No specific prenatal diagnostic measures exist to identify fetuses with FAS. Alcohol exposure screening tools such as Alcohol Use Disorder Identification Test (AUDIT); Cut Down, Annoyed, Guilty, Eye Opener (CAGE); Tolerance, Worried, Eye Opener, Amnesia, (K)Cut Down (TWEAK); Tolerance, Annoyance, Cut Down, Eye Opener (T-ACE); and Michigan Alcoholism Screening Test (MAST)[81,93,94] have been used for years in the primary care setting. Of note, however, not all of these screening tools have been developed and validated for use in pregnant women. Guidelines from the National Institute on Alcohol Abuse and Alcoholism (NIAAA) recommend that any woman who drinks more than 7 drinks per week or more than 3 drinks on any given day should be further assessed for alcohol-related problems.[95] Some evidence suggests that T-ACE and TWEAK are effective screening tools to identify women who would benefit from intervention for alcohol use during pregnancy.[57] It has been suggested, however, that a comprehensive screening tool should assess both mother and fetus to identify in utero alcohol exposure.[96]

Timeline FollowBack (TLFB) calendars, which include the date of conception and the date of pregnancy recognition, may be used to accurately assess the timing, frequency, and amount of alcohol consumed during pregnancy.[96] Combining the screening tools to include both mother and fetus may increase the accuracy and effectiveness of such tools; this will require validation work before use in the clinic. These screening tools are not diagnostic; their purpose is to identify women who may benefit from early intervention or treatment for alcohol consumption during pregnancy. Novel biologic markers may help to overcome dependence on self-reporting and may be a critical step in ensuring an accurate diagnosis of FAS in cases in which effects of in utero alcohol exposure are not yet apparent in the infant. Promising maternal serum biomarkers include mean corpuscular volume (MCV), γ-glutamyltransferase (GGT), and hemoglobin-associated acetaldehyde (HAA).[97]

Meconium fatty acid ethyl esters (FAEEs) also have been proposed as biologic markers for alcohol exposure.[98] Placental studies suggest that FAEEs do not cross the human placenta.[98] Therefore FAEEs detected in neonatal matrices are likely direct from the fetus. Although meconium FAEE studies have demonstrated the promise of using FAEE levels as the first biologic marker of alcohol exposure during pregnancy, these FAEEs are available for collection only in the first 1 or 2 days of life, reflecting a very narrow window of opportunity for collection.[98]

Serial measurements of alpha fetoprotein may suggest the occurrence of FAS because alpha fetoprotein is produced by the fetal liver, which may be damaged when exposed to alcohol. In one study, 13 women gave birth to infants with FAS; each woman had low levels of alpha fetoprotein and pregnancy-specific beta-1-glycoprotein.[99] The authors concluded that low alpha fetoprotein and pregnancy-specific beta-1-glycoprotein may be primary or secondary effects of alcohol abuse during pregnancy and may be useful in predicting FAS.[99]

Currently, the best-established markers for the detection of alcohol abuse in pregnant and nonpregnant women are increased levels of serum γ-glutamyltransferase activity and increased mean blood cell volumes.[100]

Prenatal ultrasonography has been used to visualize and catalogue the fetal malformations associated with numerous drugs and chemicals. Ultrasound examination of fetuses exposed to alcohol may reveal many associated anomalies[101,102] (Box 26-1).

Abstinence is the treatment goal in heavy social drinkers or women who are physically dependent on alcohol. If alcohol consumption totals more than 80 g/day of absolute ethanol, a gradual reduction in alcohol consumption over 4 days is recommended.[52] During detoxification and throughout pregnancy, intense supportive counseling must be provided. A diazepam (Valium)-loading regimen has been used successfully in alcohol withdrawal treatment.[103] β-Blockers can reduce the signs and symptoms of mild to moderate alcohol withdrawal.[104]

BOX 26-1

Fetal Malformations Associated With Maternal Substance Abuse Visualized by Prenatal Ultrasonography

General Anomalies
Microcephaly
Diaphragmatic hernia
Renal defects
Hypospadias
Labial hypoplasia
Fetal growth restriction
Pulmonary atresia

Cardiac Anomalies
Heart malformations
Ventricular septal defect
Atrial septal defect
Double outlet of right ventricle
Dextrocardia
Patent ductus arteriosus
Tetralogy of Fallot

Skeletal Anomalies
Short nose
Hypoplastic philtrum
Hypoplastic maxilla
Micrognathia
Small mandible
Pectus excavatum
Bifid xiphoid
Scoliosis
Poorly formed orbits
Microphthalmia
Cleft lip
Cleft palate
Radioulnar synostosis

Cocaine

Cocaine is the most potent naturally occurring stimulant. Cocaine blocks the reuptake of the biogenic amines serotonin, dopamine, and norepinephrine in the CNS and causes these neurotransmitters to bind with their receptors.[105,106] Enhanced receptor binding increases neuronal excitability, resulting in the typical cocaine "high." In addition to its effects on the CNS, cocaine acts peripherally to inhibit nerve conduction by blocking the reuptake of norepinephrine at the sympathetic nerve terminals.[107] This action increases norepinephrine levels, with consequent vasoconstriction, tachycardia, and hypertension.

Exposure to cocaine decreases blood flow to the fetus by constricting the placental vasculature. In addition, cocaine causes the myometrium to contract, potentially increasing the risk for premature rupture of the membranes with the need for induction of labor.[108,109] Vasoconstriction of the uterine arteries, causing circulatory insufficiency, has been suggested as the mechanism leading to reduced birth weight, fetal growth restriction, and labor-induced fetal stress.[110]

Cocaine abuse traditionally has involved concomitant intravenous injection of heroin. Currently, cocaine is insufflated or smoked, rather than injected. In the 1980s, in the United States, cocaine use had dramatically increased, especially among young adults. In the mid '80s, 40% of cocaine addicts used the drug nasally, 30% by free-base smoking, 20% by injection, and the remaining 10% by combining these routes.[111] According to the 2004 National Household Survey on Drug Use and Health, substance abuse during pregnancy increased over the past three decades in the United States; 4.6% of American women reported use of an illicit drug during pregnancy. Previous studies on illicit drug use during pregnancy and perinatal outcome showed inconsistent results.[5]

Pharmacology of Cocaine

A peak plasma cocaine concentration is attained within 15 to 60 minutes after insufflation.[112] The peak plasma concentration after oral administration of cocaine is reached in 50 to 90 minutes. The bioavailability of cocaine ingested orally is 60%, which is similar to that of cocaine administered intranasally. Free-base smoking and intravenous cocaine administration have comparable kinetics: Both are characterized by rapid and complete absorption of the drug. The elimination half-life of cocaine is between 20 and 90 minutes.[112] After an intranasal dose of 1.5 mg/kg, cocaine can be detected in the urine for 8 hours. Benzoylecgonine, the primary metabolite of cocaine, can be detected in the user's urine for 48 to 72 hours with chromatographic techniques and for 90 to 144 hours with radioimmunoassay.[54a]

Cocaine readily diffuses across the blood-brain and placental barriers and also transfers into breast milk. Cocaine rapidly crosses the placenta because of its low molecular weight (305), high lipid solubility, and low protein binding in human plasma. The rate of transfer of cocaine is approximately 10 times that of benzoylecgonine. Therefore the major portion of the administered dose is available to equilibrate with the fetal circulation.[22] The placenta serves as a reservoir for large amounts of cocaine and consequently offers some protection to the fetus after bolus dosing. Conversely, fetal exposure may be prolonged as cocaine and benzoylecgonine leach out of the placenta.[22] Fetal lamb studies[113] also indicate that cocaine and its metabolites in the amniotic fluid may prolong fetal drug exposure. Measurable levels of cocaine and benzoylecgonine have been detected in breast milk as late as 36 hours after consumption of the drug has ceased.

Cocaine is metabolized primarily by esterases and by cytochrome P-450 enzymes. Cytochrome P-450 accounts for the *N*-demethylation metabolism (20%) of cocaine into the bioactive metabolite norcocaine, which is more vasoactive than cocaine.[114] The remainder of the drug is extensively metabolized by plasma and liver cholinesterases, which hydrolyze the drug into an active metabolite, ecgonine methyl ester. Cocaine is spontaneously converted to benzoylecgonine in the plasma by nonenzymatic hydrolysis. The metabolites are more polar than cocaine and are readily excreted by the kidney. Less than 10% of cocaine is excreted unchanged in the urine.

The mean cocaine elimination half-life for intranasal administration is 75 minutes, for oral administration 48 minutes, and for intravenous administration 54 minutes. The volume of distribution is 1.2 to 1.9 L/kg. Differences in individual cholinesterase levels explain the variation seen in the half-life of cocaine. The elimination half-life of benzoylecgonine is considerably longer than that of cocaine, but the benzoylecgonine molecule is more polar, so the drug distributes less rapidly than cocaine.[115]

In adults, more benzoylecgonine than cocaine is found in the blood, brain, and liver.[116] In neonates, the distribution of cocaine in the tissues differs from that in adults. Klein and associates,[115] in their description of the distribution of cocaine and benzoylecgonine in a fetus born to a woman who used cocaine, detected both drugs in the fetal brain, scalp, liver, kidney, heart, placenta, blood, and hair. The neonate's liver contained substantially more cocaine than the other tissues, whereas the brain contained more benzoylecgonine than any other tissue.

Effects of Cocaine Use on the Fetus and Neonate

The potential deleterious effects on the fetus and neonate of maternal cocaine use during pregnancy are numerous. Cocaine use during pregnancy has been associated with an increased risk for spontaneous abortion, abruptio placentae, premature labor, precipitous delivery, stillbirth, and meconium staining.[117-122] After intravenous cocaine use, spontaneous abortion and abruptio placentae are more prevalent.[123] These effects may be associated with increased maternal blood pressure, increased uterine contractility and placental constriction, and decreased uterine blood flow, all of which cause fetal hypoxia.

Decreased birth weight, shorter body length, smaller head circumference, a higher malformation rate, and a more frequent need for medical support and resuscitation have been documented in newborns exposed to cocaine in utero.[118,119,122,124,125] The effects of cocaine exposure during pregnancy on intrauterine growth and growth deviation during gestation have been described by Bada and colleagues.[126] These investigators found that there is a significant interaction between cocaine exposure and gestational age. Percentile estimates for birth weight, length, and head circumference showed growth deceleration, evident after 32 weeks gestation, in infants exposed to cocaine during pregnancy. After controlling for confounders, at 40 weeks gestation, cocaine exposure was estimated to be associated with a decrease of 151 grams, 0.71 centimeters, and 0.43 centimeters in birth weight, length, and head circumference, respectively.[126]

Infants exposed to cocaine in utero also exhibit depressed interactive behavior and poorly organized responses to external stimuli. Marked tremulousness, irritability, and deficiencies in mood control and interactive behavior also have been reported in the literature.[121,123,124,127,128] In a series of 12 infants,[127] 11 exhibited poor visual attention and abnormal flash-evoked potentials. A large-scale, prospective, blinded study of 172 infants who were exposed to cocaine prenatally did not identify an increased number or consistent pattern of malformation. The study did, however, suggest that infants exposed to cocaine prenatally had a significantly smaller birth weight, length, and head circumference in comparison with unexposed infants.[129]

Doberczak and associates[130] studied the relationship between maternal cocaine abuse during pregnancy and neonatal neurologic abnormalities in 39 infants. These investigators found that 34 of the neonates displayed CNS irritability, with bursts of sharp waves and spikes, which were multifocal in 14 of 17 EEG tracings. EEG abnormalities persisted in 17 of 38 infants during the first week of life. In one neonate, an EEG was not done. In nine of these 17 infants, EEG tracings remained abnormal through the second week of life. Between 3 and 12 months later, however, only one of these infants had an abnormal EEG tracing. These findings did not suggest a correlation between fetal cocaine exposure and clinical seizures or neurologic abnormalities.

A rare but serious CNS condition associated with maternal cocaine use near delivery is perinatal cerebral infarction.[131] In the first reported case, right hemiparesis with right-sided focal seizures developed in the newborn infant of a cocaine abuser on the first day of life. The mother had used cocaine excessively (5 grams, intranasally) 3 days before delivery.[131a] A computed

tomography scan and a lumbar puncture showed evidence of cerebral infarction in the brain of the infant.

Neonates exposed in utero to cocaine showed significant differences in organizational response and interactive behavior compared with control neonates when they were assessed with the Brazelton Neurobehavioral Assessment Scale.[119,132] Oro and Dixon[122] described a prevalence of excessive tremor, hypertonia, hyperreflexia, poor feeding, and sleep disturbances among cocaine-exposed and cocaine-methamphetamine–exposed neonates. It appears that the developing brain is sensitive to cocaine exposure during early development. However, the literature does contain conflicting studies on this issue. Chasnoff and colleagues[132] showed that neonates exposed to cocaine solely in the first trimester exhibited neurobehavioral abnormalities but no growth anomalies. A large cohort of children exposed to cocaine were followed by Lewis and co-workers[133] from birth to 4 years of age. The results of their study suggested that compared with unexposed children, children exposed to cocaine had milder receptive language delay and were less likely to have higher expressive abilities. Children exposed to cocaine who were placed in foster care demonstrated language skills superior to those in children exposed to cocaine who remained in the biologic mother's care.[133] These findings support suggestions that a cocaine-specific effect on language skills in early childhood may be modified by an enriched environment. Conversely, the Motherisk group[134] showed that babies exposed to cocaine only during the first trimester had no greater risk of delayed cognitive development than that in their control groups.

Cocaine-mediated vasoconstriction of the fetal cerebral vasculature decreases cerebral blood flow.[135] Several clinical reports[136-138] described neonatal stroke (cerebrovascular accident) after prenatal cocaine exposure in the setting of abruptio placentae or birth asphyxia, each of which is a known risk factor for neonatal stroke. A vascular cause is suggested by the cases of three neonates with porencephaly who were exposed to cocaine in utero and that of one neonate with bilateral occipital infarcts after an uncomplicated delivery.[139] Ultrasound examination of the head demonstrated an increased incidence of intracranial hemorrhage and cystic lucencies among cocaine-exposed neonates, at rates (30%) similar to those seen in infants with hypoxic-ischemic encephalopathy.[140] In addition, Doppler examination revealed increased cerebral blood flow in neonates with recent cocaine exposure.[141] Coupled with systemic hypertension, such an increase in cerebral blood flow could elevate intracranial pressure, leading indirectly to intracranial hemorrhage.

To date, most studies assessing the reproductive neurotoxicity of cocaine have focused on neonatal and infant cognitive function. It is possible, however, that other neurologic damage may occur, causing attention deficit disorders or learning disabilities.[142] A recent study assessed learning abilities and intellectual functioning at age 7 of 212 full-term children with prenatal cocaine exposure. No differences were found in the estimate of relative risk for impaired intellectual functioning (IQ below 70).[143] Children exposed to cocaine, however, had a 2.8 times greater risk for development of learning disabilities by age 7 than that in unexposed children (95% CI = 1.05-7.67; $p = .038$; IQ cutoff of 70 or higher).[143]

Abnormal sleep patterns in neonates and infants also have been observed after prenatal maternal cocaine use.[122,144] The risk of SIDS attributable to maternal cocaine use during pregnancy was investigated by several groups of workers. In a study comprising 996 women who used cocaine during pregnancy,[145] 1 of the 175 infants (0.6%) in the cocaine-exposed group died of SIDS, whereas 4 of the 821 infants (0.5%) in the nonexposed control groups died. The investigators concluded that cocaine did not increase the risk of SIDS in cocaine-exposed pregnancies.

Conversely, other studies[120,121] postulated an increased risk of SIDS in neonates who were exposed to cocaine in utero. In these studies, 10 (18%) of 56 cocaine-exposed neonates died of SIDS. This figure is substantially different from other reported values and may reflect a sample-size effect or an inclusion or reporting bias. Chasnoff and co-workers[146] conducted a prospective study of cardiorespiratory patterns in 32 cocaine-exposed neonates and in 18 methadone-exposed neonates. Eight of the 32 cocaine-using mothers also abused heroin and were started on methadone maintenance therapy. Although 12 of 32 cocaine-exposed neonates and 1 of the 18 methadone-exposed neonates had abnormal pneumograms, no deaths were attributable to SIDS. Despite the methodologic weaknesses in the study design, the investigators concluded that prenatal exposure to cocaine appeared to be linked to cardiorespiratory abnormalities. It was not, however, specifically concluded that cocaine exposure was linked directly to SIDS. The same link was previously suggested by Ward and colleagues.[147] The relationship between cocaine use during pregnancy and SIDS is still not clear.[87]

A meta-analysis done by Fares and collegues[148] showed that an increased risk for SIDS could not be attributed to intrauterine cocaine exposure alone after institution of controls for the confounding variable of concurrent use of other drugs. The increase in risk for SIDS was found not to be specific to cocaine, but rather was associated with intrauterine exposure to illicit drugs in general.[148] The pathophysiology of SIDS is not completely elucidated. Many studies support the concept of abnormal CNS regulation of breathing as the most plausible mechanism.[149-151] Cocaine-mediated changes in the content of the biogenic amines, which are important respiratory control neurotransmitters, may be responsible for neonatal hypoxia. Alternatively, through the direct effect of cocaine-induced hypertension or, indirectly, through repeated episodes of hypoxia secondary to cocaine-mediated vasoconstriction of the placental vasculature, cocaine may disrupt brain structures essential to respiratory regulation.[152-154]

The effects of maternal cocaine abuse on the neonatal auditory system were studied in 18 newborns.[155] The auditory brain stem responses of neonates exposed to cocaine showed prolonged interpeak and absolute latencies (evoked potentials) compared with those of nonexposed control neonates. These abnormalities suggest a neurologic impairment or dysfunction such as delayed myelination, as well as altered DNA synthesis requiring further audiologic and neurologic follow-up evaluation.

The risk of major structural malformations attributable to in utero cocaine exposure is still undetermined. Results of a meta-analysis failed to show increased teratogenic risk associated with cocaine use alone after controlling for use of other drugs of abuse.[156] Cocaine use during pregnancy also has been associated with increased risk for the development of transient myocardial ischemia in the neonate.[157] Transient ST-segment elevation and a lower ratio of low- to high-frequency power in the spectral analysis for heart rate variability reflected increased vagal activity in cocaine-exposed neonates.[157]

The fetal cardiovascular response to cocaine is postulated to be a combination of direct and indirect effects. An indirect effect of placental hypoperfusion, fetal hypoxia, and subsequent catecholamine release has been reported.[152] The direct effect of cocaine is at the level of the fetal noradrenergic nerve terminal.[152]

The principal focus of published research on cocaine use is on the fetal risks associated with heavy maternal cocaine users, whose practices and general health also add numerous confounding variables such as polydrug use, concomitant use of cigarettes and alcohol, higher risk for vaginal bleeding, hepatitis B carrier state, and poor prenatal care. Because constituents of smoke such as carbon monoxide and nicotine are known fetotoxicants,[158] Forman and associates[125] examined the outcome for neonates exposed to cocaine alone, and to cocaine and maternal smoking, to ascertain the effects attributable to cocaine, as opposed to those attributable to tobacco. The analysis revealed that most of the detrimental effects on the fetus and neonate were the result

of cigarette smoking.[125] These results are in agreement with those of an earlier meta-analysis.[159]

Very little research has focused on the potential risks associated with social maternal cocaine use. Most social cocaine users seem to discontinue their cocaine use once they are pregnant. A comparison[142] of social cocaine users and drug-free control subjects produced no evidence that neonates born to social cocaine users have an increased risk of perinatal complications, dysmorphology, or abnormal neurobehavioral development. Analysis of all available studies pertaining to maternal social cocaine consumption suggests that cocaine is not a major human teratogen and that neonates born to social cocaine users are normal in their physical and neurobehavioral development,[142] as evidenced by Bayley scores at the age of 18 months.[1]

A specific subgroup of fetuses has been recognized to be susceptible to the adverse effects of cocaine, probably because of variability in the maternal metabolism of cocaine,[160] the placental transfer of cocaine,[161] and the placental-vascular response to cocaine, as well as fetal pharmacodynamic variability.[142] Cocaine toxicity tends to reduce the activity of the choline esterase enzyme that metabolizes cocaine. Therefore in women using similar doses of cocaine, placental and fetal exposure will vary significantly.

The reliability of the evaluation of the reproductive risks associated with cocaine use during pregnancy is dependent on the verification of fetal drug exposure, or of nonexposure in the control groups. Fetal drug exposure is based on the mother's self-reports of gestational cocaine use and a positive result on the neonatal urine test, or a negative result on the neonatal urine test in the control groups. Recall that cocaine has a short elimination half-life (see section on "Pharmacology of Cocaine"). The detection of cocaine and its metabolite in blood and urine is limited by the short elimination half-life of these compounds; they are often not detectable in urine beyond a maximum of 7 days after last consumption of the drug.[54a, 161a] However, in chronic, high-dose users taking more than 10 grams/day of cocaine, benzoylecgonine has been detected in urine for up to 22 days after last consumption.[54a,161b] If a woman chooses to deny her cocaine use and the urine test result is negative, her neonate may be erroneously identified as a nonexposed control subject.[161c]

To overcome this limitation, a cocaine hair test can be used. Cocaine and benzoylecgonine incorporate into a growing hair shaft.[161c] As is the case with nutrients, cocaine transfers into the growing hair shaft through the capillaries nourishing it. The cocaine hair test remains positive for the entire life span of the hair shaft in both the mother and the baby, often long after the urine test results have become negative.[161c]

The detection of cocaine in neonatal hair is an indicator of maternal cocaine use during the last months of pregnancy. The initial fetal hair, lanugo, sheds at 5 to 6 months of gestation. Lanugo hair is replaced by neonatal terminal hair that grows throughout the third trimester of pregnancy at an approximate rate of one centimeter/month, incorporating benzoylecgonine into its matrix, and remains intact for several months after birth.[162,162a,162b] Therefore, detecting intrauterine drug exposure becomes a problem after this time. Because maternal hair grows at a rate of 1.0 to 1.5 cm per month, the hair test also may be used to determine the time of fetal drug exposure during gestation from an analysis of the maternal hair in sections. The clinician can use the results of this analysis to predict the extent and type of deleterious effects on the fetus attributable to the drug (based on the duration of drug exposure in utero), to plan a course of treatment for the fetus and neonate.

Neonatal signs such as abnormal sleep-wake cycles, tremulousness, poor feeding, hypotonia, and hyperreflexia have been documented in infants exposed in utero to cocaine.[121,122,127] These neonatal signs may reflect the effects of cocaine's slow elimination in the newborn infant.[131] A study[120] of eight neonates exposed to cocaine in utero reported no withdrawal symptoms. Ascertaining the existence of a neonatal cocaine withdrawal syndrome is further complicated by the maternal cocaine abuser's concomitant use of opioids that are known to cause neonatal withdrawal signs and symptoms.

Clinical Management of Pregnant Cocaine Abusers

A specific clinical management algorithm for the treatment of cocaine abuse is dependent on the extent of the mother's cocaine use and all associated medical and social problems. Irregular use of cocaine does not imply that the dependence on the drug is less severe. Most patients can be managed on an outpatient basis, although some women need hospitalization. Maternal cocaine withdrawal is characterized by periods of depression ranging in duration from hours to days, hypersomnolence, and hyperphagia, followed by a period of high energy and an intense craving for cocaine.[163] Unless the depression is severe, no pharmacologic therapy is recommended. A careful history is always essential, because cocaine abusers frequently use other drugs in combination with heroin, for which treatment may be necessary.

Neonatal hyperexcitability can be treated with the administration of benzodiazepines as necessary for effective control of symptoms. Withdrawal symptoms should be managed supportively.

Cigarette Smoking

Epidemiologic data indicate that cigarette smoking in the Western world has been gradually declining, more so in men than in women. The prevalence of smoking during pregnancy decreased from 40% to 25% between 1967 and 1980.[164] This decrease was seen primarily in highly educated populations. Despite extensive negative publicity, tobacco use continues in approximately 25% of all pregnancies in the United States, overshadowing illicit drugs of abuse, including cocaine.[165] Almost half of all adolescents smoke during pregnancy in the United Kingdom.[166] The societal cost of maternal smoking is seen most readily in underweight newborns; in high rates of perinatal morbidity, infant death, and SIDS; and in persistent deficits in learning and behavior.[167]

Pharmacology of Nicotine

In addition to the well-described long-term health hazards attributable to smoking, exposure to carbon monoxide from cigarette smoke produces a progressive rise in maternal and fetal carboxyhemoglobin concentrations that parallels a fall in tissue oxygen delivery as the smoking day progresses. Carbon monoxide readily crosses the placenta. Several hours are required for the fetal carboxyhemoglobin concentration to equilibrate with maternal concentrations. Final fetal concentrations eventually become higher than maternal concentrations because fetal hemoglobin has a greater affinity for carbon monoxide and because the elimination half-life from the fetal circulation is longer than that from the maternal circulation.[158] One smoking day may result in a maternal carboxyhemoglobin concentration of 12% and an even higher fetal concentration (by 10% to 15%). A 10% carbon monoxide level means that the delivery of oxygen to the fetus may actually be reduced by as much as 20% to 25% because carbon monoxide also is bound to the cytochrome enzymes. In addition, other compounds in tobacco smoke, such as thiocyanate and other cyanides, bind irreversibly to fetal and maternal hemoglobin to reduce oxygen delivery even further.

Intense uterine vasoconstriction[1,168] and a rapid fall in the uterine blood flow have been attributed to nicotine concentrations similar to those measured in arterial blood after smoke inhalation. These effects are produced by nicotine-mediated catecholamine release from the adrenal glands. Fetal hypoxemia often accompanies this vasoconstrictive effect.

Nicotine is readily absorbed by the oral mucosa, respiratory tract, gastrointestinal tract, and skin. From 80% to 90% of nicotine is metabolized in the liver, and smaller amounts are metabolized in the lung and kidney. The volume of distribution of nicotine is 2.0 L/kg in smokers and 3.0 L/kg in nonsmokers.[169] Nicotine is rapidly transferred from the maternal serum to the breast milk. Nicotine concentrations in breast milk are linearly correlated with those measured in maternal serum.[170] Both nicotine and cotinine (the major metabolite of nicotine) transfer into breast milk.[171-173] The mean elimination half-life of nicotine in breast milk is 92 ± 15 minutes, and in plasma it is 81 ± 9 minutes. Heavy maternal smoking may alter the milk supply and may cause nausea and vomiting in the neonate.[1] Nicotine and its metabolites are excreted primarily by the kidneys. Cotinine has an elimination half-life of 10 to 20 hours.[174]

Effects of Cigarette Smoking on the Fetus and Neonate

Studies[72,175] have shown an association between maternal smoking throughout pregnancy and increased risks of spontaneous abortion, placenta previa, and abruptio placentae; early or late gestational bleeding; and IUGR. Placentas of women who smoke are markedly different morphologically from those of nonsmoking women. In smokers, the placenta tends to be heavier, with a greater degree of infarction and calcification, as well as an increased frequency of vascular anomalies. Maternal smoking directly dysregulates cytotrophoblast expression and differentiation, which helps to explain the mechanisms by which smoking negatively affects human pregnancy outcome.[176]

In a review conducted to ascertain whether perinatal fetal mortality rates were increased among mothers who smoked,[177] 5 of 17 studies found significantly increased risks for stillbirth affecting infants born to smoking women. The risk of perinatal death may not be equally distributed and may vary with maternal age, parity, the ethnic group, and socioeconomic status.[178] A study from Sweden[179] found that smoking was associated with a higher risk for early neonatal death.

A reduction in fetal growth has been associated with maternal smoking. In that regard, Scholl and colleagues[180] demonstrated that smokers were 3.1 times more likely than nonsmokers to give birth to an SGA infant. Neonatal weights averaged 272 g less than those in the nonsmoking group. A quantitative dose-and-effect relation between tobacco exposure and decreased gestational age at birth and size of the neonate has been reported.[181] In light smokers (1 to 5 cigarettes per day), the risk of giving birth to an SGA baby was increased by a factor of 1.76 for girls and 1.72 for boys. In heavy smokers (more than 21 cigarettes per day), the risk of SGA was increased 3.15-fold for boys and 3.51-fold for girls.[182] The lower oxygen saturation in infants of heavy smokers may adversely affect fetal growth.

Alternatively, a reduction in epidermal growth factor (EGF)–stimulated autophosphorylation may be associated with IUGR.[183] EGF normally is involved in human embryouterine signaling and implantation,[184] in vitro stimulation of syncytiotrophoblast formation,[185,186] and modulation of placental endocrine functions.[185-188] Receptor autophosphorylation is required for EGF to elicit normal placental cell division and differentiation.[183] Conversely, abnormal development of the placenta may interfere with fetal growth.[189] Gabriel and associates[183] and Wang and coworkers[190] showed that EGF receptor autophosphorylation was significantly reduced in the placental membranes of smokers with SGA newborns compared with that in the placental membranes of smokers who gave birth to infants without growth restriction and those of nonsmokers. Gabriel and associates[183] concluded that IUGR in infants of women who smoked during pregnancy is associated with an alteration in the EGF receptor bioactivity of the placenta and suggested that the regulatory role of EGF in placental growth and differentiation is defective in smokers.

Smoking during pregnancy is a strong predictor for low birth weight, suggesting that focusing on education within smoking cessation programs for pregnant women, particularly those who may also be illicit drug users, could help reduce the adverse health consequences of low birth weight.[191]

A case-control study[192] of childhood cancer described a dose-response relationship between the number of cigarettes smoked per day by the mother during pregnancy and the risk of cancer in her children. A 50% higher incidence of cancer was found in infants exposed prenatally to cigarette smoke than that observed in control infants. The risks for the development of Hodgkin disease, acute lymphoblastic leukemia, and Wilms tumor also were higher. A more recent case-control study[193] (the Northen California Childhood Leukemia Study) included 327 children with acute lymphocytic leukemia (ALL), 46 children with acute myeloid leukemia (AML), and 416 control subjects matched for age, sex, race, and ethnicity. Maternal smoking was not associated with an increased risk for either ALL or AML, but paternal preconception smoking was significantly associated with increased risk for both.[193] Inherent difficulties with retrospective assessments of exposure led the investigators to no definitive conclusion.

The incidence of neonatal respiratory distress syndrome is reduced by maternal smoking.[194] Children exposed to smoke during pregnancy, however, tend to manifest a higher incidence of bronchitis and pneumonia during their first year of life.[195-198] A higher incidence of neonatal respiratory tract infections also has been linked to maternal cigarette smoking.[199] Smoking has been shown to decrease the production of breast milk.[200] Said and co-workers[201] suggested that maternal smoking during pregnancy may contribute to the incidence of neonatal colic.

Epidemiologic evidence clearly supports a link between maternal smoking and SIDS, but these studies fail to make the critical differentiation between fetal nicotine exposure and passive postpartum nicotine exposure, consequently weakening the association. Naeye and associates[202] stipulated that the strength of this correlation increased with maternal smoking of 6 or more cigarettes per day. Passive inhalation of smoke also increases the risk for SIDS in infants.[203] In another study,[204] researchers found that maternal smoking during pregnancy doubled the rate of SIDS from 2.3 to 4.6 per 1000 births. None of these studies, however, attempted to differentiate between intrauterine exposure and passive exposure to smoke after birth.

Malloy and colleagues[205] studied the association of maternal smoking with infant age and the specific cause of infant death among Caucasion women having singleton pregnancies, rather than using infant mortality in general as the outcome measure. This group of investigators concluded that maternal smoking was associated with a nearly two-fold increase in SIDS. Haglund and Cnattinguis[206] reported that maternal smoking of up to 9 cigarettes per day doubled the risk of neonatal SIDS, and smoking 10 or more cigarettes per day tripled the risk of SIDS, over that in infants of nonsmoking control subjects. Both Malloy and colleagues[205] and Haglund and Cnattinguis[206] acknowledged that a study of passive smoking by either partner after birth was not conducted, and passive smoking may in fact contribute to the incidence of neonatal SIDS. A two-fold increase in the rate of SIDS associated with maternal cigarette smoking also was suggested by Anderson and collegues.[207] Infants exposed to smoke were 1.9 times more likely to die of SIDS.[207]

To investigate the effects of maternal smoking on the cognitive development of 3-year-old children, a study of 700 mother-child pairs[208] was conducted. Extensive information on growth and development, including cognitive development test results, was included in the study variables. The investigators concluded that the cognitive performance of infants born to women who continued to smoke throughout their pregnancies was significantly compromised, at least to the third year of life, after correcting for known confounding variables. One study that prospectively

followed children up to the age of 4 years suggested that in utero exposure to cocaine resulted in a deficit in special language skills.[133] Although scientists and the public continue to pay far more attention to fetal cocaine effects than to the effects of nicotine or tobacco use, a change in focus to concentrate on tobacco use during pregnancy and after birth could have a much larger impact on human health.

Clinical Management of Smokers During Pregnancy

Smoking in pregnancy remains a major public health problem. The goal of maternal therapy for smoking during pregnancy is to improve fetal outcome by preventing associated prenatal complications. Education and support are required for pregnant smoking women. Nicotine replacement therapy (NRT) in pregnancy has been tried, but with low effectiveness.[209] This poor success rate may reflect the doubling of the clearance rate of nicotine seen in late pregnancy, thereby rendering replacement levels subtherapeutic.[210,211] NRT is effective for smoking cessation in nonpregnant people, but because women metabolize nicotine and cotinine much faster in pregnancy, it is unclear whether NRT can be effective for smoking cessation in this population.[212] Bupropion is an effective agent for smoking cessation. The manufacturer's registry suggests that it is not teratogenic when used in clinical doses.

Marijuana

After alcohol, the second most commonly used recreational drug in the United States is marijuana. Prevalence of marijuana use during pregnancy in developed nations is estimated to be approximately 10%.[210]

Marijuana, or cannabis, is produced from the flowering tops of hemp plants, from which at least 61 cannabinoids and more than 300 naturally occurring compounds can be extracted. The isomer 1-Δ^9-tetrahydrocannabinol(THC) is the most potent psychoactive compound among the cannabinoids.THC and other cannabinoids are C_{21}-substituted monoterpenoid compounds.[1]

The exact mechanism responsible for the pharmacodynamics of marijuana is unknown. Marijuana smoking produces an approximately 5-fold greater increase in the blood carboxyhemoglobin level than that produced by cigarette smoking.[213,213a] This may be due to an approximately two-thirds larger puff volume, a one-third greater depth of inhalation, and a 4-fold longer breath-hold-time with marijuana than cigarettes ($p < 0.01$).[213a] This results in a greater respiratory burden due to increased carbon monoxide exposure when smoking marijuana. The resulting high carboxyhemoglobin concentration may affect fetal oxygenation and, consequently, fetal growth and development.[1,214]

Pharmacology of Marijuana

The amount of systemically absorbed THC from a single inhaled dose is between 10% and 50% (mean, 18%). The bioavailability of an oral dose is 5 to 10 times lower.[215-218,218a] The peak plasma concentration after oral administration is attained within 45 minutes and remains relatively constant for 4 to 6 hours.[219] The peak plasma concentration after smoking marijuana is attained after 7 to 8 minutes. At 30 to 60 minutes from the initial time the user consumes the drug, tachycardia and euphoria occur.

THC is almost 100% protein-bound. The drug is highly lipid-soluble. Plasma levels decline rapidly after inhalation, and a slow elimination phase ensues.The volume of distribution is estimated to be 10 L/kg.[120] The elimination half-life in long-term users is 28±1 hours, compared with 57±4 hours in nonusers of marihuana (normal volunteers without previous exposure to cannabis preparations), primarily because of the faster metabolism of the long-term user.[219-222]

THC is converted almost entirely to the active metabolite 11-hydroxy-THC on first pass through the liver. The effect of the active metabolite is identical to that of the parent drug. This metabolite is subsequently biotransformed to inactive metabolites, which are excreted by the kidneys. Less than 1% of THC is excreted unchanged in the urine. Metabolites excreted in the bile can be reabsorbed. Fecal excretion is the major route of elimination for unconjugated cannabinoid metabolites.

Both animal and human studies[223-225] have shown that Δ^9-THC crosses the placenta. The maternal blood concentration of the drug is 2.5 to 6 times higher than that in fetal blood. Duration of exposure increases the fetal-maternal concentration ratio. In heavy users, an eight-fold accumulation of Δ^9-THC in breast milk over that in maternal plasma has been reported.[226,227] The nursing neonate can therefore consume Δ^9-THC from the mother's breast milk.

Effects of Marijuana Use on the Fetus and Neonate

As with other drugs of abuse, data collected from mothers who use THC must be interpreted cautiously, because these users may practice polydrug abuse and any self-reported statistics may be grossly inaccurate. In fact, polydrug use may account for the poorer prenatal care received by marijuana users.[228]

The effect of THC on pregnancy outcome has received much attention. Documented effects of cannabinoids on pituitary and ovarian function, prolactin secretion, hormonal activity, and uterine contractility have been amassed from animal and human studies.[229] No relationship between marijuana use during pregnancy and the length of gestation, duration of labor, or birth weight is evident.[230] Heightened tremors, abnormal startle responses, and altered visual responsiveness have been observed in neonates born to women who abused THC.

In a study of pregnancy course and outcome in 35 regular marijuana users and 36 age- and parity-matched nonusers,[231] the neonates of marijuana users exhibited a common tendency toward anemia, poor weight gain, and IUGR.The results were not statistically significant, however, which may be indicative of confounding variable clustering. A higher proportion of THC users (29 mothers) than of nonusers (3 mothers) experienced prolonged, protracted, or arrested labor.[231] These findings have been confirmed in other studies.[232-234] Marijuana abusers also exhibited a higher frequency of fetal distress and more often required manual removal of the placenta.[231] The course of labor appeared to be more hazardous in the THC user group than in the nonuser control group.[231]

Among THC users, meconium passage by the fetus, associated with an increased risk of neonatal death, was found to occur with increased frequency.[1,235] By contrast, Fried and associates[236] did not find any evidence to support increased prevalence of meconium staining among newborn infants of heavy marijuana users.

The effects of marijuana use during pregnancy on infant birth weight and length of gestation are controversial. In a study by Fried and colleagues,[232] neonates born to women who consumed marijuana six or more times per week during pregnancy demonstrated a significant reduction of 0.8 weeks in the length of gestation, after controlling for the effects of nicotine and alcohol, parity, maternal prepregnancy weight, and the gender of the infant. No reduction in the birth weight of these neonates was noted. In another study,[233] however, the investigators reported contradictory results: Reduced birth weight and no change in the length of gestation were associated with marijuana use. The difference between these two study outcomes may be attributed to the younger age and lower socioeconomic status typical of the latter study population. Moreover, it is possible that alcohol effects may have caused these minor differences, because many women abusing THC also consume large amounts of alcohol.[225,236]

Any association between minor physical anomalies and prenatal marijuana exposure is controversial. No difference was observed in the frequency of such anomalies in the children of

25 marijuana-using women and the children of 25 matched nonuser control subjects.[217] Similar observations have been reported in other studies.[237,238]

A link between prenatal marijuana exposure and the associated features of FAS has been demonstrated.[217,233,234,237] Thirty-one (2%) of 1384 neonates born to women who smoked marijuana had typical features of FAS. The likelihood of giving birth to an infant with manifestations of FAS is five times higher in cannabinoid users than in nonusers.

The Brazelton Neonatal Behavioral Assessment scale[239] was used to correlate smoking cannabinoids during pregnancy with a decrease in neonatal response to light directed at the eyes. Forty-six percent of the neonates born to users of cannabinoids did not respond to the light, in contrast with 16% of those born to matched nonusers.[240,241] Neonates born to methadone-using mothers showed a similarly poor visual response. In the infants with both marijuana and methadone exposure, the neonatal response to auditory stimulation was normal.[242,243] Other characteristic features seen in neonates born to heavy cannabinoid users include marked tremor, mainly around day 9 of postnatal life, and a startle reflex. Cortical electrical responses in the exposed neonates appeared to be slightly slower than those in age-matched control infants. Similar neonatal outcomes have been documented in cases of in utero exposure to alcohol and nicotine. Other visual abnormalities, including myopia, strabismus, and unusual appearance of the optic disks, occur at a higher frequency in marijuana-exposed (33%) versus nonexposed (6%) neonates.[244,245]

The findings of neurologic dysfunction could be interpreted as manifestations of neonatal drug withdrawal. In the adult population, however, abstinence after heavy THC use produces mild withdrawal reactions that encompass restlessness, sleeplessness, anorexia, nausea, vomiting, dreaming, and sweating.[1] Neonates exposed in utero to THC are not more irritable than neonates born to women in the non–marijuana-smoking control groups.[1] Few studies have studied the effects of prenatal marijuana exposure on academic achievement; results tend to be conflicting. As children grow, different variables such as socioeconomic status, the child's emotional well-being, social support, and family stressors may affect academic achievement. Therefore these factors have to be considered during evaluation of differences in prenatal drug exposure and academic performance. The Ottawa Prenatal Prospective Study (OPPS) suggested that prenatal cannabinoid exposure was not a significant predictor of performance in 5- to 6-year-old marijuana-exposed children, nor did it predict school achievement at the 6- to 9-year follow-up evaluation.[246] This study represents a lower- to middle-class population, however, in which the environment may ameliorate the effects of drug exposure.[246]

Goldschmidt and collegues[247] evaluated prenatal marijuana and alcohol exposure on school achievement at the age of 10 years. These investigators reported that daily exposure to one or more marijuana joints during the first trimester predicted deficits in Wide Range Achievement Test-Revised (WRAT-R) reading and spelling score and a lower rating on teacher evaluation of performance.[247] Second-trimester marijuana use was significantly associated with reading comprehension and underachievement, whereas third-trimester marijuana exposure was not associated with any change in the measures of academic achievement. This study was conducted in low-income women; the effects of marijuana use persisted even after institution of controls for confounding factors.[247]

Clinical Management of Marijuana Smokers During Pregnancy

Marijuana may be consumed concomitantly with multiple drugs and cigarettes, in which case treatment must be initiated to treat the deleterious effects of the more dangerous drugs and chemicals being used during the pregnancy. Education and support for pregnant marijuana smokers are paramount.

Opioids

Opiates are natural compounds derived from the opium poppy; *opioids* are synthetically derived analgesic compounds that have morphine-like pharmacodynamic activity. More than 500,000 opiate and opioid addicts live in the United States, of whom 70,000 are enrolled in methadone maintenance treatment programs.[248] Neonates exposed in utero to either heroin or methadone account for 3% to 5% of live births in New York City municipal hospitals.[248]

Heroin or diacetylmorphine is derived from morphine and produces pharmacologic effects identical to those of the parent drug. Heroin has a greater solubility and crosses into the CNS more rapidly than morphine, thereby making heroin the drug of choice among opioid addicts. Methadone is a synthetic opioid with a different chemical makeup from that of morphine, but it has nearly identical pharmacodynamic effects. Methadone is used in clinical medicine principally to treat heroin addiction[249] and to manage pain.

The abuse of oxycodone in the form of the controlled-release formulation (OxyContin) is a recognized public health issue and a focal point for law enforcement agencies.[250] Cicero and associates examined the prevalence and magnitude of abuse of prescription drugs in the United States using the Researched Abuse, Diversion, and Addiction-Related Surveillance (RADARS) system; drug abuse experts (e.g., pain and methadone health care specialists) were used as the source of data.[251] The results, showed, in rank order, that the prevalence of abused drugs was as follows: OxyContin > hydrocodone > other oxycodone > methadone > morphine > hydromorphone > fentanyl > buprenorphine; the magnitude of abuse (5 or more cases per 100,000 persons in a three-digit ZIP code area) was most pronounced with OxyContin and hydrocodone.[251] In a retrospective chart review of data for pregnant women conducted at the University of Kentucky Chandler Medical Center, OxyContin was mentioned most frequently in patient interviews, followed by, in order of decreasing frequency, Lortab or Lorcet (hydrocodone with acetaminophen), methadone, Percocet (oxycodone with acetaminophen), hydrocodone, and morphine.[252] The average dose of OxyContin was 154.1 ± 147.8 mg (n = 68).[252] The preferred route of administration was snorting (in 35.3% of patients), but the use of intravenous OxyContin was reported to be more widespread than it was 10 years earlier, probably because of the decreased amount of drug needed to produce euphoric effects and the associated lower cost.[252]

Lower socioeconomic class, a long history of drug abuse, frequent and multiple medical complications, poor diet, heavy smoking, and the concomitant use of alcohol, marijuana, cocaine, barbiturates, or tranquilizers are the characteristic hallmarks of opioid addiction. Adverse effects of heroin and methadone addiction are encountered frequently.

Pharmacology of Opioids

Opioids affect the activity of neurons involved with respiration, pain perception, and affective behavior. Morphine is an opioid analgesic that exerts its primary effect on the CNS and organs containing smooth muscle. The drug functions as an agonist at specific, saturable opioid μ receptors in these regions. Pharmacologic effects include analgesia, decreased gastric motility, suppression of the cough reflex, respiratory depression, CNS depression, nausea and vomiting, euphoria and dysphoria, sedation (fetal), mental clouding, and alterations of the endocrine and autonomic nervous systems.[253]

Morphine is readily absorbed by the gastrointestinal tract and undergoes significant first-pass metabolism in the liver. The oral

bioavailability of morphine is less than 5% in most users. Peak blood concentrations after intramuscular or subcutaneous injection are attained within 30 minutes. Tissue concentrations are quite low within 24 hours after the last dose, because morphine does not persist in the tissue for extended periods.

The elimination half-life of morphine in adults is between 2 and 3 hours (mean, 1.9 ± 0.5 hours). Significant variation is reported in the mean duration of action, with values ranging from 2.5 to 4.2 hours. Morphine is 35% ± 2% protein-bound,[254] and the clearance of the drug is 2.02 L/hour/kg in healthy young adults and 1.66 L/hour/kg in elderly patients.[255] The elimination half-life of morphine in neonates is between 6 and 14 hours.[256-258] The neonatal clearance of morphine is 1.43 L/hour/kg.[258-261] Published information on the oral bioavailability of morphine in neonates is lacking. However, the neonatal bioavailability of morphine probably is incomplete, as it is in older children.[256]

Approximately 10% of an administered dose of morphine is excreted through the bile; the remainder is excreted in the urine as a glucuronide conjugate. Morphine is metabolized primarily by glucuronidation. Glucuronic acid conjugation of the phenolic hydroxyl group by uridine diphosphate–glucuronyltransferase causes the conversion of morphine into morphine-3-glucuronide (M3G), morphine-6-glucuronide (M6G), and normorphine. Although M3G is quantitatively the major metabolite, M6G is up to 40 times more potent than the parent compound and is thought to be the substance responsible for the analgesic properties of morphine. Morphine is *O*-methylated to produce codeine. Heroin is deacetylated to form morphine and 6-monoacetylmorphine (6-MAM). 6-MAM has been shown to be pharmacologically equipotent to heroin. It is thought that the characteristic pharmacodynamic effects of heroin are mediated by 6-MAM and morphine. Morphine, heroin, and methadone cross the placenta by simple diffusion.

Methadone is well absorbed from the gastrointestinal tract; peak plasma concentrations are attained within 4 hours. No good correlation has been found between plasma levels and analgesia.[262] A plasma level of 211 mcg/L has been associated with the best rehabilitation results in patients receiving methadone maintenance therapy.[263] The oral bioavailability of methadone is 92% ± 21%,[254] and the drug is 89% plasma protein-bound. Methadone has a volume of distribution of 3.8 ± 0.1 L/kg and a clearance of 0.08 ± 0.03 L/hour/kg. The clearance of methadone may increase during pregnancy. A study from the United Kingdom measured plasma methadone concentrations to investigate the rate of clearance of methadone prescribed for heroin dependence in the first, second, and third trimesters of pregnancy. The weight-adjusted clearance rates gradually increased from a mean of 0.17 to 0.21 L/hour/kg as the pregnancy progressed.[264] The drug is metabolized to form pyrrolidines and pyrrolines, which are excreted in the urine and bile; 24% ± 10% is excreted in the urine unchanged.[254] The elimination half-life is longer for methadone than for morphine (14.3 hours for the α phase and 54.8 hours for the β phase,[265] versus 6 to 14 hours for morphine), and methadone also causes less sedation and euphoria. Nausea and vomiting are rare.

Oxycodone is a semisynthetic opioid analgesic that is available in immediate- and controlled-release formulations. The drug has a half-life of 4 to 6 hours, a volume of distribution of 1.8 to 3.7 L/kg, and an oral bioavailability of 0.42 to 0.45.[266] Peak plasma concentrations in nine volunteers who received a large oral dose of 0.28 mg/kg had an average of 0.038 mg/L at 1 hour after administration; the elimination half-life averaged 5.1 hours.[267] Average peak plasma concentrations in adults (N = 28) given a single 20-mg prolonged-release tablet were 0.023 mg/L for oxycodone at 3.2 hours, 0.015 mg/L for noroxycodone at 4.3 hours, and 0.001 mg/L for oxymorphone at 4.5 hours.[268] In naltrexone-blocked volunteers, in whom enhanced absorption would be expected, single doses of 40 and 80 mg in controlled-release tablet form produced a mean area under the curve (AUC) (in nanograms × hour per milliliter) (with % coefficient of variation), C_{max} (in ng/mL), and T_{max} (in hours) of 423.1(33.3) and 1085.5(32.3), 39.3 (34.0) and 98.5 (32.1), and 3.1 (77.4) and 2.1 (52.3), respectively.[269] Oxycodone is metabolized by *N*- and *O*-demethylation to oxymorphone, a potent analgesic, and to the relatively inactive metabolite noroxycodone.[266] Between 33% and 61% of a single dose of oxycodone is excreted in a 24-hour urine collection as free (13% to 19%) and conjugated oxycodone (7% to 29%), conjugated oxymorphone (13% to 14%), and an unknown amount of noroxycodone.[266]

In a study of 22 infants undergoing surgery,[270] oxycodone pharmacokinetics were characterized after administration of an intravenous bolus dose of 0.1 mg/kg oxycodone HCl. Infants were stratified by age: younger than 1 week (n = 10), 1 week to 2 months (n = 6), and 2 months to 6 months (n = 6). The median results (with range) for clearance were 9.9 (2.3 to 17.2), 20.1 (3.7 to 40.4), and 15.4 (14.8 to 80.2) mL/min/kg, respectively.[270] Volumes of distribution at steady state were 3.3 (1.9 to 4.7), 5.6 (1.3 to 8.5), and 3.2 (1.8 to 6.0) L/kg, respectively, and the elimination half-lives were 4.4 (2.4 to 14.1), 3.6 (1.6 to 11.6), and 2.0 (0.8 to 3.9) hours, respectively.[270] Clearance and half-life were correlated with age (p <.05).[270] Variation in the results probably is due to the time required for demethylation mechanisms to mature in the newborn. These data indicate that there is large intraindividual oxycodone pharmacokinetic variability in the newborn; the dose of oxycodone should be titrated on an individual basis.

Effects of Opioid Use on the Fetus and Neonate

A significantly lower birth weight, shorter length, and smaller head circumference have been observed in neonates who have been exposed in utero to heroin or methadone.[271] The effects on infant growth variables are thought to be a direct result of fetal opioid exposure. These infants catch up in weight and length by 1 year of age. The head circumference of the opioid-exposed infant does not exhibit catch-up growth to an appropriate size for age until at least the age of 2 years.[1]

Early stunting of growth may be a direct effect of methadone on the hypothalamic-hypophyseal axis of the neonate.[272] Neonatal recovery is associated with decreased methadone plasma and tissue concentrations.

Growth restriction in infants born to heroin addicts is attributable mainly to a decrease in cell numbers.[180] Neonates born to women addicted to heroin alone and to the combination of heroin and methadone had mean birth weights of 2490 g and 2535 g, respectively.[273] Neonates in the control group born to women who did not use heroin or methadone had a mean birth weight of 3176 g. In heroin- and methadone-addicted mothers, a higher incidence of SGA neonates (35% and 22%, respectively) has been reported.[274] By contrast, a lower incidence of SGA (16.5%) was reported in 830 neonates born to drug-addicted women.[275] A 20% incidence of Apgar scores less than 7 at 1 minute post partum has been documented for neonates of "drug-addicted" or heroin- or methadone-addicted women, representing a two-fold higher incidence over that of infants in the control groups. A similar trend in Apgar scores has been reported at 5 minutes post partum.[273,276] These findings have been recently confirmed by an Australian group of investigators who completed a retrospective audit of obstetric and perinatal outcomes in women who had used opiates during pregnancy. Infants exposed to opiates were more likely to be born before 37 weeks of gestation, have birth weights of less than 2.5 kg, be SGA, and require admission to special care units (i.e., neonatal intensive care units) and resuscitation.[277] In addition, a two-fold increase in premature deliveries over a 10-year period was observed in a series of 384 neonates born to heroin-addicted mothers.[278] The incidence of premature deliveries was only slightly higher (7%) in methadone-addicted

mothers.[215] Premature delivery (29%) was confirmed by Fajemirokun-Odudeyi and collegues[279] in a study of 108 heroin-addicted women. This study also suggested that compared with babies of women who used only methadone, babies of women who used heroin in late pregnancy experienced a more severe neonatal abstinence syndrome (NAS) and required longer hospital stays.[279]

Infants born to heroin addicts exhibit a lower incidence of hyaline membrane disease than those born to nonaddicted women.[280] Opioids such as heroin may induce enzymes to accelerate the production of pulmonary surfactant in the fetus. In neonates exposed to opioids during pregnancy, a shift to the right in the oxyhemoglobin-dissociation curve is noted for umbilical cord samples, and 2,3-diphosphoglycerate concentrations in the neonatal red blood cells are increased.[281] 2,3-Diphosphoglycerate decreases fetal hemoglobin affinity for oxygen. Therefore the enhanced ability of red blood cells to deliver more oxygen to the tissues may contribute to the decreased incidence of hyaline membrane disease. Moreover, neonates exhibiting heroin withdrawal symptoms and signs have respiratory alkalosis in the first few days of life. This may be another protective mechanism, because acidosis is a predisposing factor for development of respiratory distress syndrome. In the first 3 days of neonatal life, a less common severe hyperbilirubinemia occurs in neonates of opioid-addicted women.[274,282]

The incidence of SIDS is increased 5- to 10-fold in neonates born to opioid-addicted women.[283,284] However, an association between SIDS and prenatal opioid exposure has not yet been clearly established, primarily because no comparative drug study has been conducted, other than studies of the opioids used by pregnant women. For neonates exposed to opioids in utero, it may be prudent to initiate cardiorespiratory monitoring. Moreover, neonates with apnea may benefit from administration of 1.5 mg/kg of theophylline (Theo-Dur) every 6 hours.[285] In a study of 1760 cases of SIDS,[286] the risk ratio for SIDS was 3.6 for methadone, 2.3 for heroin, 3.2 for methadone plus heroin, and 1.1 for cocaine plus methadone or heroin consumption (after controlling for associated high-risk confounding variables). Despite the consensus linking maternal opioid use to SIDS, no proof of causation has been developed. The most plausible hypothesis suggests that morphine and related opioids reduce brain stem responsiveness to carbon dioxide[287] and depress the pontine and medullary centers that control respiratory rhythmicity.[288] Most of these data, however, are derived from adult studies. Studies of the prolonged effects of opioids on infants after intrauterine exposure are scarce. In one such study, Olsen and Lees[289] examined the ventilatory response to carbon dioxide in nine methadone-exposed neonates and four control neonates. The investigators showed a minimal response to carbon dioxide in drug-exposed neonates during the first 4 days of life that persisted for an average of 15 days. No relationship was evident between ventilatory response and the maternal dose of methadone, serum methadone half-life, or the need to treat for neonatal abstinence.

A weaker link between maternal opioid use and neonatal SIDS was postulated by Naeye,[290] who suggested that infants dying of SIDS actually were suffering from chronic hypoxia and chronic hypoxemia. The tissue markers noted during autopsies that support this postulate are listed in Box 26-2.[290] None of these markers, however, has been specifically studied in opioid-exposed neonates who died of SIDS. In addition, no evidence exists to indicate that chronic postnatal hypoxia occurs in such infants.[87] Prenatal growth restriction and meconium staining are considered hallmarks of fetal hypoxia and have been observed in neonates exposed to heroin.[291] Hence predisposition of the neonate to SIDS may be the result of opioid-induced chronic intrauterine hypoxia, causing damage to the brain centers regulating respiration—consistent with the brain stem gliosis described by Naeye.[87]

BOX 26-2

Tissue Markers of Chronic Hypoxia and Hypoxemia in Infants Dying of Sudden Infant Death Syndrome

- Carotid body gliomic tissue changes
- Increased tissue in the adrenal medulla
- Abnormal gliosis in brain stem centers controlling respiratory drive
- Thickened pulmonary arterial walls
- Increased weight of the right cardiac ventricle
- Retention of periadrenal brown fat
- Increased hepatic erythropoiesis

Developmental outcomes were unfavorable for infants of drug-dependent mothers (IDDMs) who used heroin or heroin and methadone in combination during pregnancy compared with the developmental outcomes of infants of mothers who were not drug-dependent or infants in the general population.[292] Unfavorable outcomes in IDDMs were: decreased gestational age at birth and lower birth weight; impaired physical growth, neurologic development, and intelligence; abnormal behavior and social competency; and disturbed social state (e.g., foster care). Prenatal care with social support and methadone substitution were critical factors for favorable outcome. IDDMs in foster care exhibited even more unfavorable outcomes than those for children living with their biologic parents.[292]

In a study that used the Brazelton Neonatal Behavioral Assessment scale,[271] opioid-exposed neonates exhibited significant impairment of interactive abilities, motor maturity, and organizational response compared with their nonexposed counterparts. These neonates were more irritable and tremulous compared with control neonates, who were not exposed to prenatal opioid consumption. Opioid-exposed neonates also demonstrated deficits in general cognitive abilities and in visual, auditory, and tactile perception. Mothers of neonates exposed to methadone have noted sleep disturbances in their infants.[293] These disturbances include irritability, excitability, inability to nap, and various other sleep irregularities. A significant reduction in the complications attributable to opioid abuse was demonstrated when addicted, pregnant women were given comprehensive care that included enrollment in a methadone maintenance regimen of 20 mg/day or less.[294]

Rates of malformation in infants of opioid users typically are no different from those of control groups. In addition, no homogeneous pattern of malformation has been established. Nevertheless, in a study of 830 opioid-exposed neonates, 2.4% demonstrated major malformations, compared with 0.5% in a control group.[273] The findings of this study should be viewed with caution, however, because the rates of major malformation are known to range between 1% and 3% in the general population. In another study, Harper and associates[282] found malformations in 5.9% of neonates born to women in a methadone treatment program. These figures may not represent an increased risk, however. Several other studies[274,295] failed to demonstrate an increased risk for malformations in neonates prenatally exposed to opioids.

No increased frequency or discernible pattern of teratogenic effects has been observed in infants born to women abusing heroin.[296,297] In reports implicating heroin in congenital anomalies, the findings have been questioned, because the patient population was poorly defined for confounding variables such as polydrug use by the pregnant women. Low birth weight and an increased incidence of meconium staining were reported as perinatal adverse effects associated with maternal heroin use. After prolonged and continuous heroin use by the mother during

pregnancy, narcotic withdrawal occurs in many neonates. Strabismus has been observed in 24% of drug-exposed neonates (including those exposed to opioids), compared with 2.8% to 5.3% in the general population.[298,298a]

Morphine is believed to be excreted into breast milk in small, clinically insignificant amounts.[299] Despite the widespread licit and illicit use of morphine, information on exposure to the drug through breast milk is very limited. With the advent of highly sensitive radioimmunoassays and specific high-performance liquid chromatography (HPLC) analytical techniques, new data are becoming available to discern morphine kinetics in the nursing neonate. Robieux and colleagues[300] presented a case report of a nursing woman with systemic lupus erythematosus who was receiving morphine therapy to treat severe arthritic back pain. The neonate had a morphine plasma concentration of 4 ng/mL; breast milk concentrations ranged from 10 to 100 ng/mL. The dose needed to achieve the observed morphine plasma concentration in the infant was calculated to range between 0.8% and 12% of the maternal dose. This case demonstrates that neonates experience significant exposure to morphine even when the mother receives morphine at low doses.

For mothers being treated with methadone, the amount of methadone that passes into the breast milk is small (2% to 4%).[301] Methadone reaches its maximum levels 2 to 4 hours after maternal dosing. Even at this low level of exposure, a baby can experience withdrawal. Breast-feeding on a regimen of medium to high doses of methadone probably is safe according to conventional criteria, because the dose is less than 10% of the relative infant dose.[301] Because the absolute dose of methadone received by the infant is dependent on the maternal dose, however, the risk-benefit ratio should be considered in each case. The dose of methadone received in breast milk is unlikely to be sufficient to prevent drug-induced NAS. The benefits of breast-feeding outweigh the risks associated with subsequent withdrawal.[301]

Oxycodone is excreted into the breast milk and has a milk-to-plasma ratio of 3.4:1. Maternal use of this drug is classified as a pregnancy risk factor B (risk factor D if the drug is used for prolonged periods or in high doses at term).[302] In a recent study, Seaton and colleagues[303] investigated the relationship between maternal ingestion of oxycodone after cesarean section and the resulting maternal plasma, breast milk, and neonatal plasma drug concentrations up to 72 hours postpartum. The results showed that oxycodone administered at any dose in a 24-hour period was detectable in the breast milk, with a significant correlation between maternal plasma and milk levels ($R^2 = 0.81$); this correlation decreased (to $R^2 = 0.59$) over the next 48 hours.[303] The milk-to-plasma ratio was 3.2:1. Oxycodone levels up to 168 ng/mL were measured in the breast milk, but only 1 neonate ($n = 41$) had oxycodone detected in the plasma.[303]

Neonatal withdrawal syndrome is evident primarily after maternal heroin and methadone abuse during pregnancy. The syndrome also can manifest after prenatal codeine, pentazocine, and propoxyphene exposure. The signs and symptoms are similar but are more frequent and more severe in methadone-exposed neonates than in newborn infants of heroin-addicted women.[274,304] The amount of methadone consumed by the mother appears to correlate with the severity of the ensuing neonatal withdrawal syndrome. Although the time to onset of signs and symptoms may vary, ranging from minutes to 2 weeks post partum, in most neonates, withdrawal manifests within 48 hours. The duration of acute neonatal withdrawal ranges from a few days to several weeks.[216] CNS excitation, altered gastrointestinal tract function, respiratory distress, and autonomic symptoms characterize the neonatal opioid withdrawal syndrome. Irritability is the most common manifestation, followed by tremors and hypertonicity. Seizure activity may appear between 3 and 34 days post partum in 2% to 11% of addicted neonates.[305] Neonates born to opioid-addicted women occasionally demonstrate seizure activity.[305] It appears that the incidence of seizure activity is higher in methadone-exposed neonates than in those exposed to heroin.

Neonates exposed to low doses of morphine in utero or through breast milk may not always exhibit the morphine withdrawal syndrome. The reason for this lack of the syndrome may be the extended half-life of morphine during early life, which results in a slow decline in the concentration of morphine in neonatal plasma.[258] Alternatively, the neonate may have developed tolerance to the opioid after long-term exposure in utero and throughout the breast-feeding period.[300] Rao and Desai reported a case in which a neonate was diagnosed with withdrawal signs and symptoms after maternal OxyContin use; presence of the oxycodone metabolite oxymorphone was measured by gas chromatography–mass spectometry (GC-MS) opiate analysis.[306] Treatment consisted of administration of paregoric followed by chloral hydrate.

The Collaborative Perinatal Project[306a] found no evidence to suggest a relationship between first-trimester oxycodone exposure and large categories of major or minor malformations or to individual defects. Other data also do not support an association between oxycodone and congenital defects.[302] Additional work is needed to determine the effects, if any, of in utero exposure to oxycodone.

Clinical Management of Opioid-Addicted Women and Neonates

Mild withdrawal from opioids usually does not necessitate treatment. The treatment of neonatal withdrawal syndrome is primarily symptomatic. Symptomatic neonates may require pharmacologic intervention. Pharmacologic preparations used to treat neonatal withdrawal include diluted tincture of opium (DTO), paregoric (camphorated tincture of opium), morphine (Astramorph), methadone (Dolophine), diazepam (Valium), chlorpromazine (Thorazine), phenobarbital (Barbita), and clonidine (Catapres).[307-309]

The American Academy of Pediatrics recommends the use of DTO for NAS that is due to opioid withdrawal.[310] Many neonatal intensive care units use oral or intravenous morphine solutions; methadone also is used in the treatment of neonates withdrawing from opioids.[311] In a small case series of inpatients, methadone at a dose of 0.1 mg/kg three times a day was found to reduce peak Finnegan scores (neonatal abstinence syndrome scoring system) faster than tincture of opium administered at 0.1 mg/kg every 3 hours.[312] Paregoric was prominent in earlier reports of treatment of infants exposed to opioids but is now less frequently used, probably because of the potential hazards of the added preservatives.[313,314] Phenobarbitone frequently is used for management of polydrug NAS and is a second-line agent for treatment of opioid withdrawal.[311] Controlled trial data supporting the efficacy of any one agent are limited; the evidence is weakened by the methodologic quality of published trials. Opioid-related NAS, however, is best treated with opioids.[310,315,316]

A recent survey, showed that opioid medications are the most commonly used drugs for the treatment of opioid and polydrug withdrawal.[311] The results of a recent double-blind, randomized trial of morphine versus phenobarbitone support the use of opioids in the treatment of opioid-related NAS.[317] Infants treated with morphine had a shorter duration of treatment, reduced frequency of admission to the neonatal intensive care unit, and a reduced need for the use of second line treatments.[317] Pacifico and co-workers showed that morphine given as a single agent relieved opioid-related NAS symptoms better than did a combination of phenobarbitone and diazepam or a combination of morphine, phenobarbitone, and diazepam.[318] Morphine mixtures of variable strength also are frequently used to treat opioid-related NAS because of the short half-life of morphine.[314]

Paregoric contains 0.4 mg/mL of anhydrous morphine and is therefore a more physiologic substance because it substitutes

for the drug that is causing the withdrawal symptoms. The recommended dose for full-term neonates is 0.2 to 0.5 mL (0.08 to 0.20 mg of anhydrous morphine) administered orally every 3 to 4 hours until the signs and symptoms are well controlled.[319] The initial paregoric dose is dependent on the severity of the withdrawal symptoms. The severity is assessed based on the Finnegan Scoring System.[320] If within 4 hours no clinical improvement is observed, the paregoric dose is increased by 0.05 mL every 4 hours until it has an effect (Finnegan score ≤4). When the withdrawal score is sustained for 48 hours, the total daily dose of paregoric should be reduced by 10% each day while a constant dosing interval is maintained. The recommended dose for paregoric in premature infants is 0.05 mL/kg every 4 hours initially, with increments of 0.02 mL/kg every 4 hours until symptoms are controlled. Neonates treated with paregoric exhibited more physiologic sucking patterns, higher caloric intake, better weight gain, and improved control of seizure activity and gastrointestinal disturbances in comparison with neonates who were treated with phenobarbital.[309,321]

Overall, the opioid paregoric appears to be more effective than diazepam, phenobarbital, or paraldehyde in ameliorating withdrawal. In a clinical trial in which infants were randomly assigned to receive either paregoric or phenobarbital,[307] however, no significant difference in clinical efficacy was found between these two agents. The advantages of using phenobarbital to treat neonatal withdrawal include the drug's ability to mitigate signs and symptoms referable to the CNS and its safety. Phenobarbital is safer than an opioid[322] when sedation is required. The disadvantages include the inability to titrate the dose because of the long elimination half-life, the presence of other chemicals in the formulation, and the lack of standard dosing guidelines for phenobarbital. A chart review comparing paregoric and methadone for the treatment of neonatal opioid withdrawal showed no difference in outcome measures (time to resolution of withdrawal symptoms, rate of decrease in symptom severity, and length of hospitalization) between the two drugs; rates of adverse events were similar.[323]

Clonidine has been used in pediatrics to treat postoperative withdrawal from long-term opiate administration.[324,325] In a single, small case series reported in the literature, seven methadone-exposed infants were treated with 3 to 4 mcg/kg/day; six of the infants responded.[326] Clonidine may cause profound hypotension; additional work with this agent is required to determine its utility in treating NAS.[314] In a small case series study, diazepam was investigated in the treatment of NAS. Treatment of 23 infants born to opioid-dependent women treated over 7 days resulted in birth weight recovery by postpartum day 10; mean weight loss was 6.5%.[327] Most of the mothers in this study were polydrug users, with drugs of abuse including alcohol, cocaine, and benzodiazepines. The success of diazepam may have been due to its blocking of effects of the nonopioid drugs. Kron and colleagues,[328] however, found that diazepam significantly depressed sucking rate, nutritive consumption, and percentage of sucking time when compared with phenobarbitone. Further study of diazepam for this indication is required.

The duration of therapy is dependent on the severity of the maternal addiction and the duration of fetal exposure. A treatment regimen spanning 10 to 20 days is required in approximately 50% of opioid-exposed neonates. Another 25% require treatment for a longer duration, and the remaining 25% require a shorter course of treatment.[329] A significantly longer period of active treatment is required with use of paregoric than with use of phenobarbital, probably because of the longer half-life of the latter drug.

In the management of addicted women during pregnancy, the clinician must be acutely aware that two patients are actually being treated. Therefore a treatment regimen must be chosen that maximizes the benefits for both mother and fetus. In late pregnancy, abrupt maternal withdrawal may be accompanied by fetal withdrawal, typically characterized by hyperactivity, hypoxia, passage of meconium, and death.[330,331] Opioid antagonists such as naloxone (Narcan) should be administered to the pregnant woman only if she experiences a life-threatening overdose. Naloxone crosses the placenta to exert its antagonist effects on the fetus, thereby potentially exacerbating the withdrawal reaction in the neonate.

Heroin addicts should be encouraged to enroll in a methadone maintenance program.[332] Methadone treatment during pregnancy offers overwhelming advantages over the less acceptable option of medical detoxification or the unacceptable option of leaving heroin-addicted women dependent on street drugs. Methadone suppresses withdrawal symptoms and, in high doses, may block the opioid effect. In addition to decreasing illicit drug use, these programs improve fetal and subsequently neonatal outcome. An obstetrician who is skilled in monitoring high-risk pregnancies should be part of the maternal treatment team because of the potential adverse effects on the fetus attributable to maternal detoxification. With an accumulated experience of over 25 years, methadone maintenance has been shown to be invaluable and essential in improving the health of women during pregnancy, in improving the outcomes of these pregnancies, and in offering opiate-addicted women a chance to improve both their own lives and the lives of their families.[333]

Psychotherapeutic Drugs

The psychotherapeutic drugs include amphetamines, sedatives, tranquilizers, and analgesics. On the basis of the results of the National Pregnancy and Health Survey,[4] it was estimated that 1.5% of women using some illicit substance in the United States during pregnancy used psychotherapeutic drugs. The nonmedical use of these agents was highest among black women (3.1%), followed by women of Hispanic descent (1.8%) and white women of non-Hispanic origin (1.1%).

Benzodiazepines are widely used for therapeutic reasons and frequently are consumed by polydrug users.[334] Abuse of the benzodiazepines in high doses is not as common as it has been, but some women have been maintained on long-term therapeutic doses for many years. Because of the limited availability of these drugs, abuse of barbiturate and nonbarbiturate hypnosedatives also is not as prevalent as was described previously. These drugs include chloral hydrate (Noctec), glutethimide (Doriden), meprobamate (Equanil), and methaqualone. Butalbital (Fiorinal) is the only frequently abused barbiturate.[335] It is available only as a proprietary combination of aspirin and caffeine with or without codeine.

Use of methamphetamine, the most commonly abused type of amphetamine in pregnant women, is increasing in the United States. A recent study, primarily evaluating methamphetamine use in pregnant women, reported that 10.7% of mothers have used illicit drugs during pregnancy.[336] Amphetamine levels are found in approximately 2% of cases amassed from small, random analytical surveys of emergency department toxicology screens.[337] Illicit amphetamine formulations vary dramatically in potency and purity.[338]

Pharmacology of Psychotherapeutic Drugs

Benzodiazepines are weakly basic drugs absorbed most effectively at the high pH found in the duodenum. The oral absorption of diazepam and desmethyldiazepam, the active metabolite of clorazepate, is faster than that of the other benzodiazepines. Oral absorption is extremely rapid for triazolam. After intramuscular injection, the bioavailability of several benzodiazepines, including chlordiazepoxide and diazepam, may be unreliable. The barbiturates are weak acids that are very rapidly absorbed into the blood from the stomach and small intestine.[339]

The benzodiazepines and other sedative-hypnotic drugs cross the human placenta, thereby exposing the fetus. The rate at which the maternal and fetal blood concentrations equilibrate is slower than the rate at which the maternal blood and CNS equilibrate, partially because of the lower blood flow to the placenta.[339] Benzodiazepines are highly plasma albumin–bound; binding ranges from 60% to more than 95%.

The elimination of benzodiazepines occurs through hepatic metabolism. Most benzodiazepines undergo microsomal oxidation reactions such as *N*-demethylation and aliphatic hydroxylation. The metabolites are conjugated by glucuronosyltransferase to form glucuronides, which are excreted in the urine. Many benzodiazepines have pharmacologically active metabolites. A wide range (12 to 150 hours) in elimination half-life has been documented for the various benzodiazepines. Only insignificant amounts of barbiturates (except phenobarbital) are excreted unchanged. The major barbiturate metabolic pathway involves oxidation by hepatic enzymes. Few barbiturate metabolites are pharmacologically active. The elimination half-life of the barbiturates ranges from 18 hours (secobarbital and pentobarbital) to 4 to 5 days (phenobarbital).[339]

After an oral dose of 10 to 25 mg, peak plasma levels of amphetamines occur within 1 to 2 hours. Protein binding ranges between 15% and 34%, depending on the specific drug.[340] Amphetamines are rapidly absorbed from the gastrointestinal tract, and absorption usually is complete within 4 to 6 hours.[340] A consideration in polydrug users is that amphetamines decrease gastric emptying and intestinal motility, thereby extending the time for absorption of other drugs as they pass through the stomach and intestines. The elimination half-life of amphetamines is in the range of 8 to 12 hours after therapeutic dosing, and 18 to 24 hours after abusive consumption. Amphetamines are metabolized by deamination to form phenylacetone, which is subsequently oxidized to benzoic acid and excreted as a glucuronide conjugate.[341] β-Hydroxylation produces the active metabolite *O*-hydroxynorephedrine, which accounts for some of the drug's effects in long-term users.

Effects of Psychotherapeutic Drugs on the Fetus and Neonate

Increased risk of cleft lip and cleft palate after first-trimester exposure to benzodiazepines has been reported,[342,343] although a subsequent case-control study[344] did not confirm the initial observations. Late third-trimester use and exposure during labor may be associated with greater risk for the development of floppy infant syndrome or marked neonatal withdrawal symptoms and signs ranging from mild neonatal sedation, hypotonia, and poor suck to apneic episodes, cyanosis, and impaired metabolic responses to cold stress.[345] No specific neonatal abnormalities have been reported in cases of prenatal exposure to the newer benzodiazepines. A fetal benzodiazepine abstinence syndrome[346] was reported in seven cases; however, because of inadequate controls, a causative role remains speculative.[347] Published reports of human teratogenicity attributable to benzodiazepine use during pregnancy are lacking.[348] A meta-analysis of 23 studies (both cohort and case-control studies) pointed to an increased risk of congenital malformations associated with the use of benzodiazepines during the first trimester of pregnancy. Data from the cohort studies revealed no association between fetal exposure to benzodiazepines and the risk for oral clefting or development of any other malformations.[349] Data from case-control studies revealed a marginally significant two-fold increase in the risk for major malformations or oral cleft alone.[349] The case-control study populations were heterogeneous, however, thereby decreasing the reliability of the results. The absolute risk of clefts, if present, remains small (i.e., the incidence of oral clefting in the general population is approximately 1 per 1000).[349] No reports of long-term adverse effects on the neurodevelopment of children born to mothers who took benzodiazepines during pregnancy are found in the literature.[349]

Manifestations of neonatal benzodiazepine withdrawal, including seizures, are indistinguishable from those of narcotic or barbiturate withdrawal.[350] Neonatal withdrawal signs and symptoms have been reported even when the mother had received therapeutic doses of chlordiazepoxide[351,352] or diazepam,[346,353] with onset soon or several days after birth. Case reports also have described neonatal withdrawal from hydroxyzine (Atarax),[354] ethchlorvynol (Placidyl),[355] and glutethimide.[356] Withdrawal from these agents would not be unexpected. Because of maternal polydrug practices, however, withdrawal attributable to phenobarbital, diazepam, and heroin, respectively, cannot be excluded. An initial study[357] reported a three- to four-fold greater risk for development of cleft palate among neonates exposed in utero to diazepam. This observation was supported by other reports in the literature.[358,359] Neither Czeizel[360] nor Rosenberg and colleagues,[344] however, could confirm this association. Most of the studies from which conclusions were drawn were retrospective case-control studies that relied heavily on maternal recall. In a prospective study,[361] a diazepam-mediated cleft palate malformation was not demonstrated in neonates. Furthermore, prenatal exposure to triazolam and alprazolam in more than 600 cases was not associated with adverse neonatal outcome (data on file, Upjohn Pharmaceuticals, Kalamazoo, Mich).

Available evidence suggests that barbiturates are not teratogenic.[362] Nevertheless, the teratogenicity issue is not completely resolved. Butalbital and secobarbital have not been associated with congenital malformations. Information concerning amobarbital is controversial.

Neonates exposed in utero to barbiturates may exhibit the signs and symptoms associated with neonatal abstinence syndrome.[363-365] Desmond and colleagues[363] reported that all 15 neonates exposed prenatally to barbiturates or phenobarbital given for maternal treatment of anxiety, sedation as part of treatment of hypertension during pregnancy, or seizure control demonstrated hyperactivity, restlessness, disturbed sleep, and excessive crying, and most of the infants also were tremulous, hyperreflexic, and hyperphagic. The clinical manifestations of drug withdrawal appeared later (at approximately 1 week postpartum) in barbiturate-exposed neonates than in the narcotic-exposed group.[363] This delay is not unexpected because of the long β-elimination half-life of barbiturates. Women receiving secobarbital[364] and butalbital[365] also manifest barbiturate withdrawal. Neonates withdrawing from barbiturates can experience generalized seizures, in addition to exhibiting increased neuromuscular excitability.[366] Maternal abuse of phenobarbital during pregnancy has been shown to cause a hemorrhagic syndrome in neonates secondary to hypoprothrombinemia, interference with vitamin K metabolism, and platelet deficiencies.[367] Phenobarbital use during pregnancy increases the incidence of major malformations in neonates born to women with epilepsy.

Newborn infants of women consuming amphetamines during pregnancy have exhibited initial CNS hyperexcitability.[122] After the hyperexcitable state subsides, some infants manifest marked lethargy and require tube feeding. This state of profound lethargy is thought to be indicative of a true withdrawal syndrome, comparable with that observed during cocaine and methamphetamine withdrawal in the adult population.[368] Similar reactions in newborn infants of amphetamine-abusing women have been described.[369,370] Ramer[369] reported a case in which a neonate whose mother had been receiving parenteral amphetamine had episodes of diaphoresis, restlessness, and miotic pupils during the first day of life. By day 3, the infant was listless, with decreased muscle tone and a glassy-eyed stare. Symptoms and signs abated by postpartum day 9.

In a prospective study[362] examining 367 neonates exposed to amphetamine during the first trimester, no increased risk of

any malformation was found. Conversely, a retrospective study[371] found that congenital heart malformations were more prevalent when infants had been exposed prenatally to amphetamine. More recently, a multicenter longitudinal study was completed that assessed the neonatal effects of prenatal methamphetamine exposure. Infants in the methamphetamine-exposed group (84 subjects) were 3.5 times more likely to be SGA and to have lower birth weight than those in the unexposed group.[372] These findings suggest that prenatal methamphetamine use is associated with fetal growth restriction after adjustment for confounding factors.[372]

Clinical Management of Maternal Psychotherapeutic Drug Abusers and Exposed Neonates

A tapering regimen with diazepam obviates the drug concentration fluctuations that occur with short-acting benzodiazepines. In a socially stable woman, tapering may be achieved on 5 mg of diazepam per week, with weekly outpatient supportive counseling.[373] Abstinence usually can be achieved within 6 to 8 weeks. If the outpatient approach fails to result in abstinence, rapid diazepam tapering can be initiated in hospital. In cases of neonatal benzodiazepine withdrawal, 0.1 mg/kg intravenous diazepam every 12 hours is recommended.[350] Adjustments to the dosing interval and dose may be required to control neonatal withdrawal symptoms adequately.

Women consuming more than 400 mg of barbiturates per day are at risk for development of a withdrawal syndrome characterized by tonic-clonic seizures and delirium. These women should be admitted to the hospital for detoxification. Phenobarbital is the drug of choice, administered either on a tapering regimen[374] or by an oral loading technique.[375] Phenobarbital also is the drug used to treat neonates who exhibit signs and symptoms of barbiturate withdrawal.[350] Therapy should be initiated if the neonate manifests seizure activity, moderate to severe hyperreactivity, irritability, poor feeding, or failure to gain weight. An intravenous or intramuscular loading dose of 20 mg/kg, followed by intravenous or oral maintenance therapy at 4 mg/kg/day, should be administered.[350] The maintenance dose may be adjusted as necessary for effective management of symptoms and signs.[364] It is important to monitor serum phenobarbital concentrations to avoid toxicity. Once withdrawal symptoms have been effectively controlled for a period of 1 week, the dose can be reduced by 25% per week.[350]

CNS hyperexcitability associated with prenatal amphetamine exposure should be treated with benzodiazepines as necessary.[376] Withdrawal symptoms should be managed supportively.

SUMMARY AND CLINICAL IMPLICATIONS

Substance abuse is one of the major problems and challenges for society. Establishing the true prevalence of substance abuse among pregnant women is difficult. First, illicit drug use often occurs concurrently with licit drug use (e.g., cocaine plus alcohol). Second, obstetric complications of drug use may be complicated by coexisting factors such as a chaotic family environment or malnutrition. Third, social stigma continues to be attached to identified abusers, making women unwilling to admit alcohol and drug use, particularly during pregnancy.

Substance abuse during pregnancy is associated with significant maternal and fetal morbidity. The optimal management of pregnant, addicted women should be multidisciplinary, with input from obstetricians, pediatricians, midwives, social workers, drug counselors, and other related services professionals and agencies. Medical management of the infant should involve not only pharmacologic treatments but also assessment of parenting abilities, social support, and surveillance for transmission of infections. A multidisciplinary approach with active participation of social workers, physicians, and educators is critical for successful outcome.

27 Drug Excretion During Breast-Feeding

Michael J. Rieder

BREAST-FEEDING

The optimal feeding of human infants is with breast milk; in addition to providing psychologic benefits, breast-feeding is associated with a decreased risk for gastrointestinal and respiratory disease in infancy.[1-3] Breast-feeding has been demonstrated to be an effective part of programs to reduce neonatal mortality, and some data (albeit controversial) suggest that breast-feeding may influence ultimate neurodevelopmental outcome. Therefore promotion of breast-feeding is a major public health initiative worldwide.

The prevalence of breast-feeding among the mothers of newborn infants in the United States and Canada declined steadily from the beginning of the 20th century to 1970, falling from 70% in 1915 to the nadir of 25% in 1970.[4] Since 1970, breast-feeding among mothers of newborn infants increased steadily until 1984, when more than 60% of mothers breast-fed their newborns. Although a decline in breast-feeding in the United States was noted in the early 1980s (although breast-feeding of newborns continued to increase in Canada), recent data suggest that the number of American women who breast-feed has continued to rise, notably in the first 12 weeks post partum, and that numerous national and local initiatives have been implemented and appear to have increased the rate of breast-feeding.[5,6]

As noted, the optimal choice for feeding infants in the first 6 to 12 months of life is breast-feeding. Of major concern in this context ismore than 90% of women take medications during this time.[7,8] Many patients are aware of the possibility that medication taken by a lactating mother can pass into breast milk, from which it can be ingested by the nursing infant. Thus the potential effects of maternal medication transmitted in breast milk on nursing infants constitute an important clinical consideration.[4]

BREAST MILK

Composition

Breast milk is a complex fluid, the most abundant component of which is water, constituting on average approximately 88% of content.[9] Milk also contains carbohydrate (5.6% to 6.9%), lipids (3.4% to 4.4%), and protein (1.7% to 2.2%).[10-15] The main carbohydrate present in breast milk is the disaccharide lactose synthesized within the alveolar cell, with small amounts of α-glucosides present as well. The lipids in breast milk are almost entirely triglycerides, contained in fat globules surrounded by membranes formed from cellular material produced by the alveolar acini (98%). These membranes consist of a complex blend of phospholipids, glycolipids, triglycerides, cholesterol, and proteins, which act to emulsify lipids in the aqueous environment prevalent in breast milk. The most abundant fatty acids are oleic acid and palmitic acid, with relatively high concentrations of linoleic acid and linolenic acid. The protein in human breast milk is a mixture of casein, albumin, lactalbumin, immunoglobulins, and lysozyme with an aqueous whey-micellar casein ratio of 60-65:35-40. In addition to protein, human breast milk also contains nonprotein nitrogen in the form of free amino acids and small compounds such as urea, which make up approximately 25% of the nitrogen content of breast milk.

Breast milk is acidic with reference to plasma, the average pH of human breast milk being 7.08 (range, 6.35 to 7.65). A biphasic change in breast milk pH occurs over time. The pH of colostrum is 7.45; it falls to 7.0 in transition milk and then slowly increases to reach an average pH of 7.4 by age 10 months.[4,16] The pH of breast milk also changes during the course of feeding, foremilk (expressed during early feeding) having a more acidic pH (as well as a lower fat content) than that of hindmilk.

The composition of human breast milk is not uniform because the constituents of breast milk change over time and to some extent over the course of feeding, most markedly in the first several weeks of life. Colostrum, the first "milk" produced by a lactating mother, is produced in the first 4 or 5 days after birth; transition milk is then produced, followed at 2 or 3 weeks after birth by the production of mature milk.[17]

The protein content of breast milk is subject to changes in both concentration and content. Colostrum has a higher protein content than that of mature milk, primarily owing to increased immunoglobulin content, whereas the albumin content remains relatively constant.[18] Breast milk produced by mothers of preterm infants has much more protein and less lipid in comparison with breast milk produced by mothers of mature infants.[14] The differences between the milk produced by lactating mothers of term and preterm infants are most marked in the immediate perinatal period; changes lessen as time from delivery increases.[4] On average, the lipid content of breast milk tends to increase over time.[4]

A diurnal variation also has been noted in lipid and protein content of breast milk:The fat content and amount of breast milk per feed are highest in the morning and fall in the late evening.[19-21] Protein content reaches its nadir in the early afternoon.[20]

Production

Human breast milk is produced in the alveolar acini of mammary tissue located in the breast, in response to hormonal stimuli.[22] During gestation, estrogen and progesterone (regulated by follicle-stimulating hormone and luteotrophic hormone) stimulate the maturation of mammary tissue in the breast and inhibit milk production. The rapid decrease in estrogen and progesterone secretion immediately before parturition leads to loss of inhibition of milk production.[4] Infant suckling stimulates release of prolactin from the pituitary gland, which provides the principal stimulus for milk production and secretion.[23] Drugs containing estrogen and estrogen derivatives can inhibit breast milk production; commonly used oral contraceptives reduce the production of breast milk by 20% to 30%.

Alveolar cells are the component of mammary tissue that produces milk. Clusters of these cells are arranged around a central lumen. Milk flows down the lumen to the ducts, which join in increasing size to meet under the nipple. Milk flow from the acini to the nipple is promoted by oxytocin-mediated contraction of the myoepithelial cells surrounding the acini and ducts.[4]

A linear relationship exists between blood flow and milk production: As blood flow to the alveolar acini increases, so does milk production.[22] Average breast milk production by mothers of 6-month-old infants is approximately 800 mL/day (ranging from 600 to 1000 mL/day).[24-26]

PRINCIPLES OF DRUG EXCRETION INTO BREAST MILK

Many medications can be excreted into breast milk, thereby exposing the nursing infant. Drug exposure by this route requires three processes: transfer of the drug into breast milk, absorption of the drug from breast milk by the infant, and subsequent drug

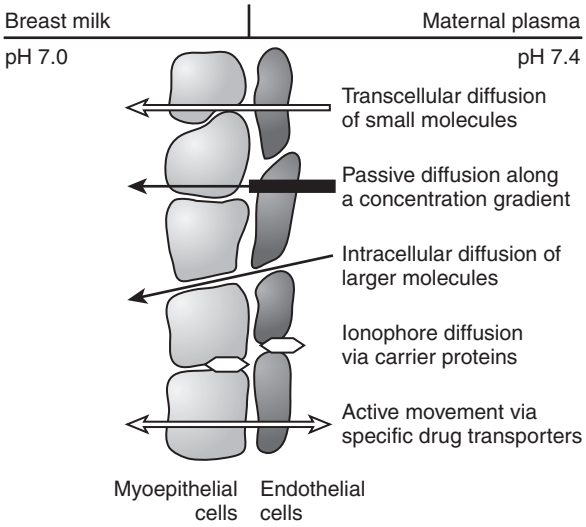

Figure 27-1 Steps involved in transfer of drugs into breast milk.

metabolism in the infant.[4,27] In most cases, drug transfer to breast milk requires the presence of the drug in the maternal circulation.[4,28] The only exception to this rule is with use of a topical agent applied to the nipple or areola, in which case direct transfer of the drug into breast milk may occur.[29] This is an uncommon but nonetheless potentially important mode of drug exposure.

Transfer of Drug From the Maternal Circulation Into Breast Milk

Drugs enter breast milk through the alveolar acini in the mammary gland. Major determinants of the amount of drug transferred to breast milk are maternal serum drug concentration and the physicochemical nature of the drug. Most drugs taken by lactating women are given orally, although less commonly, drugs may be given by the intravenous, topical, or aerosol route. The steady-state drug concentration in the maternal circulation is determined by the balance of drug absorption, distribution, metabolism, and excretion (Figure 27-1).

Drugs can be transferred from and to the maternal circulation to breast milk by several mechanisms (see Figure 27-1)[27]:

- Transcellular diffusion of small molecules, which are nonionized and have high lipid solubility, such as ethanol, for which plasma and breast milk concentrations are similar[27,30]
- Intercellular diffusion of drugs that pass between alveolar cells—possibly accounting for the passage of larger molecules, such as immunoglobulins, into breast milk[27]
- Passive diffusion along a concentration gradient
- Ionophore diffusion of polar substances by binding to carrier proteins[27]
- Active movement of specific compounds by specific drug transporters

Of note, diffusion of drugs into breast milk is a bidirectional process: Not only can drugs diffuse into breast milk from plasma, but they also can transfer from breast milk back into plasma. In addition, the principles of drug transfer into and out of breast milk apply equally to drug metabolites. In most instances, it appears that the passage of drugs from the maternal circulation to breast milk occurs by passive diffusion down a concentration gradient. This concentration gradient is across the capillaries feeding the alveolar acini and into the alveolar cells. To cross from the circulation into the alveolar acini, a drug must be present in the maternal circulation in an unbound, nonionized form. Therefore the concentration driving diffusion of drugs from the maternal circulation into breast milk is that of the free fraction of drug in the circulation.

For example, propranolol is highly protein bound, so a relatively smaller amount is available as free drug.[31] In addition, the plasma protein binding of some drugs changes during pregnancy; a decrease in the plasma protein binding of sulfisoxazole, phenytoin, diazepam, and dexamethasone occurs during gestation, with a return to prepregnancy values at 1 to 2 months after delivery of the infant.[32] Drug passage across lipid membranes by passive diffusion is a function of molecular size and lipid solubility. In order for a drug to diffuse from the maternal circulation to the acinar cells, it must be in the nonionized form.

Because most drugs are weakly acidic or basic, drug partitioning between blood and breast milk is at least partially dependent on pH.[4,33-36] The ratio of the amount of drug present in milk to the amount present in plasma, the M/P ratio, can be estimated by the following equations[4]:

For drugs that are weak acids:

$$\text{M/P ratio} = 1 + 10^{(\text{pH}_m - \text{p}K_a)} / 1 + (\text{pH}_p - \text{p}K_a)$$

For drugs that are weak bases:

$$\text{M/P ratio} = 1 + 10^{(\text{p}K_a - \text{pH}_m)} / 1 + 10\,(\text{p}K_a - \text{pH}_p)$$

where pH_m = the pH of breast milk, pH_p = the pH of plasma, $\text{p}K_a$ = dissociation constant, and $\text{p}K_a$ = the $\text{p}K_a$ of the drug of interest.[4] For acidic drugs, the lower pH of breast milk (versus plasma) leads to presence of a larger portion of the drug in the ionized form in plasma, with a lower M/P ratio; this is known as *ion trapping*. For weak bases, the opposite is the case.[4]

The question of whether breast tissue can metabolize drugs present in breast milk is unknown for most compounds.[27] Conjugation has been demonstrated for some animal species, but human, bovine, and rodent breast tissue does not appear to possess appreciable concentrations of phase I enzymes such as cytochrome P-450.[27] Both ribonuclease and reverse transcriptase have been identified in human milk; the significance of these enzymes is uncertain.[37,38] It is increasingly clear from studies of other organs that drug metabolism is both more widespread and more important that has previously been appreciated, and it is likely that this will also apply to some drugs and the human breast. Of interest, Ito and co-workers have described the differential induction of drug metabolizing enzymes in infants fed with formula as opposed to breast milk.[31] Whereas formula-fed infants demonstrate a marked increase in caffeine clearance, presumably as a result of induction of Cyp1A1, breast-fed infants do not; this appears to occur by way of pathways dependent of the aryl hydrocarbon receptor, despite the fact that the concentrations of ligands for this receptor are higher in breast milk than in formula.[31] The long- and short-term clinical relevance of this observation is currently being studied.

A pharmacokinetic model for drug transfer into breast milk has been described for drugs that have low lipid solubility. This model assigns a deep compartment for breast milk, with transfer occurring from a central compartment (maternal circulation) to the deep compartment.[28] For most drugs, a two-compartment model provides a valid pharmacokinetic model for the study of the transfer of drugs into breast milk.[39,40]

In addition to the well-known mechanisms, as described, for transfer of drugs from the maternal circulation into breast milk, emerging evidence suggests that for certain drugs, active transport systems may function to transfer these substances into or out of breast milk.[4] It appears that such transporters can be a major determinant of drug transfer into breast milk. To illustrate, the concentration of ranitidine in breast milk in vivo is markedly higher than would be predicted on the basis of simple diffusion and ion trapping, suggesting the existence of an active transport system for organic cations in human mammary glands.[34] Many drug transporters expressed in animal models—such as the organic anion transporters 1 to 4—have not been found in human

tissue, but a number of other drug transporters appear to be expressed in the human mammary gland.[34] The putative biologic relevance of the presence of drug transporters in breast milk may relate to a role for these systems in nutritional transport, wherein drug transport is a biologically unintended consequence of the presence of such transport systems. For example, it appears that the ATP-binding cassette transporter BRCP (*b*reast *c*ancer *r*esistance *p*rotein), which is highly expressed in human breast tissue, may be involved in folic acid transport.[34] The activity, specificity, and clinical relevance of drug transporter expression in human mammary gland constitute an area of ongoing research.

