnormal condition characterized by the narrowing or stricture of a duct or canal.
Stochastic Involving a random process.
Stria A streak or a linear scarlike lesion that often results from rapidly developing tension in the skin; or a narrow bandlike structure, especially the longitudinal collections of nerve fibers in the brain.
Stricture An abnormal temporary or permanent narrowing of the lumen of a duct, canal, or other passage, as the esophagus, because of inflammation, external pressure, or scarring.
Stroma The supporting tissue or the matrix of an organ as distinguished from its functional element, or parenchyma.
Stupor A lowered level of consciousness characterized by lethargy and unresponsiveness in which a person seems unaware of his or her surroundings.
Subchondral Beneath a cartilage.
Subcutaneous Beneath the skin.
Subluxation An incomplete or partial dislocation in which the relationship between joint surfaces is altered, but contact remains.
Sulcus A shallow groove, depression, or furrow on the surface of an organ, as a sulcus on the surface of the brain, separating the gyri.
Supination Assuming the position of lying horizontally on the back, or with the face upward. (Adjective: supine)
Suppuration The formation of pus, or purulent matter.
Symbiosis Mode of living characterized by close association between organisms of different species, usually in a mutually beneficial relationship.
Sympathomimetic An agent or substance that produces stimulating effects on organs and structures similar to those produced by the sympathetic nervous system.
Syncope A brief lapse of consciousness due to generalized cerebral ischemia.
Syncytium A multinucleate mass of protoplasm produced by the merging of a group of cells.
Syndrome A complex of signs and symptoms that occur together to present a clinical picture of a disease or inherited abnormality.
Synergist An organ, agent, or substance that aids or cooperates with another organ, agent, or substance.
Synthesis An integration or combination of various parts or elements to create a unified whole.
Systemic Pertaining to the whole body rather than to a localized area or regional portion of the body.

Systole The contraction, or period of contraction, of the heart that drives the blood onward into the aorta and pulmonary arteries.
Tamponade Stoppage of the flow of blood to an organ or a part of the body by pathologic compression, such as the compression of the heart by an accumulation of pericardial fluid.
Teratogen Any agent or factor that induces or increases the incidence of developmental abnormalities in the fetus.
Thrombus A stationary mass of clotted blood or other formed elements that remains attached to its place of origin along the wall of a blood vessel, frequently obstructing the circulation. (Plural: thrombi)
Tinnitus A tinkling, buzzing, or ringing noise heard in one or both ears.
Tophus A chalky deposit containing sodium urate that most often develops in periarticular fibrous tissue, typically in individuals with gout. (Plural: tophi)
Torsion The act or process of twisting in either a positive (clockwise) or negative (counterclockwise) direction.
Trabecula A supporting or anchoring stand of connective tissue, such as the delicate fibrous threads connecting the inner surface of the arachnoid to the pia mater.
Transmural Situated or occurring through the wall of an organ.
Transudate A fluid substance passed through a membrane or extruded from the blood.
Tremor Involuntary quivering or trembling movements caused by the alternating contraction and relaxation of opposing groups of skeletal muscles.
Trigone A triangular-shaped area.
Ubiquitous The condition or state of existing or being everywhere at the same time.
Ulcer A circumscribed excavation of the surface of an organ or tissue, which results from necrosis that accompanies some inflammatory, infectious, or malignant processes. (Adjective: ulcerative)
Urticaria A pruritic skin eruption of the upper dermis, usually transient, characterized by wheals (hives) of various shapes and sizes.
Uveitis An inflammation of all or part of the uveal tract of the eye.
Vector An invertebrate animal (e.g., tick, mite, mosquito) that serves as a carrier, transferring an infective agent from one vertebrate host to another.
Ventral Pertaining to a position toward the belly of the body; or situated or oriented toward the front or anterior of the body.
Vertigo An illusory sensation that the environment or one's own body is revolving.
Vesicle A small bladder or sac, as a small, thin-walled, raised skin lesion, containing liquid.
Visceral Pertaining to the viscera, or internal organs of the body.
Viscosity Pertaining to the physical property of fluids, caused by the adhesion of adjacent molecules, that determines the internal resistance to shear forces.
Zoonosis A disease of animals that may be transmitted to humans from its primary animal host under natural conditions.