Transfer of Drug from Breast Milk to the Infant

For most pharmacologic agents in routine clinical use, as a consequence of the effect of differences in molecular size and polarity on the processes just described, a predictable portion of drug in serum will pass into breast milk. It must be appreciated, however, that drug absorption from breast milk is not analogous to the enteral administration of drug to an infant for therapeutic purposes. Rather, with a drug that has passed into breast milk, it typically is present in dilute form in a relatively large volume of liquid, which includes other elements that can interact with the drug and alter the amount of drug available for absorption.

Protein and lipid components of breast milk can interact with drugs present in the aqueous phase; hence drugs with extensive protein binding will not be as available for absorption.[31] This decreased availability can be corrected for by calculating M/P ratios for these drugs on the basis of the amount of drug in skim milk.[4,40-43]

Drugs in breast milk also can interact with the lipid content of milk. The partition of highly lipid-soluble drugs in breast milk can be corrected by calculating the M/P ratio and using a correction factor for the octanol-water partition coefficient of the drug of interest.[4,42] Drugs with high lipid solubility, such as phenobarbital, can be trapped in the fat globules in breast milk, with a relative elevation in the amount present in milk versus plasma.[27]

Estimation of the Drug Dose Delivered in Breast Milk

A widely used method to estimate the amount of drug that lactating infants receive through breast milk is to calculate the drug dose in milk using the M/P ratio.[4,28,36,43] To use this method, it is necessary to know the M/P ratio and maternal steady-state plasma or serum drug concentration (C_{ss}) of the drug of interest and the volume of milk produced per day. The dose available to the infant can then be calculated using the equation

$$\text{Dose (mg/kg/day)} = C_{ss} \times \text{M/P ratio} \times \text{milk volume (mL/kg/day)}$$

To use this equation, three pieces of data must be known. The first is the C_{ss}, which can be determined by therapeutic drug monitoring of maternal plasma or serum. The second item is the M/P ratio, which is listed in various reference sources.[4] The final piece of data is an estimate of the milk volume; for term infants, the average milk volume is approximately 150 mL/kg/day (in this case, the weight is the weight of the nursing infant[22]).

Use of this equation to calculate the amount of drug received by a nursing infant is illustrated in the following example: A breast-feeding woman with epilepsy takes 300 mg of phenytoin once daily. Therapeutic drug monitoring reveals a steady-state serum concentration of 15 mcg/mL. Two M/P ratios for this drug have been reported in the literature, 0.45 and 0.13, with both values derived from small groups of infants. Using these values, the amount of drug delivered in breast milk can be calculated:

$$\text{Dose} = 15 \text{ mcg/mL} \times 0.45 \times 150 \text{ mL/kg/day} = 1.01 \text{mg/kg/day}$$

$$\text{Dose} = 15 \text{ mcg/mL} \times 0.13 \times 150 \text{ mL/kg/day} = 0.29 \text{mg/kg/day}$$

Given that the usual therapeutic maintenance dose of phenytoin for children is 5 mg/kg/day, these equations suggest that the dose of phenytoin anticipated in breast milk would be in the range of 6% to 20% of the usual therapeutic dose. An important consideration with regard to the implications of these estimates is that a three-fold difference between the M/P ratios was found in the two studies.

This equation can be useful to estimate the dose delivered to a nursing infant, but several caveats are in order with use of any equation involving the M/P ratio for determining the safety of breast-feeding.[40] First, for the equation to be accurate, the maternal serum concentration must be determined at steady state. It is possible that drugs may accumulate in breast milk over time; thus estimates made before the mother's serum concentration reaches steady state may underestimate the amount of drug present in breast milk.[4] In situations in which the C_{ss} is not available, it may be possible to estimate C_{ss} if the dose rate, bioavailability, and clearance are known.[4] Second is the accuracy of this equation is the M/P ratio itself. Although many studies have reported M/P ratios for various drugs, some of these studies have derived the M/P ratio from a single, simultaneously obtained determination of plasma (or serum) and milk from small numbers of infants.[4] Therefore, if with any temporal variation in the M/P ratio (as is suggested in the case of phenytoin by the wide range of values obtained), the estimates produced by this equation may not be accurate. The effect of changes in breast milk composition during feeding and over time (with progression from colostrum to mature milk) on the M/P ratio has not been evaluated for most drugs.[4,40] This changing composition may be particularly germane if transporter systems are involved in drug transfer into breast milk, as the expression and variability of these systems between individual patients and over time is just now being appreciated.[44] In addition, transporters can have efflux or influx capacity, so the summative effect may be difficult to predict. A better method for calculating the M/P ratio is to use multiple time points to calculate an area under the curve (AUC) for drug concentrations in milk and plasma and then use the AUC values to calculate the M/P ratio. Additionally, it has been suggested that combining use of the M/P ratio and estimates of drug clearance may be a more relevant way to evaluate the potential exposure of developing infants to drugs in breast milk.[43] Moreover, the effects of drug metabolites, especially for drugs that undergo biotransformation to active metabolites, are not considered as part of the usual M/P ratio. Given that the same considerations with respect to breast milk transfer apply to drug metabolites, the use of the M/P ratio alone may give a misleading impression of potential biologic effect(s) for compounds extensively transformed to active metabolites.

For many compounds, no M/P ratios have been described. It is possible to estimate an M/P ratio based on the physicochemical nature of the drug, using data such as the acidic strength (pK_a) of the drug, the amount of protein binding, and the octanol-water partition coefficient of the drug.[4]

An alternate approach taking advantage of the availability of sensitive analytical technology provides a method for estimation of drug dosage in breast milk by directly measuring the drug of interest in breast milk. The drug concentration can then be used to calculate the drug dose presented to the nursing infant. Ideally, multiple determinations should be made to discover any temporal variation in drug concentration during and between feeds. In addition, therapeutic drug monitoring in the infant can be used to follow the plasma or serum drug concentrations.

Finally, the value of any estimation of drug concentration in breast milk lies in the determination of potential effects on the infant. A critical and often underevaluated part of this estimation is assessment of the ability of the infant to clear the drug in question and the probable pharmacologic effects on the infant. As an

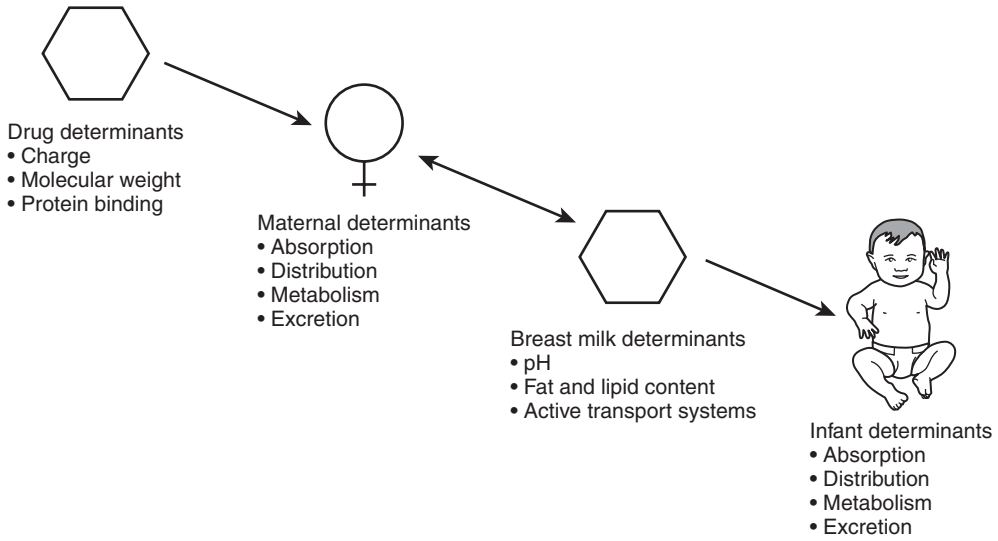

Figure 27-2 Factors affecting the potential impact of drugs in breast milk on infants.

example, ranitidine—which has an M/P ratio of 5—commonly is used in infants and has a wide margin of safety, thus being compatible with breast-feeding, whereas phenobarbital—which has an M/P ratio of 0.5—is inefficiently cleared by infants owing to differences in maturation of drug metabolism mechanisms and thus can accumulate, with the potential for adverse effects in breast-fed infants.

Clinical Implications of Drug Excretion During Lactation

The most common clinical indication for estimating drug dose in breast milk is to assess whether the drug will exert an adverse effect on a nursing infant (Figure 27-2). Fortunately the dose in breast milk (in most cases) is much lower than the usual therapeutic dose, and biologic effects (untoward and otherwise) would not be anticipated. In addition, the final determinant of the effect of any drug in breast milk on the infant is the ability of the infant to clear the drug.

As a rule, caution is warranted in prescribing drugs for lactating mothers. In instances in which therapy is clearly indicated, however, the demonstrated benefits of maternal therapy almost always outweigh theoretical risks of adverse drug effects in the nursing infant.A useful set of guidelines for a general approach to drug excretion during lactation, based on studies of drug excretion into breast milk, have been proposed by Berlin.[27] In general, it is reasonable to assume the following:

- A majority of all drugs (and environmental chemicals of molecular weight less than 200) cross from maternal plasma to breast milk.
- The time-concentration profile of drugs in breast milk parallels the time-concentration profile of drugs in plasma, with M/P ratios usually ranging from 0.5 to 1.0.
- The concentration of drugs in breast milk is almost always too low and too unpredictable to permit treating infants by giving medication to their mothers.
- The half-lives of drugs in plasma and in breast milk are similar after a single maternal dose, implying rapid transfer of the drug from plasma to milk.
- The amount of drug available in breast milk for absorption by the infant usually is less than 1% of the maternal dose.This amount can be minimized by breast-feeding during times when maternal plasma drug concentrations are low, such as just before the next dose.
- Few studies have described drug transfer in the setting of long-term maternal therapy over days or weeks; current understanding of how changes in drug transfer may occur over time is limited.
- In the case of most drugs, even those with potent pharmacologic effects, the risk for adverse drug effects in nursing infants usually is negligible, especially if attention is given to planning the nursing schedule around the time of minimal drug exposure.
- Potent drugs should be administered to breast-feeding mothers only after careful consideration, and parent counseling as to monitoring for potential adverse effects should be part of the prescribing process.This decision also should include consideration of clearance of the drug of interest by infants.

The penultimate point has been reinforced by a prospective study of breast-feeding mothers conducted by the Motherisk Program, a teratogen information service in Toronto. Between 1985 and 1991, 838 mother-infant pairs were assessed for exposure to a number of drugs taken by the mothers; no major adverse events were described among the infants.[4] Minor adverse effects were described in 11% of the infants, none of whom required medical attention.[4]

The last point in the list is highlighted by a recent report with respect to concerns when potent drugs are administered to nursing mothers.[45] Koren and associates[45] described the death of a nursing infant whose mother was receiving an analgesic containing acetaminophen and codeine. The infant died on day 13 of life of opiate overdose; detailed pharmacogenetic and drug analysis revealed that the mother's milk contained high concentrations of morphine, the active metabolite of codeine. In addition, the mother's genotype indicated that she was an ultrarapid metabolizer for CYP2D6 substrates, of which codeine is one.[45] Thus the mother metabolized codeine to morphine in much larger concentrations than would have been anticipated. Newborn infants are known to have a reduced capacity to metabolize morphine, which in this case resulted in a fatal outcome. In contrast with most case reports, in which isolated adverse effects that may be related to drug exposure through breast milk do not establish either causality or reproducibility, this report clearly correlates a fatal outcome associated with drug exposure from breast milk with a common pharmacogenetic variant.[45-48] Case reports must be interpreted with caution, however, in assessing possible risks associated with therapy in lactating mothers.[46] In this context, the ultrarapid metabolizer phenotype of CYP2D6 is seen in 1%

BOX 27-1

Drugs Contraindicated for Nursing Mothers

- Antimetabolites
  - Azathioprine
  - Cyclophosphamide
  - Doxorubicin
  - Methotrexate
- Antiocoagulants
  - Phenindione
- Ergot alkaloids
  - Bromocriptine
  - Ergotamine
- Gold
- Iodine-containing compounds
  - Amiodarone
  - Potassium iodide
  - Povidone-iodine (extensive topical use)
- Oral contraceptives (relative contraindication)*
- Psychoactive drugs
  - Lithium (relative contraindication)*
  - Phenobarbital

or less of Northern Europeans but can be seen in up to 10% of persons of Mediteranean extraction and in as many as 30% of people in populations from the Horn of Africa.[45] Thus the decision to prescribe codeine for the breast-feeding mother should be made only after careful consideration,and part of the prescribing process should include counseling about how to monitor for adverse effects in the newborn infant such as sedation.

With long-term therapy in a breast-feeding woman, her infant may be exposed to the potentially harmful drug for a period of weeks or months. In many instances, the therapy may have been started before delivery, and in such situations it is likely that the infant will be exposed to smaller concentrations through breast milk than the fetus was exposed to in utero. In the case of certain compounds, such as barbiturates, accumulation is possible, and the infant should be monitored for signs of toxicity. For most agents used in long-term therapy, however, thoughtful care and using therapy as indicated to ensure optimal maternal health are of greater importance in maintaining the health of the infant than is a nihilistic policy of drug avoidance regardless of potential effects on maternal health.

DRUGS CONTRAINDICATED FOR NURSING MOTHERS

A number of drugs are contraindicated during lactation, or preclude breast-feeding, as listed in Box 27-1.

Antimetabolites

Therapy with antimetabolites, especially for the therapy of neoplastic disease, is contraindicated during lactation. Although the absolute dose present in breast milk is small, the pharmacologic potency of these agents and the potential for serious long-term toxicity usually is believed to preclude lactation when therapy with these agents is required. The commonly used agents for immunosuppressive therapy include azathioprine, methotrexate, cyclosporine, and tacrolimus.These drugs (and the methotrexate metabolite 6-mercaptopurine) can be detected in breast milk in low concentrations.[49-51] It has been suggested that breast-feeding may be safe for mothers on low-dose therapy with methotrexate; however, this remains controversial.[52] Cyclosporine is transferred into breask milk in low concentrations. Although the older literature discourages breast-feeding during cyclosposorine therapy, in fact no adverse events have been reported among breast-fed infants of cyclosporine-treated mothers. The breast milk concentrations of cyclosporine typically are in the range of 1% to 2% of the maternal dose. On the basis of two reports of detectable cyclosporine concentrations in the blood of breast-fed infants of mothers treated with the drug, however, it would be prudent in such clinical situations to monitor nursing infants by means of serum or plasma drug level measurements. Almost no data are available on the safety of mycophenolic acid and sirolimus with respect to breast-feeding. When the parents have decided to continue with breast-feeding after being counseled about potential effects of these agents on the nursing infant, careful monitoring of the infants with respect to immunologic and hematologic status, with determinations of milk and plasma concentrations of the drug of interest, is recommended.[4]

Anticoagulants

The various warfarin (Coumadin) derivatives appear to be excreted into breast milk in differing amounts. Warfarin has not been detected in breast milk, and the infants of women receiving warfarin therapy have not had problems with coagulation[53,54] Similarly, no bleeding was found among the infants of a large cohort of women treated with dicumarol (bishydroxycoumarin).[55] This evidence suggests that therapy with warfarin and dicumarol is compatible with breast-feeding.[47,56] By contrast, the anticoagulant ethyl biscoumacetate has been detected in breast milk, and in one study, bleeding complications developed in 5 of 42 nursing infants whose mothers were being treated with this agent.[57,58] Phenindione (not available in the United States) has been detected in the milk of lactating mothers and has been associated with significant bleeding complications in the nursing infant.[56,59,60] Heparin is too large a molecule to be excreted into breast milk, and it appears that maternal use of the low-molecular-weight heparins—which again are too large for the transfer of significant concentrations into breast milk—is compatible with breast-feeding.

Ergot Alkaloids

The ergot alkaloid bromocriptine suppresses prolactin and among other indications is used clinically to prevent lactation.[61] Thus it is not surprising that bromocriptine is contraindicated when breast-feeding is planned. Ergotamine is excreted into the breast milk of mothers receiving this agent in doses used for the treatment of migraines, and ergotism, with clinical manifestations including vomiting, diarrhea, and seizures, has been described among breast-fed infants of mothers treated with this drug; moreover, ergotamine can suppress.[56,62] Only small concentrations of sumatriptan pass into human milk, and adverse effects would not be anticipated among breast-fed infants of sumatriptan-treated mothers.[63] No adverse effects have been associated with the short-term use of methylergonovine to promote uterine involution.[4]

Gold

Gold can be detected in the breast milk of women treated with that agent.[64-68] It has been estimated that nursing infants can be exposed to as much as 20% of the maternal dose through

breast milk, the clinical significance of which remains unclear.[67] In various reports, the presence of gold in breast milk was associated with no apparent adverse effects on the nursing infant; conversely, exposure to gold in breast milk has been described as potentially related to a constellation of adverse events; however, a causal link has not been established.[64,66] Some investigators think that gold salts are contraindicated during breast-feeding, although the Committee on Drugs of the American Academy of Pediatrics considers use of these agents compatible with breast-feeding.[56,67] When women breast-feeding their infants are being treated with gold, the infants should be closely observed during follow-up for adverse effects, and gold concentrations should be determined in breast milk and the infant's serum.

Iodine-Containing Compounds

Iodine is excreted into breast milk, which can lead to iodine-induced goiter and hypothyroidism in breast-fed infants.[69] This risk has been identified forboth oral preparations such as potassium iodide and topical povidone-iodine preparations.[56,70,71] Therefore compounds containing iodine should be avoided during lactation. Amiodarone is an antiarrhythmic agent that contains 75 mg of iodine in each 200-mg dose.[72] The drug is excreted into breast milk, and although no reports of adverse effects have been published in the literature, the high iodine content of this compound and the long half-life in adults suggest that amiodarone should be used onlywith great caution, if at all, during breast-feeding.[72,73]

Oral Contraceptives

The use of oral contraceptives is a relative contraindication in certain groups of nursing mothers. Use of such agents during the early phases of breast-feeding is associated with shortened duration of lactation, decreased milk production, and decreased nitrogen and protein content in milk (all of which can decrease infant weight gain).[74-78] These effects are less marked with agents containing only progesterone and have not been observed with newer combined oral contraceptives.[78] The effect of oral contraceptives on weight gain may be especially important for the infants of malnourished mothers. Therefore it has been recommended that oral contraceptives be avoided in nursing mothers who are malnourished.[4,79] It also has been suggested that oral contraceptives be avoided for the first 6 weeks after delivery.[4,76]

Both estrogen and progesterone can enter breast milk, although with currently available low-dose combination products, the estrogen content of breast milk from whose mothers are being treated with these products does not appear to be higher than that of breast milk from women who are not receiving any hormonal agents.[48] A single case report described the development of mild breast hypertrophy in a child exposed to a large dose of estrogen.[48] Use of oral contraceptives is acceptable in women who have successfully established breast-feeding.[56,76]

Psychoactive Drugs

Lithium can be detected in breast milk in variable concentrations which on occasion can result in milk concentrations similar to those of serum.[80-82] Concerns with respect to possible long-term adverse effects of exposure to lithium have led the Committee on Drugs of the American Academy of Pediatrics to consider lithium contraindicated during lactation.[56] An alternate approach is to measure lithium concentrations in breast milk and the serum of the nursing infant, to determine on an individual basis if lithium therapy can be continued during lactation; recent data have suggested that under these conditions therapy is likely to be be (in most cases) safe.[82]

TABLE 27-1

Duration of Excretion of Radioactivity into Milk After Maternal Administration of Radiopharmaceuticals

Drug	Duration of Radioactivity in Milk
Copper-64	50 hours
Gallium-67	2 weeks
Indium-111	20 hours
Iodine-123	36 hours
Iodine-125	12 days
Iodine-131	2-14 days*
Radioactive sodium	96 hours
Technetium-99	1-3 days

Modified from Committee on Drugs, American Academy of Pediatrics: The transfer of drugs and other chemicals into human milk. *Pediatrics* 93:137, 1994. Used with permission of the American Academy of Pediatrics.

*Varies depending on type of study.

Phenobarbital is excreted into breast milk, with M/P ratios between 0.4 and 0.6.[80,83-85] Elimination of phenobarbital is slower in infants than in adults, and serum phenobarbital concentrations in the infant can actually exceed those in the mother, producing sedation in the infant. Therefore, in treating lactating women with phenobarbital, infants should be followed closely for signs of sedation. Additionally, breast milk and serum concentrations of phenobarbital in the infant should be determined at periodic intervals.

Radiopharmaceuticals

Many commonly used radiopharmaceuticals are excreted into breast milk.[56] Therefore it is generally recommended that breast-feeding be avoided over the time during which the radioisotope in question is being excreted into breast milk.[56] The time interval for clearance of the radioisotope varies with the compound used for the investigation in question (Table 27-1). When this time to clearance is in doubt, an expert in nuclear medicine should be consulted. It may be possible to plan for this eventuality in advance by banking frozen milk that can be used to feed the infant while the breast milk containing the radioisotope is pumped and discarded until radioactivity has cleared from the milk.[4]

Recreational Chemicals

Recreational chemicals are a group of compounds that includes drugs used socially and drugs used under circumstances of abuse. As a general rule, all of the active compounds present in these agents can be excreted into breast milk. Thus, in view of the potent pharmacology of many of these drugs, the use of these agents is contraindicated during pregnancy and lactation.[4]

Amphetamines can be concentrated in breast milk, with M/P ratios that can range from 2.8 to 7.5.[86] The Committee on Drugs of the American Academy of Drugs considers amphetamines to be contraindicated during breast-feeding.[56] The same consideration applies with methamphetamine. Cocaine enters breast milk readily because of its low molecular weight and high fat solubility. Cocaine and benzoylecgonine, the principal metabolite of cocaine, have been detected in the urine of nursing infants, and some of these infants have had clinical signs compatible with cocaine exposure.[87,88] Signs and symptoms also have been reported in an infant whose mother used cocaine as a topical analgesic on her nipples.[29] Cocaine should be avoided at all times by lactating mothers.[56]

Ethanol is a small, lipid-soluble molecule that freely passes into breast milk at concentrations equivalent to plasma

concentrations.[30,89] By contrast, acetaldehyde, a toxic metabolite of ethanol, apparently does not enter breast milk in appreciable concentrations.[30] The elimination of ethanol from breast milk appears to be similar to that of ethanol in plasma, which follows zero-order kinetics.[30,89] The consumption of small amounts of ethanol on an infrequent basis does not appear to be associated with untoward effects in nursing infants, because that the amount of ethanol in breast milk is likely to be small.[4] It has been appreciated for some time, however, that ingestion of large amounts of ethanol in a single sitting can result in high concentrations of ethanol in breast milk, with significant signs and symptoms, including sedation, in the nursing infant.[90] It is controversial as to whether chronic ethanol use during lactation is associated with neurodevelopmental effects on the infant, although common sense suggests avoiding regular ethanol ingestion during breast-feeding.[91,92] A prudent recommendation is for lactating mothers to avoid chronic ethanol use while nursing their infants. The Committee on Drugs of the American Academy of Pediatrics considers moderate ethanol use to be compatible with breast-feeding, although caution is recommended.[56] In addition to possible effects on the infant, ethanol in high doses blocks release of oxytocin.[93]

Heroin and other opiates can be detected in breast milk. In the case of maternal heroin use, sufficient heroin is excreted into breast milk to produce dependence among nursing infants.[94] Use of heroin and other opiates, especially under circumstances of abuse, is contraindicated during lactation. As noted prevously, drug effects may be fatal in vulnerable infants.[45]

The active ingredient of marijuana is δ-9-tetrahydrocannabinol (THC); THC has been found in the breast milk of women who have smoked marijuana.[95] It appears that infants absorb THC from breast milk, which is then further metabolized.[95] No evidence has emerged to show adverse clinical consequences after exposure to THC through breast milk.[56] Long-term follow-up studies beyond 1 year of age, however, have not been performed, and many confounding variables that affect the developmental outcome of drug-exposed children have been recognized. The Committee on Drugs of the American Academy of Pediatrics regards marijuana use as being contraindicated in breast-feeding mothers.[56]

Phencyclidine can be detected in the breast milk of women who have used the drug. Furthermore, it can be detected for a considerable time after the last dose.[96,97] With respect to other hallucinogens, little information is available regarding transfer into breast milk. Of note, these drugs are small-molecular-weight compounds with considerable potency, so untoward effect(s) on nursing infants are highly probable. Thus phencyclidine and other hallucinogens, including lysergic acid diethylamide (LSD), are contraindicated during breast-feeding.

Nicotine and cotinine, the major metabolite of nicotine, have been found in the breast milk of mothers who smoke cigarettes.[98-100] Cotinine has been found in the urine of nursing infants whose mothers smoke, suggesting absorption of nicotine metabolites from breast milk or exposure to second-hand smoke.[4,101-103] Adverse effects, including increased rates of respiratory illness and possibly an increased rate of colic, have been reported in the infants of mothers who smoke.[103,104] In addition, cigarette smoking may inhibit production of breast milk.[105] The transfer of nicotine and cotinine falls sharply when a nicotine patch is used by breast-feeding mothers, suggesting that smoking cessation therapies that involve the use of the nicotine patch are safe during breast-feeding and are preferable to continued smoking.[98]

In summary, recreational chemicals pass readily into breast milk and may alter the production, composition, and volume of breast milk, with the potential for adverse effects in the nursing infant. Accordingly, breast-feeding mothers should be strongly advised to restrict their intake of recreational chemicals.[90]

DRUG CLASSES COMMONLY USED BY LACTATING WOMEN

Analgesics

Acetaminophen, aspirin, and nonsteroidal antiinflammatory drugs such as ibuprofen and ketorolac are secreted into breast milk in small concentrations. The use of these agents in usual therapeutic doses has not been associated with adverse effects on nursing infants. Salicylism has been reported in the nursing infant of a mother treated with aspirin; the pharmacokinetic profile, however, suggested that exposure occurred by routes other than breast milk.[106] Opiates transfer into breast milk; in the case of morphine, transfer to breast milk is limited. Although codeine in doses used for the ambulatory patient has been considered to be compatible with breast-feeding, the fatal case just described suggests caution, and monitoring should be considered when codeine is prescribed for breast-feeding mothers, especially if therapy will necessitate more than one or two doses.[45]

Antiasthma Agents

Asthma is among the most common chronic diseases requiring therapy in lactating women. β_2-Adrenergic selective agents are the drugs of choice for the acute therapy of asthma and typically are given by aerosol. Absorption of albuterol (salbutamol) is minimal when this drug is given by inhalation; as well, abundant data are available on the safety of direct administration of this drug in infants as young as a few months of age.[107] Thus significant excretion of these agents into breast milk is unlikely, and effects on nursing infants are highly improbable. The same considerations apply for inhaled adrenocorticosteroids, notably when the total dose is less than 1000 mcg/day. Prednisone is excreted into breast milk in small concentrations.[108] Because these concentrations are unlikely to be associated with adverse effects in the nursing infant, use of both prednisone and prednisolone is compatible with breast-feeding, especially in view of the considerable experience with the use of corticosteroids in infants and children.[56] Theophylline is excreted into breast milk in small concentrations, with an estimated infant dose that is less than 1% of maternal dose.[109] A report of irritability in the nursing infant of a mother taking a rapidly absorbed theophylline preparation suggests that nursing mothers who require theophylline therapy should be treated with slow-release preparations. Nonetheless, theophylline is considered to be compatible with breast-feeding.[56] Limited data are available with respect to the transfer of newer agents such as montelukast into breast milk, but a reasonable assumption is that a small amount is likely to enter breast milk; on the basis of the experience with these agents in children, it also is likely that they are compatible with breast-feeding.[110]

Antimicrobial and Antiinfective Agents

Essentially all of the antimicrobial and antiinfective drugs transfer into breast milk. The β-lactam antibiotics are compatible with breast-feeding. Tetracycline passes into breast milk in low concentrations, where it can associate with calcium in milk. Absorption of tetracycline from milk appears to be negligible, because tetracycline has not been detected in the blood of nursing infants whose mothers were treated with this agent.[111,112] Although use of tetracycline in younger children normally is contraindicated because of effects on developing teeth and bones, the lack of evidence of absorption has led the Committee on Drugs of the American Academy of Pediatrics to consider tetracycline therapy to be compatible with breast-feeding.[56] Erythromycin is present in breast milk during maternal therapy, but such therapyalso is compatible with breast-feeding. Clarithromycin is compatible with breast-feeding. Azithromycin is excreted into breast milk and may accumulate because of the lipid solubility of the drug and ion trapping; in

view of the pharmacokinetics of this drug, the possibility of accumulation is unlikely to be a contraindication to breast-feeding.[113]

Caution must be exercised in the use of nalidixic acid, nitrofurantoin, quinine, and sulfonamides for therapy in lactating women who belong to populations at risk for glucose-6-phosphate dehydrogenase deficiency, because drug transfer through breast milk may be associated with a risk for hemolysis in the infant.[4] The recommendation that sulfonamides be avoided during the first postnatal week to avoid displacement of bilirubin from albumin is a theoretical one.

The quinolones—norfloxacin, ciprofloxacin, ofloxacin, grepafloxacin, levofloxacin, and gemifloxacin—appear to be excreted into breast milk in low concentrations.[114] Less data exist with respect to breast milk transfer for the newer agents in this class than on the first- and second-generation drugs (ciprofloxacin, norfloxaxin, and ofloxacin). Animal studies demonstrating an arthropathy in a beagle pup model have been cited as a rationale for avoiding use of quinolones in pregnancy and lactation.[4] The expanding experience with these drugs in pediatrics, however, has not demonstrated adverse effects in humans and suggests that, when clinically indicated, quinolones are compatible with breast-feeding.[115,116] Chloramphenicol is excreted into breast milk. Caution has been recommended with use of chloramphenicol in lactating women because of the possibility of an idiosyncratic reaction or bone marrow toxicity (or both).[4] Therefore an appreciation of the severity of potential adverse reactions is essential in prescribing chloramphenicol for this group of patients. Metronidazole is excreted into breast milk.[117] Although concern has been expressed with respect to the potential mutagenic effects of metronidazole, such effects have not been demonstrated in humans.[4] In conventional dosages, metronidazole is compatible with breast-feeding. If metronidazole is given in a single large dose (such as the single 2-g dose recommended for therapy of trichomoniasis), however, the breast should be pumped and milk discarded for 12 to 24 hours after the dose, to allow for elimination of metronidazole.[56]

Isoniazid and the isoniazid metabolite acetylisoniazid are excreted into breast milk in large concentrations.[118] Although no reports of toxicity among nursing infants of mothers treated with isoniazid have appeared in the literature, it is recommended that when lactating mothers are being treated with isoniazid, nursing infants should be monitored for signs of peripheral neuritis or hepatitis.[119]

Acyclovir has been detected in breast milk in much higher concentrations than would be anticipated from the physicochemical nature of the drug.[120] This finding suggests that acyclovir may have a unique active or facilitated transport process for entry into breast milk.[120] Based on the poor oral absorption of this agent, it has been estimated that the amount absorbed by nursing infants of mothers treated with acyclovir should be minimal.[120] Therefore the Committee on Drugs of the American Academy of Pediatrics considers acyclovir therapy to be compatible with breast-feeding.[56]

Recent work has demonstrated that zidovudine transfers into breast milk in concentrations roughly equivalent to those seen in serum.[120] Postnatal transmission of humanimmunodeficiency virus (HIV) has emerged as a major public health problem worldwide; a number of regimens to reduce mother-to-infant transmission have been developed, but the optimal regimen to prevent transmission in breast milk remains controversial.[121] Many of the antiretroviral drugs, such as nevirapine, lamivudine, and zidovudine, enter breast milk in reasonably high concentrations; whether such levels are sufficient to treat or provide prophylaxis for HIV infection remains controversial.

Antihypertensives and Diuretics

β-Adrenergic blocking agents are excreted into breast milk; the extent of drug transfer is determined by the degree of protein binding. Agents such as atenolol and sotalol, which are relatively less protein bound, pass into breast milk in greater quantities than an agent such as propanolol, which is more highly protein bound.[122-124] Maternal use of propranolol, nadolol, and metoprolol is compatible with breast-feeding. Acebutolol accumulates in breast milk and should be avoided in breast-feeding mothers. Atenolol accumulates in breast milk in concentrations exceeding maternal plasma concentrations, probably owing to ion trapping; breast-fed infants of atenolol-treated mothers have had very low plasma atenolol concentrations. Data on the transfer of esmolol and pindolol into breast milk are limited. The degree of transfer of sotalol and effects on the nursing infant remain controversial; with maturation of renal function, effects in infants older than 2 months of age would not be anticipated.[122] Nursing infants of mothers being treated with a βadrenergic blocking agent should be monitored for signs of β-adrenergic blockade, notably bradycardia.

Captopril and other angiotensin-converting enzyme inhibitors are excreted into breast milk in low concentrations. The use of these agents and drugs such as hydralazine, methyldopa, and verapamil is considered to be compatible with breast-feeding.[56]

Diuretics such as chlorothiazide and hydrochlorothiazide are excreted into breast milk in low concentrations.[33] Although thiazide diuretics can suppress lactation, in the usual therapeutic doses these agents are compatible with lactation.[56] Furosemide also is excreted into breast milk and is compatible with lactation.[56]

Anticonvulsants and Psychoactive Drugs

Carbamazepine, phenytoin, and valproic acid are excreted into breast milk in small amounts; use of these agents is compatible with breast-feeding.[56] Ethosuximide is found in breast milk in concentrations roughly equivalent to those in maternal serum; however, the Committee on Drugs of the American Academy of Pediatrics considers ethosuximide therapy to be compatible with breast-feeding.[56] As described previously, ongoing phenobarbital therapy is contraindicated during lactation, primarily owing to delayed clearance by the infant. Primidone is metabolized to phenobarbital, and the same considerations with respect to phenobarbital therapy apply to primidone. Lamotrigine is transferred into breast milk in appreciable concentrations, and although this agent is not contraindicated during breast-feeding, infants should be closely monitored (a serious lamotrigine rash has been described in a breast-fed child). Topiramate, gabapentin, and valproic acid are present in low concentrations in milk and are considered compatible with breast-feeding. In the case of valproic acid, however, infants are known to be a high-risk group for valproic acid–associated hepatic failure, and it has been suggested that nursing infants of mothers treated with valproic acid should be closely followed.

As described previously, lithium therapy is believed by many authorities to be contraindicated during lactation but can be used if accompanied by a monitoring program. Most psychoactive drugs used, including the phenothiazines, benzodiazepines, and classic antidepressants, are excreted into breast milk. These agents should be used with caution in lactating women, notably if used in combination therapy.[56] Diazepman specifically has a long half-life in breast milk, and alternate agents are recommended if benzodiazepine therapy is needed. Olanzepine is transferred into breast milk in low concentrations, and maternal therapy with this agent is considered compatible with breast-feeding.

The selective serotonin reuptake inhibitors (SSRIs), a very widely used class of drugs, are excreted into breast milk in variable and usually small amounts.[125-129] In the case of fluoxetine, drug transfer into breast milk is appreciable, and although adverse events in terms of reduced weight have been noted in only a single study, it would nonetheless be prudent to consider use of

an alternate agent for breast-feeding mothers. Although isolated case reports of toxicity have appeared in the literature, series of mother-infant pairs have demonstrated minimal infant exposure to most of the SSRIs tested, notably escitalopram, paroxetine, and venlafaxine, with measured breast milk concentrations less than 10% of the maternal dose.[125-129]

Cardiovascular Drugs

Digoxin is excreted into breast milk in small concentrations and is compatible with lactation, [122] as are flecainide, mexiletine, and quinidine.[4] Procainamide and its active metabolite *N*-acetylprocainamide also are excreted into breast milk.[130] Although adverse effects associated with procainamide use by lactating mothers have not been reported, the effects of long-term exposure are unknown. Therefore infants of lactating mothers treated with procainamide should be followed closely. Disopyramide is present in milk in relatively high concentrations. Although no adverse effects have been reported among infants of lactating mothers treated with disopyramide, clinicians should observe these infants closely and consider monitoring drug concentrations in breast milk and the infant's blood.[4] Quinidine is excreted into breast milk and is compatible with breast-feeding.[56,131] A systematic review has suggested that the use of angiotensin-converting enzyme inhibitors and many of the calcium channel blockers is safe during breast-feeding.[132]

Endocrine and Gastrointestinal Drugs

Thyroid replacement therapy with agents such as levothyroxine is compatible with breast-feeding. The antithyroid agent propylthiouracil is excreted into breast milk in small concentrations; maternal therapy with total daily doses of 50 to 300 mg is considered compatible with breast-feeding, although follow-up evaluation of the infant's thyroid function on a regular basis is recommended.[133]

Tolbutamide and chlorpropamide are excreted into breast milk in low concentrations, which are unlikely to influence the infant's blood glucose concentration.[134] The molecular weight of insulin precludes entry of this agent into breast milk.

Adverse effects have not been described after maternal use of a number of laxatives, including mineral oil, phenolphthalein, and senna derivatives.[4] It has, however, been recommended that lactating mothers who require laxatives be treated with agents that are poorly absorbed, such as psyllium.[4]

Ranitidine and cimetidine are excreted into breast milk in small amounts, and use of these agents is considered to be compatible with breast-feeding.[56] Transfer of omeprazole, pantaprazole, and esomeprazole into breast milk is minimal; data on transfer of rabeprazole and lansoprazole into breast milk are very limited. Antacids that contain sodium and aluminum are considered to be compatible with breast-feeding.[135] Metoclopramide and domperidone both are compatible with breast-feeding and have been used to increase milk production.[4]

Disease-Modifying Agents and Biologic Therapies

Since 2000, a number of disease-modifying agents have become available for clinical practice, often using targeted molecules of biologic origin. Many of these agents are large-molecular-weight compounds that would not be anticipated to transfer into milk to any significant degree, infliximab being an example. Although the indications for these agents often have been among patients unlikely to breast-feed, the use of such agents is expanding into different populations, so study of their transfer into breast milk as well as their impact on breast milk production is needed.

Over-the-Counter Drugs

Numerous over-the-counter drugs used for symptomatic relief of common problems, notably self-limited upper respiratory tract infections and environmental allergies, transfer into breast milk. In usual therapeutic doses, these agents are compatible with breast-feeding; however, because these agents have the potential for causing sedation, care should be taken if they are used for a prolonged period.[22,47,48] A single case report described the development of irritability and a high-pitched cry in an infant receiving breast milk from a woman taking the antihistamine clemastine. Single or intermittent doses of clemastine, however, are compatible with breast-feeding.[48]

Herbal Medicines

Herbal and other traditional medications frequently are used by patients, and recent estimates are that up to one third of all patients take some type of complementary or alternative medicine preparation on a regular basis. Patients often assume that herbal medications are safe because they are "natural." Nevertheless, the active ingredients in herbal medications, like those in most other medications, are likely to enter breast milk. Two concerns have emerged: First, with herbal medication, the possibility of adulteration must be borne in mind if infants exhibit unusual signs or symptoms. Second, it is possible that the active elements of some herbal medications, such as St. John's wort, may be absorbed by breast-feeding infants. Although recent work has suggested that some commonly used herbal agents such as St. John's wort and gingko may be safe when used by breast-feeding women, further research is needed on the safety of herbal medications during breast-feeding.[136,137]

INFORMATION SOURCES ON DRUGS AND BREAST-FEEDING

Drug use is common, and drug utilization studies have demonstrated that a wide range of compounds and drug classes are used by patients. For example, a recent study of drug use in children—thought to be a low drug utilization group—has demonstrated that over 1 year, 4 prescriptions were dispensed per child from a list of 1400 distinct chemical entities.[138] Drug use among lactating women is even more diverse. Today's practitioners, therefore, need access to a valid and readily available information source. In addition to textbooks such as the classic *Drugs in Pregnancy and Lactation* by Briggs, Freeman, and Yaffe, the valuable website LacMed, sponsored by the NIH, provides concise and thoughtful reviews of the current literature on breast milk transfer of a number of commonly used medications (http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT). The practitioner who routinely cares for women of reproductive age should ensure that they have ready access to resources to enable them to address questions relative to the potential effects of drugs transferred in breast milk on breast-feeding infants.

SECTION IV

Intrauterine and Postnatal Growth

28

Frederick C. Battaglia

Circulatory and Metabolic Changes Accompanying Fetal Growth Restriction

Fetal growth restriction (FGR) is an important clinical problem in obstetrics and gynecology. Because of its importance, it has stimulated considerable clinical research that not only has elucidated aspects of the pathophysiology of the growth restriction but also has led to a better understanding of normal human biology. This chapter summarizes some of the work that has been directed at describing how the fetus adapts to placental dysfunction.

A plethora of terms have been used in describing the problem of FGR. In part, this potentially confusing terminology has a historical foundation. The first attempts to recognize growth restriction in newborn infants came from studies using gestational age and birth weight information.[1-3] The infants were classified as being small for gestational age (SGA) if their birth weights fell below the 10th percentile. Later reports used terms such as small for dates (SFD), basing the definition on standard deviations for the birth weight gestational age distribution. Many studies brought out the differences in birth weight–gestational age distribution data among different populations of peoples. All of these attempts to define FGR, however, were based on birth weight information to establish the norms for populations. It was clear from the beginning that preterm birth weights could hardly be considered "normal" data of in utero growth for a population. It also was clear that growth-restricted infants were not a homogeneous group but instead included some babies who were small but normally grown infants. The term *intrauterine growth retardation* (IUGR) was used initially to identify SGA infants who had truly grown more slowly in utero because of one or another disease processes, usually those affecting placental development. Later, because of concerns that "retardation" is a term parents may associate with mental retardation, the term was modified to *fetal growth restriction.* This latter designation has come to be used more and more widely and interchangeably with IUGR.

The approach to defining FGR was changed fundamentally once ultrasound techniques permitted determination of fetal body size in utero, a measurement that could be done repeatedly during the pregnancy. This capability removed the necessity to use only birth weight data at the completion of a pregnancy. It also permitted examining the rate of fetal growth, that is, the change in fetal growth with time, in any particular pregnancy. The wide application of ultrasound-derived fetal growth curves made possible the early detection of FGR. Currently, the common practice is to use equations derived from local population data to calculate an estimated fetal weight. Such equations usually rely on measurements of head circumference (HC), abdominal circumference (AC) and femur length. It is not clear, however, that such a calculation of estimated fetal weight is significantly better than relying on the actual measurements made. Alternatively, FGR may be defined as growth impairment in which the infant's abdominal circumference is two standard deviations below the norm for gestational age.

The diagnosis of FGR can be further sharpened by the use of standards that incorporate maternal and paternal size. Essentially, this approach seeks to distinguish fetuses that are small because the parents are small from those with growth restriction resulting from one or another disease process. Focusing on this approach, Gardosi and colleagues have reviewed this subject extensively.[4] Nomograms for particular countries are available.[5,6] The most compelling evidence, however, that a fetus is truly growth-restricted comes from accumulating functional evidence for those physiologic characteristics that have been shown to be altered in FGR pregnancies.

Distinguishing babies who are small but are fulfilling their growth potential (i.e., those who are normally grown) from those with FGR (i.e., those who are growth-restricted as a result of some pathology) is important for a number of reasons: (1) Intensive obstetric surveillance can be applied more effectively to the fetus; (2) neonatal intensive care can better anticipate problems for affected babies; and (3) FGR has important long-term implications for development of the infant, not only through childhood but also into adult life. Thus it behooves today's clinicians to approach the diagnosis of FGR using all available information.

In recent years, studies have begun to sort out normally grown, SGA babies from those with growth restriction by consideration of functional aspects, as well as simply the body size of the fetus and of the parents. These aspects are evident in a consideration of some of the vascular and metabolic changes clearly associated with FGR, as discussed next.

PLACENTAL DEVELOPMENT

A great deal of work has been done to delineate the changes in placental development that are associated with FGR pregnancies. The histologic changes in the placenta, including the vascular changes, have been reviewed in multiple studies.[7-9] These changes are consistent with increased uneven perfusion and increased diffusion limitations in the small FGR placenta. Surface area is significantly reduced in FGR pregnancies, along with placental mass. These findings have led to the hypothesis that the characteristic may be triggered in part by placental hyperoxia in the maternal placental circulation.[8] This hypothesis has received support from both animal studies[10] and clinical studies[11] of respiratory gas tensions in the umbilical and uterine circulations in FGR pregnancies. For many years, obstetricians believed that uterine artery blood flow was reduced in FGR pregnancies. Although such reduction may or may not

occur in the earliest stages of pregnancy, it has now been well established by Pardi and associates[11] that uterine blood flow is increased in FGR pregnancies relative to the O_2 requirements of the pregnant uterus. This relative increase is an important physiologic characteristic of FGR pregnancies and, as stated earlier, is consistent with findings in an ovine model of FGR.[10] An important point in this context is that the human placenta simulates a venous equilibrator. This subject has been reviewed by Meschia, who has brought out the implications of this similarity for both the uterine and umbilical circulations[12]: Regardless of the complexity of the fetal circulation and of perfusion patterns within the intervillous space, the human placenta is functioning as an exchange system in which the uterine venous Po_2 is the major determinant of the umbilical venous Po_2 in the fetal circulation.

FETAL VELOCIMETRY CHANGES

The fetal circulation has been studied extensively in terms of the velocity waveform changes occurring in different fetal vessels.[13] These changes do not occur in all FGR pregnancies. In the classification proposed by Pardi and associates,[14] pregnancies without velocimetry changes represented approximately one third of all FGR pregnancies. The changes in fetal velocimetry are presumed to reflect two pathophysiologic processes: (1) an increased impedance within the placental vascular bed and (2) a redistribution in fetal cardiac output secondary to fetal hypoxia. The evidence for each of these changes is reviewed next.

In normal pregnancies, the umbilical artery pulsatility index (PI) starts at a high value in early gestation and decreases until term.[15] In FGR pregnancies, however, the PI is increased over normal values even relatively early in gestation. In the ovine FGR model described previously, the increased PI is associated with an increased blood pressure in the fetal circulation and with a reduced umbilical blood flow.[10] This observation provides clear evidence of an increased impedance in the fetal vascular bed. Both an increased PI and a decreased umbilical blood flow[16] have been reported in human FGR pregnancies. Thus it is not unreasonable to assume an increased placental vascular impedance in human FGR pregnancies.

Hypoxia and lacticacidemia occur in a relatively high percentage of FGR pregnancies. Both hypoxia and lacticacidemia were found in approximately two thirds of the FGR pregnancies in which both umbilical artery velocimetry values and fetal heart rate were abnormal.[14] Fetal hypoxia has been well studied in animal models. In the ovine fetus, the changes in the distribution of fetal cardiac output that occur with acute fetal hypoxia were well described many years ago.[17] These changes include vasoconstriction to some fetal vascular beds, such as skeletal muscle, and vasodilatation to other vascular beds, such as the cerebral circulation. A number of more recent studies have addressed the high perinatal mortality and morbidity rates that are associated with these fetal velocimetry changes.[18] The same data, however, can provide additional clinical information if the sequence of velocimetry changes that occur in human FGR fetuses is considered. The physiologic significance of the velocimetry changes in different fetal vessels can be interpreted properly only by viewing these changes as a sequence of circulatory adjustments by the fetus.

The sequence of changes in fetal velocimetry has been studied in a group of FGR pregnancies that would ultimately require delivery for FHR abnormalities as well.[19] This study brought out that some vessels show alterations in velocity waveform relatively early in relation to the time of required delivery of the infant and others occur much later, within a few days of delivery. An important point is that even the "late" changes occurred some days before the FHR became abnormal, the latter triggering delivery of the fetus. Also, within any single vessel, velocimetry waveforms may show progressive changes—for example, in the umbilical artery, progressing from an increased pulsatility index (PI) to absent end-diastolic flow (AEDF) to reversed end-diastolic flow (REDF). These velocimetry changes have been described for a number of fetal vessels. Another study examining the sequential changes in fetal velocimetry pointed out that many of these changes precede any change in the biophysical profile, emphasizing the importance of velocimetry and blood flow studies.[19] It may well be that clinical practice may move toward utilizing fetal velocimetry data for decisions about the optimal delivery time for a growth-restricted infant. This change in practice rests on whether follow-up studies document that leaving the unborn infant in utero after "late" velocimetry changes have occurred, but before FHR is abnormal, contributes to potential CNS injury to a greater extent than severe prematurity. At this point, the data are not available to make this decision.

Blood Flow Measurements

From a physiologic standpoint, blood flow is the critical determinant of tissue perfusion, not the velocity of the blood. As techniques have developed to accurately determine the diameter of a vessel, it has become feasible to measure blood flow in the vessel from the diameter and the velocity of blood in the vessel. This approach has been applied in human pregnancies to measure the blood flow in three important sites:

- Uterine artery
- Umbilical vein
- Ductus venosus

Measurement of blood flow in each of these vessels is very important to an understanding of the pathophysiology in FGR pregnancies.

Uterine Artery Blood Flow

Of note, extensive research has examined the significance, frequency, and severity of uterine arterial velocimetry changes in FGR pregnancies. Measurement of uterine artery velocity waveforms has proved useful in FGR pregnancies, especially because measurement of actual blood flow has proved difficult.[20-25] Unfortunately, the few sequential studies of the changes in umbilical velocimetry did not include information on the uterine arteries so a correlation between the changes in the two circulations cannot yet be made.

Measurements of uterine artery blood flow in human pregnancies were first reported in the 1990s.[26-28] In the relevant studies, estimates of uterine blood flow were reported as approximately 500 mL/min^{-1} at term in normal pregnancies. Meschia[12] has pointed out that these estimates were likely to be too low in the context of published data for uterine venous O_2 saturation, maternal hemoglobin concentration, and estimates of uterine O_2 consumption. On the basis of these oxygen data, he calculated that uterine blood flow in human pregnancy should be approximately 1 L/min^{-1} at term. More recently, Konje and co-workers[29] used color power angiography to measure uterine blood flow in uncomplicated human pregnancies. These workers reported a blood flow at term of 970 ± 193 mL/min^{-1}, not significantly different from that estimated by Meschia from the O_2 data. Thus a blood flow of 1 L/min^{-1} appears to be a reliable estimate for normal human pregnancy. Unfortunately, no measurements of uterine blood flow in FGR pregnancies have yet been reported. Furthermore, blood flow measurements in the uterine artery probably underestimate total flow, because some flow may be contributed by the ovarian or cervical arteries as well. Because of the technical difficulties in the measurement of uterine blood flow, including the necessity to measure flow

of each uterine artery, studies of the velocity waveform in the uterine artery are likely to prove more clinically useful in the immediate future.

Umbilical Vein Blood Flow

A number of studies have reported umbilical blood flow rates at different gestational ages in uncomplicated human pregnancies.[30-35] Umbilical blood flow (mL/min^{-1}) increases exponentially during gestation, in a pattern roughly similar to the increase in fetal weight. Several other studies, however, have shown that blood flow does not increase in a fixed proportion relative to fetal body weight. When umbilical blood flow is expressed per kg of fetal weight, it decreases slightly during gestation from approximately 130 mL/min^{-1} at 20 weeks of gestation to approximately 100 mL/min^{-1} at term. Both the umbilical vein diameter and the mean velocity increase during gestation, although the increase in diameter is the dominant factor leading to the exponential increase in umbilical blood flow during gestation.

For obvious reasons, umbilical blood flow uncorrected for fetal size is low in FGR pregnancies because the fetus is smaller. But if blood flow is expressed per kg of fetal weight or normalized to fetal body mass by some other biometric index such as fetal HC or AC, it is still significantly reduced in most FGR pregnancies.[16] This is one of the more important findings in FGR pregnancies—that umbilical blood flow to the placenta is reduced even when corrected for fetal body size. Furthermore, the reduction is quite large. For example, at 34 weeks of gestation, the umbilical flow (mL/min^{-1}) in FGR pregnancies is reduced by approximately 70%. The data from a study by Ferrazzi and associates are presented in Figure 28-1.[16] In this figure, blood flow has been normalized for estimated fetal weight, which also is reduced in FGR pregnancies. The reduction is even more striking if normalized for head circumference, because head circumference is spared in FGR pregnancies. The study by Ferrazzi's group demonstrated that the decrease in flow is entirely attributable to the decrease in umbilical blood flow velocity, not in the diameter of the vessel. The reduction in umbilical blood flow can occur quite early in gestation—that is, at the time the diagnosis of FGR is first made by serial ultrasound examinations (24 weeks). As noted in Figure 28-1, umbilical blood flows in some FGR pregnancies are within the normal range. It will be important through follow-up studies to determine what differences in outcomes, both long- and short-term, are associated with a reduction in umbilical blood flow of this magnitude. These first studies were cross-sectional in design, but a subsequent longitudinal study established that these flow changes were persistent in a pregnancy.[36] A reduced umbilical vein blood flow makes it more difficult to deliver O_2 and nutrients to the fetal tissues and increases the risk for fetal hypoxia and acidosis.

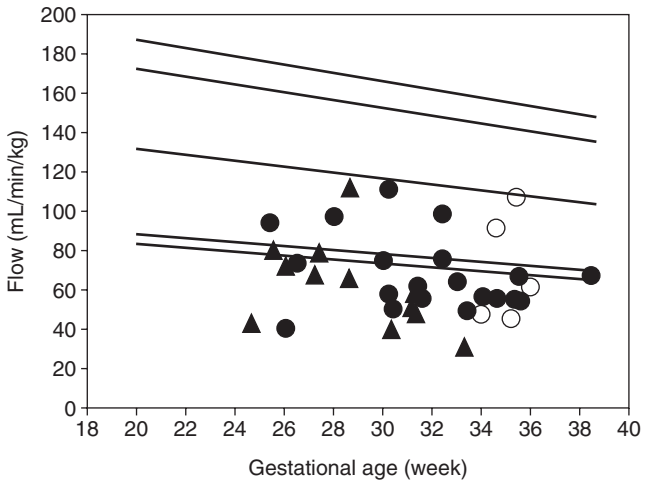

Figure 28-1 Umbilical vein flow per unit head circumference plotted against gestational age in growth-restricted fetuses: group 1, ○; group 2, ●; group 3, ▲. *Continuous lines* represent the 5th, 10th, 50th, 90th, and 95th percentiles from 70 normally grown fetuses. *(From Ferrazzi E, Rigano S, Bozzo M, et al: Umbilical vein blood flow in growth-restricted fetuses,* Ultrasound Obstet Gynecol *16:432-438, 2000.)*

Fetal Hepatic and Ductus Venosus Blood Flow

The third fetal vessel for which blood flow data in human pregnancies are now available is the ductus venosus.[37,38] As with the uterine artery, most studies have focused on the velocity waveform, rather than on measurements of actual blood flow. These studies[39-42] have pointed out the clinical significance of an increased shunt through the ductus venosus and of the presence, in severe FGR, of reversed flow in the left portal vein. In the human fetus, the ductus venosus is a small, trumpet-shaped vessel connecting the umbilical vein and inferior vena cava. Its purpose is to shunt some of the highly oxygenated umbilical vein blood away from the fetal liver and directly into the inferior vena cava. Because of its conical shape (its inlet diameter is smaller than its outlet diameter), the velocity waveform changes along the length of the vessel. More recently, in a series of studies, some of which were directed at computerized modeling of the velocity waveform as a function of conicity, several groups of investigators have measured the blood flow in the ductus venosus.[43-46] This measurement permits determination of the amount of umbilical venous blood shunted through the ductus as well as the amount perfusing the fetal liver. These flows, as well as umbilical flow, have been measured together in normal human pregnancies throughout the latter half of gestation. Figure 28-2 illustrates the fact that the percent ductal shunt decreases as pregnancy progresses. This is brought out in the figure by the fact that the ductal flow does not increase as much as the umbilical blood flow during gestation. The change is rather striking. The ductal shunt, expressed as percentage of umbilical flow, decreases from 40% at 20 weeks to 15% at term. Figure 28-2 abstracts data obtained in three studies on blood flows in human pregnancies. The uterine blood flow data are from a study by Konje and co-workers,[29] those for umbilical flow from a study by Barbera and colleagues[30] and those for the ductus, from a study by Bellotti and associates.[38] Figure 28-2, *A*, presents the flow rates in mL/min^{-1}. Figure 28-2, *B*, presents flows per kg of fetal body weight; it is clear that the increase in umbilical blood flow during gestation most closely approximates the growth of the fetus, because flow per kg decreases only slightly during gestation in normal pregnancies.

Several studies have pointed out that the ductal shunt is increased for gestational age in some pregnancies with clinically severe FGR. Because fetal hepatic blood flow is determined in large part by the umbilical blood flow and inversely by the percent ductal shunt, a growth-restricted fetus with a reduction in umbilical blood flow and an increased ductal shunt may have an enormous reduction in hepatic blood flow. Bellotti and colleagues have shown that this combined effect does indeed occur in some FGR pregnancies.[47,48] It is not surprising, in view of these vascular changes, that two different groups of investigators have reported hepatic injury unrelated to infection in growth-restricted newborns.[49,50] Obviously, this area needs more study, because it may affect the management (particularly nutritional management) of affected babies in the immediate neonatal period. A more recent study has reported an increase in ductal shunt in pregnancies in which maternal undernutrition is present; this finding is the first link between

maternal nutrition and cardiovascular redistribution in the fetal circulation.[51]

METABOLIC CHANGES IN PREGNANCIES WITH FETAL GROWTH RESTRICTION

Carbohydrates

Lacticacidemia, hypoxia, and acidosis have already been discussed as frequent complications of FGR pregnancies, particularly in those with "late" velocimetry changes such as REDF in the umbilical artery. With regard to lactic acidemia and acidosis, it is important to emphasize the unique metabolic characteristics of the fetal liver and placenta with regard to the metabolism and transport of lactate and pyruvate. In animal studies, it has been well established that the fetal liver has a large net output of pyruvate and net uptake of lactate from the fetal circulation. In view of the fact that the fetal liver is perfused with a high percentage of umbilical venous blood, the most-oxygenated blood of the fetus, it is clear that the fetal liver could play an important role in the defense of acid-base balance during fetal hypoxia. Figure 28-3 presents in graphic form some of the changes in acid-base balance and lactate concentration during severe and persistent fetal hypoxia taken from the study by Wilkening and colleagues.[52] The striking finding is that despite persistent, severe fetal hypoxia for 24 hours, the fetal acidosis is largely completely corrected as reflected in fetal arterial pH, although the lactate concentration is still elevated. This correction of metabolic acidosis occurs because of the continued uptake of lactate and release of pyruvate from the fetal liver. This important finding, that the fetal liver continues to take up lactate and release pyruvate even during persistent severe fetal hypoxia,[53] was derived from studies done on normal pregnancies, which were then made hypoxic. In FGR pregnancies, however, in which the ductus venosus shunt may be increased, this defense mechanism may be further compromised. It is

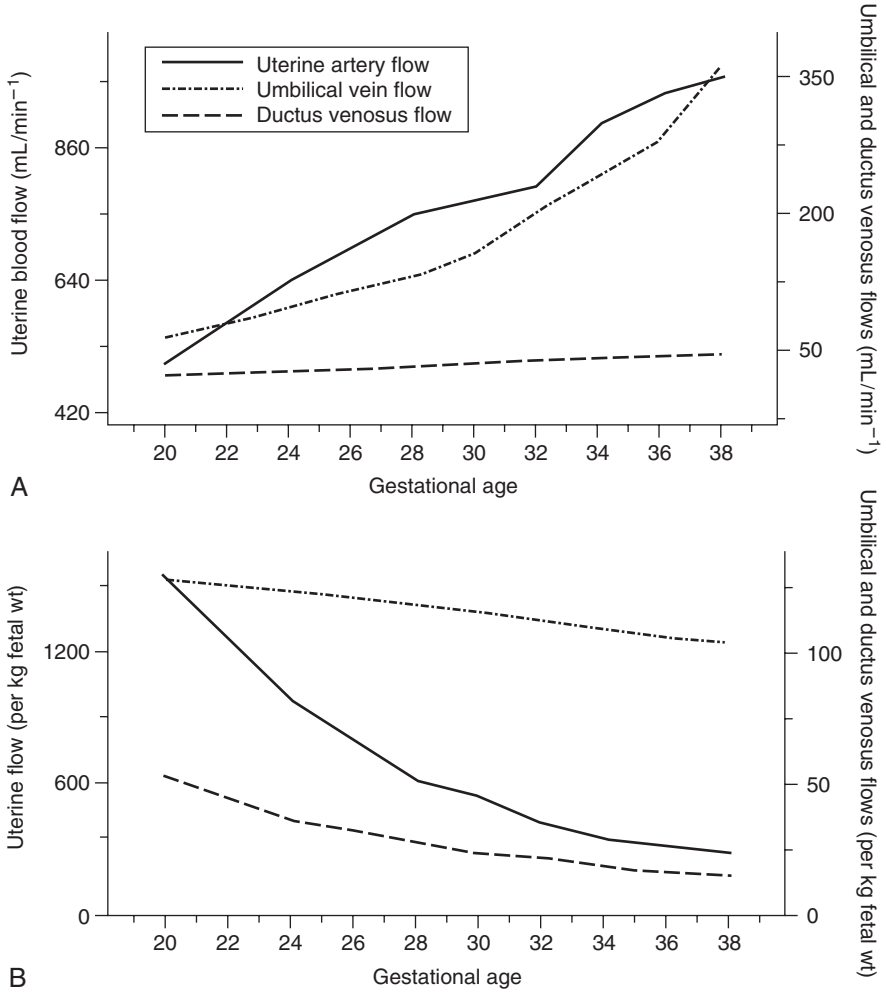

Figure 28-2 The three vessels for which flow measurements are available in human pregnancies are the uterine artery, with flow plotted as a *solid line;* the umbilical vein, with flow plotted as a *dotted-dashed line;* and the ductus venosus, for which flow is plotted as a *dashed line.* **A,** Flows in milliliters per minute = uterine artery flow. **B,** Flows in the same three vessels expressed as milliliters per minute per kilogram of fetal weight. In human pregnancies, the uterine flow is much greater than the umbilical flow. The umbilical flow, in milliliters per minute per kilogram of fetal weight, declines only slightly over the course of gestation; this finding establishes that the rate of increase in umbilical flow is roughly parallel to the rate of increase in fetal weight. *(Data from Konje J, Kaufmann P, Bell S, Taylor D: A longitudinal study of quantitative uterine blood flow with the use of color power angiography in appropriate for gestational age pregnancies,* Am J Obstet Gynecol *185:608-613, 2001; and Barbera A, Galan H, Ferrazzi E, et al: Relationship of umbilical vein blood flow to growth parameters in the human fetus,* Am J Obstet Gynecol *181:174, 1999.)*

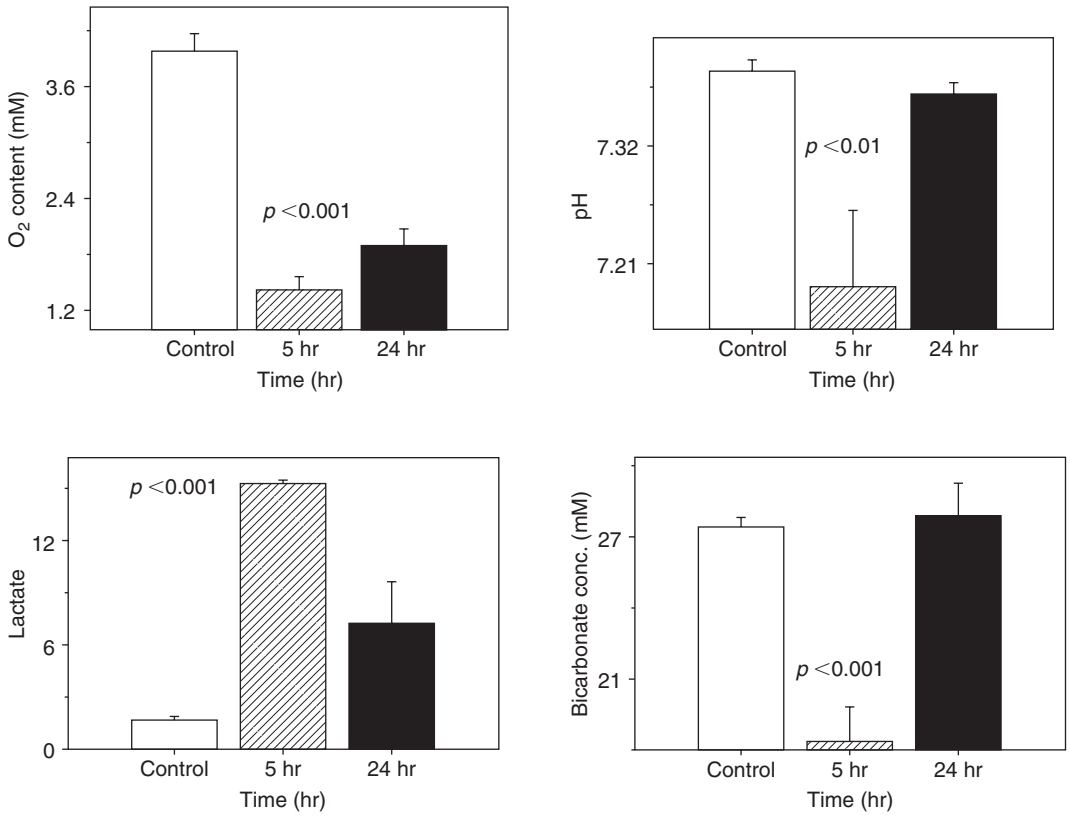

Figure 28-3 Changes in acid-base balance and lactate concentration during severe and persistent fetal hypoxia. *(From Wilkening RB, Boyle D, Meschia G: Fetal pH improvement after 24 h of severe, nonlethal hypoxia,* Biol Neonate *63:129-132, 1993.)*

the reduced hepatic perfusion in some FGR pregnancies that makes the growth-restricted fetus particularly vulnerable to fetal hypoxia.

Glucose metabolism also is altered in FGR pregnancies. In the sheep model, glucose uptake into the fetal circulation from the placenta is maintained within the normal range when expressed per kilogram of fetal weight or expressed per gram of placental weight.[54] The maintenance of a normal glucose uptake despite the small placenta in FGR pregnancies is accomplished by an increase in the transplacental glucose gradient. In women, umbilical glucose uptake cannot be measured directly. The glucose gradient across the placenta in normal human pregnancies, however, has been well described by a number of investigators.[55-59] Figure 28-4, from a study by Marconi and co-workers,[55] presents data obtained at the time of cordocentesis for the maternal "arterialized" and fetal umbilical venous glucose concentration differences throughout gestation for normal human pregnancies. It illustrates the fact that the maternal-fetal concentration difference increases with advancing gestation. As in the ovine model of FGR, however, the maternal-fetal glucose concentration difference is increased significantly over that in normal pregnancies at the same gestational stage. Figure 28-5 illustrates this increase, as well as bringing out that the magnitude of the glucose concentration difference correlates with clinical severity of the growth restriction, defined by umbilical artery velocimetry and FHR data.[55] Thus the changes in glucose gradients are linked to the fetal velocimetry changes as well. Studies of glucose transporter-1 (Glut-1) expression in human FGR pregnancies have shown that Glut-1 expression is not altered in FGR pregnancies, consistent with the foregoing data pointing to the increased transplacental glucose gradient as the primary adaptation to maintain fetal glucose uptake.[60] These findings also are consistent with the hypothesis that Glut-1 expression in the human placenta is altered in type 1 diabetes associated with high maternal glucose concentrations in early pregnancy[61] but not in gestational diabetes, in which maternal glucose concentrations are increased only in late pregnancy.[62]

Scaling of all metabolic data is critically important in studies of FGR pregnancies. Because both the fetus and the placenta in such pregnancies are smaller than normal, all of the values for uptake of nutrients and for blood flow will be reduced unless the data are normalized for body size. The smaller conceptus mass significantly reduces the metabolic demand on the mother. In human pregnancies, this issue has been addressed only for glucose.[59] Marconi and co-workers examined the relationship among three variables: (1) maternal plasma glucose disposal rate at steady state, a measure of maternal glucose utilization; (2) conceptus mass (fetal weight plus placental weight); and (3) maternal plasma glucose concentration.[59] These studies brought out the fact that, at comparable maternal glucose concentrations, the smaller the mass of the conceptus, the smaller the maternal glucose utilization rate.

Another aspect of glucose metabolism in FGR pregnancies is the question of whether significant gluconeogenesis occurs. Figure 28-6 summarizes the normal fluxes into and out of the fetal liver in the ovine fetus in late gestation (control period) taken from the study by Teng and associates.[63] Of note, the fetal liver has a very large uptake of lactate and gluconeogenic amino acids. Despite this large uptake of potential glucose carbon, no significant glucose release from the fetal liver occurs under normal conditions. Instead, carbon leaves the liver primarily as glutamate, serine and pyruvate. It is only when fetal gluconeogenesis is stimulated by a fetal infusion of glucagon that net glucose release from the liver can be found and, in response, glutamate release is virtually shut off. In human FGR pregnancies, stable isotopically labeled glucose has been infused into

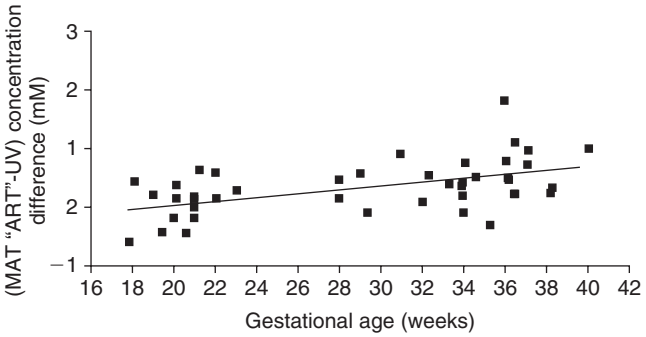

Figure 28-4 Maternal "arterial"-umbilical venous glucose concentration difference versus gestational age in AGA pregnancies. *AGA,* Appropriate for gestational age. *(From Marconi AM, Paolini C, Buscaglia M, et al: The impact of gestational age and fetal growth on the maternal-fetal glucose concentration difference,* Obstet Gynecol *87:937-942, 1996.)*

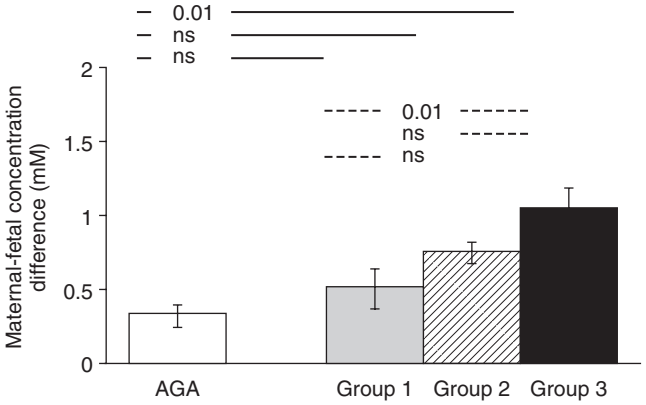

Figure 28-5 Measured mean ± SD values of maternal "arterial" umbilical venous glucose concentration (CONC) differences in appropriate-for-gestational age (AGA) fetuses and fetal growth restriction (FGR) cases of groups 1, 2, and 3. The *p* values refer to the significance of the differences for the intercepts of AGA versus FGR groups *(solid lines)* and among groups of FGR *(dashed lines)* for the regression analysis of the maternal-fetal difference versus gestational age, because there were no significant differences (ns) among the slopes of these regressions. *(From Marconi AM, Paolini C, Buscaglia M, et al: The impact of gestational age and fetal growth on the maternal-fetal glucose concentration difference,* Obstet Gynecol *87:937-942, 1996.)*

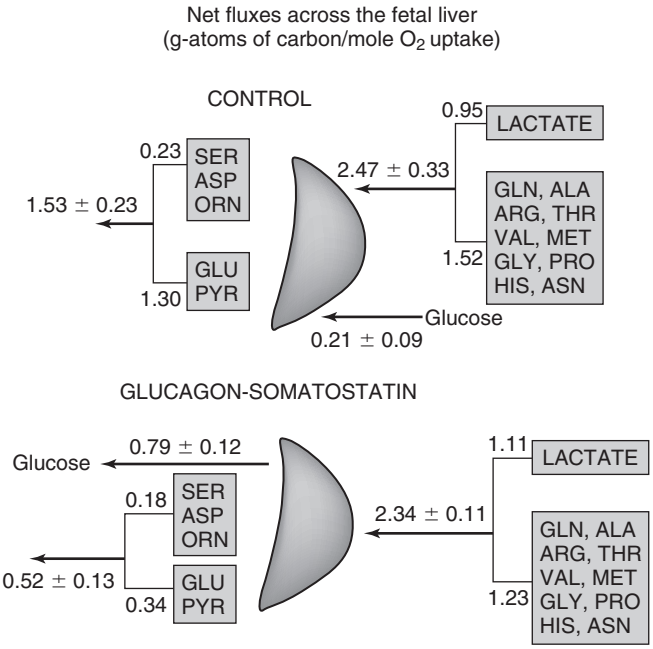

Figure 28-6 Fetal hepatic uptake and output of glucose carbon and glucogenic substrate carbon under normal physiologic conditions (control) and during a glucagon-somatostatin infusion into the fetal circulation. Each number represents a substrate carbon-to-oxygen uptake molar ratio. *ALA,* Alanine; *ARG,* arginine; *ASN,* asparagine; *ASP,* aspartic; *GLN,* glutamine; *GLU,* glutamate; *GLY,* glycine; *HIS,* histidine; *MET,* methionine; *ORN,* ornithine; *PRO,* proline; *PYR,* pyruvate; *SER,* serine; *THR,* threonine; *VAL,* valine. *(From Teng C, Battaglia F, Meschia G, et al: Fetal hepatic and umbilical uptakes of glucogenic substrates during a glucagon-somatostatin infusion,* Am J Physiol *282:E542-E550, 2002.)*

the maternal circulation to investigate whether dilution of the fetal plasma glucose enrichment occurs in FGR pregnancies.[64] Despite the fact that these measurements were carried out after an overnight fast, no evidence of dilution of the fetal glucose enrichment was found. Thus, in this study, an FGR pregnancy did not stimulate detectable fetal gluconeogenesis.

Amino Acid Transport and Metabolism

As an aspect of placental nutrient transport, amino acid transport and metabolism have been the subject of considerable research interest over the past decade. This work was stimulated in large part by advances in molecular biology that have permitted the identification of specific transporter proteins on the two plasma membrane surfaces of the trophoblast. The field of placental amino acid transport has been reviewed by several different groups of investigators.[65-67] As it applies to human FGR pregnancies, the following characteristics have been reasonably well established.

First, in microvesicle preparations from either the basal (fetal) surface or microvillus (maternal) surface of the trophoblast, transport capacity is reduced on both surfaces of the placenta in these pregnancies.[65] These defects are not present for all transport systems, nor are the problems the same on each surface. Changes in amino acid transport in vivo in FGR pregnancies can reflect changes not only in membrane transporter activity but also in placental utilization or production of an amino acid, as well as changes in perfusion of the placenta.

Figure 28-7 outlines the transplacental fluxes of an essential amino acid, leucine, in diagrammatic form. The data were obtained in normal pregnant sheep in late gestation.[68,69] Of note, the nutritionally important variable—namely, the net uptake of leucine into the fetal circulation—is determined principally by three different fluxes of approximately equal magnitude: (1) the transplacental flux from maternal plasma to fetal plasma; (2) the backflux from the fetal plasma into the placenta; and (3) the leucine flux from placental protein breakdown into the fetal plasma. In the ovine model of FGR, it has been shown for two essential amino acids, leucine and threonine, that the transplacental flux is significantly reduced.[69,70] This decrease holds even when the flux is expressed per gram of placenta. In those studies, the fetal adaptation to the reduced transplacental flux is a lower fetal plasma amino acid concentration. This change leads in turn to a lower fetal amino acid oxidation rate and a reduced backflux into the placenta. Both of these changes would tend to divert these amino acids to fetal protein synthesis. A reduced transplacental flux in ovine FGR pregnancies led

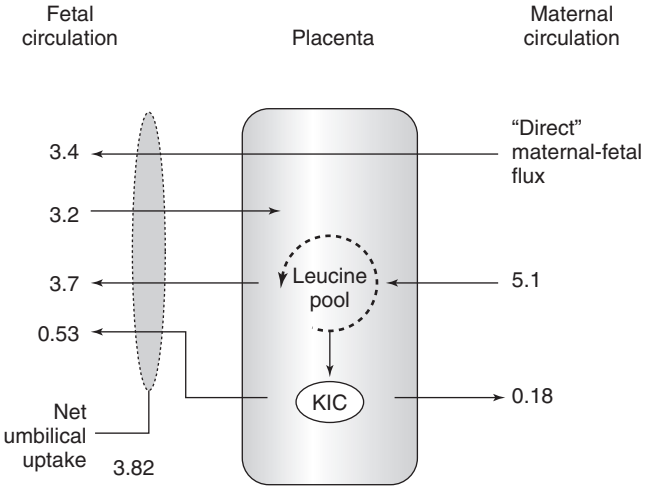

Figure 28-7 The unidirectional fluxes of leucine into and out of the placenta (μmol • min^{-1} • $kg_{fetal\ wt}^{-1}$) measured in vivo under steady-state conditions are presented. (Data are abstracted from studies by Loy [68] and Ross[69] and their colleagues.) The three major fluxes that together determine the umbilical uptake are of approximately equal magnitude. *KIC,* Alpha-ketoisocaproic acid. *(From Battaglia FC, Regnault TR: Placental transport and metabolism of amino acids,* Placenta *22:145-161, 2001.)*

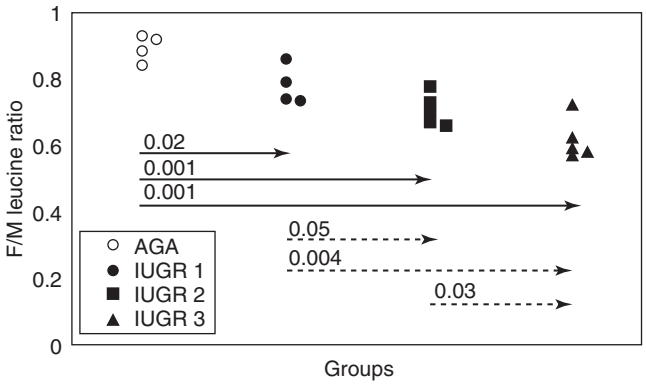

Figure 28-8 Leucine fetal-maternal (F/M) enrichment ratio in appropriate-for-gestational-age (AGA) and intrauterine growth restriction (IUGR) pregnancies at fetal blood sampling. *(From Marconi AM, Paolini C, Stramare L, et al: Steady state maternal-fetal leucine enrichments in normal and intrauterine growth-restricted pregnancies,* Pediatr Res *46:114-119, 1999.)*

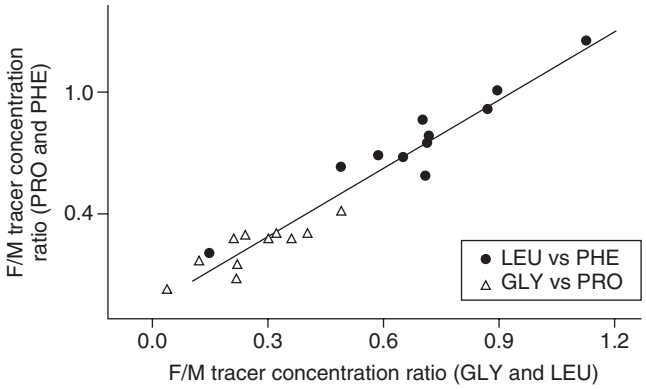

Figure 28-9 The fetal-maternal (F/M) plasma tracer concentration ratios are plotted with the values for glycine (GLY) and leucine (LEU) along the abscissa and those for proline (PRO) and phenylalanine (PHE) along the ordinate. The regression is highly significant: F/M $y = -0.0511 + 1.1274$, F/M x, $R_2 = 0.94$; $p < .001$. *(From Paolini CL, Marconi A, Ronzoni S, et al: Placental transport of leucine, phenylalanine, glycine, and proline in intrauterine growth–restricted pregnancies,* J Clin Endocrinol Metab *86:5427-5432, 2001.)*

to a significantly lower fetal-maternal (F/M) enrichment ratio for both leucine and threonine. These studies led to clinical studies of the F/M ratio in normal and FGR pregnancies. The clinical data for the leucine F/M ratio are presented in Figure 28-8, from a study by Marconi and co-workers.[71]

Two aspects of these data merit further discussion: First, the data clearly demonstrate a significant reduction in the F/M enrichment ratio for leucine in FGR pregnancies, presumably reflecting a significant reduction in the maternal-to-fetal transplacental flux. Second, the magnitude of this effect correlated with the classification of clinical severity in FGR pregnancies proposed by Pardi and colleagues,[14] which was based on fetal umbilical arterial velocimetry and FHR data. Just as with glucose data, leucine metabolic data correlated with clinical severity defined by fetal vascular changes. Studies of amino acid transporter activity and expression in vesicles prepared from the microvillus surface have provided additional information, although the interpretation of the findings is not always clear. For example, the taurine transporter TauT has been localized almost exclusively to the syncytiotrophoblast microvillus membrane.[72] Its expression is not altered in FGR pregnancies. This lack of effect could imply a reduced activity of the transporter or simply reflect the decrease in surface area represented by terminal villi in the FGR placenta. By contrast, leucine transporter activity is reduced in FGR placentas—an effect that would be magnified by the reduction in terminal villi surface area. [73]

A study by Paolini and associates in ovine pregnancy had used similar non–steady-state methodology to compare the transport rates of the nine essential amino acids in normal ovine pregnancy.[74] One of the observations coming from that study was that the three branched-chain amino acids and phenylalanine and methionine appeared to cross at similar rates, and much more rapidly than all other essential amino acids. Figure 28-9 from that study illustrates the fact that differences for the pulse fluxes from the maternal to the fetal circulation for these five amino acids were determined by differences in their normal concentrations in maternal plasma. Similar methodology has been used in human normal and FGR pregnancies to examine the relative placental transport rates for four amino acids: leucine, phenylalanine, glycine, and proline.[75] Figure 28-9 also compares the F/M plasma enrichment ratio of leucine with phenylalanine and that of glycine with proline. No significant differences in transport rate were found between leucine and phenylalanine, or between glycine and proline. However, leucine and phenylalanine crossed much more quickly than glycine and proline. Furthermore, in FGR pregnancies, the F/M ratio of leucine and phenylalanine was significantly reduced compared with that in normal pregnancies. Thus, with amino acids, it is becoming increasingly possible to assess placental function in human FGR pregnancies in vivo.

SUMMARY AND CLINICAL IMPLICATIONS

It is clear that in FGR pregnancies, the fetus experiences problems in transport of O_2 and nutrients. Most of these problems can be attributed directly to the maldevelopment of the placenta, which not only is reduced in size but also has structural abnormalities in its vasculature. These changes in the placenta, with the additional factor of chronic hypoxia, can lead to fetal circulatory

changes in many fetal vascular beds detectable by both velocimetry and blood flow studies. Circulatory and metabolic studies have demonstrated a wide range in clinical severity of FGR based on fetal size for gestation. The importance of delineating more homogeneous subsets of FGR pregnancies in terms of severity of the growth restriction stems from the potential clinical usefulness of such information: It can help direct optimal timing of delivery in pregnancies that feature severe FGR. It can form the basis for adjustments in neonatal care of affected infants. Finally, such information can provide the foundation for more focused follow-up studies in childhood and in adulthood.

29 Endocrine Factors Affecting Neonatal Growth

Dennis M. Styne

Growth reflects a complex interaction of genetic and epi-genetic, endocrine, and nutritional factors which, in turn, regulate cell division and differentiation affecting function. Various phases of growth appear "programmed" to occur within specific time intervals, which, if missed, may not be recoverable. Ever-increasing evidence indicates that the pattern and rapidity of fetal and neonatal growth affect the endocrine environment in later life. Thus, the role of endocrine factors in modulating growth during this critical "epoch" of development and the resulting long-term effects are reviewed.

PATTERN OF NEONATAL GROWTH

The greatest growth rate occurs during fetal life; in fact, the development of a single fertilized cell into a 3.5-kg neonate entails an increase in length of 5000-fold, an increase in surface area of 61×10^6, and an increase in weight of 6×10^{12}. The greatest postnatal growth rate occurs just after birth,[1] followed by slower growth during midchildhood, only to increase once more in puberty before the final cessation at epiphyseal fusion.

Both longitudinal studies (mostly from outside the United States) and cross-sectional studies (by U.S. investigators) have described the growth process after birth. The Centers for Disease Control and Prevention (CDC) released the latest version of the commonly used growth charts from birth until the age of 18 years in 2001* using cross-sectional data from the United States. The charts demonstrate growth between the 3rd to 97th percentiles of length during the first 3 years after birth. Most iterations of the charts show a different color between the 3rd and 97th percentiles. Even though the color change usually found at the 3rd percentile may cause concern in parents of an infant that falls below that line, it is important to recognize that 3% of normal children fall below that lower limit and that only a minority have a condition requiring evaluation or therapy.

Analysis of the factors affecting various phases of growth led to the development of the infant-childhood-pubertal growth charts[2] in which the amount of growth for each of three phases of growth (infancy, childhood, puberty) are considered and their sums plotted. Each component of this model can be described by specific mathematical functions (Figure 29-1).

Infancy

The slowly decelerating component in infancy occurs as the child has a decrease from the rapid fetal growth phase that starts before birth and falls off by age 3 to 4 years. An infancy-child growth spurt occurs at 6 to 9 months of age, which defines the beginning of the childhood phase, as the infant phase decreases.[3] Average total gain in height for Swedish boys (the population from which the plots were originally developed) is 79.0 cm (44.0% of final height) and for girls is 76.8 cm (46.2%).

Childhood

The childhood phase begins during the first year of life and continues until adult height is attained. It is believed to mainly exhibit the strengthening endocrine effects of thyroid hormone, growth hormone (GH), and other agents. Average total gain in height for boys is 85.2 cm (47.4%) and for girls is 78.4 cm (47.3%).

Puberty

The puberty phase is dependent on sex steroids, mainly estrogen, working in concert with GH; in the absence of either, such as in GH or gonadotropin deficiency, growth decreases markedly, as does height. According to this model, average total

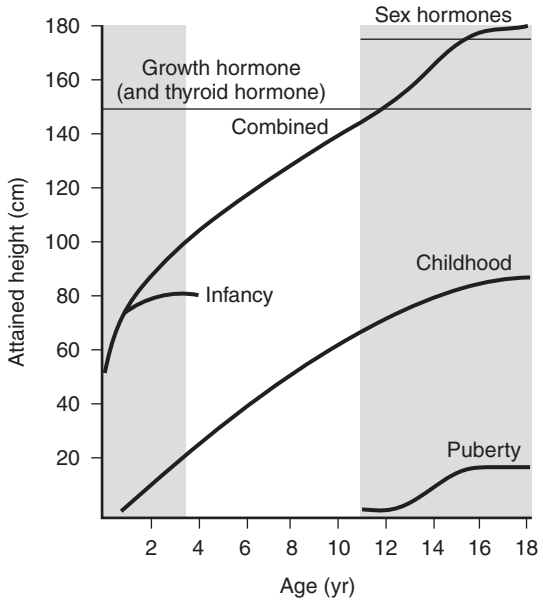

Figure 29-1 Individual components of the infancy-childhood-puberty growth chart and the combined growth curve that results from the sum of them. *(Modified from Karlberg J: On the construction of the infancy-childhood-puberty growth standard,* Acta Paediatr Scand Suppl *356:26, 1989.)*

gain in height for boys is 15.4 cm (8.6%) and for girls is 10.9 cm (6.5%) in this period.

MEASUREMENT OF GROWTH

Weight measurements are the standard method of evaluating neonatal growth. Scales used for this purpose may be accurate to 10 g if they are calibrated regularly. Nonetheless, even this variation when measuring the weight gain of a 1000-g infant during a period of 1 week can lead to an error of as much as 2.9 g per day: If the infant was weighed daily rather than weekly the error might be as much as 20 kg per day.[4]

The accurate measurement of length at birth is just as important as the measurement of weight because the growth velocity can be determined and a pathologic tendency for a baby to cross percentiles in length for age will become apparent.[5] Unfortunately, accurate and reproducible measurement of neonates and infants is difficult to obtain in clinical practice. A study of the measurement of infants as well as inanimate dolls led to inaccuracies of up to 25% in length measurements, and weight measurement errors exceeded 10%.[6] Even if a measurement is assumed to be accurate, the points plotted on the growth chart are also prone to error due to rounding of the measurement by inattentive personnel or to lack of attention to adjustment for gestational age (if the baby is premature).[7,8] Measurement of growth can be performed accurately if two individuals gently straighten the infant and hold the child against a calipers-like device such as a Neo-Infantometer (Graham-Field, Inc., Hauppauge, New York) that expands and contracts to measure the linear distance from a perpendicular plate at the top of the head to a perpendicular plate at the bottom of the feet; staff can be trained to perform this with accuracy.[6,9,10]

Measurement of length is not just a matter of academic interest. Most analyses of infant deaths have been based on birth weight. However, careful analysis of the relationship between birth length and death after premature birth in the Swedish population showed the important effect of length in preterm infants.[11] Although low weight or ponderal index led to a greater risk of early death, those factors at 4 to 5 days of age no longer exerted such a strong effect; however, having a length less than −1 standard deviation (SD) at birth continued to increase the risk of long-term mortality.[11]

Knemometry is a technique that measures minute changes in length of the lower leg[12] and is applicable even to seriously ill children in the neonatal intensive care unit.[13] Although the yearly growth rate is considered linear and consistent, knemometry demonstrates the waxing and waning pattern of growth that occurs over days and weeks; the time between peak growth rate and the nadir of growth rate may be 10 to 20 days.[9,14,15] This fluctuating growth in length may be accompanied by changes in the pattern of weight gain; however, this pattern is innate, perhaps genetic in origin, and is not affected by variations in caloric intake unless frank malnutrition develops.[16] Further, knemometry demonstrated the effect of dexamethasone or chronic lung disease on decreasing growth.[12] Glucocorticoid treatment may increase weight while decreasing length velocity, so measuring weight cannot be a substitute for measuring growth in length. Knemometry is mainly used in research studies, but it adds important information in the clinical setting by some. However, even the knee-to-heel measurement is shown to have problems of accuracy and sensitivity.[17]

Therefore it is apparent that measuring weight and height is important in the evaluation of neonates. Although in the clinical practice of most centers, weight measurements are more accurate than length measurements, with extreme care in measuring length by trained staff, accurate length measurements can be obtained and plotted.

GROWTH CHARTS

The CDC full-term neonatal growth charts were revised and released in 2001 and are based on cross-sectional data for large numbers of infants: thus they can be assumed to be accurate. However, the derivation of premature infant growth charts is another matter. In Chapter 28, Battaglia provided detailed discussion of fetal growth and its measurement. Premature growth charts are based upon data obtained from the birth weight of premature babies at various gestational ages. The gestational age used in these charts are based on the mothers' last menstrual period or postnatal examination, which is considered to be accurate only within 2 to 4 weeks. Furthermore, it has been estimated that up to 40% of infants born at 23 weeks gestation are small for gestational age: Using these data to develop a growth chart to purportedly represent normal premature baby growth is therefore problematic.[18] Thus neonatal premature growth charts may be affected by inaccuracies of average weight for gestational age and indeed inaccuracies of estimated gestational age: Both the *x*- and *y*-axes may be inaccurate.[4] This is important because the American Academy of Pediatrics states that the growth of preterm infants should replicate that of a fetus of the same gestational age. If clinicians do not know what the normal growth of normal fetuses is at a given gestational age, they will have difficulty trying to ensure this happens. Likewise, feeding and postnatal nutritional supplementation practices vary in relation to goals for growth, complicating the situation further. It has been suggested that new longitudinal data collection is needed to allow reexamination of this concept.[19] At present, no consensus has emerged regarding the optimal reference for the growth of premature infants.

An alternative attempt to improve the relevance of neonatal growth charts used a population study in Burgundy, plotting the birth weights in each week of gestation for one cohort with maternal diseases likely to affect fetal growth and another for healthy mothers without these diseases.[20] Regardless of the group in which the mother was placed, small-for-gestational-age (SGA) infants born at term had a increased risk of death,

however, SGA preterm infants born at 32 to 36 weeks gestational age was not associated with increased mortality and morbidity compared with appropriate-for-gestational-age (AGA) term infants. Infants determined to be SGA at 28 to 31 weeks according to the healthy population standards were at higher risk for pulmonary disease and intraventricular hemorrhage, leading to the conclusions that standards based on healthy maternal populations may better indicate those infants at most risk for complications. Customized British birth weight percentile charts based on characteristics of the mother (e.g., height, weight, parity) and the physiologic characteristics of the neonate (e.g., gestational age, sex) are available for that population[21,22] and are likewise believed to be helpful.

Despite these concerns about standards of height, weight, and weight-for-height adjusted for gestational age, such standards are in general use for preterm low-birth-weight infants and are expected to help determine appropriate weight gain, evaluate failure to thrive, and observe patterns of excessive weight gain in low-birth-weight infants.[23,24]

Longitudinal measurement of length in an infant helps predict childhood growth patterns and other factors in the evaluation of neonates. The risk for attaining an adult height 2 SD less than the mean was five-fold higher in children with a low birth weight and seven-fold higher in those with a low birth length.[25] The length of a full-term newborn is closely correlated with the maternal stature and weight[26] and parity status; the babies of short or thin mothers who are born SGA are more likely to have a positive outcome than those who are born SGA to primiparous mothers.[27] Once free from the constraints of the uterus, the full-term infant will often adjust growth to achieve the growth channel of the percentile that will be followed for most of childhood. An increase in percentiles during childhood occurs sooner after birth as the childhood percentile is reached by 11 to 12 months, and a downward adjustment will allow the child to reach the new lower percentile by a later mean age of 13 months of age.[28] These changes are gentle, however, and show no abrupt change in growth velocity, which would indicate pathology. Accurate data on weight and height velocity, as well as body composition changes, are available in neonates.[28a] Determining the percentile or standard deviation score of velocity is more accurate than plotting a single height or weight as the velocity will change first.

Prematurity, Intrauterine Growth Restriction, and Small for Gestational Age

As reviewed by Saenger[28b] in 2007, the definition of intrauterine growth restriction (IUGR) and SGA are often confused; even the medical literature is not always clear. The term IUGR indicates a documented decrease in intrauterine growth noted by two fetal ultrasound examinations; a baby with IUGR may have a temporary problem that will still allow a normal or near-normal birth weight and length. Thus the accuracy of fetal ultrasonography becomes an issue in this diagnosis. Because many infants are born with low birth weights, the description of SGA is in fact a proxy for IUGR in many, but not all, situations.

The description of SGA refers to an infant whose weight (and presumably length) are below a limit, usually weight or crown-heel length at birth is at least 2 SD less than the mean for the infant's gestational age, equivalent to the 2.3 percentile, based on data derived from an appropriate reference population; however, in some publications, SGA refers to babies with birth weights below the 3rd, 5th, or 10th percentile for gestational age, confusing interpretation of clinical studies during various eras. Furthermore, the difference in percentiles used for diagnosis is of practical importance because medical insurance companies may adhere to one diagnosis and eliminate treatment of children fulfilling other criteria. The World Health Organization (WHO) defines "low birth weight" as a weight at birth less than 2500 g in an infant of any gestational age; this inclusion of all gestational ages becomes problematic because long-term outcomes are likely to be different for a baby who was premature but AGA and for a full-term infant who is SGA even if of the same weight.

Recently a consensus conference on treating babies born SGA with GH suggests a diagnostic criterion of a weight or length more than 2 SD below the mean for gestational age[29]; that is the convention used in this chapter. SGA may be further classified as SGA with a low birth weight, SGA with a below-normal birth length, or SGA with a low birth weight and below-normal length, and the difference may change the outcomes of therapy. Two other descriptors of IUGR are used: *symmetric IUGR* denotes normal body proportions (a small head and a small body) and may be considered a more severe and longstanding form of IUGR, dating from the second trimester; *asymmetric IUGR* denotes small abdominal circumferences (due mostly to a small liver), decreased subcutaneous and abdominal fat, reduced skeletal muscle mass, and a head circumference in the normal range, probably resulting from stress effects in the third trimester. These definitions do not consider ethnic background, parity, or maternal size, so further classification is possible but not objectively defined.[29] A low ponderal index (birth weight/length^2) is a marker for asymmetric growth restriction and is associated with an increased risk for cerebral palsy.[30]

Although premature infants are expected to have catch-up growth by 2 years, it is those born after 29 weeks gestation who exhibit catch-up growth; those born before 29 weeks more likely have a decreased rate of length and weight gain, which may be noted in the first week after birth and lasts up to 2 years.[6,31,32] Although it was previously assumed that SGA babies, in contrast to AGA premature babies, did not have catch-up growth in length, evidence from longitudinal (as well as less powerful cross-sectional) studies show that the majority, up to 80%, that started with lengths greater than 2 SD below the mean, do indeed show catch-up in height for age.[25,33,34] It has been demonstrated for decades that catch-up growth can be demonstrated soon after birth if careful measurements are utilized,[35] which seems to be crucial because much of the catch-up growth occurs in this period.[36] Indeed, an acceleration of growth in length is noted in the first 6 months of SGA babies who will catch up.[36,37] In one study, 44% of infants with neonatal length more than 1.28 SD below normal (i.e., −1.28 SD), and therefore considered SGA, caught up to attain a length that was less than −1.28 SD by 3 months, 51% caught up by 3 years, and 73% by 6 years.[38] A large study (n = 3650) of SGA infants found that 88% of healthy singleton SGA infants showed catch-up growth by 2 years, with most showing the catch-up growth by 2 months; those that remained short at 2 years had a greater risk of shorter adult stature.[25] In a prospective study of SGA babies (the criteria for the classifications of the infants in the study appeared to be birth weight and ponderal index, suggesting that SGA rather than IUGR was under investigation), 38% were under the 10th percentile of height at 6 months of postnatal age versus 7% of control babies; proportionate SGA infants had greater catch-up growth than disproportionate SGA babies, but the differences were in the range of 1 cm of increased growth per 6 months.[39] In general, children born SGA will achieve an adult height standard deviation score (SDS) equivalent to their SDS in childhood because skeletal development is normal. Approximately one fifth of extremely short children have a history of IUGR.[40,41]

Controversy exists about the infantile growth rate of very SGA infants (<1500 g); some studies show similar growth in length and head circumference in very SGA infants compared with those of the same birth weight but shorter gestation (preterm but AGA).[42] Others found the opposite—that SGA infants

are shorter and lighter at 3 years and have delayed growth.[43] Of 166 children with birth weight less than 1000 g and SGA, 81% demonstrated catch-up growth in length during childhood, with 78% showing catch-up growth in length by 3 years of age.[44]

Longitudinal evaluation of growth in neonates in intensive care units demonstrates an almost universal growth impairment.[45] Gestational age is the most important predictor of growth impairment, followed by birth weight and length standard deviation scores. The babies born at younger gestational age with higher weights were at greatest risk for both types of growth impairment. Because this early growth impairment appears to be common, it is thought that recreating the intrauterine environment for a premature baby is a virtual impossibility. Not only is growth impaired in the immediate postnatal period, but such impairment continues for months. Enhanced infant formulas have been tried in an attempt to increase growth during these vulnerable periods.

However, catch-up growth is associated with dangers even outside the neonatal intensive care unit.

DANGERS OF RAPID NEONATAL GROWTH

As noted in other chapters, children born with lower birth weight are shown to be at higher risk for impaired glucose tolerance and cardiac disease as adults.[46,47] Rapid growth in such children, however, also leads to adult risk for cardiovascular disease and glucose intolerance,[48-50] as reviewed by Gluckman and colleagues[51] The early weight gain during the first months of life may be more of a risk factor for obesity and the onset of disease related to insulin resistance than later weight gain during childhood, according to the results of longitudinal studies in Avon, Stockholm, and other sites.[52] Infants with the greatest increase in linear growth during this period have decreased flow-mediated endothelium-dependent dilation (FMD) (a measure of vessel dysfunction), which is as significant an event as seen with insulin-dependent diabetes mellitus or smoking in adults.[53] Likewise measures of insulin resistance are higher in those with the greatest weight gain in the postnatal period.[54] It has been suggested that somewhat slow growth in the postnatal period may not be undesirable.[45]

Prematurity itself affects insulin sensitivity. Premature babies who are born AGA and demonstrate slow catch-up weight gain nonetheless have postnatal insulin resistance, just like SGA babies.[55] Rapid, excessive weight gain in full-term neonates also has been correlated with the development of hypertension, obesity, and comorbid illnesses by the age of 30 years.[56,57] However, recent conflicting data from birth cohorts in Brazil, Guatemala, the Philippines, and South Africa indicate that weight gain at any age relates to increased adult blood pressure and that weight gain in infancy does not pose a higher risk than at other ages.[58] It is not clear how to reconcile this finding with those noted previously.

Low birth weight can affect pubertal development in girls. Girls born with low birth weights extending to the classification of SGA defined previously tend to have early onset of puberty.[59] In addition girls with low birth weight have increased prevalence of insulin resistance by 1 year of age[60] and a tendency toward developing polycystic ovarian syndrome characterized by hyperinsulinemic hyperandrogenism. Girls with average birth weight who tend towards early breast development have an extended duration of time between breast development and menarche; therefore the age of menarche is relatively stable even if the age of onset of breast development is more variable. However, girls with low birth weight do not demonstrate such an extension of the time between breast development and menarche; it has been postulated that the hyperinsulinemia characteristic of these girls is related to early menarche.[2] The effect of low birth weight on the reproductive axis in males is not well-known, but aromatase activity due to elevated estradiol levels, 5α-reductase activity reflected by elevated dihydrotestosterone, and elevated inhibin B, reflecting activity of the seminiferous tubules, are inversely proportional to birth weight, but at present the effects of these changes are not known.

The U.S. Food and Drug Administration (FDA) has approved treating SGA infants lacking catch-up growth by 2 years after birth with GH in a dose of 0.48 mg/kg/day. Controversy remains about optimal dose as well as frequency and duration of therapy, but treated children clearly can reach an adult height in the normal range.[61-63] GH is most effective when used at a young age; therefore caregivers of SGA babies should be aware that if catch-up growth does not occur by 2 years of age, they should consider the possibility of using GH. Because the neonatologists who care for the babies at birth do not care for them in the subsequent months and a program of treatment would optimally start at 2 years old, effective communication between the neonatologists and pediatricians who follow the children as well as the endocrinologist who may evaluate the child for GH therapy is important.[64] SGA babies tend towards insulin resistance, and GH therapy can produce insulin resistance. Thus the potential for the development of type 2 diabetes in GH–treated SGA babies is of concern, but so far an increase in the prevalence of type 2 diabetes after the increase in insulin levels that occurs during growth hormone treatment has not been demonstrated.[65,66] However, not enough treatment years have passed to ensure that adult diabetes or abnormalities of lipid metabolism caused by growth from treatment in SGA children does not occur. However, some evidence exists for an increase in proinflammatory tendencies[67] so that GH-treated children must be watched long term.

AGA infants born preterm who grow poorly in the initial postnatal months are considered to be growth restrained; these children grow in a manner similar to SGA babies throughout childhood and reach similar adult size.[2] It has been suggested that these individuals should be approved for the use of GH as SGA babies.[68]

Turner syndrome occurs in one in 2000 girls and is another condition for which the FDA has approved GH to increase height.[69] In addition to low birth weight, Turner syndrome is often diagnosed in the neonatal period because of numerous characteristic, somatic abnormalities, and frequent occurrence of left-sided heart disease, such as coarctation of the aorta and related hypertension. These infants grow poorly starting in early life.

Controversy exists about the long-term effects of SGA on intellectual function. A 26-year follow-up study comprising 1064 infants born SGA (defined as birth weight below the 5th percentile) and 14,189 non-SGA (control) infants found no difference in years of education, employment, marital status, or satisfaction with life between the two groups.[70] However, persons whose birth history included SGA were less likely to be in the top 15% of their high school class and more likely to be recommended for special education; in addition, they demonstrated small but significant defects in academic achievement. They also attained shorter adult heights (−0.55 SDs) Furthermore, persons in the SGA group were less likely to hold managerial or professional employment and had lower incomes compared with those in the non-SGA group. Another 20-year longitudinal follow-up study of persons whose birth history included very low birth weight (less than 1500 g) demonstrated a lower mean intelligence quotient (IQ) (87 versus 92), lower academic achievement scores, lower likelihood of high school graduation, and less post–secondary school study but, on the positive side, less alcohol and drug abuse than those born at normal weight.[71]

Neonatal growth may be affected by metabolic bone disease in preterm infants, probably as a result of vitamin D deficiency

in view of the association with elevated serum alkaline phosphatase. For example, the finding of a peak neonatal alkaline phosphatase of greater than 1200 IU predicted shorter stature to age 12 years. The effect exceeds that of maternal or paternal height, sex, parental educational achievement, and hypertension during pregnancy—other factors shown to affect childhood height.[72,73] Human milk increases bone mass as shown in a 20-year follow-up of preterm infants randomized to various diets in the neonatal period.[74] C-type natriuretic peptide appears to be a useful marker because it plays an essential role in endochondral bone growth and when measured in plasma can be used as a reflection of bone turnover in infants.[75]

MIDCHILDHOOD GROWTH SPURT

Although the striking pubertal growth spurt attracts much attention, two periods after birth are characterized by brief growth spurts before puberty occurs: the infant-childhood growth spurt between 8 months and 3 years and the midchildhood growth spurt between 6 and 7 years. Furthermore, in the context of body weight and fat content, an "adiposity rebound" of accelerating weight gain and rising body mass index occurs in midchildhood after a period of relative stability of weight gain beforehand. An early adiposity rebound is a risk factor for the development of obesity later in childhood and thereafter.

THE HORMONAL CONTROL OF NEONATAL GROWTH

The hormones that mediate postnatal growth do not play the same roles in fetal growth. As noted in chapter 178, GH is present in very high concentrations in the fetus in contrast to the limited presence of GH receptors. Although this discrepancy suggests limited activity of GH in the fetus, GH does play a role in fetal growth that is reflected in the mean birth weight 1 SD below the mean characteristic of GH-deficient infants. Infants with Laron syndrome (OMIM 262500) (i.e., GH resistance due to reduced or absent GH receptors) have elevated GH and low serum insulin-like growth factor (IGF)-1 levels; they have decreased birth length and weight. Insulin excess, as in the infant of a mother with diabetes, causes increased growth. One patient with congenital IGF-1 deficiency (not due to GH receptor defects)[76,77] had a birth length 5.4 SD below the mean and was 6.9 SD below the mean for height at age 15 years old. Because no IGF-1 was found, no feedback to GH (OMIM 608747) secretion was obtained and GH values were high, similar to those typical for Laron dwarfism. In addition, children were reported with IGF-I receptor mutations (OMIM 608747 and 270450) demonstrating intrauterine and postnatal growth retardation, again demonstrating the importance of IGF-I in both periods of growth.[78]

Thyroid hormone deficiency does not directly affect human birth weight, but prolonged gestation is a feature of congenital hypothyroidism, and this factor will itself increase weight. Placental lactogen exerts no apparent effect on birth size in human beings. However, the concentration of placental GH (from the *GHV* gene; see later) is significantly decreased in the serum of a pregnant woman bearing a fetus with IUGR.

In the postnatal phase, these hormones have important but, in many cases, different roles.

GROWTH HORMONE

Human GH is produced as a single chain, 191–amino acid, 22-kDa containing two intramolecular disulfide bonds[79] (Figure 29-2) A 20-kDa variant of pituitary GH accounts for 5% to 10% of circulating GH.[80] The genes for a family of GH-related proteins share a common structural organization with four introns separating five exons. The gene for GH is located on the long arm

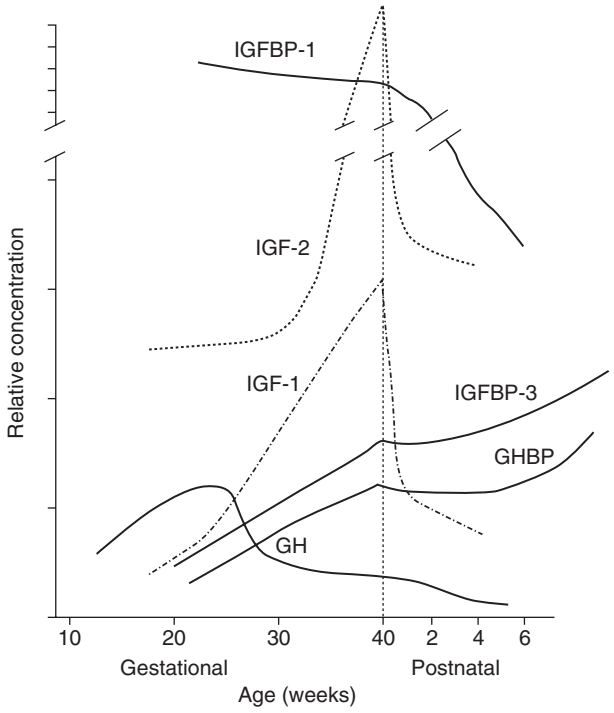

Figure 29-2 Relative concentrations of GH, GHBP, Igfs, and IGFBPs during gestation and perinatally. *(Adapted from Wollman HA,* Horm Res *53[Suppl 1]: 50, 2000.)*

of chromosome 17 in a cluster of five genes with evolutionary relationships: *GHN* codes for human GH (a single 191–amino-acid polypeptide chain with a molecular mass of 22 kDa), *GHV* codes for a variant GH produced in the placenta, *CSH1* and *CSH2* code for prolactin, and *CSHP1* codes for a variant prolactin molecule.[81]

GH is released in a pulsatile pattern in which peaks are rare, which are measurable by most assays and nadirs when only the most ultrasensitive assays can detect GH (e.g., values of 0.04 μg/L). These peaks and valleys of GH are under the control of the two hypothalamic regulatory peptides: GH-releasing hormone (GHRH) a stimulatory peptide also released in a pulsatile manner, and somatostatin (or somatotropin release-inhibiting factor), an inhibitory factor.[82] GHRH contains 44 amino acids, but alternative forms have 40 and 37 amino acids, although the amino terminus of GHRH must be present for biologic activity. GHRH exerts effects by binding to a G protein–related receptor on the pituitary somatotropes, increasing intracellular cyclic adenosine monophosphate (cAMP) production, and subsequently increasing GH synthesis. Somatostatin, however, regulates the timing and amplitude of the pulses of GH but has no effect upon synthesis of GH. In contrast with the action of GHRH on the pituitary, when somatostatin binds to its receptor, it inhibits adenylate cyclase activity and reduces intracellular calcium levels.[83] Pulses of GH secretion occur when a decrease in the release of somatostatin and an increase in the release of GHRH occurs from the hypothalamus; however, when somatotropin release-inhibiting factor is released without GHRH, a nadir of the GH pulse occurs.

A plethora of neurotransmitters regulate the release of these hypothalamic factors including serotonin, histamine, norepinephrine, dopamine, acetylcholine, γ-aminobutyric acid, thyroid-releasing hormone, vasoactive intestinal peptide, gastrin, neurotensin, substance P, calcitonin, neuropeptide Y, vasopressin, galanin, and corticotropin-releasing hormone (reviewed by Reiter and colleagues[84]). The physiologic state also affects

GH secretion including stress, sleep (deep sleep during later childhood), hemorrhage, fasting, hypoglycemia, and, at least in older subjects, exercise. GH-stimulatory tests are employed in the evaluation of GH secretory capacity in neonates if indicated. The secretion of GH is also influenced by a variety of hormones such as estrogen, which in most cases increases basal and stimulated GH secretion (androgens exert their effect through aromatization to estrogens), thyroid hormone, which is essential in allowing GH secretion, and glucocorticoids, which decrease GH secretion when in excess. IGF-1 exerts negative feedback control of GH secretion by interaction with pituitary IGF receptors. Small (6 amino acid) peptides, GH-releasing peptides, regulate GH secretion through pituitary and hypothalamic receptors separate from GHRH and somatotropin release-inhibiting factor. Receptors for ghrelin, a recently discovered GI hormone that stimulates GH secretion, are identified.[85,86] Ghrelin values at term are negatively correlated to postnatal growth as values increase after birth. However, ghrelin values do not correlate with growth in preterm infants.[87]

The cell membrane GH receptor has 620 amino acids and a molecular mass of 70 kDa and contains an extracellular hormone-binding domain, a single membrane-spanning domain, and a cytoplasmic domain. A circulating GH binding protein (GHBP), which has the same amino acid sequence as the extracellular domain of the GH receptor (approximately 55 kDa) is derived from proteolytic cleavage of the extracellular domain of the receptor.[88] The major GHBP in human plasma binds GH with high specificity and affinity but with relatively low capacity because only 45% of circulating GH is bound. Levels of GHBP are low in early life, increase through childhood, and plateau during puberty and adulthood. Patients with abnormalities of the GH receptor (e.g., Laron dwarfism) also have the defect reflected in the serum GHBP concentration in that those with decreased numbers of GH receptors have decreased serum GHBP concentrations.[89] Nutritional state and other factors regulate both GH secretion and GHBP values.

It has long been recognized that cord blood values of GH are higher than in adults[90] and decrease during the 2 weeks to 2 months after birth.[91] Adults exhibit pulsatile GH release, but the difficulty of sampling blood for the analysis of pulsatile GH secretion in neonates has presented technical and ethical difficulties. Recently, safe micro sampling techniques allowing blood withdrawal every 20 to 30 minutes over 12 hours or longer were developed.[92] By using this technique, all infants demonstrate a pulsatile pattern of GH release, but infants, unlike adults, have not yet developed entrainment of the GH secretory rhythm with sleep. At 4 days of age, GH secretion and insulin secretion are correlated, which demonstrates a relationship between feeding and GH secretion.[93] On the first day after birth infants from gestational age 33 to 41 weeks sampled every 20 minutes in 6 hours demonstrated elevated GH (9 to 191 μg/L) released in pulses, with 5 to 6 busts found in 6 hours leading to a pulse periodicity of 73 minutes and a half-life of 18 minutes.[94] This elevation of GH was due to increased secretion rather than decreased clearance. Prolactin was also high but not released in pulses, and prolactin release was not related to the GH peaks. In another study, sampling term infants every 30 minutes for 12 hours demonstrated higher GH pulse frequency and amplitude soon after birth (8 to 40 hours) compared with later (63 to 85 hours), with no difference between boys and girls.[95] Studies of GH secretion at 1 to 13 days after birth revealed higher values of GH in the neonates than in later life, and even higher peaks of GH were found in SGA babies compared to AGA infants.[96-98] Basal mean and peak GH values in AGA and SGA babies were 17 versus 54 and 63 versus 190 μg/L, respectively. The pulse frequency was greater in SGA (5.1 for 12 hours) than in AGA (4.0 for 12 hours), with a pulse periodicity of 180 minutes in AGA and 140 minutes in SGA infants. Premature infants (mean 33 weeks gestation) sampled every 30 minutes for 12 hours at approximately 40 hours after birth had high basal (24 to 26 μg/L), incremental (20 to 24 μg/L), and peak (45 to 51 μg/L) GH values with a frequency of 3 for 12 hours; no difference was seen between males and female infants.[96] Elevated GH is not related to growth rate in premature infants, but persistent elevation of serum GH has been linked to the development of retinopathy of premature infants.[99] Premature infants had higher secretory burst amplitudes, higher production rates, and a higher mass of GH per secretory burst than term infants. The integrated plasma GH concentration exhibited a strong trend toward a higher value in the premature infants.[100] Although serum GH is elevated in SGA infants, values normalized by 1 month of age, and although this elevation was related to the pattern of intrauterine growth, it was not related to postnatal growth.[98] Thus children born SGA have a different profile for GH and IGF-1 from that in infants born at a normal weight; at birth and at 3 days of age, basal GH was high, peak amplitude was low, and frequency of peaks of GH was higher, but serum IGF-1, IGF-binding proteins (IGFBP-3), and leptin were significantly reduced.[25,97,101] When evaluated later in life for GH secretion, however, the children who were SGA at birth showed normal amplitude and normal baseline IGF-I and IGFBP-3.

The bioactivity of GH measured in a Nb2 cell assay changed in a pattern similar to the immunoactive GH with higher values when first measured at 5 days, which decrease by 1 and 4 months in term infants.[102] Urinary GH excretion is higher in SGA and AGA premature and term infants than in older child controls.[103]

Although serum GH is high in the neonate, GH receptors are decreased, as reflected in the lower serum GHBP. An increase in GHBP occurs at 6 months of age, which just predates the phase of increasing IGFF-1 and IGFBP-3 (after approximately 10 months), suggesting a greater GH dependence of GH responsive factors and GH dependent growth in the infant of this age and denotes the end of the infancy phase of growth and the beginning of the childhood phase of growth.[104] Nonetheless, even though infants with congenital GH deficiency are of near normal length at birth, growth rate decreases soon and, even a few months after birth, may descend to more than 3 to 7 SD below the mean.[105] Treatment with GH increases growth rate and catch-up growth proceeds to increase height by 2 years. Recent studies demonstrate that the d3-isoform (genomic deletion of exon 3) of the GH receptor, when present in heterozygous or homozygous patterns, is associated with catch-up growth in SGA infants in the neonate[106] as well as increased responsiveness to GH treatment in non-GH deficient short stature[107] and Turner syndrome. However, adult height is not ultimately increased compared with those who do not have this isoform in patients with severe isolated GH-deficiency treated with GH, suggesting a temporary effect. Remarkably the same isoform is associated with decreased third trimester growth in SGA babies.[108]

Various congenital defects of the pituitary hypothalamic axis lead to deficiency of GH or other pituitary hormones. Defects range from pituitary hypoplasia to other midline defects to holoprosencephaly; any midline defect of the central nervous system area should be suspect as an etiology of hypopituitarism. The pituitary gland resides in the sella turcica near the optic chiasm. A decrease in the size of the sella turcica is an indication of reduced pituitary development. The anterior pituitary and pituitary stalk are often smaller than normal, and a bright spot representing the posterior pituitary is located in the hypothalamus rather than in its normal location. This finding is referred to as an ectopic posterior pituitary. Congenital hypopituitarism is associated with breech birth, forceps delivery, and intrapartum and maternal bleeding. Alternatively a combined defect can be found in the function of the pituitary

gland and visual ability as is found in the syndrome of (septo-) optic dysplasia (OMIM 182230), in which congenital blindness or nystagmus is an indication of potential pituitary defects. This condition is sporadic or due to homozygosity of an inactivating mutation of the *Hesx-1* gene. Although nutrition was always of concern in such cases, 4% of cases of cleft palate or lip are associated with GH deficiency and the prevalence rises to 32% if short stature is associated.

GENETIC FORMS OF HYPOPITUITARISM

Genetic defects account for more than 5% of cases of isolated GH deficiency or combined pituitary hormone deficiencies (reviewed by Parks[109,110]).

Isolated Growth Hormone Deficiency

Autosomal recessive complete deletions of the *GH1* gene have isolated growth hormone deficiency (IGHD) type IA (OMIM 262400). This condition is reported to lead to the development of antibodies to GH after treatment with GH. Birth weight is moderately decreased rather than leading to true SGA. Autosomal recessive IGHD type IB (OMIM 612781) have various sizes and sites of deletions in the GH gene or mutations in the GHRH-receptor gene. Autosomal dominant IGHD type II is caused by mutations in the *GH1* gene. However, the gene responsible for X-linked IGHD type III has not yet been identified; some affected persons have associated immunoglobulin deficiency. In similar terminology, autosomal recessive multiple pituitary hormone deficiency is type I, and the X-linked form is type III (OMIN 262600).

Mutations may be found in the pituitary transcription factors PROP1 (OMIM 601538) (causing luteinizing hormone and follicle-stimulating hormone as well as GH, prolactin, and thyroid-stimulating hormone [TSH] deficiencies and possibly adrenocorticotropic hormone deficiencies in a pattern of recessive inheritance) and POU1F1 (OMIM 173110) (autosomal dominant pattern of GH and prolactin deficiency as well as some degree of TSH deficiency).

Children with Laron syndrome (OMIM 262500) lack GH receptor structure or function[111]; affected children will not grow when treated with GH but must receive IGF-1 treatment. Increased growth was shown in several studies of IGF-1 treatment in such children.[112] Serum GHBP is decreased in those with GH receptor deficiency; others have adequate numbers of receptors, which are inactive or have lesser activity, and these children have normal amount of GHBP.

INSULIN-LIKE GROWTH FACTORS

The effects of GH are mediated mainly by the IGFs (reviewed by Reiter and colleague[84]), originally called sulfation factor, subsequently nonsuppressible insulin-like activity, then somatomedin; see later, but GH also has direct effects such as lipolysis, increased amino acid transport into tissues, and increased protein synthesis in liver. Administration of GH produces a degree of insulin resistance and is a diabetogenic substance, increasing blood sugar. Two IGFs, IGF-1 and IGF-2, share 45 of a 73-amino acids sequence and have structures similar to that of the proinsulin molecule (50% homologous with the A and B chains of insulin with these chains connected by disulfide bonds).[113,114] Both the IGFs and proinsulin have a connecting peptide or a C chain, although the homology is not complete in terms of amino acid structure because the IGF-1 C-peptide region has 12 amino acids and the IGF-2 C-peptide region is 8 amino acids long; neither show homology in amino acid sequence with the C-peptide region of proinsulin. Further, the IGFs have a carboxyl-terminal extension, or D-peptide, unlike proinsulin.

The gene for IGF-1 is located on the long arm of chromosome 12 and contains at least five exons.[115] IGF-1 is produced in most tissues and appears to be exported to neighboring cells to act upon them in a paracrine manner.[116] Thus serum IGF-1 concentrations may not reflect the most significant actions of this growth factor. The liver is a major site of IGF-1 synthesis, and much of the circulating IGF-1 probably originates in the liver; serum IGF-1 concentrations vary in liver disease with the extent of liver destruction. IGF-1 is a progression factor, so that a cell which has been exposed to a competence factor, such as platelet-derived growth factor, in stage G0 of the cell cycle and has progressed to G1 can, with IGF-1 exposure in G1, undergo division in the S phase of the cell cycle.[117] Aside from the stimulatory effects of IGF-1 on cartilage growth, IGF-1 has stimulatory effects upon hematopoiesis, ovarian steroidogenesis, myoblast proliferation and differentiation, and differentiation of the lens.

The IGF-1 cell membrane receptor (the type I receptor) resembles the insulin receptor in its structure of two alpha and two beta chains.[118,119] Binding of IGF-1 to type I receptors stimulates tyrosine kinase activity and autophosphorylation of tyrosine residues in the receptor. This leads to cell differentiation or division or both. The type I IGF receptor messenger RNA is present in almost all tissues except liver. IGF-1 receptors are down-regulated by increased IGF-1 concentrations, whereas decreased IGF-1 concentrations lead to an increase in IGF-1 receptors. The structural similarity of the IGFs and insulin explains why IGFs are able to bind to the insulin receptor and why insulin in excess can bind to the type I IGF receptor (in physiological levels insulin has little binding to the IGF-1 receptor), although the structural differences may explain why insulin cannot bind to the IGFBPs (see later).

IGF molecules may be bound to one of the IGF-binding proteins (IGFBPs), some of which are found in the circulation and some of which are found in tissue.[120] Some IGFBPs are considered to be inhibitory to IGF effects, although there is evidence that some IGFBPs can enhance IGF activity.

IGFBP proteases (for IGFBP 2 to 5) metabolize the IGFBPs by proteolysis, leading to another level of control of the IGF axis. There is evidence that SGA babies have at least two different proteases, which, by digesting IGFBP-3, increase the effectiveness of IGF-1.[121] IGFBP-1 is a 25-kDa protein that inhibits IGF action and is suppressed by insulin but is not affected by GH. IGFBP-1 is present in high concentrations in fetal serum and amnionic fluid. Serum values of IGFBP-1and IGFBP-2 in blood are inversely proportionate to birth weight, suggesting that IGFBP-1 exerts suppressive effect upon fetal growth. This suggests that growth is restricted to some degree by elevated IGFBP-1 but after birth the IGF system becomes more active, increasing the likelihood of catch-up growth.[36] IGF-1 circulates bound to IGFBP-3 and an acid labile subunit in a 150-kDa complex. Serum IGFBP-3 concentrations are directly proportional to GH concentrations as well as to IGF-1 concentrations and are regulated by nutritional status as is IGF-1. Thus, in malnutrition, IGFBP-3 and IGF-1 levels fall while GH rises. IGFBP-3 increases with advancing age throughout childhood, with highest values achieved during puberty.

IGF-2 is a 67-amino-acid acidic peptide coded by a gene on the short arm of chromosome 11, close to the gene for preproinsulin.[115] Information about the function of IGF-2 is limited. The type II IGF receptor preferentially binds IGF-2 and is identical to the mannose 6-phosphate receptor, a single-chain transmembrane protein. Although most of the effects of IGF-2 presently described appear mediated by its interaction with the type I receptor, independent actions of IGF-2 via the type II receptor are described. The ratio of IGF-2 to IGF2-R (a soluble form of the type 2 IGF receptor which exhibits inhibitory effects on IGF-2 action) is directly related to birth weight and is even more closely related to placental weight.[122]

IGF-1 in the fetus is regulated by metabolic factors rather than undergoing significant influence by GH, as is the case in postnatal life (see Chapter 178). One explanation is that there are fewer GH receptors in the fetus than after birth. The GH receptor is first found at about 30 weeks gestation in human fetuses.[123] In the human fetus, serum GH level decreases during later gestation owing to maturation of central nervous system negative control; serum IGF-1 and IGFBP-3 increase during gestation, demonstrating their differing pattern and independence from GH stimulation. Serum GH level in the last half of gestation decreases, but IGF-1 increases, as does IGF-2 and IGFBP-3.[98]

Early studies demonstrated that IGF-1 (then measured as nonsuppressible insulin-like activity) is directly related to gestational age and birth weight.[124] The serum values of IGF-1 are 50% or less of adult values; IGF-2 values are approximately 50% adult values in term neonates. Cord blood IGF-1 values are correlated with birth weight in some but not all studies. IGF-1 concentrations are more highly correlated in monozygotic twins than in same-sex dizygotic twins, indicating a genetic effect upon IGF-1 regulation. Premature infants have lower serum IGF-1 and IGFBP-3, lower GHBP but higher IGFBP-1 and -2 than term newborns; these differences were greater with gestational age.[125] Decreased IGF-2 is also seen in SGA infants. The most severely SGA infants have evidence of increased GH resistance; GH was higher and the GH-dependent growth factors were lower compared with AGA infants in one study of SGA infants.[126] Alternatively, in large-for-gestational-age (LGA) infants, IGF-1, insulin, and IGFBP-3 were increased but IGFBP-1 was decreased.[127] Preeclampsia further lowers cord blood IGF-1 values after correcting for gestational age and for birth weight.[128] IGFBP-1 is elevated in SGA infants and decreased in LGA infants, as is IGF-1. IGF-1 is inversely related to birth weight.[129,130] However, in Spanish infants, IGF-1 and IGFBP-3 had direct relationship to ponderal index, IGF-1, IGFBP-3, and GHBP increased with gestational age and IGFBP-1 decreased.[131]

Some data are available concerning IGF and early postnatal growth. At a mean of 4 days after birth, IGF-1 was higher in AGA than SGA infants, and peak, mean, and incremental GH and IGFB-1 was higher in SGA infants.[93] Measurements during the first week after birth demonstrated the following patterns: IGF-1 decreased in term infants for the first 3 days and then increased at the end of the week, IGF-1 stayed stable in preterm infants, and IGFBP-3 and IGF-2 did not change significantly during this first week.[132]

The pattern of change between birth and 1 to 3 months of age in normal term newborns is one of a decrease in IGFBP-1 and IGFBP-2 and an increase in IGF-2 by 3 months along with a decrease in GH. GHBP values did not change much during this time period in one study[133] but an increase during 30 days is demonstrated in others.[102,125] An increase is demonstrated at 4 and 6 months of age.[102,133] Values of IGF-1 and IGFBP-3 remain relatively low in childhood until a peak is reached during puberty, with values higher than at any other time in life. Because IGF-1 is so low in the neonate, IGFBP-3 values, which are higher in normal neonates, may serve better as an indication of GH deficiency than serum IGF-1. Cord blood IGF-1 correlates with postnatal growth in SGA and AGA infants during the first month.[134] A correlation is found between IGF-1 and IGFBP-3 and catch-up growth for the first year in SGA babies.[135] Some studies show a relationship between catch-up growth and higher IGF-1 and IGFBP-3[98,101,135] and some do not.[121] One study reports a relationship between serum IGF-2 values at 3 months and catch-up growth.[136] IGF-1 and IGFBP-3 are related to length in growing preterm infants on enteral nutrition.[137]

Phosphorylated IGFBP-1 is less active and more inhibitory than nonphosphorylated IGFBP-1. The proportion of nonphosphorylated IGFBP-1 to total IGFBP-1 was higher in infants' cord blood than in mothers' serum, and, although this form did not vary by gestational age, the concentration was lower in SGA infants. However, phosphorylated isoforms were higher in SGA fetuses. Thus the isoforms vary with fetal growth and may be of importance.[138] During an 8-week period after birth, the growth of leg length was related to IGF-1 and rate of increase in weight related to IGFBP-3 values. The ratio of low phosphorylated IGFBP-1 and high phosphorylated IGFBP-1 was correlated with weight growth velocity[139]; this ratio also decreases with advancing gestational age.

Gene manipulation and infusion of growth factors in animals demonstrate the influence these factors exert on fetal growth.[140,141] IGF-1 knockout mice (which produce no IGF-1) have reduced late fetal and postnatal growth as well as diaphragmatic muscular hypoplasia (which ultimately causes their death), organ hypoplasia, and delayed ossification of cartilage.[142,143] IGF-2 knockout mice have an earlier fetal growth deficit than IGF-1 knockout mice even though their growth rate is normal later in gestation.This suggests a role for IGF-2 in growth in early gestation and one for IGF-1 in later gestation. Elimination of type 1 receptors (by gene knockout) leads to a more profound growth failure than is found in IGF-1 knockout mice alone, suggesting that factors other than IGF-1 exert effects upon fetal growth through the type 1 receptor (IGF-2 is one of these factors).

Artificial elevation of maternal IGF-1 can increase growth in mouse and rat fetuses and overcome the restraint imposed by uterine limitations of liter size.[144] Knockout of the maternal gene for the type 2 receptor leads to high birth weight, generalized organomegaly, and other anomalies, usually leading to rapid postnatal death; the type 2 receptor appears necessary for postnatal life.[145,146] Transgenic mice overexpressing IGFBP-1 have smaller birth size, lower birth weight, and poorer postnatal weight gain (as well as more frequent postnatal death) with proportional decrease in the size of all organs except the brain, which is much smaller in proportion to other organs; fasting hyperglycemia and impaired glucose tolerance occurs.[147,148] Early postnatal growth restriction occurs in mice experiencing excess IGFBP-1, suggesting an inhibitory role for IGFBP-1 in growth in late gestation and thereafter. Overexpression of IGFBP-3 in mice led to organomegaly of the spleen, liver, and heart, although birth weight was not different from that in wild-type mice.[147,149] Thus excess IGFBP-1 stunts fetal growth, but excess IGFBP-3 leads to selective organomegaly. IGF-1 exerts prenatal effects in the primate[150]: An increase in spleen, thymus, and kidney weights and an increase in small intestinal length were seen in fetal rhesus monkeys given synthetic IGF-1.

INSULIN

Although insulin is a major regulatory factor for carbohydrate metabolism, many lines of evidence demonstrate its importance in fetal growth as well. Macrosomia is a well-known effect of fetal hyperinsulinism and may be seen in the infant of a mother with diabetes.[151,152] These infants have increased body fat at 1 year[153] and by 10 years of age have a higher prevalence of obesity than that seen in nonmacrosomic infants. At the other end of the spectrum is the SGA infant born to a mother with diabetes with vascular disease, or under extremely tight control, or who has eclampsia or preeclampsia; this demonstrates that limited nutrient delivery compromises the growth of the infant. These SGA infants have long-term metabolic defects and severe hypoglycemia (described in Chapter 18). They have a tendency to develop renal, hepatic, and adrenal tumors and others. Postnatal growth is rapid and tall adult heights are achieved.

Errors in the normal pattern of IGF-2 gene expression from the paternal chromosome and type II IGF receptor for IGF-2 from the maternally derived gene may underlie the pathogenesis of Beckwith-Wiedemann syndrome (OMIM 130650).[154] Affected infants are large and have elevated insulin concentrations.

Just as increased insulin stimulates fetal growth, syndromes of fetal insulin deficiency such as are found in congenital diabetes mellitus, pancreatic dysgenesis, or fetal insulin resistance (e.g., leprechaunism [OMIM 147670]) are characterized by IUGR and decreased muscle and fat mass.[155,156] The ability of insulin to either signal metabolic processes or to stimulate growth seems to relate to the ability of insulin to autophosphorylate insulin receptor substrate-1; gene knockout of the insulin receptor substrate-1 leads to a growth-restricted fetal mouse that is born viable but has fetal and postnatal growth deficiency and hyperglycemia (knockout of insulin receptor substrate-2 leads to diabetes).[157] Insulin values are lower in SGA than in normal subjects, but values are elevated in LGA babies.[132]

Two states of decreased insulin effects are known; congenital absence of insulin in pancreatic aplasia and congenital absence of the insulin receptor as found in Donohue leprechaunism syndrome. Infants lacking insulin receptors have severe postprandial hyperglycemia, as expected from the lack of insulin effect. Remarkably, they have preprandial hypoglycemia at first but fasting hyperglycemia months after birth. They also are able to demonstrate some effects of insulin, such as suppression of ketone formation, and the inverse relationship between insulin and IGFBP-1 is maintained, suggesting some insulin effects upon the liver.[158] GH is low as well in leprechaunism. It is possible that the insulin effects are caused by the extremely elevated insulin concentration acting through the type I IGF receptor. Survival is limited to a matter of months. Other infants with insulin deficiency due to absence of the islets of Langerhans have severe diabetic ketoacidosis in the untreated state[159] and have poor growth, which may be less related to the lack of insulin effects than to the severe illness the children experience.

Recent studies evaluated the effects of insulin infusion in very-low-birth-weight infants.[160] Infants characteristically have decreased serum IGF-1 levels, which has been linked to the development of retinopathy of prematurity: Insulin infusion decreased blood sugar to more normal levels and increased IGF-1, but as yet it is not known whether this will decrease the retinopathy.

LEPTIN

Leptin is produced in adipose tissue and in older individuals is correlated with fat mass, although androgens decrease leptin values so that values are higher in females than in males.[161] Leptin also correlates with body weight and body fat mass in cord blood.[162-164] SGA infants have lower leptin than controls because SGA infants have lower fat mass.[165] This direct relationship to birth weight is independent from IGF-1 control mechanism.[166]

Although SGA and control infants follow a similar pattern of body mass index change during the first year, body mass index is lower in the SGA group. However, the customary relationship between leptin and body mass index is present in the control infants but not in the SGA infants in a period of 2 years; nor was there a sexual dimorphism as is normally found.[167] The higher leptin in SGA suggests a degree of leptin resistance during this period of catch-up growth or an adipocyte defect.

THYROID HORMONE

Thyroid hormone is a major factor in postnatal growth, although, like GH, it has relatively little effect in the growth in length of the fetus. The pattern of thyroid function in the fetus is detailed in Chapter 182. After birth, TSH is acutely released, followed by a rapid decline during the first 24 hours and a slower decline during the next 5 days. The initial peak of TSH causes an increase in serum T_4 and T_3 (owing to increased conversion from T_4) by a few hours after birth. Thus thyroid hormone values change by the hour and day in the neonatal period. During the next weeks after birth, serum T_4 and T_3 decrease.

The effects of thyroxine in the neonate and infant are best reflected in the growth of patients with untreated and treated congenial hypothyroidism. Although endemic goiter due to iodine deficiency is the most common cause of hypothyroidism worldwide, in most of the developed world, anatomic or metabolic defects of the thyroid gland, rather than nutritional causes, prevail. Congenital hypothyroidism is found in approximately 1 of 4000 infants; defects in the development of the thyroid gland (thyroid dysgenesis) account for 90% of infants; approximately one third of those have complete aplasia,[168] although most of the remainder of these neonates have an ectopic location of thyroid tissue. The two interior and hypothalamic deficiency of TSH and thyrotropin-releasing factor (TRF), respectively, were initially thought to be rare—in the range of 140 of 60,000. Recent studies in the Netherlands suggest that the prevalence may be closer to 1 in 20,000. The infusion of TRF is recommended as a diagnostic modality to establish the diagnosis of TRF deficiency.[169,170]

However, TRF has not been available in the United States for several years. Screening programs in the United States utilize TSH levels, looking for elevated levels characteristic of primary hypothyroidism. Children who lack TSH or TRF effects will have decreased TSH and therefore will not be identified by the screening programs; TSH or TRF deficiency is known as secondary or tertiary hypothyroidism, respectively. The genes *TTF-1, TTF-2,* and *PAX-8* are important transcription factors for thyroid development; mutations of the *PAX-8* gene are described in some affected neonates with either hypoplasia or ectopy. Alternatively blocking antibodies may be transferred from the mother that caused the thyroid defect. In addition to the anatomic defects, metabolic defects of thyroid function, usually associated with goiters and usually transmitted in autosomal recessive patterns, cause congenital hypothyroidism. TSH deficiency may be isolated or may occur in cases with *Pit-1* mutations. Infants born with resistance to the actions of thyroid hormone may demonstrate elevated T_4 without euthyroidism and may have growth failure as found in hypothyroidism.

Infants with congenital hypothyroid are of normal length or, because gestation is often prolonged, length might be increased. Careful study of the growth rate demonstrates a decrease in growth in length in the untreated state during the first few weeks of age with profound growth failure lasting as long as the infant is not treated. Analysis of infant growth using the infant-childhood-pubertal chart demonstrated a delay in the onset of the childhood component even if thyroxine therapy is begun early. Thus, an effect of thyroxine is exerted on the onset of the childhood component of growth in the last months of the first year of life.[171] Remarkably, growth is decreased in congenital hypothyroidism compared with normal controls during the first 2 and 4 weeks of thyroid therapy; this demonstrates that the early dependence of neonatal growth on thyroid hormone lasts for weeks after institution of therapy. A greater decrease in growth rate is seen in those infants most deficient in thyroid hormone in the weeks after the onset of therapy.[172]

In addition to a direct effect on epiphyseal cartilage and growth, thyroid hormones have a permissive effect on GH secretion because individuals with hypothyroidism have decreased spontaneous GH secretion and blunted responses to GH provocative tests. A small study of congenital hypothyroid infants demonstrated a decrease in GHBP for the first 6 months of therapy with thyroxine suggesting a degree of GH resistance in congenital hypothyroidism that continues even after replacement therapy.[173] Serum IGF-1 is so low in normal children that patients with congenital hypothyroidism appear to have no decrease in IGF-1 and IGFBP-3 at the time of diagnosis if the diagnosis is made within the first month after birth.[174,175] However, if the

diagnosis is not made early, the values of IGF-1 and IGFBP-3 decrease below control levels. With appropriate therapy with thyroxine, the values of IGF-1 and IGFBP-3 increase to age appropriate levels.[176]

Untreated hypothyroidism starting after the first 2 years of the postnatal period can cause profound growth failure and virtual arrest of skeletal maturation, although intellectual impairment is not permanent. A bone age determination in an infant is performed on radiograph of the foot and leg, which shows calcification of the distal femoral epiphysis at 40 weeks gestation, proximal tibial epiphyses at 38 weeks, and cuboid epiphysis at 36 weeks; an infant with severe intrauterine hypothyroidism will have absence of some or all of them. Treatment with thyroid hormone after a long delay results in rapid catch-up growth, which is typically accompanied by marked skeletal maturation; if doses are excessive epiphyseal fusion may be overly rapid and adult height may be compromised. Epiphyseal dysgenesis is seen when calcification of the epiphyses progresses with thyroxine treatment after initial delay in development.[177] The normal decrease in the upper to lower segment ratio with age is delayed (and therefore this ratio elevated) owing to poor limb growth in hypothyroidism in infancy and childhood.

Congenital hypothyroidism diagnosed at birth and treated appropriately soon thereafter will lead to normal height and weight during infancy. Early treated congenital hypothyroidism is compatible with normal height at 1 year[178] and 3-4 years.[179] If the diagnosis is delayed up to 1 year, the child may still achieve catch-up growth and normal height by 10 months after starting therapy,[179-181] and even if thyroxine therapy is started as late as 2 years of age, catch-up growth in length appears to be possible (although IQ will not be optimal).[182] However, a study from Canada showed an inverse relationship between bone age at birth and length of time until treatment begins and height at 9 years, demonstrating long-term effects of intrauterine hypothyroidism on long-term growth.[183] Adult height is related to genetic potential in early treated congenital hypothyroidism because complete catch-up growth occurs in those treated in the first month of life.[184,185]

The starting dose of thyroxine in neonates is now 10 to 15 μg/kg, higher than previously recommended, although no effect has been reported of this change in recommended dose upon growth velocity.[186] In fact, a review of cohort studies of different doses of thyroxine therapy for congenital hypothyroidism demonstrated no clear trend of the effects of high (10 to 15 μg/kg) versus low dose (4 to 8 μg/kg) thyroxine on growth or cognitive development of behavior.[187] The long-term intellectual development of patients with congenital hypothyroidism treated early is usually normal, although evidence of decreased IQ and abnormal coordination or other neurological manifestations is also found in the literature. In general, the use of the higher replacement doses of thyroxine (10 to 15 μg/kg/day) and maintenance of high normal serum T_4 (upper one half to one third of the normal range) are usually associated with normal IQ and neurological functioning in most studies.[171,186,188-191]

Due to the interruption of the normal development of the hypothalamic thyroid axis, premature infants, especially those with very low birth weights, have low serum thyroxine levels.[192] Some have treated these low levels in the assumption that they are pathologic. Unfortunately no randomized controlled studies prove the efficacy or even the safety of this process. A study followed very-low-birth-weight children treated with thyroxine for 10.5 years for this probable physiologic hypothyroxinemia and demonstrated improvement in school performance and motor function in infants born before 28 weeks; however, worsening of function occurred if treatment was administered to those born after 29 weeks gestation.[193] Clearly, more evaluation is necessary before this therapy can be recommended.

NEONATAL HYPERTHYROIDISM

Neonatal hyperthyroidism is temporary and usually results from the transplacental passage of thyroid stimulating immunoglobulin from the affected mother to the fetus causing a temporary disorder.[194] Infants with congenital hyperthyroidism may manifest IUGR. After birth they have poor weight gain that will tend to limit growth during the temporary hyperthyroid phase.[195,196] In older children with hyperthyroidism, if nutrition is adequate, increased growth may occur but this tendency is overcome by the hypermetabolic state.

SEX STEROIDS

Gonadal sex steroids exert an important influence on the pubertal growth spurt, but absence of these factors is not noticeable in prepubertal growth.[197] But even in early life, gonadal and adrenal sex steroids in excess can cause a sharp increase in growth rate as well as the premature appearance and progression of secondary sexual features. Sex steroids exert a direct effect on long bone growth, mainly through conversion to estrogen, and can increase GH secretion, once GH receptors are present in adequate supply. Untreated virilizing congenital adrenal hyperplasia is compatible with survival, sometimes for years, as long as severe hypoglycemia or shock does not develop; in those children who have achieved such a state of stability, growth acceleration may occur early in infancy; if the adrenopathy also is of the salt-losing type, the failure to thrive will mask any tendency toward increased growth rate, and the child will grow poorly until treatment is supplied or the child dies from hyponatremia, hyperkalemia, and hypoglycemic shock. Familial Leydig and germinal cell maturation may also cause increased growth early in the first year. If unabated, increased sex steroids will cause advancement of skeletal age, premature epiphyseal fusion, and short adult stature. Thus, just as growth deceleration requires evaluation, growth acceleration can be just as abnormal and may be a sign of precocious puberty or virilizing congenital adrenal hyperplasia.

GLUCOCORTICOIDS

Although glucocorticoids are necessary for normal metabolic function, endogenous or exogenous glucocorticoids in excess will quickly decrease or stop growth; this effect occurs more quickly than weight gain. An infant treated with excess glucocorticoids for, say, incorrect diagnosis of congenital adrenal hyperplasia will exhibit a remarkable decrease in growth rate.[198] The absence of glucocorticoids has little effect on growth if the individual is clinically well in other respects (i.e., if hypotension and hypoglycemia are absent).

Cord blood cortisol was inversely related to growth achieved in the first 3 months of life in a preliminary study of normal term infants.[199] When IUGR infants are considered, an inverse relationship between serum cortisol and catch-up growth in the first 6 months of postnatal life is seen.[200]

SOCIOECONOMIC AND NUTRITIONAL FACTORS

Worldwide, the most common cause of poor growth and short stature is poverty and its effects. Thus poor nutrition, poor hygiene, and poor health, including infectious disease, influence growth both before and after birth.

Human Milk Composition and Function in the Infant

Human milk, like the milk of many other mammals, is specifically adapted to the needs of the newborn. Transfer of nutrients and bioactive components from mother to infant occurs through the placenta before birth and in colostrum and milk after birth. The substitution of infant formula for human milk deprives the infant not only of nutrients that are more accessible from human milk than from formula but also of many bioactive and immunoprotective factors directed specifically against pathogens in the infant's environment. In many instances, human milk components compensate for immature function in the newborn, in whom endogenous production of digestive enzymes, immunoglobulin A (IgA), taurine, nucleotides, and long-chain polyunsaturated fatty acids (LC-PUFAs) is insufficient. Many of these components are resistant to pasteurization, indicating that it may be advisable to feed pasteurized human donor milk to infants whose mothers are unable to nurse. The benefits of these bioactive components are the reason for the superiority of human milk to even the best infant formulas.

MILK VOLUME

Milk volume seems to be relatively constant regardless of maternal nutritional status. In general, healthy infants have an average daily intake of 750 to 800 mL milk within the first 4 to 5 months after birth.[1,2] A wide range of intake of volumes, from 450 to 1200 mL/day, has been reported, however.[1,3] Similar findings are reported from developing countries,[1,3] although maternal nutritional status may be subject to seasonal variation and may be less adequate than in industrialized countries. Increasing the intake of fluid does not seem to affect milk volume; therefore lactating women should maintain adequate fluid intake, but they should be aware that "fluids consumed in excess of natural thirst have no effect on milk volume."[1]

MILK COMPOSITION

Table 30-1 presents estimates of the concentration of nutrients in mature human milk (i.e., after the colostrum-producing stage of early lactation). The nutrients in milk have three different sources: some are synthesized de novo within the lactating mammary gland (e.g., medium-chain fatty acids), some are modified within the mammary secretory cells from precursors taken up from the circulation (e.g., long-chain fatty acids incorporated into milk triglycerides), and some are transferred into milk directly from plasma (e.g., vitamins and minerals, which are taken up from the circulation, without modification within the mammary gland). Endocrine changes specific to lactation are known to modulate mammary gland function and milk composition. For example, the marked increase in mammary gland lipoprotein lipase activity and the concomitant sharp decrease in adipose tissue at the onset of lactation[4] (both under the effect of prolactin[5]) result in channeling of dietary fat to the mammary gland for incorporation into milk lipids, rather than deposition in adipose tissue.

Lactose is synthesized within the mammary gland from the precursors galactose and glucose provided from the circulation. Lactose, present at a concentration of 7 g/dL, is the most constant nutrient of human milk and is not affected by maternal nutrition. The protein content of mature human milk is

TABLE 30-1

Estimates of the Concentrations of Nutrients in Mature Human Milk

Nutrient	Amount*
Major Nutrients	***g/L***
Lactose	72.0 ± 2.5
Protein	10.5 ± 2.0
Fat	39.0 ± 4.0
Minerals	
Macronutrient Elements	**mg/L**
Calcium	280 ± 26
Chloride	420 ± 60
Magnesium	35 ± 2
Phosphorus	140 ± 22
Potassium	525 ± 35
Trace Elements	**mg/L**
Chromium	50 ± 5
Copper	250 ± 30
Fluoride	16 ± 5
Iodine	110 ± 40
Iron	300 ± 100
Manganese	6 ± 2
Molybdenum	NR
Selenium	20 ± 5
Zinc	1200 ± 290
Vitamins	
Fat-Soluble	**mg/L**
Vitamin A, in RE	670 ± 200 (2230 IU)
Vitamin D	0.55 ± 0.10
Vitamin E	2300 ± 1000
Vitamin K	2.1 ± 0.1
Water-Soluble	**mg/L**
Vitamin B_6	93,000 ± 8000
Vitamin B_{12}	0.97
Biotin	4 ± 1
Vitamin C	40,000 ± 10,000
Folate	85 ± 37
Niacin	1500 ± 200
Pantothenic acid	1800 ± 200
Riboflavin	350 ± 25
Thiamine	210 ± 35

TABLE 30-2

Factors That Affect Milk Fat Content and Composition

Variable	Change
Gestation	LC-PUFA levels higher in preterm* and transitional milk
Lactation	Phospholipid, cholesterol higher in colostrum (preterm > term)
	LC-PUFAs decrease during lactation (3 mo–1 yr) in term milk, but remains constant in preterm milk for 6 months
Parity	P10+: lower endogenous synthesis of fatty acids (C_6-C_{16})
Volume	Low–milk fat concentration associated with high volume
Feed	Fat: foremilk < "midmilk" < hindmilk
Diet	
High carbohydrate intake	Increase in endogenous synthesis of fatty acids (C_6-C_{16})
Low caloric intake	Increase in palmitic acid (C_{16})
High margarine intake	Increase in *trans* fatty acids
Pregnancy weight gain	Positively associated with gain in milk fat content
	Weight loss increase

From Hamosh M: Lipid metabolism in pediatric nutrition, *Pediatr Clin North Am* 42:839, 1995.

LC-PUFA, Long-chain polyunsaturated fatty acid.

**Preterm* or *term* refers to milk or colostrum of women whose infants are born prematurely or at term, respectively.

approximately 0.9 g/dL,[1] and based on studies in industrialized and developing countries, it seems to be unaffected by maternal diet or body composition.[1] Limited information is available, however, indicating that short-term high-protein diets increase the protein and nonprotein nitrogen content of human milk, whereas limited maternal food supply leads to lower milk protein levels.[1]

Most milk proteins participate in the immune and nonimmune protection of the newborn from infection. These proteins, IgA, IgG, IgM, lactoferrin (LF), and lysozyme, have various functions in the newborn.[6] Whether the level of these protective proteins in milk is affected by maternal diet is not clear at present.[7-10]

Although the amount and composition of carbohydrate and protein remain relatively constant in mature human milk, the composition of fat is highly variable and to a large extent is immediately (within several hours) affected by maternal nutrition. Table 30-2 lists the factors that affect milk fat content and composition. Length of gestation and duration of lactation particularly affect the content of lipids that constitute the milk fat globule membrane, phospholipid and cholesterol.[11] Levels of the latter are higher in the early stage of lactation (colostrum and transitional milk) because the milk fat globules are much smaller than in mature milk.[12,13] The total membrane lipid level is therefore higher in colostrum and transitional milk.

LC-PUFAs—C20:4 *n*-6 and C22:6 *n*-3, arachidonic acid (AA) and docosahexaenoic acid (DHA)—are essential for growth, brain development, and retinal function.[14] These fatty acids are stored in the fetus only in the last trimester of pregnancy, and preterm infants depend on human milk for the provision of these essential nutrients. Using measurements of mean melting points of plasma phospholipids as an indicator of fatty acid composition, Holman and colleagues[15] reported lower levels of LC-PUFAs in pregnant and lactating women, a finding suggesting preferential transfer of these essential fatty acids from mother to fetus or to the newborn through milk, even at the cost of possible depletion of maternal reserves. Studies in lactating and suckling ferrets showed that the adipose tissues of the suckling animals contain approximately three-fold higher concentrations of LC-PUFAs than maternal adipose stores.[16] The latter contain, however, only slightly lower levels of LC-PUFA than the adipose depots of virgin females, a finding suggesting that the suckling ferret's higher LC-PUFA adipose tissue reserves result from increased storage of these fatty acids by the suckling newborn.[16]

It has long been known that milk fat content changes drastically during each feeding,[17,18] and milk fat composition is markedly affected by maternal diet.[19] Studies have shown that the mechanism for endogenous synthesis of fatty acids seems to be exhausted in women of high parity,[20] that infants who receive low-fat milk tend to nurse more frequently and for longer periods, thereby causing an increase in milk volume,[21] and that a strong positive relationship exists between weight gain during pregnancy and milk fat content.[22]

As mentioned previously, the vitamin content of human milk depends on the mother's vitamin status, and when maternal

intake of specific vitamins is chronically low, these vitamins are also present at lower levels in the milk. With supplementation of vitamins, levels in milk also increase. Water-soluble vitamins in milk generally are more responsive to maternal dietary intake than are fat-soluble vitamins.[1] The relationship between maternal intake and milk concentration varies among vitamins, however. For example, excess vitamin C does not further increase the level in milk (above that associated with adequate intake), whereas milk vitamin B levels continue to rise with higher intakes; milk folate levels remain normal even at the expense of maternal folate stores and do not decrease until the latter are depleted.[1] Based on the concentrations of fat-soluble vitamins in human milk and infant needs, it is advised that in the United States all newborns should receive 0.5 to 1 mg of vitamin K by injection or 1 to 2 mg orally immediately after birth[2]; infants should receive 5 to 7.5 mg vitamin D per day if exposure to sunlight seems inadequate.

The concentration of trace minerals varies as a function of length of lactation (iron, copper, zinc, selenium). Although the concentrations in milk seem to be independent of maternal nutrition for iron[23, 24] or fluoride,[25] concentrations of manganese,[26] iodine,[27] and selenium[28] are dependent. Iodine is unique among trace elements in that it is avidly accumulated by the mammary gland. It is recommended that breast-fed infants be supplemented with fluoride if the family water supply has a low fluoride content (0.3 ppm). Because of the high bioavailability of iron in human milk, exclusively breast-fed infants do not need iron supplements during the first 6 months of life. When supplementary foods are introduced (as recommended after 4 to 6 months of exclusive breast-feeding), iron should be supplemented in the diet.

It is important to assess not only the concentration of milk components but also the amount delivered to the infant. Thus, although some milk components are present at a higher concentration in colostrum than in milk, the marked differences in volume must be taken into consideration: Colostrum amounts to approximately 100 mL/day, whereas average milk volumes are 750 to 850 mL/day.

The recommendation by the American Academy of Pediatrics is that breast-feeding should be of longer duration, 12 months, as compared with the previous recommendation by the Institute of Medicine of the American Academy of Sciences (4 to 6 months).[1] Therefore the need for proper supplementation after 4 to 6 months of exclusive breast-feeding should be strongly emphasized to patients, especially in view of the resurgence of rickets[29-31] and zinc deficiencies[32] in breast-fed infants. It is known that in some populations, human milk does not provide sufficient vitamin D during the first 6 months of lactation[33] (e.g., persons with dark skin or limited exposure to sunlight)[34-36]; this deficiency can be overcome by provision of vitamin D supplements. Furthermore, the global increase in atmospheric pollution may put mothers and breast-fed infants everywhere at risk of vitamin D deficiency.[37] The report of hypovitaminosis D, in 42% in young black women and 4.2% in the same age-group of white women,[38] emphasizes the importance of supplementation during pregnancy and lactation.

Zinc supplements are indicated for breast-fed infants during the second half of the first year of life if the complementary foods are low in zinc. Furthermore, some infants may require supplementation even during early lactation because of a low milk zinc content secondary to a defect in zinc transfer from maternal serum to breast milk.[39] Although zinc homeostasis and normal milk levels during the first 2 months of lactation in a population with low zinc intake seem to be achieved by high fractional absorption and intestinal conservation,[40] clinical zinc deficiency during breast-feeding is reported to occur because of a combination of low fetal zinc accumulation and insufficient zinc in breast milk.[41,42]

Although iodine is unique among trace elements in that it is widely accumulated by the mammary gland,[1] the iodine content of human milk varies greatly according to geographic region and maternal intake, from a low of 15 mcg/L in areas in which iodine deficiency disorders are prevalent to 150 mcg/L in areas with sufficient iodine.[43] Despite the importance of iodine for normal growth and cognitive development, only a few studies have measured its concentration in human milk. In light of the newest recommendations for iodine (minimum 8 mcg/100 kcal and maximum 35 mcg/100 kcal),[1,24] further studies worldwide are necessary to estimate accurately the daily intakes of iodine by breast-fed infants throughout lactation.

GROWTH OF BREAST-FED INFANTS

The growth of breast-fed infants in affluent populations differs from that of formula-fed ones.[44,45] When evaluated using the 1977 and 2000 National Center for Health Statistics growth charts, breast-fed infants gain weight rapidly during the first 2 to 3 months of life, followed by a downward trend in percentile ranking thereafter.[44,45] The earlier growth charts were obtained by evaluating mainly formula-fed infants, and when breast-fed infants were included, no information on exclusivity or duration of breast-feeding was available. The acceptance of a clear definition of breast-feeding[46] and the availability of newer studies that measured infant growth during breast-feeding for up to 12 to 18 months (breast-feeding exclusively for the first 4 to 6 months, followed by quantified complementary feeding)[44,45] resulted in a reevaluation, led by the World Health Organization (WHO), of the specific growth pattern of breast-fed infants, with the aim of creating specific reference growth curves for these infants.[47]

The major differences in growth patterns between breast-fed and formula-fed infants can be summarized as follows: For weight, breast-fed infants gain less than formula-fed infants during the first year of life (at 12 months, this difference is 600 to 650 g); for length, linear growth seems to be unaffected by type of feeding, with no difference or only slightly lower gain in the breast-fed group; for head circumference, feeding mode makes no difference. Breast-fed infants generally are leaner than formula-fed ones (after approximately 4 months of age), a finding consistent with the observed association between duration of breast-feeding and greater decline in weight-for-length Z-scores during the first 12 months of life.[44,45,48] The physiologic reason for slower weight gain is that breast-fed infants self-regulate their energy intake[1,44,45,49,50] at a lower level than that observed in formula-fed infants. This lower activity may be related to the lower body temperature and metabolic rate of breast-fed infants.[51] It also may be associated with the different endocrine environment of breast-fed as compared with formula-fed infants,[49,51] which could be affected by the marked differences in protein content of human milk and infant formula.[51] The question of whether formula feeding (which is regulated by the mother) leads to a higher incidence of obesity than that associated with breast-feeding (which is infant-regulated) is still open, although a difference in adiposity by mode of feeding persists at least until the age of 18 to 24 months, with overweight infants amounting to 13% versus 35% of those fed human milk versus formula-fed groups, respectively.[44]

The slower weight gain documented with breast-feeding does not seem to be associated with short- or long-term deleterious effects. A recent metaanalysis on the topic indicates that mortality rates from infectious diseases are lower in breast-fed infants, and cognitive development seems to be enhanced by this mode of feeding. Furthermore, only a modest protective effect of breast-feeding on childhood obesity has been documented.[52] Indeed, reduced morbidity and long-term health benefits of breast-feeding may become apparent only in childhood

and adolescence.[53] The 12th International Conference of the International Society for Research in Human Milk and Lactation (in 2004, in Cambridge, United Kingdom) was devoted to the topic "Breast Feeding: Early Influences on Later Health."[54]

BIOACTIVE MILK COMPONENTS

This section focuses on milk nutrients that protect the infant against infection. Support for the relatively immature state at birth of the human infant derives in part from the mother's milk, engineered to provide many components that facilitate the postnatal development of specific organs such as the brain, the immune system, and the digestive system. During this critical period when the newborn is exposed to infectious agents, protective factors in the mother's milk are essential to the infant's health. Provision of digestive enzymes facilitates the digestion and absorption of nutrients, and the provision of specific nutrients ensures normal development of the brain and other organs. Thus what is unique to human milk, and so far has not been duplicated, is the bioactive function of many human milk nutrients.

Many nutrients in human milk have to be considered multifunctional agents. First, they provide an essential bioactive function; subsequently, they are digested and used as nutrients.

Protection Against Microorganisms

The antiinfective properties of human milk were recognized millennia ago (as in the ancient Indian medical treatise *Sushruta Samhita*), but only recently has the rationale for this protection from infection (i.e., the immaturity of the immune system in the newborn and the reciprocal relationship between protection by human milk and the postnatal development of the newborn's immune system) been explored extensively. Furthermore, in addition to providing protective agents, human milk components also modulate the development of immune function in the newborn. Indeed, the thymus of breast-fed infants is twice as large as that of formula-fed infants, and a dose-dependent response of thymus size to human milk intake has been reported.[55]

Earlier studies carried out mainly in developing countries that showed protection against diarrhea, infectious diseases, and otitis media from breast milk were found to be methodologically flawed.[56,57] In the 1990s, however, carefully designed studies confirmed without any doubt that breast-feeding protects the newborn from diarrhea, respiratory infections, and otitis media, not only in developing countries (where inocula may be higher)[58] but also in industrialized nations.[59-61] Furthermore, early observations that if infection occurs, it is less severe in breast-fed than in formula-fed infants,[1] have been complemented by studies showing that breast-feeding may protect against nosocomial infections.[62]

Ongoing research since the 1980s has started to elucidate the nature of the protective factors in milk, as well as the mechanisms by which this protection is provided. These studies have shown that protection from infection is provided by two main mechanisms: classic immune protection provided by IgA, IgG, and IgM in human milk, as well as by many other milk components that act as ligands for bacteria and viruses; and factors that refine the interaction among these agents and that also may enhance the maturation of the infant's own immune potential. The protective agents in milk share several characteristics that enable them to be active in the infant[63]: They act at mucosal sites and are well adapted to resist the environment of the gastrointestinal tract (hydrolytic enzymes, changes in gastric and intestinal pH, presence of bile salts). Furthermore, action on microorganisms often is accomplished synergistically, and protection is achieved without triggering inflammatory reactions. As is the case for many milk components, secretion of many protective factors during lactation is inversely related to the infant's capacity for their release at mucosal sites.

Immunoglobulins

The protective role of immunoglobulins is well reviewed in the literature.[64,65] Briefly, whereas IgG, IgM, and IgD are present in human milk and may protect both the lactating mammary gland and the newborn from infection, polymeric IgA is the main component of human milk (consumption by the infant is 4 g on day 1 and approximately 1 g/day after day 4 postpartum). In addition to the resistance of IgA to proteolysis, the functional advantages of IgA are the presence of four to eight antigen-binding sites, carbohydrate moiety–mediated antiadherence proteins, and inhibition of complement activation. Although the protective effect of IgA is exercised mainly at mucosal surfaces, internalization by cells expressing various IgA receptors suggests additional protective functions.[66]

Nonimmune Protection

Nonimmune protection is provided by many components in human milk that act in a nonspecific way and thus provide a broad spectrum of antiinfective activity (Tables 30-3 and 30-4). These components are reviewed only briefly here, because many excellent reviews on this topic are available in the literature.[53,64-72]

Proteins

Lactoferrin (LF), a 79-kDa, 692–amino acid, single-chain glycosylated protein, consists of two globular lobes, each containing one iron-binding site (Table 30-5). Although this protein was once considered an iron transporter and its antiinfective

TABLE 30-3

Multiple Functions of the Major Nutrients of Human Milk in the Infant

Nutrients	Amount	Function
Protein	***mg/dL***	
SigA	50-100	Immune protection
IgM	2	Immune protection
IgG	1	Immune protection
Lactoferrin	100-300	Antiinfective, growth-promoting, iron carrier (?)
Lysozyme	5-25	Antiinfective
α-Lactalbumin	200-300	Induces tumor apoptosis, part of lactose synthase, ion carrier (calcium)
Casein	200-300	Ion carrier, inhibits microbial adhesion to mucosal membranes, growth factor for probiotics
Carbohydrate	***g/L***	
Lactose	6.5-7.3	Energy source
Oligosaccharides	1.0-1.5	Microbial ligands
Glycoconjugates		Microbial and viral ligands
Fat	***g/L***	
Triglyceride	3.0-4.5	Energy source
Long-chain polyunsaturated fatty acids		Essential for brain and retinal development and for infant growth
Free fatty acids, monoglycerides*		Antiinfective

*Free fatty acids and monoglycerides produced from triglycerides during fat digestion in the stomach and intestine.

function was ascribed to its high affinity for iron (which could deprive microorganisms of needed iron), more recent studies cast doubt on both functions[73,74] and showed that LF-associated protection is provided by several other mechanisms. LF is bactericidal, antiviral, and antiinflammatory, and it modulates cytokine function. The bactericidal activity is provided by an 18–amino acid residue loop formed by a disulfide bond between cysteine residues 20 to 37 of human LF and 19 to 36 of bovine LF. This domain, called lactoferricin and located in the N-terminus of LF in a region distinct from its iron-binding site, has broad antimicrobial properties.[75] Partial gastric hydrolysis of LF actually enhances antiviral activity against herpes simplex virus (HSV), cytomegalovirus, and human immunodeficiency virus (HIV), and it occurs during the early stage of infection, probably at the stage of virus adsorption or penetration. Immunomodulating activity leads to reduced release of interleukins 1, 2, and 6 and tumor necrosis factor–α from monocytes and of prostaglandin E_2 from macrophages. This activity is the result of LF binding to LF receptors on these cells.[76] Other LF activities include activation of natural killer cells, modulation of complement activation, effects on coagulation, and inhibition of adhesion of enterotoxigenic *Escherichia coli*[77] and of adhesion and invasiveness of *Shigella flexneri.* The last is caused by LF-induced disruption of outer membrane virulence proteins required for invasion (IpaB) and for intracellular and extracellular spread (IcsA).[78] Antiinflammatory activity involves scavenging of iron, which inhibits iron-catalyzed formation of hydroxyl radicals from superoxide and hydrogen peroxide,[77] inhibition of lipopolysaccharide-mediated activation of neutrophils,[79] and endotoxin-induced cytokine release.[80] Large fragments of LF are present in the stool[81] and urine[82] of breast-fed infants, suggesting that protection is provided within the gastrointestinal tract and systemically. Enhancement of neonatal intestinal growth,[83,84] hepatic protein synthesis, intestinal recovery from injury[83,84] (associated with avid LF interaction with nucleic acids),[85] and stimulation of growth of probiotic intestinal bacteria are additional LF-mediated mechanisms to reduce intestinal infections and the development of protein allergy.[86]

Lysozyme, a 14.4-kDa, 130–amino acid containing glycoprotein, hydrolyzes the β1-4 linkage between *N*-acetyl glucosamine and *N*-acetylmuramic acid in bacterial walls. Lysozyme, like LF, is present in other exocrine secretions and lyses gram-positive and a few gram-negative bacteria. In constrast with the other protective proteins in human milk (IgA and LF), concentrations of which decrease during lactation, those of lysozyme increase with prolonged lactation. Concentrations in milk are higher than in serum. In addition, lysozyme concentrations are severalfold higher in human than in bovine milk.[69,87]

κ-*Casein,* a 30- to 40-kDa, 162–amino acid, highly glycosylated human milk protein, has been shown to inhibit adherence

TABLE 30-4

Protective Functions of Minor Nutrients in Human Milk

Immune Protection	Function
IgA, IgG, IgM, IgD	Specific antigen-targeted antiinfective activity
Nonspecific protection	Antibacterial, antiviral, and antimicrobial toxins; enhance newborn's immune system maturation
Major nutrients	See Tables 30-1, 30-3, and 30-5
Minor nutrients	
Nucleotides	Enhancement of T cell maturation, NK cell activity, antibody response to certain vaccines, intestinal maturation and repair after diarrhea, growth factors for probiotics
Vitamins	
• A (β-carotene)	Antiinflamatory (scavenging of oxygen radicals)
• C (ascorbic acid)	Antiinflamatory (scavenging of oxygen radicals)
• E (tocopherol)	Antiinflamatory (scavenging of oxygen radicals)
Enzymes	
Bile salt–dependent lipase	Production of free fatty acids with antiprotozoan and antibacterial activity
Catalase	Antiinflamatory (degrades hydrogen peroxide)
Glutathione peroxidase	Antiinflamatory (prevents lipid peroxidation)
PAF acetylhydrolase	Protects against necrotizing enterocolitis (hydrolysis of PAF)
Hormones	
Prolactin	Enhancement of the development of B and T lymphocytes, affects differentiation of intestinal lymphoid tissue
Cortisol, thyroxine, insulin, and growth factors	Promotion of maturation of the newborn's intestine and development of intestinal host defense mechanism
Cells	
Macrophages, PMNs, and protective agents	Microbial phagocytosis, production of lymphokines and cytokines, interaction with and enhancement of other lymphocytes
Cytokines	Modulation of function and maturation of the immune system

Modified from Hamosh M: *Pediatr Clin North Am* 45:53, 2001.

IgA, IgG, IgM, IgD, Immunoglobulins A, G, M, D; *PAF,* platelet-activating factor; *PMNs,* polymorphonuclear leukocytes.

TABLE 30-5

Protective Function of Human Milk Proteins

Protein/Normal Levels	Protective Function
Lactoferrin 500-600 mg/dL in colostrum, 150 mg/dL in mature milk	Iron chelation: Bacteriostatic for siderophilic bacteria and fungi Lactoferricin, 18–amino acid residue loop with broad-spectrum antimicrobial action Antiviral activity (HIV, CMV, HSV), probably by interfering with virus adsorption or penetration Immunomodulating activity: reduced release of IL-1, IL-2, and IL-6 and TNF-α from monocytes and of prostaglandin E_2 from macrophages; activation of NK cells, effect on complement activation and coagulation Antiadhesive for *Escherichia coli* and antiinvasive for *Shigella flexneri* Affects neonatal intestinal growth and recovery from injury, thereby reducing intestinal infections
Lysozyme 5-25mg/dL; increases with prolonged lactation	Bacterial lysis: hydrolysis of β1-4 link between *N*-acetyl-glucosamine and *N*-acetylmuramic acid in bacterial walls Immunomodulating activity: muramyl dipeptide enhances IgA production, macrophage activation Binding to bacterial lipopolysaccharides: reduces endotoxin effect
α-Lactalbumin 200-300mg/dL	Causes apoptosis in tumor cells after structural change induced by association with oleic acid
κ-Casein <100 mg/dL	Antiadhesive: Inhibits binding of *Helicobacter pylori* to human gastric mucosa and *Streptococcus pneumoniae* and *Haemophilus influenzae* to human respiratory tract epithelial cells
Casein macropeptide	A strong growth-promoting factor for the probiotic *Bifidobacterium bifidum*

CMV, Cytomegalovirus; *HIV,* human immunodeficiency virus; *HSV,* herpes simplex virus; *IL,* interleukin; *NK,* natural killer; *TNF–α,* tumor necrosis factor–α.

of *Helicobacter pylori* to human gastric mucosa and of *Streptococcus pneumoniae* and *Haemophilus influenzae* to human respiratory tract epithelial cells. The C-terminal proteolysis product of κ-casein is a strong growth-promoting factor for *Bifidobacterium bifidum,* an acid-producing anaerobe that reduces the growth of intestinal pathogenic microorganisms in breast-fed infants.[69] The genes for the foregoing human milk proteins have been cloned.

α-Lactalbumin and Apoptosis of Malignant Cells

α-Lactalbumin is present in the mammary gland and in human milk and is part of the lactose synthase complex. Studies showed that it also may prevent growth of human adenocarcinoma cells in culture.[86] Detailed structural studies showed that a partial unfolding of the protein and association with oleic acid result in a variant able to induce apoptosis in tumor cells and immature cells, whereas healthy cells are resistant to this effect.[89] Conditions in the newborn's stomach favor formation of this complex, which may explain the lower incidence of cancer in persons who were breast-fed as infants.

Other proteins with potentially protective functions in human milk are fibronectin, protectin, and components of the complement system.[90] The extent to which milk proteins provide protection to the breast-fed newborn has yet to be quantitatively evaluated, although good data are currently available for immunoglobulins and LF. Whether supplementation of infant formula with recombinant human milk proteins will have protective effects remains to be evaluated in the future.

Most proteins in human milk are heavily glycosylated[87] and are therefore resistant to proteolysis after ingestion by the infant,[69,72] as well as after short-term storage (for 4 to 24 hours) at elevated ambient temperatures (15° to 38° C).[91]

Glycoconjugates and Oligosaccharides

These milk components act as ligands for microorganisms, viruses, and their toxins and thereby inhibit binding of pathogens to epithelial surfaces (Table 30-6). These components are present in the milk fat globule membrane and in skim milk and amount to 1.5 g/dL. Thus they are the third most abundant components in human milk. Among the best-known components in this group are mucin-1 (400 kDa)[92] and lactadherin (46 kDa)[72]; mucin decreases adhesion of *S*-fimbriated *E. coli* to buccal epithelial cells,[82] and lactadherin inhibits replication of rotavirus in vitro[93] and protects infants against symptomatic rotavirus infection.[94] Other glycoconjugates in milk inhibit binding of the HIV envelope glycoprotein gp 120 to its host cell receptor CD_4 (chondroitin-rich glycosaminoglycan in the milk fat globule membrane),[95] and they act as receptor analogues for *Vibrio cholerae* and *E. coli* heat-labile toxins, as well as for *V. cholerae* El Tor and enterotoxigenic *E. coli.* Oligosaccharides in human milk prevent the attachment of *H. influenzae* and *S. pneumoniae* to the respiratory epithelium.[69]

No significant digestion of milk oligosaccharides occurs during intestinal transit, with resulting excretion of 40% to 50% of intact milk oligosaccharides in the breast-fed infant's stools.[96,97] The presence of these oligosaccharides in urine[97,98] suggests that they provide protection not only in the infant's intestinal tract but also systemically.[97-99] The extent of fucosylation of oligosaccharides, which affects the binding and inhibition of bacteria, is controlled by fucosyl transferase and fucosidases present in human milk at different levels of activity in the course of lactation.

Milk glycolipids such as the ganglioside Gb_3, the receptor of the β subunit of Shiga toxins, are present in the cream fraction (the milk fat globules) of human milk. Shiga toxin–associated diarrhea and the more serious complications of hemolytic uremic syndrome are caused by *Shigella dysenteriae* and some strains of *E. coli* (O157:H7 and O11:NM). Protection against this disease may be accomplished by the combined action of Gb_3 and specific IgA antibodies.[100]

TABLE 30-6

Protective Functions of Oligoconjugates in Human Milk

Structure	Distribution in Milk	Function*
Oligosaccharides	Skim milk	Protect against heat-stable *Escherichia coli* enterotoxin, attachment of *Haemophilus influenzae* and *Streptococcus pneumoniae* to respiratory epithelium, *Vibrio cholerae* hemagglutinin activity
Glycoproteins	MFGM/skim milk	Prevent binding of *V. cholerae* El Tor
Mucin	MFGM	Prevents binding of *S*-fimbriated *E. coli*
Lactadherin	MFGM/skim milk	Prevents binding of rotavirus
Gangliosides	MFGM	Receptor analogues for heat-labile toxins of *V. cholerae* and *E. coli*
Glycosaminoglycan	MFGM	Inhibits binding of HIV glycoprotein g 120 to CD4 receptor

Modified from Hamosh M: *Pediatr Clin North Am* 45:53, 2001.
HIV, Human immunodeficiency virus; *MFGM,* milk fat globule membrane.
*Most of the listed activities are based on in vitro studies; however, lactadherin prevents rotavirus-caused diarrhea in mice and human infants.

Lipids

Milk fat globules, the second most abundant component of human milk, protect the infant from infection by two separate mechanisms. As noted earlier, the membrane glycoconjugates act as specific bacterial and viral ligands, whereas the digestive product of the core triglycerides, free fatty acids, and monoglycerides have a detergent-like lytic action on enveloped viruses, bacteria, and protozoa[101,102] (Table 29-7). Although products of lipolysis are qualitatively similar in formula-fed and breast-fed infants, quantitatively the breast-fed infant benefits from higher rates of gastric lipolysis[102] and duodenal lipolysis associated with the structure of milk fat globules and the presence of milk bile salt–dependent lipase, respectively.[102] Hydrolysis of milk triglyceride during storage at 4° to 38° C probably contributes to resistance to bacterial and viral growth in milk.[91] Indeed, addition of lipases or free fatty acids and monoglycerides to human milk or formula increases antiviral (respiratory syncytial virus, HSV-1) and anti–gram-positive microbial (*H. influenzae,* group B streptococci) activity.[69,90,103] Antiprotozoal activity against *Giardia lamblia* was shown to be directly related to the release of free fatty acids from milk triglycerides by bile salt–dependent lipase and lipoprotein lipase.[69]

The structural determinants associated with the highest level of microbial and protozoal lysis are fatty acid chain length (C12:0), degree of unsaturation (C18:2), and nature of the active group (highest with carboxyl-containing lipids, i.e., fatty acids). Lauric acid (C12:0) and linoleic acid (C18:2) amount to 5% and 15% of total fatty acids in human milk, respectively, and are the most readily released during gastric lipolysis.[69]

Antiinflammatory Components

Antiinflammatory components in human milk that consist of antioxidants (e.g., vitamins A, C, and E and enzymes such as catalase and glutathione peroxidase) are reviewed in detail in the literature.[67,104] Therefore they are not discussed here.

TABLE 30-7

Protective Functions of Lipids in Human Milk

Feature	Example(s)
Structural determinants of antiinfective activity	Free fatty acids and monoglycerides, most active: lauric acid (C12:0) and linoleic acid (C18:2)
Role of digestion	Milk triglycerides (98% of milk fat) have to be hydrolyzed in the stomach* and intestine to free fatty acids and monoglycerides†
Antiinfective function	Antiprotozoal: *Giardia lamblia* Antimicrobial: *Haemophilus influenzae,* group B streptococci, *Staphylococcus epidermidis* Antiviral: respiratory syncytial virus, herpes simplex virus 1

Modified from Hamosh M: *Pediatr Clin North Am* 45:53, 2001.

*Gastric lipolysis of milk triglycerides is higher in human milk–fed infants (25%) than in those who are formula-fed (14%).

†Human milk bile salt–dependent lipase enhances intestinal fat digestion in breast-fed infants.

Cells in Human Milk

The topic of cells in human milk[64,65] has been studied extensively and reviewed in the literature, so it is not discussed here.

Nucleotides in Human Milk

Nucleotides are considered conditionally essential nutrients because of their insufficient synthesis by the newborn.[105] Nucleotides present in human milk differ qualitatively and quantitatively from those in bovine milk and are another agent shown to enhance intestinal repair after injury[106] and to potentiate the immune response to certain vaccines.[107] Certain nucleotides also may promote the growth of *Lactobacillus bifidus,* which is known to suppress the growth of enteropathogens in the newborn's intestine.

Enzymes in Human Milk

Human milk, like the milk of other species, contains many enzymes[87,101]; however, the specific enzymes and their activity levels vary among species. Only those milk enzymes that may benefit the human infant are considered here. Among these enzymes are those involved in protective function (see earlier) such as lysozyme (see Table 30-3), peroxidase, the antiproteases, catalase, glutathione peroxidase, and platelet-activating factor acetylhydrolase (see Table 30-4). Milk enzymes have been shown to aid in the digestion of carbohydrates and fats during the period of pancreatic exocrine immaturity, which results in low pancreatic lipase levels and the absence of amylase for up to 2 months after delivery at term.[87,108,109] Milk bile salt–dependent lipase and amylase are secreted into human milk and have been shown to be active in the infant,[87,108,109] thereby providing the breast-fed premature and full-term babies with better digestive potential (Table 30-8) than that of formula-fed infants.

Probiotics and Prebiotics

Prebiotic and probiotic substances have received much attention as potential protective factors. *Probiotics* consist of viable organisms that have a beneficial effect on intestinal microbial balance. Human milk feeding stimulates the growth of lactobacilli and bifidobacteria, lactic acid–producing microorganisms that generate an intestinal milieu inhibiting the growth of pathogens such as *E. coli* and *Clostridium difficile.*[86] *Prebiotics* are nondigestible food ingredients that enhance the growth or metabolic activity of certain bacteria in the colon. For example, *L. reuteri* produces reuterine, a bacteriocin with broad antimicrobial activity.[86]

TABLE 30-8

Enzymes With Digestive Function in the Infant

Characteristic	Bile Salt–Dependent Lipase	Amylase
Maternal factors		
Parity (=10)	?	Low activity
Diurnal and within feed activity	Constant	Constant
Secretion		
Prepartum*	Present	?
Postpartum	Constant	Decreases before first month
Preterm versus term delivery†	Equal activity	Equal activity
Milk characteristics		
Distribution	Skim milk	Skim milk
Storage (−20° C, −70° C)	Stable years	Stable years
Pasteurization (62° C, 30 min)	Inactivated	85% of activity maintained
Storage (15-38° C)	Stable (at least 24 hr)	Stable (at least 24 hr)
Stable at low pH (stomach)	>3.0	>3.0
pH optimum	7.4-8.5	6.5-7.5
Enzyme characteristics	Identical to pancreatic cholesteryl ester lipase	Isoenzyme of salivary amylase
Evidence of activity in infants	Yes	Yes
Present in milk of other species: primates, carnivores, rodents		?

Modified from Hamosh M: *Pediatr Clin North Am* 45:53, 2001.

†Infants delivered preterm (26 to 36 weeks gestation) and term (37 to 40 weeks gestation.)

*Prepartum: 2 to 3 months secretion.

BREAST-FEEDING AND ATOPIC DISEASE

In contrast with the protective effect of breast-feeding against infectious diseases in infants,[53-65] the relationship between breast-feeding and infant allergy is poorly understood.[111] It seems that allergy-preventing effects, if present, may be limited to infants with a genetically determined increased risk of atopic disease.[111] Deleterious effects of breast-feeding also have been reported; thus an abnormal ratio between LC-PUFAs of the *n*-6 and *n*-3 series in mother's milk is associated with the development of allergic disease in infants during the first year of life.[112] Furthermore, although breast-feeding is associated with lower rates of wheezing illnesses in infancy, this effect varies according to maternal asthma status. In children of asthmatic mothers, the development of childhood asthma increases significantly with duration of exclusive breast-feeding.[113] Exclusive breast-feeding and development of cow's milk allergy also have generated controversy. Studies showed that although early feeding of cow's milk increases the risk of allergy development, exclusive breast-feeding does not seem to reduce the risk. [114]

LATE EFFECTS OF BREAST-FEEDING

Among the late-onset diseases that may be affected by the mode of infant feeding are diabetes mellitus, cancer, inflammatory bowel disease, and celiac disease.[53,115] Controversy is ongoing regardingt the specific role of breast-feeding in the origin of these diseases, which are known to have multiple causes, including environmental factors (e.g., early feeding pattern) and genetic susceptibility.[53,115-117] The apoptosis-inducing effect of modified α-lactalbumin[89] lends support to the epidemiologic data indicating lower incidence of certain forms of cancer in children who were exclusively breast-fed during infancy.[115]

The controversy about the role of breast-feeding in protection against celiac disease[53] seems to have been resolved by studies showing that the gradual introduction of gluten-containing foods into the diet of infants while they are still being breast-fed reduces the risk of celiac disease in early childhood and probably also subsequently.[118]

The controversy about whether breast-feeding protects against obesity in later life remains unresolved.[49,119,120] This issue was one aspect of the previously mentioned conference dealing with the effect of infant feeding modality (breast milk or infant formula) on later health (such as obesity, sensory perception, type 2 diabetes, cardiovascular disease, hypertension, and some cancers arising later in life).[54]

Human milk contains a number of growth factors or hormones that affect food intake and energy regulation, such as leptin,[130-132] ghrelin,[133,134] adiponectin,[135,136] and motilin.[137] These factors are present in the milk secreted by women whose infants were born at term as well as prematurely and may affect appetite regulation, development of gastrointestinal function, and growth. Whether these early effects are expressed in later life and contribute to differences in metabolism of adults who were exclusively breast-fed as infants, as compared with those who were formula-fed, is currently unknown.

Breast-Feeding, Long-Chain Polyunsaturated Fatty Acids, and Cognitive Function

LC-PUFAs are essential for normal growth and development.[121-123] The two families of LC-PUFAs, the *n*-3 derived from α-linolenic acid and the *n*-6 originating from linoleic acid, have specific functions. DHA (22:6n3) has an important role in retina and brain development, and AA (20:4n6) is the precursor of prostaglandins, leukotrienes, and other eicosanoids. These highly unsaturated fatty acids affect many aspects of membrane function including membrane order, permeability, and lipid-lipid as well as protein-lipid interactions. Specific interactions of membrane proteins with particular lipids may in turn affect receptor function, enzyme activities, signal transduction, and membrane excitability. For the developing infant, DHA is of major importance because it is the major PUFA in cerebral cortex and retinal membranes. The photoreceptor outer segments of the retina contain very high concentrations of DHA, and most molecular species contain at least one DHA moiety. Retinal DHA is important for normal photochemical activity of the visual pigment rhodopsin.

LC-PUFA requirements in the newborn are a major focus of research.[121-129] The reason for this intense interest is based on several observations. Accretion of LC-PUFAs occurs primarily during the last trimester of pregnancy, thereby making the preterm infant particularly vulnerable to LC-PUFA deficiency. Plasma levels of LC-PUFAs decrease markedly after birth in formula-fed preterm infants, as compared with nearly constant levels in breast-fed infants of comparable gestational age, and brain levels of DHA are lower in formula-fed than in breast-fed full-term infants.

Studies indicate that the newborn can synthesize LC-PUFAs from essential fatty acid precursors; however, the extent of de novo synthesis seems to be insufficient to meet demand at this age.[122-124] Postnatally, human milk provides LC-PUFAs to the newborn. Maternal LC-PUFA reserves depend on diet and can be improved by supplementation of DHA and AA during pregnancy and lactation. This, in turn, affects fetal LC-PUFA accretion and postnatal provision through mother's milk. Supplementation of formula-fed preterm or full-term infants with DHA and AA leads to plasma and red blood cell LC-PUFA levels similar to those in breast-fed infants.

Studies conducted in larger numbers of formula-fed infants clearly showed that full-term infants do not benefit from supplementation with DHA and AA,[123-125] whereas definite visual and cognitive benefits are found in preterm infants.[126] Indeed, the Life Sciences Research Office's assessment of nutrient requirements for term infant formulas prepared for the U.S. Food and Drug Administration (FDA) did not recommend supplementation of formulas for term infants with DHA or AA.[126] DHA and AA are now supplemented in preterm human formulas.

In this context, the effect of breast-feeding, to provide the infant with mother's milk containing the LC-PUFAs DHA and AA, is supported by numerous studies in infants as well as studies showing that 80% of the FAs in retinal photoreceptors is DHA. Furthermore, recent studies have shown that DHA may affect photoreceptor signal transduction.[138] The beneficial effect of breast-feeding on visual function has led to recommendations for supplementation of infant formulas with both DHA and AA. The role of DHA in brain function is much less understood. It is known that DHA is present in high concentration in neural gray matter, and that it regulates genes involved in synaptic plasticity and the functions derived from the latter.[127] Low brain DHA is associated with lower cytochrome *c* oxidase activity and glucose uptake[138]; the latter could have important functional consequences because of the high metabolic activity of the developing brain.[127] Low DHA activity in the developing brain also has been shown to affect dopamine and serotonin metabolism,[140,141] which in turn can affect cognitive function during early development.

The effect of mode of infant feeding on subsequent cognitive function has been investigated for the past 80-some years[142-154] (Table 30-9). IQ and motor development measured during infancy, in early or later childhood, or even in adulthood showed that feeding breast milk rather than formula has beneficial effects on the infant. The effects were small, however, especially with correction for confounding factors such as maternal age and education, socioeconomic status, and birth order. More recent studies indicate a relationship between duration of breast feeding and IQ in adolescence and adulthood. It is interesting that breast feeding for more than 9 month is associated with a decrease in IQ levels. Whether this is due to lack of proper nutritional complementation during prolonged breast feeding is not known.

Although cognitive benefits may be associated with DHA in human milk, the latter may affect the former through additional mediators such as growth factors, especially nerve growth factor (NGF) in human milk and with other components. Furthermore, breast-feeding also may be an indicator of material involvement in the infant's well-being and development not only during infancy but well beyond it. Well-designed, prospective studies are needed to ascertain the exact role of human milk and its components on cognitive development and function.

RECENT FINDINGS OF INTEREST

Although much of the research conducted since publication of the previous edition of this book has been rather repetitive of the seminal work carried out in 1970s to the 1990s, several more recent reports on various aspects of breast milk function and composition warrant mention.

Atopic disease: Studies have continued on the link between higher LC-PUFA *n*-6:*n*-3 ratio and eczema or asthma in the offspring, often with attention to parental, especially maternal allergies and asthma,[155-159] as well as the effect of growth factors and cytokines in maternal milk on allergy in infants.[160]

Trans *fatty acids:* Because of the detrimental effect and their known presence in human milk,[161,162] research has focused on the effect of lower consumption of these fatty acids by lactating women on their level in breast milk. Recent studies show that *trans* fatty acids in human milk have indeed decreased in Canada, where their amount in food has to be listed.[163] These fatty acids are still found at much higher levels in human milk in the United States[164] and Canada[163] than in Europe[161] or especially Africa,[165] however.

TABLE 30-9

Effects of Breast-feeding or DHA Supplementation on Cognitive Function

Study	Duration of Breast-Feeding*	Effect (IQ Points)	Age at Assessment
Hoefer and Hardy, 1929[141†]	4-9	Higher IQ	7-13 years
Menkes, 1977[142]		Less breast-feeding in children with learning disability Higher IQ (small difference)	
Fergusson et al., 1982[143]		Higher IQ (small difference)	5-7 years
Rodgers, 1978[144]		Higher IQ (small difference)	8-15 years
Morrow-Tlucak and Hande, 1988[145]	4 months	Higher IQ (small difference)	1-2 years
Florey et al., 1995[146]		Higher IQ (small difference)	18 months
Rogan and Gladen, 1993[147]		Higher IQ (small difference)	
Lucas et al., 1992[148‡]		Higher IQ (7-8 point difference)	7.5-8 years
Lanting et al., 1994[149]		Higher IQ	9 years
Horwood and Fergusson, 1998[150§]		Higher IQ	18 years
Gale and Martyn, 1996[151§]		Higher IQ	
Mortensen et al., 2002[152†]	1-9 months	Higher IQ (7 points)	adults
Helland et al., 2003[153‖]		Higher IQ (4 points)	4 years
Gustafsson et al., 2004[154¶]		Higher IQ	6.5 years

DHA, Docosahexaenoic acid; *IQ,* intelligence quotient; *LPC,* lysophosphatidylcholine.

*If duration is not indicated, breast-feeding lasted for several months.

†Breast-feeding duration longer than 9 months was associated with the poorest cognitive development.

‡Preterm infants were gavage-fed expressed human milk.

§Increase in IQ related to length of breast-feeding.

‖Maternal supplementation with *n*-3 LPC during pregnancy and lactation; higher IQ attributed to exposure to higher *n*-3 LCP level during pregnancy.

¶Controlled study; milk long-chain polyunsaturated fatty acid (LC-PUFA) assay was performed at 1 and 3 months of lactation, and correlation between total IQ and verbal and performance IQ was measured. Length of breast-feeding contributed significantly to total IQ.