Appendix A

Lab Values

TABLE A-1 Prefixes Denoting Decimal Factors

Prefix	Symbol	Factor
mega	M	10^{6}
kilo	k	10^{3}
hecto	h	10^{2}
deci	d	10^{-1}
centi	c	10^{-2}
milli	m	10^{-3}
micro	μ	10^{-6}
nano	n	10^{-9}
pico	p	10^{-12}
femto	f	10^{-15}

TABLE A-2 Hematology

Test	Conventional Units	Conversion Factor	SI Units
Erythrocyte count (RBC count)	M. 4.2–5.4 × 10^{6}/μL F. 3.6–5.0 × 10^{6}/μL	1.0	M. 4.2–5.4 × 10^{12}/L F. 3.6–5.0 × 10^{12}/L
Hematocrit (Hct)	M. 40–50% F. 37–47%	0.01	M. 0.40–0.50 F. 0.37–0.47
Hemoglobin (Hb)	M. 14.0–16.5 g/dL F. 12.0–15.0 g/dL	10.0	M. 140–165 g/L F. 120–150 g/L
Mean corpuscular hemoglobin (MHC)	27–34 pg/cell		0.40–0.53 fmol/cell
Mean corpuscular hemoglobin concentration (MCHC)	31–35 g/dL	10.0	310–350 g/L
Mean corpuscular volume (MCV)	85–100 fL/cell		
Reticulocyte count	1.0–1.5% total RBC	1.0	
Platelet count	150–400 × 10^{3}/μL	1.0	150–400 × 10^{9}/L
Leukocyte count (WBC count)	4.8–10.8 × 10^{3}/μL	1.0	4.8–10.8 × 10^{9}/L
Basophils	0%–2%		
Eosinophils	0%–3%		
Lymphocytes	24%–40%		
Monocytes	4%–9%		
Neutrophils (segmented [Segs])	47%–63%		
Neutrophils (bands)	0%–4%		

TABLE A-3 Blood Chemistry*

Test	Conventional Units	Conversion Factor	SI Units
Alanine aminotransferase (ALT, SGPT, GPT)	7–56 units/L†	0.017	0.12–0.95 μkat/L†
Alkaline phosphatase	41–133 units/L†‡	0.017	0.7–2.3 μkat/L†‡
Ammonia	18–60 μg/dL	0.590	11–35 μmol/L
Amylase	20–110 units/L†	0.017	0.34–1.87 μkat/L†
Aspartase aminotransferase (AST, SGOT, GOT)	0–35 units/L†	0.017	0–0.59 μkat/L†
Bicarbonate	24–31 mEq/L	1.0	24–31 mmol/L
Bilirubin (total)	0.1–1.2 mg/dL	17.100	17.1–21 μmol/L
Direct	0.1–0.5 mg/dL		<8 μmol/L
Indirect	0.1–0.7 mg/dL		<12 μmol/L
Blood urea nitrogen (BUN)	8–20 mg/dL	0.360	2.9–7.1 mmol/L
Calcium (Ca^{2+})	8.5–10.5 mg/dL	0.250	2.1–2.6 mmol/L
Chloride	98–106 mEq/L	1.000	98–106 mmol/L
Creatine kinase (CK, CPK)	32–267 units/L†	0.017	0.54–4.53 μkat/L†
Creatinine (serum)	0.6–1.2 mg/dL‡	83.300	50–100 μmol/L‡
Gamma-glutamyl-transpeptidase (GGT)	9–85 units/L†	0.017	0.15–1.42 μkat/L†
Glucose (plasma, fasting)	<100 mg/dL	0.055	<5.6 mmol/L
Glycosylated hemoglobin (HbA_{1c})	3.9–6.9%		
Lactate dehydrogenase (LDH)	88–230 units/L†	0.017	1.46–3.82 μkat/L†
Lipids			
Cholesterol	<200 mg/dL (optimal) 200–239 mg/dL (borderline) ≥240 (high)	0.26	<5.2 mmol/L (optimal) 5.2–6.1 mmol/L (borderline) >6.2 mmol/L (high)
LDL cholesterol	<130 mg/dL	0.026	<3.37 mmol/L
HDL cholesterol	<40 low >60 high	0.026	1.04 mmol/L 1.56 mmol/L
Triglycerides	<165 mg/dL	0.01	<1.8 mmol/L (fasting)
Lipase	0–160 units/L†	0.017	0.272 μkat/L†
Magnesium	1.8–3.0 mg/dL	0.50	0.75–1.25 mmol/L
Osmolality	275–295 mOsm/kg H_2O		275–295 mmol/kg H_2O
pH (arterial)	7.35–7.45		
Phosphorus (inorganic)	2.5–4.5 mg/dL	0.32	0.80–1.45 mmol/L
Potassium	3.5–5.0 mEq/L	1.0	3.5–5.0 mmol/L
Prostate specific antigen (PSA)	0–4 ng/mL	1.0	0–4 μg/L
Protein total	6.0–8.0 g/dL	10.0	60–80 g/L
Albumin	3.4–4.7 g/dL	10.0	34–47 g/L
Globulin	2.3–3.5 g/dL	10.0	23–35 g/L
A/G ratio	1.0–2.2	10.0	10–22
Thyroid tests			
Thyroxine (T_4) total	5.0–11.0 μg/dL	12.80	64–142 nmol/L
Thyroxine, free (FT_4)	9–24 pmol/L†		
Triiodothyronine (T_3) total	95–190 ng/dL	0.015	1.5–2.9 nmol/L
Thyroid-stimulating hormone (TSH)	0.4–4.2 μU/mL	1.0	0.4–4.2 mU/L
Thyroglobin	3–42 ng/mL	1.0	3–42 μg/L
Sodium	135–145 mEq/L	1.0	135–145 mmol/L
Uric acid	Male: 2.4–7.4 mg/dL Female: 1.4–5.8 mg/dL	59.48	Male: 143–440 μmol/L Female: 83–345 μmol/L