Free amino acid concentration: Amino acid levels have been shown to be high in human milk,[166] especially that of glutamic acid,[167,168] so breast milk is a good source of nitrogen for the nursing infant.

Iodine: Ongoing controversy debates whether iodine is currently higher than that previously reported in human milk[169] or lower because of the effect of perchlorate.[170]

Vitamin K: This nutrient is still found to be present in insufficient amounts in human milk.[171,172]

31 Physiology of Lactation

James L. McManaman and Margaret Cobb Neville

Unlike most other organs in the body the mammary gland achieves its mature function, the secretion of milk, only after a developmental program that takes place in the adult, guided by reproductive hormones. Formation of the glandular structure of the breast, however, is initiated during embryonic development and reaches maturity during puberty. We first describe development of the functional anatomy of the mammary gland through puberty and pregnancy to its completion several days after parturition when milk assumes mature composition. We next describe the functional changes that take place during the first week post partum and that transform a prepared, but nonsecretory, gland into a fully functioning organ. Most lactation problems arise during this period. This section is followed by a description of the synthetic and secretory processes that are integrated during lactation to produce milk and the physiologic processes that regulate milk production and its ejection through the ducts and out the nipple. We conclude with a discussion of the effects of lactation on the mother.

OVERVIEW OF THE FUNCTIONAL ANATOMY OF THE BREAST

The human female breast is composed of a tubuloalveolar parenchyma embedded in a connective and adipose tissue stroma. The glandular component of the mature breast is composed of radially organized lobes, each of which is connected to the nipple by a single milk duct. Each lobe is composed of multiple lobules containing the alveolar structures responsible for milk production and an associated network of small ducts that join to form larger ducts that drain into the milk duct. Most textbooks describe the mature breast as containing 15 to 20 lobes on the basis of cadaver dissections; however, more recent ultrasound measurements put this number at approximately 9, with some individuals having as few as 4 and others as many as 14.[1] Figure 31-1 depicts the developmental origin of the lobuloalveolar units (referred to as *terminal duct lobular units* by pathologists) starting with embryogenesis, which begins in the 18- to 19-week fetus, at which time a bulb-shaped mammary bud can be discerned extending from the epidermis into the dense subepidermal mesenchyme (see Figure 31-1, *A*).[2] A nipple forms in the epidermal portion of the structure, and ducts invade the fat-pad precursor, branching and canalizing to form the rudimentary system that is present at birth.[2,3] Limited milk secretion occurs in the infant after birth because of changes in maternal hormones. The immature gland remains as nipple with a set of small branching ducts that grow in parallel with the child.

At puberty, estrogen[4] and a pituitary factor that is probably a growth hormone[5] stimulate the further elongation and branching of the mammary ducts. In early puberty, bare ducts course through the fat pad (see Figure 31-1, *B*). With the onset of menses and ovulatory cycles, the progesterone secreted by the ovary during the luteal phase brings about some lobular development as shown in Figure 31-1, *C*. The lobular clusters are dynamic structures that increase in size and complexity during each luteal phase but tend to regress with the onset of the menses and the loss of hormonal support.[4]

The hormones of pregnancy bring about expansion and functional differentiation of alveoli. In addition to increasing levels of progesterone, a lactogenic hormone, either prolactin or human placental lactogen, possibly aided by growth hormone, is thought to be essential for the final stages of mammary growth and differentiation.[6] By midpregnancy, the gland has developed extensive lobular clusters (see Figure 31-1, *D* and *E*), and, indeed, small amounts of secretion product are formed. However, differentiation continues until parturition, with full secretion being inhibited by the high circulating concentrations of progesterone. Secretory activation represents the onset of *copious* milk secretion and takes place during the first 4 days post partum. A major volume increase that occurs around 40 hours post partum is often referred as the *coming in* of the milk. Both the fall in progesterone, resulting from loss of the placenta, and maintenance of prolactin secretion from the pituitary gland are necessary for milk secretion.

Lactation is the process of milk secretion; it will continue as long as milk is removed from the gland on a regular basis. In women prolactin is required to maintain milk secretion, and oxytocin is required to produce the let-down that allows the infant to extract milk from the gland. An example of the swollen ducts and alveoli that occur when milk is not removed from the gland is shown in Figure 31-1, *E*. The actual volume of milk secreted is adjusted to the requirements of the infant by as yet unidentified local factors that may be activated by stretching and flattening of the mammary epithelial cells.

The later parts of this developmental program are repeated during each pregnancy because the glandular epithelium responsible for the secretion of milk regresses after weaning to a state resembling that of the prepregnancy condition. Involution takes place when regular extraction of milk from the gland ceases or, in many but not all species, when prolactin is withdrawn. Like lactogenesis this stage involves an orderly sequence of events that include cessation of milk secretion, apoptosis of the mammary epithelium,[7] and remodeling of the gland, which return it approximately to a prepregnant state.

SECRETORY ACTIVATION

The most critical time in the establishment of lactation is its onset during the transition from pregnancy to lactation, a period we now call *secretory activation* (previously termed *lactogenesis stage II*). Secretory activation takes place after birth in women, in contrast to many animal species where it occurs concomitantly with parturition.[6] Most lactation problems arise during this period as the result of stress of childbirth or problems with the mechanics of suckling. If unresolved these problems can lead to lactation failure.

Milk Volume and Composition During the First Week Post Partum

Figure 31-2, *A,* shows milk volumes in 11 American women who weighed their infants before and after every feeding for the first week post partum. Although there is wide variation among individuals, the trend is revealed by the averaged data in Figure 31-2,

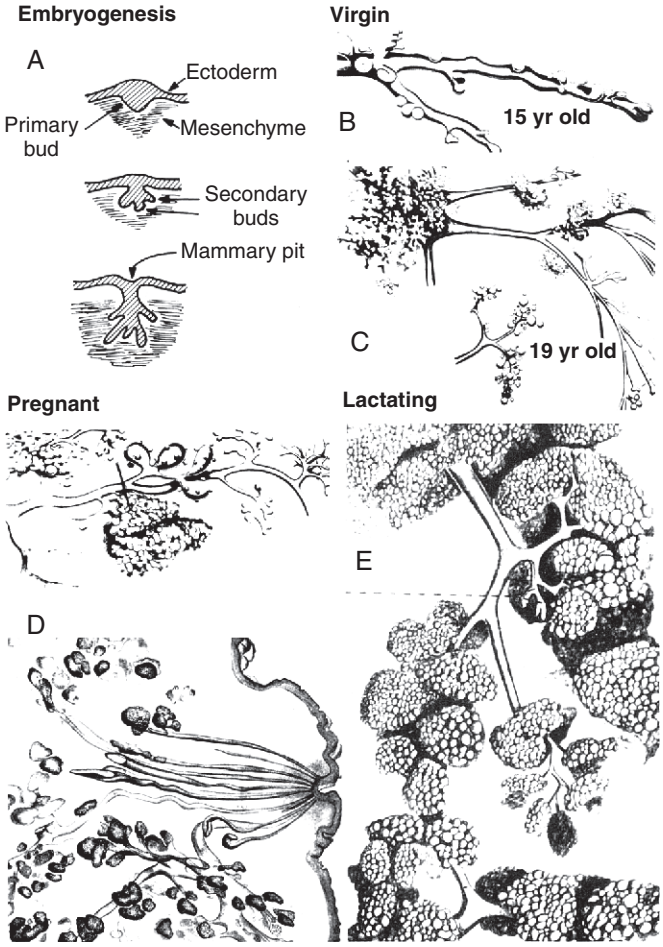

Figure 31-1 Human mammary development. A, A thickening of the ectoderm called the placode pushes branches into the underlying stroma to produce the rudimentary mammary gland with the nipple present at birth in both sexes. **B,** At the onset of puberty, ductal structures branch and elongate into the fat pad. **C,** With the onset of the menstrual cycles, progesterone secretion during the luteal phase brings about budding of alveolar complexes called terminal duct lobular units from the sides and ends of the ducts. **D,** The terminal duct lobular units undergo extensive development during pregnancy. **E,** This picture of the lactating gland was drawn from a section of the breast of a woman who died 2 days after last suckling her infant. Note that each alveolus is engorged with milk. *(The camera lucida drawings of sections of the human breast are from Dabelow A: Die postnatale Entwicklung der menschlichen Milchdruse und ibre Korrelationen,* Morphol J *85:361-416, 1941. With permission for publication from Springer-Verlag.)*

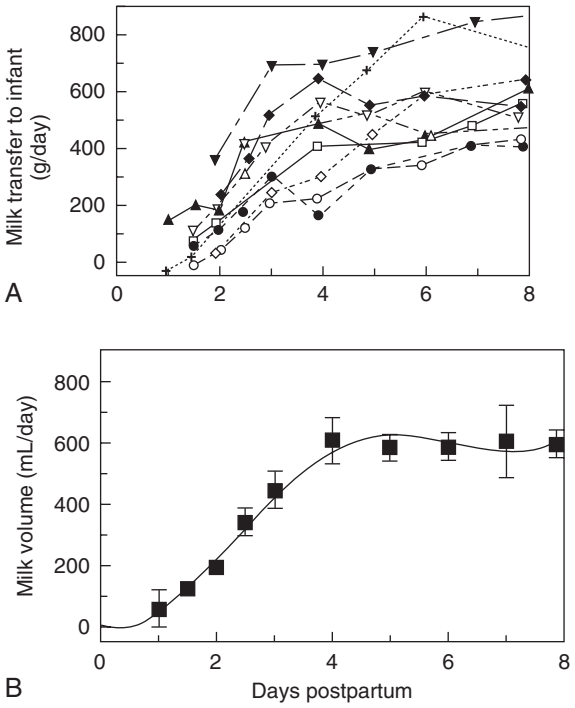

Figure 31-2 Milk volumes during the onset of lactation in American women. A, Eleven multiparous women weighed their infants before and after every feeding for 7 to 8 days post partum. Milk output was averaged by 0.5-day intervals for the first 3 days and then daily for the remainder of the experiment. All women had successfully breast-fed at least one previous infant. Note the extensive variation in the volumes of milk produced. All these women breast-fed successfully for at least 6 months. **B,** Mean output in the women shown in **A.** *(Plotted from data in Neville MC, Keller RP, Seacat J, Lutes V, Neifert M, Casey CE, et al.: Studies in human lactation: milk volumes in lactating women during the onset of lactation and full lactation,* Am J Clin Nutr *48:1375-1386, 1988. Graphs from Neville MC: Lactogenesis in women: a cascade of events revealed by milk composition. In Jensen RD [ed]:* The Composition of Milks. *San Diego, Academic Press, 1995, pp 87-98. Used by permission.)*

B: volumes of breast secretion of less than 100 mL per day characterize the first 2 days post partum, after which a rapid increase in milk volume leads to production of an average of 600 mL/day by the fourth day post partum. A detailed study of milk composition over this period reveals a carefully programmed cascade of events that leads to a mammary secretion product with a composition close to that of mature milk. Although the secretion product in the first few days is usually called *colostrum*, we avoid that term here because it implies a secretion product with a fixed composition. In fact, as we shall see, milk composition changes dramatically during the first 3 to 4 days post partum.

The first compositional change to occur after delivery is a fall in the sodium and chloride concentrations in the milk and an increase in lactose levels (Figure 31-3, *A*). These modifications commence immediately after delivery and are largely complete by 72 hours post partum.[6] They precede the rapid increase in milk volume by at least 24 hours and can be explained by closure of the tight junctions that block the paracellular pathway during lactation. With the paracellular pathway closed, lactose, produced by the epithelial cells, can no longer pass into the plasma, and sodium and chloride can no longer pass directly from the interstitial space into the milk space and must be secreted by the cellular route.

The next changes to occur are increases in the concentrations of serum immunoglobulin (Ig) A and lactoferrin (see Figure 31-3, *B*).[8] The concentrations of these two important protective proteins remain high for the first 48 hours post partum, the two together comprising as much as 10% by weight of the milk before they decrease rapidly after day 2 post partum, as a consequence of both dilution as milk volume increases and an actual decrease in the rate of secretion, particularly in the case of Igs. By day 8 post partum, these protective proteins together comprise less than 1% of the total weight of the milk; however, their secretion rate is still substantial, amounting to 2 to 3 g/day for each protein. Concentrations of oligosaccharides in milk are also high in

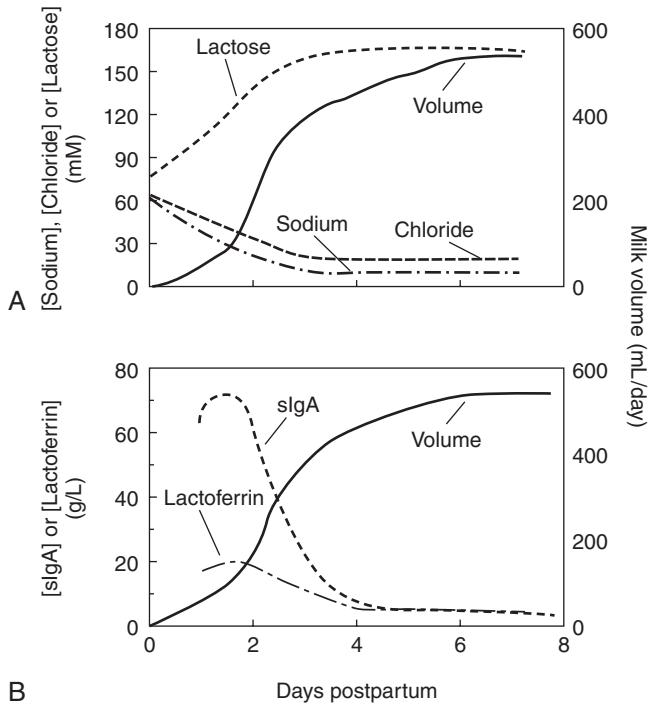

Figure 31-3 Changes in the concentration of certain milk components during the first week post partum. A, Time course of changes in the lactose, chloride, and sodium concentrations contrasted with the mean milk volume transfer to the infant. Changes in these milk components begin immediately post partum and are complete at least 24 hours before achievement of a steady state in milk volume. As described in the text, the decrease in sodium and chloride and increase in lactose concentration reflect closure of the tight junctions between the mammary epithelial cells. *(Data from Neville MC, Allen JC, Archer PC, Casey CE, Seacat J, Keller RP, et al: Studies in human lactation: milk volume and nutrient composition during weaning and lactogenesis.* Am J Clin Nutr *54:81-92, 1991.)* **B,** Changes in the concentration of secretory IgA and lactoferrin during the onset of lactation in women. *(Data replotted from Dils R, Clark S, Knudsen J: Comparative aspects of milk fat synthesis. In Peaker M [ed]:* Comparative Aspects of Lactation*. London, Academic Press, 1977, pp 43-55. Figure modified from Neville MC, Keller RP, Seacat J, Lutes V, Neifert M, Casey CE, et al:* Pediatr Clin North Am *48:35, 2001. Used by permission.)*

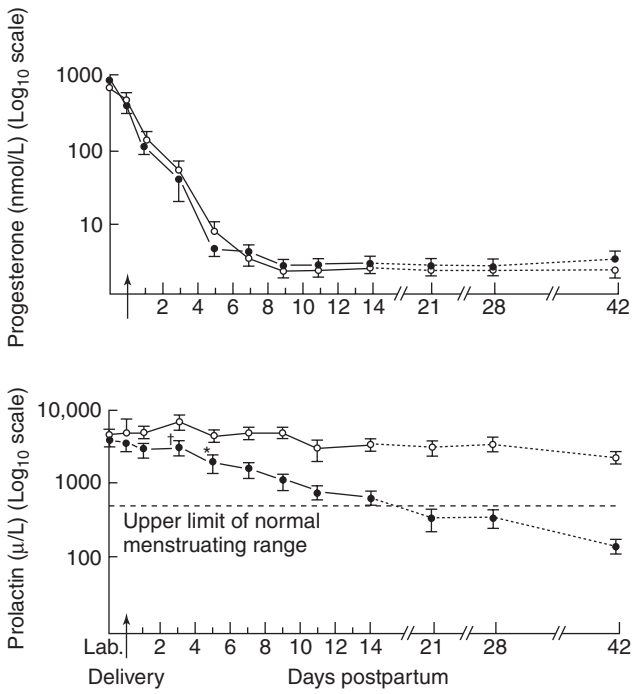

Figure 31-4 Maternal hormone levels after parturition in breast-feeding and non–breast-feeding women. Breast-feeding subjects (n = 10; *open circles*); non–breast-feeding subjects (n = 9; *filled circles*); $p = .01$. *(From Martin RH, Glass MR, Chapman C, Wilson GD, Woods KL, et al: Human alpha-lactalbumin and hormonal factors in pregnancy and lactation,* Clin Endocrinol *13:223, 1980. Reprinted with permission.)*

the early secretion product of the mammary gland, amounting to as much as 2% of milk weight on day 4 post partum. These complex sugars are also considered to have substantial protective effect against a variety of infections including human immunodeficiency virus.[9-11]

Finally, 36 to 48 hours post partum, milk secretion begins in earnest (see Figure 31-3). This volume increase is perceived by the parturient woman as the coming in of the milk and reflects a massive increase in the rates of synthesis and secretion of almost all the components of mature milk including but not limited to lactose, protein, lipid, calcium, sodium, magnesium, and potassium.

Hormonal Requirements for Secretory Activation

It has been clear for nearly three decades that the major inhibitor of milk production during pregnancy is progesterone.[6] Once birth occurs, a developed mammary epithelium, the continuing presence of high levels of prolactin, and a fall in progesterone are necessary for the onset of copious milk secretion. The levels of these hormones are shown in Figure 31-4. Evidence is clear for the inhibitory effect of progesterone during pregnancy in women. Thus removal of the placenta, the source of progesterone during pregnancy in this species, has long been known to be necessary for the initiation of milk secretion.[12] Conversely, retained placental fragments with the potential to secrete progesterone have been reported to delay secretory activation.[13] The conundrum that progesterone does not inhibit established lactation was solved when Haslam and Shyamala[14] showed that progesterone receptors are lost in lactating mammary tissues.

In most species high levels of plasma prolactin also appear to be essential for secretory activation; although the level declines with continued lactation some prolactin is thought to be necessary for active milk secretion. In women bromocriptine and other analogues of dopamine, drugs that effectively prevent prolactin secretion, inhibit the onset of lactation when given in appropriate doses.[15] Conversely, an older hypothesis that a prolactin surge is the trigger for secretory activation is probably incorrect. Although a biphasic rise in prolactin is associated with the stress of parturition in women,[16] it precedes the onset of copious milk secretion by 2 days.

Delays in Secretory Activation

A delay in the onset of milk secretion is a significant problem for the initiation of breast-feeding in a large number of women. For normal women the timing of secretory activation has been determined carefully from milk volume or composition in a few studies of middle-class white women.[6] Most of these data are in reasonable accord, but some do suggest that either parity

or previous lactation experience may influence the timing of secretory activation. Various pathologic conditions have been reported to delay secretory activation in women including cesarean section, diabetes, obesity,[17] and stress during parturition.[18] The role of cesarean section is controversial, no effect having been found in a large study from the laboratory of Hartmann[19]; a small effect, statistically significant, was found in a more recent study where breast fullness and the appearance of casein in the secretion were measured.[18]

Women with poorly controlled diabetes, studied in both the United States[20] and Australia,[21] often had a delay in secretory activation. In a recent, well-controlled study, stress during parturition, accompanied by an increase in cord blood glucose level, had the same result, and milk production on day 5 post partum was significantly decreased. Another cause of delayed milk secretion, obesity, has come to our attention only recently. In studies reviewed by Rasmussen and associates,[17] women with a high prepartum body mass index had more difficulty initiating lactation. Is there a common thread in all these conditions? Poorly controlled type I diabetes is associated with higher blood glucose level. Both type II diabetes and obesity can be associated with increased plasma insulin level. It is not clear how exposure to increased glucose or insulin during pregnancy could alter the onset or course of lactation, but these factors require serious investigation in the future.

CELLULAR MECHANISMS FOR MILK SYNTHESIS AND SECRETION

Milk components are secreted into the alveolar lumina by five distinct pathways as illustrated diagrammatically in Figure 31-5.[22] Four secretory processes are synchronized in the alveolar cell: (1) exocytosis, (2) fat synthesis and secretion, (3) secretion of ions and water, and (4) transcytosis of immunoglobulins and other substances from the interstitial space. These processes are summarized briefly here, followed by an introduction to the role of a fifth pathway, the paracellular pathway, in determining the composition of the mammary secretion.

Exocytosis

Most components of the aqueous phase of milk are secreted by the exocytotic pathway (see pathway I, Figure 31-5). The basic mechanisms of exocrine secretion, worked out in the pancreas more than 40 years ago by Palade,[23] are thought to apply essentially to all exocrine cells including milk-secreting cells. Like the exocytotic pathway in all cells, exocytosis in the mammary gland ultimately begins in the nucleus with the synthesis of messenger RNA molecules specific for milk proteins. The mature messenger RNA serves as a template for protein synthesis. The protein molecules are transported into the endoplasmic reticulum where they are folded and transported through the Golgi system to take part in secretory vesicle formation. In the Golgi, molecules destined for release are packaged in vesicles as a highly condensed granule matrix visible in the electron microscope as electron-dense structures. Distinct mechanisms appear to exist for concentrating proteins in secretory granules.[24] Pancreatic exocrine granules, for example, exhibit pH-dependent aggregation of granular proteins and require Ca^{2+} for stability, whereas caseins, the major type of protein found in milk, are packaged into electron-dense granules as micellar aggregates that are cross-linked by colloidal calcium phosphate.[25] Once formed, secretory vesicles move to the apical membrane where they discharge their contents into the alveolar lumen by exocytosis. Several specialized reactions within this pathway give the composition of milk its final form. For example, in addition to secretion of milk proteins such as casein, lactose and the oligosaccharides, which together comprise almost 8% of the weight

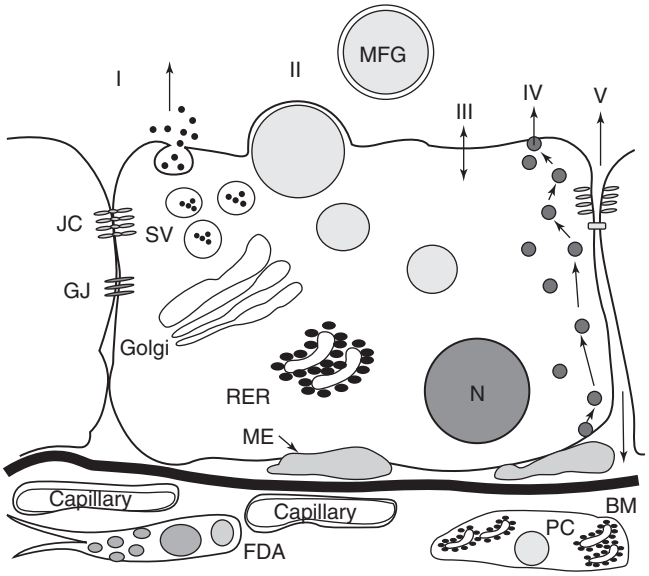

Figure 31-5 Cartoon of a mammary epithelial cell showing pathways for milk secretion. *Pathway I,* Exocytotic pathway for secretion of milk proteins, lactose, calcium, and other components of the aqueous phase of milk. *Pathway II,* Milk fat secretion with formation of cytoplasmic lipid droplets that move to the apical membrane to be secreted as a membrane-bound milk fat globule (MFG). *Pathway III,* Transporters for the direct movement of monovalent ions, water, and glucose across the apical membrane of the cell. *Pathway IV,* Vesicular transcytosis of proteins such as immunoglobulins from the interstitial space. *Pathway V,* The paracellular pathway for plasma components and leukocytes. of human milk, are synthesized and secreted by this pathway. In mammary glands of most species, lactose is an important regulator of the osmotic movement of water into milk and maintenance of isoosmolarity. Lactose is synthesized in the Golgi from uridine diphosphate–galactose and glucose, which enter from the cytoplasm, by the enzyme β-galactosidase with α-lactalbumin acting as a cofactor. The high concentration of lactose present in the Golgi during lactation osmotically stimulates the influx of water that contributes to the fluidity of milk.[24] The importance of this mechanism in the maintenance of milk fluidity was established by the observation that α-lactalbumin–deficient mice produce highly viscous milk.[26]

Lipid Synthesis and Secretion

The majority of lipid in milk exists as triacylglycerols (98%).[27] Triacylglycerols are synthesized from precursor fatty acids and glycerol by enzymes of the smooth endoplasmic reticulum membrane of the mammary alveolar cell. They then undergo assembly into protein and phospholipid–coated structures referred to as cytoplasmic lipid droplets.[28] After transport to the apex of the cell (see pathway II, Figure 31-2), these droplets become enveloped in apical plasma membrane and are

secreted into milk as plasma membrane bilayer–coated structures (milk fat globules) by a process that is distinct from the classical secretory pathway used for lipid secretion by hepatocytes and enterocytes.[24] The occasional inclusion of a crescent of cytoplasm within the membrane-bound globule[29] enables any substance contained in the cytoplasm to enter milk. The membrane surrounding the milk fat globule is the primary dietary source of phospholipids for the breast-fed infant and serves to prevent the triglyceride globules from coalescing into large fat droplets that might interfere with milk removal. In addition this membrane may enhance the uptake of lipid and lipid-soluble vitamins by the neonatal intestine.[30]

Transport of Small Molecules Across the Apical Membrane

Unlike other pathways for milk secretion, the pathways for the direct transport of substances across the apical membrane of the mammary alveolar cell are poorly understood (see pathway III, Figure 31-5). Linzell and Peaker[31] devised a clever technique to determine which molecules could use this pathway, infusing isotopes of small molecules up the teat of a goat and calculating how much of the substance left the milk and entered the blood. They found that sodium, potassium, chloride, and certain monosaccharides, as well as water, directly permeated this membrane, but calcium, phosphate, and citrate did not. Although the mechanisms are not understood, it is clear that apical membrane transport pathways are limited to a modest number of small molecules that also include glucose and possibly amino acids. Recently it has become clear that calcium is also transported across the apical membrane by a well-studied transporter called PMCA 2, a plasma membrane calcium adenosine triphosphatase.[32]

Transcytosis of Interstitial Molecules

Intact proteins in the interstitial space surrounding the basal and lateral surface of the mammary alveolar cell can cross the mammary epithelium in two possible ways: by transcytosis and through the paracellular pathway. Because the paracellular pathway is closed during lactation, plasma proteins must enter milk through transcytosis (see pathway IV, Figure 31-5). The best-studied molecule in this regard is IgA.[33] IgA is synthesized by plasma cells that reside in the interstitial spaces of the mammary gland or elsewhere in the body. Dimeric IgA binds to receptors on the basal surface of the mammary alveolar cell, after which the entire IgA-receptor complex is endocytosed and transferred to the apical membrane, where the extracellular portion of the receptor is cleaved and secreted together with the IgA. The many proteins including serum albumin, insulin, prolactin, IgF1, and possibly other growth factors that find their way into milk from the plasma are also thought to be secreted by a similar, but much less well-studied, pathway.

The Role of the Paracellular Pathway in Milk Secretion

Pathway V (see Figure 31-5) involves passage of substances between epithelial cells, rather than through them, and for this reason is designated the *paracellular pathway.* During lactation the passage of even low-molecular-weight substances between alveolar cells is impeded by a gasketlike structure called the *tight junction* that joins the epithelial cells tightly, one to another.[34] Although immune cells apparently can elicit diapedesis between epithelial cells to reach the milk,[35] the junctions seal tightly behind them and leave no permanent gap. During pregnancy, and probably mastitis, these tight junctions are leaky and allow components of the interstitial space to pass unimpeded into the milk. At the same time, milk components can enter the plasma. This leakiness is useful during these periods, inasmuch as secretion products are allowed to leave the gland and inflammatory cells can enter. It is not clear when junctions open during involution, but when milk volume drops below approximately 400 mL/day, the concentration of sodium and chloride in the mammary secretion increases suggesting a change in the permeability barrier.[36] When the junctions are open, mammary secretions have a high concentration of sodium and chloride, a fact that is sometimes useful in diagnosing breast-feeding problems.[37]

REGULATION OF MILK SYNTHESIS, SECRETION, AND EJECTION

Milk is synthesized continuously and secreted into the alveolar lumen where it is stored until it is ejected from the breast by a let-down reflex. This means that two levels of regulation must exist: regulation of the rate of synthesis and secretion and regulation of milk ejection. Although both processes ultimately depend on sucking by the infant or other stimulation of the nipple, the mechanisms involved, both central and local, are very different. Prolactin mediates anterior pituitary regulation of milk secretion, but its influence is greatly modified by local factors that depend on milk removal from the breast. Oxytocin, on the other hand, participates in a neuroendocrine reflex that results in stimulation of the myoepithelial cells that surround the alveoli and ducts. When these cells contract, milk is forced out of the alveoli to the nipple. Only then does it become available to the suckling infant. If the let-down reflex is inhibited, milk cannot be removed from the breast and local mechanisms bring about an inhibition of milk secretion. With consistent partial removal of milk, these local factors adjust milk secretion to a new steady-state level.[38] If milk removal ceases altogether, involution sets in and the gland loses its competency to secrete milk within days to weeks depending on the species.

MILK VOLUME PRODUCTION IN LACTATING WOMEN

A metaanalysis of the volume of milk secreted by exclusively breast-feeding women showed that milk volume at 6 months post partum is remarkably constant at about 800 mL/day in populations throughout the world.[38] Milk volume increases 5% to 15% in women with very low body fat because of secretion of milk with reduced lipid content, which has a caloric density of up to 15% lower than milk with normal fat content. This observation illustrates the important principle that *milk volume secretion in lactating women is regulated by infant demand.* Thus when the milk has a lower caloric density, increased sucking by the infant is thought to result in increased emptying of the breast, in turn bringing about an increase in milk secretion. Mothers of twins, and occasionally even triplets, are able to produce volumes of milk sufficient for complete nutrition of their multiple infants. Studies of wet nurses, completed in the 1930s, show that at least some women are capable of producing up to 3.5 L of milk per day. Conversely, if infants are supplemented with foods other than breast milk, milk secretion is proportionately reduced. For example, in countries such as Peru and the Gambia where infants' diets are customarily supplemented with small amounts of food at mealtimes, but the infants are given several breast-feedings a day, the daily milk production remains at approximately 600 mL/day for 12 months or longer.

The mechanisms by which the volume of milk is regulated are still under study. Although prolactin is necessary for milk production, and prolactin levels are consistently above baseline for the duration of lactation,[39] they are not proportional to milk

volume secretion. Local mechanisms, including autocrine and stretch, have been implicated in the regulation of milk volume production.[40-42] Definitive evidence in support of either mechanism remains elusive. However, cellular transduction of stretch responses remains an attractive mechanism for regulating milk production, because stretch is a known regulator of signal transduction and gene expression in physiologic systems affected by mechanical tension[43,44] and stretch-dependent effects on gene expression have been reported for mammary epithelial cells.[45]

OXYTOCIN, MILK EJECTION, AND SUCKLING

Milk removal from the breast is accomplished by the contraction of myoepithelial cells, the processes of which form a basketlike network around the alveoli where milk is stored. When the infant is suckled, afferent impulses from sensory stimulation of nerve terminals in the areolas travel to the central nervous system where they promote release of oxytocin from the posterior pituitary. In the woman, oxytocin release is often associated with such stimuli as the sight or sound, or even the thought, of the infant, indicating a significant psychologic component in this so-called neuroendocrine reflex. The oxytocin is carried through the bloodstream to the mammary gland where it interacts with specific receptors on myoepithelial cells, initiating their contraction and expelling milk from the alveoli into the ducts and subareolar sinuses. The process by which milk is forcibly moved out of the alveoli is called *milk ejection* or *let-down* and is essential to milk removal from the lactating breast.

During correct suckling, the nipple and much of the areola are drawn well into the mouth so that a long teat reaching nearly to the infant's soft palate is formed.[46] The mammary sinuses extend into this teat. Milk is removed not so much by suction as by the stripping motion of the tongue against the hard palate. This motion carries milk through the teat into the baby's mouth. The sinuses refill as the continued action of oxytocin forces milk from the alveoli into the ducts.

It has been known for some time that psychologic stress or pain decreases milk output. Recently the basis for this finding was shown by Ueda and colleagues[47] to be inhibition of oxytocin release. In relaxed, undisturbed women suckling their infants, oxytocin release begins with the onset of suckling or even before suckling when the infant cries or becomes restless. When the suckling women were asked to carry out difficult mental calculations or were fed traffic noise through earphones while nursing the infant, the number of oxytocin pulses was significantly reduced. Interestingly, the prolactin response to suckling was not impaired by psychologic stress, implicating different neural pathways in the release of the two hormones.

Alcohol and drugs of abuse may have effects on let-down. Building on earlier studies showing that ethanol inhibits milk ejection in a dose-dependent manner, Coiro and colleagues[48] measured plasma oxytocin concentrations in response to breast stimulation in nonlactating women and found that 50 mL of ethyl alcohol completely abolished the rise in oxytocin levels. Minor effects of long-term maternal ethanol consumption on motor development of breast-fed infants in a well-controlled study in humans[49] were attributed to alcohol transfer to the infant rather than suppression of milk secretion. A potent effect of morphine on oxytocin release has been described in rats,[50] but the effects of opioids and other drugs of abuse on lactation have not been studied in women.

EFFECTS OF LACTATION ON THE MOTHER

Nutritional Effects

In many species such as dairy cattle and laboratory mice, a large portion of the metabolic output is directed to milk synthesis so that careful management of nutrient intake is critical for lactation success. In humans the energetic costs of milk production are estimated to be about 700 kcal/day,[51,52] which can represent as much as a third of a woman's metabolic output. Typically the increased energy requirements of lactation are met by relatively small increases in food intake or decreased metabolic rate in healthy individuals.[53] Nonetheless, it is important to remember that, as already stated, the amount of milk produced is almost entirely regulated by infant demand. If a woman is breast-feeding twins, she will produce double the usual volume of about 800 mL/day.[38] Under these circumstances the nutritional demands may be substantial and attention should be paid to nutritional intake, particularly in malnourished women, so that maternal nutrient depletion does not result. One maternal effect that seems clear is that lactating women whose menses have not yet returned have a significant loss of calcium from their bones.[54] Both secretion of parathyroid hormone (PTH)–related peptide from the mammary epithelium and the lack of estrogen caused by postpartum amenorrhea may be involved. That PTH-related peptide plays an active role in mobilizing bone calcium during human lactation is suggested by findings that plasma calcium and alkaline phosphatase are elevated in lactating women and that the calcium regulatory hormone PTH is decreased.[54] After weaning, bone calcium levels return to normal.

Effects of Lactation on Reproduction

The most marked maternal effect of lactation is on fertility. In the early postpartum period, secretions of the ovarian follicle remain suppressed for a period of time the duration of which depends to a substantial extent on the pattern of suckling.[55] In non–breast-feeding women, fertility returns about 6 weeks post partum as pulsatile secretion of gonadotropin-releasing hormone returns to normal. In breast-feeding women who suckle their infants at regular intervals, follicle-stimulating hormone secretion returns to normal follicular phase levels during the course of lactation, but pulsatile secretion of luteinizing hormone tends to remain in a suppressed state so that the preovulatory surge of luteinizing hormone does not occur. The contraceptive effects of lactation may also reflect effects of breast-feeding intensity on maternal metabolism and associated reproductive hormone suppression.[56]

Postpartum suppression of fertility is thought to play a significant role in birth spacing on a population basis in developing countries where prolonged breast-feeding may be the rule and the use of supplementary feedings delayed. In developed countries, women who wish to ensure against pregnancy during lactation are usually advised to use other contraceptive means, often progesterone-containing compounds that do not interfere with milk secretion.[15]

SUMMARY

Milk secretion is a robust process that proceeds according to plan in at least 85% of women post partum. With assistance in the techniques of breast-feeding, anecdotal evidence suggests that at least 97% of women can successfully breast-feed their infants. The reasons for lack of success in breast-feeding are not well understood because it is easy to substitute formula when infants fail to thrive on the breast, at least in Western societies. Although this is not the place to discuss possible pathologic mechanisms, it should be noted that breast-feeding failure usually takes place in the first week or so post partum, and a much better understanding of the mechanisms by which milk secretion is initiated during this period may help us to understand why some women have serious problems with lactation. Other areas that require attention are the behavioral correlates of breast-feeding and the transfer of drug and toxins into milk. The latter may have a long-term impact on infant health and should receive additional attention.

32 Nutritional Assessment

Gilberto R. Pereira

Newborn infants, especially those born prematurely or who are ill, are at great risk for the development of nutritional deficiencies that can adversely affect their postnatal growth.The susceptibility of the neonate to the development of such deficiencies results from the rapid growth velocity of the newborn period, the metabolic immaturity of several organ systems, and the difficulty in meeting the additional nutritional needs imposed by illness, surgical stress, or excessive nutrient losses.

The purpose of this chapter is to outline a practical approach to the nutritional assessment of neonates through the combined evaluation of the following: (1) medical history; (2) physical examination; (3) nutritional intake; (4) body composition; (5) anthropometry; and (6) biochemical markers.

MEDICAL HISTORY

The nutritional evaluation of the newborn infant begins with the analysis of both the maternal medical history during the pregnancy and the neonatal medical history.

The maternal medical history can be obtained by interviewing the mother and by reviewing her medical record. Both are often necessary to retrieve pertinent data, such as (1) maternal weight gain during the pregnancy; (2) maternal nutritional intake before and during the pregnancy; (3) history of chronic illness; (4) family history of chromosomal, metabolic, and endocrinologic disorders; (5) results of amniocentesis and fetal ultrasonographic examinations; (6) use of medications during pregnancy; (7) complications of pregnancy known to cause either retardation or acceleration of fetal growth (Table 32-1); and (8) specific maternal nutrient deficiencies (e.g., iron, folate, and vitamin B_6).

The medical history of the neonate from birth should be reviewed, including the identification of factors known to alter energy requirements such as medications (theophylline, corticosteroids), medical illnesses (respiratory distress, bronchopulmonary dysplasia, congestive heart failure, sepsis, surgery, cold stress), and nutrient losses (chronic diarrhea, excessive drainage from chest tubes, ostomies, and fistulas). Special attention should also be paid to the use of medications known to decrease the metabolic rate by limiting physical activity such as sedatives and muscle-paralytic agents.

PHYSICAL EXAMINATION

The general physical examination of the newborn infant offers a unique opportunity for the evaluation of nutritional status. By simple inspection, one can assess the lack or presence of physical activity, muscle wasting, and subcutaneous fat. In addition, the examination of the head configuration, skin, hair, and mucous membranes can be instrumental in identifying the deficiency of specific nutrients. By palpation, one can assess the presence of craniotabes, raised skin rashes, and bone prominences such as rachitic rosary and healing fractures (Table 32-2). The use of anthropometry for protein-energy assessment is described in a separate section of this chapter.

NUTRITIONAL INTAKE

Optimal nutritional intake by neonates is considered as the diet that supports appropriate growth according to standards without imposing stress on the infants' immature metabolic and excretory functions.[1] Other models for the estimation of nutritional requirements include net uptake of nutrients from the umbilical circulation,[2] nutrient balance studies,[3,4] infusion of stable isotopes,[5,6] intake of human milk,[7] and the determination of the optimal intake that prevents nutritional deficiencies and allows for favorable growth and developmental outcome.[8] The estimation of dietary intake in neonates is much simpler than that in older children and adults because of the lack of diversity in the neonatal diet, the practice of routinely recording the infant's dietary intake, and the well-documented composition of milk, infant formulas, parenteral nutrition solutions, and nutritional supplements. Accurate estimation of dietary intake in breast-fed infants, however, is more complicated because of the known variability in the composition of human milk among individual mothers and the difficulty of estimating milk intake during feedings. In practice, the composition of human milk is assumed to approximate the average values described for preterm and term human milk, and the volume of breast milk ingested is estimated by weighing the infant immediately before and after feeding, using electronic scales.[9] Computerized programs for assessment of dietary intake are now commonly used by nutrition support services to facilitate the calculation of nutritional intake for patients receiving parenteral and enteral nutrition.

TABLE 32-1

Common Conditions Leading to Acceleration and Retardation of Fetal Growth

Growth Acceleration	
Maternal	Diabetes classes A and B
	Obesity
	Hyperglycemia resulting from steroid treatment
	Use of lithium during pregnancy
Fetal	Transposition of the aorta
	Beckwith-Wiedemann syndrome
	Soto syndrome (cerebral gigantism)
Growth Retardation	
Maternal	Malnutrition
	Pregnancy-induced hypertension
	Chronic hypertension
	Drug addiction (heroin, alcohol)
	Placental insufficiency
	Diabetes classes C, D, and E
	Smoking
	High altitude
Fetal	Multiple pregnancy
	Congenital anomaly
	Congenital infection
	Radiation

Resting energy expenditure (REE) in premature and in full-term infants can be measured by open circuit indirect calorimetry or by the elimination of stable isotope doubly labeled water ($^2H_2{}^{18}O$); both methods show comparable results.[10] The estimation of total energy requirement is done by adding the REE to the energy cost of the following: (1) physical activity; (2) thermoregulation; (3) growth; (4) thermic effect of food; and (5) fecal and urinary losses. Energy requirements in healthy full-term neonates receiving enteral feedings vary from 100 to 120 kcal/kg/day.[11] Energy intake as high as 148 kcal/kg/day has been recommended for premature infants to promote weight gain at in utero rates.[12] Nevertheless, this level of intake is currently considered excessive because it leads to fat retention at rates significantly greater than those observed in the fetus of similar gestational age.[13] Higher energy requirements than those presented earlier may be present in patients with fever, increased work of breathing,[14] and hypothermia, and in those with ostomy losses or exhibiting catch-up growth. On the contrary, lower energy requirements should be prescribed for patients receiving parenteral nutrition (85 to 100 kcal/kg/day) (because energy is neither used for intestinal digestion and absorption of feedings nor lost in the stools) and for infants with limited physical activity due to administration of skeletal muscle relaxants or heavy sedatives. Failure to recognize these changes in energy requirements may have a detrimental effect on the infant's postnatal growth velocity.[15]

The evaluation of nutritional intake in neonates should encompass the period from birth to the time of assessment. The adequacy of nutritional intake can be evaluated by comparing actual intake of a nutrient to a recommended optimal level. Daily nutritional requirements for premature and full-term infants are given in Table 32-3.

BODY COMPOSITION

At birth, the body composition of the neonate varies both with the length of pregnancy and with the occurrence of intrauterine complications that affect fetal growth. Ziegler and co-workers[16] and Widdowson[17] have been foremost in describing the changes in body composition that fetuses undergo with increasing gestational age. These changes include a progressive decrease in total body water, extracellular water, sodium, and chloride, and a progressive increase in intracellular water, potassium, calcium, and magnesium. In addition, the body stores of protein, fat, glycogen, and mineralized bone also increase with gestational age (Table 32-4). Complications of pregnancy known to either retard or accelerate fetal growth can influence the body composition of the neonate. For example, infants who are small for gestational age (SGA) have reduced total body fat, whereas infants who are large for gestational age (LGA) have increased total body fat when compared with infants who are appropriate for gestational age (AGA). Enzi and associates[18] demonstrated that the body fat content approximated 12% in SGA infants, 14% in AGA infants, and 18% in LGA infants. Similarly, Fee and Weil[19] reported a total body fat content of 21% in the LGA infant of a diabetic mother.

Significant changes in body composition are observed with growth during the neonatal period and throughout the first year of life (Figure 32-1).These changes include (1) a progressive increase in the amount of adipose tissue (which peaks between 4 and 6 months of postnatal life[20] and declines slightly by 12 months of age) and (2) a progressive decrease in total body water, with a relative increase in the amount of intracellular water.[21] The proportion of body weight represented by minerals and protein remains relatively constant from birth to 1 year of age (see Figure 32-1).

Widdowson and Dickerson[22] described the contributions of various organ systems to the total body mass of premature and full-term infants compared with that of adults (Table 32-5). From their data, it can be seen that certain organ systems such as the heart, bony skeleton, kidneys, and liver maintain the same percentage of total body weight at 24 weeks and 40 weeks gestational age, as well as during childhood. The skin and the brain make up a larger proportion of neonatal body weight than of adult body weight, whereas skeletal muscle represents a relatively lower percentage of neonatal body weight. These studies, performed by chemical analysis of infant cadavers, are still considered the gold standard for measurements of body composition.

Over the past several decades, various methods have been developed for the indirect assessment of body composition in living infants. Although some of these methods have technical limitations, they have the advantages of being noninvasive and applicable for longitudinal measurements in growing infants.

The total body potassium (K40) counter has been used to assess lean body mass (LBM) because potassium resides only in the LBM and not in adipose tissue. This method is based on the supposition that naturally occurring potassium (K39) contains a fixed proportion of the radioactive K40, which can be measured by a counter. Fat mass is determined by subtracting the calculated LBM from total body weight. Limitations to the use of this method include the insufficient sensitivity of the K40 counter for small infants and the variable potassium content of viscera and skeletal muscle in children of different ages. Spady and colleagues[23] used this method to assess the effect of maternal smoking on infant body composition.

Neutral fat does not bind water and, therefore, methods to estimate total body water have been developed to determine the nonfat compartment of the body. The oral administration of doubly labeled water, with a known amount of the stable isotopes deuterium (^2H) and oxygen 18 (^{18}O), has been used for the estimation of total body water in adults.[24] This method is based on the dilution of the ^2H and ^{18}O isotopes in body fluid such as saliva, urine, or serum, after a period of equilibration.[24] The changes in the water content of the LBM, which occur at various ages and among different individuals, represent a major limitation of this method, which is further explained in the stable isotope section of this chapter.

Total body electrical conductivity (TOBEC) has been used to estimate fat-free mass (FFM) by detecting a change in the electromagnetic field. This change is caused by shifts in the amount and volume distribution of electrolytes that are present in the FFM.[25] Fat mass can be estimated by subtracting the FFM from the total body weight. This method is safe, noninvasive, and rapid, but it has some limitations. First, the model used to calibrate this method was the infant miniature pig and not the human neonate. Second, the TOBEC scan is costly, not portable, and not uniformly available. Standard values for FFM and for total body water in infants using TOBEC have been reported by Fiorotto and associates.[25]

A dual-energy x-ray absorptiometry (DEXA) method has been proposed for the determination of lean and fat body masses.[26] This technique employs low-radiation x-ray sources that provide alternating pulses of 70 and 140 kV. After passing through the infant's body, the rays are filtered for analysis. Estimates of body composition derive from the x-ray absorption capacity of different body tissues. This method is safe, rapid, and noninvasive and allows for measurements of bone mineral content as well as lean and fat body masses.

Magnetic resonance imaging (MRI) is a noninvasive method that allows for fast and reproducible measurements of adipose tissue content in neonates with low intracoefficients and intercoefficients of variability.[27] The MRI measurements of total body fat have been validated against stable isotope dilution methods in term infants with reasonable correlation.[28] A comparison of the various methods of body composition employing different methods is presented in Table 32-6.

ANTHROPOMETRY

Anthropometric assessment provides insight into the quality and quantity of growth in newborn infants. The assessments done at the time of birth reflect the pattern of fetal growth, whereas longitudinal assessments reflect postnatal growth.

The three single measurements most often used for the nutritional assessment of neonates at birth are weight, length, and

head circumference (HC). When plotted on standard growth charts against gestational age, these measurements indicate whether the infant is AGA, SGA, or LGA. Pathophysiologic conditions that cause aberrant fetal growth increase the risks for perinatal morbidity and mortality.[29] Numerous standard curves for the assessment of birth weight, length, and HC have been published, and major differences among them can be observed.[30-37] These differences appear to be related to the various ethnic, socioeconomic, and environmental characteristics of the reference population. Measurements of weight, length, and HC are also used longitudinally for the assessment of postnatal growth. In the hospitalized neonate, these measurements are performed frequently to determine whether adequate growth is occurring on a particular nutritional regimen. Nevertheless, it should be acknowledged that changes in nutritional intake or in infant needs might take several days to be reflected in anthropometric parameters.

There are several growth charts available for postnatal assessment of premature infants, some of which are based on intrauterine standards.[29-35] Among them, the Fenton growth chart[35] was recently developed to update the commonly used Babson and Benda's growth chart[31] published in 1976. Advantages of this newer chart include: (1) the assessment of premature infants with gestational ages as early as 22 weeks, instead of 26 weeks; (2) the display of the growth curves in percentiles, instead of standard deviation and; (3) the use of 100-g increments, instead of 500-g increments, for plotting weight measurements. There are also premature growth charts that are based on postnatal growth rates.[36-38] The most contemporary of these charts[38] was based on a large multicenter sample of 1660 premature infants with birth weights between 500 and 1500 g. These charts display growth curves for weight, head circumference, length, and midarm circumference (MAC) for the first 17 weeks of life. All these charts encompass the early neonatal and postnatal periods and are therefore suitable for in-hospital use.

Growth charts for long-term growth assessment of premature infants are also available.[39,40] These charts were developed by the Infant Health and Development Program with basis on the premise that premature infants grow differently than full-term infants during infancy and early childhood. The growth percentiles were based on a large sample of premature infants born with less than 37 weeks of gestation with birth weights of less than 1500 g or between 1501 and 2500 g. These charts are suitable for follow-up of premature infants up to 38 months of gestation-adjusted age and are available for premature boys and girls.

Growth standards on long-term assessment of full-term infants were published by the Centers for Disease Control and Prevention (CDC) in 2000.[41] More recently, growth charts for the assessment of full-term infants who were partially or exclusively breast-fed were made available by the World Health Organization (WHO).[42] These standards were based on a large sample of infants from a multicountry population derived from Brazil, Ghana, India, Norway, Oman, and the United States. A study comparing the CDC and the WHO charts demonstrated significant differences in growth between the two samples. Infants in the WHO chart had faster growth rates during early infancy and lower rates of weight gain and greater linear growth throughout infancy.[43] These differences were mostly attributed to differences in dietary intake during infancy of the two study samples: breast-feeding for the WHO chart and formula feeding for the CDC chart.

Weight

Weight for age is often considered the gold standard for the assessment of postnatal growth. Hospitalized infants are routinely weighed on a daily basis. However, care must be taken to weigh the infant unclothed and to correct for the weight of attached equipment, such as endotracheal tube, chest tube, intravenous board, gauze, and tape. The assessment of weight gain velocity over time is more useful than one single measurement of weight for age. Premature infants are expected to gain weight at rates comparable to in utero standards.[44] Although this appears to be the best approach available, a number of investigators have questioned the validity of this assumption.[36,37] Dancis and associates[36] published growth curves that take into account the birth weight of the preterm infant and the expected percentage of weight loss during the first 50 days of life. These curves have been modified, demonstrating that advances in medical care and nutritional support have increased the rates of postnatal growth in premature infants.[37] In a recent observational study from our institution of AGA infants with birth weights less than 2000 g, 48% of these infants had weight values that fell below the 5th percentile on the growth chart, based on intrauterine standards at some time during their hospital course despite adequate nutritional intake. In addition, one must be cautious when interpreting weight loss in the first postnatal week because it is caused predominantly by loss of extracellular water.[45] Weight measurements alone cannot be considered an accurate indicator of lean body mass, nor can they distinguish between gains in lean body mass and fluid gains. The expected rate of fetal weight gain during the last trimester of pregnancy is 10 to 15 g/kg/day.

Length

Length for age is an extremely useful measurement of nutritional status in older children.[46] Neonates, however, are difficult to measure accurately. An accurate length measurement in neonates can be obtained when two trained observers use a rigid surface containing a stationary headboard, a movable footboard, and a built-in centimeter scale. When interobserver and intraobserver reliability can be assured, serial measurements of length are excellent for following longitudinal growth. Unlike changes in weight, changes in length are not influenced by fluid status. The expected rate of fetal growth in length during the last trimester of pregnancy is 0.75 cm/week.

Head Circumference

The measurement of HC provides an indirect measurement of brain growth and is, therefore, an important part of the nutritional assessment, both at birth and in longitudinal studies. At birth, the detection of microcephaly indicates retarded brain growth during fetal life, which may result from various causes, such as chromosomal abnormalities, maternal drug addiction, infection, or lack of nutrient availability secondary to placental insufficiency. The lack of brain growth associated with a lower number of cells indicates an insult that occurred during the first trimester of pregnancy.

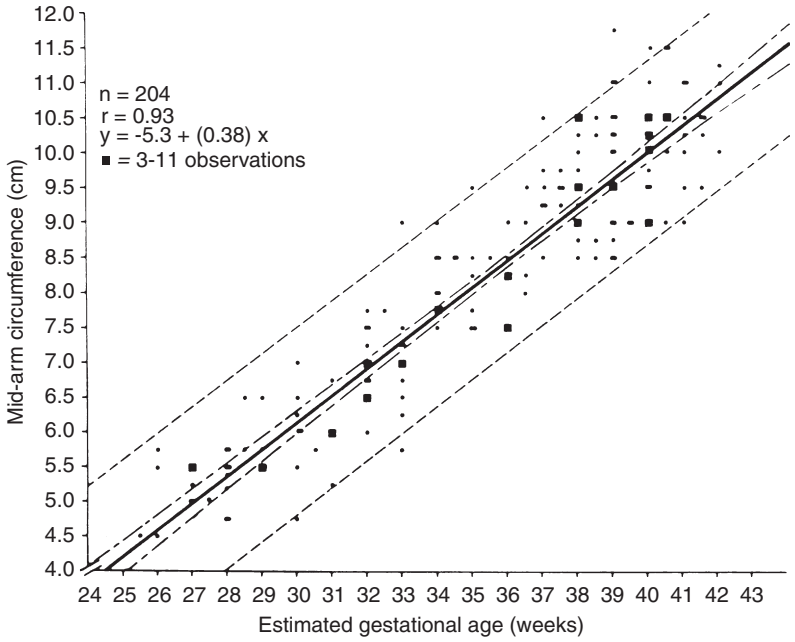

Figure 32-2 Correlation between midarm circumference and gestational age. — represents mean midarm circumference; -—- represents 95% confidence limits on predicted mean; --- represents 95% confidence limits for one observation.

Lack of brain growth caused by small cell size generally indicates a chronic insult throughout pregnancy. Neurologic outcome can be poor in microcephalic infants, particularly if no catch-up head growth is observed during the neonatal period.[47-52]

When measured longitudinally, HC is a useful tool for nutritional assessment, except in the presence of hydrocephalus. Decreases in HC are not unusual during the first few days of life, while head molding and scalp edema are still resolving. For that reason, the HC should be remeasured 3 days postnatally. In the newborn period, the brain is spared during mild to moderate malnutrition. In premature infants, a decrease in nutritional intake that results in slowing of weight and length velocities might not necessarily affect head growth velocity. In addition, in premature infants on a regimen of advancing caloric intake, head growth precedes the onset of growth in weight and length. The maintenance of normal head growth in the neonatal period is important because a rapid period of brain growth, evidenced by DNA synthesis, formation of dendritic synapsis, and myelination, occurs between 28 and 44 weeks after conception.[34-36] Infants who are born with normal head size but who become microcephalic during the postnatal period are at significantly increased risk for poor developmental outcome.[48] The expected rate of fetal head circumference growth during the last trimester of pregnancy is 0.75 cm/week.

Midarm Circumference

The MAC reflects the combination of muscle mass and fat stores in the upper arm and rapidly diminishes when protein and fat stores are depleted.[46] Standard values for MAC obtained from neonates born between 24 and 42 weeks gestation have been reported by Sasanow and colleagues.[53] These data document a predictable linear rise in MAC with increasing birth weight and gestational age (Figure 32-2). MAC is measured at the midpoint of the upper arm, which is found by measuring the distance between the acromion and the olecranon with the arm held in a horizontal position. In one study, serial measurements of MAC were more sensitive than those of weight or length for assessing nutritional status in growing premature infants.[53]

Skinfold Thickness

The simplest way to estimate body fat is to measure the thickness of the subcutaneous tissue.[54] Standard measurements of skinfold thickness for premature and term infants have been reported.[55] In addition, serial measurements of skinfold thickness at the triceps or at the scapular site can provide information on the rates of fat accretion in premature and term infants.[56] The correct technique for measurement of skinfold thickness requires firm placement of the calipers without slippage for a minimum of 15 seconds. Several investigators have shown that holding the calipers for 60 seconds while measuring the skinfold thickness of the triceps is useful in eliminating false values resulting from edema.[57,58] Dauncey and colleagues[59] have estimated total body fat percentages from measurements of skinfold thickness from multiple sites. However, the rapidly changing distribution of fat accretion in premature infants makes it difficult to generate a consistent equation for predicting total body fat.[60] Ultrasonography has been used to measure skinfold thickness; however, these measurements appear to be less reproducible than those obtained with skinfold calipers.[61]

Arm Muscle and Arm Fat Areas

Once the measurements of MAC and triceps skinfold thickness at 15 seconds (TSF_{15}) and at 60 seconds (TSF_{60}) are obtained, one can then calculate the arm area (AA), the arm muscle area (AMA), the arm fat area (AFA), and the arm water area (AWA), using the following formulas.[62,63]

$$AA = MAC^2 / 4\pi$$

$$AMA = (MAC - \pi TSF_{15})^2 / 4\pi$$

$$AFA = AA - (MAC - \pi TSF_{60})^2 / 4\pi$$

$$AWA = AA - AMA - AFA$$

The measurement of TSF_{15} is thought to reflect subcutaneous fat and water; however, the TSF_{60} measurement is thought to reflect fat only, assuming the water has been squeezed out

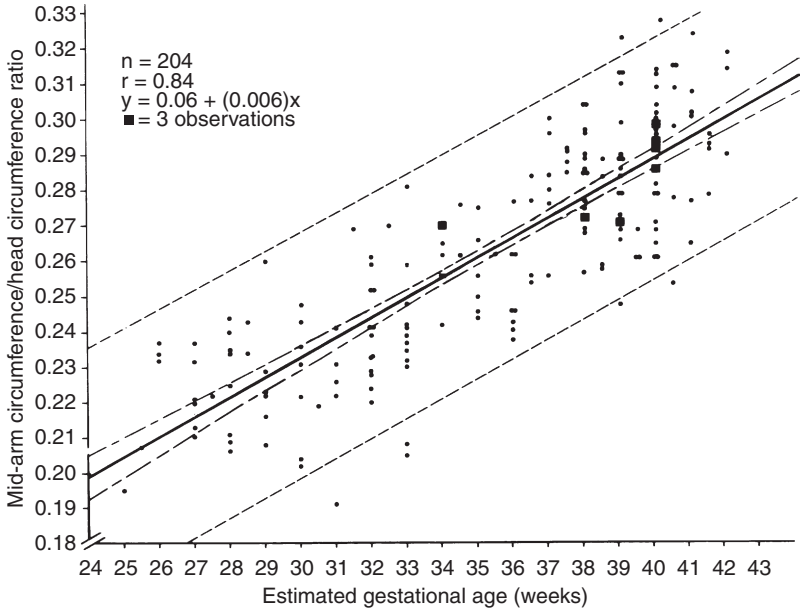

Figure 32-3 Correlation between midarm circumference/head-circumference ratio and gestational age. -—- represents 95% confidence limits on predicted mean; --- represents 95% confidence limits for one observation.

of the subcutaneous tissue.[58] Standard measurements of arm muscle and fat areas for infants at term have been published.[62]

Measurements of arm muscle and fat areas can be useful in the assessment of newborn infants who have experienced either fetal growth restriction or acceleration. For example, these measurements can identify reduced muscle or fat stores in growth-restricted infants who might be classified as AGA by weight criteria. Similarly, the measurements of TSF and AFA are proportionately greater in infants of diabetic mothers.[64,65] These infants are known to have a greater percentage of their body mass as fat, compared with infants born to nondiabetic mothers.[19]

Ponderal Index and Midarm-Head Circumference Ratio

The ponderal index and the MAC/HC ratio provide information on the proportionality of body growth. As such, they potentially allow the estimation of stunting and wasting that has occurred either in utero or postnatally. When measured at birth, both indices have been shown to be more specific than weight for age alone in determining the risk for perinatal morbidity associated with intrauterine growth disorders.[55] When used longitudinally, these indices can assess whether length is spared at the expense of weight, or whether head growth is spared at the expense of somatic growth.

The ponderal index is calculated by using the following formula[66]:

$$\text{Weight (g)} \times 100 / \text{length (cm}^3\text{)}$$

The ponderal index has been shown to vary with the gestational age of the infant[67] and is useful for the identification of growth-restricted infants who are at risk for neonatal hypoglycemia.[66] The ponderal index can be greatly misleading if measurements of length are performed inaccurately because this potential error is cubed during the calculation. The ponderal index has proved not useful for screening macrosomic infants at risk for hypoglycemia;[68] its use for longitudinal assessment of nutritional status in neonates has yet to be studied.

The MAC/HC ratio has proved useful as an index of body proportionality in neonates because it compares an anthropometric measurement likely to be affected by lack of nutritional intake (MAC) with another measurement that is less likely to be affected by nutritional intake (HC). The rationale for its use is based on the observation that head growth is spared relative to somatic growth in malnourished infants. Standard values for the MAC/HC ratio obtained from infants born between 24 and 42 weeks gestation have been reported by Sasanow and colleagues.[53] The MAC/HC ratio values increase progressively with the gestational age of the neonate (Figure 32-3).

When used at birth, the MAC/HC ratio is more sensitive than either the ponderal index or weight for age in identifying neonates at risk for morbidity in association with intrauterine growth restriction or acceleration.[68] We have compared the serial measurements of the MAC/HC ratio and weight and length for age measurements in a large group of premature infants during the first few weeks of life. Although the two indices had comparable sensitivity, the MAC/HC ratio had greater specificity in identifying protein-energy malnutrition in these infants.[69] We have also serially measured the MAC/HC ratio in premature infants to determine the proportionality of body growth throughout the first year of life. Our results indicate that premature infants, despite their small size at birth, maintain proportional growth similar to that of term infants (MAC/HC ratios <0.3) during the first year, even though they demonstrate no catch-up weight gain. Thus, it appears that premature infants have a regulatory mechanism that keeps their growth proportional as long as they receive adequate nutritional intake.[69]

Thigh Circumference and Thigh-Head Circumference Ratio

Ultrasonographic measurements of thigh, head, and abdominal circumferences have been used for the estimation of fetal weight during the last trimester of the pregnancy.[70] The chronology of adipose tissue deposition, being last in the lower extremity after occurring in other parts of the body, explains the benefits of the thigh circumference (TC) and the thigh-head ratio (THR) over other fetal parameters. Measurements of the TC are known to be affected by the position of the lower leg at the time that the measurement is being obtained. Ideally, the leg should be maintained at 90 degrees of flexion in relation to the thigh. Because of the inability to control leg position in utero, Warda and colleagues[71] identified a specific plane in the

thigh (transitional plane), at the level of the nutrient foramen of the femur, that allows for ultrasonographic measurements to be performed in an accurate and reproducible manner.

Standard values for TC and THR have been reported for neonates born at gestational ages varying from 27 to 41 weeks and have been plotted against birth weight and gestational age.[72] The same study also reported a good correlation between the THR and the ponderal index. The usefulness of the TC and THR for the evaluation of infants who are either large or small for gestational age needs further study.

BIOCHEMICAL ASSESSMENT

Measurements of various biochemical markers in serum and in whole blood have been used to assess protein, mineral, and vitamin status in newborn infants. Although some of the data on the use of these indices are extrapolated from older children and adults, most of the data presented in this section are derived from studies performed in neonates. A major limitation to the interpretation of the serum concentration of any nutrient as a marker of nutritional status is that the intravascular space generally represents a small portion of the total body pool and, therefore, might not reflect total body stores. This principle can be applied to most minerals, vitamins, and trace elements. The only exceptions are the serum proteins and some electrolytes such as sodium and chloride, which are predominantly concentrated in the extracellular fluid.

Serum Albumin

Serum albumin concentrations have been the mainstay of the biochemical assessment of nutritional status in neonates, children, and adults for several decades.[73] Serum albumin levels are lower in premature infants than in full-term infants because of a more rapid turnover of the albumin pool and a presumed decrease in the rate of synthesis by the immature liver. Albumin levels increase progressively with gestational age, varying from 2.5 to 3.5 g/dL in premature infants and 3.5 to 4.5 g/dL in term infants.[74] The serum half-life of albumin ranges from 14 to 21 days in the full-term neonate and from 5 to 7 days in the premature neonate, which makes it ideal for long-term assessment of nutritional status, but less than optimal for assessing short-term responses to changes in nutritional intake.[75]

Serum Transferrin

The serum concentration of transferrin has been used to assess protein status after nutritional rehabilitation in surgical adult patients and in pediatric cancer patients.[75-77] Transferrin has a serum half-life of 8 to 12 days, which potentially makes it a more responsive marker than albumin to recent changes in protein intake. However, serum transferrin represents 80% of the total iron-binding capacity, and for that reason the serum level of this protein is elevated during iron deficiency, regardless of the protein status.[78] Serum levels of transferrin range from 90 mg/dL in neonates born at 25 weeks gestation to 300 mg/dL in those born at term.[79] Like other serum proteins, transferrin concentrations increase with gestational age and body weight. LGA babies have higher concentrations than do AGA babies. Growth-restricted infants also have elevated serum levels of transferrin, most likely on the basis of iron deficiency.[79,80] Despite its usefulness for nutritional evaluation in the pediatric population, we were unable to demonstrate a role for serum transferrin in the longitudinal assessment of protein status in premature infants.[80,81] In our study, changes in serum transferrin concentration, unlike serum transthyretin changes, neither reflected changes in protein intake nor correlated with weight gain velocity.[82-84]

Serum Transthyretin (Prealbumin)

Transthyretin is a minor thyroid-binding globulin and a co-carrier of vitamin A with retinol-binding protein (RBP).[85] Its half-life of about 2 days makes its serum concentrations responsive to recent changes in protein-energy intake. In contrast, serum transthyretin levels are not particularly useful for long-term nutritional assessment. The serum concentrations of transthyretin at birth range from 5 to 20 mg/dL and are lower in preterm than in term infants.[86,87] The serum concentrations of this protein in adults are almost twice the values observed in newborn infants.[88] In newborns, increases in the serum concentrations of transthyretin occur rapidly with increases in protein intake, and these increases can predict weight gain velocity more accurately than the actual protein intake per se.[82] Nevertheless, several nonnutritional factors can affect the serum levels of transthyretin, thus limiting its usefulness for nutritional assessment. Transthyretin can act as an acute-phase reactant during neonatal sepsis.[88] In addition, either liver or renal disease can affect the production and degradation of transthyretin, thereby affecting its serum concentrations. Corticosteroids are known to increase the liver synthesis of transthyretin. For this reason, infants who receive dexamethasone for the treatment of bronchopulmonary dysplasia and infants whose mothers received betamethasone prenatally have elevated serum concentrations of transthyretin for about 2 weeks after these medications are discontinued.[89,90]

Retinol-Binding Protein

RBP is synthesized in the liver and has a serum half-life of about 12 hours. RBP is the main carrier of retinol (vitamin A), and its synthesis and release from hepatocytes are modulated by the availability of vitamin A. The serum concentrations of RBP at birth range from 1.2 to 3.5 mg/dL, and the values in premature infants are lower than those in term infants.[87-91] Because premature infants can become relatively vitamin A deficient after birth, a low serum level of RBP might represent vitamin A deficiency rather than protein deficiency. Like transthyretin, the RBP serum concentrations can be elevated significantly by the administration of corticosteroids.[89-90] To date, no studies have been undertaken to evaluate the usefulness of RBP in determining protein status in newborn infants.

Plasma Aminogram

The plasma concentration of amino acids is a dynamic function of the following variables: (1) recent protein intake (usually from the previous 24 hours), (2) gastrointestinal assimilation of dietary protein, and (3) uptake of amino acids from the plasma for protein synthesis in the liver. The plasma aminogram pattern has been used for the evaluation of both the quantity and quality of protein ingested by the neonate. The standard pattern of the plasma aminogram has been defined as the one observed postprandially in growing newborn infants fed human milk. It remains to be determined whether this pattern should also be used for nutritional evaluation in sick or malnourished infants. Rassin and colleagues[92,93] and Gaull and co-workers[94] have studied the plasma aminogram in low-birth-weight infants fed formula containing either high (3 g/100 kcal) or low (1.5 g/100 kcal) protein content; infant feedings containing two types of protein with a predominance of either whey or casein were also evaluated in these studies. These investigators concluded that low-birth-weight infants fed formulas containing high protein with a predominance of casein had a higher concentration of plasma amino acids than did infants fed human milk. They also demonstrated that low-birth-weight infants had a limited capacity to convert methionine to cysteine and taurine, or phenylalanine to tyrosine, thus suggesting that

the amino acids cystine, taurine, and tyrosine are essential for the premature infant, but not for the full-term infant. Heird and associates[95] reported a study in which the plasma aminogram was used for the evaluation of a pediatric amino acid solution. The study documented that infants receiving that particular amino acid mixture had plasma amino acid levels within the 95% confidence limits of the plasma concentration observed in breast-fed infants, except for one amino acid, phenylalanine. The study also showed that the ability of low-birth-weight infants to tolerate parenterally administered amino acids is not as limited as was previously thought.

3-Methylhistidine

This amino acid, a constituent of muscle protein, has unique properties in that it is not available for protein synthesis in the liver, and on its release from the muscle it is excreted unchanged in urine. Therefore, the excretion of this amino acid in the urine has been regarded as a reflection of skeletal muscle catabolism. Although the renal excretion of 3-methylhistidine has been shown to correlate with nitrogen balance in adults, this may not be clinically applicable to the neonate for several reasons: (1) the relative contribution of skeletal to total body mass is smaller in neonates than in adults (25% vs. 40%); (2) the muscle content of 3-methylhistidine in neonates is lower than that in adults (1.7 vs. 4.2 mL/g protein); and (3) the gastrointestinal tract of the neonate might provide a greater portion of 3-methylhistidine than does that of the adult.[96-99]

NUTRIENT BALANCE STUDIES

Nutrient balance studies have long been used to estimate nutrient retention in infants.[100,101] One can measure the total body balance of virtually any substance, including nitrogen, minerals, vitamins, and trace elements, by estimating intake and excretion.[100-103] Balance studies are labor intensive because of the need for meticulous methodology. A common goal of balance studies is to define parenteral and enteral nutrient requirements based on accretion and retention of administered compounds. Such studies have been reported for nitrogen,[98] fat,[102] calcium,[102-104] magnesium,[105] zinc, and copper,[106] among others. The techniques employed in these studies are not practical for routine clinical evaluations. Simplified balance studies have been performed with the goal of modifying a patient's nutritional regimen. Most often, these types of studies are used to give an estimate of energy and nitrogen balance, or to document excessive losses of specific nutrients in stools, urine, or other body fluids.

The single greatest limitation to any nutrient balance study is the accuracy with which specimens are collected.[107] This limitation is greater when applying balance techniques to young infants because the loss of collected specimens, especially urine, is a frequent occurrence. Fomon and Owen[108] have emphasized that a significant overestimation in nitrogen retention can result from a small error either in the measurement of dietary intake or in the volume of urine collected. Another limitation of this method is that, although information can be obtained about net nutrient absorption and retention, no conclusions can be drawn about how the retained nutrient is used.

Balance studies imply measuring the differences between the enteral-parenteral intake and the excretion of nutrients. The nutrients can be excreted whole or in the form of metabolites in urine, feces, sweat, or exhaled gases. Skin losses, particularly in extremely premature infants, can be large. Urine collections can be performed with relatively simple equipment such as urine bags and diapers, but this approach is fraught with problems because of specimen losses. Bag urine collections from female infants are particularly problematic, especially if the balance study lasts longer than 24 hours.[109-110] The use of metabolic beds ensures accuracy in the quantitation of urine and stool collected during balance studies.[107]

Several factors must be considered when balance studies are being interpreted for clinical or experimental purposes. Assuming adequate collection technique, the next issue is whether the data are representative of the infant's nutritional status. Typically, the shorter the collection period, the greater is the chance that the data are not representative. Six-hour urine collections for nitrogen balance have been criticized on this basis. Furthermore, it is important to know the expected length of time that the body will retain a nutrient. If the excretion of a particular nutrient that was administered enterally is to be measured in the stool, one should mark the feedings with a nonabsorbable dye, such as carmine red, to increase the accuracy of the collection period.[107] Balance studies of enterally fed nutrients generally require 72- to 96-hour collections because of the slow intestinal transit time of the neonate. On the other hand, the balance of exclusively parenterally administered nutrients, particularly in patients who are not stooling, can be done over shorter periods of time and extrapolated to a "daily" nutritional requirement. This is frequently done when assessing sodium, potassium, and nitrogen balances in critically ill neonates.

Nitrogen balance can be used to determine protein requirements in neonates by determining the difference between nitrogen intake and excretion (urinary and fecal nitrogenous compounds). It is important to measure the total urinary nitrogen, as opposed to the more commonly used, but incomplete, urea urinary nitrogen, when recording urinary nitrogen losses. The estimation of protein requirements from balance studies is predicated on the assumption that the dietary requirement is satisfied once maximal nitrogen retention is attained. Protein requirements in neonates based on nitrogen balance studies range from 1.6 to 4.2 g/kg/day, depending on the type of protein received by the infant, the infant's clinical status, and the infant's gestational age.[94,111]

Daily energy requirements are not typically assessed by classic balance studies; rather, they are estimated by energy utilization techniques. These include direct and indirect calorimetry. Indirect calorimetry using an open circuit metabolic gas analyzer has been extensively validated in the neonatal literature. These studies can be done in patients who require mechanical ventilation if there is no air leak around the endotracheal tube, or in patients who are in an oxygen tent. Measurements are made of oxygen that is entrained and then removed from the system, with a subsequent calculation of the rate of oxygen consumed by the patient per unit of time. This oxygen consumption rate can then be converted to resting energy expenditure (REE) by using the Weir equation.[112] The REE value approaches, but is not equal to, the basal metabolic rate. Measurements of REE can be used to identify infants with increased energy needs (such as those with bronchopulmonary dysplasia or congestive heart failure) and to then prescribe adequate amounts of energy to meet these infants' basal requirements. It is important to perform the study at various points in a 24-hour period, especially if infants are being enterally fed. This ensures that the thermic effect of feeding and other energy-consuming activities is included in the overall REE value. Infants must be studied in the resting state because the variance of data generated when they are active renders the values uninterpretable. Typically, less than 5% to 10% variation during the study is the expected norm. Finally, it must be realized that the total energy intake must exceed the REE value by approximately 50 kcal/kg to meet basal energy requirements and to maintain a weight gain of approximately 10 to 15 g/kg/day.

Direct calorimetry can also be performed in neonates. The infant is placed in a chamber and the amount of heat generated is measured. This lost energy is directly related to oxygen consumption. The routine use of this technique in the nursery

is precluded by the need for specialized equipment required for the measurement. Longer-term assessment of energy needs can be estimated by using doubly labeled water, a technique that is discussed in the section on stable isotopes.

SPECIAL STUDIES

Stable Isotopes

Stable isotopes are naturally occurring atoms that contain one or more neutrons in their nuclei, which makes them heavier than their parent species (i.e., ^{13}C for ^{12}C [carbon]; ^{15}N for ^{14}N [nitrogen]; and ^{2}H for ^{1}H [hydrogen]). Stable isotopes are suitable for clinical studies because they naturally occur in a predictable ratio to one another, which allows for their quantification in body fluids by measurement of their isotopic ratios using mass spectrometry. The use of stable isotopes in humans is considered safe because they do not decay and, therefore, do not emit ionizing radiation. In general, the stable isotope methodology for clinical studies includes the administration of a known amount of an isotope-labeled substrate, followed by the quantification of the isotope present in body fluids, such as blood or urine, to determine the metabolic fate of the labeled substrate.

Several aspects of glucose metabolism in neonates have been studied by using stable isotopes. For instance, continuous administration of a known amount of ^{13}C glucose and the subsequent measurement of the isotopic ratio of ^{13}C glucose in blood, at steady state, allow for the estimation of the rates of endogenous glucose production. Furthermore, the concomitant measurement of the ^{13}C isotopic ratio in expired carbon dioxide (CO_2) allows for the determination of the rates of glucose oxidation. Studies by Bier[113] and Kalhan[114] and their co-workers demonstrated that the rates of glucose production in neonates vary from 4 to 6 mg/kg/minute. Studies by Denne and Kalhan[115] estimated that approximately 53% of the glucose produced by the neonate is oxidized. Other studies[116,117] have shown that the endogenous production of glucose can be suppressed by the exogenous infusion of dextrose at rates exceeding 8 mg/kg/minute.

The use of stable isotopes in the form of ^{15}N amino acids provides a method to measure the absolute rates of protein synthesis and degradation. Such studies are based on the assumption that there is a single metabolic pool of nitrogen into which nitrogen enters from either diet or protein catabolism and exits by either protein synthesis or excretion in the form of ammonia or urea. Once the ^{15}N amino acid is administered and a steady state is attained, the flux of nitrogen entering and leaving the pool is equal, thus allowing estimation of the rates of protein synthesis and degradation.^{15}N-glycine has been safely administered intravenously and intragastrically to newborn infants with a variety of problems.[118] Stable isotope technology has permitted determination of fractional catabolic and synthetic rates for a large number of proteins[119] and can be used to determine which amino acids are essential for the premature neonate.[120]

Doubly labeled water has been used for the determination of rates of CO_2 production and oxygen (O_2) consumption, and values were found to be comparable to those obtained using indirect calorimetry.[121-123] The doubly labeled water technique has been validated for nutritional studies in neonates.[119] This method involves the administration of both $^{2}H_2O$ and $H_2{}^{18}O$ and the subsequent measurement of the enrichment of these isotopes in blood, urine, or saliva. This method is based on the principle that the disappearance of $H_2{}^{18}O$ from body fluids reflects the elimination of CO_2 and H_2O, whereas the disappearance of $^{2}H_2O$ reflects the elimination of H_2O only. The rate of CO_2 production and, therefore, its elimination are represented by the difference between the turnover of H_2O and that of CO_2. A major concern about the use of doubly labeled water in neonates is that the body composition changes rapidly after birth, and this methodology requires body water volume to remain constant throughout the study period.

Bone Mineralization Measurements

Decreased bone mineralization (osteopenia) has often been reported in sick premature infants.[124-127] Most premature babies with osteopenia are initially asymptomatic and may remain so for several weeks until the occurrence of pathologic fractures or overt rickets. Therefore, the early recognition of osteopenia is of clinical importance for the nutritional assessment of sick premature infants.

Vitamin deficiency has been clearly identified as a potential cause of osteopenia and rickets in premature infants.[128] However, current practices of routinely supplementing vitamin D to parenteral nutrition solutions and to enteral feedings have eliminated vitamin D deficiency as a common etiologic factor. Studies indicate that mineral deficiency is the major cause of osteopenia in premature infants being treated in contemporary neonatal intensive care units. Factors contributing to this mineral deficiency include (1) inability to provide adequate amounts of calcium and phosphorus in parenteral nutrition solutions,[129] and (2) increased renal losses of calcium due to the chronic use of diuretics, such as furosemide.[130]

Assessment of bone mineralization can be performed noninvasively by densitometry with the use of single- or dual-photon absorptiometry techniques.[131-137] The standard values for bone mineral content in premature and in full-term infants have been developed by several investigators. Their results are summarized in Table 32-7. There are several factors that are known to affect the rates of bone mineralization in neonates. At birth bone mineralization can be adversely affected by prematurity and postnatally by a variety of conditions, including the type of feeding; the type of dietary fat; the intakes of vitamin D, calcium, and phosphorus; the infant's body size; and the degree of physical activity.

Calcium-Regulating Hormones

CALCIUM

Calcium accounts for 1% to 2% of adult human body weight.[1] More than 99% of total-body calcium is found in teeth and bones in hydroxyapatite form;and the remaining fraction is in intracellular fluids and soft tissues. Close to 1% of the calcium present in the skeleton serves as a reservoir and is freely transferable with the extracellular fluid. Although this is a small percentage, it is approximately equal to the total content of calcium in the extracellular fluid and soft tissues.

The extracellular concentration of calcium ions (Ca^{2+}) is approximately 10^{-3} M, whereas the concentration of Ca^{2+} in the cytosol is approximately 10^{-6} M. In the blood, Ca^{2+} exists in three forms: 40% is present as a nondiffusible complex with protein; 5% is a diffusible but undissociated complex with citrate, bicarbonate, and phosphate; and 55% is present as free ionized calcium. The total normal concentration is between 2.25 and 2.75 mM. The nondiffusible complex is bound largely to the carboxyl groups in albumin, and this binding is highly pH-dependent. Acute acidosis decreases binding and increases free ionized calcium, and acute alkalosis increases binding with a decrease in free ionized calcium.

Alteration in extracellular calcium concentration must be sensed to allow rectification by the homeostatic system. The recent cloning of a Ca^{2+}-sensing, G protein–coupled receptor from bovine and human parathyroid, and from rat kidney and brain, has confirmed that Ca^{2+} can function as a conventional first messenger. The calcium-sensing receptor (CaR) is a membrane-bound G protein–coupled receptor present in parathyroid and kidney cells that monitors the level of extracellular calcium and transduces signals involved in serum calcium regulation. Like other family members, it contains seven hydrophobic helices that anchor it in the plasma membrane. The large extracellular domain (spanning approximately 600 amino acids) is known to be critical to interactions with extracellular calcium. The receptor also has a rather large cytosolic tail (approximately 200 amino acids long) (Figure 33-1) Activation of the calcium sensor has two major signal-transducing effects: (1) activation of phospholipase C, which leads to generation of the second messengers diacylglycerol and inositol trisphosphate, and (2) inhibition of adenylate cyclase, which suppresses intracellular concentration of cyclic adenine monophosphate (cAMP). The sensor also can activate the mitogen-activated protein kinase pathway, suggesting an ability to influence nuclear function. The calcium sensor is expressed in a broad range of cells, including parathyroid cells and C cells (parafollicular cells) in the thyroid gland. Functional studies and investigation of animals with mutations in the calcium sensor gene have confirmed that the calcium sensor directly affects secretion of parathyroid hormone (PTH) and calcitonin.[2]

The calcium sensor also is expressed in several cell types in the kidney, osteoblasts, a variety of hematopoietic cells in bone marrow, and the gastrointestinal mucosa. A surprising finding is that it also is present in the squamous epithelial cells of the esophagus. Such a broad distribution of expression supports the concept that calcium, acting as a hormone, has direct effects on the function of many cell types. Elucidation of the role of the calcium sensor in calcium homeostasis has benefited greatly from the study of mutations in the human gene encoding this receptor:

Inactivating mutations: A large number of different mutations in the calcium sensor gene have been identified in patients affected by a type of calcium resistance known as familial hypocalciuric hypercalcemia. The different mutations result in a spectrum of calcium sensor dysfunctions, ranging from total inactivation to a moderate decrease in affinity of the receptor for calcium. A prominent clinical consequence of such mutations is an abnormal set point or sensitivity of the parathyroid gland to blood calcium concentration, resulting in hypercalcemia. Abnormalities in renal excretion of calcium also are observed, resulting in hypocalciuria.

Activating mutations: Certain types of mutations lead to a calcium sensor with an elevated sensitivity to calcium. The clinical consequence of such mutations is familial hypercalciuric hypocalcemia—basically the opposite of what is seen with inactivating mutations in the sensor gene. High blood calcium affects the normal calcium sensor to suppress PTH secretion. If the calcium sensor is constitutively more active, then a type of hypoparathyroidism results.

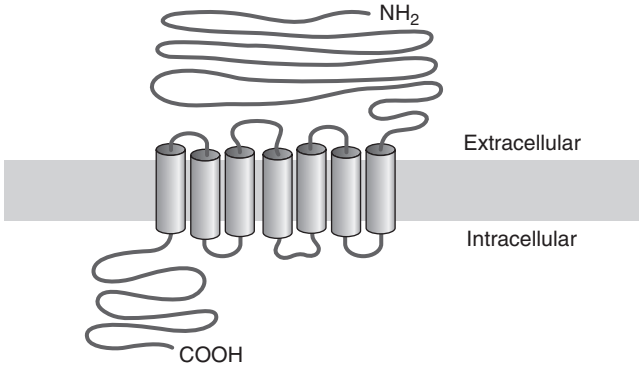

Figure 33-1 Calcium-sensing receptor (CaR). The CaR is a G protein–coupled receptor that contains seven plasma membrane anchoring hydrophobic helices. The large extracellular domain is known to be critical to interactions with extracellular calcium. *NH_2,* Amino terminus; *COOH,* carboxyl terminus. *(Reprinted with permission from Brown EM: Physiology and pathophysiology of the extracellular calcium-sensing receptor,* Am J Med *106:238, 1999.)*

Identification of the calcium-sensing receptor (CaR), expressed in the plasma membrane of parathyroid and kidney cells in particular, along with some aspects of CaR function, has been a major advance in elucidating mechanisms in control of extracellular calcium homeostasis.[3,4]

Cellular Calcium Metabolism

The control of cellular calcium homeostasis is multifaceted (Figure 33-2). The following discussion highlights some of the most important roles of the calcium ion in cellular physiology.

Extracellular fluids contain approximately 10^{-3} M of Ca^{2+}, whereas in the cytoplasm, the concentration of ionized calcium is approximately 10^{-6} M, or $\frac{1}{1000}$ that present in the extracellular fluids. The mitochondria and microsomes contain 90% to 99% of the intracellular calcium. The low calcium concentration in the cytosol is maintained by three pump transport systems: an external system, located in the plasma membrane, and two internal systems, located in the microsomal membrane and the inner mitochondrial membrane, respectively. Each pump acts like a Ca^{2+} outlet from the cytosol and requires energy to operate. Calcium ion is the most important factor linking excitation and contraction in all forms of skeletal and cardiac muscle.[5] Depolarization of the plasma membrane is accompanied by the entry of a small amount of extracellular calcium into the cell. The rise in cytosolic calcium engenders interaction with troponin, a specific calcium-binding protein, leading to a conformational change and the actin-myosin interaction that constitutes muscle contraction. In a number of cells, calcium serves as a second messenger, mediating the effects of membrane signals on the release of secretory products (e.g., neurotransmitters, amylase, insulin, aldosterone).[5] The calcium messenger system involves two pathways: (1) a calmodulin pathway and (2) a C-kinase pathway. It is now recognized that the calcium messenger system and the cAMP messenger system are related and integrated in such a way that the net cellular response to a given stimulus is determined by a complex interplay between these two systems.[5]

Many important aspects of life are regulated by the free cytosolic Ca^{2+} concentration. The regulation of cytosolic Ca^{2+} homeostasis is essential for all cells, particularly vascular smooth muscle cells. The extracellular calcium concentration, which itself is the first informative hormone-like messenger in this system, plays an important role. Expression of the calcium-sensing receptor protein, which belongs to the C subfamily of seven transmembrane-spanning G protein–coupled receptors, in tissues with functions not linked to systemic calcium homeostasis, indicates that extracellular calcium operates as a first messenger to regulate diverse cellular functions.[2,6] The biology of the low-affinity, G protein–coupled CaR and the effects of its activation in various tissues play a significant role in the regulation of PTH secretion and

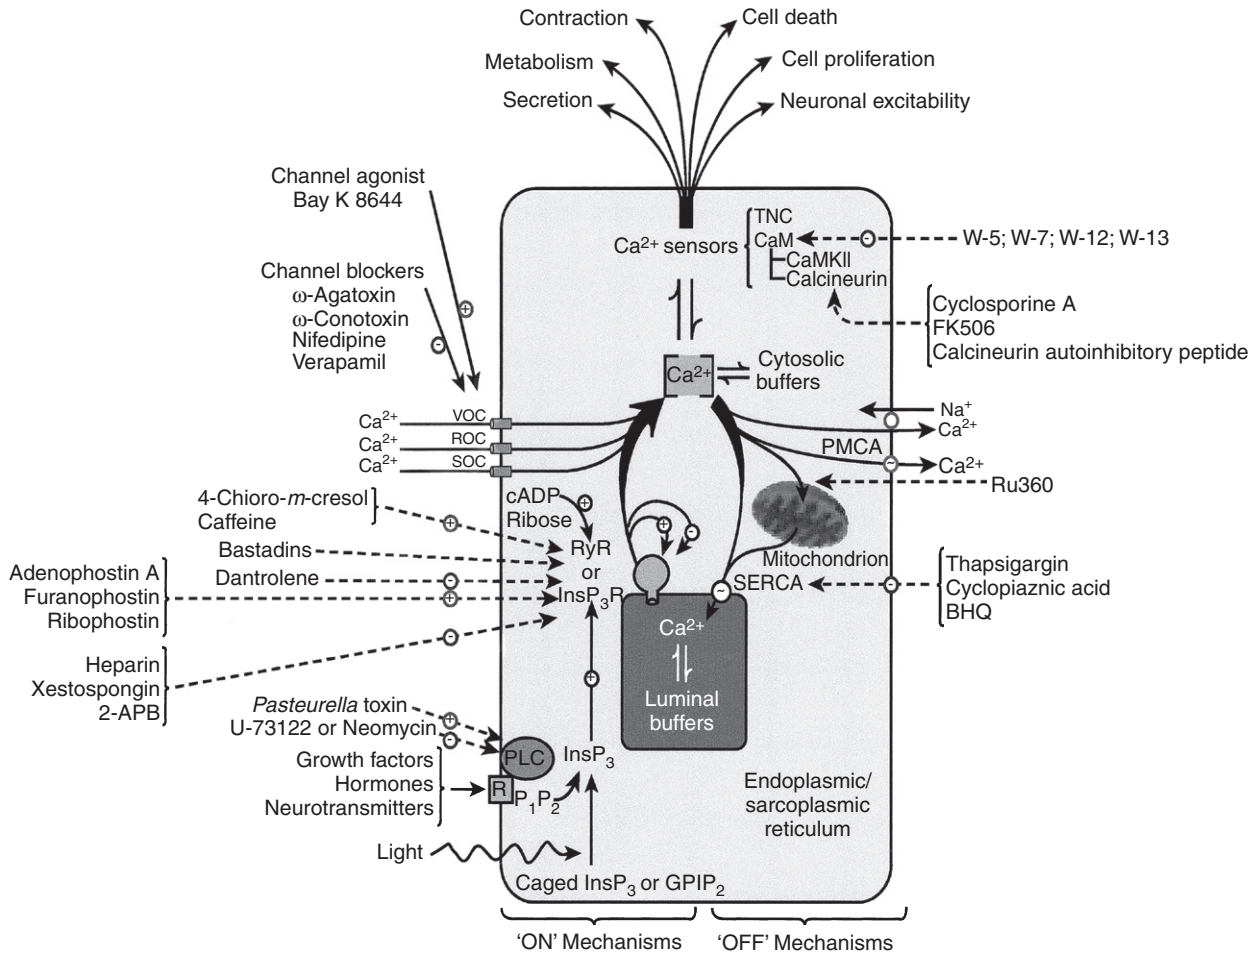

Figure 33-2 ON and OFF mechanisms for modulation of intracellular calcium. Many cellular processes are regulated by the second messenger Ca^{2+}, which is derived from two separate sources. The ON mechanisms depend on Ca^{2+} entry through channels in the plasma membrane or Ca^{2+} release through ryanodine receptors (RYRs) or inositol triphosphate receptors ($InsP_3Rs$). The OFF mechanisms remove Ca^{2+} from the cytoplasm using pumps. *BHQ,* 1,4-Benzhydroquinone; *cADP,* cyclic adenosine diphosphate. *(Courtesy Calbiochem, 2001.)*

urinary calcium excretion by small changes in extracellular Ca^{2+}. CaR also affects the renal handling of sodium, magnesium, and water.[7-9]

Calcium Ion Balance and Mechanism for Systemic Mineral Homeostasis

The total extracellular amount of calcium in an adult is approximately 900 mg. This amount is in dynamic equilibrium with calcium entering and exiting by way of the intestine, bone, and renal tubules. In zero balance, bone resorption and bone formation are equivalent, and the net quantity of calcium absorbed by the intestine (approximately 175 mg/day in an adult) is excreted into the urine. Under normal conditions, net calcium absorption provides a surplus of calcium that exceeds systemic requirements. Normal adults lose 1% of their skeleton yearly after the age of 20 years; this is the equivalent of a calcium loss of approximately 25 mg/day.

The ionized fraction of calcium is the physiologically important fraction of calcium. It is regulated by fluxes occurring at the levels of bone, kidney, and intestine; these fluxes are controlled by calciotropic hormones, which in turn are controlled by the calcium-sensing receptor protein.[6] The human body is equipped with an efficient protection system against hypocalcemia. Any modification of the extracellular calcium concentration triggers a series of integrated hormonal homeostatic reactions that incorporate PTH, 1,25-dihydroxycholecalciferol ($1,25\text{-}[OH]_2D_3$), and calcitonin.[10]

PARATHYROID HORMONE

PTH is synthesized and secreted by the chief cells of each of the four parathyroid glands. Its primary role is the maintenance of the normal concentrations of circulating calcium and inorganic phosphate, but many other tissues that are not involved in Ca^{2+} regulation also express PTH receptors.[11] PTH is a single-chain 84–amino acid polypeptide with a molecular weight of 9500. The structures of human, bovine, and porcine PTH are shown in Figure 33-3.

The PTH molecule initially is synthesized as a 115–amino acid precursor polypeptide, pre-proparathormone.[12] In the endoplasmic reticulum,[13] the amino-terminal (N-terminal) 25–amino acid sequence is proteolytically cleaved to form a 90–amino acid polypeptide proparathormone, and in the Golgi complex, proparathormone is successfully cleaved to yield the final hormonal product, the 84–amino acid PTH. The most N-terminal portion is required for the classic actions of the hormone on mineral ion homeostasis, mediated by type 1 PTH receptor (P1R) activation.[12,14-17] Proteolysis of the 84–amino acid PTH results in two or more fragments: PTH(37-84) and a large N-terminal fragment PTH(1-36).[18,19] PTH has a half-life of approximately 4 minutes and is metabolized mainly in the liver by Kupffer cells into a biologically inactive carboxyl-terminal (C-terminal) fragment and a biologically active N-terminal fragment.[20] PTH is synthesized and secreted continuously at normal plasma calcium concentrations in a pulsatile fashion,[20] with peak plasma levels occurring in the early morning hours.[21,22]

Human parathyroid glands are functionally active as early as 12 weeks of gestation.[23] PTH does not appear to cross the placenta in either direction. Maternal parathyroid dysfunction, however, can adversely affect fetal parathyroid function through variations in calcium concentration. Maternal hyperparathyroidism results in maternal hypercalcemia, which leads to fetal hypercalcemia and suppression of fetal and neonatal parathyroids. Conversely, untreated maternal hypoparathyroidism leads to maternal hypocalcemia, fetal hypocalcemia, and secondary fetal and neonatal hyperparathyroidism. Under normal circumstances, serum PTH levels measured by radioimmunoassay are lower in the fetus than in the mother, owing to the relative hypercalcemia that exists during fetal life.[24] After birth, with the abrupt termination of maternal calcium supply, the serum calcium concentration decreases, and serum PTH increases correspondingly. Both term and preterm infants show a PTH response to a falling serum calcium concentration.[25] Infants of diabetic mothers (IDMs), however, demonstrate impaired PTH production during the first days of life.[26] Infants with birth asphyxia also may exhibit a decreased PTH response to hypocalcemia.[27]

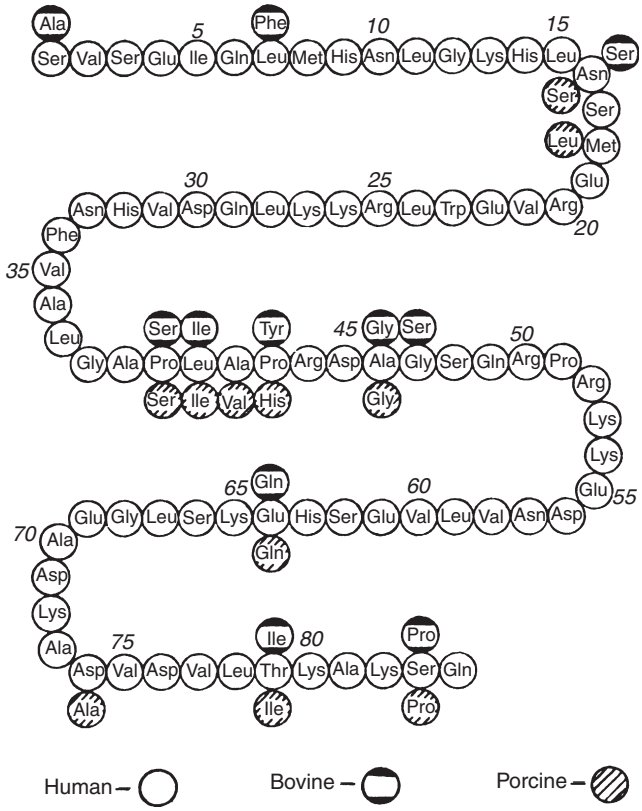

Figure 33-3 The molecular structure of parathyroid hormone. The human, bovine, and porcine sequences are illustrated. The fully active portion comprises amino acids 1 to 34. Regions 28 to 34 and 34 to 48 are produced by enzymatic cleavage. Positions 48 to 84 are the biologically inactive C-terminal region. *(Reprinted with permission from Keutman HT, Sauer MM, Hendy GN, et al: The complete amino acid sequence of human parathyroid hormone,* Biochemistry *17:5723, 1978. Copyright 1978, American Chemical Society.)*

Secretion

The extracellular fluid calcium concentration sensed by the CaR is the main determinant of PTH secretion.[28] PTH is secreted in response to small declines in ionized calcium concentration in the extracellular fluid, according to a tight feedback control mechanism. Decreases in ionized calcium of as little as 0.4 mmol/L are transduced by the CaR and detected in the plasma membrane of the parathyroid gland to stimulate PTH secretion.[29-31] Extracellular calcium has been shown to regulate the vitamin D receptor expression by parathyroid cells independently of calcitriol ($1,25\text{-}[OH]_2D_3$); by this mechanism, hypocalcemia may prevent the feedback effect of calcitriol on the parathyroids.[32]

Catecholamines,[33] aluminum,[34] histamine,[35,36] and hormones, including active vitamin D metabolites,[37] glucagon,[38] cortisol,[39] and calcitonin,[40] also have been shown to influence PTH

secretions. Acute decreases in magnesium stimulate PTH secretion[41,42]; however, chronic magnesium deficiency paradoxically decreases PTH secretion, probably by altering the calcium-sensitive magnesium-dependent adenylate cyclase involved in PTH secretion.[43] PTH secretion dramatically increases when Ca^{2+} levels are decreased to approximately 1 mM; however, further lowering of the calcium concentration does not elicit an additional increase in PTH secretion.

Metabolism

Intact PTH is cleared rapidly from the circulation by hepatic and renal tissues, with a half-life of less than 4 minutes.[19,44-46] The more efficient hepatic clearance involves three cell types: macrophages, Kupffer cells, and hepatocytes.[47,48] Kupffer cell clearance is high and does not discriminate between active and inactive PTH, whereas uptake by hepatocytes specifically removes active hormone. Renal clearance mechanisms are complex. A small amount of biologically active hormone is removed by the basal-lateral surface of tubule cells. This mechanism may be receptor-mediated. Both intact and C-terminal fragments are removed by glomerular filtration, however.[49] C-terminal fragments are more abundant than intact PTH and are released into the circulation where they have a half-life several times longer than intact PTH.[50] C-terminal fragments may account for up to 70% to 95% of the circulating immunoreactive PTH.[51] Radioimmunoassays specifically measuring the intact PTH molecule are believed to reflect PTH secretion more accurately.

Mechanism of Action

PTH regulates calcium homeostasis and phosphate metabolism by a complex interaction affecting both bone turnover and renal excretion of calcium and phosphate. In addition, PTH increases the synthesis of 1,25-$(OH)_2D_3$, which promotes intestinal calcium absorption. PTH administration leads to a release of calcium from the surface of bone.[52] Chronic administration of PTH leads to an increase in the number and activity of osteoclasts[53]; intermittent administration, however, results in increased deposition of trabecular bone.[54] PTH increases the serum calcium concentration directly, by increasing bone resorption and by increasing renal calcium reabsorption, and indirectly, by increasing renal synthesis of 1,25-$(OH)_2D_3$ through activation of 25-(OH) D_3-1-hydroxylase in the proximal tubular cell. Administration of PTH also causes a release of phosphate from bone and increased phosphaturia by inhibiting reabsorption of phosphate in the proximal (and in part distal) tubules. Although serum phosphorus may increase as a consequence of PTH-induced resorption of bone, PTH lowers the serum phosphorus concentration through its phosphaturic action, thereby minimizing the possible adverse effect of hyperphosphatemia on calcium homeostasis.[55] The direct result of all of these actions is an increase in the concentration of blood calcium and a decrease in the concentration of blood phosphate.

Cellular Actions

Two PTH receptor subtypes, type 1 (PTH1R) and type 2 (PTH2R), have been identified.[56] Type 1 PTH receptor binds both PTH and N-terminal peptides of parathyroid hormone–related protein (PTHrP). This molecule is a G protein–coupled receptor with seven transmembrane segments. The extracellular domain has six cysteine residues. Binding of ligand to this receptor activates both adenyl cyclase and phospholipase C systems, generating protein kinase A and protein kinase C signals, respectively. The cAMP–protein kinase A pathway is predominant. As might be expected from the actions of PTH, the messenger RNA (mRNA) encoding the type 1 receptor is most abundant in bone (especially in chondrocytes at growth plates) and kidney. The mRNA also is expressed at lower levels in many other tissues, probably reflecting its use as a receptor for PTHrP. The type 2 PTH receptor binds PTH but shows very low affinity for PTHrP. This molecule is expressed in only a few tissues, and its structure and physiologic significance are poorly characterized. Like the type 1 receptor, it is coupled to adenyl cyclase, and ligand binding induces a rise in intracellular concentration of cAMP. Their complementary DNA (cDNA) sequences share 70% similarity with those of members of a subfamily of G protein–coupled receptors to which the receptors for calcitonin, secretin, and glucagon also belong.[57,58] Expressions of recombinant receptors have established that type 1 and type 2 PTH receptors each alone are capable of stimulating increases in Ca^{2+} and intracellular cAMP.[59-62] Although PTH acts on bone to increase osteoclast number and activity, osteoclasts surprisingly contain no PTH receptors, and PTH has no effect on isolated osteoclasts.[63] PTH receptors are found on bone-forming osteoblasts, which secrete factors that stimulate osteoclast activity. In the kidney, PTH blocks the sodium-dependent phosphate cotransport[64] in proximal and distal tubule cells. In the distal tubule cell, however, PTH also stimulates calcium absorption against an electrochemical gradient.

PTH does not act directly in the cytoplasm of target cells; instead, PTH binds to specific receptors on the surfaces of those cells. This binding stimulates the release of cytoplasmic "second messengers" that mediate the distal effects of PTH. Binding of PTH to its receptors requires the first 34 amino acids of PTH, and the function of the carboxyl portion is unclear. PTHrP, produced by certain tumors, resembles PTH in its first 13 amino acids.[65] Peptide fragments of this protein bind to PTH receptors in bone and kidney[66]; this proclivity explains many activities of the protein and the similarities between hyperparathyroidism and the humoral hypercalcemia of malignancy.

The major mediator of PTH action is cAMP. Exposure of bone or kidney cells to PTH increases intracellular cAMP, and administration of cAMP analogues mimics many of the effects of PTH. Binding of PTH to its receptor on the cell stimulates the release of guanosine diphosphate (GDP) from the G_s protein, and enables the binding of intracellular guanosine triphosphate (GTP) to G_s. GTP G_s then stimulates membrane-bound adenylate cyclase. The cAMP produced by adenylate cyclase binds to the regulatory subunit of cAMP-dependent protein kinase A. This binding causes the regulatory subunit to dissociate from the catalytic subunit. The free catalytic subunit then phosphorylates specific serines and threonines in target proteins.[67] PTH also stimulates phosphatidylinositol turnover in culture cells,[68] causes a rapid rise of free cytosolic calcium,[69] and promotes a shift of protein kinase C to the cell membrane.[70] These effects are different from the actions of cAMP, suggesting that multiple second messengers may mediate some actions of PTH. A review of the molecular structure of PTH and its interaction with various receptors, as well as recent technical advances in PTH assays, is available.[71]

PARATHYROID HORMONE–RELATED PROTEIN

PTHrP comprises a family of protein hormones produced by most if not all tissues in the body. PTH and PTHrP bind to the same receptor, but PTHrP also binds to several other receptors. PTHrP was discovered as a protein secreted by certain tumors that caused hypercalcemia in affected patients. It was soon shown that the uncontrolled secretion of PTHrP by many tumor cells induces hypercalcemia by stimulating resorption of calcium from bone and suppressing calcium loss in urine, similar to what is seen with hyperparathyroidism. It quickly became apparent, however, that PTHrP had many activities not seen with PTH. PTHrP is an important paracrine and autocrine regulator of proliferation, apoptosis, and differentiation of several normal cell types.[72,73] Many tissues produce PTHrP, which plays a number

of physiologic roles, particularly in the mother during pregnancy and in the developing fetus.[73,74] PTHrP has been isolated from malignant tumors[75,76] and has been identified as being primarily responsible for "humoral" hypercalcemia of malignancy.[77] PTHrP expression in normal and tumor cells may be regulated by glucocorticoids,[78] epidermal growth factor,[79] tumor necrosis factor-α,[80] and vitamin D.[81]

Hormone Structure

PTHrP contains 141 amino acids; 8 of the first 13 are identical to those in PTH.[82,83] A single gene that is highly conserved among species encodes PTHrP. It should probably be described as a polyhormone, because a family of peptide hormones is generated by alternative splicing of the primary transcript and through use of alternative posttranslational cleavage sites. To make matters even more complex, some cells appear to use alternative translational initiation codons to produce forms of the protein that are targeted either for secretion or nuclear localization.

The diverse activities of PTHrP result not only from processing of the precursor into multiple hormones but also from use of multiple receptors. It is clear that N-terminal peptides of PTHrP share a receptor with PTH, but they also bind to a type of receptor in some tissues that does not bind PTH. In addition to the secreted forms of this hormone, considerable evidence indicates that a form of PTHrP is generated in some cells that is not secreted and, by means of nuclear targeting sequences, is translocated to the nucleus, where it affects nuclear function. The consequences of this "intracrine" mode of action are not yet well characterized, but this hormone may modulate such important activities as programmed cell death.

PTHrP is secreted from a large and diverse set of cells, during both fetal and postnatal life. Among tissues known to secrete this hormone are several types of epithelium, mesenchyme, vascular smooth muscle, and central nervous system tissue. Although PTHrP is found in serum, a major portion of its activity appears to reflect paracrine signaling. PTHrP can interact with PTH receptors in classic PTH target tissues such as bone and kidney.[84,85] Synthetic peptides that include the N-terminal region PTHrP(1-34) mimic all of the classic activities of PTH on bone and kidney, as well as nonclassic activities such as smooth muscle relaxation and vasodilation.[86]

Physiologic Effects

One thing to recognize about PTHrP is that its name is inadequate to describe its activities. As with PTH, some of the effects of PTHrP result from its effects on transepithelial fluxes of calcium, but many of its actions have nothing to do with calcium homeostasis. Most prominently, PTHrP peptides exert significant control over the proliferation, differentiation, and death of many cell types. They also play a major role in development of several tissues and organs.[87]

Much of the current understanding of the biologic effects of PTHrP comes from experiments with genetically altered mice. Mice with targeted deletions in the PTHrP gene (knockout mice), mice that overexpress PTHrP in specific tissues (transgenic mice), and crosses between knockout and transgenic mice have been critical in delineating many effects of this hormone. Humans with mutations in the PTHrP gene or the parathyroid receptor have also played a role in confirming the activity of PTHrP. Some of the physiologic effects of PTHrP collected from these studies are described next.

Cartilage and Bone Development

Mice with homozygous inactivation of the PTHrP gene die at birth, if not earlier. They manifest severe chondrodysplasia and premature epiphyseal closure, reflecting a developmental defect in proliferation and differentiation of cartilage. These and other types of studies indicate that PTHrP stimulates the proliferation of chondrocytes and suppresses their terminal differentiation. These effects of PTHrP appear to be due to interaction of the PTH-like peptide with the PTH receptor.[74]

Mammary Development and Lactation

The mammary glands of female mice with homozygous inactivation of the PTHrP gene fail to develop, except for the earliest stages. Development of the mammary gland depends upon a complex interaction between epithelial and mesenchymal cells that apparently requires PTHrP. In normal animals, mammary epithelial cells secrete large amounts of PTHrP, which suggests a role of this hormone in adapting maternal metabolism to the calcium demands of lactation. PTHrP concentration in milk is 10,000 times the normal circulating levels and 1000 times higher than average plasma concentrations in hypercalcemic cancer patients.[88] Because PTHrP production can be induced by lactation,[89] it has been suggested that this "milk protein" serves to condition the gastrointestinal absorption of calcium during breast-feeding.[88]

Placental Transfer of Calcium

The "midregion" peptide of PTHrP has been shown to control the normal maternal-to-fetal pumping of calcium across the placenta. In the absence of fetal PTHrP, this gradient is not established. PTHrP and the common PTH and PTHrP receptors have been identified in gestational tissues, including myometrium, fetal membranes, and placenta.[90-97]

Smooth Muscle Functioning

PTHrP is secreted from smooth muscle in many organs, usually in response to stretching. It acts to relax smooth muscle, serving as a vasodilating hormone. Transgenic mice that express PTHrP in vascular smooth muscle manifest hypotension. PTHrP may also have effects on contraction of muscle in the bladder, uterus, and heart. Studies also indicate that endogenous PTHrP is essential for optimal differentiation of keratinocytes.[98,99] PTHrP and its mRNA have been identified in syncytiotrophoblast and cytotrophoblast cells.[100,101] Potential autocrine, paracrine, and endocrine roles for PTHrP during pregnancy include regulation of cellular growth and differentiation,[102,103] vasodilation of the uteroplacental vasculature,[91,104] relaxation of uterine muscle,[105-107] and stimulation of placental calcium transport.[108] Because of its wide distribution, PTHrP may utilize novel (non-PTH) signal transduction systems in autocrine and paracrine fashion in controlling normal physiologic processes.[109]

Other Effects

PTHrP is highly expressed in skin. Transgenic mice that overexpress PTHrP in skin show alopecia, and treatment of mice with a PTHrP antagonist leads to increased numbers of hair follicles and a shaggy appearance. Another interesting defect in PTHrP-knockout mice is that their teeth develop normally but fail to erupt. Finally, both PTHrP and its receptors are widely expressed in the central nervous system and appear to influence neuronal survival by several mechanisms. A recent study has suggested that activation of the calcium-sensing receptor is responsible for increased synthesis and secretion of PTHrP.[110]

VITAMIN D

Vitamin D is synthesized in the skin on exposure to ultraviolet (UV) light. The initial step in the production of vitamin D_3, the conversion of 7-dehydrocholesterol (7-DHC) to previtamin D_3, requires a UV spectrum that peaks at 295 nm, with conversion dropping to zero at 315 nm.[111] This waveband, known as UVB, is at the short wavelength limit of solar radiation reaching the

earth's surface. When the sun is low in the southern sky, the incoming radiation must travel further and is subject to more scattering and absorption than when the sun is directly overhead. Because Rayleigh scattering (scattering of light waves by particles with dimensions much smaller than their wavelengths) and UV absorption at more northern latitudes are strongly wavelength-dependent, skin synthesis of previtamin D_3 is affected by latitude, season of the year, and weather conditions.

Vitamin D also is absorbed from dietary sources in the duodenum and jejunum, as either vitamin D_3 (from animal sources) or vitamin D_2 (ergocalciferol, from vegetable sources). The metabolism of vitamin D_3 does not differ appreciably from that of vitamin D_2. Regardless of its origin, vitamin D is transported to the liver, where it is converted into 25-hydroxyvitamin D, and subsequently to the kidney, where it is transformed to the final, active metabolite 1,25-$(OH)_2$ vitamin D. In the liver, 25-hydroxylation is a fairly unregulated process; 25-hydroxyvitamin D is the major circulating vitamin D metabolite and its concentration is an indicator of vitamin D status, reflecting both intake and sunshine exposure. By contrast, renal 1-hydroxylation, leading to the active metabolite, appears to be tightly regulated. The main factors increasing the synthesis of 1,25-$(OH)_2D_3$ are PTH, hypocalcemia, and hypophosphatemia. 1,25-$(OH)_2D_3$ is a steroid and binds to a receptor in target tissues, leading to synthesis of calcium-binding (calbindin-D) proteins.[112]

Three major sites of action for 1,25-$(OH)_2D_3$ are known: (1) intestine, where it increases the absorption of calcium and phosphorus; (2) bone, where it mobilizes calcium and phosphorus; and (3) kidneys, where it increases calcium reabsorption. Thus vitamin D is necessary to maintain normal calcium and phosphorus homeostasis. The most completely studied target tissue for 1,25-$(OH)_2D_3$ is the intestine, which depends on the hormone for adequate absorption of dietary calcium in adults.[113,114] In the intestinal mucosa, the steroid receptor complex induces synthesis of a specific calcium-binding protein (molecular weight, 28,000). In addition to the endocrine actions of 1,25-$(OH)_2D_3$, interaction of 1,25-$(OH)_2D_3$ with hematopoietic cells[115] and with the immune system[116] has been documented. The actions of 1,25-$(OH)_2D_3$ appear to involve changes in gene expression in target cells.[117-119]

Regulation and Metabolism

1,25-$(OH)_2D_3$ is synthesized by the kidney. In the kidney mitochondrion, 25-hydroxyvitamin D_3 (25-[OH]D_3), the major circulating form of vitamin D, is hydroxylated to either 1,25-$(OH)_2D_3$ or 24,25-$(OH)_2D_3$ by either 1α- or 24-cytochrome P-450 hydroxylating enzymes, respectively[120] (Figure 33-4). The predominant product formed depends on vitamin D and PTH status. In the vitamin D–deficient state, 1-hydroxylase activity is high and 24-hydroxylase is low; 1,25-$(OH)_2D_3$ (the product of 1-hydroxylase) represses 1-hydroxylase and induces 24-hydroxylase activity. Directly or by depleting renal cortical inorganic phosphate concentration, PTH increases 1-hydroxylase activity and decreases 24-hydroxylase activity. cAMP mediates the effect of PTH, but protein kinase C also may be involved in 25-$(OH)D_3$ metabolism.

In a vitamin D sufficiency state, 1-hydroxylase activity is low and 24-hydroxylase activity is high. Once synthesized by the kidney, 1,25-$(OH)_2D_3$ can be converted by enzymatic oxidation into different metabolites. These include 1,24,25-$(OH)_3D_3$; 1,23,25-$(OH)_3D_3$; 24-keto-1,23,25-$(OH)_3D_3$; 1,25-$(OH)_2D_3$-(23-26) lactone; and 1α-(OH)-24,25,26-tetranor-23(COOH) vitamin D_3.[121]

Molecular Mechanisms of Action

1,25-$(OH)_2D_3$ can generate biologic responses by activation of voltage-dependent Ca^{2+} channels coupled to appropriate signal transduction pathways.[120,122,123] A target cell must have three key components for its genes to be regulated by a steroid hormone: (1) a protein receptor for the hormone that contains a unique binding domain for the steroid *and* a DNA-binding domain for the receptor to locate the genes in the nucleus of the cell

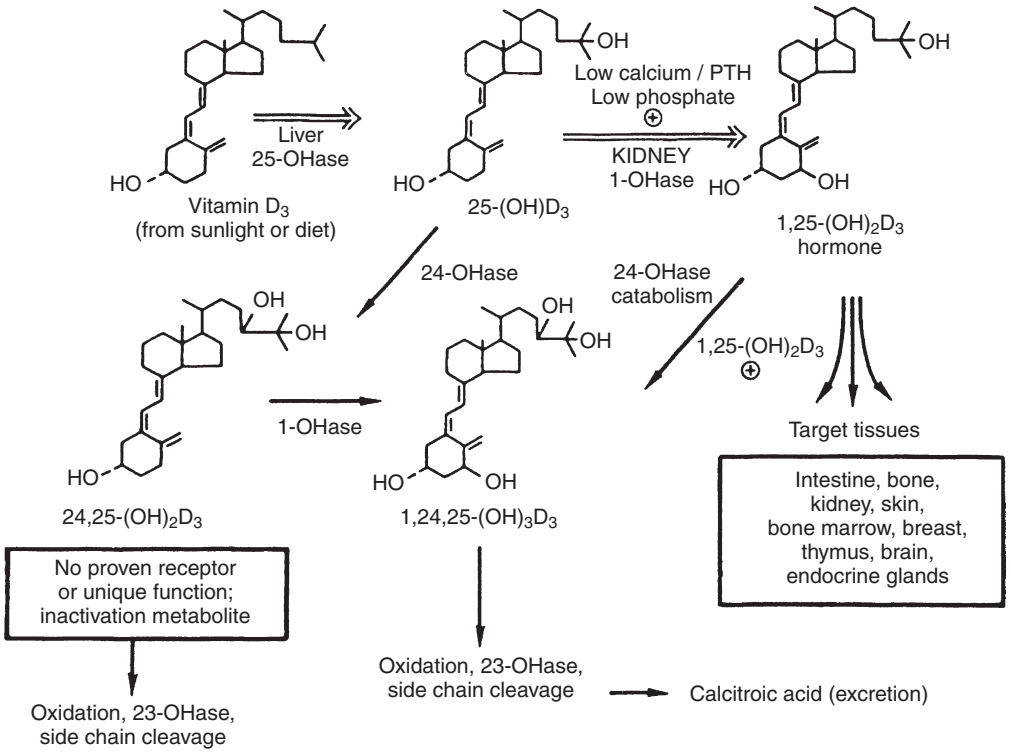

Figure 33-4 Schematic depiction of the metabolic pathways of the vitamin D endocrine system. *(From MacDonald PN, Dowd DR, Haussler MR: New insight into the structure and functions of the vitamin D receptor,* Semin Nephrol *14:101, 1994.)*

it will regulate; (2) responsive elements that consist of specific sequences of DNA nucleotides that promote an interaction between the occupied receptor and the genes to be regulated; and (3) access to the steroid hormone.

The vitamin D receptor is a member of the steroid hormone receptor superfamily.[124] The receptor is primarily a nuclear protein (51,000 daltons) that functions as a transactivating factor.[117] Although this protein is universally termed *vitamin D receptor,* in reality it binds to 1,25-$(OH)_2D_3$, the metabolite with hormonal activity, with much higher affinity than for any other vitamin D metabolite.[125] Vitamin D receptor is a DNA-binding protein, with a typical highly conserved DNA-binding domain located near the N terminus of the molecule and a hormone-binding domain at the carboxyl end (C terminus).[117,124] Transcriptional regulation occurs by way of the variable N-terminal domain, which also may be involved in regulating DNA binding. Although the precise mechanisms of protein-DNA interaction are not totally known, it is thought that after binding to 1,25-$(OH)_2D_3$, the vitamin D receptor undergoes conformational changes that increase its affinity for DNA.[118] The vitamin D receptor is widely distributed in classic and nonclassic target tissues. Tissues in which binding sites have been described include the hematopoietic, lymphatic, and reproductive systems; endocrine glands; the skin, liver, and lungs; and skeletal and smooth muscle.[120] Initial studies for the expression of the cloned vitamin D receptor seem to confirm the hypothesis that a single receptor mediates the protein actions of vitamin D metabolites in the different target cells.[120]

Biologic Actions

The classic target organs for vitamin D are bone, intestine, and kidney. The actions of 1,25-$(OH)_2D_3$ on bone cells are essential for bone formation: Hypovitaminosis D leads to rickets or osteomalacia. In hematopoietic cells, 1,25-$(OH)_2D_3$ promotes the differentiation of promonocytes into monocytes and macrophages, and finally into osteoclasts, which promote bone resorption but are devoid of receptors for 1,25-$(OH)_2D_3$.[126] If administered at high doses, however, 1,25-$(OH)_2D_3$ induces bone resorption by a receptor present on osteoblasts. The biologic effects of 1,25-$(OH)_2D_3$ on bone are indirect and transduced from the osteoblast to the osteoclast.[127] The transduction may occur through the secretion of a soluble factor by the osteoblast. 1,25-$(OH)_2D_3$ stimulates the synthesis of noncollagenic matrix proteins, such as osteocalcin,[128,129] matrix G1a protein,[130] osteopontin,[131,132] and fibronectin,[133] and increases alkaline phosphatase activity.[134] It is thought that stimulation of matrix proteins is transcriptional. The regulatory actions of 1,25-$(OH)_2D_3$ on all of these important components of bone matrix imply an important role in bone matrix formation.

1,25-$(OH)_2D_3$ stimulates the transcription of the gene encoding calbindin-D,[114,135] which is a calcium-binding protein that mediates Ca^{2+} transport through the intestinal epithelium.[136] 1,25-$(OH)_2D_3$ also induces nongenomic changes in Ca^{2+} transport in intestinal cells. These include stimulation of Ca^{2+} uptake in the intestinal epithelium,[137] increased net Ca^{2+} transport in duodenal loops,[138] and release of lysosomal enzymes.[139] 1,25-$(OH)_2D_3$ also stimulates phosphate transport[140] and induction of enterocyte growth and differentiation.[141,142] The actions of 1,25-$(OH)_2D_3$ on the kidney have not been studied as well as they have been in other target organs. 1,25-$(OH)_2D_3$ is involved in calcium and phosphate transport.[120,143] Stimulation of phosphate transport in proximal tubule brush border membranes occurs by altering plasma membrane fluidity.[144] An important action of 1,25-$(OH)_2D_3$ on the kidney is its feedback inhibition on 1α-hydroxylase activity and the associated stimulation of 24-hydroxylase, the first step in the inactivation pathway of vitamin D metabolites.[145,146]

Knowledge of the spectrum of biologic actions of 1,25-$(OH)_2D_3$ and broad distribution of vitamin D receptors has expanded current understanding of the role of the hormone as an important regulator of cell development and proliferation in many tissues, as well as in neoplasia. Further discovery of effects of 1,25-$(OH)_2D_3$ on tissues other than those regarded as classic targets is anticipated. Reviews on this subject are available in the literature.[120,147]

Biologic Concentration of Vitamin D and Its Metabolites

The normal adult range for blood 25-$(OH)D_3$ concentrations for healthy subjects is 10 to 80 ng/mL, and the range for 24,25-$(OH)_2D_3$ is 1 to 4 ng/mL. The normal circulating concentration of 1,25-$(OH)_2D_3$ is 15 to 70 pg/mL.[148] 25-$(OH)D_3$ appears to cross the placenta, whereas little transfer of 1,25-$(OH)_2D_3$ seems to take place.[149,150] Fetal vitamin D status seems to depend on maternal transfer of 25-$(OH)D_3$.[151] In term infants, serum 1,25-$(OH)_2D_3$ concentrations are low at birth but increase to a normal range by 24 hours of life, possibly reflecting the need for increased intestinal absorption of calcium and phosphorus.[149] Studies from the United Kingdom have suggested that maternal vitamin D deficiency may predispose infants to "late" neonatal (at 1 week of age) hypocalcemia. In extremely premature infants, end-organ resistance to 1,25-$(OH)_2D_3$ may exist, theoretically predisposing them to the development of hypocalcemia.[152] The vitamin D concentration is 20 to 60 IU/L in human milk, approximately 400 IU/L in regular milk (fortified) formulas, and 500 to 1200 IU/L in "preterm" formulas. A daily intake of 200 to 400 IU/day is recommended for both preterm and term infants. Breast-fed term infants with adequate sunshine exposure (30 to 120 minutes per week, with only face and hands exposed) do not appear to require supplemental vitamin D.[153]

CALCITONIN

Calcitonin is a 32–amino acid peptide with a molecular weight of 3600. It is secreted primarily by the parafollicular or C cells of the thyroid gland (Figure 33-5). Its main biologic effect is to inhibit osteoclastic bone resorption. Secretion of calcitonin varies with acute changes in serum calcium concentration: It increases when the serum calcium concentration increases and decreases when the serum calcium concentration decreases. The calcitonin receptor has been cloned and shown to be a member of the seven-transmembrane, G protein–coupled receptor family. The U.S. Food and Drug Administration (FDA) currently approves calcitonin for the treatment of Paget disease, osteoporosis, and the hypercalcemia associated with malignancies. The kidney and the liver metabolize calcitonin.

Physiologic Actions

A diverse set of effects has been attributed to calcitonin, but in many cases, these were seen in response to pharmacologic doses of the hormone. The physiologic effects of calcitonin are opposite those of PTH; however, calcitonin and PTH share similar target tissues. Calcitonin plays a role in calcium and phosphorus metabolism. Calcitonin can decrease blood calcium concentrations at least in part by effects on two well-studied target organs, bone and kidney.

Calcitonin suppresses resorption of bone by inhibiting the activity of osteoclasts, a cell type that "digests" bone matrix, through production of cAMP, and increments in cytosolic calcium in the osteoclast,[154-156] releasing calcium and phosphorus into blood. Calcitonin inhibits tubular reabsorption of these two ions, leading to increased rates of their loss in urine.

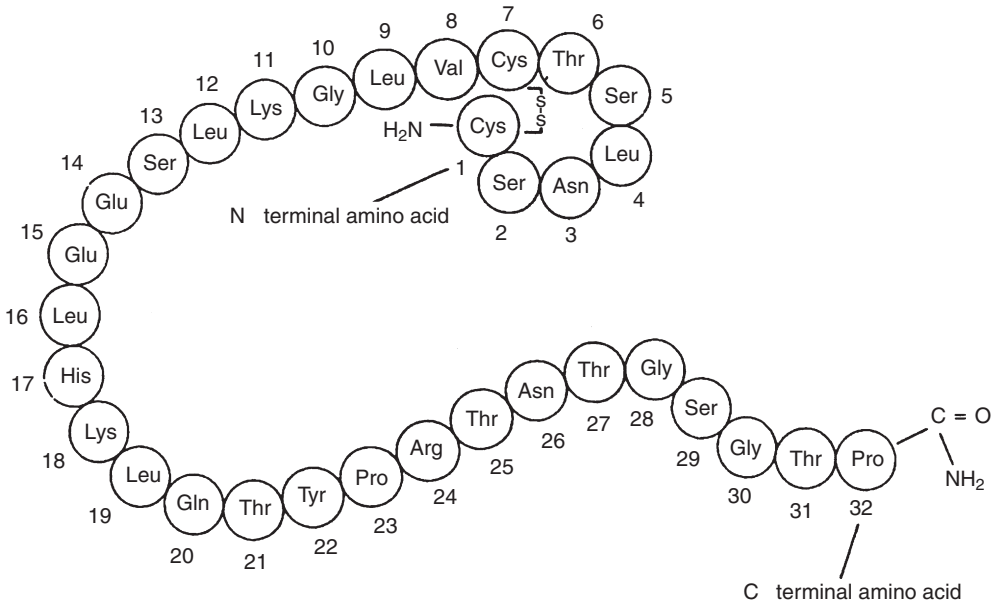

Figure 33-5 The molecular structure of calcitonin. Calcitonin, a hormone produced by the thyroid gland, is a single-chain, 32–amino acid polypeptide with a molecular weight of 3600. *(From Miacalcic Calcitonin-Sandoz:* A Profile of Sandoz's Salmon Calcitonin, *London, 1989, Meditext Ltd, p 13.)*

In the kidney, calcitonin is involved in transport of ions such as Na^+, K^+, Cl^-, Mg^{2+}, and Ca^{2+}. Calcitonin also enhances calcium excretion in tubule cells.[157] Despite the effects on calcium described earlier, it seems that calcitonin has at best a minor role in regulating blood concentrations of calcium. As evidence to support this statement, humans with chronically increased (medullary thyroid cancer) or decreased (surgical removal of the thyroid gland) levels of calcitonin in blood do not show alterations from normal in serum calcium.

In the central nervous system, calcitonin may be involved in the modulation of prolactin secretion.[158] Evidence for a physiologic role of calcitonin in the gastrointestinal tract is circumstantial. It is possible that some of the reported actions of calcitonin in the gastrointestinal tract may be secondary to cross-reaction with receptors of structurally related peptides.[159,160] From more recent studies it appears that calcitonin also may play an important role in a variety of processes ranging widely from embryonic or fetal development to sperm function and physiology.[161]

A large number of diseases are associated with abnormally increased or decreased levels of calcitonin, but pathologic effects of abnormal calcitonin secretion per se generally are not recognized. Calcitonin has several therapeutic uses. It is used to treat hypercalcemia resulting from a number of causes and has been a valuable therapy for Paget disease. Calcitonin also appears to be a valuable aid in the management of certain types of osteoporosis. A review of the literature on this subject is available.[161]

Biochemistry

Twelve species of calcitonin have been identified (including human), and common features include a 1- to 7-amino acid disulfide bridge that causes the N terminus to assume the shape of a ring, a C-terminal proline amide residue, and a glycine at residue 28. Five of the nine N-terminal residues are identical among many species.[162] The calcitonin gene encodes two distinct hormones in the initial gene transcript: a 141–amino acid precursor for calcitonin and a 128–amino acid precursor for calcitonin gene–related peptide (Figure 33-6). Calcitonin is the major processed peptide in C cells, whereas calcitonin gene–related peptide is the processed peptide in neurons.

Biosynthesis and Metabolism

Calcitonin is secreted by mitochondria of thyroid parafollicular C cells. Other tissue sources of calcitonin are the pituitary, neuroendocrine cells, and carcinomatous lesions such as medullary thyroid carcinoma and small cell lung cancer.[163,164] Calcitonin is therefore used as a tumor marker for those cancers. The serum calcium concentration is the most important regulator of calcitonin secretion.[162]

The effects of chronic hypercalcemia and chronic hypocalcemia are controversial.[165] C cells respond to hypercalcemia by increasing calcitonin secretion. If the hypercalcemia is severe and prolonged, however, the C cells exhaust their secretory reserve.[162] Calcitonin concentrations are lower in women than in men.[166,167] The mechanism responsible for this gender difference is unclear, but the effect of gonadal steroids on calcitonin secretion may play an important role. Newborn infants have high serum concentrations of this hormone, and a significant rise in blood immunoassayable circulating calcitonin (iCT) occurs between the ages of 6 and 12 years, concurrent with a fall in PTH.[168] Calcitonin may condition skeletal remodeling in the growing child by modulating the rate of bone resorption. The metabolism of calcitonin is complex and involves many organ systems. Degradation of the hormone occurs in kidney, liver, bone, and thyroid gland.[169] Inactivation is more important than excretion, and relatively small amounts of calcitonin can be detected in urine. The physiologic significance of calcitonin in calcium homeostasis is not well established.

CALCITONIN GENE–RELATED PEPTIDE

Two calcitonin gene–related peptides (α- and β-CGRP), in addition to calcitonin, form the calcitonin family of regulatory peptides.[170] β-CGRP is the product of a separate gene, but it is structurally similar to α-CGRP, differing only by three amino acids; both peptides have similar biologic properties.[171-173] α-CGRP has been identified in brain, thyroid, heart, smooth muscle, and nerve fibers.[170,174,175] Neurons containing CGRP have been identified in the heart, where it is considered an essential regulator of

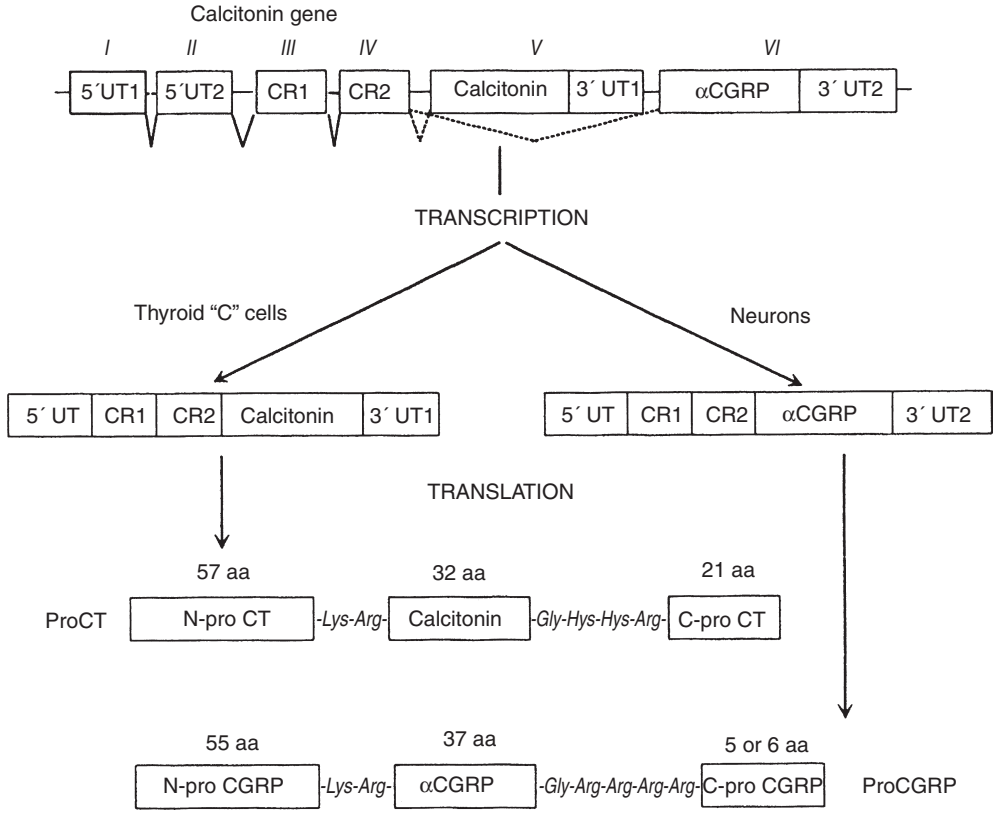

Figure 33-6 The structure of the calcitonin gene. The calcitonin (CT) gene is composed of six exons that encode the calcitonin (exon V) and the calcitonin gene–related peptide-α (α-CGPR, exon VI). *(From Civitelli R, Avioli LV: The biochemistry and function of calciotropic hormones. In Crass MF, Avioli LV [eds]:* Calcium-Regulating Hormones and Cardiovascular Function, *Boca Raton, FL, 1995, CRC Press.)*

cardiovascular function and vascular tone.[156,174,176] The calcitonin and CGRP molecules are approximately the same size, and both contain a disulfide bridge at the N terminus. These similarities may account for the ability of these hormones to bind to each other's receptor, and to produce similar in vivo biologic responses.[43,159,177]

Because very little CGRP is released into the circulation, CGRP is thought to exert its effects in a paracrine-autocrine fashion.[178] CGRP's potent vasodilatory activity is induced by its binding to two CGRP receptors: CGRP-1 and CGRP-2.[178] CGRP-1 and CGRP-2 receptors have been identified in the human fetoplacental unit[91]; however, only CGRP-1 receptors are demonstrable in the human uterine artery.[179] The mechanism of action of CGRP is unclear. It appears that CGRP interacts with receptors on smooth muscle cells that are coupled to cAMP production.[180] In rat aorta, CGRP exerts endothelium-dependent relaxant effects by releasing nitric oxide.[178] CGRP activity in human placenta, however, is independent of nitric oxide.[91]

34 Calcium, Phosphorus, and Magnesium Transport Across the Placenta

Shahid M. Husain, M. Zulficar Mughal, and Reginald C. Tsang

PLACENTAL TRANSPORT OF CALCIUM

During mammalian pregnancy, the placenta transports large amounts of calcium to allow rapid fetal skeletal mineralization. In all species that have been studied so far, the rate of maternofetal calcium transfer increases dramatically during the last third of pregnancy. In the human, two thirds of the 28 g of calcium accumulated in a healthy term fetus is transported during the third trimester.[1] Similarly, in the rat, fetal calcium content increases from 0.45 mg on day 17 of gestation to 12.3 mg at term (22 days).[2]

Active Calcium Transport

In late pregnancy, the concentration of total, ultrafilterable, and ionized calcium in fetal plasma is higher than in maternal plasma (Table 34-1); in the human, this maternofetal gradient is present as early as 20 to 26 weeks of gestation.[3,4] It is likely, therefore, that maternofetal transfer of calcium uses active *transcellular* mechanisms that overcome the concentration gradient across the placenta. As indicated by physiologic evidence, however, placental *paracellular* water-filled channels could be used by any solute, although the morphologic correlate of these channels is difficult to identify. The relative contribution of transcellular and paracellular calcium transport is unclear, but the latter mechanism may be of greater significance in the human.[5] The remainder of this discussion deals only with active transport of calcium across the placenta.

Considerable evidence has accumulated to support the concept of active maternofetal calcium transport in the placenta. Using a method in which the fetal circulation of the in situ rat placenta is artificially perfused, Štulc and Štulcová[6] noted that the maternofetal clearance of ^{45}Ca (37.4 ± 0.8 μL/minute) is considerably greater than that of inert, electrically neutral, hydrophilic molecules, such as sucrose (2.6 ± 0.3 μL/minute), which are believed to move across the placenta by passive diffusion. In earlier studies, perfusion of the fetal circulation of the in situ guinea pig placenta with plasma from an adult guinea pig[7] and the in situ ovine placenta with autologous blood[8] resulted in an increase in the ionized[8] and total[7,8] Ca^{2+} concentrations of the perfusate effluent compared with the concentration in the inflowing fluid.

Further evidence of active maternofetal placental calcium transport has been provided by numerous observations. Shaw and co-workers[9] reported a significant decrease in the unidirectional maternofetal clearance of ^{45}Ca across in situ perfused rat placenta after the addition of potassium cyanide (metabolic inhibitor) to perfusion media (Figure 34-1), or after lowering the temperature of the perfusate (Figure 34-2), findings confirming the earlier report by Štulc and Štulcová.[6] Using in vitro perfusion of a human placental lobule, Abramovich and colleagues[10] reported an increase in both ionized and total Ca^{2+} concentrations in the fetal perfusate reservoir during recycling perfusion. Finally, Štulc[5] provided evidence that the transcellular component of unidirectional maternofetal calcium flux ($^{Ca}J_{MF}$) across the isolated human placental cotyledon is saturable and sensitive to cyanide.

Thus, maternofetal transport of calcium across the placenta takes place against a concentration gradient, is temperature dependent, is inhibited by metabolic inhibitors such as cyanide, and is considerably faster than that of molecules that cross the placenta by simple diffusion. All of these findings support the conclusion that placental calcium transport involves active transfer processes.

Bidirectional Placental Calcium Transport

Studies employing radioactive isotopes of calcium as tracers have revealed that transport of calcium across the mammalian placenta is bidirectional, with marked species variation in the relative magnitudes of unidirectional maternofetal, unidirectional fetomaternal, and net calcium fluxes. In the sheep near term, placental calcium transport is highly asymmetric, with a calculated $^{Ca}J_{MF}$ of 215 mg/day/kg of fetal weight and a $^{Ca}J_{FM}$ of 12 mg/day/kg.[11] A similar situation probably prevails in the rat because the value for net calcium flux estimated from the increase in fetal calcium content between days 20 and 21 of gestation (100 ± 4 nmol/minute) is close to the $^{Ca}J_{MF}$ (100 ± 7 nmol/minute) estimated in nonanesthetized animals at 21 days.[6] By contrast, in the rhesus monkey, the magnitudes of bidirectional placental calcium fluxes are comparatively similar to one another ($^{Ca}J_{MF}$, 391 mg/kg/day; $^{Ca}J_{FM}$, 326 mg/kg/day).[11] In the human, bidirectional clearances of calcium also are similar (unidirectional maternofetal clearance, 40.9 ± 14.7 μL/minute/g of placental weight; unidirectional fetomaternal clearance, 39.1 ± 21.8 μL/minute/g).[5] These fluxes and clearances are considerably higher than the rate of daily fetal calcium accumulation or the net flux, which in the rhesus monkey at term has been estimated to be 40 mg of calcium per day/kg of fetal body weight,[12] and in the human, 200 mg of calcium per day during the last trimester.[1] A similar situation also exists for placental transfer of sodium across the human placenta.[13]

Mechanisms of Placental Calcium Transport

Although the placental content of total calcium is high,[14] the free cytosolic Ca^{2+} concentration must be maintained in the submicromolar range, by analogy with other transporting epithelia,[15] if viability is to be preserved. In isolated placental cells, the cytosolic concentration of free calcium is in the nanomolar range.[16] Therefore the large traffic of calcium ions across the trophoblast poses a threat to normal cellular function, and efficient mechanisms for intracellular calcium buffering and translocation from the maternal-facing cytosol to the fetal-facing cytosol must exist. Whereas bidirectional movements may occur by diffusion through water-filled paracellular channels, asymmetric active

transport necessitates a transcellular route. Transcellular placental calcium transport is likely to involve three steps:

1. Influx or entry of Ca^{2+} from maternal plasma across maternal-facing placental membrane
2. Movement of calcium through trophoblastic cytosol
3. Efflux or exit of Ca^{2+} from cytosol across the basolateral or fetal-facing placental membrane

Little is known of the mechanisms involved in Ca^{2+} influx from maternal plasma into trophoblastic cytosol, but it is possible that the entry mechanism involves a variety of apical calcium channels.[17] The unidirectional influx of calcium is higher on the fetal than on the maternal side of the placenta in the guinea pig,[18] and the fluxes are equal on both sides of the human placenta.[19] The net maternofetal flux, however, is higher than the fetomaternal flux in both placental types. In studies involving uptake of ^{45}Ca from artificial media used to perfuse both fetal and maternal circulations of guinea pig placenta, van Kreel and van Dijk[20] demonstrated that calcium enters the trophoblast as a charged ion. Thus placental calcium transport is likely to be similar to that in the intestine, in which entry of calcium ions across the brush-border membrane occurs by passive diffusion down an electrochemical gradient. As in the gut,[15] this process in the placenta is saturable.[5,18] Evidence of a carrier has been obtained by examining calcium uptake into human placental microvillous membrane vesicles in which a two-site model was characterized with kinetic estimates of the Michaelis constant (K_m) of 18 μM and 1.5 mM, and maximum velocity (V_{max}) of 3.2 and 47 nmol/mg/minute, respectively. The K_m of calcium uptake in intestine is approximately 1 mM,[21] much higher than the K_m for efflux, which is in micromolar concentrations. Therefore the rate of calcium influx into the cells is probably the rate-limiting step for transcellular Ca^{2+} flux. In the intestine, 1,25-dihydroxyvitamin D_3 (1,25-$[OH]_2D_3$), the biologically active metabolite of vitamin D, appears to increase the V_{max} of calcium influx, without altering the K_m.[22] In other words, 1,25-$(OH)_2D_3$ probably increases the synthesis of Ca^{2+} carrier or channel units in this organ.

Little is known about passage of calcium through the trophoblastic cytosol. Clearly, in all calcium-transporting epithelial cells, an efficient mechanism for efflux of Ca^{2+} as well as intracellular compartmentalization or buffering of calcium ions in transit must exist if the cytosolic Ca^{2+} concentration, which is approximately 1000 times lower than the extracellular Ca^{2+} concentration, is to remain unaffected. This maintenance function may be the role of calcium-binding proteins (CaBPs), a family of proteins involved in the transport and binding of calcium, which may serve as an intracellular calcium buffer or an intracellular shuttle and may thus facilitate transcellular calcium transport.

CaBPs have been identified in numerous species. Placental CaBP in the rat is immunologically identical to the vitamin D–dependent CaBP in the intestine,[23] but it seems to lack the classic dependency of the latter on 1,25-$(OH)_2D_3$ in intact animals.[24-26] However, the administration of 1,25-$(OH)_2D_3$ to thyroparathyroidectomized pregnant rats does result in an increase in the concentration of placental CaBP.[27] Thus the role of maternal vitamin D in control of placental CaBP is not entirely clear.

In the rat, placental concentration of CaBP increases rapidly during the period of increased rate of fetal growth and calcium accumulation in late gestation,[23,28] suggesting a role for this protein in placental Ca^{2+} transport. This concept is supported by the finding of a temporal relationship between CaBP messenger RNA (mRNA) expression and $^{Ca}J_{MF}$ of calcium in the placenta of the rat[29] and by the demonstration that uptake of calcium by human placental microsomal membrane vesicles is inhibited by preincubation with antihuman CaBP antibodies.[30] Investigators have shown that CaBP enhances diffusion of Ca^{2+} through an aqueous compartment,[31] and in the presence of CaBP, the rate of cytosolic Ca^{2+} diffusion in enterocytes is 60 to 70 times higher than across cytosol of CaBP-depleted cells.[32] Thus CaBP may act as an intracellular shuttle to facilitate the diffusion of Ca^{2+} through trophoblastic cytosol.

Intracellular organelles may serve as cytosolic calcium buffers and reservoirs in the placenta. In the guinea pig placenta, the subcellular distribution of ^{45}Ca is mainly in the nuclear fraction (48%), 28% is bound to cytoplasmic proteins, and approximately 10% is in the mitochondrial fraction.[20] Electron microscopy of human placenta has revealed granular calcium deposits, localized to endoplasmic reticulum and mitochondria, and in vesicles within the trophoblast.[33] Intracellular calcium sequestration is supported by the observation that a human placental microsomal membrane fraction can be reconstituted into vesicles that exhibit a magnesium (Mg^{2+})– and adenosine triphosphate (ATP)–dependent Ca^{2+} uptake mechanism.[34]

Mechanisms involved in the efflux of Ca^{2+} from cytosol across the fetal-facing trophoblastic membranes to fetal plasma against a steep concentration gradient are not clearly delineated. In other absorptive epithelia (e.g., the intestine and the kidney), at least two mechanisms are involved in efflux of Ca^{2+} out of the cytosol across the basolateral cell membrane:

- Calcium- and magnesium-dependent adenosine triphosphatase (Ca^{2+}-ATPase)
- The Ca^{2+}-Na^+ exchanger (NCX)

Growing evidence suggests that, in the placenta, a Ca^{2+}-ATPase may be responsible for the translocation of calcium from trophoblast cytosol to fetal extracellular fluid across the basal plasma membrane. Hydrolysis of ATP could provide the required energy to overcome the Ca^{2+} concentration gradient. Ca^{2+}-ATPase has been identified in placentas of guinea pigs,[35] mice,[36]

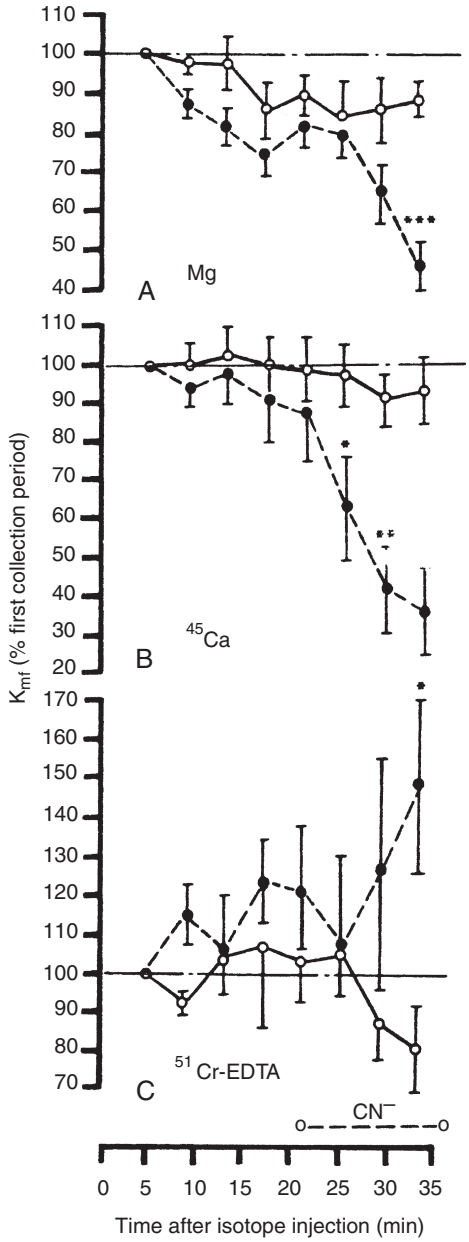

Figure 34-1 Effects of potassium cyanide (CN) (1 mmol/L final concentration) to perfusate fluid on maternofetal clearance (K_{mf}) of magnesium (Mg) **(A),** calcium (^{45}Ca) **(B),** and chromium 51 ethylenediaminetetraacetic acid (^{51}Cr-EDTA) **(C)** across in situ, fetally perfused rat placentas (n = 6/group). cats,[37] and humans.[34,38,40] It is clear that the Ca^{2+}-ATPases are a heterogeneous group of enzymes,[41] not all of which are involved in calcium transport[42,43]; this heterogeneity may explain the reported dissociation between Ca^{2+}-ATPase transport activity and Ca^{2+}-ATPase hydrolytic activity.[34,39] Calcium uptake into highly purified human placental basal plasma membrane vesicles has been described.[44,45] This uptake may be mediated by one of the Ca^{2+}-ATPases. Monoclonal antibodies against the human erythrocyte plasma membrane calcium pump show greater specific staining in the human placental basal membrane and in the fetal-facing membrane of the rat placenta, and they inhibit by 50% transport of calcium into human placental basal plasma membrane vesicles.[46] Expression of Ca^{2+}-ATPase mRNA and protein[47] in both human[47, 48] and rat[29] placenta shows little

change as gestation proceeds; it appears, therefore, that this protein is not rate-limiting in placental calcium transport.

Current evidence indicates that the NCX is unimportant in regulating transplacental Ca movement. Van Kreel and van Dijk,[20] who perfused both the maternal and fetal circulations of the term guinea pig placenta with calcium-free media containing ^{22}Na and unlabeled sodium, found that the addition of 2 mM Ca^{2+} to the media after 30 minutes of equilibration does not affect the release of preloaded ^{22}Na from placental cells into the media. The presence of an NCX has been sought in the in situ rat placenta by perfusing the fetal circulation and measuring the maternofetal flux of calcium in the presence or absence of sodium in the perfusate. In the absence of sodium, maternofetal flux of calcium is either unaltered[49] or decreased.[50] In the latter study, however, the effect on $^{Ca}J_{MF}$ was delayed. In addition, $^{Ca}J_{MF}$ is unaffected during perfusion with sodium-containing perfusate to which ouabain, a potent Na^+,K^+-ATPase inhibitor, had been added; by dissipation of the sodium gradient, an effect on calcium flux would be expected in the presence of an NCX. In vitro placental membrane vesicle studies showed a lack of effect of sodium or ouabain on calcium uptake.[34,45] By contrast, in a later study using human placental basal membrane vesicles, these workers suggested the presence of an NCX in this membrane[51]; however, the number of experiments was small, and the orientation of the vesicles (cytoplasmic side inside versus outside) was mixed, features that call into question the significance of this finding in relation to calcium transport across the basal membrane. Using a cDNA probe to the cloned human cardiac NCX, Kofuji and co-workers[52] demonstrated that the expression of the gene encoding this NCX in human placenta is some 250-fold less than in human heart. The presence of a high-affinity, low-capacity facilitated diffusion transporter in human placental basal membrane vesicles has been reported,[53] but the functional significance of this transporter in relation to maternofetal transfer of calcium is unknown.

Control of Placental Calcium Transport

Factors that may influence the supply of calcium to the fetus include maternal and fetal plasma Ca^{2+} concentrations, maternal and fetal blood flow, and the capacity and efficiency of placental transport mechanisms. In the rat, the maternofetal clearance of calcium per gram of placental tissue increases 70-fold in the last 6 days of gestation,[29] far more than would be expected with an increase in placental surface area or blood flow; uterine horn blood flow increases five-fold per placenta by day 21 of gestation compared with the virgin state.[54] In the human, over the whole of pregnancy, 170 L of maternal plasma would have to be cleared of its calcium content to account for the total amount of calcium accumulated in a term human fetus.[55] Because the estimated uterine blood flow rate in the human at term gestation is 500 mL/minute,[56] placental calcium transfer appears limited by the area and the efficiency of placental transfer mechanisms, rather than by uteroplacental blood flow.[55] Mughal and colleagues,[57] however, observed a marked decrease in the unidirectional maternofetal clearance of ^{45}Ca, but not chromium-51 ethylenediaminetetraacetic acid (^{51}Cr-EDTA, the reference diffusional marker), in growth-restricted rat fetuses induced by uterine artery ligation compared with control fetuses. These investigators speculated that placental ischemia from chronic reduction in uteroplacental blood flow could result in depletion of the necessary energy supply for active placental calcium transport. Thus flow limitation is unlikely to be important for placental calcium transport.

Influence of Maternal Calcium Concentration

As suggested by indirect evidence from human studies, maternal plasma calcium concentration appears to influence placental calcium transport. Maternal dietary deficiency leading to hypocalcemia can be associated with congenital rickets and neonatal hypocalcemia.[58] Transient congenital hyperparathyroidism has been reported in infants born to mothers with hypocalcemia secondary to poorly treated hypoparathyroidism.[59] It is postulated that under these conditions, reduced net placental calcium transport leads to fetal hypocalcemia, which in turn results in fetal hyperparathyroidism. Conversely, transient neonatal hypoparathyroidism caused by untreated hyperparathyroidism has been reported in infants born to hypercalcemic mothers.[60] Thus, in the pregnant human, placental calcium transport appears to be dependent on the maternal plasma calcium concentration. Similar observations have been made in the guinea pig,[61] pig,[62] and rabbit,[63] but not in the sheep,[64] cow,[65] and rat.[66] In the rat, a doubling of maternal plasma Ca^{2+} concentration causes only a 30% increase in the $^{Ca}J_{MF}$ across the in situ perfused rat placenta. It appears, therefore, that in this species an active placental pump must be working at almost maximal capacity under normal conditions.[6] By contrast, studies using the in situ perfused guinea pig placenta have demonstrated that maternal hypercalcemia results in a significant increase in $^{Ca}J_{MF}$,[67] which may result from submaximal saturation of the active Ca^{2+} pump or from the existence of a quantitatively important and possibly unphysiologic paracellular leak pathway in this preparation.[68]

In sheep, maternal hypocalcemia does not lead to any change in fetal plasma calcium concentrations.[69] By contrast, acute maternal hypocalcemia in the rat[70] and monkey[71] results in a fall in fetal calcium concentration, but chronic maternal hypocalcemia induced by maternal vitamin D deficiency and thyroparathyroidectomy does not alter the $^{Ca}J_{MF}$ across in situ perfused placentas.[72] The evidence clearly points to marked species variation in the fetal response to maternal hypocalcemia or hypercalcemia, which may be physiologic or methodologic.

Hormonal Regulation of Placental Calcium Transport

The placenta has no nerve supply. Accordingly, factors that increase placental calcium transport capacity as gestation proceeds must be either genetically preprogrammed or hormones produced by the mother, fetus, or placenta itself. Hormonal signals controlling placental calcium transfer may act on either the maternal or fetal side of the placenta. Possible regulatory hormonal candidates include 1,25-$(OH)_2D_3$, parathyroid hormone (PTH), calcitonin, and other peptides secreted by the parathyroid glands.

Infants born in summer are reported to have a lower bone mineral content at birth when compared with infants born in winter.[73,74] The reason for this difference is not entirely clear but may be related to seasonal variation in maternal and fetal calciotropic hormone levels[74,75] and their speculative effect on placental transport of calcium and magnesium.

1,25-Dihydroxyvitamin D_3, 1α-Hydroxycholecalciferol, and the Vitamin D Receptor

Anecdotal clinical reports have described maternal vitamin D deficiency causing neonatal rickets,[76] consistent with the thesis that maternal vitamin D may be important for placental calcium transfer. This concept is supported by the presence of cytosolic receptors for 1,25-$(OH)_2D_3$ in the human and the rat.[77] Potential sources of 1,25-$(OH)_2D_3$ available to the fetus include that transferred from maternal plasma across the placenta,[78] that synthesized by the fetal kidneys,[79] and the placenta itself.[80] Because fetal plasma concentration of 1,25-$(OH)_2D_3$ falls after fetal nephrectomy in sheep,[81] it appears that in sheep, the fetal kidney is a major source of this metabolite of vitamin D.

The data on the role of maternal vitamin D in placental Ca transfer are conflicting. Administration of 1,25-$(OH)_2D_3$ to pregnant guinea pigs increases fetal calcium content and increases

maternoplacental, but not maternofetal, transfer of ^{45}Ca.[82] In sheep, maternal treatment with 1α-hydroxycholecalciferol (1α-OHCC), the hydroxylated derivative of vitamin D, for 12 days leads to a significant increase in fetal calcium content, as well as maternofetal calcium transfer.[83] In the same species, maternal prolactin injections can stimulate placental calcium transfer[84]; this hormone theoretically could exert an effect on the placenta by stimulating production of 1,25-$(OH)_2D_3$ in the mother. By contrast, in the rat, maternal vitamin D deficiency[72,85] and parathyroidectomy[72] do not affect the maternofetal calcium gradient,[85] the total fetal calcium content,[72,85] or the maternofetal clearance of ^{45}Ca.[72] The concentrations of CaBP[24,25] and its mRNA[26] are significantly reduced in rat maternal intestine, but not placenta, under experimental conditions of maternal vitamin D deficiency. The inconsistent data reported thus far may simply reflect interspecies variation.

The effect of fetal 1,25-$(OH)_2D_3$ on placenta calcium transport also is unclear. Fetal nephrectomy in the rat does not alter the maternofetal total calcium gradient,[86] although injection of a pharmacologic dose of 1,25-$(OH)_2D_3$ into 19-day rat fetuses increases the fetal Ca^{2+} concentration on day 21 of gestation, compared with control fetuses.[87] Fetal nephrectomy in sheep leads to a marked decrease in the fetal plasma concentration of 1,25-$(OH)_2D_3$ associated with reversal of the usual maternofetal calcium gradient, which is restored by infusion of 1,25-$(OH)_2D_3$ into the fetal circulation.[81,88] It is not clear whether these findings reflect control of placental calcium transport by 1,25-$(OH)_2D_3$ synthesized by fetal kidneys or present evidence of short-term dependence of fetal plasma calcium concentrations on mobilization from fetal bone.

In support of a direct permissive effect of fetal 1,25-$(OH)_2D_3$ on placental calcium transfer is the observation of Robinson and colleagues[89] that 1,25-$(OH)_2D_3$ stimulates $^{Ca}J_{MF}$ across in situ perfused placentas of rat fetuses parathyroidectomized by gross decapitation,[90] but not across placentas of intact fetuses. Because PTH is an important trophic stimulator of 1,25-$(OH)_2D_3$ synthesis, it is likely that plasma 1,25-$(OH)_2D_3$ concentration is lower in parathyroidectomized rat fetuses than in intact fetuses. Therefore 1,25-$(OH)_2D_3$ probably stimulates placental calcium transfer only when fetal plasma concentrations are initially low.

Using a vitamin D receptor (VDR) gene–knockout mouse model, Kovacs and colleagues investigated fetal mineralization and maternofetal transfer of calcium in the fetuses of heterozygous males and females. They suggested that the VDR is not required for fetal mineralization or placental maternofetal transfer of calcium.[91] Placental transport of calcium was measured indirectly, however, and the values in the three fetal genotypes were normalized to heterozygous littermates. Further studies directly measuring placental calcium transfer are required to define the role of the VDR.

Parathyroid Hormone and Fetal Parathyroid Hormone–Related Protein

In the rat, fetal parathyroidectomy by decapitation[89,92] or by injection of antibovine PTH serum[93] leads to a fall in fetal plasma total calcium concentration, which is restored by administration of parathyroid extract.[93,94] In the sheep, fetal thyroparathyroidectomy with thyroxine replacement results in a rapid fall in fetal Ca^{2+} concentration within 24 hours.[95-97] Similarly, in the *Hoxa3*-knockout mouse, complete absence of fetal parathyroids results in lower fetal total and ionized calcium concentrations, whereas indirect measurement of placental calcium transfer is unaffected.[98] As previously mentioned, a significant fall in maternofetal clearance of ^{45}Ca occurs across the in situ perfused placentas of decapitated rat fetuses,[89] and clearance is increased (but not returned to normal) by subcutaneous administration of bovine PTH(1-84) to the fetuses. This stimulatory effect of PTH(1–84) on maternofetal ^{45}Ca clearance may result from its direct action on the placental Ca^{2+} pump; alternatively, the hormone may increase fetal 1,25-$(OH)_2D_3$ production. Perfusion of the fetal circulation in intact and decapitated rat fetuses with a medium containing forskolin (an activator of adenylate cyclase) stimulates maternofetal clearance of ^{45}Ca. Synthetic rat PTH amide (r[Nle,Tyr])PTH[1-34]), however, has no effect under these conditions,[99] and because this amide also can increase placental cAMP release,[100] the role of placental adenylate cyclase in calcium transfer is not clear.

Another candidate hormone that may stimulate placental calcium transport is PTH-related protein (PTHrP).[101] The addition of fetal parathyroid gland extract, partially purified PTHrP from a human lung cancer cell line, or recombinant PTHrP, but not bovine PTH(1-84) or rat PTH(1-34),[102] to autologous fetal blood used to perfuse placentas of thyroparathyroidectomized sheep fetuses in situ leads to an increase in the rate of calcium accumulation in the fetal blood reservoir.[95,102-104] In sheep, it appears that mid-molecule fragments of PTHrP may be responsible for the stimulation of placental calcium transport.[95,105,106] When human PTHrP (hPTHrP)(1-34) or hPTHrP(75-86) is infused into the fetal circulation of the in situ rat placenta, these peptides have no effect on calcium transport.[99] Indirect evidence, however, suggests that fetal PTHrP fragments increase maternofetal transport of calcium in murine[107] and human[108] placentas. Surprisingly, net fetal calcium accretion is increased in the absence of fetal PTHrP.[109] Taken together, these findings seem to indicate that, in the absence of fetal PTHrP, maternofetal flux of calcium is decreased, but fetomaternal flux is decreased to a greater extent; the change in the former may be related to PTHrP absence or secondary 1,25-$(OH)_2D_3$ deficiency in fetal plasma, or both.

Calcitonin

In sheep, Barlet[110] demonstrated that chronic maternal calcitonin deficiency (achieved by maternal thyroparathyroidectomy and thyroxine replacement) leads to a significant increase in the total fetal calcium content and fetal accumulation of ^{45}Ca on day 140, but not on day 77, of gestation (term gestation, approximately 150 days). Calcitonin replacement in these ewes normalizes both the fetal calcium content and the maternofetal transfer of ^{45}Ca. Thus, in this species, maternal calcitonin deficiency appears to increase $^{Ca}J_{MF}$. Studies using the calcitonin–calcitonin gene–related peptide-α–knockout mouse model (Ct/Cgrp) suggest that neither maternal nor fetal calcitonin–calcitonin gene–related peptide-α modulate placental calcium transfer.[111]

In situ perfusion of the rat placenta has been used widely in the study of placental transfer mechanisms and their control. The recent validation of this technique in the mouse[112] and its application in transgenic mice is expected to elucidate the control of placental transport at the molecular level.

PLACENTAL TRANSPORT OF PHOSPHORUS

Provision of an adequate supply of phosphorus to the developing fetus is important because of its role in intermediary metabolism and skeletal mineralization. In mammals during the latter part of gestation, the plasma concentration of phosphorus in the fetus is higher than that in the mother (Table 34-2). Thus placental transfer of phosphorus in the maternofetal direction occurs against a concentration gradient and is likely to involve an active transport process. Most fetal phosphorus content is transported to the fetus during the latter stages of pregnancy.[113,114]

Mechanisms of Placental Phosphorus Transport

The flux of phosphorus across the placenta is bidirectional, with flux in the maternofetal direction exceeding that in the fetomaternal direction.[49,115] As shown in Figure 34-3, for a 60-g fetus,

TABLE 34-2

Concentrations of Inorganic Phosphorus in Maternal and Fetal Plasma (mmol/L)

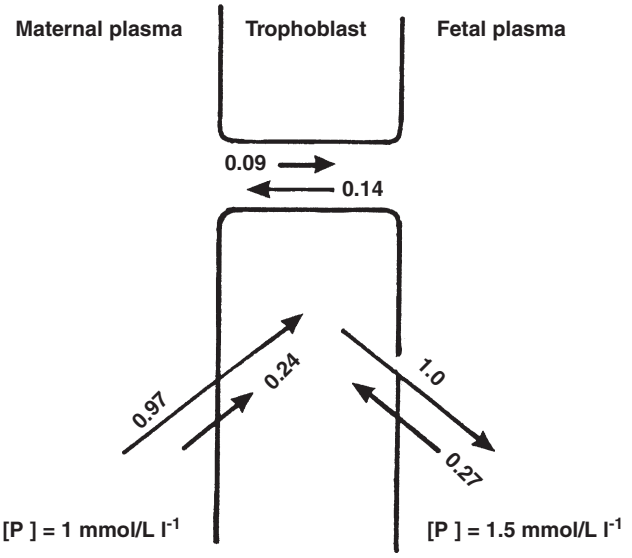

Figure 34-3 The components of phosphorus fluxes expressed in micromoles across fetal[49] and maternal[115] faces of a guinea pig placenta. The net phosphorus flux, 0.7 μmol/minute, is similar to the retention of phosphorus by the guinea pig fetus of comparable weight.[113] The paracellular fluxes constitute only a small fraction of the total bidirectional trophoblastic phosphorus fluxes. *P,* Plasma phosphorus concentration. *(Modified from Štulc J, Štulcová: Transport of inorganic phosphate by the fetal border of the guinea-pig placenta perfused in situ,* Placenta *5:9, 1984. Additional data from Štulc J, Stulcová B, Svihovec J: Uptake of inorganic phosphate by the maternal border of the guinea-pig placenta,* Pflugers Arch *395:326, 1982.)*

the calculated net flux of phosphorus is 0.7 μmol/minute, a value similar to that obtained with retention of phosphorus by guinea pig fetuses of comparable weight.[113] Placental uptake of phosphorus at both the maternal and fetal faces of guinea pig placenta is reduced by anoxic conditions, by the addition of cyanide, or by the reduction or elimination of sodium from the perfusion media.[113] From these results, it appears that the transcellular, bidirectional phosphorus transport is highly asymmetric and depends on a sodiumdependent active transport mechanism. Maternofetal flux prevails over fetomaternal flux and is reduced by anoxic conditions or addition of cyanide.

In vitro phosphorus uptake studies using human placental brush-border membrane vesicles support the presence of a high-affinity (K_m of 87 μM; pH 7; 35° C) sodiumependent transport system[116,117] that is likely to be saturated in vivo. At pH 8, the K_m increases (to 500 μM), whereas an increase in the Na^+ concentration of the incubation medium increases phosphorus uptake by an increase in V_{max} but not K_m. Temperature influences phosphorus uptake by changing both K_m and V_{max}. The uptake of phosphorus by these vesicles is noncompetitively inhibited by glycine, alanine, and proline. Thus, in the human, pH, temperature, and sodium and amino acid concentrations appear to modulate the transport of phosphorus from maternal plasma into the trophoblastic cytosol.

Hormonal Regulation of Placental Phosphorus Transport

Factors that modulate placental phosphorus transport have not been extensively studied. Based on the presence of receptors for 1,25-$(OH)_2D_3$[77] and for PTH[118] in the placenta, it has been suggested that these hormones may regulate placental phosphorus transport. In the rat, maternal vitamin D deficiency does not affect the maternofetal plasma phosphorus concentration gradient or fetal phosphate content at term gestation.[84] By contrast, intravenous administration of 1α-OHCC to pregnant sheep results in significant increase in both maternal and fetal phosphorus concentrations.[119] Similarly, Barlet and co-workers[65] observed that feeding of *Solanum glucophyllum* leaves, which contain 1,25-$(OH)_2D_3$, to pregnant cows results in hyperphosphatemia in both mother and fetus. From these studies, it is not clear whether the maternal 1,25-$(OH)_2D_3$ or its analogues given to the mother increase fetal serum phosphorus concentrations by stimulating net placental phosphorus transport or simply by increasing the concentration of phosphorus in maternal plasma.

There is some evidence of modulation of placental phosphorus transport by vitamin D or its analogues in sheep. Injection of 1α-OHCC to pregnant ewes for 12 days results in increased maternofetal transport of ^{32}P at day 140 of gestation.[83] Lowering of fetal plasma 1,25-$(OH)_2D_3$ by fetal nephrectomy leads to increased fetal plasma concentration of phosphorus, which can be prevented by daily intravenous injections of 1,25-$(OH)_2D_3$ into the fetuses.[88] The investigators speculated that unidirectional fetomaternal phosphorus transport in this species could be regulated by 1,25-$(OH)_2D_3$ produced by fetal kidneys.

The uptake of phosphorus by human placental brush border membrane is inhibited by PTH, with its action possibly mediated by cAMP.[120] Because adenylate cyclase is located in the basal plasma membranes, fetal PTH may reduce placental phosphorus transfer in the fetomaternal direction. Thus 1,25-$(OH)_2D_3$, acting on the maternal as well as the fetal side of the placenta, and fetal PTH may regulate placental phosphorus transport. By contrast, MacIsaac and associates showed that extracts of fetal parathyroid glands and purified PTHrP, as well as recombinant PTHrP(1-84, 1-108, and 1-141), do not stimulate phosphorus transport across the placenta of thyroparathyroidectomized sheep fetuses that are perfused with autologous blood.[97]

PLACENTAL TRANSPORT OF MAGNESIUM

Toward the end of pregnancy, the plasma concentrations of total and ultrafiltrable magnesium[121] in the fetus exceed those in the mother (Table 34-3). Therefore maternofetal magnesium transfer occurs against a concentration gradient and is likely to involve active transport mechanisms. Support for this concept comes from studies by Shaw and colleagues,[9] who observed that the unidirectional maternofetal clearance of magnesium across perfused rat placentas in situ is considerably higher (26.7 μL/g/minute) than

TABLE 34-3

that of ^{51}Cr-EDTA, the reference diffusional marker (3.2 αμL/g/minute).They also showed that the maternofetal clearance of magnesium is significantly reduced by the addition of cyanide to fetal perfusate (see Figure 34-1) or by lowering of perfusate temperature (see Figure 34-2).

In human pregnancy, fetal magnesium content increases rapidly after the fifth month of gestation, with net fluxes of approximately 4.5 mg of magnesium per day.[122] However, only 0.06% of magnesium injected into the maternal arterial circulation (to achieve twice the physiologic concentration) of in vitro perfused human placental lobule was transferred into the fetal perfusate.[123] Bidirectional magnesium flux has been demonstrated in sheep, with maternofetal flux (0.042 mg/kg of fetal weight/hour) exceeding fetomaternal flux (0.012 mg/kg/hour).[124]

Mechanisms of Placental Magnesium Transport

Little is known of the mechanisms of placental magnesium transport. Influx of Mg^{2+} across the maternal-facing placental membrane may be a passive process depending on the intracellular free Mg^{2+} concentration and transmembrane potential difference. Membrane proteins mediating this influx have not been identified, but they could be Mg^{2+} channels or facilitated-type carriers. The mechanism by which magnesium is translocated across the placental cytoplasm is unknown, but it may be by simple diffusion in either the free or bound state. Mg^{2+} efflux across the fetal-facing placental membrane is likely to be an energy-dependent process. It is clear that the mechanisms involved in placental magnesium transport are separate from those of calcium transport.[9,125,126]

In the rat, administration of amiloride or furosemide reduces maternofetal magnesium flux, consistent with the presence of a Na^+-Mg^{2+} exchanger and an Mg^{2+}-HCO_3^- co-transporter.[127] The presence of a Na^+-Mg^{2+} exchanger is supported by the studies of Shaw and collaborators,[50] who found that the maternofetal clearance of magnesium across the in situ perfused rat placenta is reduced when the perfusate is either sodium-free or contains ouabain, both of which would reduce the electrochemical gradient for sodium. The presence of acetazolamide (a carbonic anhydrase inhibitor) in the perfusate, however, has no effect on the clearance of magnesium, so a role for an Mg^{2+}-HCO_3^- cotransporter remains speculative.[54] Using choriocarcinoma cells as a model for human trophoblast cells, Standley and Standley demonstrated the presence of a functional Na^+-Mg^{2+} exchanger that serves to maintain low Mg^{2+} concentrations within cytotrophoblast cells.[128] Lowering of extracellular Na^+ causes progressively larger, transient increases in Mg^{2+} concentrations within cytotrophoblast cells; these transient changes also are dependent on extracellular Mg^{2+} concentrations.

Control of Placental Magnesium Transport

No direct information on the regulation of placental magnesium transport is available. Insight into placental transfer mechanisms, however, is provided by observing the effect of therapeutic and experimental manipulations of maternal plasma Mg^{2+} concentrations on fetal plasma and carcass Mg^{2+} concentrations and the fetomaternal plasma magnesium gradient. Treatment of preeclampsia with magnesium leads to maternal and fetal hypermagnesemia[129]: either the magnesium-transporting pump apparently is not saturated at physiologic plasma Mg^{2+} concentrations, or a high diffusional permeability to magnesium is characteristic of this species. By contrast, in the rat, maternal intraperitoneal administration of magnesium leads to a three-fold increase in the maternal plasma Mg^{2+} concentration but only a slight increase in fetal plasma Mg^{2+} concentration.[130] Maternal hypomagnesemia in the rat produced by dietary deficiency, however, leads to reduced fetal plasma and carcass Mg^{2+} concentrations and a loss of the fetomaternal magnesium gradient.[121,131] In sheep, neither maternal hypermagnesemia nor maternal hypomagnesemia affects the fetal plasma Mg^{2+} concentration.[132] Thus, in sheep, placental magnesium transport appears to be saturated even when the mother is hypermagnesemic. In addition, any diffusional component of transfer must be small in relation to the carrier-mediated component. The interspecies variation in fetal response to maternal hypomagnesemia and hypermagnesemia may be related to differences in placental structure. Using the Ct/Cgrp-knockout mouse model, McDonald and co-workers[111] showed that serum and total-body magnesium content is significantly lower in fetuses born to Ct/Cgrp-null mothers compared with Ct/Cgrp$^{+/-}$ and wild-type mothers. These workers concluded that Ct/Cgrp may be involved in regulation of placental magnesium transport.

Hormonal Regulation of Placental Magnesium Transport

Some evidence indicates that in sheep, magnesium transport is increased by fetal parathyroid gland extract and mid-molecule fragments of hPTHrP(67-86) and hPTHrP(75-86), whereas the amino-terminal end (hPTHrP[1-34]) has no effect.[95] The same is not true for mid-molecule PTHrP fragments in the rat.[99] These contradictory findings may reflect methodology or species differences.

MINERAL TRANSFER IN DIABETIC PREGNANCIES AND IN INTRAUTERINE GROWTH RESTRICTION

Disturbances in fetal growth commonly are encountered in diabetic pregnancy in both animals and humans. In the rat, fetal growth restriction is a consistent finding.[133] By contrast, infants born to diabetic pregnant women tend to be overgrown at term, although in the first trimester of pregnancies with maternal diabetes the fetus may be growth-restriction and may more closely resemble that in rat pregnancies.[134] Many different qualitative and quantitative changes have been reported in placentas of diabetic pregnancies, but data on measurement of placental nutrient flux in such pregnancies are limited.

An early report using single-photon absorptiometry suggested that the radial bone mineral content in infants of diabetic mothers is reduced by approximately 10% when compared with infants of nondiabetic mothers.[135] By contrast, a recent study in which whole-body bone mass was measured using dual x-ray absorptiometry suggests that bone mineralization is increased in

infants of diabetic mothers compared with reference curves.[136] The effect of maternal diabetes mellitus on fetal mineralization is more consistent in animal studies. Fetal histomorphometric analysis and ashing studies demonstrated reduced mineralization in the offspring of diabetic rats.[133] Whereas the increased incidence of hypocalcemia and hypomagnesemia reported in infants of diabetic mothers may result from disturbances in calciotropic hormone responsiveness,[134-139] the reduced fetal bone mineral accretion in animal studies is likely to be associated with lower net placental transport of bone minerals.

We investigated this situation in more detail by measuring the maternofetal flux of calcium and magnesium across the in situ perfused placenta of the streptozocin-induced diabetic rat.[140] Our results indicate that, in the presence of untreated maternal diabetes, the maternofetal flux of both calcium and magnesium is reduced by between 20% and 40%, accompanied by lower net fetal accretion of calcium and magnesium. These disturbances can be prevented by control of the diabetes with insulin. Fetuses in the untreated diabetic group weighed significantly less than those in the other groups, but even when an allowance was made for this difference, the calcium content, but not the magnesium content, remains significantly lower in the untreated diabetic group of animals. Thus, the net flux of calcium across the diabetic rat placenta is reduced to a greater degree than that expected from growth restriction alone. This situation is different from that in which growth restriction is induced in the rat by reducing uterine blood flow. In that model, net calcium flux is appropriate for fetal size.[57]

The pathophysiology of these disturbances in placental transport of calcium and magnesium during diabetic rat pregnancy is not fully understood, and it is likely that a combination of factors leads to altered placental transport and fetal accretion of calcium and magnesium. Hypomagnesemia[141] and hypermagnesuria[142] are common in diabetes mellitus, and pregnancy has an additive effect on renal Mg^{2+} excretion.[143] However, our observations in the untreated diabetic rat pregnancy do not support reduced cation availability as a cause of the reduced maternofetal flux of these cations,[140] although they do support the finding that CaBP is reduced in the placentas of diabetic rats.[144] Our data, confirmed by other investigators,[145] demonstrate that the expression of CaBP mRNA in placentas of diabetic rats is reduced by a factor of 12 to 15.[140]

Infants who are small for gestational age have a lower bone mineral content compared with those whose size is appropriate for gestational age,[74] even after allowing for seasonal variation.[74] The reasons for this discrepancy are unclear but may be related to differences in calciotropic hormones between infants who are small for gestational age and those of a size appropriate for gestational age.[74] Using an experimental model of fetal growth restriction in the rat (uterine artery ligation), we showed that maternofetal transfer of calcium across the placenta is reduced in proportion to the reduction in body size.[57] This finding may simply reflect the smaller requirement for calcium in a small fetus, but it also may indicate a depletion of the necessary energy supply for active placental calcium transport secondary to a chronic reduction in uteroplacental blood flow.

35 Fetal and Neonatal Iron Metabolism

Raye-Ann Odegaard deRegnier and Michael K. Georgieff

OVERVIEW

Iron is the fourth most abundant element and constitutes approximately 0.0075% of human body composition[1] It is a cofactor in some of the most basic biologic reactions, yet its beneficial effects are tempered by the fact that it is highly toxic in its unbound state and participates in the generation of reactive oxygen species (ROS). In a human term newborn, the whole-body amount of elemental iron has been determined to be 275 to 300 mg, most of which is complexed in hemoglobin.[1,2] In addition to its predominant role in erythropoiesis, iron is important for normal growth and function of all rapidly developing organ systems. Rapidly dividing cells need more iron. Indeed, much of what has been learned about cellular iron homeostasis comes from investigation of cancer cells and bacteria.

The clinical signs of iron deficiency are highly variable because iron-containing proteins are important in many facets of human biology.[3] These include cellular energetics, DNA replication, tissue oxygenation, neurotransmitter synthesis, thyroid status, white cell function, and fatty acid synthesis.[4-8] The consequences of deficiency have been studied most extensively in the hematopoietic system, heart, skeletal muscle, gastrointestinal tract, and brain. The corresponding clinical manifestations include anemia, cardiomyopathy, skeletal muscle weakness, fatigue, intestinal dysmotility, and abnormal motor and mental function.[4-8]

Negative iron balance occurs more commonly during three time periods in child development: the late fetal–early neonatal period (up to 6 months postnatal age), 6 to 24 months of age, and the teenage years. The acute clinical effects and long-term hematologic and nonhematologic sequelae of iron deficiency in the fetal and neonatal period remain largely unknown. The lack of investigation until recently in this field was a consequence of the misperception that neonatal iron deficiency occurs only secondary to severe maternal iron deficiency. The incidence of fetal iron deficiency as a consequence of maternal anemia is low in developing countries because most mothers are supplemented with iron during pregnancy. From 30% to 50% of mothers worldwide, however, are iron-deficient during pregnancy. Moreover, a relatively high incidence of reduced iron stores and frank iron deficiency has been described in certain groups of infants born to iron-sufficient mothers.[9-12] Iron deficiency in these groups is due to reduced placental iron transport secondary to placental vascular disease or to increased fetal iron demand that exceeds the capacity of placental iron transport.

More attention has been focused recently on the negative consequences of iron overload in the fetus and neonate. This condition is rarely due to nutritional iron overload but far more often results from excessive red cell transfusions, congenital hemochromatosis, or reperfusion injuries. Iron overload of any cause is dangerous because iron reacts with oxygen (in the Fenton reaction, as described further on) to create ROS, which damage cell membranes and promote apoptosis and cell death. Studies have tried to delineate the role of iron overload in neonatal diseases characterized by oxidative injury such as bronchopulmonary dysplasia, necrotizing enterocolitis, and retinopathy of prematurity.[13-15]

This chapter begins with a review of the biochemistry of iron-containing proteins, their biologic functions and the regulation of cellular iron accretion. The subsequent discussion of fetal iron balance emphasizes the mechanisms of maternal-fetal iron transport with particular attention to the relative contributions of maternal and fetal iron status to regulating placental iron transport proteins. The section on postnatal iron balance addresses the various sources of iron and the overall iron requirements of term and preterm infants. Finally, the potential physiologic consequences of fetal and neonatal iron deficiency and iron excess are discussed.

GENERAL PRINCIPLES OF IRON METABOLISM

The Biology of Iron

Iron is a ubiquitous mineral that exists in trace conditions in humans. It is vital for the proper function of multiple proteins and is incorporated into their structures, typically as heme moieties or iron-sulfur clusters. The greatest amount of iron in the human is found within red cells in the hemoglobin molecule. Hemoglobin is prototypical of hemoproteins whose function is to carry oxygen or transfer electrons. Closely related compounds (because of their iron-containing porphyrin ring) include the cytochromes that are necessary for electron transport during oxidative phosphorylation and ATP generation. Iron therefore participates in the most basic aspects of cellular respiration during aerobic metabolism. In addition, iron-containing proteins reside in crucial pathways for detoxification (cytochrome P-450), neurotransmitter and hormone synthesis (tyrosine hydroxylase), and fatty acid production. Consequently, iron deficiency manifests as dysfunction of multiple organ systems including red blood cells, white blood cells, brain, heart, and skeletal muscle. Although iron deficiency anemia can produce classic signs and symptoms of fatigue, lethargy, and growth failure, most clinical manifestations are due to primary failure of nonhematologic organ systems dependent on iron-containing proteins and enzymes.

Iron not only is a necessary element whose deficiency produces symptomatology, but also is a highly toxic metal whose excess can cause severe organ damage through its interaction with oxygen in the Fenton reaction to generate ROS, which cause lipid membrane peroxidation. The Fenton reaction to generate ROS is as follows:

$$2O_2^- + 2H^+ \rightarrow H_2O_2 + O_2$$

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + OH$$

Iron generally is found in the ferric (Fe^{3+}) or ferrous (Fe^{2+}) state but in either case is always meant to be protein-bound, whereby the structure of the protein physically shields the iron, effectively keeping it from reacting with oxygen. Multiple degenerative disorders and reperfusion injuries are postulated to be caused in part by free iron–mediated ROS, including Alzheimer disease, Parkinson disease, and brain injury after stroke and myocardial injury after infarction. Neonatal investigators have explored a potential deleterious role for free iron in the pathogenesis of birth asphyxia, necrotizing enterocolitis, bronchopulmonary dysplasia, and retinopathy of prematurity.[13-16]

Regulation of Cellular Iron Homeostasis and Iron Transport

It is clear that iron is a highly necessary but potentially toxic mineral that requires tight regulation to maintain adequate but safe concentrations in blood and tissue. An elegant posttranscriptional system regulates the expression of proteins involved in cellular iron uptake, storage, and export. All cells need iron to survive. Most cells take up iron specifically for utilization within themselves. These cells require a mechanism for iron uptake but typically do not express proteins that excrete iron. Others, such as duodenal epithelial cells, mammary epithelial cells, endovascular endothelial cells in the blood-brain barrier, and the syncytiotrophoblast, additionally take up iron in order to transport it from one compartment to another (Table 35-1). These cells require proteins not only for iron uptake but also for its excretion.

Cellular iron uptake is mediated primarily by transferrin receptor (TfR-1), a transmembrane dimeric glycoprotein that actively internalizes diferric transferrin from the serum as well as from cerebrospinal fluid (CSF) and the brain parenchyma into the cytosol by way of clathrin-coated endosomes.[17-19] Because each transferrin receptor dimer binds two molecules of transferrin, each of which contains two molecules of ferric iron, a total of four iron molecules per TfR-1 unit are internalized. Although most cells use TfR-1 to internalize iron, iron uptake from intestinal lumen into the duodenal epithelial cell does not involve TfR-1 but instead requires the divalent metal transporter-1 (DMT-1) or lactoferrin (in the preweaning stage). The dimeric TfR-1 has a molecular weight of approximately 180 and contains *O*-linked and three *N*-linked carbohydrate chains with a disulfide bridge in its extracellular domain. The extracellular, carboxy terminal component is large, approximately 140 kD in size.[20] For optimal binding to occur, the receptor must be fully glycosylated, with an intact disulfide bridge that binds the two monomers close to the cell membrane surface.[20] TfR-1 isolated from cytosolic membranes demonstrates a lower binding affinity for transferrin[21] because of a presumably immature or incomplete glycosylation pattern. Similarly, truncation of the oligosaccharide side chains, particularly at Asn137, reduces the binding affinity for diferric transferrin.[22] Within the cytosol, the endosome is acidified, releasing the iron molecules from transferrin (see Figure 35-1). The subsequent ferrous (2+) iron is exported from the endosome into the cytosol by DMT-1. Once in the cytosol, the iron is available for incorporation into heme complex proteins or into proteins that contain iron-sulfur clusters.

Within the cell, excess cytoplasmic iron not immediately used for cellular functions is stored in the form of cytoplasmic ferritin. Ferritin is a nonheme iron protein complex consisting of a protein shell (apoferritin) made up of 24 protein subunits.[20] In human tissue, two important subunits have been identified, designated as H (heavy) and L (light). These subunit chains form a shell into which iron can bind reversibly and be stored. Under various conditions, apoferritin has the capability of storing as many as 270 atoms of elemental ferric iron to form ferritin.[23] The greatest concentrations of fetal ferritin are located in the cells of the reticuloendothelial system in the liver, placenta and spleen. Iron in these cells serves as a reservoir for iron used for other fetal organ systems. Late in fetal life, a major shift of iron (and erythropoiesis) from the liver to the bone marrow occurs. Ferritin also is present in all other cells to serve as a short-term storage depot for unused cytoplasmic iron, but cellular concentrations in most tissues outside the reticuloendothelial system are small.[23]

An additional step is necessary for cells that act as conduits for iron from one compartment to another (see Table 35-1). These interfaces include the duodenal epithelium, the syncytiotrophoblast, the mammary epithelial cell, and the blood-brain barrier. Iron export from the basal or basolateral membrane to the receiving compartment is mediated through ferroportin-1, a transmembrane protein that transports ferrous iron.[24] Ferroportin-1 has been localized to the duodenal epithelium, the basal (fetal-facing) surface of the syncytiotrophoblast, and the blood-brain barrier.[24,25] Mutations of ferroportin-1 resulting in iron overload of these transporting cells have been identified.[26] The mechanism by which ferroportin transports ferrous iron across the basal or basolateral membrane remains unclear. However, a positive charge donated from the copper moiety of one of two multicopper ferroxidases, hephaestin[27] or ceruloplasmin,[28] is necessary for converting the transported ferrous iron to ferric iron in anticipation of postextrusion binding by transferrin (Figure 35-1). Ferroportin expression, and thus iron transport activity, are negatively regulated by the liver protein hepcidin.[29] When cells are iron-sufficient or iron-overloaded, hepcidin concentrations increase, repressing ferroportin-mediated iron transport. Of interest, inflammation induces a similar increase in hepcidin activity, which may explain the observation that during inflammatory states, iron is sequestered in the reticuloendothelial system (as ferritin) and therefore is not available in the circulation for cellular accretion and erythropoiesis, leading to the anemia of inflammation.[30,31] Thus it may be worth considering that one aspect of the chronic anemia seen in premature infants despite normal or elevated iron stores may be due to chronic inflammatory states common in this group of infants.

The regulation of cellular iron accretion and storage has been elucidated in erythrocyte, hepatocyte, placental trophoblast, and mammary epithelial cell lines. A tightly controlled regulatory mechanism is necessary to ensure adequate availability of cytoplasmic iron while guaranteeing efficient removal of potentially toxic excess cellular iron. This dual process is accomplished by coordinated regulation of the synthesis of the TfR-1 and DMT-1, responsible for uptake of iron into cells, and of ferritin, responsible for conversion of excess cytoplasmic iron into its storage form.[31,32] The simultaneous regulation of the iron uptake proteins and the iron storage protein occurs through post-transcriptional modification of TfR-1 and ferritin messenger RNAs (mRNAs).[31,33] TfR-1, DMT-1, and ferritin mRNAs have specific binding sites known as iron-responsive elements (IREs). These elements represent conserved palindromic mRNA stem loops with a specific six-base sequence 5′-CAGUGN-3′. One IRE is found on the 5′ untranslated sequence of ferritin mRNA whereas five are found in the 3′ region of TfR-1 and DMT-1 mRNA.[33,34] These structurally and functionally identical sets of IREs are able to bind competitively iron-sensitive–specific cytoplasmic mRNA binding proteins known as iron regulatory proteins (IRPs). Two IRPs are recognized. IRP-1 is constitutively expressed but changes its conformation and binding affinity for the IREs based on whether it is

TABLE 35-1

Vectoral Iron Transport Across Single-Cell Membrane Barriers

Tissue	Source	Single-Cell Barrier	Destination
Intestine	Lumen	Intestinal epithelium	Blood
Placenta	Maternal blood	Syncytiotrophoblast	Fetal blood
Mammary gland	Maternal blood	Mammary epithelium	Milk
Brain			
Vascular	Blood	Vascular epithelium	Parenchyma/ ?astrocyte
Choroid plexus	Blood	Choroid epithelium	CSF
Ventricular ependyma	CSF	Ependymal cell layer	Parenchyma

CSF, Cerebrospinal fluid.