*Values may vary with laboratory. The values supplied by the laboratory performing the test should always be used because the ranges may be method specific.
†Laboratory and/or method specific
‡Varies with age and muscle mass

Values obtained from Tierney L.M., McPhee S.J., Papadakis M.A. (2007). *Current medical diagnosis and treatment* (46th ed., pp. 1769–1777). Stamford, CT: Appleton & Lange; Fischbach F. (2004). *A manual of laboratory and diagnostic tests* (7th ed.). Philadelphia: Lippincott Williams & Wilkins; and other sources.

  structure and function of, 93
Transient left ventricular apical ballooning. *See* Takotsubo cardiomyopathy
Transitional epithelium, 23, 24f
Translation, RNA in, 95–97
Translocation, in chromosome, 118, 118f
Transmembrane proteins, 3, 3f
Transmigration, 31
  inflammatory response, 57–58
Transmissible neurodegenerative diseases, 301
Transplantation
  heart, 498–499
  of hematopoietic cells, 354
  immunopathology of, 353–355
  kidney, for CKD, 654
  liver
    for hepatitis, 741
    for liver failure, 750
  lung, 593
Transport maximum, 607
Transport mechanism, of cell membrane, 14–17, 14f–15f
Transpulmonary pressure, 525, 526f
Transtentorial herniation, of brain, 931, 931f, 933, 934f
Transverse fracture, 1103, 1103f
Trauma
  brain injury, 935–938
  corneal, 969
  malnutrition in, 236–237
Traumatic pneumothorax, 571
Tremor, 899
Treponema pallidum, 1077–1078
Tricarboxylic acid cycle. *See* Citric acid cycle
Trichomonas vaginalis, 1072–1073, 1072f
Trichomoniasis, vaginal, 1072–1073, 1072f
Trigeminal neuralgia, 881
Triglycerides, in energy storage, 225
Trigone, 659, 660f
Triplet repeat mutations, 115
Trisomy 21. *See* Down syndrome
Trivalent inactivated influenza vaccine (TIIV), 545
tRNA. *See* Transfer RNA
Tropomyosin, 27, 27f
Troponin, 27, 27f
Troponin assays, 455–456
Trousseau sign, 188, 188f
Truncal ataxia, 908
TTP. *See* Thrombotic thrombocytopenic purpura
T tubules, 26, 26f
Tuberculosis (TB), 549–553, 550b
  diagnosis of, 552
  etiology of, 549–550, 549f
  with HIV, 369–370
  pathogenesis of, 550, 551f
  primary, 550–551, 551f
  secondary, 551–552, 551f
  treatment of, 552–553
Tuberculosis osteomyelitis, 1111
Tubulin, 7, 8f
Tubulointerstitial disease, 627–630, 628f–629f. *See also specific disease*
Tumor(s)
  benign
    biology of, 133, 134t
    characteristics of, 131–139, 132b
  cell characteristics of, 134–136, 135f
  cell transformation to, 142, 142f
  growth of, 135–137, 136f
  in inflammation, 55
  of kidneys, 637–639
  malignant
    biology of, 133–134, 134t
    characteristics of, 131–139, 132b
  staging and grading of, 150–151
  terminology of, 132–133, 133t
Tumor antigens, 143
Tumor markers, 149–150, 149t
Tumor necrosis factor-α (TNF-α)
  in acute inflammation, 61, 61f
  in chronic inflammation, 63
Tumor-suppressor genes, 139–140, 140f
Tunicae, 396, 396f, 405, 406f
Tunnel vision, 984
Turbulent airflow, 525
Turbulent blood flow, 380–381, 383, 383f
Turner syndrome, 120–121, 121f
Tympanic membrane, 989, 989f
Typical pneumonia, 546–549, 546f, 548t
Tyrosinase, 1161

U

UA. *See* Unstable angina
Ubiquitin, 34
Ubiquitination, 6
Ulcers