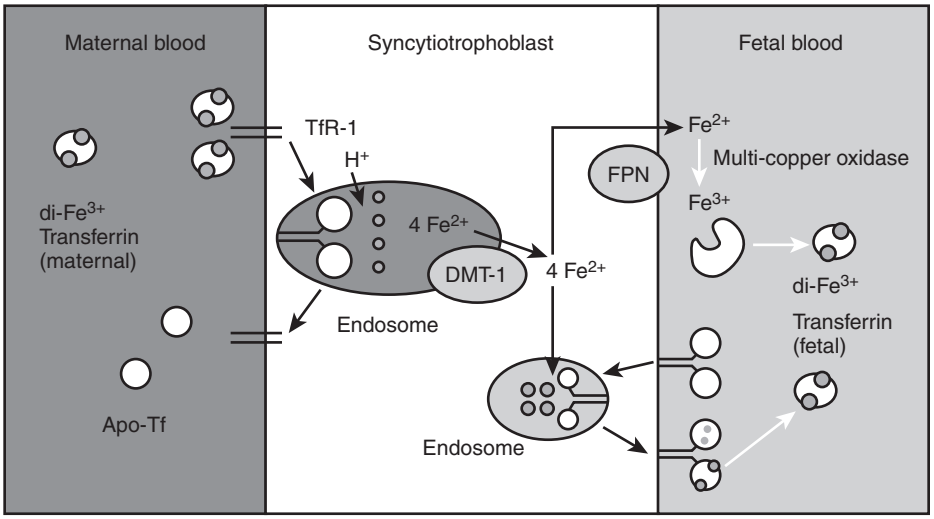

Figure 35-1 Iron transport across the syncytiotrophoblast. *Left panel,* Diferric transferrin is bound to transferrin receptor-1 (TfR-1) at the apical (maternal-facing) membrane. *Middle panel,* Ferrous iron is transported out of the endosome into the cytoplasm by the divalent metal transporter-1 (DMT-1). *Right panel,* Iron export at the basal (fetal-facing) membrane is proposed to occur either through ferrous iron transport by ferroportin-1 (FPN) or through ferric iron transport by TfR-1. See text for details.

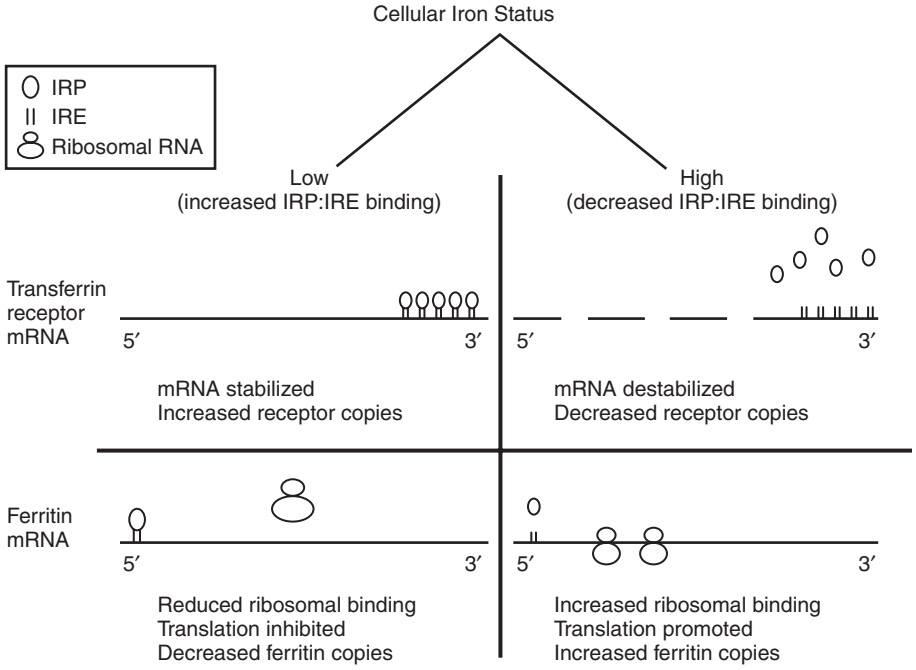

Figure 35-2 Coordinated regulation of transferrin receptor and ferritin recombinant messenger RNAs (mRNAs) by iron-regulatory proteins (IRPs) and iron-regulatory elements (IREs) during low and high cellular iron status. See text for full description of stabilization and translation of mRNA. *(Data from Harford JP, Klausner RD: Coordinate post-transcriptional regulation of ferritin and transferrin receptor expression: The role of regulated RNA-protein interaction.* Enzyme *44:28, 1990; Eisenstein RS: Iron regulatory proteins and the molecular control of mammalian iron metabolism,* Annu Rev Nutr *20:627-662, 2000; and Bierings MB, Baert MR, van Eijk HG, van Dijk JP: Transferrin receptor expression and regulation of placental iron uptake,* Molec Cell Biochem *100:31, 1991.)*

in its iron-sulfur cluster is in its iron-deficient Fe3S4 or its iron-sufficient Fe4S4 form. The Fe3S4 form has higher affinity for the IRE.[33,35] IRP-2 is more classically regulated, with increased mRNA expression in response to iron deficiency. When cellular iron concentrations are low, the IRPs bind the IREs found in the 3′ untranslated region of TfR-1 and DMT-1 mRNA, stabilizing it and producing more copies (Figure 35-2). At the same time, IRP binding of the IRE in the 5′ untranslated region of ferritin mRNA prevents ribosomal binding. The combination results in increased synthesis of the iron importers and decreased synthesis of ferritin. High cytoplasmic iron concentrations lead to reduced IRP binding to the IREs on both mRNAs. This decreased binding leads to destabilization of the mRNAs of the importers while improving the binding of ferritin mRNA to ribosomes, increasing apoferritin synthesis, and promoting of storage of cytoplasmic iron[33,36] (see Figure 35-2). Perinatal models of iron deficiency in humans and rodents demonstrate increased IRP activity in placenta[37,38] and in brain.[39]

Regulation of Placental Iron Transport

The entry point for iron into the fetus is at the trophoblast or syncytiotrophoblast (see Figure 35-1). Human placental iron transport is mediated by TfR-1 localized primarily but not exclusively to the apical syncytiotrophoblast membrane.[18] DMT-1 serves as the intracellular endosomal ferrous iron transporter. The mechanism of basal transport remains elusive, although the presence of ferroportin on the basal membrane suggests that ferrous iron is transported to the fetus at that site.[24,25,38] Nevertheless, the presence of TfR-1 at the basal membrane leaves open the possibility that it is involved in transferrin-mediated iron transport at that site[18] (see Figure 35-1). This receptor-mediated system pumps iron against an ever-increasing gradient from mother to fetus. Mammals with hemochorial placentas use this system, in contrast with other mammalian species that accrete iron by placental erythrophagocytosis.[40]

When the maternal iron status and fetal iron demand are normal, TfR-1 expression is inversely related to placental nonheme iron

content.[41] Placental nonheme iron is found largely in the form of ferritin in fetally derived cells, including Hofbauer cells. These macrophage-derived cells may constitute a form of placental iron storage, much as the Kupffer cells are major iron storage cells in the liver. Placental nonheme iron concentrations are closely correlated with cord blood serum ferritin concentrations and calculated total body storage iron at birth.[37] In clinical studies, the placental nonheme iron status (as well as the fetal storage iron content) correlates inversely with syncytiotrophoblastic TfR-1 expression in both iron-sufficient[41] and iron-deficient fetuses.[42] This finding suggests that increased fetal iron demand positively influences TfR-1 expression. In cell culture, the intracellular iron content of the syncytiotrophoblast determines TfR-1 expression on the apical membrane[19,43,44] by a mechanism that involves stabilization of TfR-1 mRNA.[17,22] Although the intracellular iron status of the syncytiotrophoblast has not been measured in clinical studies, it probably parallels the placental nonheme iron and fetal storage iron concentrations.

Fetal Iron Accretion and the Relationship of Maternal and Fetal Iron Status

The normal human fetus contains 70 to 75 mg of elemental iron per kilogram of body weight during the third trimester of gestation. This represents an accretion rate of 1.35 mg/kg of body weight between 24 and 40 weeks gestation. The iron is distributed in erythrocyte hemoglobin (50 to 55 mg/kg), liver, spleen, bone marrow, hemosiderin, and kidney storage ferritin (totaling 10 mg/kg) and nonstorage tissue iron such as hemoproteins and iron-sulfur proteins, (totaling 7 mg/kg) that are found in virtually all tissues.[1,2,45] The pregnant woman is the source of iron for the fetus, and the placenta is the delivery system. Pregnant women will require increased iron over amounts adequate for the nonpregnant state, especially during the second and third trimesters, characterized by significant fetal growth and maternal blood volume expansion.[46]

Conditions that reduce maternal-fetal iron transport, such as maternal iron deficiency anemia and placental vascular disease, and those characterized by increased fetal iron demand, such as chronic fetal hypoxemia, threaten the normal accretion and distribution of fetal iron. Neonatal iron status is a function of the duration of gestation, fetal sex, maternal iron status, efficiency of placental iron transport, and fetal iron demand. Fetal iron stores as indexed by cord serum ferritin concentrations increase with advancing gestational age.[47,48] A meta-analysis has determined that the mean ferritin concentration for term infants is 134 mcg/L, with 5th and 95th percentiles of 40 and 309 mcg/L, respectively. Preterm infants have lower values, with a mean of 115 mcg/L and 5th and 95th percentiles of 35 and 267 mcg/L, respectively. In term infants, ferritin concentrations are higher in females than in males.[49]

Fetal iron status correlates poorly with maternal iron status when the mother is iron-sufficient.[47] The fetus accretes iron against a concentration gradient through active transport by the syncytiotrophoblast, resulting in higher ferritin concentrations in the fetus than in the mother.[50] With progressive degrees of maternal deficiency, however, fetal iron stores initially are spared,[51] with compromise of those stores occurring later. Infants born to mothers with ferritin concentrations less than 10 mcg/L, but without iron deficiency anemia, have lower but nevertheless normal ferritin concentrations and normal hemoglobin concentrations.[52] Infants born to mothers with frank iron deficiency anemia have low cord blood ferritin and serum iron concentrations. Typically, the risk to the fetus increases when the maternal hemoglobin is less than 100 g/L.[53] These findings suggest that the fetus can accumulate iron normally in the face of maternal iron deficiency,[54] most likely through compensatory up-regulation of placental iron transport,[51] but

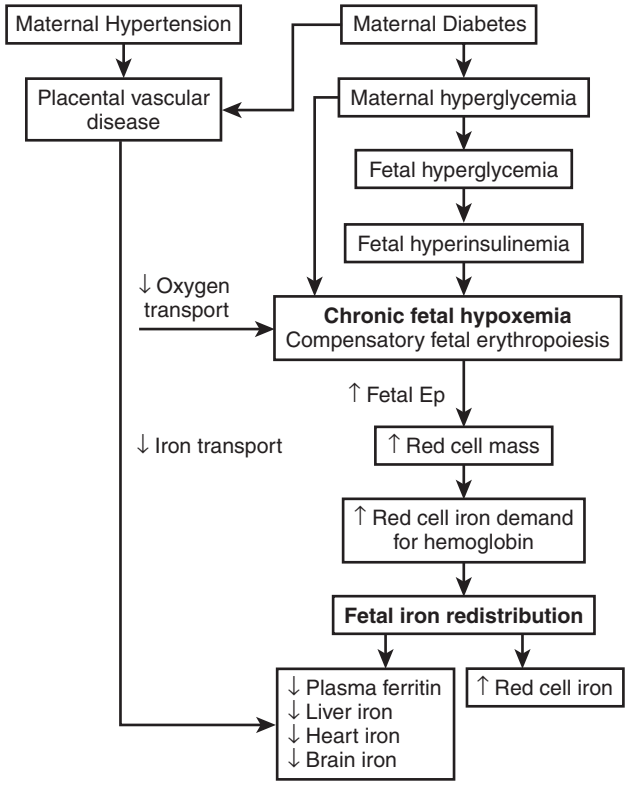

Figure 35-3 Pathophysiology of fetal iron deficiency in pregnancies complicated by maternal hypertension and diabetes mellitus. *(Modified from Petry CD, Eaton MA, Wobken JD, et al: Iron deficiency of liver, heart and brain in newborn infants of diabetic mothers,* J Pediatr *121:109-114, 1992.)*

with a threshold effect, so that during severe maternal iron deficiency, fetal iron status ultimately becomes compromised. The degree of nonheme (e.g., brain, heart) tissue iron depletion in the fetus resulting from severe maternal iron deficiency is unknown.

The fetus also can become iron-deficient despite maternal iron sufficiency in pregnancies characterized by placental vascular disease or in those in which increased iron demand exceeds placental transport capacity[9,35,55] (Figure 35-3). In both circumstances, the reduction in measured or calculated fetal iron stores reflects a true decrease in total body iron, not just an intrafetal redistribution of iron from liver stores into an expanded red cell mass.[9,52,53]

Several studies have shown an increased prevalence of reduced cord serum ferritin concentrations in pregnancies complicated by placental vascular disease,[10-12] most often associated with intrauterine growth restriction. Moreover, up to 50% of infants of appropriate size for gestational age born to mothers with preeclampsia also demonstrate ferritin concentrations below the 5th percentile for gestational age.[10] In an autopsy study of infants who died at birth after pregnancies complicated by uteroplacental vascular insufficiency, the hepatic iron concentrations were reduced by 62% compared with control subjects.[56] The reduction in hepatic iron is likely to reflect the lack of iron transport adequate to fill the iron storage pool. In a similar autopsy study of infants affected by intrauterine growth restriction secondary to Potter's syndrome, a reduction of brain iron by 33% was found.[57]

Increased fetal iron demand also can lead to abnormal iron distribution and iron deficiency at the tissue level. Fetal iron

demand increases most markedly when erythropoiesis is augmented by chronic fetal hypoxemia, especially when it is accompanied by rapid fetal growth. Clinically, this sequence commonly is seen during pregnancies complicated by diabetes mellitus.[58,59] An autopsy study of large-for-gestational-age infants born to diabetic mothers demonstrated that hepatic iron concentrations were 7% of those in control (normal) infants, implying complete depletion of the iron storage pool.[55] Brain and heart iron concentrations were reduced to 61% and 46% of control levels, respectively. The reduction in nonstorage tissue iron is consistent with conventional iron deficiency theory, in that storage iron must be reduced to less than 25% of normal before nonstorage tissue iron concentrations are compromised.[3]

The causes of tissue iron deficiency in pregnancies complicated by diabetes mellitus and chronic fetal hypoxia have been studied in animal models[60-62] (see Figure 35-3). Chronic fetal hyperinsulinemia and hyperglycemia, which are characteristic of poorly controlled diabetic pregnancies, result in increased fetal cellular oxygen consumption in a relatively oxygen-limited environment.[63,64] The resultant chronic fetal hypoxemia stimulates erythropoietin release with consequent expansion of the red cell mass by up to 40%.[9,60,65,66] The red cell mass may be further expanded by the rapid growth of the fetus with the attendant increase in the vascular volume.[59]

The hypoxic fetus has two potential sources for iron to supply this rapidly expanded red cell mass: increased maternofetal iron transport and mobilization of endogenous fetal hepatic iron stores. The latter has been demonstrated in both human[9,10,56,58,67] and animal studies.[60-62] When hepatic iron is depleted to less than 10% of control levels by chronic erythropoietic stimulation in fetal sheep, heart, brain, and skeletal muscle iron concentrations fall in direct proportion to the reduction in organ iron concentration[62] (Figure 35-4). The status of TfR-1 during diabetic pregnancies characterized by fetal iron deficiency also has been studied.[37,67] TfR-1 mRNA and IRP-1 activity both are increased by 40% in iron-deficient diabetic placentas, supporting the hypothesis that up-regulation is possible and probably is controlled by fetal iron demand.[67] However, the diabetic placenta cannot completely compensate the fetus through increased transport, in part because of the decreased binding affinity of TfR-1 for maternal transferrin secondary to hyperglycosylation.[68] The lack of compensation forces a redistribution of fetal iron toward the red cell mass and away from vital organs such as the heart and brain (see Figure 35-3).

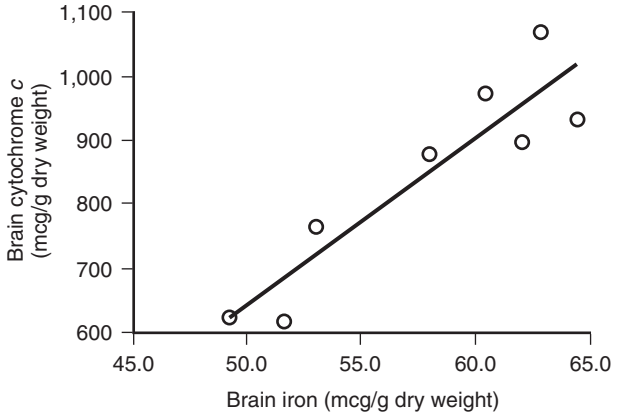

Figure 35-4 Brain cytochrome *c* concentration graphed as a function of brain iron concentration in chronically hypoxic, iron-deficient fetal sheep. $R = 0.91$; $y = -642.79 + 25.70x$; $P = .01$.

POSTNATAL IRON BALANCE

In general, iron deficiency in full-term infants during the first 2 postnatal months has been of minimal concern. An abundance of hemoglobin during fetal life generally ensures an adequate source of iron for the newborn as the red cell mass breaks down in postnatal life. This supply is likely to be particularly abundant if the infant has received a transfusion of red cells from the placenta because of delayed cord clamping. The higher Pa_{O_2} of postnatal life improves the oxygen-carrying capacity of the blood, eliminating the need for high hemoglobin concentrations; thus the first 6 to 8 postnatal weeks are characterized by declining hemoglobin concentrations with subsequent liberation of heme iron. Because this iron is not lost from the body, the healthy term newborn infant is well supplied with iron for the first 2 postnatal months. Thereafter, as the infant grows and the blood volume expands, the iron necessary for hemoglobin synthesis continues to be derived from the reticuloendothelial stores and from absorption of dietary iron. The estimated daily dietary iron requirement for the term infant is 1 mg/kg body weight/day,[69] but the percent absorption from the intestine varies inversely with the iron status of the individual infant.[70,71]

The serum ferritin concentration is a reasonable reflection of iron stores, with each 1 mcg/L of serum ferritin thought to represent 8 to 10 mg of stored iron.[70,71] Serum ferritin concentrations (and iron stores) are higher in newborn infants than in older infants, children, and adults. Full-term newborn infants have slightly higher ferritin concentrations (mean, 134 mcg/L; 5th to 95th percentile range, 40-309 mcg/L) than those measured in preterm infants born at less than 37 weeks of gestational age (mean, 115 mcg/L; 5th to 95th percentile range, 35 to 267 mcg/L) (48). Ferritin concentrations increase during the first postnatal month and then drop precipitously by the age of 6 months,[12,72,73] presumably as storage iron is used for the rapidly expanding blood volume of the growing infant.

Dietary iron is absorbed by the duodenum and proximal jejunum.[74] Absorption is modulated not only by iron need but also by the dietary source of the iron. Heme iron, in the form of hemoglobin and myoglobin, is enhanced by the ingestion of meat and inhibited by calcium. Nonheme iron, which represents the major portion of dietary iron, is absorbed more avidly in the presence of ascorbic acid. Its absorption is inhibited by calcium, phytates (found in soy protein–based formulas), manganese, and polyphenols.[74]

The iron content of breast milk is low compared with that of iron-fortified cow's milk formula, but its bioavailability is high, mostly because of the presence of lactoferrin, which enhances absorption through a species-specific brush border membrane receptor.[75] Iron absorption from human milk may approach or exceed 50%.[75] Lactoferrin concentrations are particularly high in colostrum and decline throughout each feed[76] and with increasing postnatal age.[77] Lactoferrin resists proteolytic digestion in the gut and thus remains largely intact.[78] Iron also is found in xanthine oxidase, a membrane-bound enzyme that accounts for up to 30% of total iron in human milk. Its biologic function is not completely understood, but it may be involved in energy generation.[79] A form of ferritin also is found in human milk; this form of ferritin, however, is unlikely to contribute much to the iron nutrition of the newborn because it is poorly saturated with iron.[80] Although studies assessing iron status of breast-fed infants are difficult to perform because of multiple confounding variables, the bulk of the data supports the concept that infants fed human milk exclusively for 6 months have normal iron status at 6 and 9 months[81] and have higher hemoglobin concentrations than those in infants fed iron-supplemented formula.[82] However, some breast-fed infants may be at higher risk for iron deficiency and iron deficiency anemia, including infants with low iron stores at birth[83] and infants exclusively breast-fed for more than

6 months,[84] particularly in the setting of maternal iron deficiency. This increased risk for iron deficiency may specifically reflect the rapidly declining iron content of breast milk after the age of 6 months. A double-blind, placebo-controlled trial of iron supplementation in breast-fed infants demonstrated higher hemoglobin concentrations, higher mean corpuscular volumes (MCVs), better visual acuity, and better motor development in the iron-supplemented groups,[85] suggesting that some breast-fed infants may become iron-deficient.

The bioavailability of iron from infant formulas is significantly lower than from human milk, accounting for the need for higher iron concentrations in infant formulas. Infant formulas fortified with at least 4 mg/L of iron are most likely to prevent depletion of iron stores and iron deficiency, although infants fed formulas with this amount of iron demonstrate lower ferritin and higher transferrin receptor concentrations than those measured in infants fed formulas with higher iron contents.[86] This observation suggests that 4 mg/L may be close to the minimum concentration of iron content that can support iron sufficiency. Most iron-fortified formulas in the United States contain 12 mg/L. Low-iron formulas are defined by the U.S. Food and Drug Administration (FDA) as containing less than 6.7 mg/L of elemental iron. Current iterations of low-iron formulas contain 4 mg/L of iron or more and appear to present sufficient dietary iron to the young infant who does not have additional risk factors for early iron deficiency. However, because no scientific evidence implicates dietary iron as a cause of common infant symptoms such as colic, constipation, or diarrhea, no compelling reason to feed infants low-iron formulas has been emerged.[87,88] One formula manufacturer has never marketed a low-iron formula, whereas another formula manufacturer in the United States has eliminated low-iron formula from production. Most term infants fed human milk or iron-fortified infant formulas maintain normal iron balance during the first postnatal year.

The iron status of the preterm infant is more labile than that of the term infant. Placental iron transport begins during the first trimester, but two thirds of maternal-fetal iron transfer occurs during the third trimester,[1,2,46] resulting in low iron stores in preterm infants. Preterm infants with intrauterine growth restriction are at risk for further reductions in iron stores owing to placental insufficiency and poor placental iron transfer. In an autopsy study, preterm growth-restricted infants were found to have 40% of normal liver iron concentrations for age.[56]

For all preterm infants, not only are iron stores at birth lower, but postnatal estimated daily iron needs per kg of weight are greater than those in full-term infants, based on estimates of third-trimester fetal iron accretion.[1,2,69] The iron balance of preterm infants can be markedly affected by the management of their hematologic status (i.e., whether they receive red cell transfusions or recombinant human erythropoietin). Iron intake can be compromised because of delayed onset of enteral feedings and a reluctance to give intramuscular or intravenous iron.

Preterm infants undergo a phase of relative anemia (anemia of prematurity), characterized by decreasing hemoglobin concentrations, low reticulocyte counts, and reduced rates of growth. Whether this anemia is due to low rates of erythropoietin synthesis, reduced bone marrow sensitivity to erythropoietin, or lack of iron availability to the bone marrow is a subject of investigation. Evaluation of iron deficiency in preterm infants is difficult, but a growing body of evidence suggests that iron deficiency may contribute to the magnitude and duration of anemia of prematurity. As early as 1977, Lundstrom and associates[89] demonstrated that iron supplementation of preterm infants at 2 weeks of age resulted in a lower incidence of anemia at 3 months of age. Hall and colleagues[90] demonstrated that preterm infants (birth weight less than 1800 g) fed a high-iron (15 mg/L) preterm infant formula had a lower incidence of anemia (hemoglobin less than 9 g/dL) and better iron status at discharge than did infants fed a low-iron formula (3 mg/L). Most recently, Miller and colleagues[91] noted that provision of iron to hospitalized preterm infants (3 to 12 mg/kg/day) resulted in a decrease in the zinc protoporphyrin–heme ratio (ZnPP/H) in treated versus untreated control infants. Because zinc substitutes into protoporphyrin when iron supplies are limited, these data suggest that preterm infants' needs for supplemental iron may be greater than was previously recognized. In previous eras, supplemental iron was administered indirectly through repeated blood transfusions of preterm infants. Many neonatologists now use restricted red blood cell transfusion protocols, and the number of transfusions per infant has declined in recent years.[92] The unintentional effect of this change in management is to decrease the provision of iron to preterm infants, so a fresh look at the iron requirements of preterm infants is needed.

The use of erythropoietin in preterm infants also results in increased iron requirements. Trials of recombinant human erythropoietin to prevent or modify the anemia of prematurity have shown that the young preterm infant is capable of mounting a modest erythropoietic response.[93-95] The stress of augmented erythropoiesis on the iron axis of the preterm infant is considerable[94] and may be rate-limiting in the erythropoietic response.[96] Because these infants receive fewer red cell transfusions, their total body iron is likely to be reduced, and their reliance on exogenous iron is increased.[93] Infants treated with recombinant human erythropoietin require at least 6 mg/kg/day to maintain adequate serum ferritin concentrations.[97] Low-birth-weight infants absorb approximately 30% to 40% of enterally delivered iron regardless of iron status,[98] although the percent of absorbed iron incorporated into hemoglobin varies with the degree of erythropoietic pressure. To this end, Widness and colleagues[99] measured ^{58}Fe incorporation into red blood cells after administration of recombinant erythropoietin to preterm infants and found much higher rates of incorporation in the treated group than in the untreated control group during the first 4 weeks of therapy.

The current recommendation for iron intake for preterm infants is 2 to 4 mg/kg/day.[100] Commercially available iron-fortified preterm formulas contain 1.8 mg Fe/100 calories. An iron-containing human milk fortifier is available that contains 1.44 mg in 4 packets (used to fortify 100 mL of human milk). Use of either preterm formula or fortified human milk at 120 kcal/kg/day will provide preterm infants with the low end of recommended iron intake when goal feedings have been achieved.

After discharge, iron intakes of 2 mg/kg/day are recommended through the first year of life.[100] Breast-fed infants may meet this requirement through the use of multivitamin supplements with iron, which provide 10 mg/mL of iron. However, most infants will outgrow this dose before supplemental foods (such as cereal) are added. Formula-fed infants meet this requirement when taking in 120 calories/kg of body weight. Formula intakes drop over the first 6 months, however, and iron intakes may be low during that time. Some evidence indicates that younger preterm infants may develop iron deficiency anemia[101] before the age of 6 months, and evaluation of hemoglobin is recommended at 4 months postnatal age.

CONSEQUENCES OF FETAL AND NEONATAL IRON DEFICIENCY

The nonhematologic consequences of fetal and neonatal iron deficiency have only recently been considered. When fetal iron is in short supply (as with maternal iron deficiency anemia or uteroplacental insufficiency) or when fetal iron demand is increased (as with chronic fetal hypoxemia), prioritization of available fetal iron will occur. This prioritization takes place among organs and among iron-containing compounds within organs.

The prioritization of iron among organs in postnatal iron deficiency has been well established.[3,4] Typically, hepatic storage iron is depleted before nonstorage tissue iron. Among nonstorage

organs, the erythron, brain, and heart have priority over skeletal muscle and the gastrointestinal tract. A similar pattern appears to exist in utero. In severely iron-deficient newborn infants of diabetic mothers, liver iron is depleted first. Heart and brain iron concentrations decrease only after hepatic iron is less than 25% of normal.[55] A similar relationship exists between liver and brain iron in the iron-deficient perinatal rat.[102] In fetal sheep, chronic erythropoietic stimulation causes reductions in heart, skeletal muscle, and brain iron concentrations to preserve and expand the red cell mass.[62]

Prioritization of iron-containing proteins within an individual organ such as the heart also occurs when placental iron transport is inadequate to meet fetal demand. As with interorgan iron redistribution, preservation of oxygenation has the highest priority. Fetal guinea pigs subjected to both chronic hypoxemia and a decreased maternal iron supply exhibit reduced fetal myocardial iron concentrations.[103] All iron-containing myocardial proteins are not, however, uniformly or proportionately affected. Under conditions of chronic fetal hypoxia and iron deficiency, myocardial myoglobin has high priority in the utilization of iron and is preserved or even elevated despite cellular iron depletion. This preservation of myoglobin compensates for decreased oxygen delivery and improves intracellular oxygen transport in the fetal heart. By contrast, cytochrome *c* decreases in direct proportion to organ iron content, suggesting an intermediate priority.[103] Other nonheme iron proteins such as cellular ferritin are likely to occupy a low priority for myocardial iron utilization in an iron-depleted fetus and are reduced out of proportion to the degree of tissue iron deficiency. Whether this interorgan redistribution of iron occurs in other fetal organs is not known.

The physiologic consequences of fetal and neonatal iron deficiency are based on principles elucidated from postnatal iron deficiency models.[3-6] Potential short-term and long-term effects must be considered for each of the organ systems involved during fetal and postnatal life.

No direct physiologic effects of reduced hepatic storage iron are known. Nevertheless, infants born with low iron stores (infants of diabetic mothers, infants with intrauterine growth restriction) are likely to be at higher risk for postnatal iron deficiency, particularly if the low stores are not due to sequestration of iron in an expanded red cell mass. Thus infants with low serum ferritin concentrations and normal or low hemoglobin concentrations at birth may be at highest risk for later iron deficiency. A group of newborn infants with low umbilical cord blood ferritin concentrations were found to have persistently lower serum ferritin concentrations at 9 months of age.[83]

The physiologic consequences of a postnatal deficiency in cardiac and skeletal muscle iron are well described.[4-6] Myopathies of both organ systems are characterized by decreased contractile force and easy fatigability, contributing to the clinical picture of weakness and lethargy. The biochemical basis for these findings is unknown, although it has been speculated that reduced cytochrome *c* concentrations result in decreased ATP generation, and that reduced myoglobin levels result in reduced oxygen delivery and greater dependence on anaerobic glycolysis. Blayney and coworkers[5] demonstrated decreased mitochondrial *c* content and respiratory function in iron-deficient heart muscle. Similarly, Mackler and associates[6] showed reduced rates of oxidative metabolism in iron-deficient rat skeletal muscle. These findings are clearly independent of the presence and degree of anemia. Furthermore, although newborn infants of diabetic mothers frequently are lethargic and cardiomyopathic, the role of iron deficiency in these conditions has not been defined. The possibility exists that the inability of iron-deficient tissue to withstand hypoxic and hypoglycemic stress contributes to the higher rates of fetal distress and intrauterine death seen in diabetic pregnancies.

The biochemical, anatomic, and neurochemical effects of perinatal brain iron deficiency have been characterized in rat and sheep models. Chronic intrauterine hypoxia in fetal sheep results in reduced brain iron concentrations.[62] Brain cytochrome *c* concentrations parallel the reduction in brain iron (see Figure 35-4). Perinatal iron deficiency in the rat causes reduced oxidative metabolism in the hippocampus and frontal cortex, elevated intracellular glutamate concentrations, reduced dopamine concentrations in the striatum, altered fatty acid profiles, and central nervous system hypomyelination.[102,104-106] Development of the brain is impaired, with truncation of dendritic branching, particularly in the hippocampus.[107] Rodents show behavioral deficits consistent with targeted areas of the brain including trace recognition memory, procedural memory, and spatial navigation. These effects last well beyond the period of iron deficiency, suggesting the possibility of long-term iron deficiency–induced alterations in brain structure and function.[108-112] The effects on energy metabolism, dendritic structure, monamine metabolism, and myelination all appear to work together to alter brain processing, particularly in memory domains.

Growth-restricted infants, infants of poorly controlled diabetic mothers, and preterm infants are clearly at increased risk for poorer long-term developmental outcomes.[113,114] Although the etiology of cognitive impairments in these groups of children is likely to be multifactorial, the relationship of developmental outcomes to perinatal iron status may be of importance, because an iron-deficient brain may be less likely to tolerate hypoxic or hypoglycemic events.[115] Only a few studies have evaluated perinatal iron status and development, but their findings suggest that areas of the brain affected in animal models may map onto behavioral and neurophysiologic abnormalities seen in human infants. For example, in animal models of maternal diabetes, brain iron stores are depleted from portions of the developing explicit memory system as well as from areas that are important for emotion,[116] including the hippocampus and other medial temporal lobe structures. The hippocampus and the hippocampus-dependent memory system develop very early in humans,[117] and recognition memory has been demonstrated in the newborn infant[118-120] using behavioral and neurophysiologic methods of evaluation. In one study, a neurophysiologic technique known as event-related potentials was used to study infants of diabetic mothers with and without perinatal iron deficiency (defined as an umbilical cord blood ferritin level less than 35 mcg/L).[121] Neurophysiologic manifestations of maternal voice recognition were intact in infants of diabetic mothers with normal iron status, but not in infants with perinatal iron deficiency, who demonstrated markedly attenuated responses. At the age of 1 year, infants with perinatal iron deficiency also had lower motor quotients than those in infants with normal iron status.

Wachs and colleagues[122] investigated the relationship between neonatal iron status and temperament development. Iron deficiency results in alterations in areas of the brain such as the amygdala and in neurotransmitters such as dopamine and serotonin[102] that are important in emotional processing. Neonatal anemia, low serum iron levels, and low ferritin levels were associated with higher levels of negative emotionality and lower levels of alertness and soothability, even after adjustment of data for confounding factors.

These two studies evaluated specific aspects of neurodevelopmental function that have been linked to iron deficiency in animal models. Global neurodevelopmental function also has been studied. Armony-Sivan and colleagues[123] evaluated the early development of neurologic reflexes in preterm infants (born before 34 weeks gestation) who were medically stable but anemic with or without low ferritin. Their study found a higher incidence of abnormal reflexes among infants who were anemic with low ferritin concentrations than among nonanemic infants. The findings were thought to be consistent with poor myelination of the brain. Tamura and colleagues[49] reported findings from a large study correlating umbilical cord serum ferritin

concentrations and results of cognitive testing at 5 years of age. Infants in the lowest quartile of umbilical cord ferritin concentration (less than 76 mcg/L) had poorer scores of language comprehension, fine motor skills, attention, and tractability than those in children with umbilical cord ferritin concentrations in the two median quartiles. Taken together, these studies seem to indicate that animal models can be used to reveal areas of the brain affected by perinatal iron deficiency that are consistent with findings in human infants. The long-term development of the brain after perinatal iron deficiency and the potential for behavioral recovery with nutritional mediation have not been adequately evaluated, however.

POTENTIAL IRON TOXICITY IN THE FETUS AND NEONATE

Iron deficiency is not the only iron-related problem that may affect the developing human. The newborn infant also is at risk for iron toxicity due to free radical formation. Newborn infants are considered to be at particular risk for oxidant injury as a consequence of immature antioxidant systems (e.g., vitamin E, selenium, superoxide dismutase) and increased sensitivity of rapidly growing tissues to free radicals.[16] The vitamin C system appears to mature after the age of 2 weeks, so antioxidant abilities improve thereafter.[124] Free radical formation is less likely to occur when iron is tightly bound and hidden by the three-dimensional protein structure of hemoglobin, myoglobin, transferrin, or ferritin. Non–protein-bound or loosely bound iron, however, can generate free radicals through the Fenton reaction, potentially resulting in serious tissue damage from the effects of oxidant stress on cell membranes.[125] Because newborn infants have low levels of iron-binding proteins, rapid infusions of iron may result in oversaturation of the iron-binding capacity, potentially resulting in liberation of free serum iron. Finally, newborn infants are prone to hypoxic-ischemic events, which may result in tissue reperfusion. Tissue reperfusion after hypoxia-ischemia potentiates the likelihood of the Fenton reaction and, consequently, the possibility of iron-related oxidant activity. Indeed, iron deposition has been noted in perivascular areas of the brain associated with neuronal loss in animal models of hypoxia-ischemia.[126] For these reasons, newborn infants are thought to be at particular risk for iron toxicity.

Although these considerations have raised considerable concern about the oxidant properties of iron, only indirect evidence is suggestive of clinical effects of possible iron toxicity in newborn infants. In theory, the highest-risk situation would arise with rapid intravenous boluses of iron, either via parenteral iron infusions or by transfusions of senescent blood cells that hemolyze and release iron. Blood transfusions have been associated with increased free iron levels and an increased risk of chronic lung disease in preterm infants.[13] These findings were not associated with lipid peroxidation; accordingly, the study investigators were not able to provide evidence that blood transfusions result in oxidative injury to the lung.

Regarding the use of oral iron supplements, it is possible that high doses of enteral iron may be sufficient to result in non–protein-bound serum iron and oxidative stress. Investigation on this topic has been minimal, but the available research suggests that current doses of iron given to preterm infants do not result in oxidant stress. Early supplemental iron given during treatment with erythropoietin was not associated with increased malondialdehyde in plasma or F-2 isoprostanes in urine.[127] Miller and colleagues[91] gave 3 to 12 mg/kg of enteral iron sulfate daily to hospitalized preterm infants and found no change in blood and urine isoprostanes, nor did they find any relationship between the iron sulfate dose and the isoprostane levels.

Overall, the relationship among iron toxicity, markers of oxidant stress, and organ damage in preterm infants has been inadequately studied to date. The available evidence, however, suggests that current practices for blood transfusion and oral iron supplementation appear to be safe.

A related consideration is iron overload in the newborn infant. Primary iron overload occurs in the hereditary hemochromatosis syndromes, which are not seen in the newborn infant and are rare even during childhood. Neonatal hemochromatosis previously was thought to be a syndrome of primary iron overload. However, the biochemical abnormalities found in neonatal hemochromatosis also have been shown to occur nonspecifically in severe liver disease, and the patterns of organ injury in neonatal hemochromatosis are not consistent with juvenile or adult forms of hemochromatosis.[128] Although the full-blown disease generally is fatal, a few survivors have been described who have resolution of their liver disease and who do not have ongoing manifestations of hemochromatosis. It is now postulated that iron deposition is a consequence rather than a cause of the liver disease. According to some evidence, the primary inciting factor in many patients may be an alloimmune process targeting an antigen present on fetal hepatocytes. Intravenous immune globulin has been given to fetal siblings conceived after the birth of an affected infant. Nearly all treated infants have shown biochemical evidence of neonatal hemochromatosis but with an apparent reduction in clinical symptoms and no deaths.[129]

Secondary iron overload syndromes have been described in several case reports in which infants with Rh disease had undergone multiple fetal transfusions.[130,131] The affected infants showed severe liver disease, marked elevation of serum ferritin concentrations, and iron overload on liver biopsy. Resolution of symptoms was reported after treatment with desferroxamine.

Despite the number of transfusions received by many premature infants, no cases of secondary iron overload have been reported in the literature. An autopsy study of infants receiving multiple blood transfusions revealed significant correlations between hepatic iron concentrations, volumes of blood transfused and antemortem serum ferritin concentrations, but clinical manifestations of iron overload were not observed in any infants.[132]

CONCLUSION

Iron sufficiency is important for normal growth, development, and function of fetal and neonatal organ systems. The regulation of maternofetal iron transport and intracellular iron accretion and storage continues to be investigated. Certain pregnancy subgroups are associated with an increased risk for fetal and neonatal iron deficiency, either because of inadequate maternal-fetal iron transport, in the case of maternal anemia or intrauterine growth retardation, or because of excessive iron demand, as seen in diabetic pregnancies. In the neonatal period, preterm infants treated with recombinant human erythropoietin and receiving fewer red cell transfusions appear to be at greatest risk for early depletion of iron stores. Iron excess also may play a role in certain neonatal disease processes through peroxidation of lipid membranes. The physiologic consequences of iron imbalances in all of these settings are important to document.

36 Neonatal Calcium, Phosphorus, and Magnesium Homeostasis

Ran Namgung and Reginald C. Tsang

BODY DISTRIBUTION

Calcium

Calcium is the most abundant mineral in the body and the major inorganic constituent of bone. An adult human body contains approximately 1 to 2 kg of elemental calcium.[1] In term newborn infants, the total-body calcium content is approximately 30 g,[1] most of which (approximately 80%) accrues during the last trimester of pregnancy at a rate of up to 150 mg/kg of fetal weight/day.[2]

At all ages, 99% of total-body calcium is either in bone in the form of hydroxyapatite, integrally associated with collagen fibrils and other components of bone matrix, or in a noncrystalline, amorphous calcium phosphate form (a predominant form in early life).[3] One percent of total-body calcium is contained in the extracellular fluid (ECF) and soft tissues. The calcium of the mineral phase (at the surface of the crystals) is in equilibrium with that in the ECF, but only a minor portion of the skeletal content (approximately 1%) is freely exchangeable with the ECF calcium.[4] Although this exchangeable pool represents a small percentage of skeletal content, it is approximately equal to the total content of calcium in the ECF and soft tissues and serves as a reservoir of calcium. In children 3 to 16 years of age, the size of this total exchangeable pool (TEP) of calcium, measured using stable isotope technique, correlates with age independent of variations in body weight. Bone calcium accretion rate (V_0^+) and the V_0^+/TEP ratio are greater in children than in adults, indicating higher rates of Ca^{2+} flux associated with relatively higher exchangeable calcium pools in children than in adults.[5]

The calcium in plasma is in three forms: as the free ion, Ca^{2+} (50% of total plasma content); bound to plasma protein (40% of total calcium, of which 80% is bound to albumin and the remainder to globulins); and, to a small extent (approximately 10%), as diffusible complexes (complexed with bicarbonate, phosphate, or citrate).[6] Complexed and free (ionized) forms of calcium also are termed *ultrafiltrable* calcium (or non–protein-bound calcium), so that approximately 60% of total calcium in plasma crosses semipermeable membranes. Calcium binding to proteins is reduced at acid pH. Alterations in the concentration of serum albumin can exert a major influence on the measured total serum calcium and ionized calcium concentrations. The serum ionized calcium concentration decreases significantly with addition of serum albumin. Thus a fast infusion of albumin in the human neonate has the potential for acutely lowering the serum ionized calcium concentration.[7] Free calcium—that is, ionized calcium—is the only physiologically active fraction in blood.

Ionized calcium influences many cellular functions and is subjected to tight hormonal control, especially through parathyroid hormone (PTH). Although changes in ionized calcium frequently are reflected in changes in total calcium, and a general correlation exists between serum total calcium and serum ionized calcium, total calcium can be a poor predictor of a specific ionized calcium value, especially in neonates. The ionized calcium can be measured directly with the use of ion-selective electrodes,[8] using capillary blood in newborn infants.[9,10] Several factors, however, may affect ionized calcium determination: Higher ionized calcium values are recorded with the ICA-1 Radiometer than with the Orion SS20 electrode; ionized calcium may be decreased proportional to the concentration of heparin used as anticoagulant; and ionized calcium concentrations vary inversely with blood pH. The serum sample should be analyzed immediately or, alternatively, placed in 5% carbon dioxide–containing tubes and frozen, to minimize pH variations.[11]

Ca^{2+} inside the cell mediates a variety of cellular functions. Most of the cellular calcium is in the form of insoluble complexes (99%) at a concentration of approximately 1×10^{-6} M of cell water. Free calcium (1%) within the cell, which is critical for functional regulation, is present in lower concentrations, approximately 2.5×10^{-7} M.[12] The gradient between plasma and intracellular free calcium is approximately 10,000:1[13] and is tightly regulated.

The Ca^{2+} concentration in the ECF is kept constant by processes that constantly feed calcium into and withdraw calcium from the ECF. Calcium enters the plasma by absorption from the intestinal tract and by resorption of ions from bone. In conditions of calcium balance, rates of calcium release from and uptake into bone are equal. In normal adults, the total serum calcium concentration ranges from 2.2 to 2.6 mmol/L (8.8 to 10.4 mg/dL) and is remarkably constant. The ionized calcium concentration, although subject to changes directed by PTH, calcitonin, vitamin D, and blood pH, also is stable within an individual patient over prolonged periods and ranges from 1.2 to 1.3 mmol/L (4.8 to 5.2 mg/dL).[8]

At birth, an abrupt termination of the maternal-to-fetal calcium supply occurs. To maintain serum calcium homeostasis at this time, it is estimated that an increase of 16% to 20% in calcium flux from bone to extracellular space is required, unless sufficient exogenous intake is achieved.[14] In term newborn infants, cord blood total calcium concentrations are 2.6 mmol/L (10.2 mg/dL), and ionized calcium concentrations are 1.5 mmol/L (5.8 mg/dL).[15] By 2 hours of age, serum total calcium declines by 5%, and by 24 to 36 hours, serum calcium reaches its nadir of 2.3 mmol/L (9.0 mg/dL) for total calcium and 1.2 mmol/L (4.9 mg/dL) for ionized calcium[15] (Table 36-1). After a period of stabilization, serum calcium concentration slowly rises, reaching levels by 1 week of age similar to those found in childhood[16] (Table 36-2). In preterm infants, the mean cord serum ionized calcium concentration is 1.45 mmol/L (95% confidence interval [CI], 1.29 to 1.61 mmol/L), or 5.8 mg/dL (CI, 5.74 to 5.86 mg/dL]), which decreases during the first 24 to 36 hours of life and subsequently rises at approximately 6 days of age to values that exceed original cord blood concentration.[16,17] The early fall in ionized calcium levels may be associated with parathyroid glandular unresponsiveness secondary to prematurity[18] or hypomagnesemia,[19] and severe hypocalcemia may result. Very-low-birth-weight infants are likely to exhibit the lowest nadirs of ionized calcium; in most cases, however, low levels are unassociated with tetany or decreased cardiac contractility.[20,21]

Cord serum calcium concentrations differ by season of birth (being lower in summer-born than in winter-born infants)[22] and may vary in accordance with mode of delivery (lower for elective

cesarean section without labor than for elective cesarean section with labor, spontaneous vaginal delivery, or emergency cesarean section).[23] Cord serum calcium concentrations are unaffected by gender, race, or weight appropriateness for gestation.[24]

Phosphorus

Phosphorus is a major component of bone and of all other tissues and, in some form, is involved in almost all metabolic processes. The total amount of elemental phosphorus in normal adults is approximately 1 kg.[1] In term newborn infants, total-body phosphorus content is approximately 16 g.[1] As with calcium, approximately 80% of the phosphorus contained in term newborn infants is accumulated during the last trimester of pregnancy at a rate of approximately 75 mg/kg of fetal weight/day and is closely linked to the accretion of calcium, with a calcium-phosphorus ratio of 1.7:1.[1,2]

Approximately 85% of total-body phosphorus is in bone, primarily as hydroxyapatite but also found as more loosely complexed amorphous forms of bone crystal,[3] so phosphorus plays a key structural role in bone. In contrast to Ca, phosphorus is widely distributed in nonosseous tissues both in inorganic form and as a component of various structural macromolecules. Approximately 15% of total-body phosphorus is present in the ECF, largely in the form of inorganic phosphate ions, and in soft tissues, almost totally in the form of phosphate esters. Intracellular phosphate esters and phosphorylated intermediates are involved in a number of important biochemical processes, including the generation and transfer of cellular energy.

The phosphorus in body fluids is divided between an organic fraction, composed of phospholipids and phosphoesters, and inorganic phosphate (P_i). The latter comprises two ionic forms, monovalent $H_2PO_4^-$ and divalent HPO_4^{2-}. Divalent HPO_4^{2-} is the major ionic species of phosphorus in serum at pH 7.4. Serum P_i also exists as three fractions: ionized (approximately 55%); protein-bound (11%); and complexed to sodium, calcium, and magnesium (approximately 34%).[6] Approximately 90% of the P_i in plasma is ultrafiltrable. In contrast with calcium, only a small portion (11%) is protein-bound.[6] The intracellular and extracellular concentrations of ionized phosphorus (HPO_4^{2-}) are 1×10^{-4} M and 2×10^{-4} M, respectively.[12] Because so many phosphorus species are present, depending on pH and other factors, it is the convention to express concentrations in terms of mass of elemental phosphorus (i.e., mmol/L or mg/dL). In contrast with the calcium concentration, the serum phosphorus concentration varies quite widely, exhibits daily variations of as much as 50%, and is influenced by age, gender, diet, pH, and a variety of hormones. An adequate serum phosphorus concentration is important in maintaining a sufficient ion product (with calcium) for normal mineralization.[25]

Serum total phosphorus concentrations are higher in children than in adults. Adult concentrations may vary, with a normal range of 1.24 to 1.86 mmol/L (3.0 to 4.5 mg/dL). At birth, the infant's serum phosphorus concentrations are relatively low in comparison with older newborn or childhood values. In normal term infants born at a weight appropriate for gestational age, cord serum phosphorus concentrations do not differ by gender, race, season of birth,[22] weight appropriateness for gestation,[24] or mode of delivery.[23] The relatively low initial values, 2.6 mmol/L (range, 1.5 to 3.4 mmol/L), equivalent to 6.2 mg/dL (3.7 to 8.1 mg/dL), begin to rise shortly after birth. The reason for this acute rise is not well understood. The rise may be due to increased gluconeogenesis and endogenous phosphorus release or secondary to a low glomerular filtration rate and reduced phosphorus excretion. Mean serum phosphorus concentrations increase to 3.4 mmol/L (8.1 mg/dL) by 1 week of age and decrease to 1.7 mmol/L (4.1 mg/dL) in childhood.[26]

TABLE 36-1

Serum Concentrations of Total and Ionized Calcium in Term Infants During the First 24 Hours of Life

	SERUM CONCENTRATION: mg/dL*	
Age	Total Calcium	Ionized Calcium
Birth (cord blood)	10.2 (9.0-11.4)	5.82 (5.22-6.42)
2 hr	9.7 (8.5-10.9)	5.34 (4.84-5.84)
24 hr	9.0 (7.8-10.2)	4.92 (4.40-5.44)

Magnesium

Magnesium is the second most abundant intracellular divalent cation in the body. Adult humans contain approximately 27 g of elemental magnesium.[1] In term newborn infants, the total-body magnesium content is approximately 0.8 g,[1] and approximately 80% of this is accrued during the last trimester of pregnancy at a rate of approximately 3 mg/kg of fetal weight/day.[2]

Magnesium is distributed in three major compartments in the body: Approximately 65% of the total-body magnesium is contained in bone in crystalline form, 34% in the intracellular space complexed with nucleic acid and protein, and only 1% in the

TABLE 36-2

Serum Calcium, Inorganic Phosphorus (P_i), and Magnesium Concentrations in Term Infants Younger Than 6 Months of Age

		SERUM CONCENTRATION: mg/dL*			
		CALCIUM			
Age	Type of Feeding	Free	Ionized	P_i	Magnesium
2 wk	Human milk	10.1 (9.1-11.1)	3.8 (3.6-4.0)	4.2 (3.4-5.0)	
	Human milk + vitamin D	9.9 (9.1-10.7)	3.8 (3.6-4.0)	5.1 (4.5-5.7)

Modified from Roberts CC, Chan GM, Folland D, et al: Adequate bone mineralization in breast-fed infants, *J Pediatr* 99:192, 1981; and Specker BL, Lichtenstein P, Mimouni F, et al: Calcium-regulating hormones and minerals from birth to 18 months of age: A cross-sectional study. II. Effects of sex, race, age, season, and diet on serum minerals, parathyroid hormone, and calcitonin, *Pediatrics* 77:891, 1986.

ECF.[27] Magnesium in bone is not an integral part of the hydroxyapatite lattice structure but appears to be located on the crystal surface. Only a minor fraction of magnesium in bone is freely exchangeable with extracellular magnesium. In infants aged 4 to 11 months, the calculated apparent magnesium exchangeable pool size, measured using the stable isotope ^{25}Mg, ranges from 5.5 to 7.6 mmol/kg of body weight and diminishes with age.[28] Because only 1% of the total-body magnesium is located in the extracellular space,[29] the plasma concentration does not consistently provide a reliable index of either total-body or soft tissue magnesium content.

The magnesium in plasma exists in three forms: as free ion (55%), bound to plasma protein (30%), and complexed to various anions such as phosphate and oxalate (15%).[29] About 70% of the total magnesium is ultrafiltrable and freely filtered at the renal glomerulus.[30] The protein-bound fraction interacts with carboxyl groups of albumin and is influenced by pH in a fashion analogous to that for calcium. The ionized fraction of magnesium is physiologically important (e.g., to plasma membrane excitability).

In contrast with the low concentrations of intracellular calcium, the concentration of free magnesium ions (Mg^{2+}) is 5×10^{-4} M in the cytosol, and this concentration is rigidly maintained and stable.[12] This stability is a reflection of the many critical roles that magnesium plays in cellular metabolism. Cellular magnesium is important as a cofactor for a number of enzymatic reactions and in regulation of neuromuscular excitability.

The serum concentration of magnesium is maintained within relatively tight limits and is essentially the same for neonates, infants, children, and adults, with a normal range of 0.62 to 1.16 mmol/L (1.5 to 2.8 mg/dL).[31] In the cord blood of normal term infants, cord serum magnesium concentrations are 0.68 (0.6 to 0.76) mmol/L (1.6 [1.45 to 1.83] mg/dL) and do not vary by gender, race, season of birth,[22] appropriateness of weight for gestation,[24] or mode of delivery.[23] Serum ionized magnesium concentrations in cord blood appear to be higher in large for gestational age infants and higher in the umbilical vein than in the umbilical artery (the latter values being similar to maternal venous levels).[32] Preterm infants born at the eighth month of gestation have cord serum magnesium concentrations similar to those of the term infant, with a mean of 0.81 (0.59 to 1.0) mmol/L (1.95 [1.43 to 2.45] mg/dL).[33] After birth, both term and preterm infants initially exhibit a decrease in serum magnesium concentrations. At 48 hours of life, serum magnesium concentrations reach mean concentrations of 0.77 mmol/L (1.87 mg/dL).[33] Subsequently, serum magnesium increases over the first week of life, followed by a decline toward childhood values by the end of the first month[34] (see Table 36-2).

Ionized magnesium concentration varies in several neonatal conditions: It is increased in neonatal hyperbilirubinemia,[35] acidosis,[36] and preterm respiratory distress syndrome (RDS).[37] Plasma Mg^{2+} concentration was significantly higher in term infants with severe hyperbilirubinemia (total bilirubin concentration of 304 ± 83.3 μM) than in infants with moderate hyperbilirubinemia (bilirubin level of 94.1 ± 54.7 μM): 0.6 ± 0.12 versus 0.49 ± 0.1 mmol/L. Increase in plasma ionized magnesium also may be due to extracellular movement of Mg^{2+}, a principal intracellular ion, resulting from generalized cellular injury.[35] Cord Mg^{2+} was significantly increased in infants with acidosis (umbilical arterial cord pH 7.0) over that in both preterm and term control infants (umbilical arterial cord pH 7.3), with values of 0.58 versus 0.51 and 0.49 mmol/L, and declined significantly 2 hours after delivery to 0.49 mM, whereas control infants showed constant Mg^{2+} concentrations during the observation period.[36] In preterm infants with RDS, plasma Mg^{2+} concentration is significantly higher than in infants without RDS (0.8 versus 0.57 mmol/L); and within the study group, significant negative correlations were found between plasma Mg^{2+} levels and values for umbilical cord arterial pH ($r = -0.621$) and base excess ($r = -0.746$), whereas no correlations were observed in the control group. The newborns who died later had significantly higher plasma Mg^{2+} levels than those in infants who survived (0.89 versus 0.63 mmol/L). From these data, it is suggested that increase of plasma Mg^{2+} may be due to extracellular movement of Mg^{2+} as a result of acidosis, hypoxia, and probable cellular injury during the early course of RDS.[37]

REGULATION OF SERUM CONCENTRATION

Calcium

The homeostasis of calcium in blood is maintained primarily through the interaction of three hormones—PTH, calcitonin, and vitamin D—and their actions on the gastrointestinal tract, kidney, and bone.

Parathyroid Hormone

PTH is a peptide hormone produced in the parathyroid glands. Under normal circumstances, a decrease in the serum ionized calcium concentration stimulates production and secretion of this hormone.[38] PTH, in turn, acts directly on bone, stimulating resorption, thereby releasing calcium and phosphorus into the ECF and the circulation. PTH also acts directly on the kidney to increase urinary excretion of phosphorus (which removes the phosphorus released into the circulation by its bone action) and decreases the urinary excretion of calcium. PTH indirectly enhances the gastrointestinal absorption of calcium through its effects on synthesis of 1,25-dihydroxyvitamin D (1,25-$[OH]_2$D).[39]

The integrated actions of PTH on bone resorption, distal renal tubular calcium reabsorption, and 1,25-$(OH)_2$D–mediated intestinal calcium absorption are responsible for the fine regulation of the serum ionized calcium concentration. The precision of this integrated control is such that in a normal person, the serum ionized calcium level probably fluctuates by no more than 0.025 mmol/L (0.1 mg/dL) in either direction from its normal set point value throughout the day. Osteoclastic bone resorption and distal tubular calcium reabsorption are the major control points in serum calcium homeostasis; of these two processes, the effect of PTH on the distal tubule is quantitatively the most important. Together, these effects of PTH on bone and kidney constitute a classic short-loop feedback system on the parathyroid chief cell. Adjustments in the rate of intestinal calcium absorption by way of the PTH–1,25-$(OH)_2$D axis require approximately 24 to 48 hours to become maximal. This axis represents a classic long-loop feedback system. PTH production is closely regulated by the concentration of serum ionized calcium. This feedback system is the critical homeostatic mechanism for maintenance of ECF calcium.[25]

With birth of the infant comes abrupt interruption of the transplacental calcium supply. Regardless of whether the newborn infant is fed enterally or given intravenous fluids, calcium delivery over the first hours to days post partum does not match that enjoyed by the fetus near the end of gestation. This decrement sets the stage for a rapid, dramatic decline in serum total and ionized calcium concentrations. In normal term infants, when serum calcium concentrations fall slightly after birth, PTH concentrations increase appropriately (two- to five-fold increase during the first 48 hours of life) and remain elevated for several days postnatally. The PTH secretion in term newborn infants appears substantial, and blood concentrations negatively correlate with calcium levels. Over the course of the first week of life, the role of PTH appears to be enhanced, and neonates show an appropriate calcemic response when challenged with PTH.[26]

In the cord blood of normal term infants, the mean serum PTH concentration is 2.96 ng/L (range, 0.5 to 18 ng/L) (ng/L units are

equivalent to pg/mL). Cord serum PTH concentrations do not differ by gender, race, season of birth, or weight appropriateness for gestation[22,24] but may vary with mode of delivery (being higher in infants delivered by elective cesarean section without labor versus elective cesarean section with labor, emergency cesarean section, or spontaneous vaginal delivery).[23]

In infants of diabetic mothers, the PTH response is blunted and may relate to the magnesium deficiency state characteristic of the diabetic pregnancy.[14] In very-low-birth-weight infants, the serum PTH concentration rises significantly in association with a decline in serum calcium concentration and is suppressed by intravenous calcium infusion, indicating that the parathyroid glands of very low birth weight infants are responsive to changes in serum calcium levels.[20] In infants and young children undergoing cardiac surgery, the PTH response to both hypocalcemia and rising ionized calcium concentrations appears at least as great as that of adults. Thus, in general, the calcium–parathyroid–vitamin D axis functions in infants and young children in a fashion similar to that in adults.[40]

Calcitonin

Calcitonin is a hypocalcemic peptide hormone produced by the parafollicular cells of the thyroid,[41] which in many ways acts as the physiologic antagonist to PTH. The hypocalcemic activity of calcitonin is accounted for primarily by direct inhibition of osteoclast-mediated bone resorption (decreasing the amount of calcium and phosphorus released from bone)[42] and secondarily by increasing renal calcium and phosphorus excretion (at high doses).[43] These effects are mediated by receptors on osteoclasts and renal tubular cells and depend on the rate of preexisting bone resorption; the greatest effects of this hormone apparently are seen in circumstances in which bone resorption is increased.[44] The net consequence of the actions of calcitonin is to decrease serum concentrations of calcium and phosphorus.

The secretion of calcitonin is under the direct control of blood calcium: An increase in calcium causes an increase in calcitonin, and a decrease in calcium causes a decrease in calcitonin concentrations.[45] An increase in the production of calcitonin may also be observed with an increase in circulating magnesium levels or after ingestion of food (which increases circulating levels of gastrointestinal hormones [gastrin, glucagon, and pancreozymin]). Thus it has been suggested that this gastrointestinal-thyroid-cell system serves to prevent marked increases in serum calcium during food ingestion.[46] Once secreted, calcitonin disappears quite rapidly from the circulation, with a half-life of 2 to 15 minutes.[44]

In the cord blood of normal term infants, cord serum calcitonin concentrations are 44.1 (24.3 to 63.9) ng/L or pg/mL.[22] They do not differ by gender, race, or season of birth[22] but decrease with increasing gestational age. Infants born before 32 weeks gestation have nearly three times the cord serum calcitonin concentrations of term infants.[47] In the newborn infant, cord serum calcitonin concentrations are higher than those of the pregnant mother.[48] In both preterm and term infants, serum calcitonin concentrations further increase after birth, with a peak at 24 to 48 hours of age followed by a decline to childhood values by 1 month of age.[47-49] The physiologic importance of this increase in serum calcitonin is unclear but may relate to its effect on counteracting the bone-resorptive action of PTH.

Vitamin D

Vitamin D is either produced in the skin under the influence of ultraviolet light[50] or ingested in the diet and absorbed from the gastrointestinal tract. Before it reaches its final active form, 1,25-$(OH)_2$D, vitamin D must first undergo two hydroxylation steps—the first in the liver and a second in the proximal tubule of the kidney.[51] 25-Hydroxylation in the liver is a relatively unregulated process, and serum 25-hydroxyvitamin D (25-OHD) concentrations generally reflect the patient's vitamin D status (as determined by intake and sunlight exposure). The production of 1,25-$(OH)_2$D by the renal proximal tubule is enhanced by hypocalcemia, hypophosphatemia, and PTH[52] and appears to be tightly regulated. 1,25-$(OH)_2$D is transported through the blood to its target tissues (small intestine and bone), where it regulates calcium homeostasis. 1,25-$(OH)_2$D acts on the small intestine to stimulate the active absorption of calcium and phosphorus,[53] on bone (in conjunction with PTH) to stimulate bone resorption of calcium and phosphorus,[54] and on kidney to conserve calcium and phosphorus. Thus vitamin D is necessary for maintenance of normal calcium and phosphorus homeostasis. The net action of 1,25-$(OH)_2$D is to increase the serum concentration of calcium.

In the cord blood of normal term infants, the mean serum 1,25-$(OH)_2$D concentration is 76 pmol/L and ranges from 31 to 151 pmol/L (32 pg/mL; range, 13 to 63 pg/mL). It varies by season of birth, being high in summer-born versus winter-born infants[22] (Figure 36-1), and by weight in relation to gestation—concentrations are lower in infants who are small for gestational age (SGA) versus those born at a weight appropriate for gestational age (AGA),[24] but not by gender or race.[22] These variable concentrations of serum 1,25-$(OH)_2$D have been suggested as an adaptive response to low bone mineral content in summer-born newborn infants (in the United States) or may reflect decreased production of 1,25-$(OH)_2$D in SGA infants, possibly as a consequence of reduced uteroplacental blood flow. In normal term infants, serum 1,25-$(OH)_2$D concentrations are low at birth but increase to adult normal ranges by 24 hours of life, possibly reflecting the need for optimum intestinal calcium and phosphorus absorption.[55]

In preterm infants, serum 1,25-$(OH)_2$D concentrations at birth are comparable with reference values for healthy children and adults, increase significantly during the first few days of life,[56-58] and are far above reference values between 3 and 12 weeks of life.[58] In preterm infants, serum concentrations of vitamin D–binding protein are lower, serum total 1,25-$(OH)_2$D concentrations are higher, and the calculated free 1,25-$(OH)_2$D index (total 1,25-$[OH]_2$D/D binding protein ratio, which may represent the physiologically active component of 1,25-$[OH]_2$D) is four to six times higher than in previously studied term infants; the free 1,25-$(OH)_2$D index increases significantly with age and does not correlate with serum phosphorus or PTH.[59]

Cord serum 25-OHD concentrations are influenced by season of birth and maternal vitamin D status. In Cincinnati, human milk–fed infants in the first year of life have low serum 25-OHD concentrations in winter (33% to 50% of summer values),[60] paralleling measures of actual sunshine exposure.[61] Cord serum 25-OHD concentrations in Cincinnati, however, do not differ by season of birth, possibly because a large percentage of women take prenatal vitamins, which would obscure any sunshine-related effects on vitamin D metabolism.[22] In contrast with those reported from Cincinnati, cord serum 25-OHD concentrations of Korean neonates are significantly lower in winter (approximately one third of summer values), and 97% of winter-born infants have subnormal 25-OHD concentrations (less than 28 nmol/L [11 ng/dL]), consistent with suboptimal maternal vitamin D nutrition status and reduced seasonal sunlight exposure.[62] The lower vitamin D status in winter may influence fetal bone mineralization during late fetal life; in one study, the total body bone mineral content in winter-born infants was lower (by 6%) than in summer-born infants in Korea.[62]

Phosphorus

The serum concentration of phosphorus appears to be regulated primarily through the kidney by means of tubular reabsorption of P_i; serum phosphorus concentrations are maintained at a value

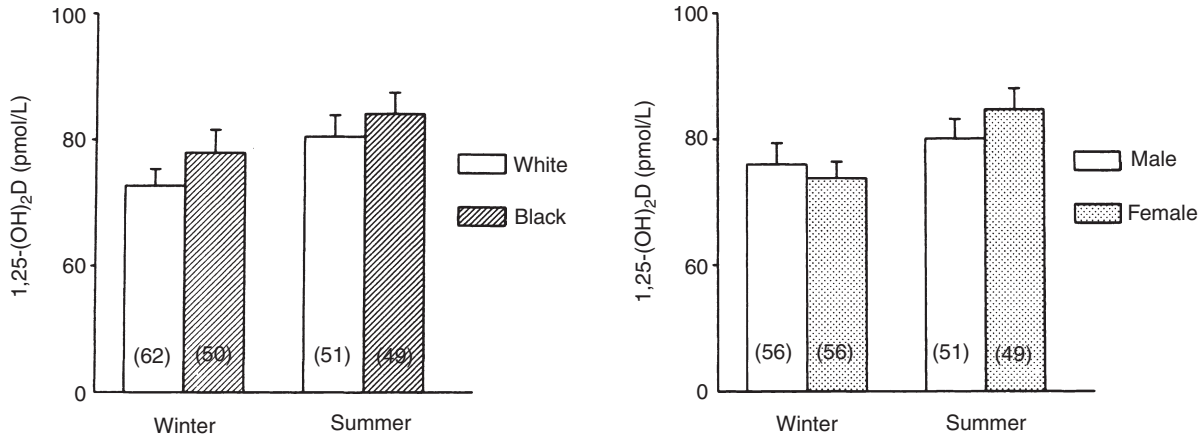

Figure 36-1 Serum 1,25-dihydroxyvitamin D (1,25-$[OH]_2D$) concentrations were higher in summer-born than in winter-born infants (p = .02) and did not differ by race or gender. Values are means ± SE, with numbers of newborns *in parentheses. (From Namgung R, Tsang RC, Specker BL, et al: Low bone mineral content and high serum osteocalcin and 1,25-dihydroxyvitamin D in summer- versus winter-born newborn infants: An early fetal effect?* J Pediatr Gastroenterol Nutr *19:220, 1994.)*

close to the tubular phosphorus threshold, or the tubular maximum for phosphorus/glomerular filtration rate (TmP/GFR).[25] Because of the normal high efficiency and lack of fine regulation of phosphorus absorption in the intestine, only in unusual circumstances is the intestinal absorption a limiting factor in phosphorus homeostasis.

During phosphorus depletion, phosphaturia decreases before the serum phosphorus concentration declines. This adaptive response (i.e., increasing tubular transport when luminal concentrations are decreasing) is an intrinsic property of these cells. The following sequence of events is initiated in the face of a hypophosphatemic challenge: (1) stimulation of 1,25-$(OH)_2D$ synthesis in the kidney, (2) enhanced mobilization of phosphorus and calcium from bone, and (3) hypophosphatemia-induced increase in tubular maximum for phosphorus, resulting in reduced phosphorus excretion. The increased circulating concentration of 1,25-$(OH)_2D$ leads to increases in phosphorus and calcium absorption in the intestine and provides an additional stimulus to phosphorus and calcium mobilization from bone. The increased flow of Ca^{2+} from bone and intestine inhibits the secretion of PTH, resulting in lowered phosphate excretion. The net result of this series of adjustments is a return of serum phosphorus concentration to normal without change in the serum calcium concentration.[25]

The defense against hyperphosphatemia consists largely of a reversal of the just events described. The principal humoral factor that combats hyperphosphatemia is PTH. An acute rise in the serum phosphorus concentration produces a transient fall in the concentration of serum ionized calcium and a stimulation of PTH secretion. This in turn reduces TmP/GFR (increasing urinary phosphorus excretion), leading to a readjustment in serum phosphorus and calcium concentrations. A prolonged rise in the serum phosphorus concentration results in (1) an intrinsic downward adjustment in TmP/GFR that is independent of PTH and (2) a persistent increase in PTH secretion that ultimately can lead to parathyroid chief cell hyperplasia.[25]

The wide variation in serum phosphorus concentrations may be secondary to a few direct regulatory mechanisms. PTH, which has the greatest impact on serum phosphorus concentrations, primarily responds to changes in ionized calcium concentrations, not phosphorus. Phosphorus is freely filtered at the glomerulus and presents to the renal tubule in high concentrations. The renal tubule reabsorbs phosphorus in both the proximal and the distal nephron. In states of low PTH concentrations, the renal tubular cells reabsorb up to 95% to 97% of filtered phosphorus. In states of high serum PTH concentration, reabsorption of phosphorus in proximal and distal tubules is inhibited, resulting in excretion of high concentrations of urinary phosphorus. Although markedly affected by PTH in the usual state, renal tubular cells appear to have a decreased responsiveness to PTH in conditions of severe phosphorus deficiency or overload. Hence, phosphorus is reabsorbed in the face of high circulating PTH in severe phosphorus deficiency, and phosphorus is excreted despite low PTH concentrations when serum phosphorus is high.[63] Other hormones also may have an effect on the excretion of phosphorus by the kidney. Growth hormone, 1,25-$(OH)_2D$, insulin, and possibly somatomedins (insulin-like growth factors) all have been shown to increase renal tubular reabsorption of phosphorus.[63] The extent to which these hormones contribute to the normal regulation of serum phosphorus is unclear.

In preterm infants, a phosphorus depletion syndrome has been observed in infants fed human milk,[64] in infants with restricted enteral mineral intakes (owing to inadequate formula content), and in infants with chronic illnesses who receive prolonged parenteral nutrition without mineral supplements.[65] In this latter group of patients, biochemical signs of phosphorus deficiency are prominent and may be associated with rachitic bone changes; serum 1,25-$(OH)_2D$ concentrations are increased with evidence of increased bone resorption and turnover (increased serum bone resorption marker, cross-linked carboxyl-terminal [C-terminal] telopeptide of type I collagen) and osteocalcin levels in infants with rickets versus controls).[66] These changes appear to be an extreme example of phosphorus depletion because of low enteral mineral intakes during the first month of life in very-low-birth-weight infants.

Magnesium

In contrast with calcium and phosphorus, little is known about the hormonal regulation of systemic magnesium homeostasis. Maintenance of the serum magnesium concentration seems to result from the combined fluxes of magnesium at the levels of intestine, kidney, intracellular fluids, and perhaps the skeleton. Regulation of the total-body magnesium balance resides principally within the kidney and tightly matches the intestinal absorption of Mg^{2+}. The kidney provides the most sensitive control for magnesium balance[67]: Approximately 80% of the total plasma Mg^{2+} is filtered through the glomerular membrane,[68] the major portion of which is subsequently reabsorbed along the nephron[69]; 85%

of the filtered Mg^{2+} in the proximal tubule and the thick ascending limb of Henle, and 5% to 10% in the distal convoluted tubule (DCT). The final urinary excretion of Mg^{2+} is determined mainly by the active reasorption of Mg^{2+} in the DCT.[69] Mg^{2+} transport in the DCT is transcellular in nature and influenced by dietary magnesium restriction[70] and a number of hormones.[71] The molecular details and regulation of this pathway, however, remain largely unknown. With a rise in serum magnesium concentration, the fraction of filtered magnesium that is excreted increases sharply, whereas a decrease in serum magnesium concentration (which occurs when a low-magnesium diet is ingested for a few days) leads to the near-disappearance of magnesium from the urine.[72] The excretion of magnesium is directly related to the renal magnesium threshold and a tubular maximum–limited process and is primarily responsible for maintaining serum magnesium concentration within rather narrow limits.[25]

The body's stores of magnesium appear to be important in the maintenance of calcium homeostasis. Magnesium deficiency may decrease bone calcium release in vitro[73] and increase the percentage of bone calcium, compared with that of magnesium-replete rats in vivo.[74] A heteroionic bone exchange of magnesium for calcium has been demonstrated in vitro.[73] The release of both calcium and magnesium from bone also is stimulated by PTH and decreased by calcitonin.[75]

Congenital rickets may occur in infants whose mothers have received prolonged magnesium infusion for tocolysis.[76] Fetal magnesium toxicity impairs bone mineralization and can lead to serious bone demineralization that may cause fractures in the newborn period that complicate recovery from respiratory disease.[77]

Many of the same hormones that regulate serum calcium concentrations also appear to affect serum magnesium, although the relationships are not as well defined as for calcium. Acute changes in serum magnesium concentration have effects on PTH secretion similar to those for acute changes in serum calcium concentrations, but magnesium is in general a less potent stimulus than clcium.[78] An acute increase in serum magnesium concentration leads to a decline in serum PTH.[79] Reduced activity of PTH may increase the tubular clearance of magnesium, resulting in renal magnesium losses. Conversely, an acute decrease in serum magnesium results in an increase in PTH secretion. The increase in PTH secretion results in an increase in serum magnesium concentrations, probably through increased bone resorption and, more important, decreased losses in the urine. PTH affects tubular reabsorption of magnesium, through a mechanism similar to that used for the transport of calcium and phosphorus involving cyclic adenosine monophosphate (cAMP).[72] It has been difficult, however, to identify a direct effect of PTH on tubular magnesium transport because concomitant changes in serum or urinary calcium or other factors also can affect tubular magnesium transport.[72]

Paradoxically, chronic magnesium deficiency results in decreased PTH secretion and a blunting of the action of PTH on target organs,[80,81] partly because of alterations in the calcium-sensitive, magnesium-dependent adenylate cyclase system that is involved in the secretion of the hormone.[82] Therefore magnesium deficiency may lead to or exacerbate hypocalcemia by inhibiting the parathyroid response to declining serum calcium concentrations.

The role of calcitonin in the regulation of serum magnesium concentrations appears to be minimal. Elevated serum magnesium concentrations increase calcitonin release. In vitro studies have shown that a 100% increase in the magnesium concentration of the extracellular bath leads to a discharge of calcitonin from the thyroid parafollicular cells.[83] This compares with a similar calcitonin response with a 20% increase in the calcium concentration. Because calcitonin inhibits bone resorption, the release of magnesium from bone is apparently decreased by calcitonin.[84] Calcitonin decreases renal tubular reabsorption of magnesium in humans.[85] The physiologic role of calcitonin in the regulation of magnesium homeostasis, however, is not well defined, and there are no major difficulties with magnesium (or calcium) or skeletal homeostasis in humans with congenital or acquired calcitonin deficiency.[86]

Under physiologic conditions, the role of vitamin D in the regulation of serum magnesium concentration probably is of minor importance and appears to have at best an indirect influence on metabolism. Little effect on intestinal magnesium transport or absorption is seen at physiologic concentrations of 1,25-$(OH)_2$D, but increased intestinal magnesium absorption occurs at pharmacologic doses of vitamin D.[87,88] Furthermore, no significant correlation exists between magnesium absorption and plasma 1,25-$(OH)_2$D concentrations[89]; however, magnesium is an essential cofactor for the 25-hydroxylation reaction in the hepatic formation of 25-OHD,[90] and magnesium deficiency is associated with decreased serum 1,25-$(OH)_2$D concentrations in adults, presumably because of its role as a cofactor for 25-$(OH)_2$D–1α-hydroxylase in renal tubular cells.[91]

Other hormones known to have a direct or indirect effect on serum magnesium concentrations are estrogens, thyroxine, and aldosterone, which lower serum magnesium, and epinephrine, glucocorticoids, and progesterone, which increase serum magnesium. The overall effect of these hormones in healthy persons appears to be minimal.[72]

GASTROINTESTINAL TRANSPORT

Calcium

The gastrointestinal tract generally is considered the primary site involved in the long-term regulation of calcium balance. In adults, the average dietary calcium intake is approximately 600 to 800 mg/day, and less than half of this amount is absorbed.[92] In preterm low-birth-weight infants, calcium absorption has been reported to range from 50% to 80% at intakes of 80 to 140 mg/kg/day.[93,94] Calcium absorption increases during periods of rapid growth in children and decreases with advancing age. The percentage of true calcium absorption in preterm infants, however, does not change with birth weight or gestational age.[95]

Most calcium has been considered to be absorbed in the proximal small intestine, and the efficiency of absorption decreases in the more distal small intestinal segments. Several in vivo studies,[96,97] however, have shown that the bulk of Ca^{2+} absorption can be accomplished in the distal small intestine, in particular the ileum, a segment known to have a limited capacity for *active* calcium absorption.[98]

Calcium absorption involves two major processes: *transcellular (active)* movement, predominant in the duodenum and upper jejunum; and *paracellular (passive)* movement through the tight junctions between intestinal cells, throughout the length of intestine.[98,99] When dietary calcium is low, the *vitamin D–dependent transcellular pathway* is thought to play a major role,[98-100] and is down-regulated as total calcium intake rises. At high calcium intakes, the *passive paracellular pathway* is dominant, being linear increase in calcium absorption over a wide range of calcium concentrations (50 to 200 mmol/L) and unchanged as a result of increasing calcium intake.[98,100] The coexistence of mediated and nonmediated transport processes assures the organism of an adequate calcium supply, yet prevents excessive calcium absorption. The passive absorption of calcium does not require metabolic energy and is not subject to acute regulation. According to some studies, however, bile salts and lactose may increase ileal calcium absorption by increasing the permeability of the paracellular pathway.[97,101]

Transcellular transport of calcium is a three-step process consisting of (1) entry across the apical membrane of the enterocyte, by way of Ca^{2+}-selective channels, termed calcium transport

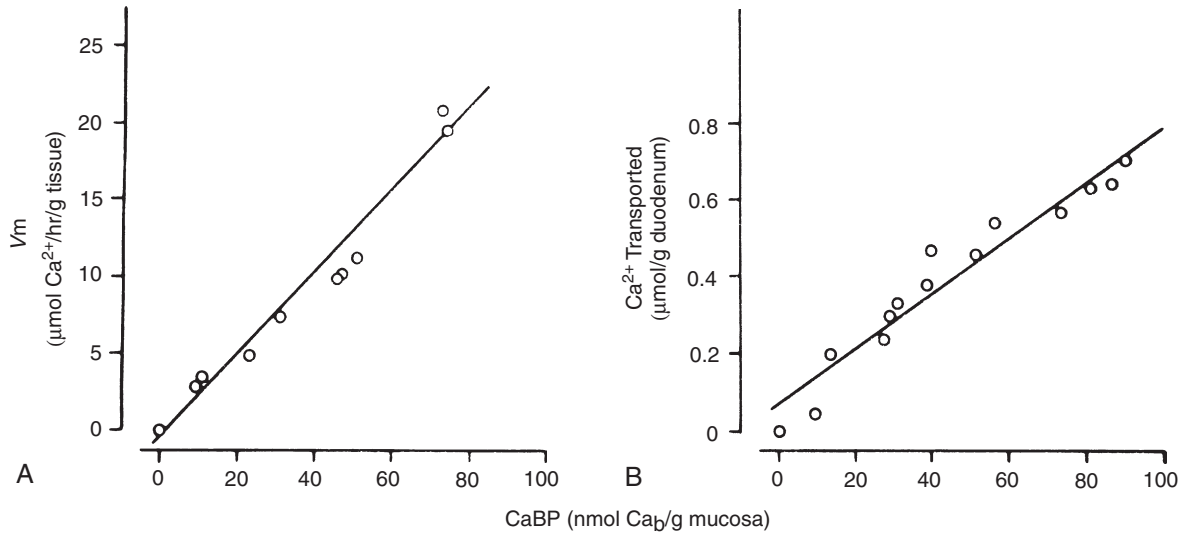

Figure 36-2 The relationship between intestinal Ca^{2+} transport and calbindin-D9k (calcium-binding protein [CaBP]) content. **A,** V_m, calculated from in situ duodenal, jejunal, and ileal loop experiments, shown as a function of CaBP content. protein (CaT1)[102] and epithelial calcium channel (ECaC)[103,104]; (2) intracellular calcium transfer, facilitated by vitamin D–dependent cytosolic calcium-binding protein, calbindin-D9k[105]; and (3) active extrusion across the opposing basolateral membrane against an electrochemical gradient, mediated by a high-affinity ATP-dependent Ca^{2+}-ATPase (PMCA1b) or Na^+-Ca^{2+} exchanger (NCX1)[106,107] (Figure 36-2).

The understanding of calcium absorption has been increased by the identification of the apical calcium channel in Ca^{2+}-transporting epithelia, CaT1 (also known as ECaC2 and recently renamed *transient receptor potential vanilloid* [TRPV6][108]), from the rat intestine,[102,103] which acts as facilitative transporter, mediating cellular uptake of Ca^{2+} down its electrochemical gradient with saturation kinetics.[109] TRPV family members are involved in the absorption of Ca^{2+} in intestine; TRPV5 and TRPV6 have been cloned, initially from vitamin D–responsive Ca^{2+}-transporting epithelia, termed the epithelial calcium channels ECaC1 (CaT2) and ECaC2 (CaT1), and play a major role in the intestinal uptake of Ca^{2+}.[102,103] Functional expression reveals the characteristic features of a constitutively activated Ca^{2+} permeability, a large $Ca^{2+} > Na^{2+}$ selectivity, and a current-voltage relationship showing inward rectification.[110]

The active transport of calcium is under the control of hormones, and 1,25-$(OH)_2$D is the primary regulator of Ca^{2+} transport or absorption. The hormone 1,25-$(OH)_2$D acts through nuclear vitamin D receptors (VDRs),[111] which are present within the enterocytes of the intestine.[112] Possible targets involved in vitamin D–dependent active duodenal calcium absorption are calcium influx through CaT1 and ECaC,[104,113,114] and intracellular calcium transfer by calbindin[105,115] and plasma membrane Ca^{2+}-ATPase (PMCA1b).[116,117] Thus, in wild-type mice and human duodenum, 1,25-$(OH)_2$D up-regulates CaT1 (TRPV6), ECaC, calbindin-D9k, and PMCA mRNA.[116-122] Studies in both humans[123] and animals[105] have demonstrated a direct correlation between mucosal concentration of calcium-binding protein (calbindin-D) and the rate of intestinal calcium absorption, thus supporting a link between the physiologic action of vitamin D and calbindin-D[99] (Figure 36-3).

CaT1 in the intestine is highly responsive to 1,25-$(OH)_2$D and shows both fast and slow calcium-dependent feedback inhibition to prevent calcium overload.[109] Maximum transcellular transport is directly proportional to the cellular content of calcium-binding protein (CaBP), to which greater than 90% of the transported calcium is bound.[113] When Ca^{2+} enters the cytosol, its self-diffusion through the cell interior is enhanced up to 70-fold by calbindin-D9k.[124] Vitamin D deficiency leads to no synthesis of calbindin-D9k and virtually no transcellular calcium transport.[105] Moreover, interference with calcium binding by CaBP interferes with active Ca transport. Theophylline, when added to the incubation medium of everted duodenal sacs prepared from rats on a low-calcium diet, inhibits transcellular calcium transport in a concentration-dependent manner: Calcium binding by CaBP also is depressed by theophylline in a concentration-dependent manner and parallels the inhibition of transcellular calcium transport, supporting a CaBP function as a "calcium ferry" in transcellular transport[125] (Figure 36-4). Thus active calcium transport is regulated by vitamin D or processes that modify the action or metabolism of the sterol. However, there is an opposing view regarding the role of calbindin-D9k in vitamin D–mediated calcium absorption. Recently Akhter and associates[126] produced a calbindin-D9k–null mutant 129/OlaHsd mouse and examined directly whether the mutant mouse can absorb calcium from the intestine in response to the active form of vitamin D. The calbindin-D9k–null mutant mouse is fully able to absorb calcium from the intestine in response to 1,25-$(OH)_2D_3$. From this study, it is suggested that calbindin-D9k is not required for vitamin D-induced intestinal Ca^{2+} absorption.[126]

Calcium extrusion is affected by Ca^{2+}-ATPase, occurs against an electrochemical gradient, and requires a supply of energy.[127] It is not the rate-limiting step, however, because extrusion capacity is more than sufficient to handle the maximum transcellular flux of calcium. It is the flow of Ca^{2+} inside the cell, from the brush-border pole to the calcium pump at the basolateral side, that is rate-limiting.

Intestinal calcium transport declines with age in parallel with the expression of calcium channel,[120] calbindin-D9k,[128] and

Ca^{2+}-ATPase.[129] These age-related changes in the regulation of calcium absorption are reflected in intestinal CaT1,[120] calbindin,[128] and calcium pump levels.[129] This decline in expression may reflect the marked drop in serum 1,25-$(OH)_2$D concentrations from young to adult rats.[128] The capacity of a low-calcium diet and 1,25-$(OH)_2$D itself to increase calcium absorption also declines with age.[120]

The relative importance of active versus passive intestinal absorption of calcium in the human neonate is uncertain. In rats, it has been observed that during the suckling period, before the time of natural weaning, the absorption of calcium is linearly related to the intraluminal Ca^{2+} concentration.[130,131] With increasing age, a decrease in the intestinal permeability of calcium is noted, and the relationship between intraluminal Ca^{2+} concentration and calcium absorption becomes increasingly curvilinear. It is during this time that measurable active intestinal absorption of calcium increases. Just before this increase in active absorption, receptors for 1,25-$(OH)_2$D become identifiable,[132] and a marked increase in mucosal vitamin D–dependent calcium-binding protein is observed.[133] Although an increase in active intestinal absorption of Ca is observed around the time of weaning even in vitamin D–deficient rat pups, the marked increase in absorption that normally is observed occurs only in the presence of 1,25-$(OH)_2$D.[134] Furthermore, the increase in active calcium absorption induced by 1,25-$(OH)_2$D is not observed until the appearance of its cytoplasmic receptor.[134]

Neonates of several species are almost insensitive to 1,25-$(OH)_2$D[134,135] and lack detectable concentrations of calcitriol receptor and calbindin in their mucosa.[132,133] The potential importance of calcitriol-independent neonatal calcium absorption is supported by in vivo studies of calcium absorption in newborn and weaned piglets suffering from pseudovitamin D–deficiency rickets type 1 (PVDRI). In this disorder, renal production of calcitriol is absent.[136] Despite the defect, however, affected animals of this strain are normocalcemic and clinically normal at birth and absorb calcium from the gut in amounts similar to those in control animals during the first 4 weeks of life (although the plasma concentrations of calcitriol are already reduced at birth to an unphysiologically low level[137,138]). By the fourth week post partum, significant calcium malabsorption, hypocalcemia, and typical clinical signs of rickets have developed in PVDRI piglets.[139] In weaned PVDRI piglets, concentrations of Ca^{2+} are significantly lower than in control animals and are associated with significantly lower 1,25-$(OH)_2$D concentrations.[138]

A study by Schroder and colleagues[138] demonstrated that the normal absorption of calcium by newborn PVDRI piglets in the early postpartal period occurs by an *active* mechanism. By measuring unidirectional calcium flux rates using stripped duodenal mucosae (in the absence of an electrochemical gradient), significant net calcium fluxes were found in both newborn (less than 1 week old) PVDRI and control piglets, whereas active net Ca^{2+} absorption was completely absent in weaned (older than 6 weeks of age) PVDRI piglets. Because the impairment of calcium absorption does not develop during the first 4 weeks post partum in newborn PVDRI piglets, it is concluded that *active* Ca^{2+} absorption in neonatal piglets is vitamin D–*independent*. In human neonatal intestine, the possible

presence of vitamin D–independent active Ca^{2+} absorption has not been studied. In newborn PVDRI piglets, active calcium absorption is present despite low 1,25-$(OH)_2$D concentrations and decreased numbers of vitamin D receptors, indicating the presence of a vitamin D–independent active absorption mechanism. In weaned PVDRI piglets, however, active net calcium absorption is absent, with low serum 1,25-$(OH)_2$D concentrations but similar vitamin D receptor number relative to those in control animals.[138]

The timing of similar events in the human is unknown. Because vitamin D–responsive, active calcium absorption occurs in a relatively restricted portion of the small intestine and passive absorption occurs throughout the entire small intestine at similar rates, it should not be surprising that the latter process contributes significantly to the net intestinal absorption of calcium.

In a study of preterm infants 2 to 4 weeks of age (mean gestational age of 32 weeks at birth) using metabolic balance techniques, Senterre and Salle[140] demonstrated that human milk–fed and formula-fed infants supplemented with vitamin D exhibited significantly greater absorption of calcium (expressed as a percentage of intake) than in their unsupplemented counterparts: With human milk feeding, rates in supplemented and unsupplemented infants were 70% and 49%, respectively; with formula feeding, rates in supplemented and unsupplemented infants, 32% and 20%. On the assumption that the absorption of calcium in the unsupplemented groups gives a rough estimate of the passive component, the passive route accounts for a significant portion of absorption in preterm infants. Likewise, the data from the vitamin D–supplemented groups suggest that vitamin D–responsive, active intestinal absorption of calcium was present at the time of study, and that this component of calcium absorption was present before the normal term date. Alternatively, intestinal maturation with regard to vitamin D responsiveness may have been accelerated by preterm delivery.

Although these observations do not establish the relative importance of passive and active mechanisms or the timing of intestinal vitamin D responsiveness with regard to calcium absorption, they do indicate that absorption of calcium is not a limiting issue for the preterm infant. With proper attention to dietary manipulation, adequate calcium balance should be attainable.

Generally, fractional calcium absorption can adapt to high calcium intake. Hardwick and colleagues[141] examined Ca^{2+} transluminal uptake across intact duodenal epithelium at three different levels of the absorptive processes: net absorption in the intact animal, transepithelial transport in everted duodenal sacs, and transapical uptake across intact duodenal epithelium in vitro. In the face of a fivefold difference in calcium intake, net calcium absorption remained relatively constant because of a decrease in fractional absorption from 70% with normal calcium intake to 20% under conditions of high calcium intake. This decrease in fractional absorption could be due to a combination of depressed true absorption and increased intestinal secretion of calcium in response to increased dietary calcium. Previous studies, however, noted that intestinal secretion of calcium is small compared with intake and is not altered by changes in dietary intake.[142] The drop in fractional absorption of calcium probably is due to down-regulation of calcium absorption. This intestinal adaptation to the effect of dietary calcium is well known and is believed to be mediated through changes in 1,25-$(OH)_2$D synthesis.[143] High intake of dietary calcium reduces the production of this metabolite, thereby reducing the rate of intestinal calcium absorption.

In contrast with the findings in experimental animals described previously (the apparent adaptation of the calcium-absorptive rate to high dietary calcium intake), studies in low-birth-weight infants have yielded extremely variable results regarding the fractional and total calcium absorbed and retained.[144-150] Early investigations in preterm infants demonstrated a linear relationship between calcium intake and absorption: As calcium intake increases, so does the intestinal absorption of calcium.[151-153] As noted previously, however, more recent balance studies that measure only net absorption (i.e., true absorption – endogenous fecal excretion) have shown great variability in calcium retention (80 to 170 mg/kg/day) even when the same preterm formula was used,[144,145,148-150] possibly as a result of significant intersubject variability in calcium bioavailability. These variations may represent true differences in the ability of low-birth-weight infants to absorb calcium, the cause of which may relate to as-yet unidentified physiologic or hormonal factors. As indicated by the findings of calcium-absorptive consistency in perimenopausal women,[154] interindividual variability may be an expression of specific absorptive setpoints for different people. Calcium absorption evidently is consistent for each person across differing calcium loads (ranging from 15 to 500 mg). Thus a woman who absorbs calcium poorly with one calcium-containing food is likely to absorb calcium poorly with other foods.

Studies using a dual-tracer, stable isotope technique also have shown variable results. Abrams and colleagues[155] reported that net calcium retention in low-birth-weight infants fed a high-calcium formula is determined primarily by the total dietary calcium absorbed: net calcium retention correlated closely with true calcium absorption ($r = .98$; $p < .001$). The net calcium retention rate for low birth weight infants weighing 1693 ± 174 g (mean ± SD) at 20 ± 10 days of age was 103 ± 38 mg/kg/day at calcium intakes of 216 ± 13 mg/kg/day, which meets the lower estimates of the in utero calcium retention rate (100 to 130 mg/kg/day) during the third trimester.[156] This value was consistent with previous studies of calcium retention determined using mass balance technique, lower than that in other reports describing calcium retention rates of 130 to 170 mg/kg/day,[144,145,149,150] and slightly higher than that in a report of an approximate 80 mg/kg/day retention with this formula.[148] Thus the use of high-calcium formulas may possibly achieve in utero rates of calcium retention in low-birth-weight infants, although some infants retain well below in utero rates and may remain at risk for inadequate bone mineralization.[155]

In preterm infants, feeding strategies can influence the retention of minerals in the first 4 weeks early postnatal period. Schanler and associates[157] have shown that early initiation of feeding (gastrointestinal priming) in preterm infants, using 20 mL/kg/day of milk from days 4 to 14, was associated with better calcium retention (104 versus 78 mg/kg/day) and phosphorus retetention (79 versus 68 mg/kg/day) at 6 weeks of postnatal age. The net retention rates in the early-fed infants approximated the intrauterine accretion rates for calcium and phosphorus. The investigators suggest that early programming is necessary for optimal mineral absorption.

Hillman and colleagues[95] measured the percentage of true absorption and calcium retention rates in low-birth-weight infants (1400 ± 210 g) fed specially formulated preterm formula with differing calcium contents. The percentage of true calcium absorption from the preterm formula studied was around 50%, the same as or slightly higher than that from standard formula (460 mg/L, 47.1%). Increasing the calcium content of formula from the level of 460 mg/L to the levels studied—780 mg/L, 940 mg/L, and 1340 mg/L—resulted in nearly identical levels of true fractional calcium absorption (range, 47.1% to 56.1%) but higher net calcium retention rates with a wide variability. Because multiple factors were different between the formulas studied (e.g., fat composition [content of medium-chain triglycerides], whey-predominant protein, calcium-phosphorus ratio), however, the effect of increased calcium content alone cannot be assessed from the findings in this study.

Significant but small amounts of endogenous calcium are lost daily through intestinal secretion. Substantial quantities of

calcium enter the gastrointestinal tract as constituents of bile and other digestive juices.[158,159] From studies in rats, it also appears that calcium can be secreted into the gastrointestinal tract by way of paracellular channels when the serum ionized Ca^{2+} concentration exceeds the intraluminal Ca^{2+} concentration.[130,159] Although the secreted calcium can participate in normal intestinal absorptive mechanisms, it appears that this portion of the intraluminal calcium is reabsorbed at a level of efficiency less than that of dietary calcium.[160]

Simultaneous administration of both intravenous and oral stable isotopic calcium tracers with subsequent monitoring of fecal and urinary tracers has permitted direct calculation of endogenous calcium secretion. In adults, secretion of calcium into the intestinal lumen is small in amount, constant, and independent of absorption.[160] In children (aged 3 to 14 years), endogenous fecal calcium excretion, measured using a stable isotope technique (^{42}Ca), averages 1.4 ± 0.4 mg/kg/day and is lower than urinary calcium excretion,[161] consistent with values in healthy adults.[4,160] In preterm infants, endogenous fecal calcium excretion is high and quite variable (4 to 150 mg/day) and may exceed even urinary excretion of calcium.[149,162,163] Thus significant amounts of calcium can be lost by way of this route, which might explain some of the variability in reported calcium balance studies, because the mass balance technique does not differentiate between unabsorbed and endogenously secreted fecal calcium. In a study of low-birth-weight infants fed a high-calcium formula, endogenous fecal calcium excretion averaged 15 ± 9 mg/kg/day (7.2% ± 4.1% of intake) and was much greater than concurrent urinary calcium excretion.[155] The reasons for these high rates of endogenous fecal calcium excretion in preterm infants are unknown but may be related to gastrointestinal immaturity.[149]

In a study by Hillman and colleagues,[95] endogenous fecal calcium excretion in low-birth-weight infants fed preterm formula with varying calcium contents ranged from 6.9 to 19.0 mg/kg/day; infants fed human milk excreted 5.1 mg/kg/day. Endogenous fecal excretion is independent of calcium intake (and the true absorption rate), and not related to gestational age or postnatal age at study. A number of carbohydrates (especially lactose) and glucose polymers enhance the intestinal absorption of calcium,[164,165] probably independent of the actions of vitamin D.[164,166] In vitro studies have established that mucosal lactose directly stimulates ileal[167,168] but not duodenal or jejunal calcium absorption.[169] Lactose, in contrast with other monosaccharides and disaccharides, is not hydrolyzed in the proximal small intestine, and large quantities of this sugar are delivered to the ileum.The observation that lactose feeding can reduce duodenal calcium-binding protein content and calcium absorption[170] may be attributed to increased calcium retention from augmented ileal Ca^{2+} absorption. Lactose, by itself, does not solubilize precipitated calcium; it does not maintain calcium in a soluble form in the presence of precipitating agents such as phosphate.[101] The lactose effect on Ca^{2+} absorption may be mediated through its action on the permeability of ileal epithelium, through a paracellular mechanism.[171] The observation that lactose also stimulates intestinal absorption of other divalent cations (e.g., Mg^{2+}, Ba^{2+}, Sr^{2+}, Ra^{2+})[101] further supports the possibility that this sugar may cause a general increase in permeability to divalent ions across the junctional assembly. In rats, osmotic forces that enhance the net intestinal absorption of water also enhance the passive absorption of calcium.[166] It appears from such data that "solvent drag" plays a significant role in the augmentation of calcium absorption, leading to the speculation that this may be the mechanism through which carbohydrates act.

Bile salts stimulate calcium absorption in the chick.[172] The mechanism for bile salt–mediated calcium absorption is not clear, but the stimulatory action is not vitamin D–dependent. Bile salts solubilize lipids for absorption through the formation of micelles.[173] The surfaces of micelles bear negative charges, which strongly bind Ca^{2+} and Na^{+}.The process of micellar solubilization may explain the observation that although the physicochemical environment of ileum favors calcium precipitation,[142] the bulk of calcium absorption occurs in this segment in vivo.[174] In addition to increasing the amount of calcium available for absorption, bile salts also may influence calcium absorption by acting directly on the intestinal epithelium. In a variety of in vivo and in vitro perfusion studies[175,176] using isolated, short-circuited rat and rabbit colons, increased permeability of gastrointestinal barriers has been observed with changes in tight junction complexes. This is reflected by increases in transepithelial conductance[177,178] and permeation of paracellular pathway markers.[178] In addition to the paracellular action, bile salts can also influence enterocytes directly: Bile salts have potent calcium ionophoric effects (mimicking the effect of 1,25-$(OH)_2$D) across a variety of artificial and plasma membranes, including the jejunal brush border membrane.[179]

As mentioned, the bulk of Ca^{2+} absorption occurs in the distal small intestine, in particular the ileum,[96] a segment that is relatively insensitive to 1,25-$(OH)_2$D, devoid of calcium-binding protein, and poorly equipped for active Ca^{2+} absorption.[98] Under in vivo postprandial conditions, the simultaneous arrival in ileum of bile salts and calcium could foster a highly efficient Ca^{2+}-absorptive state.The calcium load, solubilized by bile salts,[175] would create a calcium concentration gradient in the absorptive direction (i.e., $[Ca^{2+}]_m > [Ca^{2+}]_s$).This, in concert with the bile salt–induced increase in the permeability of the intercellular conduit, could promote rapid Ca^{2+} absorption, both economically and in substantial quantities.[97]

Fat malabsorption has the potential to impair intestinal calcium absorption. Preterm infants are not likely to have an intraluminal concentration of bile salts sufficient for the establishment of a micelle phase, which has the potential to reduce the absorption of fat.[180] The unabsorbed free fatty acids would then be available to interact with ionic calcium to form insoluble calcium soaps, which in turn would not be available for absorption. Although steatorrhea can be significantly reduced in preterm infants by administering a significant proportion of dietary fat as medium chain triglycerides (which do not require micelle formation for absorption), it is not clear that this practice significantly improves intestinal calcium absorption.[181] Furthermore, despite these general theoretical considerations, the absorption of calcium during this period is high, particularly in comparison with that in other stages of life.

Fractional intestinal absorption of calcium is enhanced by dietary restriction of calcium or P_i. Under these conditions, rats[182,183] and humans[184] demonstrate increased production of 1,25-$(OH)_2$D, with a resultant increase in active intestinal absorption of calcium.The effect of short-term moderate dietary phosphorus restriction on intestinal net calcium fluxes and external calcium balance was studied in growing rabbits that were fed a phosphorus-deficient diet (containing approximately two thirds of the estimated minimum requirement for phosphorus) for 10 consecutive days.[185] During phosphorus restriction, intestinal calcium absorption rose significantly to reach maximal values within 96 hours; sustained high rates of calcium absorption persisted for the 10 days of phosphorus restriction. When the rabbits were consuming the phosphorus-replenished control diet, calcium absorption fell to control values during the first 9 days of recovery, implying the persistence of mechanisms for calcium hyperabsorption for at least 1 week after this degree of phosphorus restriction. Despite increased intestinal calcium absorption, calcium balance during phosphorus restriction was less positive because the increase in urinary calcium excretion was even greater. The increased efficiency of calcium absorption in response to moderate dietary phosphorus restriction is

consistent with the well-established effect of calcitriol on intestinal calcium transport.[142]

Phosphorus

In comparison with calcium, much less is known about the intestinal absorption of P_i. Fewer direct studies have been performed in humans, so that much of the available information has been derived from animal studies. Phosphorus absorption is remarkably efficient, much more so than calcium absorption. At low levels of intake (less than 2 mg/kg of body weight per day), 80% to 90% of ingested phosphorus in adults is absorbed. Even with levels of intake greater than 10 mg/kg of body weight per day in the form of dairy products, cereals, eggs, and meat, absorption is approximately 70%.[89] In term and preterm infants, the fractional absorption of phosphorus is high, ranging from 86% to 97% regardless of phosphorus or calcium intake.[186] Thus the dietary P_i intake is an important determinant of the amount of phosphorus absorbed.

The absorption of P_i occurs throughout the entire small intestine. On the basis of transepithelial P_i flux measurements and uptake studies with isolated brush border membrane (e.g., of rabbits and rats), small intestinal absorption of P_i has been reported to occur mostly in the duodenum and at the beginning of the jejunum.[187-189] In in vivo segmental P_i absorption analysis in intact rats fed ^{32}P-labeled P_i liquid meal containing a nonabsorbable marker ([^{14}C]-polyethylene glycol), the duodenum, which had the highest transit and absorption rates, accounted for a third of total absorption; the terminal ileum, with a lower absorption rate but a longer transit time, also accounted for one third of the total absorption (equal to P_i absorbed in the duodenum); the remaining one third was absorbed by the intervening small intestinal segments[190] (Figure 36-5).

The movement of phosphorus across the intestinal epithelium can be resolved into two unidirectional fluxes: an absorptive, mucosa-to-serosa flux and a secretory, serosa-to-mucosa flux. Each unidirectional flux, in turn, consists of two components, a *transcellular (active, energy-dependent transport) flux* and a *paracellular (passive, diffusional) flux*. The paracellular flux is driven by transepithelial chemical and physical (electrical and hydrostatic) gradients, whereas the transcellular flux is unaffected by the transepithelial electrochemical gradients, with the movement across the brush border membrane appearing to be the rate-limiting step.[191]

An active, sodium-dependent transcellular P_i-absorptive mechanism has been demonstrated in rat jejunum by measuring net P_i absorptive flux under short-circuited conditions.[192] Sodium stimulates both unidirectional mucosa-to-serosa flux and serosa-to-mucosa flux for P_i (measured in the absence of transepithelial potential differences). Thus absorption at the brush border membrane involves the obligate transport of sodium and P_i and occurs in an electroneutral fashion.[193] The absorbed P_i then traverses the cytoplasm by means of unknown processes; at the basolateral membrane, it moves down its electrochemical gradient by means of simple diffusion[193] or through carrier-mediated facilitated transport.[194] Transcellular transport of P_i in the small intestinal segment is initiated by a sodium-dependent transport step through the apical membrane of the enterocytes. Three classes of sodium-dependent phosphate (Na^+-P_i) cotransporters have been identified: type 1 (NPT1), type 2 (NPT2), and type 3 (NPT3). Among them, type 2 Na^+-P_i cotransporter (NPT2), the major molecule in the renal proximal tubule, is responsible for most resorption of P_i in the kidney and can be strictly controlled by P_i-regulating hormones such as PTH and vitamin D.[195]

Three isoforms of NPT2—NPT2a, NPT2b, and NPT2c—have been identified. NPT2a (type IIa) and NPT2c (type IIc) are expressed mainly in the kidney. NPT2b (type IIb) are expressed specifically in the small intestine and can be regulated by vitamin D.[196,197] Those transporters are found solely in the apical brush border membrane of the renal proximal tubular cells or intestinal epithelial cells.[198] To date, the Na^+-P_i cotransporter NaPi-IIb (SLC34A2)[199] represents the only known protein that mediates Na^+-dependent transport of P_i through the apical membrane of the enterocytes.[200] Intestinal phosphorus absorption is closely linked to expression of the Na^+-P_i cotransporter NaPi-IIb.[200-204]

In a recent study by Radanovic and colleagues,[204] expression of NaPi-IIb and its correlation with Na^+-P_i cotransport activity was assessed in the small intestine of mouse. The highest amount of NaPi-IIb protein was detected in the ileum, whereas in the jejunum, the content of the NaPi-IIb protein was minimal. In agreement, the highest rate of NaPi-IIb cotransport was observed in brush border membrane vesicle (BBMV) isolated from the ileum, whereas in BBMV isolated from the jejunum, sodium-dependent transport of P_i was not measurable.

The regulation of intestinal P_i absorption appears to be centered on the cotransport of sodium and P_i at the brush border. It is at this site that 1,25-$(OH)_2$D acts to enhance the intestinal absorption of P_i.[205] 1,25-$(OH)_2$D increases mucosal border P_i entry, and this stimulating action is mediated through the sodium-dependent component of the total measured influx.[192]

Alterations in dietary P_i intake significantly affect intestinal absorption of Pi. With restriction of dietary P_i, fractional intestinal

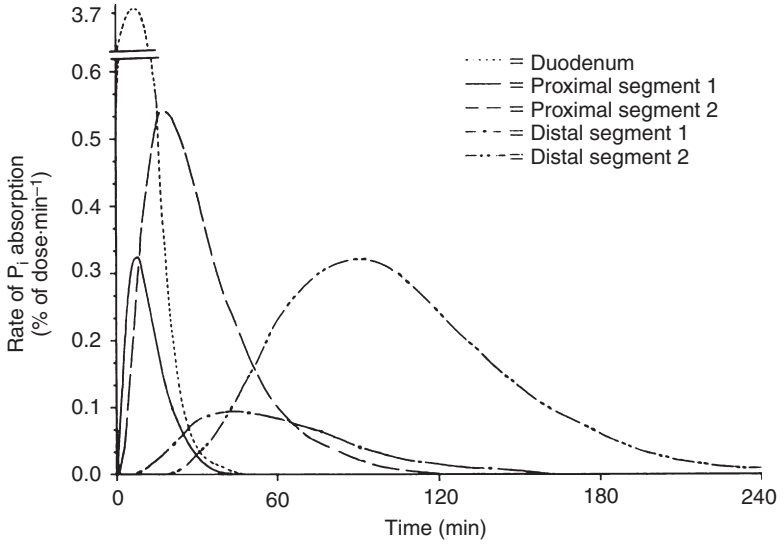

Figure 36-5 Segmental absorption rate profiles for inorganic phosphorus (P_i). Rates for each segment are shown over time. The rates for absorption of P_i from duodenum through distal segment 2 as a function of time were constructed from the compartmental model: The gastrointestinal tract was divided into duodenum and four equal-length segments of small intestine (proximal segments 1 and 2 and distal segments 1 and 2). *(From Kayne LH, D'Argenio DZ, Meyer JH, et al: Analysis of segmental phosphate absorption in intact rats: A compartmental analysis approach,* J Clin Invest *91:915, 1993.)*

absorption of P_i increases.[182-184,206] In growing rabbits,[185] moderate short-term dietary phosphorus restriction induces both intestinal and renal adaptations to conserve calcium and P: Net intestinal phosphorus secretion is observed on the first day of phosphorus restriction, but this changes to increased absorption beginning on the second day, indicating intestinal adaptation. With dietary phosphorus replenishment, adaptations persist to restore the positive mineral balances that were lost because of dietary phosphorus restriction during growth.[185] The mechanisms underlying the increased efficiency (greater fractional absorption) and capacity (hyperabsorption during recovery) of intestinal phosphorus absorption in rabbits in response to moderate dietary phosphorus restriction are not defined, but 1,25-$(OH)_2$D may play a role by increasing the absorptive capacity of the Na^+-P_i cotransporter,[207,208] or by increasing the affinity of this transporter for P_i as well.[208] Selective restriction of dietary phosphorus decreases plasma phosphorus concentration,[209] minimizes cumulative phosphorus balance, and increases plasma 1,25-$(OH)_2$D concentrations in rabbits,[209] humans,[210] and rats.[211] Low-phosphorus diet–induced increases in 1,25-$(OH)_2$D production, however, cannot account for the entire increase in phosphorus absorption in experimental animals,[212] supporting the contention that the regulation of phosphorus absorption is not always predictably a function of 1,25-$(OH)_2$D activities.

Low-P_i diet provokes an increase of the NaPi-IIb mRNA abundance along the entire small intestine. Adaptation to a low-P_i diet results in upregulation of NaPi-IIb and NaPi-IIb cotransport both in the jejunum and the ileum of mouse. From these data, it is suggested that in mouse small intestine, phosphate is absorbed transcellularly by an Na^+-dependent pathway in the ileum, whereas in the duodenum and jejunum, this pathway is of minimal importance. Along the entire mouse small intestine, low-P_i diet affects transcription or the stability of NaPi-IIb mRNA.[204] These data are in agreement with P_i flux measurements, shown in rat small intestine; even when the different transit times are taken into consideration, P_i is absorbed to an equal extent (approximately one third of ingested P_i) in the ileum and in the duodenum.[189,190] However, rat small intestinal localization of the NaPi-IIb cotransporter remains to be determined.

Vitamin D–deficient or thyroparathyroidectomized rats placed on a P_i-restricted diet demonstrated a 50% increase in intestinal P_i absorption as measured using isolated in situ intestinal loops. The presence of active phosphorus absorption in rats severely depleted of vitamin D raises the possibility of non–vitamin D–dependent factors in the regulation of active phosphorus absorption.[213] Bile salts, lactose, and prolactin are examples of agents that can stimulate phosphorus absorption through vitamin D–*independent* mechanisms.[135] An interesting example of vitamin D–independent regulation of phosphorus absorption is the ability of local (perienterocyte) factors to modify or reverse the effect of 1,25-$(OH)_2$D. Because there is often marked fluctuation in luminal concentrations of solutes such as phosphorus, some local regulation of phosphorus absorption may be needed to avoid phosphorus overloading. In support of a locally mediated vitamin D–independent mechanism, Lee[213] has demonstrated that active jejunal transport of phosphorus in vitamin D–deficient rats was not different between rats eating a phosphorus-replete diet and rats eating a phosphorus-deficient diet.

Hydrogen ion concentration also has been observed to influence the activity of the Na^+-P_i cotransport system. Under acidic conditions (media pH ranging from 5.8 to 6.9), rat small intestine BBMV demonstrate high rates of P_i uptake.[214] In rat jejunum, reduction in extracellular pH from 7.4 to 6.0 is associated with a 150% increase in P_i influx, an observation consistent with the reported reciprocal relation between intestinal BBMV P_i uptake and extravesical pH. Because the vesicles are oriented with the intraluminal surface of the BBM facing the bathing media, these results indicate that intestinal absorption is enhanced when the intraluminal environment is somewhat acidic. Paradoxically, when extracellular pH was increased from 7.4 to 8.5, there is an increase (50%) in mucosal P_i influx in intact epithelium studies.[192] In metabolic acidosis (decreased intracellular pH), markedly decreased P_i uptake has been observed in rats as measured by in situ perfused jejunal loops and jejunal BBMV.[214] The observed decrease in P_i transport may represent a decrease in the activity of the Na^+-P_i cotransport system. Treatment of acidotic rats with 1,25-$(OH)_2$D fails to improve the defect in intestinal P_i absorption. It is unclear how changes in pH specifically alter P_i transport. Alterations in pH change the chemical equilibrium between the monovalent and divalent forms of P_i. It is possible that if one of these forms of P_i is transported in preference to the other, changes in pH will shift the chemical equilibrium to either favor or hinder transport. The effective pH of 5.4 at the transporting surface dictates that all P_i in the immediate ambience be in the monobasic form. Furthermore, the properties of the Na^+-P_i cotransport system may be pH-dependent; hence changes in pH may alter the efficiency of this system to transport P_i. The acidic microenvironment, however, does not explain the observation[192] that P_i influx also is increased, though to a much lesser extent, when pH is raised from 7.4 to 8.5. One possibility is that alkaline pH may affect phosphorus permeation through the tight junction. This is a reasonable postulate because electrical conductance is increased at high pH. The mechanisms that mediate changes in P_i influx with changes in either extracellular Na^{2+} concentration or pH remain to be elucidated.

Stauber and colleagues[215] recently demonstrated that metabolic acidosis leads to an increase in intestinal sodium-dependent P_i uptake as a result of to an increased abundance of NaPi-IIb protein in the BBM of the small intestine. The stimulation of intestinal P_i absorption during metabolic acidosis may contribute to the buffering of acid equivalents by providing phosphorus and also may help to prevent excessive liberation of phosphorus from bone.[215]

In preterm and full-term neonates, numerous studies have demonstrated that P_i is well absorbed from the gastrointestinal tract regardless of the type of feeding given, and it is generally independent of the intake of vitamin D.[216,217] Expressed as a percentage of total P_i intake, intestinal absorption ranges between near 70% to greater than 90%. In general, the percentage of P_i absorbed increases as P_i intake decreases, but the absolute absorption of P_i (measured in mg/kg/day) increases proportionally with increasing intake. In infants fed soy-based formulas, the intestinal absorption of P_i is lower than that of a comparable group of infants fed a similar P_i intake from cow milk based formula.[218] Measurements of bone mineral content have also been found to be lower in soy-fed infants compared with cow milk milk-based formula-fed infants, consistent with reduced mineral utilization with soy formulas.[219,220] It is presumed that phytic acid, which is present in soy formulas, complexes with dietary P_i, thereby limiting its bioavailability for absorption. By increasing the calcium and P_i content of soy formulas, however, this problem evidently may be overcome.[219]

Magnesium

Intestinal magnesium absorption is the normal source through which the body repletes its magnesium store or meets the additional demand for magnesium imposed by anabolic states such as growth and pregnancy.

Magnesium absorption, as with calcium absorption, varies with age. In adults, intestinal absorption of magnesium ranges between 34% and 62% of total intake.[89,221] Term and preterm infants have greater intestinal magnesium absorption, in the range of 60% to 86%.[28,222] Magnesium absorption does not appear to vary with gestational age in low-birth-weight infants between 29 and 34 weeks of gestation. Magnesium absorption

and retention increase with increasing postnatal age in very-low-birth-weight infants with low calcium and phosphorus intake or high magnesium intake.[223]

Absorption of magnesium occurs in all segments of the intestine. The predominant site of magnesium absorption, based on transit time and studies using isolated segments of the intestine, is the distal small intestine, in particular the ileum.[224] Because of its relatively greater length and mass, the distal small intestine is likely to be the principal location in which the bulk of magnesium is absorbed. Indeed, the removal of 50% of the distal small intestine results in a 40% drop in magnesium absorption in rats.[225] The colon also is a dominant site for magnesium absorption, as indicated by studies in selected segments of the intestine,[226,227] but not when absorption is measured in the entire undisturbed intestinal tract.[228]

Where and when magnesium absorption normally occurs can be ascertained only in an intestine in which the natural physiologic conditions and regulatory mechanisms are not altered and the transit of the meal is not impeded. Kayne and Lee[229] have demonstrated that significant magnesium absorption occurs in the distal portions of the intestine, using the technique of compartmental modeling to analyze and integrate segmental absorptive events of mineral from a spontaneously propelled liquid meal along the intact intestinal tract: the estimated rate constants for intersegmental transit and segmental absorption reflect in vivo events. Based on the intestinal transit data of a liquid meal labeled by a nonabsorbable marker, ^{14}C-polyethylene glycol, it is apparent that the proximal small intestine has a short exposure time to the rapidly advancing isotope bolus and is therefore responsible only for the modest magnesium absorption observed during the first 2 hours. Thereafter, the food bolus moves more slowly through the ileum and colon, where the bulk of magnesium is absorbed at a steady, higher, and more sustained rate. Thus both transit time through the gastrointestinal tract and availability of magnesium for absorption in various segments may profoundly influence the amount of magnesium absorbed along the intestinal tract. This approach allows the analysis of the mechanism and the regulation of mineral absorption under more authentic in vivo conditions[229] (Figure 34-6).

Intestinal magnesium absorption occurs by two different pathways: a saturable active transcellular transport system and a nonsaturable passive paracellular transport sytem.[230] Saturation kinetics of the transcellular transport system are explained by the limited capacity of active transport. Intestinal luminal Mg^{2+} concentration drives passive diffusional absorption along the paracellular pathway. At low intraluminal concentrations, magnesium is absorbed primarily through the active transcellular route and, with rising concentrations, through the paracellular pathway, yielding a curvilinear function for total absorption. Saturable magnesium absorption is small compared with the total magnesium-absorptive flux, indicating a modest cell-regulated Mg^{2+} flux.[25]

Based on studies in both experimental animals and humans, it appears that passive diffusion through the paracellular pathway accounts for the major portion of magnesium absorbed. Passive diffusion is driven by the electrochemical gradient across the epithelium. Absorption by this process is expected to vary with the luminal Mg^{2+} concentration and not exhibit saturation kinetics. In young, growing rats, luminal Mg^{2+} uptake in duodenum is a linear, concentration-dependent process, not a saturable magnesium-absorptive process, and exhibits no age-related changes.[141] However, it is possible that depletion of luminal Mg^{2+} may loosen the

Marked boxes represent the sites of absorption at different time intervals: 1 to 2 hours *(vertically striped box),* 2 to 4 hours *(black box),* 4 to 6 hours *(dotted box),* 6 to 8 hours *(cross-hatched box),* longer than 8 hours *(open/diagonally striped box).* **B,** The *lower diagram* depicts the movement of ^{14}C-polyethylene glycol over time observed in another study. *(***A,** *From Graham L, Caesar JJ, Burgen AS: Gastrointestinal absorption and excretion of ^{28}Mg in man,* Metabolism *9:646, 1960;* **B,** *from Kayne LH, Lee DB: Intestinal magnesium absorption,* Miner Electrolyte Metab *19:210, 1993.)*

tight junctions, resulting in transepithelial diffusion. Furthermore, a high luminal Mg^{2+} concentration may reduce transepithelial permeability, the latter accounting for the reduction in fractional magnesium absorption observed with a high-magnesium diet.[141]

Net magnesium absorption in adults is linearly related to dietary magnesium over a normal range of intakes (130 to 490 mg/day),[231] consistent with a diet-dependent passive process for magnesium absorption. Fine and colleagues[230] measured magnesium absorption in adults over a wide range of intakes (with a standard meal supplemented with 0 to 80 mEq of magnesium acetate). These investigators observed that net magnesium absorption rose with each increment in intake but that fractional magnesium absorption fell progressively (from 65% at the lowest to 11% at the highest intake), so that the relationship between net magnesium absorption and intake was curvilinear. This observation is consistent with a magnesium absorption process that simultaneously uses (1) a mechanism that reaches an absorptive maximum and (2) a mechanism that endlessly absorbs a defined fraction (7%) of ingested magnesium, indicating that magnesium absorption is mediated by both a saturable carrier and passive diffusion[230] (Figure 36-7).

A saturable component of intestinal magnesium absorption has been consistently reported in animal studies.[224,227] Ross[224] reported curvilinear uptake of Mg^{2+} in the small intestine of rats when the Mg^{2+} concentration was varied from 0.1 to 12 mmol/L. Meneely and associates[227] found that Mg^{2+} absorption was saturable in the colon of adolescent rats but not in the jejunum or ileum, possibly owing to down-regulation of active transport of Mg^{2+} in the colon.[224] Active transport has seemed likely because Mg^{2+} can be absorbed against an electrochemical gradient in the intestine. Studies using the Ussing chamber have documented that Mg^{2+} is actively transported in the descending colon. Karbach and Feldmeier,[232] measuring unidirectional fluxes in the absence of transepithelial electrochemical gradients and under voltage-clamp conditions, have reported active mucosa-to-serosa Mg^{2+} transport in the ileum and in both the proximal and distal colon of the rat. Because no definite evidence supports either an uphill or an energy-dependent Mg^{2+} transport process, however, other investigators have proposed that the observed saturation characteristics are mediated by facilitated diffusion. Active transport of Mg^{2+} has been conclusively demonstrated in the colon, and indirect evidence also points to the existence of an active cellular mediated component of Mg^{2+} transport in the small intestine. This component is probably saturated under conditions of usual dietary magnesium intake and therefore may be critical only to total Mg^{2+} absorption in the intestine under conditions of rapid growth or extremely low dietary magnesium intake.

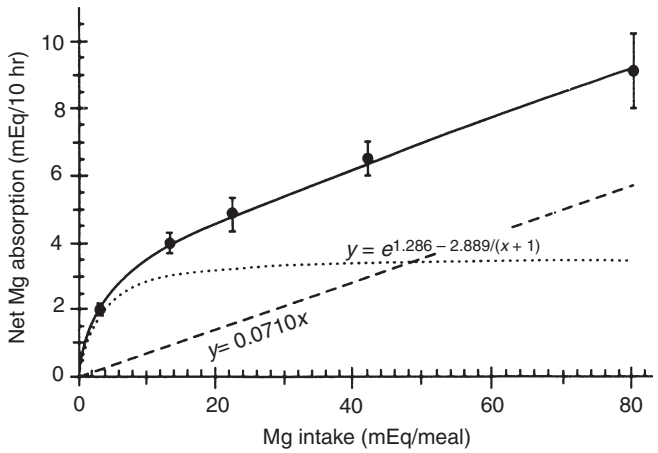

Figure 36-7 Net magnesium (Mg) absorption versus intake as derived by nonlinear regression analysis. The equation for net absorption, $y = e^{1.286 - 2.889/(x+1)} + 0.0710x$, represents a hyperbolic function plus a linear function. These separate components and their respective equations are shown. *(From Fine KD, Santa Ana CA, Porter JL, et al: Intestinal absorption of magnesium from food and supplements,* J Clin Invest *88:396, 1991.)*

As with active Ca^{2+} absorption in the small intestine through epithelial Ca^{2+} channels TRPV5 and TRPV6,[105,106,233,234] transcellular Mg^{2+} transport is a three-step process consisting of (1) entry across the apical membrane of the enterocyte, driven by a favorable transmembrane potential, through the apical epithelial Mg^{2+} channel TRPM6 (*t*ransient *r*eceptor *p*otential cation channel, subfamily *m*elastatin, member *6*), (2) cytosolic diffusion of Mg^{2+}, and (3) active extrusion across the basolateral membrane,[235] with most physiologic studies favoring a sodium-dependent exchange mechanism at this membrane.[236] Mg^{2+} entry seems to be the rate-limiting step and the point of regulation.

The transcellular transport of Mg^{2+}, comprising luminal uptake and basolateral extrusion, requires membrane proteins that increase the low permeability of the membranes and facilitate the movement of Mg^{2+} through these lipid bilayers. The molecular mechanisms mediating transcellular transport are still not completely understood. In recent years, significant progress has been made toward the isolation of genes (and their products) involved directly in transporting Mg^{2+} across biologic membranes in mammalian cells. Identification of the gene defect in patients with hypomagnesemia with secondary hypocalcemia, a disorder characterized by a combined defect of intestinal and renal Mg^{2+} transport, resulted in the discovery of TRPM6 as a crucial component of epithelial Mg^{2+} transport.[237,238] TRPM6, the gatekeeper in transepithelial Mg^{2+} transport, is a member of the TRP gene family of cation channels, and represents *the first molecularly identified protein involved directly in active Mg^{2+} absorption*.[238,239] From the recent electrophysiologic characterization of TRPM6, it is suggested that TRPM6 is an Mg^{2+}-permeable channel localized to the brush border membrane of the Mg^{2+}-absorptive cells in the duodenum, the site of transepithelial Mg^{2+} transport, and is in turn regulated by changes in intracellular Mg^{2+} or Mg^{2+}-ATP level.[235,240] TRPM6 is predominantly expressed in intestinal epithelium and kidney tubule, suggesting a key role of TRPM6 in Mg^{2+} absorption and whole-body magnesium homeostasis. Recently, Groenestege and associates[241] have demonstrated that TRPM6 is expressed predominantly in kidney, lung, cecum, and colon. As indicated by the predominant expression of TRPM6 in cecum and colon, together with the low expression level in duodenum and jejunum, active Mg^{2+} absorption may take place exclusively in the distal part of the intestine. The highly abundant expression of TRPM6 in colon is further supported by the fact that colectomy in rat results in a syndrome of magnesium deficiency, with decreased urinary magnesium excretion, normal serum magnesium concentrations, and decreased bone magnesium content.[242]

Several hormones, including PTH, calcitonin, vitamin D, and sex steroids have been reported to influence the Mg^{2+} balance.[67,243,244] It is suggested that these hormones are only indirect regulators of magnesium homeostasis, because Mg^{2+} lacks specific endocrine control comparable with that for Ca^{2+}.[243] Recently, Groenestege and associates[241] demonstrated that 17β-estradiol (17β-E_2), but not 1,25-$(OH)_2$D or PTH, specifically up-regulates TRPM6 mRNA expression in kidney, pointing to the *first magnesiotropic hormone* in the maintenance of the Mg^{2+} balance. In ovariectomized rats, the renal TRPM6 mRNA level was significantly reduced and subsequently normalized by 17β-E_2 supplementation. It seems that 17β-E_2 increases magnesium reabsorption through an enhanced renal TRPM6 expression. Thus estrogen is involved in magnesium homeostasis through the regulation of the magnesium channel TRPM6 in kidney.

TRPM6 is regulated by dietary magnesium content. Magnesium depletion increased TRPM6 mRNA expression in kidney (but not the colon), whereas a magnesium-enriched diet increased TRPM6 mRNA levels in colon, supporting the gatekeeper function of TRPM6 in transepithelial Mg^{2+} transport. Dietary magnesium restriction in mice resulted in hypomagnesemia and renal Mg^{2+} and Ca^{2+} conservation, whereas a magnesium-enriched diet led to increased urinary Mg^{2+} and Ca^{2+} excretion. Thus it appears that mice can increase their transcellular Mg^{2+} absorption capacity in intestine when fed a magnesium-enriched diet. Physiologically, an excess of Mg^{2+} absorption as a result of high dietary magnesium intake together with TRPM6 up-regulation in colon can be totally corrected by the kidney, by increasing urinary Mg^{2+} and Ca^{2+} excretion. From the unaltered expression levels of TRPM6 mRNA in colon during magnesium restriction, it seems that the Mg^{2+}-absorptive capacity is sufficient to obtain maximal transcellular Mg^{2+} transport. [241]

Mg^{2+} efflux occurs along Na^+-dependent and Na^+-independent pathways.[236,245] Although current data suggest no significant chemical gradient for magnesium across the cell membrane, the significant uphill electrical gradient for the exit of a cation such as Mg^{2+} suggests the participation of an energy-dependent mechanism.[230]

Absolute intestinal absorption of magnesium appears to depend on the magnesium content of the diet and on body magnesium status.[230] Relatively higher Mg^{2+} absorption occurs in patients who have previously ingested low-magnesium diets or in clinical situations characterized by overall negative Mg^{2+} balance, for instance, in pregnancy, lactation, or excessive renal excretion. The factors controlling intestinal magnesium absorption are not well delineated.[232,246] A significant amount of magnesium absorption, however, is vitamin D–independent: It persists under conditions of vitamin D deficiency. Absorption also may be negatively affected by intraluminal complexing agents, such as phytates found in cereal grain.

Repletion of vitamin D in vitamin D–deficient animals and humans is associated with increments in magnesium absorption.[87] In vitamin D–replete animals and humans, pharmacologic doses of vitamin D[87,88] appear to increase magnesium absorption, whereas spontaneous fluctuations in circulating levels of 1,25-$(OH)_2$D have little effect on Mg^{2+} transport. The importance of vitamin D–stimulated magnesium absorption on overall magnesium homeostasis remains uncertain,[87,88] particularly in light of the dramatic increases in urinary excretion of Mg^{2+} that have been associated with vitamin D administration.[246]

For many years, it was assumed that calcium and magnesium were handled similarly at different steps in the intestinal absorptive process. Data from Hardwick and colleagues,[141] however, cast doubt on that assumption. In their studies using young, growing (postweaning) rats, duodenal calcium absorption was mediated both actively and passively (with the former predominating), whereas magnesium absorption was predominantly a concentration-dependent mechanism. It appears, therefore, that calcium and magnesium are handled differently at various steps of the absorptive process.

In rats, several studies have demonstrated that net absorption of magnesium in vivo is depressed by a high calcium intake.[247,248] Karbach and Ewe,[88] however, reported that increasing the calcium concentration in intestinal perfusate from 1.25 to 10 mM/L in vivo had no effect on magnesium absorption in the colon of rats. This study does not rule out that calcium at lower concentrations may significantly alter magnesium absorption.

In humans, several studies have shown that increasing calcium in the diet significantly depresses magnesium absorption.[249,250] In very-low-birth-weight infants,[223] high dietary calcium intakes that allow retentions equivalent to the in utero accretion rates do limit magnesium retention, and a significant magnesium deficiency can occur in comparison with intrauterine accretion.[156] Calcium and phosphorus supplementation reduce magnesium absorption and retention; however, with magnesium intakes approaching 20 mg/kg/day, appropriate retention is achieved in very-low-birth-weight infants. [223]

The effect of increased magnesium intake on calcium absorption and retention is more controversial. Karbach and Ewe[88] demonstrated absence of any limitation in calcium absorption when increasing concentrations of magnesium (1.25 to 10 mmol/L) were used to perfuse the large intestine of the rat. When calcium and magnesium interactions were examined in the descending colon of the rat using the Ussing system, however, magnesium exerted a significant negative effect on net calcium absorption. Specifically, increasing the magnesium concentration to 1.25 mmol/L decreased the mucosa-to-serosa flux of Ca^{2+} by 50% and abolished net calcium absorption. The effect was due to a depression of the voltage-dependent component—that is, the paracellular pathway.

Increasing magnesium in the diet has been reported to increase fecal calcium significantly in humans.[251] Fine and colleagues,[230] however, demonstrated that an increased magnesium intake in adults had no effect on calcium absorption, indicating that even when present in great excess, magnesium does not inhibit active or passive calcium absorption. Urine calcium excretion increases with increased magnesium intake and absorption (Figure 36-8).

Much of the evidence for intestinal interactions between calcium and magnesium has come from studies in which transport of one nutrient was studied in the absence of dietary intake of the other nutrient.[247,252] Moreover, the results of previous studies do not exclude an adaptive effect of calcium on magnesium transport in the intestine. The mechanisms by which calcium and magnesium interact, however, have not been well defined. Several possibilities have been proposed, including competition for a common carrier system, a calcium-induced change in membrane permeability to magnesium, and modulation of a specific magnesium carrier by calcium.[253] Intestinal membrane permeability is sensitive to alterations in luminal Ca^{2+} and Mg^{2+} concentrations.[254] The physiologic changes in these luminal

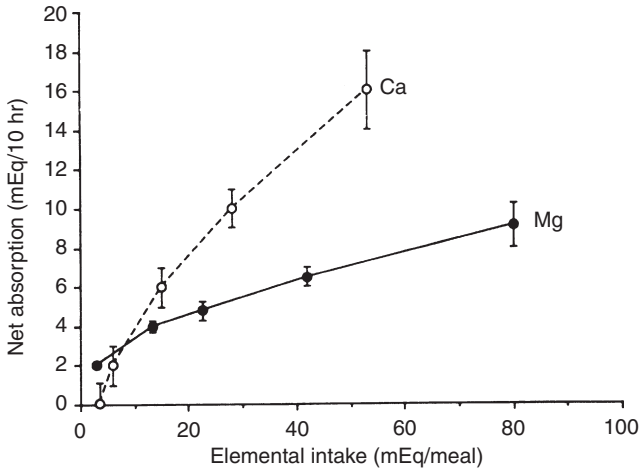

Figure 36-8 Comparison of net magnesium (Mg) absorption with net calcium (Ca) absorption measured from similar meals supplemented with various amounts of calcium carbonate or magnesium acetate. (Mean ± SE values are shown.) At low levels of intake, more magnesium than calcium is absorbed. At intakes greater than 8 mEq, increasingly more calcium than magnesium is absorbed. *(From Fine KD, Santa Ana CA, Porter JL: Intestinal absorption of magnesium from food and supplements,* J Clin Invest *88:396, 1991.)*

concentrations also may influence diffusion through the paracellular pathway. Further investigation is required to test this hypothesis and to determine its importance in short- and long-term regulation of calcium and magnesium transport.

Several other factors can affect intestinal magnesium absorption. Glucose polymers have been observed to enhance jejunal absorption of magnesium.[165] The absorption of magnesium has been found to be directly related to the net absorption of water, consistent with carbohydrate-enhanced magnesium absorption by means of solvent drag. Dietary lactose, a poorly digestible disaccharide, significantly enhances the apparent absorption of magnesium in rats.[261] Theoretically, this effect of lactose may involve a decrease in pH in the intestinal lumen, caused by bacterial fermentation,[255] thereby altering the solubility of magnesium in the digesta. The observed negative relationship between pH in the ileal lumen and intestinal magnesium absorption in the rat supports the notion that the decrease in ileal pH (from 7.5 to 7.2) after lactose feeding is the major mechanism responsible for the improved magnesium absorption.[255] In a study investigating the effect of lactose on magnesium absorption in term infants,[256] magnesium retention was similar between infants fed a formula containing lactose compared with one that was lactose free.

Starch, which is poorly digestible, also influences magnesium absorption by a mechanism similar to that of lactose.[257] In rats fed native starch, magnesium absorption is increased. Furthermore, the ileal pH is significantly lowered, and magnesium concentrations in liquid cecal contents are raised.[257] Whether changing the carbohydrate composition of formula (especially the relatively poorly digestible carbohydrates, e.g., starch) can affect magnesium absorption has not been studied in human infants.

Magnesium absorption may be improved with use of easily absorbed fat in the form of medium chain triglyceride.[258] An increase in dietary protein concentration increases apparent magnesium absorption in rats[259,260] and in humans.[261]

Increased phosphorus intake may decrease magnesium absorption owing to the formation of less soluble phosphorus-magnesium complexes.[262] In full-term breast-fed infants, however, the addition of phosphorus supplements to human milk improved magnesium absorption and retention.[263] In very-low-birth-weight infants, increased dietary phosphorus resulted in a higher fecal loss of magnesium and lower net absorption and retention of magnesium.[264]

Finally, significant amounts of magnesium are secreted into the intestinal tract. Bile, pancreatic juice, and gastric juice all contain large amounts of magnesium. Almost all of the secreted Mg^{2+} is reabsorbed, so that under normal conditions, this fraction accounts for only a small proportion of the total fecal content.[29] In rats, a significant portion of magnesium in feces is of endogenous origin and is changed by dietary protein intake—high levels of soybean protein lead to greater excretion of endogenous magnesium.[28,265,266] By contrast, endogenous Mg^{2+} excretion in feces is significantly depressed in rats fed a threefold higher casein diet, whereas urinary Mg^{2+} excretion is increased.[267] It is uncertain how protein intake affects the excretion of endogenous magnesium in the feces.

Endogenous magnesium losses in adult humans[268] range from 6 to 36 mg/day. In term newborn infants, endogenous magnesium secretion, measured using radioisotopes, ranged from 6.8 to 16 mg/day, similar to the values noted in adults but much greater if expressed per kg of body weight or as percent of total magnesium intake.[28]

37 Zinc in the Fetus and Neonate

K. Michael Hambidge and Nancy F. Krebs

In a remarkably short time, the general perception of zinc has progressed from that of a rather obscure essential trace mineral of doubtful significance for human health to that of a micronutrient of exceptional biologic and public health importance. This is most evident in relation to early development, both prenatal and postnatal. Space allotted to an overview of trace minerals other than iron and zinc in previous editions of this book is therefore devoted entirely to zinc in this edition, and the reader is referred to other texts for information on other trace minerals.[1, 2] The principal focus of this chapter is the complex biology of zinc that underlies its clinical importance.

BIOCHEMISTRY AND BIOLOGY OF ZINC

The abundance of zinc in the human body (approximately 2 g in the adult)[3] is second only to that of iron among those trace elements for which a nutritional requirement has been established in humans. In contrast with iron and iodine, however, zinc is distributed relatively evenly throughout the body, being found as a component of thousands of zinc metalloproteins or zinc-binding proteins, and also of nucleic acids, so it is less readily detectable. The identification and application of zinc fluorophore sensors are required to assist in the selective and efficient detection of trace Zn^{2+}.[4]

With an atomic weight of 65.39, zinc is adjacent to several first-transition elements of biologic importance, yet its biochemical properties are very different from those of other elements of similar atomic weight. One of the properties of the zinc atom that has proved to be of outstanding value in biology is its ability to participate in strong but readily exchangeable ligand binding.[5] Coupled with this feature is the notable flexibility of the coordination geometry of this metal. These two properties are responsible for the unique ability of zinc to interact with a wide range of organic ligands and thus to be incorporated in myriad biologic systems. The principal amino acids supplying ligands that bind with zinc are histidine, glutamic acid, aspartic acid, and cysteine.[6] In catalytic sites, zinc forms complexes with water and with any three nitrogen-oxygen-sulfur donors, especially histidine. Structural zinc sites have four protein ligands, with cysteine the preferred ligand. Zinc affects tertiary and quaternary protein structure, and the resulting scaffolding of these zinc coordination spheres is important to the function and reactivity of the metal atom.

Zinc can participate in oxidation-reduction (redox) reactions in special circumstances,[7] specifically through the combined biochemistry of zinc, metallothionein, and glutathione. In contrast with iron and copper, however, the zinc atom has no oxidant properties, and it exists virtually entirely in the divalent state. This chemical attribute has simplified the safe transport of Zn^{2+}, both extracellularly and intracellularly, and its incorporation into biologic systems.

As understanding of its biology evolves, the exceptional importance of this micromineral becomes increasingly impressive.

The biologic role of zinc is now recognized in protein structure and function, including those for enzymes, transcription factors, hormonal receptor sites, and biologic membranes. Zinc has numerous central roles in DNA and RNA metabolism,[8] and it is involved in signal transduction, gene expression, and apoptosis.

First to be appreciated were the catalytic properties of zinc, a function of its biochemistry outlined earlier. The number of zinc metalloenzymes with known three-dimensional structures exceeds 200.[9] Although zinc also has a structural role in numerous enzymes, its primary importance is as an active component of the catalytic site. Zinc metalloenzymes have been identified in each of the six major enzyme classifications. Several of the key enzymes involved in nucleic acid metabolism, cellular proliferation differentiation, and growth are either zinc metalloenzymes or zinc-dependent enzymes.[10]

A major advance in the understanding of the biology of zinc was the identification of proteins that contain a *zinc finger motif*.[11] Structurally, the zinc finger motif is a recurring pattern of amino acids with conserved residues of cysteine and histidine at the base to which zinc binds in a tetrahedral arrangement. Subsequently, hundreds of zinc finger motifs were identified. More than 1000 genes in the human genome encode members of three protein families with zinc finger domains alone: C2H2 zinc fingers, RING fingers, and LIM domains.[9] The number of genes containing zinc finger domains exceeds 3% of all identified human genes. Although all zinc fingers are quite similar, they vary in their precise conformation. Steroid hormone receptors, for example, have several such domains that are involved in the structure itself, and one each for binding to DNA and RNA polymerases. Among the identified zinc transcription factors are several involved in early intrauterine development.[12]

Many transcription factor proteins have the zinc finger motif, thus giving this metal a broad role in gene expression. This role perhaps has been best characterized by the self-regulation of this metal of its own metabolism,[13] and that of metallothionein, with which zinc is so closely associated. Gene expression in this context is considered later, in the discussion of zinc metabolism.

Zinc is an important regulator of apoptosis.[14] This micronutrient has cytoprotective functions that suppress major pathways leading to apoptosis and also directly influences apoptotic regulators, especially the caspase family of enzymes. In airway epithelial cells, zinc is colocalized with the precursor forms of caspase 3, mitochondria, and microtubules. A decline in intracellular zinc may trigger pathways leading to caspase activation. An early and direct effect of zinc deficiency not only on proliferation and differentiation but also in inducing apoptosis, has been demonstrated in growth plate chondrocytes of the chick.[15] The development of the human epiphysis also is sensitive to zinc deprivation.[8]

There is evidence of a direct signaling function of zinc on all levels of signal transduction.[16] Zinc can modulate cellular signal recognition, second-messenger metabolism, and protein kinase and protein phosphatase activities. In the brain, zinc is sequestered in the presynaptic vesicles of *zinc-containing neurons,* from which zinc is released into the cleft and is then recycled into the presynaptic terminal.[17] Synaptically released zinc functions as a conventional synaptic neurotransmitter or neuromodulator, but also, analogous to calcium, it functions as a transmembrane neural signal. The best-established physiologic role of this vesicular zinc is the tonic modulation of brain excitability. Vesicular-rich regions such as the hippocampus are responsive to dietary zinc deprivation, which causes brain dysfunction, including learning impairment and susceptibility to epileptic seizures. Normal neuronal function is dependent on normal zinc homeostasis in the brain.[18]

The biology of zinc is closely linked with that of metallothionein, a unique small intracellular protein of less than 7 kDa that is strongly conserved across species. Of the 61 to 68 amino acids, more than one third are cysteine, and it has a unique metal-binding capacity (copper > cadmium > zinc). It consists of two subunits: an α domain, which under typical physiologic circumstances will bind four zinc atoms, and a more reactive β domain, binding three zinc atoms in tetrahedral formation. Of the four known metallothionein isoforms, MT-1 and MT-2 are most abundant, and MT-3 occurs in the brain. Metallothionein occurs in all tissues, including those of the conceptus, and is especially abundant in liver and also in pancreas, intestine, and kidney. Zinc is the major physiologic inducer of metallothionein. Zinc binds directly and reversibly to the zinc finger domains of the metal-response element–binding transcription factor-1 (MTF-1), which functions as a cellular zinc sensor. As a result of this binding, MTF-1 assumes a DNA-binding conformation and translocates to the nucleus, where it binds to metal-response elements of the metallothionein gene thereby initiating transcription.[13] Cytokines, especially the interleukins IL-1 and IL-6 and tumor necrosis factor-α, and stress hormones (glucocorticoids and catecholamines) also are powerful inducers of metallothionein.[19] This finding suggests a key role for zinc in the inflammatory response, as well as in zinc metabolism, and as a metal detoxicant, and several functions for zinc in this context have been hypothesized.[20]

One of these functions is in the role of metallothionein as an antioxidant. The intracellular redox state is intimately related to metallothionein and intracellular zinc metabolism.[7] Increasing intracellular oxidized glutathione can result in the release of all seven zinc atoms, whereas this is inhibited by reduced glutathione. Oxidants cause greater damage to the liver of $MT^{-/-}$ mice than to that of $MT^{+/+}$ mice.[21] Despite its central role in zinc metabolism (see later), metallothionein is not essential for survival. Late-gestation $MT^{-/-}$ mouse fetuses have decreased hepatic zinc and are prone to obesity in later life.[22] More important, they are disadvantaged when the normal environment is compromised, especially when zinc intake is suboptimal. Factors that increase the induction of maternal hepatic metallothionein during early pregnancy may divert zinc from the conceptus to the maternal liver, potentially resulting in a conceptus that is deficient in zinc. Curtailment of fetal zinc uptake can occur with maternal ingestion of alcohol, and this mechanism may be important in the origin of the fetal alcohol syndrome.[23] Close similarities have been recognized between the teratogenicity of maternal zinc deficiency and alcohol administration to mice in early gestation, and this effect can be diminished by parenteral administration of zinc.[23] Cytokines cause a similar disturbance of maternal zinc metabolism and also are teratogenic in rodents.

PHYSIOLOGY OF ZINC

Intracellular Zinc Metabolism

Zinc metabolism is tissue- and organ-specific. Although this specificity is important to an understanding of zinc metabolism, the following discussion is limited to selected aspects of more universal intracellular zinc metabolism. The intracellular concentration of unbound "free" Zn^{2+} is extremely low. An elaborate homeostatic system of proteins regulates cellular Zn^{2+} distribution and perhaps controls a hierarchy of zinc-dependent functions.[7] Eukaryotic zinc transporters have a major, but still only partly defined, regulatory role.[24] These transporters are encoded by ancient gene families that span all phylogenetic levels. The ZIP family is involved in cellular Zn^{2+} uptake. One member of this family, Zrt3, is known to transport stored Zn^{2+} out of a vacuolar intracellular compartment during adaptation to zinc deficiency. The CDF (cation diffusion facilitator) family of transporters mediates efflux of Zn^{2+} out of cells or facilitates intracellular storage. These transporters are regulated by transcriptional and posttranscriptional mechanisms to maintain zinc homeostasis at a cellular and organ level: ZnT-1 and ZnT-4 are expressed ubiquitously, whereas ZnT-2 expression is limited to the small intestine, kidney, placenta, and liver. When zinc intake is restricted, intestinal and kidney ZnT-2

expression is extremely low, and both ZnT-1 and ZnT-2 messenger RNAs (mRNAs) are increased in intestine, kidney, and liver with high zinc intake.[25] Although zinc transporter expression is responsive to variations in dietary zinc intake, many details of the molecular regulation of zinc metabolism and homeostasis await clarification.

The expression of ZnT-1 and ZnT-2 is comparable to zinc-induced changes in metallothionein mRNA levels, suggesting a similar mode of regulation of these genes. Regulation of metallothionein at the protein level by ligand binding[26] and at the gene level by multiple inducers, including zinc, provides a means of controlling the intracellular availability of zinc by regulating the quantity of metallothionein and the ratio of metallothionein to its redox partner thionein (T) (i.e., MT/T). This role of metallothionein is closely linked to both cellular redox and energy status.

Maternal, Placental, Fetal, and Mammary Gland Zinc Metabolism

Maternal Metabolism

A physiologic increase in maternal hepatic metallothionein in pregnancy has been documented[23]; this increase may enhance a maternal store of zinc that is readily available to the conceptus. It is only when zinc is abnormally diverted to the maternal liver, as with alcohol ingestion, that the inappropriately large shift of Zn^{2+} from the plasma compartment is potentially deleterious to the embryo or fetus. A progressive physiologic decline in maternal plasma zinc also occurs as pregnancy advances,[27] and it is only when this decline is excessive because of maternal zinc deprivation or disturbed metabolism that the embryo or fetus is at risk.

Placental and Fetal Metabolism

Uptake of Zn^{2+} into placental villous syncytiotrophoblast is the first step in the transfer of this metal from the mother to the fetus, and it is the rate-limiting process.[28] This zinc is thought to be derived from the low-molecular-weight maternal plasma zinc pool, probably by a carrier-mediated process, and also from zinc bound to serum protein, possibly by an endocytic mechanism.[29] A potassium-zinc transporter is present in the vesicular membranes.[30] α_2-Macroglobulin binds to human trophoblasts in a specific saturable manner, a finding suggesting the possibility of receptor-mediated uptake of zinc.[31] Affinity for zinc (K_m values) by human syncytiotrophoblast microvillous membrane vesicles does not vary with gestational age or with low maternal plasma zinc concentrations. Zinc uptake capacity (V_{max}) is higher in preterm than in term placentas and with low maternal plasma zinc.[32] Fetal plasma zinc is higher than maternal concentrations. Short-term changes in fetal zinc status do not influence placental zinc transfer, suggesting that no ready mechanism is available for adjusting to fetal zinc deprivation once (or if) it occurs.[33] As gestation progresses, marked increases occur in fetal hepatic zinc concentration. These concentrations decline as the third trimester progresses. The increase in hepatic zinc concentration early in the third trimester appears to be secondary to hepatic metallothionein induction, rather than its cause.[34]

Metallothionein has been found in fetal amniotic cells, syncytial trophoblasts, and villous interstitial cells.[35] The mammalian embryo is surrounded by cells that actively express MT-1 and MT-2 genes, suggesting that metallothionein has a functional role in the establishment, as well as the maintenance, of normal pregnancy.[36] MT-3 and MT-4 mRNAs are abundant in the maternal deciduum, in contrast with fetal tissues, and these genes are refractory to induction by either zinc or inflammation in the deciduum.[37] Metallothionein gene expression may have a physiologic role in placental transport of Zn^{2+}.[38]

As with the intestine, further research is essential to determine how the roles of these and other factors, such as zinc transporters, are integrated to achieve regulation of placental Zn^{2+} transport. Only then will it be possible to understand how regulation, and hence the zinc status of the embryo or fetus, may be compromised, especially early in gestation.

Mammary Gland Metabolism

ZnT-1 (present in serosal membrane), ZnT-2, and ZnT-4 (present intracellularly) have been identified in the mammary gland. Milk zinc concentration is regulated through co-coordinated regulation of these mammary gland zinc transporters.[39] Vitamin A, which has substantial interactions with zinc,[40] has a role in the maintenance of zinc homeostasis in the mammary gland.[39] The regulatory changes responsible for the notable decline in human milk zinc concentrations as lactation progresses,[41,42] have not been elucidated, but they may be responsive to changes in the hormonal milieu.

Rarely, the mammary gland has a defect in the ZnT-4 gene resulting in impaired secretion of zinc.[43] Breast milk zinc concentrations are less than the normal range at all stages of lactation. Infants breast-fed by these mothers typically display the classic phenotype of acrodermatitis enteropathica by approximately 2 months of postnatal age. Infants with the clinical syndrome respond rapidly and completely to an oral zinc supplement of 2 mg/kg of body weight/day and then a smaller maintenance dose while breast-feeding continues. This syndrome has been described in term infants but is more likely to affect those infants born preterm, suggesting an increased vulnerability of the preterm infant to clinically significant zinc deficiency syndromes.[44]

Whole-Body Zinc Homeostasis

Postnatally, the gastrointestinal tract, specifically the small intestine and the pancreas, has the major role in maintaining whole-body zinc homeostasis.[45,46] Zinc transporter expression is a major component of homeostatic regulation, including regulation of zinc absorption by the small intestine and excreting zinc through both pancreas and small intestine. A total of 16 zinc transporters have been identified in these organs.[25] When dietary zinc intake is reduced, Zip4 is up-regulated at the apical surface of the small intestine. This transporter is defective in classic acrodermatitis enteropathica.[47] Of note, it is the quantity of zinc ingested rather than zinc status that is the principal factor triggering regulation of expression of the transporters involved with zinc absorption into and through the enterocyte.[45]

Zn^{2+} absorption into and through the enterocyte is a saturable transport process.[48,49] Fractional absorption, therefore, declines with increasing zinc intake, and vice versa. Passive paracellular diffusion also occurs in animal models but has not been detectable in modeling human zinc absorption.[50] When data are adjusted for differences in length of the small intestine, the term infant can absorb ingested zinc as efficiently and with the same capacity as in the adult.[51] This also appears to be true for the preterm infant at 33 weeks after conception,[51] suggesting that synthesis of zinc transporters and other zinc-containing molecules in the enterocyte is mature by this stage of development. However, the length of the small intestine is, of course, shorter. The shorter small intestinal length is commensurate with the lower requirements for absorbed zinc in the term infant. Nevertheless, absorption of adequate zinc is a challenge in the premature infant because of the especially short small intestinal length and the high zinc requirements of this population.

Regulation of the quantity of endogenous zinc excreted has a major role in maintaining whole-body zinc homeostasis in most circumstances.[45,46,52] The zinc exporters ZnT-1 and ZnT-2 exhibit progressive down-regulation, most notably in the pancreas, when dietary zinc is reduced.[25] The ability to regulate endogenous zinc losses through the intestine appears to be well developed in early postnatal life in the term infant.[53,54] In the premature infant, the rate of endogenous zinc excretion is positively correlated with

the quantity of zinc absorbed, as in term infants. In other words, when absorption decreases, endogenous zinc is conserved. Although the premature infant may be able to regulate intestinal excretion of endogenous zinc as efficiently as the term infant, more, unfortunately, is required to help meet the greater needs. Endogenous zinc losses through the kidneys, although small in comparison with the intestinal losses, also are relatively high in the very-low-birth-weight infant on a body weight basis.

Model-based compartmental analysis of zinc metabolism in the adult[55] has identified several pools of zinc that intermix with zinc in plasma within 3 days. The combined size of these pools (exchangeable zinc pool [EZP]) can be estimated from what appears as a single exponential between 3 and 9 days after administration of a zinc tracer and from urine enrichment with this zinc-stable isotope tracer.[56] On a body weight basis, the size of the EZP is approximately seven-fold higher in premature infants at 33 weeks after conception, according to unpublished data of S. Jalla and co-workers.[57] than in adults. This finding may be attributable to more than one possible difference in zinc metabolism or nutrition, but it is explained in part by higher concentrations of metallthionein in the fetal liver earlier in the third trimester.[58]

ZINC DEFICIENCY IN THE CONCEPTUS AND EARLY INFANCY

Embryogenesis

An adequate supply of maternal zinc is critically important for the oocyte and embryo.[12] The teratology in rodents resulting from maternal zinc deficiency is quite exceptional.[59-61] Consequences include a high mortality rate and congenital malformations affecting nearly all organ systems. Relevant data in the human are very limited, and prospective trials of zinc supplementation in carefully selected population groups that encompass the perinatal period will be required. Suggestive evidence points to a causal association between severe maternal zinc deficiency resulting from acrodermatitis enteropathica and congenital malformations including neural tube defects.[62] Although one study did not find any evidence of hypozincemia in the first trimester in pregnancies that resulted in neural tube defects,[63] this lack of correspondence may not apply in maternal populations in which the dietary supply of available zinc is especially limited.[64] Epidemiologic evidence from a presumably well-nourished population points to a link between maternal zinc status and neural tube defects.[65] Preliminary data from West Timor, where intake of available zinc is low and the incidence of cleft lip or palate is high, indicate that maternal zinc supplementation commencing by 8 to 10 weeks gestation is associated with a significant reduction in the incidence of these malformations.[66] The association among maternal alcohol consumption, diversion of maternal zinc from the conceptus, and the fetal alcohol syndrome is discussed earlier. This also is a putative paradigm for any maternal stress or infection that increases cytokine production and consequently increases induction of maternal hepatic metallothionein.

Fetal Development

Maternal zinc restriction during fetal development is associated with intrauterine growth retardation in rodent models.[67] Another reported effect is a decrease in nestin, a marker of proliferation of neural stem cells.[68]

In reported data for humans, findings are conflicting regarding the effects of maternal zinc supplementation on gestational age at delivery and birth weight.[66,69-71] Multicenter, carefully designed, prospective intervention studies will be required to resolve the question of whether maternal zinc deficiency contributes to low birth weight by reducing the duration of gestation or the rate of growth in utero. Perhaps unexpectedly, more consistent evidence suggests that maternal zinc supplementation starting in the second trimester and discontinued at delivery is associated with decreased infectious disease morbidity during the first 6 months of infancy.[72] This effect, which presumably is mediated through an effect of fetal zinc status on the developing immune system, is itself is an important reason for ensuring optimal maternal zinc intake.

Infancy

The effects of zinc deficiency in infancy require consideration both from a global public health standpoint and from an individual perspective. With the latter perspective, cases can usefully be subdivided into acute or severe[73] and mild,[74] but with the recognition that acute or severe zinc deficiency can enter a chronic phase; in addition, apparently mild cases with nonspecific clinical features carry the risk of death[75] as well as severe morbidity.[76,77] Moreover, intermediate clinical presentations, as exemplified by the original descriptions of human zinc deficiency, have been documented.[78]

The prototype of the acute severe presentation is the disorder *acrodermatitis enteropathica,* of autosomal recessive inheritance.[73] Identification of the underlying genetic defect or one of the underlying genetic defects is likely to be imminent. The clinical features of this syndrome manifest between the ages of 2 and 6 months, although presentation may be delayed with the universal zinc fortification of infant formulas in North America and elsewhere. Before this fortification policy, the onset of the disorder in breast-fed infants typically was later than in formula-fed infants, and breast milk was found to be of some therapeutic benefit. The single most important diagnostic feature, although not pathognomonic, is the skin rash. This erythematous rash may be widespread but characteristically is most evident around the body orifices and the extremities. Diarrhea and hair loss, although not inevitable, complete the classic triad of features. Untreated cases are marked by anorexia, marked apathy, progressively severe failure to thrive, and recurrent infections resulting in death in later infancy. Similar syndromes have been reported as a result of exclusive breast-feeding by mothers with a genetic defect in ability to secrete normal quantities of zinc by the mammary gland[42] or secondary to severely restricted zinc intake. The latter was seen quite frequently in parenterally fed patients in the early days of intravenous feeding. Premature infants appeared to be especially vulnerable to a lack of zinc in these infusates.

Many different abnormalities of the immune system have been observed in acrodermatitis enteropathica. Although it has been difficult to separate the effects of zinc deficiency from those of the resulting protein-energy malnutrition, extensive experimental data substantiate the far-reaching effects of zinc deficiency on every aspect of the immune system,[79] defects in which undoubtedly underlie the global public health concerns about zinc deficiency (see later). As one of the systems with the most notable rapid turnover of cells, the immune system is especially vulnerable to the fundamental defects in cellular proliferation, growth, and metabolism that result from an inadequate supply of this mineral.

On a global basis, zinc deficiency is now recognized as a major public health issue. Solid evidence indicates that as many as 20% to 25% of cases of diarrhea and 40% of cases of pneumonia in developing countries can be prevented by preventing zinc deficiency.[80] The risk of malaria also may be reduced. Acceleration of delayed linear growth and weight gain,[81] and probable improvement in brain development and function,[82] have been documented with correction of zinc deficiency in the same or similar populations of young children and also in North America.[74,83] Taken together, these features encompass all of those, with the exception of human immunodeficiency virus infection, that are of greatest public health concern for young children worldwide.

Low-birth-weight infants are at greater risk for zinc deficiency and its sequelae. In India, zinc supplementation from very early postnatal life has resulted in a significant decrease in mortality

rates for infants with intrauterine growth retardation.[75] Improvements in brain function[84] and physical growth velocity and diminution of infectious disease morbidity also have been documented.

EARLY POSTNATAL ZINC REQUIREMENTS OF THE PREMATURE INFANT

For the young, exclusively breast-fed term infant, zinc intake provides an excellent guide to requirements, that is, approximately 2 mg of zinc/day.[41] A rapid rate of physiologic decline in breast milk zinc concentration has been documented, with a resultant decrease in intake to approximately 1 mg of zinc/day for the exclusively breast-fed infant by approximately 4 months, with subsequent further decline.[41] Whether this intake is adequate after 4 to 6 months has not been determined,[85] but complementary sources of zinc clearly are required around this age. For the formula-fed infant, less favorable bioavailability dictates the apparent need for higher intakes, but these have not been well defined.

Estimation of zinc requirements depends primarily on a factorial approach. Such determinations are complex in any population but are especially so in low-birth-weight infants. One reason is that it remains unclear to what extent intrauterine accumulation rates in the premature infant can or should mimic thoseat corresponding gestational ages.[86] As determined in two different studies, postnatal weight gain requires zinc intakes of 17 g/kg body weight/day[87] and 20 mcg/g of weight gain[88]; the very-low-birth-weight infant needs an average daily zinc intake of 340 μg/kg of body weight. How much needs to be retained to meet this intake requirement depends on the extent to which, and the rate at which, hepatic stores of zinc at birth are or can be used by the neonate and young infant. Although the weight of the premature liver is quite small, zinc concentrations are exceptionally high.[58,86] On the basis of several assumptions and complex calculations, the Life Sciences Research Office (LSRO) report determined that 130 μg of zinc/day (or approximately 90 μg of zinc/kg/day) is available from hepatic stores (after 28 weeks gestation) for postnatal growth.[87] Thus retention of exogenous zinc required for growth is 250 μg of zinc/kg/day. With losses of endogenous zinc in feces and urine averaging 215 μg of Zn/kg/day in very-low-birth-weight infants fed either breast milk with fortifier or a premature infant formula (as determined by S. Jalla and co-workers[57]) the estimated average physiologic zinc requirement (amount of absorbed zinc required) is 465 μg of zinc/kg/day. In this study, average fractional absorption from formula and breast milk plus fortifier was 0.25, indicating a dietary requirement approaching 2 mg of zinc/kg/day. The quite strong positive correlation between zinc intake and weight gain in this study suggests, but does not prove, that zinc intakes any lower than this level can limit growth. Relatively high zinc intakes may need to be maintained for many months if lack of adequate zinc is not to limit growth.[89] The results of zinc supplementation studies in early infancy[75,90] suggest that the early postnatal zinc requirements of the small-for-gestational-age infant are at least as high as those of the premature infant.

At a molecular level, more is known about the regulation of excretion of endogenous zinc in response to high zinc concentrations[25] than about the regulation of uptake. The transporter genes that are regulated are ancient, indicating that all eukaryotic cells have developed mechanisms for minimizing the accumulation of zinc in circumstances of environmental excess. This observation suggests that excess zinc is toxic even though little is known about its deleterious effects. In fact, the margin between optimal and toxic levels of zinc may be quite narrow for individual tissues. Moreover, the maintenance of zinc homeostasis by the gastrointestinal tract, although good, is imperfect.[52] Moreover, excess zinc may not need to reach beyond the enterocyte to be deleterious, at least in terms of metal-metal interactions.[91] Therefore appropriate caution is required to ensure that the quantity of zinc supplied to the very-low-birth-weight infant is not excessive. As noted, the margin between optimal and excessive intake may eventually prove to be quite narrow.[92] No evidence has emerged, however, to suggest that the levels of intake from premature infant formulas and human milk fortifiers in current use are excessive. Rather, the foregoing calculations indicate that these are very reasonable, in light of present knowledge.

CONCLUSION

The emergence of the impressive biology of zinc and recognition of the public health implications of zinc deficiency in infants and young children[93] are now alerting the medical community to the need for special attention to this trace element. This need is more apparent in the very-low-birth weight-infant than in any other population group. From a practical standpoint, the most pressing requirement is to delineate the zinc requirements of the infant born very or extremely prematurely, including, as a special subgroup, those with intrauterine growth retardation.

38 Vitamin A Metabolism in the Fetus and Neonate

Jayant P. Shenai

Vitamin A is a fat-soluble micronutrient recognized since 1912 as a dietary constituent that is essential for growth.[1,2] The vitamin A compounds (retinoids) are present in three natural forms: retinol, retinaldehyde, and retinoic acid (Figure 38-1). Retinol (vitamin A alcohol) is a dietary component present in the form of retinyl esters in food sources of animal origin and also is formed in vivo from its precursor, beta carotene, which is present in food sources of plant origin. Retinyl esters are derived from esterification of retinol and constitute the principal storage forms of vitamin A; the major retinyl esters found in animal and human tissues include retinyl palmitate and stearate and, to a lesser extent, oleate and linoleate. Retinaldehyde, also called *retinal,* is derived from reversible oxidation of retinol and, in combination with various lipoproteins, forms the visual pigment of the retina.[3] The photoisomerization of retinaldehyde is necessary for vision.[4] Retinoic acid is derived from irreversible oxidation of retinaldehyde in the tissues[5] and is the active metabolite of vitamin A in functions related to growth and differentiation.[6]

VITAMIN A METABOLISM

Transport in Plasma

Vitamin A is transported in plasma as retinol bound to a specific carrier protein, retinol-binding protein (RBP) (Figure 38-2). The human RBP molecule consists of a polypeptide chain of approximately 180 amino acid residues; it has a molecular mass of approximately 21 kDa and a single binding site for one molecule of retinol.[7,8] The RBP is synthesized in liver and secreted into plasma as retinol-RBP complex.[9] In plasma, the retinol-RBP complex interacts with another protein, transthyretin, and circulates as an RBP-transthyretin complex.[9] The transthyretin molecule is a stable, symmetric tetramer composed of four identical subunits with a molecular mass of approximately 55 kDa.[10] Vitamin A is distributed to the target tissues in the form of retinol-RBP complex bound to transthyretin. The cellular uptake of vitamin A depends on a specific plasma membrane receptor that recognizes RBP.[11,12] After delivery of vitamin A to the plasma membrane, RBP is returned to the circulation and is partly reused for vitamin A delivery and partly eliminated by the kidney.[13] The mechanisms involved in the processing of transthyretin are not known.

Metabolism in the Cell

The movement of vitamin A within the tissue cells involves two intracellular vitamin A–binding proteins, cellular retinol-binding protein (CRBP) and cellular retinoic acid–binding protein (CRABP)[14] (Figure 38-3). The CRBP molecule consists of a polypeptide chain with a molecular mass of approximately 14.6 kD and a single binding site for one molecule of a specific isomer of retinol, all-*trans*-retinol. The CRBP participates in the enzymatic esterification of retinol into retinyl esters for storage in the cell. The CRABP molecule also consists of a 14.6-kDa polypeptide chain with a single binding site for one molecule of a specific isomer of retinoic acid, all-*trans*-retinoic acid. Given the apparent absence of a plasma delivery system specific for retinoic acid, it seems likely that the retinoic acid within the cell is derived mostly from oxidation of retinol occurring within the cell. The CRABP participates in the interconversion of two specific isomers of retinoic acid, all-*trans*-retinoic acid and 9-*cis*-retinoic acid. Both CRBP and CRABP are suggested as transport proteins for retinoids between the cellular and nuclear membranes.

Processing in the Nucleus

The nuclear uptake of all-*trans*-retinoic acid is mediated exclusively by a family of receptors called *retinoic acid receptors* (RARs) (see Figure 38-3).[15] Three different isomers of RARs—RAR-α, RAR-β, RAR-γ—exist and are expressed in distinct patterns throughout development. The RARs modulate gene expression by binding as homodimers or heterodimers to specific DNA sequences known as *retinoid acid receptor elements* (RAREs). In contrast with that of all-*trans*-retinoic acid, the nuclear uptake of 9-*cis*-retinoic acid is mediated partly by RARs but mostly by another family of receptors called *retinoid X receptors* (RXRs).[15] As with RARs, three different isomers of RXRs—RXR-α, RXR-β, RXR-γ—exist and are expressed in distinct patterns throughout development. RXRs modulate gene expression by binding to specific DNA sequences known as *retinoid X receptor elements* (RXREs). The mechanisms by which retinoic acid influences nuclear metabolism, genomic expression, and growth and differentiation of the target tissue remain under investigation.

Vitamin A Excretion

The excretory end products of vitamin A metabolism are derived largely from retinoic acid.[16] Retinoic acid is excreted partly in the ester form of β-glucuronide through the biliary system and is subject to reabsorption in the gut.[17] The enterohepatic circulation of retinoic acid serves to conserve this biologically active form of vitamin A. The rest of the retinoic acid is excreted largely in the urine in the form of oxidation products.[18]

FETAL ACQUISITION OF VITAMIN A

Vitamin A is transferred from the mother to the fetus during pregnancy, particularly in late gestation, in most animal species.[19-25] The transplacental transport of maternal retinol-RBP complex appears to be the predominant route for providing vitamin A to the fetus in early gestation. In late gestation, RBP synthesized by the fetal liver appears to be involved in extracting vitamin A from the placental circulation. Swallowing of amniotic fluid containing vitamin A[26,27] and transfer of maternal lipoproteins containing retinyl esters[23] are other possible means of vitamin A acquisition for the fetus.

The transplacental transfer of vitamin A in humans has been studied by examining paired samples of maternal blood and fetal or cord blood obtained at various gestational ages.[28-32] The ratio of maternal to fetal concentrations of plasma vitamin A in healthy

human pregnancies is approximately 2:1. In conditions in which the maternal vitamin A status is marginal or deficient, the fetal plasma vitamin A concentration often is maintained within normal limits and may exceed the maternal plasma vitamin A concentration.[28,33,34] Conversely, in studies involving maternal vitamin A supplementation, the cord blood vitamin A concentration in the supplemented cohort remains similar to that in unsupplemented control infants.[28,35,36] Thus the plasma vitamin A concentration in the fetus appears to be maintained within a normal range despite variations in maternal vitamin A status and intake. The regulatory mechanisms by which this homeostasis is achieved remain unclear, nor is it known whether such mechanisms can compensate successfully for extremes of maternal vitamin A deprivation or excess.

VITAMIN A STATUS AT BIRTH

Plasma Vitamin A Indices

Plasma concentration of vitamin A is the most commonly used biochemical marker of vitamin A status. In healthy human adults, the plasma vitamin A concentration ranges from 20 to 80 mcg/dL.[37] In children, including infants, a plasma vitamin A concentration below 20 mcg/dL is indicative of vitamin A deficiency.[38] Most preterm infants, in contrast with those of term gestation, are born with plasma vitamin A concentrations that are in the deficient range.[39,40]

Plasma concentration of RBP is another biochemical marker of vitamin A status. In healthy human adults, the plasma RBP concentration averages 4.6 mg/dL (± SD of 1.0 mg/dL).[41] The plasma RBP concentrations in infants and children are approximately 60% of the adult values,[30] and those below 2.5 mg/dL are indicative of vitamin A deficiency.[42] Most preterm infants, unlike those of term gestation, are born with plasma RBP concentrations that are in the deficient range.[40,43]

Another useful biochemical marker of vitamin A status involves plasma RBP response to vitamin A administration. This functional measure of vitamin A status is based on the varied rates of secretion of RBP from the liver to the plasma, depending on the availability of vitamin A.[44,45] In vitamin A–deficient animals, RBP secretion is blocked, leading to its accumulation in the liver and resulting in high liver and low plasma concentrations of RBP. When these animals are given vitamin A, mobilization of RBP from the liver occurs, which leads to a rapid decrease in the liver RBP concentration and a concomitant increase in the plasma RBP concentration.[44] In vitamin A–sufficient animals, on the other hand, RBP does not accumulate in the liver, and minimal or no change in plasma RBP concentration is observed after vitamin A administration.[44] The percent increase in plasma RBP concentration (ΔRBP) from its baseline value in response to vitamin A administration is therefore useful for determining the vitamin A status. A high ΔRBP value (above 8%) is indicative of vitamin A deficiency.[46] In preterm neonates, the plasma RBP response to vitamin A administration, characterized by high ΔRBP values, provides further evidence that these infants are vitamin A–deficient

at birth.[46] It is likely that such deficiency is due to deprivation of the transplacental vitamin A supply that normally allows accrual of adequate vitamin A by full gestation.

Tissue Vitamin A Storage

As much as 90% of the total body reserve of vitamin A is stored normally in the liver in most animal species.[47] The liver vitamin A concentration ranges from 100 to 300 μg/g in healthy human adults,[48] and it varies with age in children, being low during infancy relative to later childhood.[49,50] A liver vitamin A concentration below 40 μg/g is indicative of low vitamin A reserve, and that below 20 μg/g is considered deficient.[49-51] Most preterm infants, unlike those of term gestation, are born with low liver vitamin A stores.[50,52-55] In the absence of an adequate intake of vitamin A in the postnatal period, therefore, these infants are at an added risk for vitamin A deficiency.

Although the liver is the principal storage site for vitamin A, other organs, including the developing lung, are capable of storing vitamin A.[56-58] In the perinatal rat, significant vitamin A storage occurs in the fetal lung during the last third of prenatal life.[57,58] Depletion of these stores that begins before birth and continues into early postnatal period suggests that the developing lung may depend on these local stores of vitamin A during the period of active growth and differentiation associated with rapid alveolarization of the lung. Prematurely born animals, deprived of adequate stores of vitamin A in the lungs, may be susceptible to the adverse pulmonary effects of vitamin A deficiency. The fetal lung stores of vitamin A can be augmented by prenatal maternal administration of supplemental vitamin A.[59] Conversely, prenatal interventions, such as maternal glucocorticosteroid treatment, can deplete the fetal lung stores of vitamin A.[60] Whether the developing fetal lung of humans is capable of vitamin A uptake, esterification, and storage remains undetermined. Moreover, the possibility that administration of vitamin A to human mothers with imminent preterm delivery may augment the lung vitamin A stores of their newborn infants remains unexplored.

VITAMIN A AND ENTERAL NUTRITION

Vitamin A Content

The vitamin A value of a diet is expressed in international units (IU) or retinol equivalents (RE).[37] One IU of vitamin A is equal to 0.3 μg of retinol; one RE of vitamin A is equal to 1.0 μg of retinol.

The vitamin A content of human milk is variable and influenced by several factors, such as age, parity, and socioeconomic status of the mother; postpartum age; and the volume and fat content of the milk.[61] The vitamin A concentration of human milk in colostrum is high (above 333 IU/dL); levels decrease gradually in the first few months of lactation.[61-64] The vitamin A concentration of mature human milk ranges from 110 to 257 IU/dL.[61-63, 65-67] The milk of mothers giving birth prematurely differs in composition from that of mothers delivering at term gestation. The vitamin A concentration of preterm milk is lower than that of term milk during the first week of lactation, but is higher thereafter.[67-69] At approximately 35 days postpartum, the vitamin A concentration of preterm milk ranges from 277 to 333 IU/dL.[68,69] More than 90% of the vitamin A in human milk is in the form of retinyl esters contained in the core of the milk fat globules; less than 10% of the vitamin A is present as free retinol.[66,70-73]

Various infant formulas designed to meet the nutritional needs of a preterm infant are commercially available. The vitamin A content of these formulas varies, ranging fromapproximately 296 to 1000 IU/dL.[74] Preterm infants receiving full enteral

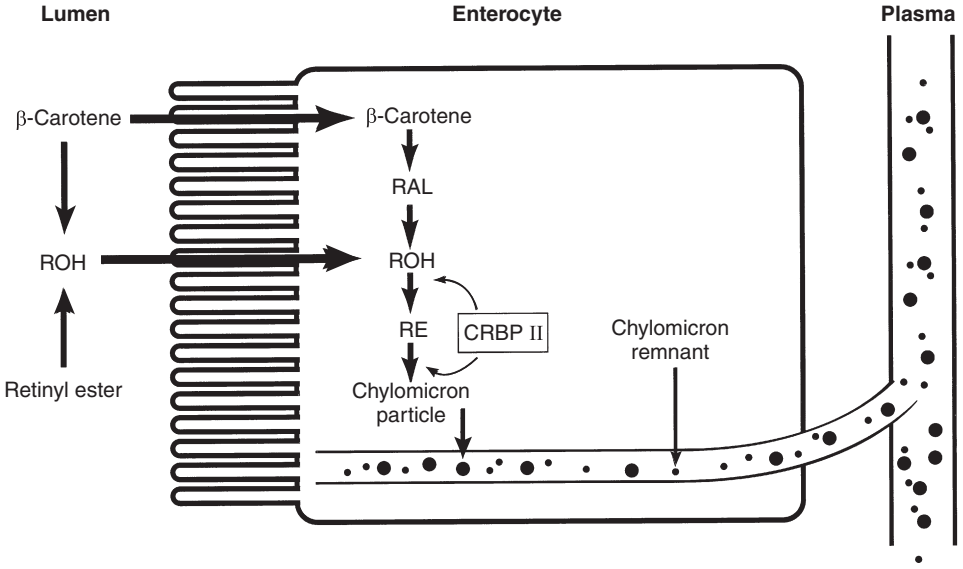

Figure 38-4 Vitamin A absorption in the enterocyte. *CRBP II,* Cellular retinol-binding protein type II; *RAL,* retinaldehyde; *RE,* retinyl ester; *ROH,* retinol.

feedings often are given multivitamin supplements. The vitamin A content of a typical multivitamin supplement is 1500 IU/dL.[74] As in human milk, most vitamin A in the infant formulas and multivitamin supplements is in the form of retinyl esters. Thus the efficiency of use of vitamin A in a neonate fed human milk or an infant formula with or without a multivitamin supplement depends largely on the ability of the infant's gastrointestinal tract to process retinyl esters.

Vitamin A Digestion and Absorption

Dietary retinyl esters are processed by a coordinated series of physical and chemical events in the bowel lumen.[47] These events include dispersion and emulsification of retinyl esters in the stomach, their hydrolysis in the intestinal lumen by pancreatic and other enzymes, and solubilization of retinol (derived from retinyl ester hydrolysis) with bile salts in mixed micelles. These intraluminal events facilitate uptake of vitamin A by the enteral mucosal cells (Figure 38-4). Retinol within the mucosal cells, also partly derived from beta carotene, is largely reesterified with long-chain fatty acids. The retinyl esters are then incorporated, together with other lipids and apolipoproteins, into chylomicron particles. The chylomicrons are secreted by the enteral mucosal cells into the intestinal lacteals and enter the plasma compartment through the intestinal lymphatics, largely through the thoracic duct. Retinyl esters found in the lymph chylomicron are retained almost entirely in the particle during its processing to a chylomicron remnant. The chylomicron remnants and their retinyl esters are almost completely removed from the circulation by the liver.

The reesterification of retinol in the enteral mucosal cells and its subsequent absorption into the lymph are influenced by a specific carrier protein called *cellular retinol-binding protein type II* (CRBP II) (see Figure 38-4).[75] The CRBP II molecule consists of a polypeptide chain with a molecular mass of approximately 16 kDa. In the adult rat, CRBP II is present almost exclusively in the absorptive cells of the small intestine.[76] Its concentration in the small intestine appears to be age-related: Concentrations are is lower in immature fetuses relative to those in mature newborns and adults.[75] A similar gut-specific CRBP II is present in the human small intestine.[77] Its localization in the mature, villus-associated enterocytes of the jejunum suggests that CRBP II may facilitate vitamin A absorption in the gut. The ontogeny of CRBP II during fetal and neonatal development in humans has not been studied. It is possible that the lower concentrations of CRBP II in the small intestine of preterm neonates relative to those in mature term infants may result in differences in vitamin A absorption in these infants.

VITAMIN A AND PARENTERAL NUTRITION

Preterm infants who experience difficulties with enteral feeding often are sustained exclusively with intravenous nutrition. A protein-dextrose solution and a lipid emulsion are commonly used for intravenous nutrition. Various nutrients, including vitamins, generally are administered in the protein-dextrose solution. The vitamin A concentration of the protein-dextrose solution is estimated at approximately 930 IU/dL.[78] In a newborn infant on total parenteral nutrition receiving the protein-dextrose solution at a conventional rate of 120 to 135 mL/kg/day, therefore, expected vitamin A intake ranges from 1116 to 1256 IU/kg/day. Of note, however, vitamin A in protein-dextrose solution is subject to photodegradation, and it binds to intravenous tubing.[79-82] Thus both photodegradative and adsorptive losses of vitamin A render its intravenous administration inefficient. Until such losses can be reduced substantially or eliminated, either through development of new materials for intravenous tubing or with improved administration of fat-soluble vitamins in the lipid emulsion,[83] alternative methods of vitamin A administration, such as by intramuscular route, may be necessary to optimize the vitamin A status of neonates on long-term parenteral nutrition.

VITAMIN A DEFICIENCY

Vitamin A promotes orderly growth and differentiation of epithelial cells, and its deficiency affects various organ systems, including the lung.[84] The histopathologic changes in the respiratory system generally precede other consequences of vitamin A deficiency involving the genitourinary system, eye, and skin.[84] Vitamin A deficiency results in a progressive sequence of changes in the epithelial lining of pulmonary conducting airways.[84-86] These changes consist of necrotizing tracheobronchitis in early stages and squamous metaplasia in advanced stages of the deficiency. The pathophysiologic consequences of these changes include (1) loss

of normal secretions of goblet cells and of other secretory cells; (2) loss of normal water homeostasis across tracheobronchial epithelium; (3) loss of mucociliary transport with resultant predisposition to airway infection; and (4) narrowing of lumina and loss of distensibility of airways with resultant increase in airway resistance and work of breathing. The histopathologic changes of vitamin A deficiency and associated pathophysiologic consequences are reversible with restoration of normal vitamin A status.[87,88]

Preterm infants are susceptible to lung injury from such insults as hyaline membrane disease, barotrauma or volutrauma from mechanical ventilation, oxygen toxicity, and airway infection.[89] These infants are at risk for the development of a form of chronic lung disease called *bronchopulmonary dysplasia* (BPD).[89] The histopathologic changes of BPD—now described as "classic" BPD—consist of necrotizing tracheobronchitis in early stages and squamous metaplasia in advanced stages of the disease, which are remarkably similar to those seen in vitamin A deficiency.[90] Preterm infants who have BPD, unlike those with no lung disease, often manifest clinical, biochemical, and histopathologic evidence of vitamin A deficiency.[91-93] Vitamin A supplementation from early postnatal life in these infants can improve their vitamin A status and also ameliorate the lung disease, as evidenced by a decreased incidence of BPD and of the associated morbidity.[94,95]

Recent advances in neonatal care, including the use of surfactant, continuous positive airway pressure, efficient strategies of mechanical ventilation, and enhanced nutrition, have altered the epidemiology of BPD.[96] In contrast with the classic form of BPD, seen in preterm infants with significant initial lung disease or those requiring high-level oxygen and ventilator support, the "new" BPD is emerging as a disease of the extremely preterm infant, often without much preceding lung illness or need for intensive support. Whereas airway injury—characterized by epithelial metaplasia, smooth muscle hypertrophy, and parenchymal fibrosis—has been the hallmark of classic BPD, the new BPD features a striking decrease in alveolar septation and microvascular development.[97] Normally, the gas exchange region of the immature lung is composed of large saccules.[98] These saccules undergo subdivision by an outgrowth of septa from their walls into smaller, more numerous structures termed alveoli. This septation is critical for increasing the alveolar number and surface area for gas exchange in early lung development. In humans, the alveolar septation occurs in late gestation and during the first few years after birth.[99,100] This septation may be inhibited by several postnatal factors, such as oxygen exposure, stretch injury from assisted ventilation, activation of inflammatory cascades, bacterial infection, and use of drugs such as dexamethasone.[96] These adverse effects on alveolar septation may be reversible with vitamin A. In newborn rats, daily treatment with retinoic acid has been shown to increase the number of alveoli[101] and also to prevent the inhibitory effect of dexamethasone on alveolar septation.[102] Whether such treatment is effective in prevention or amelioration of new BPD in humans remains unexplored.

VITAMIN A TOXICITY

Hypervitaminosis A may result from acute intoxication or from chronic ingestion of vitamin A. Administration of a single large dose of vitamin A in excess of 100,000 IU may cause acute intoxication in infants.[37] The major clinical manifestation of acute hypervitaminosis A is increased intracranial pressure. Prolonged ingestion of vitamin A in excess of 25,000 IU per day may cause chronic intoxication in infants.[37,103,104] The clinical manifestations of chronic hypervitaminosis A include symptoms and signs of increased intracranial pressure, bone and joint pains, and mucocutaneous lesions; hepatomegaly and hepatic injury, hypercalcemia, and hematologic abnormalities are sometimes seen.[105] Radiographic findings in chronic hypervitaminosis A in infants younger than 6 months of age include widened metaphyses, especially of the distal ulna, and radiolucent zones in the radius proximal to the metaphysis.[106] Cortical hyperostosis of multiple long bones and soft tissue changes are seen typically in infants older than 6 months.[106] In hypervitaminosis A, the plasma vitamin A concentration generally is in excess of 100 μg/dL, whereas the plasma RBP concentration usually remains normal.[107]

Hypervitaminosis A is reversible with restriction of vitamin A intake. Infusion of 2-hydroxypropyl-β-cyclodextrin as a means of solubilizing retinoids and enhancing their urinary excretion has been used occasionally as adjunct therapy.[108]

GUIDELINES FOR VITAMIN A NUTRITION

The recommended dietary intake of vitamin A for term newborn infants is 333 IU/kg/day.[109] In preterm infants, a vitamin A intake below 700 IU/kg/day is associated with a marked decline in plasma vitamin A concentrations.[92] Normalization of plasma concentrations of vitamin A and RBP is possible in preterm infants with a vitamin A intake above 1500 IU/kg/day.[46,92-94] Lack of clinical and biochemical evidence of toxicity in studies of vitamin A–supplemented infants and maintenance of their plasma vitamin A concentrations below 80 μg/dL suggest that a total vitamin A intake in the range of 1500 to 2800 IU/kg/day is safe for preterm infants.[46,93,94,110]

The potential role of vitamin A in facilitation of healing from lung injury has led to the development of guidelines for optimizing vitamin A nutrition in preterm infants at risk for BPD.[111] According to these guidelines, preterm infants meeting the following criteria are eligible for vitamin A supplementation: birth weight below 1250 g, estimated gestational age at birth less than 31 weeks, appropriate growth for gestational age, need for mechanical ventilation at 24 hours postnatal age, and absence of major congenital anomalies. In addition to standard vitamin A intake from parenteral and enteral sources, these infants are given supplemental vitamin A (retinyl palmitate) in two phases. Phase I entails an intramuscular injection of 2000 IU/kg/dose on postnatal day 1 and on alternate days thereafter until establishment of full enteral feeding. Full enteral feeding is considered to be established when energy intake by enteral route exceeds 75% of total energy intake. Phase II entails orogastric administration of 4000 IU/kg/dose on the first day of full feeding and daily thereafter until discharge from the neonatal intensive care unit. Each infant is monitored for evidence of vitamin A toxicity by serial measurement of plasma concentrations of vitamin A and RBP, careful physical examination, and periodic determination of blood chemistry profiles, as well as hematologic indices. Ultrasonographic scanning of the brain to detect intracranial hemorrhage and assessment of intracranial pressure by noninvasive methods such as fontanelle tonometry also are useful.

Dexamethasone, a glucocorticosteroid hormone, is being used occasionally in the postnatal treatment of preterm infants with BPD.[112] Postnatal dexamethasone treatment induces a significant, although short-term, increase in plasma concentrations of both vitamin A and RBP in these infants.[113,114] Thus, in the event dexamethasone treatment is initiated, supplemental vitamin A is withheld throughout the course of the dexamethasone treatment. This precautionary measure is intended to avoid the vitamin A toxicity associated with use of this agent. With the guidelines for vitamin A supplementation already discussed, monitoring of plasma vitamin A indices, clinical evaluation for potential toxicity, and careful consideration of concomitant therapies, the goal is to optimize vitamin A nutrition in vulnerable preterm infants at risk for lung disease.

Vitamin E Metabolism in the Fetus and Newborn Infant

Although vitamin E has been shown to be essential to maintenance of pregnancy in female rats, such a role has not been adequately demonstrated in humans. This is perhaps because the severe deficiency state that can be induced in experimental animals does not occur spontaneously in healthy women of child-bearing age. Frank deficiency, however, is not the only concern.[1-3] A growing body of evidence documents the need for protection from oxidant free radical damage throughout life.[2-9] In the case of the fetus, this protection involves provision of an antioxidant reserve for combating the increased production of reactive oxygen species associated with complications of pregnancy such as placental insufficiency, preeclampsia, and gestational diabetes.[9] Antioxidant reserves also are needed for protection against potential episodes of vascular compromise, hypoxemia, and ischemia-reperfusion during gestation and the birth process and in early postnatal life; such episodes are recognized to be associated with serious risk for oxidant-mediated injury in the fetus, despite the low-oxygen environment of the fetoplacental unit, and in the neonate.[4,10]

This chapter focuses on studies related to the dependence of the human on not only an adequate supply of dietary vitamin E but also the ability to discriminate among the four naturally occurring tocopherols—α, β, γ, and δ—to maintain at least minimal serum and tissue levels of the α form, by far the most biologically active (Table 39-1). The implications of the physiologic hyperlipidemia of pregnancy for tissue levels of vitamin E in mother and fetus and the associated requirement for vitamin E in the maternal diet are discussed. Also addressed is the importance of defining tissue levels of the vitamin in relation to membrane lipid content, composition, and metabolic function, because the need

TABLE 39-1

Nomenclature and Food Sources of Naturally Occurring Vitamin E Compounds: RRR Isomers*

Common Name Mean ($\bar{X}$) Content† (μg/mL)	Chemical Name	Activity Relative to α-Tocopherol (%)	Food Source(s)	Contribution to Total Vitamin E‡ (%)
α-Tocopherol Plasma $\bar{X}$ = 9.6 RBC $\bar{X}$ = 1.4	5,7,8-Trimethyltocol	100	Nuts, seeds, wheat, rye, rice, vegetable oils, olive, safflower, sunflower Animal fat: butter	20-25
β-Tocopherol Plasma trace RBC n.d.	5,8-Dimethyltocol	25-40	Wheat germ, barley, and oats, lettuce	≤10
γ-Tocopherol Plasma $\bar{X}$ = 1.6 RBC $\bar{X}$ = 0.24	7,8-Dimethyltocol	10-20	Many vegetable oils, especially soybean, corn, and coconut	40-50
δ-Tocopherol Plasma trace RBC n.d.	8-Methyltocol	<10	Soybean, coconut, and peanut oil	~20
α-Tocotrienol Plasma trace RBC n.d.	5,7,8-Trimethyltocotrienol	40-50	Oats, barley, rye (whole cereals)	Minimal
β-Tocotrienol Unknown	5,8-Dimethyltocotrienol	~20	Palm oil	Insignificant
γ-Tocotrienol Plasma trace RBC n.d.	7,8-Dimethyltocotrienol	~10	Coconut oil	Minimal
δ-Tocotrienol Plasma trace RBC n.d.	8-Dimethyltocotrienol	<1	Rubber tree oil	None

*Among the naturally occurring tocopherol and tocotrienol RRR isomers, the most important determinants of activity are the number and position of methyl groups in the benzene ring. The fully methylated compound has the greatest biologic activity.

†On thin-layer chromatography, β-tocotrienol peak could not be separated from α-tocopherol peak. As indicated by its minimal presence in foods, plasma β-tocotrienol level is judged to be negligible. (Data from Chow CK: Distribution of tocopherols in human plasma and red blood cells, *Am J Clin Nutr* 28:756, 1975.)

Data compiled from references 14, 17, 80-84.

for antioxidant protection varies from tissue to tissue and during different stages of development and environmental conditions. This variability is especially pronounced during reproduction and periods of rapid growth. The dynamic balance of oxidizing to reducing equivalents (i.e., oxidation-reduction [redox] state) essential for normal differentiation and development during early, mid-, and late gestation has yet to be defined and characterized as a basis for management of pregnancy in general and as a guide for design of treatment protocols to prevent abnormalities in pregnancies characterized by increased oxidant stress.

BRIEF HISTORY OF VITAMIN E

The semipurified diet of Osborne and Mendel—composed of casein, starch, lard, butter fat, salts, and brewer's yeast—was known to contain vitamins A, B, C, and D and to support superior growth and vigor in the laboratory rat. In the pregnant female, however, it often was associated with fetal death and resorption of the conceptus and with testicular degeneration in the young male rat. (The Osborne-Mendel diet probably was not totally deficient in vitamin E because both butter and lard are sources of α-tocopherol.) In 1922, Evans and Bishop demonstrated that the missing dietary factor, which they termed "factor X," was present in wheat germ and fresh lettuce. In 1925, they suggested that this "oil of fertility" be given the name *vitamin E.* The classic 1927 monograph of Evans and Burr summarized these early years, when vitamin E was recognized solely as a dietary factor necessary for fertility in the rat. The related fertility bioassay quantifies the ability of animal tissues, foods, or preparations of vitamin E to prevent fetal resorption when fed to the pregnant, vitamin E–deficient rat during the first 10 days after impregnation. It remains the standard, but no longer the only, assay for assessing in vivo potency of the vitamin.[11,12]

Mechanisms underlying the dependence of mammalian species and nonreproductive as well as reproductive tissues on a dietary supply of vitamin E were poorly understood for many years. In 1928, Evans and Burr described a paralysis in suckling young of mother rats fed a diet low in vitamin E, from which spontaneous recovery occasionally occurred. In 1931, Pappenheimer and Goetsch described encephalomalacia in chickens fed the same semipurified diet used by Evans and Burr. In ducklings, this diet resulted in widespread lesions in the skeletal muscles but no sign of encephalomalacia. These nonreproductive tissue lesions, in all three species, were signs of vitamin E deficiency, but this deficiency was not recognized for another 10 years.

Progress in understanding the role of vitamin E in intermediary metabolism was greatly advanced by the 1936 report of Evans and colleagues on the isolation of an alcohol from wheat germ oil with marked vitamin E biologic activity. They assigned the chemical formula $C_{29}H_{50}O_2$ to this "isolate" of fertility and proposed the name α-tocopherol, from the Greek *tokos,* meaning "childbirth," and *phero,* "to bear or bring forth," with the suffix *ol* to indicate that the substance was an alcohol (Figure 39-1). In 1937, the same workers isolated β-tocopherol and γ-tocopherol from other vegetable oils and made note of their lesser biologic activity. Almost simultaneously, Olcott and Emerson presented evidence that the tocopherols were effective antioxidants, as suggested by the earlier report of Olcott and Mattill on the association of "inhibitols" and vitamin E in lettuce oil.

In 1940, Pappenheimer demonstrated that α-tocopherol prevented the myopathy observed in ducklings fed the Evans and Burr diet, and, in the same year, Mackenzie and colleagues presented evidence that the myopathic changes found in vitamin E–deficient rabbits could be prevented by feeding α-tocopherol. They also noted that simultaneous feedings of cod liver oil and

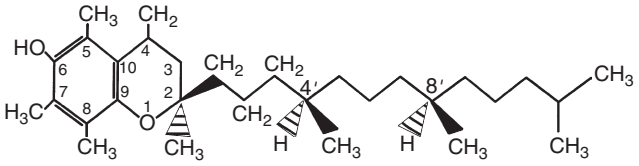

Figure 39-1 Structure of RRR-α-tocopherol, the most active and abundant form of vitamin E. other lipids high in unsaturated fatty acids inactivated dietary vitamin E, especially in the presence of pro-oxidant ferric salts. These observations presaged the many studies, still ongoing, addressing the importance and interrelationships of prooxidants, oxidant vulnerability, and antioxidant defenses during intermediary metabolism.

ESSENTIALITY OF VITAMIN E AS A CHAIN-BREAKING LIPID ANTIOXIDANT OF CELLULAR MEMBRANES

A large body of work now argues convincingly that the mechanism of action of vitamin E in curing the diverse vitamin E deficiency syndromes depends on its singular effectiveness as a biologic antioxidant, strategically located in every cellular membrane and essential for their structural integrity and function.[13-16] Subtle, radical-mediated perturbations of membrane structure can alter receptor sites, membrane functions, and membrane-bound enzyme activities. Such changes can have serious consequences in some tissues (and some species) and can leave those less vulnerable seemingly unaffected.[16-18] This spectrum of susceptibility would explain much if not all of the variability in vitamin E deficiency syndromes among species, organs, developmental periods, dietary intake, and environmental conditions.[13-15]

For example, vitamin E–deficient rabbits typically exhibit muscular dystrophy, but, in contrast with the vitamin E–deficient rat, they have red blood cells (RBCs) that are resistant to peroxidative hemolysis. In rabbits maintained on standard laboratory chow, RBCs contain two to three times as much linoleic as arachidonic acid, the more highly unsaturated and readily oxidized of the two. By contrast, rabbit muscle contains up to four times more arachidonate than linoleate. The opposite is true of the rat. Therefore rabbit muscle is the target tissue in tocopherol deficiency, whereas in the rat it is the RBC. Supplementing the diet of vitamin E–deficient rabbits with arachidonic acid, however, makes the rabbit RBC susceptible to oxidant damage. Specific membrane phospholipid architecture also influences the different patterns of susceptibility displayed by the rabbit and rat RBC.[19] Disruption of function in membranes deficient in vitamin E also is influenced by the physical location of α-tocopherol in the membrane,[16] the degree of local oxidative stress, and the juxtaposition and adequacy of other antioxidant defense systems.[13,15,16,18,19]

NON-ANTIOXIDANT FUNCTIONS OF VITAMIN E

Although some investigators believe that all functions of vitamin E will eventually be explainable on the basis of antioxidant properties, certain actions, especially in invertebrates and lower mammals, appear to be based on other mechanisms. Such actions include the prevention of fetal resorption in the rat and the influence of vitamin E on the growth, phenotype, and reproduction of *Rotifera,* a freshwater metazoan.[15] Of more pertinence to higher primates and humans is the observation that α-tocopherol functions as an ionophore for potassium and rubidium ions in mitochondria but not for sodium and lithium.[15] Furthermore, α-tocopherol and its oxidation product, α-tocopherol quinone, are specific inhibitors of sodium-potassium adenosine triphosphatase (Na^+,K^+-ATPase) in brain microsomes.[15] Boscoboinik and colleagues[20,21] demonstrated a regulation by the tocopherols of vascular smooth muscle cell proliferation and protein kinase C activity, which is distinct from their activity as antioxidants. Other investigators[22,23] observed an erythropoietic effect of vitamin E in human patients infected with human immunodeficiency virus, especially when they are treated with zidovudine. These observations lend support to the earlier suggestion of Drake and Fitch[24] that humans may have a latent requirement for vitamin E in erythropoiesis. Studies of such possible non-antioxidant functions may lead to elucidation of the role of vitamin E nutrition during gestation.

FUNCTIONAL REQUIREMENTS FOR VITAMIN E

The earliest marker of vitamin E deficiency in the human, as in the rat, is increased hemolysis of RBCs on exposure to peroxide radicals. This effect can be seen before onset of, or in the absence of, clinical anemia.[25-27] Membrane susceptibility to oxidant stress is related to the content of readily oxidized unsaturated fatty acids.[28-31] Of greater clinical importance, however, are the slowly developing signs of oxidant damage to the central and peripheral nervous systems that are seen when vitamin E nutrition is inadequate for an extended period, especially if such dietary inadequacy begins soon after birth. Susceptibility of the RBC and brain to oxidant damage relates to similarities in the lipid composition of their cellular membranes. Furthermore, in the case of the RBC,[32] it also relates to their oxygen-rich, iron-rich environment and to the lability of their vitamin E content, which is readily exchanged with the vitamin E present in the high-density lipoprotein (HDL) and other lipoprotein fractions of the blood.[33,34] Of considerable clinical importance, the amount of vitamin E in the plasma, the RBC membrane, and other membranes of the body is determined largely by the overall concentration of these lipid-rich components of the blood.[35-38] The rate of equilibration between the plasma vitamin E and that of cellular membranes in different tissues varies greatly, however. For example, the content of α-tocopherol is highest in gray matter from the frontal cortex and thalamus, whereas that in gray matter from the cerebellum and spinal cord is significantly lower.[39] Depletion, when it occurs, is seen first in the cerebellum and spinal cord and last in the cerebral hemispheres and medulla and pons.[39-43] Once depleted, the content of vitamin E in the central nervous system is restored only slowly and in the reverse order. Accordingly, tocopherol therapy for prevention or reversal of nervous system lesions must be continued indefinitely, and signs of improvement cannot be expected until long after correction of the RBC defect.

From a practical standpoint, vitamin E deficiency in humans usually is defined as a plasma ratio of vitamin E to total lipids (in milligrams per gram) of less than 0.8, with RBC hemolysis in the standard hydrogen peroxide hemolysis test of greater than 10%. The recommendation for vitamin content of the diet relative to polyunsaturated fatty acid content of dietary lipids is for a ratio of vitamin E to polyunsaturated fatty acids of at least 0.7 (in milligrams per gram).[35,36,44,45] Neither of these lipid ratios is entirely satisfactory, owing to the highly variable fatty acid composition and content of dietary lipids and the difficulty in assessing the effect of dietary polyunsaturated fatty acid on membrane antioxidant requirements.[15,16,19,44,45] As discussed later, an assessment of membrane peroxidizability is the best measure of adequacy of vitamin E nutrition for the rapidly growing and differentiating tissues of the fetus and newborn. The RBC has been widely

used for this purpose because of its accessibility and because the peroxide hemolysis test (despite its limitations) provides useful information and is simple to perform.

HUMAN VITAMIN E DEFICIENCY SYNDROMES

In humans, none of the manifestations of vitamin E deficiency—spinocerebellar degeneration, myopathy, retinopathy, hemolytic anemia—occur in the absence of predisposing conditions such as (1) prematurity coupled with feeding of formulas rich in polyunsaturated fatty acid relative to the tocopherol content,[46-49] especially if the formulas are enriched with iron; (2) chronic pathologic states that interfere with the absorption of fats and fat-soluble vitamins, such as primary biliary atresia, hepatobiliary cholestasis, and fibrocystic disease[37,38,50-52]; and (3) inborn errors of metabolism that interfere with absorption, distribution, and retention of the vitamin, such as the several abetalipoproteinemia syndromes,[53-59] and the mutations in the liver α-tocopherol transfer protein, which cause familial isolated vitamin E deficiency (FIVE) and certain of the Friedreich ataxia syndromes.[60-65] Study of the disposition and metabolism of the tocopherols in these disorders has greatly advanced understanding of a complex and highly regulated system that maintains critical levels of RRR-α-tocopherol (i.e., 2R,4′R,8′-α-tocopherol) in plasma and tissues, even under conditions of dietary restriction.

PRESERVATION OF MEMBRANE: α-TOCOPHEROL

This paucity of vitamin E deficiency syndromes in humans is related not only to the widespread availability of tocopherols in diets of the world and the efficient uptake and retention of α-tocopherol in plasma and tissues but also to the avidity with which membrane content of vitamin E is protected during oxidant stress by other biologic antioxidant systems. Except in the presence of free iron, which is a potent prooxidant, the tocopherol peroxy radical formed in the lipid membrane during encounters with oxidant free radicals results in neither propagation of a free radical chain reaction nor formation of the stable oxidized product, tocopherol quinone. This is the case because the tocopherol peroxy radical is returned to its original state by transfer of the radical to vitamin C and the closely linked selenium-dependent glutathione peroxidase–reduced glutathione–glutathione reductase antioxidant network.[6,13,14,39,66-73] Coenzyme Q_{10} is a lipid antioxidant that interacts directly with the aqueous phase of the cell and also functions to spare vitamin E.[74] Like vitamin C, it is consumed before the membrane content of vitamin E is depleted. For example, in vitamin E–deficient humans and rats, none of these plasma-based systems, the availability of urate or protein sulfhydryl groups, or up-regulation of glutathione peroxidase or superoxide dismutase activity or coenzyme Q_{10} can substitute for α-tocopherol in its role as antioxidant and structural stabilizer for the complex, lipid-rich cellular membrane.[43,66-69]

These considerations underline the importance of general nutritional support for maintaining the body's antioxidant defenses. Such support is especially critical during periods of rapid growth or illness and in the premature infant, with meager nutrient reserves. With the availability of parenteral amino acids, lipid emulsions, and pediatric multivitamin infusate, which includes generous amounts of vitamin E, the management of sick premature infants from the nutritional standpoint has greatly improved.

INTESTINAL ABSORPTION OF VITAMIN E

Vitamin E is absorbed in the upper intestine, together with digested fats, in particular, the medium chain triglycerides.[75,76] An absolute requirement for micellar solubilization of unesterified vitamin E by intraluminal bile acids before it can be absorbed by the enterocyte has been documented.[37,51] If this requirement is met, α-tocopherol and γ-tocopherol, the major forms of vitamin E in the diet, are equally well absorbed by a process of nonsaturable, non–carrier-mediated passive diffusion.[37,45] Within the intestinal cell, reesterified free fatty acids (FFAs), apolipoproteins, phospholipids, cholesterol, α-tocopherol, and γ-tocopherol are incorporated into chylomicrons for secretion by way of the lymphatics and thoracic duct into the systemic circulation.[77-79] Liver uptake of postabsorptive chylomicrons is discussed later, under "Plasma Transport of Vitamin E."

EXCRETION OF VITAMIN E

Although the liver preferentially secretes α-tocopherol in very-low-density lipoproteins (VLDLs) and γ-tocopherol in bile, both forms are consistently found in the bile after oral intake, with the proportion of γ to α decreasing as increasingly generous amounts of both forms are fed. Between 10% and 75% of an oral dose of vitamin E is excreted in the feces, depending on size of the dose and functional health and maturity of the intestinal tract.[77] These phenomena probably explain the relative lack of toxicity of vitamin E compared with that of other fat-soluble vitamins.

SOURCES AND ACTIVITY OF VITAMIN E COMPOUNDS

Vitamin E activity is found in eight naturally occurring compounds in the tocopheryl class, all of which are derivatives of 6-chromanol. Four compounds consist of a tocol structure attached to a saturated phytyl chain, the tocol structure designated αβγδ, depending on the number and position of methyl groups on the benzene ring. Four corresponding tocols with three double bonds in the phytyl side chain are designated tocotrienols (see Table 39-1). The tocopherols have greater biologic activity than the tocotrienols on the basis of standard vitamin E activity assays. Both are widespread in plants such as nuts, seeds, oils, fruits, vegetables, grains, and grasses (mainly in an unesterified form), and they appear to play a developmental role in plant life. For example, the germinating capacity of grain is related to its tocopherol content.[80] Biogenesis of tocopherols in plants probably is through the intermediate of the trienol structure by hydrogenation.[80] Little is known about the importance of tocotrienols for human nutrition, but studies in this regard suggest a role for the tocotrienols in suppression of epidermal growth factor and reduction of protein kinase C (α) activation.[81]

The antioxidant activity of the tocopherols and tocotrienols requires the presence of the free alcohol group on the benzene ring.[82-85] Ester forms are totally inactive as antioxidants until hydrolysis has occurred. Because the free alcohol form is highly susceptible to oxidation, commercial preparations are in the form of acetate, succinate, or nicotinate esters (Table 39-2). Ester hydrolysis occurs readily in the intestine but is only slowly accomplished after parenteral injection. In both dogs and humans, measurable levels of the ester (at least 10% of the peak 4- and 8-hour levels) are still present in the bloodstream after intramuscular administration.[86] One stable preparation of free α-tocopherol has been developed but is not commercially available.[86]

Each of the four tocopherols and the four tocotrienols can occur in eight stereoisomeric forms related to the chirality (handedness) of carbon atom 2. Only the RRR isomers occur in nature and have been shown by various assays to have significantly greater biologic activity than that of synthetic preparations of the other isomers. The chemical composition and configuration[39,87] of free α-tocopherol (molecular weight, 430.66) are shown in Figure 39-1. Biologic activity of the free tocopherol alcohols is modified by the number and position of methyl groups on the benzene ring; full methylation, as in the α form, results in the greatest activity (see Table 39-1). Activity also depends on

TABLE 39-2

Biologic Activity and Stereochemical Configuration of Vitamin E Compounds

1 mg	All-racemic-α-tocopheryl acetate, 2RS,4′RS,8′RS configuration (the synthetic mixture of four mirror-image pairs) Formerly (DL)-α-tocopheryl acetate	1.0 IU*
1 mg	RRR-α-tocopheryl acetate, 2R,4′R,8′R configuration (the natural stereoisomer) Formerly (D)-α-tocopheryl	1.36 IU*
1 mg	All-racemic-α-tocopherol, 2RS,4′RS,8′RS configuration	1.1 IU†
1 mg	RRR-α-tocopherol, 2R,4′R,8′R configuration	1.49 IU†

*Activity expressed as international units (the USP standard) and based on standard biologic assays as confirmed by several investigators (rat fetal resorption, erythrocyte hemolysis, muscular dystrophy, exudative diathesis, encephalomalacia). Most of the difference in activity of the stereoisomers of α-tocopherol results from differences in the chirality at the 2 carbon position, where the phytyl tail meets the chromanol ring. For example, by comparison, 2RS,4′ R,8′R-α-tocopherol (2-ambo-α-tocopherol) and 2S,4′R,8′′R α-tocopherol (2-epi-α-tocopherol, the International Standard before 1956) have approximately 60% and 40% activity, respectively, on the basis of the fetal resorption bioassay. Because of their greater stability, currently available commercial preparations of vitamin E are in the ester form, primarily the acetate, but also the succinate and nicotinate forms.

†Activity calculated on basis of molecular weight compared with the acetate form. The free alcohol forms are available only on an investigative basis.

USP, United States Pharmacopeia.

the following: the length of the phytyl side chain (shortening or absence markedly decreases activity); the chirality (stereospecificity) of carbon atom 2, in which the phytyl tail meets the chromanol ring; and, to a lesser extent, the chirality of carbon atoms 4′ and 8′ in the phytyl side chain.

Discrimination in Favor of α-Tocopherol During Intermediary Metabolism

γ-Tocopherol, 7,8-dimethyl tocopherol (molecular weight, 416.66), is the major tocopherol found in soy and corn oil. With the increasing substitution of vegetable for animal fats, γ-tocopherol now accounts for 40% to 50% of vitamin E content of the average U.S. diet. Traditional diets of countries such as Brazil[87] contain predominantly the γ form (see Table 39-1). Because γ-tocopherol has only 10% (at most 20%) of the biologic activity of α-tocopherol, however, it makes only a modest contribution (in the range of 10 to 20%) to overall vitamin E nutrition.[83]

The greater biologic activity of RRR-α compared with that of γ-tocopherol (and the non–RRR-α isomers) results from discrimination, during normal intermediary metabolism, in favor of the α form. This discrimination does not occur in the intestine unless esterified forms are fed, in which case hydrolysis of the RRR esters is faster and more complete.[39] The unesterified α-tocopherol–to–γ-tocopherol ratio in postabsorptive chylomicrons is similar to that in the diet. Once in the bloodstream, postabsorptive chylomicrons undergo triglyceride hydrolysis by action of endothelial lipoprotein lipase, with the formation of chylomicron remnants, excess surface components, and, to a small extent, FFAs and free γ-tocopherol and α-tocopherol. An interchange occurs between apoprotein E (apo E) of HDL and α-tocopherol and γ-tocopherol in excess surface components and chylomicron remnants. Subsequently, the modified remnants and downsized chylomicrons (now containing apo E) are taken up by the liver.[60,61]

During liver uptake of chylomicrons and chylomicron remnants, a major discrimination in favor of α-tocopherol over γ-tocopherol occurs, through the action of a liver binding and transfer protein. This protein, first demonstrated in the rat,[88,89] has 10 times the affinity for α-tocopherol versus γ-tocopherol.[61,77,90] It appears to be critical in the uptake and transfer of α-tocopherol to liver organelles for incorporation into nascent VLDL for secretion into the blood. Catabolism of nascent VLDL, enriched in α-tocopherol, results in a sustained increase in the level of α-tocopherol in the plasma and subsequent tocopherol enrichment of low-density lipoprotein (LDL) and HDL through interchanges between the various lipoproteins. By contrast, the increase in plasma γ-tocopherol is transitory because of its preferential excretion in the bile after liver uptake. As a result, γ-tocopherol accounts for only approximately 15% of vitamin E content of the plasma.[60,61,83,84,91]

Patients with the genetic vitamin E deficiency syndrome FIVE have a missense mutation in the gene that codes for this liver uptake and transfer protein.[60-63] Persons homozygous for this defect have extremely low to undetectable levels of total vitamin E in the plasma, with the level of α-tocopherol consistently less than that required to meet critical tissue needs. As a result, signs of nervous system dysfunction (spinocerebellar degeneration) develop in the absence of any abnormality in fat absorption, lipid metabolism, or dietary deficiency; the age at onset depends on the completeness of the genetic defect. Studies in these patients have shown that the liver transfer protein discriminates not only in favor of α-tocopherol over γ-tocopherol but also in favor of the natural RRR-α isomer over other synthetically prepared isomeric forms, for example, the 2S epimer (2S,4′R,8′R-α-tocopherol).[60,61]

Fortunately, in patients with FIVE syndrome, moderately high doses of α-tocopherol (800 to 1200 IU/day), continued over time, can compensate for the defect in tocopherol enrichment of the VLDL.[60,61] This compensation is accomplished through direct transfer of α-tocopherol in postabsorptive chylomicrons to the HDL and LDL, independent of the liver transfer protein and VLDL.

Discrimination at the Tissue Level

A further discrimination in favor of α-tocopherol occurs at the level of the RBC, brain, and spinal cord, which take up and retain RRR-α-tocopherol in preference to the γ form. As a result, the ratio of α to γ in these (but not other) tissues is greater than that in the plasma.[39,91] As in the case of the liver tocopherol transfer protein, the RBC and central nervous system also retain RRR-α-tocopherol in preference to its other isomeric forms. This tissue discrimination relates to the spatial relationship of the tocopherols and their lipoprotein carriers. A moderate chiral selectivity relative to plasma is exhibited by the RBC in favor of the RRR form, presumably because of accentuation of the chiral properties of phospholipids, cholesterol, and proteins by the more structured lipid environment of the RBC, brain, and spinal cord compared with the more relaxed environment of the plasma lipoproteins.[39] As a result, α-tocopherol comprises approximately 87% of RBC vitamin E, compared with 83% in the plasma.[84]

ROLE OF γ-TOCOPHEROL IN HUMAN NUTRITION

The importance of these relationships for the central nervous system has been demonstrated in feeding studies with α-tocopherol and γ-tocopherol and with natural RRR-α-tocopherol and its other stereoisomers. After 3 months on a low–vitamin E diet, rats fed α-tocopherol and γ-tocopherol for only 24 hours demonstrated 15 times as much α-tocopherol (versus γ-tocopherol) in the brain and 8 times as much α-tocopherol in the adrenal gland.[91] When rats were fed only γ-tocopherol, the brain still contained 3 times as much α-tocopherol as γ-tocopherol, but the adrenal contained 10 times more γ-tocopherol than α-tocopherol.[90] Similarly, Bieri and Evarts,[83] in long-term feeding studies in rats on diets containing up to 4 times as much γ-tocopherol as α-tocopherol, reported that, after 3 months, γ-tocopherol accounted for 60%

of vitamin E in adipose tissue, 50% in muscle, and 40% in kidney and spleen. It remained low in the testes (25%), liver (19%), and plasma (27%). Unfortunately, the relative content of α-tocopherol versus γ-tocopherol was not measured in the RBCs or the central nervous system, which are the tissues most able to discriminate in favor of the α form.[39,40] One would predict (had they been measured) that the brain and RBC would have shown the least accumulation of γ and the greatest retention of α. This prediction is supported by studies by Ingold and colleagues,[39] in which vitamin E was provided as equal amounts of deuterated RRR- and SRR-α-tocopherol. All tissues discriminated in favor of the natural isomer. The greatest discrimination, however, occurred in the brain, which accumulated more than five times more deuterated RRR- than SRR-α-tocopherol, with no decrease in rate of RRR accumulation after 5 months on the diet.[39]

γ-Tocopherol and Vitamin E Nutrition in the Fetus and Young Infant

The importance of γ-tocopherol to overall vitamin E nutrition may relate to its role in sparing α-tocopherol for the brain and RBC when dietary intake of the α form is limited. This effect could have significance for the rapidly growing fetus and newborn, especially under conditions of marginal maternal nutrition. Bieri and Evarts[83] estimated that γ-tocopherol, when present in a diet sufficient in α-tocopherol but at a γ/α ratio of 2 to 3:1, may account for as much as 20% of the total vitamin E activity of the diet. Plasma levels of γ-tocopherol in infants fed a formula (Nutramigen) with three times as much γ-tocopherol as α-tocopherol (total tocopherol content, 29.7 μmol/L) were found to have plasma levels in which the γ form contributed 15% of total plasma tocopherol.[92] Cord blood γ-tocopherol levels of infants in Japan, where the intake of soy products is high, have been reported as accounting for 13% of total tocopherols in cord blood.[93]

Not yet determined, however, is how much γ-tocopherol as opposed to α-tocopherol is advisable in the feedings of infants whose natural food is colostrum and breast milk, both of which are rich in α-tocopherol. At least in young infants, a small study from Japan suggests that the concentration of non-α forms should be limited, even if the amount of α-tocopherol is adequate.[93] This study compared the effects of breast and formula feedings on plasma and RBC concentrations of tocopherol. The formula used contained 2712 μg/dL of total vitamin E, of which large amounts were contributed by β-tocopherol, γ-tocopherol, and δ-tocopherol—2.4%, 45%, and 29%, compared with 24% from α-tocopherol. Breast milk collected 5 to 7 days post partum had a total vitamin E content of 749 μg/dL, of which 10% was γ-tocopherol and 90% was α-tocopherol. The actual concentration of α-tocopherol in the two milks was nearly the same, 671 μg/dL for breast and 645 μg/dL for formula milk, but the total vitamin E content was more than three times higher in the latter. Surprisingly, during the first few months after birth, the mean concentration of α-tocopherol in plasma and RBCs of breast-fed infants was greater ($p < .05$ for both) than in those fed formula: 786 μg/dL ± 47 SEM in plasma and 274 μg/dL packed cells ± 22 SEM in RBCs in the breast-fed infants, versus 596 g/dL ± 60 SEM in plasma and 154 μg/dL ± 9.4 SEM in RBCs in the formula-fed infants. (Non–α-tocopherol forms either were not detectable in the RBC or, possibly, were not measured, because no values were given for these parameters.) Plasma total vitamin E concentrations were comparable in breast-fed and formula-fed infants at 873 and 891 μg/dL, respectively, with non-α forms accounting for 10% (γ) of total plasma tocopherol in breast-fed and 33% (26% γ and 7% δ) in formula-fed infants.[92] These data suggest that, at least in the rapidly growing newborn, a competition exists among the different vitamers[90,92] when the amount of α-tocopherol is relatively low compared with other tocopherol forms. This possibility, of course, amounts to yet another argument in favor of breast milk.

PLASMA LIPOPROTEINS

The principal classes of lipoproteins in the blood are the chylomicrons (density gradients below 0.95), VLDLs (gradients of 0.95 to 1.006), LDLs (gradients of 1.006 to 1.063), HDLs (gradients of 1.063 to 1.21), and very-high-density lipoproteins (VHDLs) (gradients above 1.25). Chylomicrons, on a dry weight basis, are made up of 80% to 95% triglyceride and have a protein content of only 1% to 2%; VLDLs have 40% to 80% triglycerides and 5% to 10% protein; LDLs consist of 10% triglycerides and 25% protein; and HDLs contain 1% to 5% triglycerides and 45% to 50% protein. The primary function of the lipoproteins is transport of lipids, chiefly triglycerides (chylomicrons and VLDLs) and cholesterol (LDLs and HDLs). In addition, the protein component of lipoproteins, the apolipoproteins, has important metabolic functions. The association of apolipoproteins and lipids involves the same sort of noncovalent interactions seen in membrane formation, and the components are quite free to move around, both within the lipid aggregates and between different lipoproteins in the circulation. The apolipoproteins fix the general character of the aggregates but do not create exactly reproducible assemblies. Accordingly, the lipoproteins are heterogeneous mixtures that become even more heterogeneous during transit in the bloodstream.[94]

Plasma Transport of Vitamin E

Vitamin E is transported in plasma in association with lipoproteins and chylomicrons. No specific lipoprotein or lipid is solely responsible for this function. Plasma tocopherol concentration depends largely on plasma lipid concentrations, and a direct and high correlation has been documented between elevated (or depressed) plasma lipid levels and elevated (or depressed) plasma tocopherol levels.[33-38] In patients with primary hyperlipidemia, the lipid primarily responsible for the hyperlipidemia also carries the bulk of the tocopherol. Plasma tocopherol levels may be markedly elevated. To a lesser degree, plasma vitamin E also is elevated in obesity, diabetes mellitus, and hypothyroidism.[51,93] A study in healthy Japanese schoolchildren found a higher plasma tocopherol level and a significantly lower RBC tocopherol level in obese children than in children of normal weight.[93]

If hyperlipidemia is complicated by impaired intestinal absorption of vitamin E, as in cholestatic liver disease, the elevated plasma lipids may compete so successfully with tissues for the limited supply of vitamin E that signs of RBC and central nervous system vitamin E deficiency appear despite plasma tocopherol levels within or above the normal range. When, however, the plasma vitamin E content is corrected for plasma lipid content, the relative deficiency in the plasma becomes evident. A tocopherol–to–total lipid ratio greater than 0.8 (mg/g) has been recommended as an indication of vitamin E sufficiency that takes into account the interdependence of lipid and tocopherol concentrations.[35-38]

Influence of Apolipoproteins on the Distribution of Tocopherol in Plasma

Despite the aforementioned considerations, the distribution of tocopherol between tissue and lipid constituents of the plasma is not entirely passive and nonspecific. The tocopherol content of lipoproteins is influenced by the content of apolipoproteins, as is clearly shown in the work of Behrens and colleagues[95] (Figure 39-2).

The apolipoproteins are grouped into five families designated A to E, all of which have important but incompletely understood

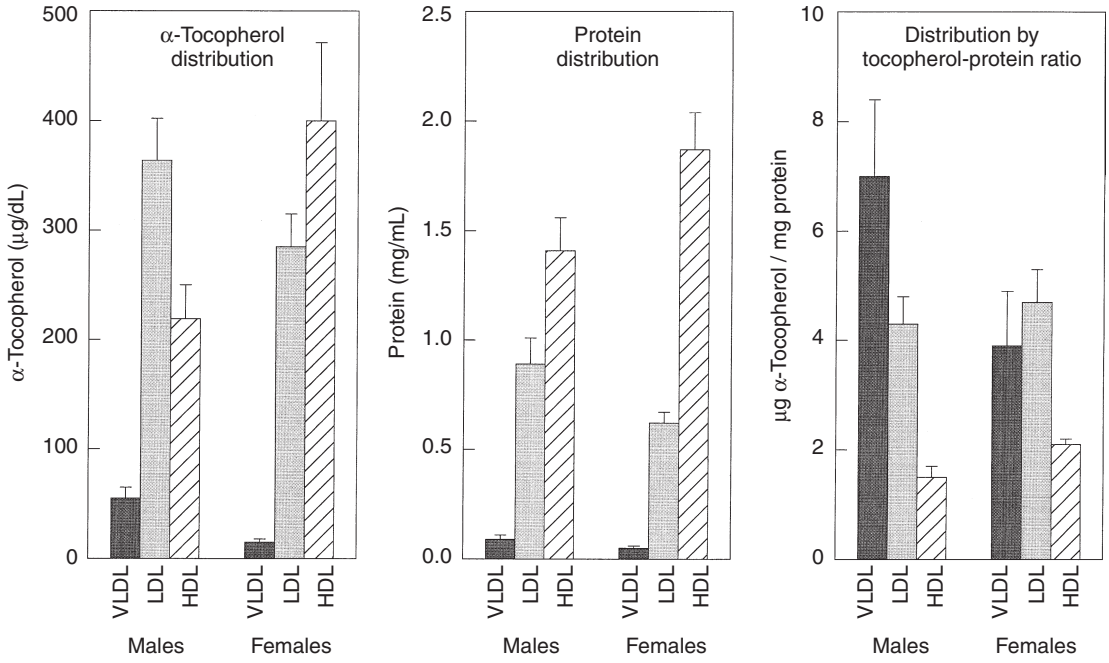

Figure 39-2 α-Tocopherol and protein content of plasma lipoproteins in healthy adults with normal lipid and cholesterol levels (mean ± SD for total tocopherol, μg/dL for plasma; males, 835 ± 82 μg/dL; females, 1035 ± 86 μg/dL.) As has been consistently reported by various investigators, more high-density lipoprotein (HDL) than low-density lipoprotein (LDL) was found in the plasma of women than in that of men in this study. The difference in distribution of tocopherol between the sexes was a reflection of the difference in protein content of the three different lipoprotein classes. Quantitatively, very-low-density lipoproteins (VLDLs) account for only a small proportion of total lipoproteins in either gender. They carry the greatest amount of tocopherol, however, relative to protein. This finding may have relevance to the adequacy of vitamin E nutrition during the hyperlipidemia of pregnancy, which is characterized by a disproportionately large increase in triglycerides and VLDL. The study population was from the Ottawa area of Canada. *(Data from Behrens WA, Thompson JN, Madère R: Distribution of alpha-tocopherol in human plasma lipoproteins,* Am J Clin Nutr *35:691, 1982.)*

metabolic functions. Apo B in VLDL, for example, has a primary role in triglyceride transport. Apo C-II and apo A-I are activators of enzymes involved in lipolysis, lipoprotein lipase, and lecithin cholesterol acyl transferase. Apo E binds to specific liver and endothelial receptors. In adults, the apo B lipoproteins in LDLs are primarily responsible for cholesterol transport to tissues.[78,94] Specific LDL receptor sites are present in the plasma membranes of most cells, and cholesterol, together with vitamin E, is delivered to the cells by this mechanism.[96] HDL apolipoproteins are primarily responsible for cholesterol transport to the liver (catabolic).[94]

The different distribution of the apolipoproteins and tocopherol in the HDL and LDL of men and of women, as seen in Figure 39-2, has been reported by many investigators. When data from men and women are considered together, the correlation of tocopherol with lipoprotein protein is highest for HDL, lowest for LDL, and intermediate for VLDL (HDL: correlation [r] = .93; VLDL: r = .72; LDL: r = .51). When data for men and women are considered separately, however, a significant correlation of tocopherol with protein (within the LDL class) is found in men but not in women.[95] Moreover, in a small but probably significant segment of the population, intake of vitamin E seems to influence the proportion of cholesterol carried by HDL relative to that carried by LDL.[97,98] This response to increased intake of vitamin E is seen most often in young, nonobese men who have high LDL and low HDL cholesterol levels and in patients with spinal cord injury. In such circumstances, an increased intake of vitamin E has been associated with a redistribution of cholesterol in favor of the HDL to an extent of 10% to 20%.[97,98] The significance and mechanism of these phenomena are poorly understood, but in rabbits fed a cholesterolemic diet, supplements of vitamin E result in significantly lower concentrations of serum cholesterol, triglycerides, and VLDL than those found in rabbits not supplemented with vitamin E.[99]

Transfer of Tocopherol to Tissues

Several mechanisms have been identified by which α-tocopherol is transferred from human lipoproteins to tissue. A specific high-affinity LDL lipoprotein receptor mechanism has been shown to mediate the delivery of vitamin E from human LDL to fibroblasts.[96] LDL (and tocopherol) can be taken up and degraded by receptor-independent processes. LDL-specific receptor pathways are therefore not the only mechanism for tocopherol delivery to the tissues. For example, human chylomicrons have been shown to transfer tocopherol to human RBCs and fibroblasts during the hydrolysis of triglycerides by lipoprotein lipase. This process involves binding of the lipase to the cell membrane.[38,90,100] Transfer of tocopherol to tissues by the HDL is less well characterized, but it is known that HDL readily transfers tocopherol to the RBC,[33,34] and high-affinity receptors have been described for tocopherol in the RBC and adrenals.[18,90,101] In adults and newborns, it is probably the HDLs that are the primary means of delivery and exchange of tocopherol with RBCs, which lack LDL receptors.[101]

PATTERN OF PLASMA LIPIDS AND LIPOPROTEINS IN THE NEWBORN

Newborns have low plasma levels of total lipids, apolipoproteins, cholesterol, and tocopherol. Newborn plasma also is characterized by a relatively high content of HDLs, a low content of LDLs,

TABLE 39-3

Concentration and Distribution of α-Tocopherol in Red Blood Cells and the Plasma Lipoproteins of Newborns and Pregnant and Nonpregnant Women*

	PLASMA CONCENTRATION (μg/dL)		
Fraction	Nonpregnant Women	Pregnant (at Term)	Newborn (Cord)
Plasma tocopherol	772 ± 144	1417 ± 388	237 ± 62
RBC tocopherol (packed cells)	193 ± 22	201 ± 34	179 ± 33
VLDL tocopherol	60 ± 31 (9%)	332 ± 184 (25%)	14 ± 8 (6%)
LDL tocopherol	271 ± 58 (41%)	558 ± 197 (41%)	68 ± 20 (30%)
HDL tocopherol	331 ± 53 (50%)	454 ± 131 (34%)	143 ± 43 (64%)

*Values are means ± SD: nonpregnant (n = 8); pregnant (n = 20); newborn (n = 20). In the newborn, 64% of plasma tocopherol is carried by the HDL, which constitutes the major lipoprotein class (greater than 60%) in their plasma. By contrast, only 34% of plasma α-tocopherol in the mother is carried in the HDL, which accounts for a lower proportion of her total plasma lipids. The greatest increase in lipid class during pregnancy occurs in the VLDL, which also shows the greatest increase in tocopherol level. Compared with newborns and their mothers, nonpregnant women have intermediate levels of percent distribution for all parameters. Total plasma lipid levels (mg/dL) are much lower in newborns (193 mg/dL ± 52) than in adults (pregnant women: 800 ± 131 mg/dL; nonpregnant women: 389 ± 29 mg/dL; adult men: 501 ± 106 mg/dL). The percent distribution of VLDL, LDL, and HDL within the total lipids is similar to the percent distribution of total vitamin E among the same lipoprotein fractions. In this small sample, no significant difference in RBC tocopherol levels was noted between either adult group and the newborn cohort, probably because of the predominance in cord blood of HDL, the primary carrier for α-tocopherol to the RBC. The mean RBC tocopherol level in the newborns, however, was somewhat lower. The study population was from the Osaka area of Japan.

HDL, High-density lipoprotein; *LDL,* low-density lipoprotein; *RBC,* red blood cell; *VLDL,* very-low-density lipoprotein.

and a very low content of VLDLs, which are poor in triglycerides but rich in cholesterol esters. Newborn HDLs include the subclasses HDL_2 (density gradients 1.063 to 1.092) and HDL_3 and VHDL (gradients greater than1.125).[102-106] These HDL lipoproteins[107] carry the bulk of plasma tocopherol in the newborn (Table 39-3). After birth, VLDL and LDL concentrations increase dramatically,[108] together with the triglyceride content of VLDL (Figure 39-3). The proportions of plasma cholesterol, apo A-I, and apo A-II carried by the HDLs in cord blood are high compared with adult values.[105,106] Nevertheless, despite low levels of LDL and cholesterol in the plasma, cholesterol transport to the tissues is high.[103-106]

Apolipoprotein E in High-Density Lipoprotein of the Fetus and Newborn Infant

The enhanced transport of cholesterol to the tissues by the HDL of cord blood results from the presence of apo E in HDL (not present in the HDL of most children and adults).[109,110] In the neonate, however, and in patients with abetalipoproteinemia (who lack apo B and LDL and have plasma cholesterol levels less than 50 mg/dL), the HDL contains a subfraction rich in apo E and apo E–apo A-II, which migrates with the HDL. This same HDL subfraction, rich in apo E, also is present in many lower species. Apo E–containing HDLs bind to apo B, apo E receptors in fibroblasts, and many other tissues and are responsible for delivering cholesterol to cells and regulating cholesterol metabolism in a manner comparable to that for the LDLs. These distinctive plasma lipoprotein profiles in the fetus and newborn infant,[102-110] as well as the rapid changes that occur in the first weeks after birth, are poorly understood. They almost certainly have importance for the transport and delivery of nutrients to the tissues and may also influence the prenatal and early postnatal transport of vitamin E.

Hyperlipidemia of Pregnancy

Maternal plasma lipids are elevated during pregnancy,* and levels of total lipids, triglycerides, cholesterol, and phospholipids are significantly higher than in the neonate (Figure 39-4). Maternofetal nutrient transfer through the placenta can be accomplished by different mechanisms, including facilitated diffusion, active transport, and simple diffusion. Simple diffusion is the most important mechanism for lipid-derived moieties. By this process, nutrient molecules are carried from a high-concentration to a low-concentration region, and the rate of movement is directly proportional to the concentration gradient. The rate of transfer is a direct function of the concentration gradient and decreases with molecular size and hydrosolubility.[78,79,111]

The tendency to accumulate fat ceases during late gestation because maternal lipid metabolism changes to a catabolic state. Also characteristic of this gestational stage are hepatic overproduction of triglycerides and enhanced absorption of dietary lipids, which result in a marked progressive increase in maternal circulating triglycerides. Furthermore, during late gestation (when tissue accretion in the fetus is at a maximum), an associated increase in FFAs, glycerol, and triglyceride-rich VLDLs and chylomicrons occurs.[78,79,111] The fetus requires not only essential fatty acids from the mother to support growth and brain development but also nonessential lipids as substrates during early postnatal life. Investigations in guinea pigs, primates, and rats indicate that the amount of fatty acids crossing the placenta exceeds that needed to fulfill lipid storage requirements. Maternal FFAs (esterified fatty acids that have been hydrolyzed at the placental level) and FFAs in unmodified lipoproteins are the potential sources of fatty acids that cross the placenta to the fetus.[78,79,111]

Differences in Fatty Acid Composition of Maternal and Fetal Plasma

Essential and nonessential fatty acids share a common transfer mechanism, regulated by the transplacental nonesterified fatty acid gradient, which consistently favors transport to the fetus. The estimated FFA transfer across the placenta is substantial, although less than for compounds such as glucose and alanine. Placental esterification of FFAs appears to be involved in one type of placental FFA transport. Although maternal circulating triglycerides contribute FFAs directly to the fetal circulation, this probably represents a minor contribution to FFA transport except in conditions of exaggerated maternal hypertriglyceridemia (e.g., in diabetic pregnancies).[111]

The fatty acid mixture entering the fetal circulation from the placenta reflects the maternal FFA concentrations of different fatty acids, with the common exception of arachidonic acid. Concentrations of arachidonic acid and docosahexaenoic acid are higher in cord blood than in maternal plasma. The opposite is the case for linoleic acid, which is present in higher concentrations in maternal plasma.[79,111,113] The fatty acid composition of adipose tissue triglycerides in the newborn also differs from that in the mother in a pattern similar to that for plasma. Placental arachidonic acid synthesis by an active desaturation and elongation system that synthesizes arachidonic from linoleic acid is believed to be important to the supply of arachidonic acid to the fetus. Tissue enrichment in arachidonic acid plays an important role during fetal life by maintaining normal function of biologic membranes and perhaps by providing a substrate for prostaglandin biosynthesis. Although postnatal brain development is

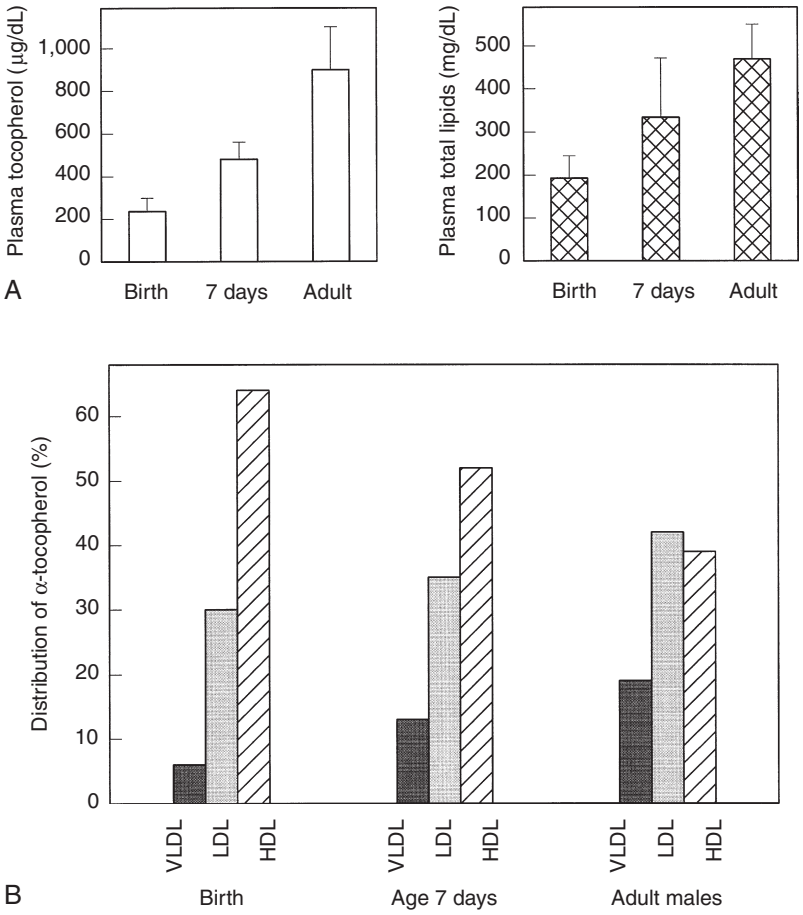

Figure 39-3 **A,** Age-related changes in plasma α-tocopherol and lipid concentrations. **B,** Age-related changes in distribution of α-tocopherol in plasma lipoproteins. In comparison with adults (n = 20), plasma tocopherol levels in the newborns (n = 11) were even lower than plasma lipid levels. More than 60% of plasma α-tocopherol in the cord blood was carried in the high-density lipoprotein (HDL) class. In men, less than 40% of plasma α-tocopherol was carried in the HDL. Newborn very-low-density lipoprotein (VLDL) and low-density lipoprotein (LDL) fractions increased and the HDL fraction decreased over the first 7 days after birth. Lipoprotein fractions were estimated by ultracentrifugation, and total lipids by the sum of cholesterol, phospholipid, and triglycerides. The study population was from the Osaka area of Japan. *(Data from Ogihara T, Mujake M, Kawamura N, et al: Tocopherol concentrations of leukocytes in neonates,* Ann N Y Acad Sci *570:487, 1989.)*

characterized by an increase in linoleic acid content, chain elongation desaturation products do not increase for several weeks, suggesting that placental transfer of polyenoic fatty acids is of primary importance in fetal accretion of these fatty acids.[79] Such transfer may be compromised under conditions of intrauterine growth restriction.

FETAL ACCUMULATION OF VITAMIN E AND FUNCTIONAL REQUIREMENTS DURING GESTATION

In a series of studies conducted during the 1940s and early 1950s, Mason[114] and Dju and colleagues[115] demonstrated that the concentration of vitamin E, as total tocopherols, in fetal tissues was low and that concentration and body content of vitamin E gradually increased during pregnancy, with a close, direct correlation for content of tocopherol in the body, body weight, and body fat. These early studies were confirmed by Mino and colleagues[116] using more sophisticated biochemical techniques (Figure 39-5). Despite the long-known increased susceptibility of the newborn RBC to peroxide hemolysis, a state of vitamin E deficiency in neonates has been questioned.[44,117,118] In that regard, the ratios of *milligrams of total tocopherol to grams of total fat* present in the body of the newborn (2.7) and the adult (2.5) are comparable. This calculation of this ratio does not take into account the greater proportion of unsaturated to saturated fatty acids in the plasma and RBC membranes of newborns than that in adults, as described previously and shown in Table 39-4. In addition to being highly unsaturated, the lipid content of membranes in newborns is higher than in adults, in whom lipids reside to a greater extent in accumulations of white fat.[31,32,112,113,119]

PATTERNS OF MEMBRANE TOCOPHEROL CONTENT IN THE NEWBORN AND YOUNG INFANT

Because samples are readily obtainable, a large body of data has been accumulated on the uptake, retention, and functional needs of the RBC. Studies of the tocopherol content of platelets, white blood cells, and buccal mucosal cells also have provided important data, but in lesser amounts because of greater assay complexity and difficulty in obtaining an adequate sample size. All of these studies show a decreased membrane α-tocopherol content in newborns compared with that in 1-year-olds, children, and adults[120-124] (Figure 39-6).

Figure 39-6 shows the content of vitamin E for several accessible tissues in the newborn infant, including tissues with and without LDL lipoprotein receptors. All tissues show a low level of α-tocopherol compared with that in older children and adults. Of note is the low concentration of tocopherol in platelets. In human adults and rats, levels of tocopherol in platelets have been shown to reflect changes in the dietary intake of vitamin E more accurately than levels in RBCs, which in turn are more sensitive than levels in plasma lipids and lymphocytes.[125] The low levels of vitamin E in platelets of the newborn probably reflect a marginally adequate supply of the vitamin.[120-125] This limited supply is suggested by the high concentrations of α-tocopherol in colostrum and breast milk, the first foods of the newborn on entry to the oxygen-rich extrauterine environment. Breast milk feedings result in a rapid increase in blood and tissue content of vitamin E, with a peak in platelet tocopherol concentration at age 6 months, which is about the time when other foods, less rich in α-tocopherol, are added to the diet.[124]

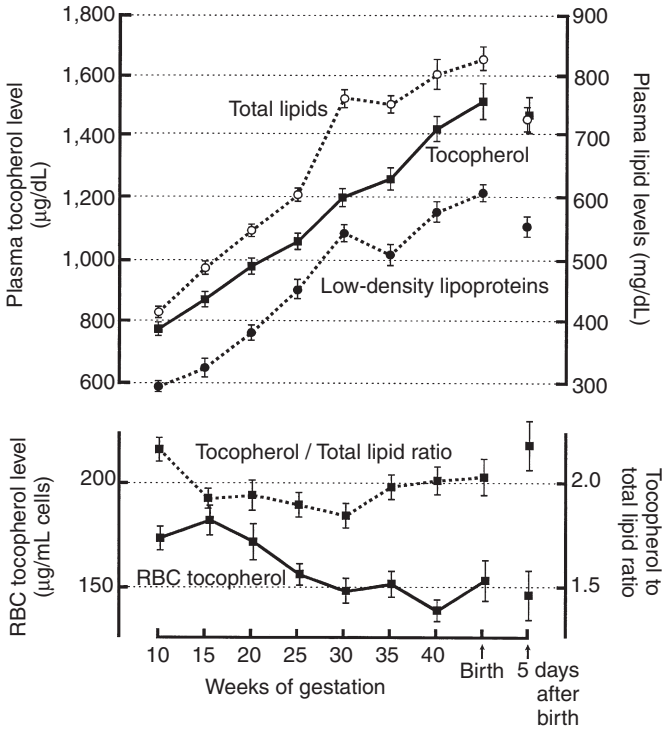

Figure 39-4 Maternal vitamin E nutrition during pregnancy. This graphic summary shows maternal red blood cell (RBC) α-tocopherol in relation to increasing maternal plasma levels of α-tocopherol, total lipid, and low-density lipoproteins during gestation. The greatest relative increase in lipids occurred in the triglyceride class. Despite the rise in plasma E level and the relatively stable α-tocopherol/total lipid ratio, maternal RBC α-tocopherol levels decrease as pregnancy progresses. The study population was from the Osaka area of Japan. *(Data from Mino M, Nagamatu M: An evaluation of nutritional status of vitamin E in pregnant women with respect to red blood cell tocopherol level,* Int J Vit Nutr Res *56:149, 1986.)*

Healthy breast-fed infants not uncommonly have plasma total tocopherol levels of 2.5 to 3.5 mg/dL while they are taking only milk for nourishment. Preliminary studies estimating the delivery of vitamin E to the fetus by measurement of umbilical vein–to–umbilical artery gradients indicate that over a 24-hour period, a surprisingly large per-kilogram transfer occurs to meet the demands of rapid fetal growth. The magnitude of transfer is, of course, greater during the last trimester. This finding is consistent with the much greater difficulty in maintaining plasma vitamin E levels in the sufficient range in small premature infants than in term infants, who have significantly greater stores of the vitamin.[126-129]

IMPLICATIONS OF MATERNAL HYPERLIPIDEMIA FOR FETAL VITAMIN E NUTRITION

Need for Generous Supplies of Vitamin E in the Maternal Diet

The hyperlipidemia of pregnancy involves an increase in triglycerides in the VLDL and LDL fractions.[79,111,112] This increase in plasma lipids usually is associated with an increase in plasma vitamin E level such that the ratio of tocopherol to total lipids is maintained above 0.8. Accordingly, several laboratories have demonstrated a small decrease in the mean maternal RBC tocopherol content in the last trimester of pregnancy,[112] and in some women (as many as 30% in one study), levels of RBC tocopherol are in the deficient range[17] (Figure 39-7). These findings suggest that in a significant number of women at term, the plasma lipids have increased their tocopherol content at the expense of the vitamin E content in RBCs. Data from a Japanese study demonstrating this relationship are shown in Figure 39-4. This finding is relevant to the observation that the concentration of α-tocopherol in maternal RBCs highly correlates with that in the fetus and newborn, after as well as before controlling for differences in lipid levels.[112,119-121]

Effect of Fatty Acid Composition on Functional Requirements for Vitamin E

The decreased resistance to hydrogen peroxide–induced hemolysis in newborns was first described in the classic studies of Rose and Gyorgy[25,-26] and of Gordon and colleagues[27]; this finding

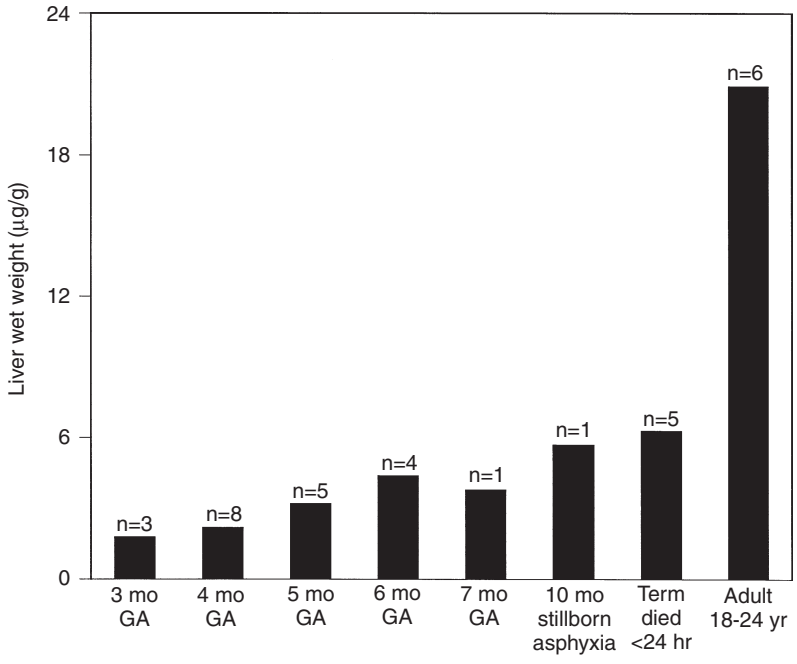

Figure 39-5 Tocopherol concentration in fetal, newborn, and adult human liver. Liver samples were obtained at autopsy after artificial interruption of normal pregnancy, after death from anencephaly or erythroblastosis fetalis on the day of delivery, or after adult accidental death. Liver tocopherol concentrations reported in two studies were in good agreement. *GA,* Gestational age. *(Data from Mino M, Nishino H, Yamaguchi T, Hayashi Met al: Tocopherol level in human fetal and infant liver,* J Nutr Sci Vitaminol (Tokyo) *23:63, 1977; and Dju MY, Mason KE, Filer LJ: Vitamin E (tocopherol) in human fetuses and placentae,* Etudes Neonatales *1:49, 1952.)*

Modified from Miyake M, Miki M, Yasuda H, et al: Vitamin E and the peroxidizability of erythrocyte membranes in neonates, *Free Radic Res Commun* 15:41, 1991.

has since been extended and confirmed by other investigators[28,31,32,118-122] (Tables 39-5 and 39-6 and Figures 39-8 to 39-12; see also Figure 39-7). The mechanism behind this increased risk of oxidant damage (despite tocopherol RBC concentrations that are at the lower range of normal for adults) was clarified by analysis of the composition of maternal and newborn RBC membranes.[118-122] These studies made it clear that the greater requirement for antioxidant protection of newborn and maternal RBC membranes results from their increased content of lipid, their greater complement of highly unsaturated fatty acids, and their greater number of active (bis-allylic) hydrogen atoms compared with the RBCs of nonpregnant women, older children, and men.[119-121]

These important data and interrelationships are shown in Tables 39-4 to 39-6 and in Figures 39-7 through 39-12, which summarize findings from three different countries on the increased sensitivity of RBC membranes in the fetus and newborn to peroxide injury. The report by Jain and associates,[121] which is summarized in Table 39-6 and in Figures 39-9 to 39-12, examined data for 26 healthy term newborn infants and their mothers from a population with low plasma levels of α-tocopherol. This study noted strong correlations between maternal and newborn plasma and RBC tocopherol concentrations (even without controlling for plasma lipids). Plasma α-tocopherol levels, in paired samples, also correlated significantly, but only after lipid normalization. In a much earlier study involving more than 500 infants, a significant correlation of maternal and newborn plasma vitamin E levels was found without consideration of plasma lipid content.[130]

In a study population of pregnant women with higher plasma tocopherol levels who required investigation at 20 to 40 weeks by percutaneous umbilical blood sampling, analysis of the relation between fetal and maternal plasma tocopherol concentrations showed no such correlation.[120] As in the study by Jain and colleagues,[121] however, strong, consistent correlations were found for concentrations of α-tocopherol in maternal, fetal, and

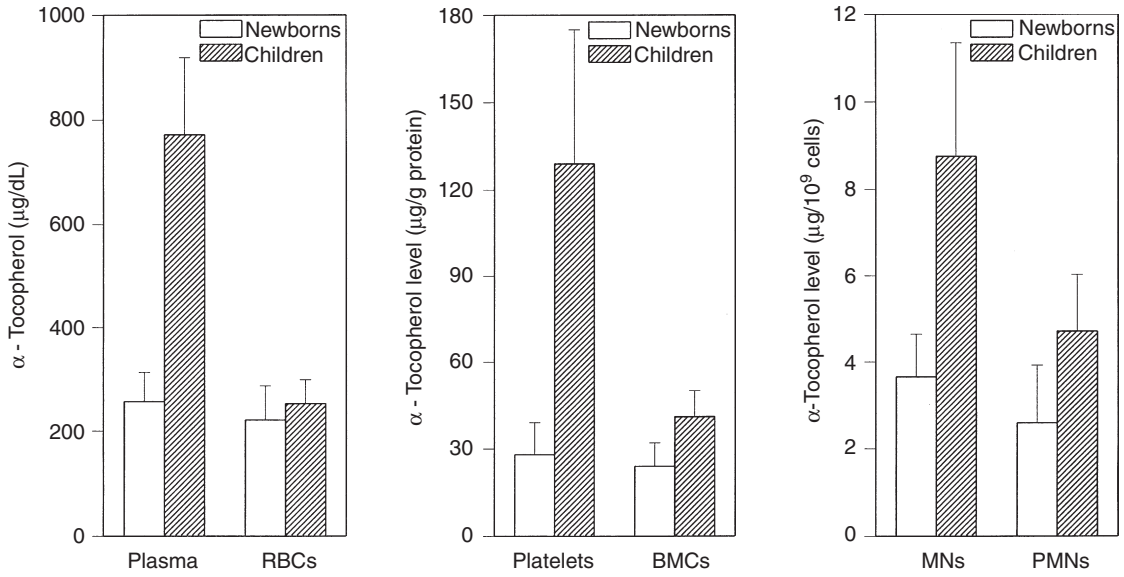

Figure 39-6 Age-related changes in α-tocopherol concentration in plasma, packed red blood cells (RBCs), platelets, buccal mucosal cells (BMCs), and mononuclear (MNs) and polymorphonuclear (PMNs) leukocytes in term newborns and children (3 to 16 years of age). The α-tocopherol level in tissues as well as in plasma was significantly lower in newborns than in children, except for levels in the RBCs, which were comparable. The study population was from the Osaka area of Japan. *(Data from Kaempf DE, Miki M, Ogihara T, et al: Assessment of vitamin E nutritional status in neonates, infants and children—on the basis of alpha-tocopherol levels in blood components and buccal mucosal cells,* Int J Vit Nutr Res *64:185, 1994.)*

newborn RBCs. Similar data also have been reported by investigators in Japan. This consistent finding (i.e., a correlation between concentrations of tocopherol in maternal and fetal RBC membranes) is important because it means that vitamin E supplements to the mother, continued over time, can increase the content of vitamin E in the RBC membranes of the fetus.[120,121] Presumably, this would apply to other membranes as well, in particular those of the brain and spinal cord.

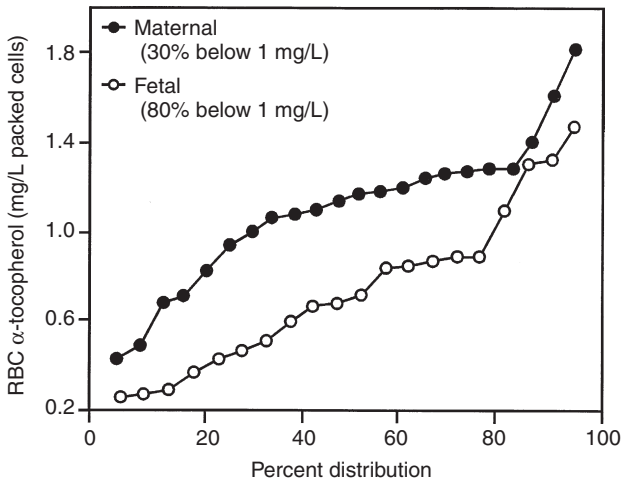

Figure 39-7 Frequency distribution of vitamin E content of centrifugation-packed red blood cells (RBCs). Maternal and fetal samples were obtained by percutaneous umbilical blood sampling between 20 and 40 weeks of gestation for diagnosis of malformations, intrauterine growth delay, toxoplasmosis, and other viral or parasite infections. The mean RBC α-tocopherol level in these fetuses was 0.74 ± 0.16 mg/L, which is less than the critical level for oxidant protection in the H_2O_2 hemolysis assay. The mean maternal RBC α-tocopherol level was 1.08 ± 0.14 mg/L (i.e., 108 μg/dL). Maternal and fetal levels were significantly correlated ($r = .66$; $p = .002$). The study population was from the Montpellier area of France. *(Modified from Cachia O, Léger CL, Boulot P, et al: The red blood cell vitamin E concentrations in fetuses are related to but lower than those in mothers during gestation: a possible association with maternal lipoprotein(a) plasma levels,* Am J Obstet Gynecol *173:42, 1995.)*

As reported by Mino and colleagues,[123] who studied premature and sick term infants for the first 6 months of life, the minimum concentration of RBC α-tocopherol to prevent hemolysis in the peroxide hemolysis test was 100 to 125 μg/dL of packed cells (see Figure 39-8). Based on these figures, the RBC tocopherol concentrations of 85% of fetuses and 15% of mothers in the study by Cachia and associates[120] mentioned earlier (see Figure 39-7) were lower than this critical level. As pointed out by these authors, because of the close correlation of the maternal and fetal RBC tocopherol content, it is reasonable to assume that dietary supplementation in most of these mothers would have benefited the antioxidant defenses of their soon-to-be-born infants.[120]

ESTIMATES OF OXIDANT RISK

In the oxygen-rich, relatively unstable extrauterine environment, antioxidant reserve of the rapidly growing newborn is precarious, even in the absence of perinatal and neonatal complications. For example, in a population of newborns characterized by low plasma and RBC concentrations of vitamin E,[31,32] significant spontaneous peroxidative membrane lipid damage was demonstrated in fresh, untreated RBCs, not exposed to an artificial environmental stress. This peroxidative membrane damage was evidenced by thiobarbituric acid reactivity, lipid fluorescence, and phospholipid-malonyldialdehyde (MDA) adduct formation at twice the magnitude of those observed in adult cells under the same conditions. Additional evidence indicates that at birth, the blood of newborn infants has increased coagulability owing to a marginal to deficient content of vitamin E in RBC membranes.[31,120] Even in adults, with adequate vitamin E nutrition, decreasing platelet adhesiveness is highly correlated with increasing plasma levels of vitamin E within the physiologic range.[131] These observations may have pertinence to the hypercoagulability of the blood of newborn infants, especially sick neonates.[32,120]

The functional requirement for α-tocopherol in the brain is thought to be at least as great as that of the RBC and probably greater. Membranes of the brain and retina, especially during fetal life and early infancy, have a high lipid content and an even higher complement of highly unsaturated fatty acids, particularly docosahexaenoic acid. The lipids of retinal photoreceptors, for example, are made up of 40% to 50% docosahexaenoic

acid.[79,111,132] Even a small decrement in membrane supply of vitamin E places such tissues at risk for oxidant damage. This risk is present during fetal life and the birth process and in the perinatal and newborn period because hypoxic or ischemic episodes followed by reoxygenation result in excessive production of oxidant radicals regardless of initial oxygen tensions.[2,4,133,134] In the rat, a number of studies have shown a protective effect of previous supplements of vitamin E on the outcome of episodes of umbilical cord clamping and release in utero.[135,136] A similar protective effect against hypoxia has been demonstrated in newborn rats.[137] These data are of importance to elucidating the ongoing occurrence of severe retinopathy of prematurity and cerebral palsy among very premature infants, especially those born at 23 to 27 weeks of gestation, who are now surviving as a result of sophisticated care in neonatal intensive care units. Almost all of these infants have been exposed to alternating exisodes of hypoxia and hyperoxia, periods of pulmonary and gastrointestinal failure, repeated systemic infection, and weeks of suboptimal nutrition before reaching a gestational age that even approaches term.[2,4,138-143]

From Jain SK, Wise R, Bocchini JJ Jr: Vitamin E and vitamin E-quinone levels in red blood cells and plasma of newborn infants and their mothers, *J Am Coll Nutr* 15:14, 1996.

*The low plasma α-tocopherol levels in these New Orleans newborns were significantly below those of their respective mothers *after* as well as *before* normalization for their minimal plasma lipid concentrations. Even in these infants, however, the level of tocopherol in the red blood cell (RBC) was not significantly below that of the mother unless the greater lipid content of the newborn RBC membrane was taken into account (i.e., *after* lipid normalization). It is the greater membrane content of lipids, rich in unsaturated fatty acids, in newborn RBCs that makes them more susceptible to lipid peroxidation than adult RBCs at any given concentration of tocopherol per mL of packed cells. Therefore physiologic characteristics as well as tocopherol concentration determine functional adequacy of vitamin E at the tissue level.

†Number of samples given in parentheses. Values are means ± SE (5.46 nmol/mL = 2.38 μg/mL = 238 μg/dL).

FUTURE DIRECTIONS AND ONGOING STUDIES

Functional Requirement for Vitamin E

An absolute membrane requirement for α-tocopherol that varies from tissue to tissue has been documented and depends to a significant extent on composition of the cellular membrane, stage of development and metabolic, constitutional, and environmental stress and on composition of the diet. In mammals, this requirement cannot be met by any other antioxidant or antioxidant system.[39-43,66-68,74] In humans, in addition to its essentiality for reproduction, the most critical requirement is that for the central nervous system, in which the α-tocopherol content of the cerebral hemispheres, medulla, and pons is tightly guarded.[41] Deterioration of mental function[144] and of the retina[51] occurs later than deterioration of spinocerebellar function in patients with vitamin E deficiency associated with childhood cholestasis and abetalipoproteinemia.[53-65] Long-term, high-dose vitamin E supplementation decreases clinical evidence of deficiency in these and related conditions, but successful pregnancy has not been reported.

The Complexity of Early Stages of Reproduction, Both Normal and Abnormal

Recent work[145-220] suggests that a critical balance of prooxidant and antioxidant elements in tissues and cells of the fetoplacental unit is necessary for normal differentiation and development and confirms an important role for vitamin E in its achievement and maintenance. Other closely linked factors important

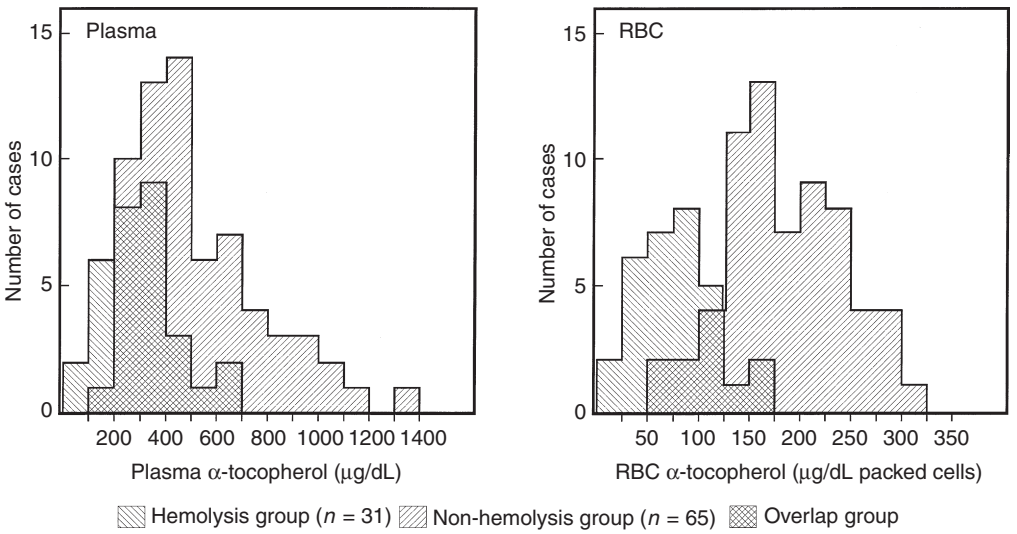

Figure 39-8 Plasma and red blood cell (RBC) α-tocopherol levels as determinants of susceptibility to oxidant stress. Samples were obtained from 96 premature and sick infants ranging in age from birth to 6 months. Under standard conditions, RBC α-tocopherol level predicts H_2O_2-induced hemolysis better than plasma α-tocopherol level (11.5% versus 25% overlap of RBC versus plasma tocopherol levels associated with presence or absence of hemolysis). The RBC level of α-tocopherol in 90% of infants in the hemolysis group was less than 125 μg/dL. Hemolysis did not occur if the RBC tocopherol level was higher than 175 μg/dL. The study population was from the Osaka area of Japan. *(From Mino M, Nakagawa S, Tamai H, et al: Clinical evaluation of red blood cell tocopherol,* Ann N Y Acad Sci *393:175, 1982.)*

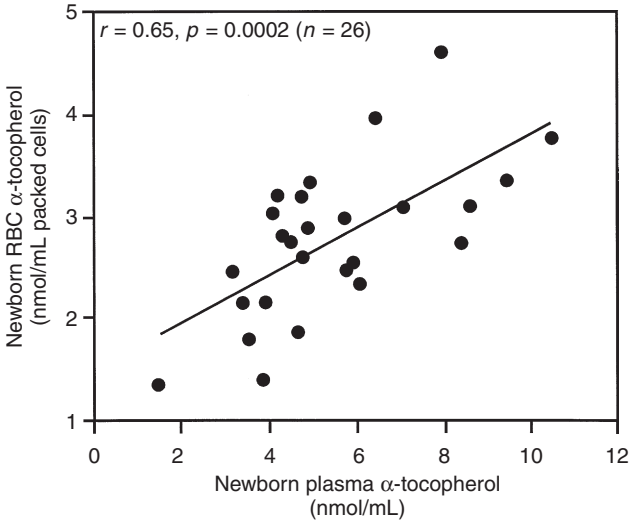

Figure 39-9 Correlation of α-tocopherol concentrations in plasma and red blood cells (RBCs) of 26 term newborns. In these newborns, with a mean RBC α-tocopherol level of only 1.18 μg (2.77 nmol) per mL of packed cells, good correlation was found between plasma and RBC α-tocopherol without normalization for plasma and RBC lipid level as shown, as well as with lipid normalization (RBC α-tocopherol as nmol/μmol RBC total lipid in relation to plasma α-tocopherol as nmol/μmol plasma total lipid; $r = .63$). The study population was from the New Orleans, Louisiana, area. *(From Jain SK, Wise R, Bocchini JJ Jr: Vitamin E and vitamin E-quinone levels in red blood cells and plasma of newborn infants and their mothers,* J Am Coll Nutr *15:44, 1996.)*

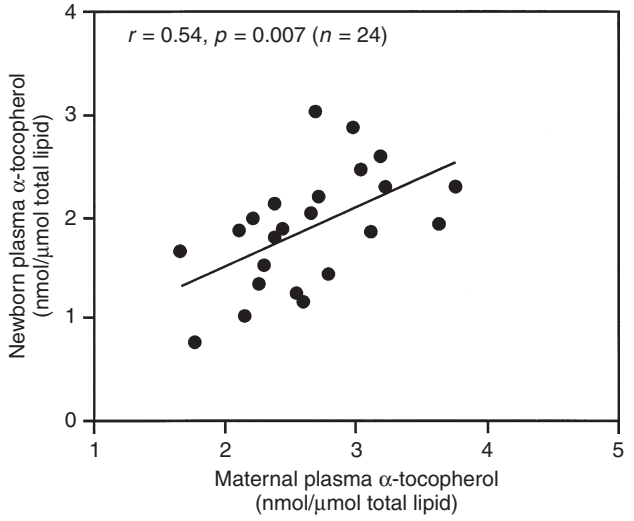

Figure 39-10 Plasma α-tocopherol concentration in 24 mother-infant pairs at term delivery. Good correlation was found between maternal and infant plasma α-tocopherol levels when expressed as nmol tocopherol/μmol total lipid. No correlation was found when levels were expressed as nmol tocopherol/mL plasma ($r = .09$; data not shown). The study population was from the New Orleans, Louisiana, area. *(Modified from Jain SK, Wise R, Bocchini JJ Jr: Vitamin E and vitamin E-quinone levels in red blood cells and plasma of newborn infants and their mothers,* J Am Coll Nutr *15:44, 1996.)*

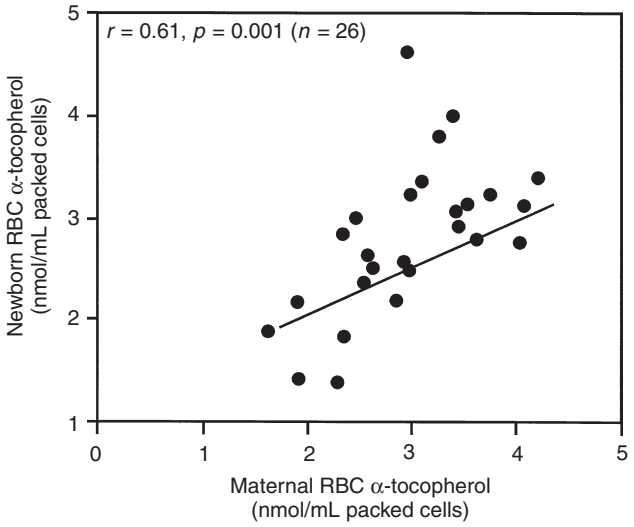

Figure 39-11 Red blood cell (RBC) α-tocopherol concentration in 26 mother-infant pairs at term delivery. As evident in this figure, a good correlation was present between newborn and maternal RBC γ-tocopherol levels expressed as nmol/mL of packed cells. The correlation also was present when levels were expressed as nmol/μmol of total lipid ($r = 0.46$; $p = .02$). The study population was from the New Orleans, Louisiana, area. *(Modified from Jain SK, Wise R, Bocchini JJ Jr: Vitamin E and vitamin E-quinone levels in red blood cells and plasma of newborn infants and their mothers,* J Am Coll Nutr *15:44, 1996.)*

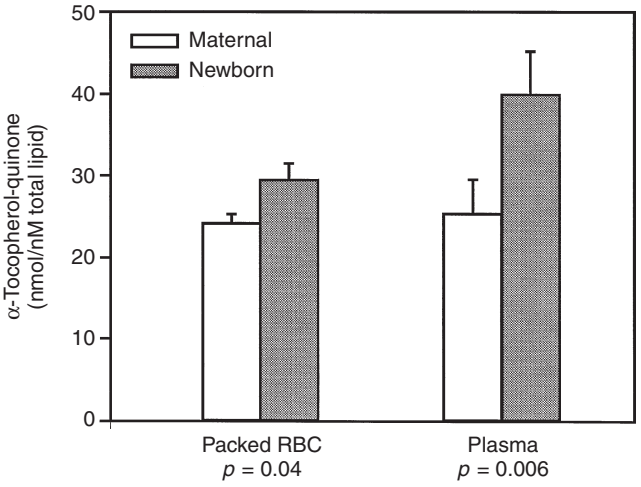

Figure 39-12 α-Tocopherol-quinone levels in 26 mother-infant pairs. Red blood cell (RBC) and plasma levels of α-tocopherol-quinone, the oxidation product of α-tocopherol, were measured in mother-infant pairs at birth and were found to be significantly higher in the infant. The mean newborn RBC α-tocopherol level was 2.77 ± 0.14 nM (1.19 μg/mL); in the mothers, it was 2.95 ± 0.13 nM (1.29 μg/mL). Quinone levels in the infant did not correlate with quinone levels in the mother. Blood specimens were protected against oxidant exposure throughout the analytic procedure. The study population was from the New Orleans, Louisiana, area. *(Data from Jain SK, Wise R, Bocchini JJ Jr: Vitamin E and vitamin E-quinone levels in red blood cells and plasma of newborn infants and their mothers,* J Am Coll Nutr *15:44, 1996.)*

to redox balance include vitamin C and carotene; the antioxidant enzymes superoxide dismutase, glutathione peroxidase, and catalase; and the metabolic intermediaries reduced glutathione and cysteine; saturated and unsaturated lipids; and intra- and extracellular calcium ions.[145,146] The expanding number of markers of oxidant stress now being identified and measured during human pregnancy and in animal and in vitro models testifies to the complexity of the phenomena under investigation. Currently these markers include leptin, placental growth factors, indices of placental endothelial dysfunction of which the most important is the plasminogen activator-inhibitor ratio (PAI-1/PAI-2), a range of pro- and antiinflammatory cytokines such as the T_H1 helper cell profile (interferon-γ, tumor necrosis factor-α, and the interleukins IL-l l and IL-12), the T_H2 helper cell profile (IL-4 and IL-10), and nuclear factor-κ B, 8-isoprostane, 8-epi-prostaglandin, IL-6 and IL-8, leukemia inhibitory factor, peroxynitrites, and uric acid.[148-221]

Presented next are selected quotes, followed by the abstract from the paper by Allen and Venkatraj, "Oxidants and antioxidants in development and differentiation,"[145] that are pertinent to the ongoing search for safe, effective treatment interventions for management of high-risk pregnancies and for selection of the readily available, easily administered and inexpensive antioxidant vitamins E and C as early choices for study in controlled clinical trials in humans.

"The redox status of cells is the ratio of oxidizing equivalents to reducing equivalents present in the cell. It can be regarded as the net balance of the interaction of all cellular oxidants and antioxidants. Redox state is strongly modulated by a variety of environmental factors, including nutritional status. For example, increasing dietary antioxidants such as ascorbate, alpha tocopherol or beta carotene tends to depress the synthesis of GSH (reduced glutathione) as well as the activity of the enzymic antioxidant defenses.

"Both cell cycle and development are associated with enormous changes in redox balance.

"Cellular environments enriched with antioxidants appear to impede differentiation.

"The underlying cause of these effects appears to stem from the influence of redox status on calcium metabolism.

"Metabolic gradients are known to influence cellular differentiation at critical junctures of development. The existence of these gradients will stimulate variations in the rate of generation of active oxygen metabolites by metabolic pathways. Recent evidence suggests that cellular oxidation can induce changes in gene expression during normal development. Conversely, antioxidants such as ascorbate, alpha tocopherol and beta carotene are inhibitory to differentiation in many types of cells. One basis of oxidative influence on gene expression stems from changes in cellular calcium distribution."

Ongoing Evidence of the Essentiality of α-Tocopherol for Reproduction

An exciting body of ongoing research[146-220] is investigating the need for vitamin E during implantation, early, middle, and late stages of gestation as modulated by genetic, imunologic, nutritional, and environmental factors.[192,198,209-211,215-221] Isotopic and immunochemical studies of α-tocopherol transfer protein (α-TTP) in human placental tissues, and in α-TTP–null and –heterozygous and wild-type mice, support the essentiality of vitamin E for implantation and placental development.[212-217] Vitamin E has been identified in the syncytiotrophoblast, the villous and extravillous invading cytotrophoblast, basal decidual cells, and amnion and fetal capillaries.[215-218] Among five human tissues, including brain, the quantified placental expression of α-TTP mRNA by 5′-nuclease assay is second only to that of the liver.[215]

The gestational sac in the early first trimester limits, rather than facilitates, oxygen transfer. Oxygen tensions are in the clearly hypoxic range, metabolism is essentially anaerobic, and nutrition is accomplished by means of uterine glandular secretions.[216-221] Antioxidant molecules, are limited to vitamin C, uric acid, and α- and γ-tocopherol and are made available by diffusion through the exocelomic cavity, rather than by a yet-to-be-developed placental vasculature. Antioxidant enzymes are essentially undetectable.[144,218,219] During this initial trimester, the fetus is most vulnerable to oxidant stress and in need of antioxidant protection if exposure to an excess of oxidant radicals occurs.[189-193,201-203,209-212]

Studies of Antioxidant Supplements During Pregnancy

From many studies in animals and humans, it is known that overproduction of reactive oxygen species occurs in diabetic pregnancies and pregnancies characterized by preeclampsia and pregnancy-induced hypertension,[135-137,148-155,190,205] intrauterine growth restriction,[174,184,188,190,205] diabetes,[156-166,205] maternal smoke inhalation,[167-169] maternal ethanol ingestion,[170-173] premature rupture of membranes,[146,175] and maternal nutritional deprivation.[176,180,184,185] In addition to the recognized adverse neonatal outcomes associated with such pregnancies, they are implicated as contributors to the fetal origins of pediatric and adult diseases.[143,174-184,202]

In vitro studies and animal models of abnormal pregnancy have shown consistent, clearly beneficial results in association with preventive or corrective treatment with vitamins E and C.* For example, in a recent study of human placental villous explants exposed to hypoxia-reoxygenation, vitamin E– and vitamin C–blocked activation of the signaling pathways of nuclear factor κB, p38, and stress-activated and mitogen-activated protein kinase, which regulate downstream release of proinflammatory cytokines. Nevertheless, results of randomized, placebo-controlled, clinical trials of vitamin E and C treatment in human pregnancies classified as at high risk for pathologic oxidant stress have shown inconsistent benefit[187-190,208] and sometimes unexpected, possibly harmful side effects. Such side effects were most evident when normal pregnancies made up a major proportion of the study population and when doses of vitamin E in excess of 400 IU of all-racemic α-tocopherol were used.[195,196] The recommended dietary supplement of vitamin E for normal pregnancies is 22 to 30 mg/day.

Accurate early identification of clinically significant oxidant stress, with provision of prompt, targeted treatment in the first trimester, is not yet possible in humans. Unrestricted access to maternal, fetal and placental blood and tissues, as well as control of absence or presence of disease and its severity, can be achieved only in animal models of pregnancy complicated by diabetes, maternal nutritional deprivation, and excessive smoking and ethanol intake.[157-173] No such animal models for preeclampsia and pregnancy-induced hypertension have been described.

Diabetic Pregnancies

Oxidant stress and overproduction of oxidant radicals, with a range of abnormal outcomes, occur in all human diabetic pregnancies, including those involving gestational diabetes as well as diabetes type 1 and type 2.[201-203,206,211] The risk of preeclampsia in diabetic pregnancies is two to four times higher than in nondiabetic pregnancies.[201,206] Without antioxidant treatment, strict maintenance of normoglycemia is remarkably effective in decreasing all diabetes-related abnormalities, including preeclampsia, but initiation and maintenance of strict normoglycemia must begin

*References 135-137, 148, 157, 159-166, 206, 207, 221.

very early in pregnancy to be effective.[205-207] The potential for antioxidant therapy with vitamins E and C to improve outcome in diabetic pregnancies was investigated in 20 metabolic antenatal units in the United Kingdom taking part in DAPIT (the Diabetes and Pre-eclampsia Intervention Trial).[200]

The DAPIT trial enrolled women with a diagnosis of type 1 diabetes, monitored for glycemic control, who presented between 8 and 22 weeks gestation from April 2003 to June 2008. Women were randomly assigned to receive 1000 mg of vitamin C and 400 units of α-tocopherol (presumably dL racemic) or placebo until delivery.

By intention-to-treat analysis of the 379 vitamin and 383 placebo women who completed the study, no differences in the primary outcome of incidence of preeclampsia were found. In two of 11 predefined subgroups that categorized enrollees by baseline antioxidant status, however, the risk of preeclampsia was significantly reduced in women with low baseline antioxidant criteria (<10 μmol/L plasma ascorbate or serum α-tocopherol ≤5 μmol/mmol cholesterol) who received vitamin treatment as compared to placebo during pregnancy. No adverse side effects of antioxidant supplementation were found for either mother or infant in the study population as a whole or in any of the 11 subgroups.

The authors concluded that this finding deserved further investigation and suggested that vitamin supplementation may be beneficial in preventing preeclampsia in diabetic pregnancies only in women with vitamin depletion. The finding and its interpretation was consistent with earlier clinical trials assessing the effect of antioxidant supplements for prevention of preeclampsia in women with higher versus lower estimates of oxidant stress, antioxidant depletion, and risk for disease.[188-190,195-199]

Pregnancies Complicated by Preeclampsia

Worldwide, preeclampsia occurs in 2% to 3% of all pregnancies.[205,220] The effect of antioxidant therapy with vitamins E and C for prevention of preeclampsia (proteinuric hypertension) in nondiabetic pregnancies associated with high risk for the disease has been reported in a number of controlled clinical trials.[†] In these trials, the first-trimester predictive markers used to identify a high-risk study population were associated with a placebo incidence of preeclampsia of 15% to 20%.[188,195,208] An additional comparable percentage of pregnancies were associated with intrauterine growth restriction (IUGR) without preeclampsia.[190,195,199] Therefore, at least in relation to these pathologic conditions, 50% to 60% of the study population randomized for treatment had no recognizable clinical disease and may not have had clinically significant overproduction of oxidant radicals in the first trimester. Additionally, treatment did not begin until the second trimester. Improved early prediction would allow more targeted, timely antioxidant therapy,[191] clarify treatment results, and mimize possible deleterious effects of treatment in the absence of clinically significant overproduction of oxidant radicals.[189-191,195,196]

One controlled clinical trial in South Africa[187] involved 56 women with already diagnosed severe preeclampsia at 24 to 32 weeks of gestation. Only minimal benefit was obtained from treatment with allopurinol as well as vitamins E and C initiated at diagnosis. These results emphasize the need for initiating therapy early in the pathologic process. One of the trials[208] was terminated early because interim analyses indicated that the sample size was likely to be inadequate.

Three completed controlled clinical trials[188,195,199] in which treatment was initiated in the mid–second trimester and a small case-control study in "normal" pregnancies[196] in which treatment was started in the early first trimester are summarized here because of the insights provided for improved protocol development and direction of future research.

Summary of Antioxidant Clinical Trials

Clear benefit from antioxidant treatment was reported in 1999 for a controlled clinical trial from the Guy's, King's College, and St. Thomas Hospitals in London,[188-190] which included serial measures of oxidant stress in both treatment groups after randomization. The study population was confined to pregnancies classified as being high risk for preeclampsia because of a previous history of preeclampsia or abnormal findings on two-stage uterine artery Doppler analysis. Serial measures of oxidant stress were measured until delivery in the 142 placebo- and 141 vitamin-treated women enrolled in the study. Oral treatment was begun at 16 to 22 weeks gestation and continued until birth of the infant. Treatment consisted of 400 IU α-tocopherol (presumably all-racemic) and 1000 mg of vitamin C or placebo. Of the 283 enrollees, 160 (81 placebo and 79 vitamin) completed all aspects of the study, including monthly plasma assessments of oxidant stress and placental function.

In the intention-to-treat analysis, there was a decrease in incidence of preeclampsia ($p = 0.02$), from 17% in placebo-treated mothers to 8% in vitamin-treated mothers ($n = 283$). In the cohort who completed the study, the decrease in incidence of preeclampsia was at the $p = 0.002$ level. There also was a 21% decrease ($p = 0.015$) in the ratio of plasminogen-activator inhibitor (PAI)-1 to PAI-2 (placental dysfunction) in vitamin- versus placebo-treated mothers.

In further analysis, other measures of oxidative stress and placental dysfunction were found to be abnormal in placebo-treated compared with vitamin-treated enrollees and compared with a group of untreated, low-risk mothers who received perinatal care during the same period and were similarly monitored for oxidative stress and placental function. These measures included decreased concentrations of ascorbic acid, PAI-2, and placental growth factor; increased concentrations of 8-epi-prostaglandin and leptin; and decreased PAI-1 to PAI-2 ratio. The best predictors of preeclampsia in the 17% of women ($n = 142$) in the placebo group in whom preeclampsia developed were leptin, placental growth factor, uric acid, and the PAI-1 to PAI-2 ratio.[189]

No treatment benefit but possible deleterious side effects were reported in the large controlled clinical trial, the Vitamins in Preeclampsia (VIP) trial, organized by the Maternal and Fetal Research Center of Kings College and St. Thomas Hospital (London). It was conducted in 25 participating U.K. hospitals[195] and enrolled a study population ($n = 2404$) of pregnant women classified as being at high risk for preeclampsia on the basis of "a range of clinical risk factors." Treatment consisted of placebo or 400 IU of RRR α-tocopherol plus 1000 mg of vitamin C per day from the second trimester until delivery; after randomization, 1205 women received placebo and 1199 received vitamin supplementation. RRR-α-tocopherol has 1.36 times the biologic potency of the all-racemic preparation on the basis of older biologic assays (see Table 39-2) and a potency approaching 2 times that on the basis of recent more sophisticated studies.[214-216] Despite this larger dose of vitamin E, no significant difference in incidence of preeclamspsia was found between treatment groups (16% for the placebo group versus 15% for the vitamin supplementation group); significantly more babies had lower birth weights (within the normal range) in the vitamin treatment group (28%, versus 24% in the placebo group), a possibly deleterious side effect. No difference in incidence of small-for-gestational age (SGA) status among infants born to these women was noted between the placebo group and the vitamin treatment group: 19% versus 21%, respectively. Data from 99.6% of patients were analyzed.

No treatment benefit and no untoward side effects were reported in a third controlled clinical trial in 1877 nulliparous women receiving care in the Australia and New Zealand

[†]See references 187, 188, 195, 196, 199, 208.

Neonatal Network,[199] who were randomized without further risk assessment to receive placebo or 400 IU of (presumably) all-racemic α-tocopherol and vitamin C at 14 to 22 weeks of gestation. The placebo group included 942 women, with 935 women in the vitamin treatment group. The study investigators reported no significant between-group differences in outcome variables including the incidence of preeclampsia (5.0% in the placebo group versus 6.0% in the vitamin treatment group; r = 1.20), SGA in infants born to these women (9.9% in the placebo group versu 8.7% in the vitamin group; r = 0.87), and death or other serious outcome (12.1% with placebo versus 9.5% with vitamins; r = 0.79).

In addition to these three controlled clinical trials, a case-control study also evaluated the effect of vitamin E supplementation on preeclampsia risk: No treatment benefit but possible deleterious side effects were reported in a nonplacebo, nonrandomized trial in normal pregnancies in 82 women managed in the Motherisk program of Toronto, Canada.[196] Women were enrolled, without risk assessment, early in the trimester and started on treatment with daily doses of 400 to 1200 IU of vitamin E (presumably all-racemic α-tocopherol) without vitamin C. Treatment was continued only during the first trimester. The rates for live births, premature deliveries, miscarriages, and stillbirths were compared with those in a matched control group from the same Motherisk program. Of note, preeclampsia was not diagnosed in either group. (The incidence of preeclampsia worldwide[205,218] is estimated at 2% to 3%.) One case of omphalocele was diagnosed in the vitamin treatment group. Of importance, and also unexpected, was the finding of a highly significant (p = .0015) decrease in mean birth weight (within the physiologic range) associated with the vitamin E supplementation regimen: The mean birth weight of infants born to vitamin-treated mothers was 3173 ± 467 g, versus 3417 ± 565 g for infants of control (untreated) mothers.

Discussion of Results

Differences in outcome among the three controlled clinical trials as summarized may have been related, in terms of biologic potency, to the relatively higher dose of vitamin E used in the second trial[195] and to differences in the high-risk classification criteria. All three trials initiated treatment in the second trimester rather than the first. The placebo-related incidence of preeclampsia was similar at 17% in the first[188] and 16% in the second[195] of these trial and, as expected, lower (at 5%) in the study population of nulliparous women without risk assessment in the third.[199] The second trial[195] specified use of RRR α-tocopherol, the naturally occurring form, which has close to twice the biologic potency of the all-racemic α-tocopherol[213,214] used in the other two. As in the case of brain cells, it is preferentially transferred across the placenta.[212] The much larger sample size of the second trial would be expected to ensure a more equal distribution of preeclamptic risk between treatment arms and a greater power to detect beneficial as well as harmful effects of the higher antioxidant dosage in pregnancies without preeclampsia. The third trial,[199] with its larger proportion of normal pregnancies and the 400-IU dose of all-racemic α-tocopherol, showed results paralleling those in the larger second trial in regard to lack of treatment benefit and those of the first in regard to absence of possible harmful side effects. The fourth nonrandomized trial, with an apparently normal study population, used a much higher dose of vitamin E, 400 to 1200 IU (presumably all-racemic α-tocopherol), which was started early in the first as opposed to the second trimester and was continued through only the first trimester.[199] The potential for deleterious side effects was most clearly suggested in this trial.

The possibility that untoward side effects can result from antioxidant treatment in "normal" pregnancies is an important observation and indicates that the safe but effective antioxidant dosage range for prophylaxis and treatment is more narrow than had been anticipated, especially in the absence of oxidant radical excess.[196,198,209]

Clinical and Laboratory Studies Pertinent to Trials of Treatment Interventions

That antioxidants can be harmful was reported in a study of pregnant diabetic rats (n = 166) treated at daily doses of 25, 50, 100, 150, and 500 IU of vitamin E (presumably all-racemic α-tocopherol). Increasingly greater benefit in decreasing malformations, increasing maturation and size of offspring and decreasing rate of reabsorption was associated with increasing doses up to 150 IU per day. At this dosage the reabsorption rate in treated vs untreated diabetic rats was 12.5% versus 24.7% and the malformation rate 13.9% versus 50%, respectively. By contrast, at the 500-IU dose, a clearly deleterious effect was found, with a reabsorption rate of 43.9% in treated rats versus 24.7% in untreated rats. The malformation rate at the 500-IU dose was 10.8% in treated rats versus 50% in untreated rats.

Recent studies have suggested that, especially in human pregnancies without increased oxidant stress, more vitamin E than is strictly needed for metaboloic efficiency may interfere with the immunologic switch from T_H1 to T_H2 cytokine profiles that is essential to normal placental physiology in early (versus late) pregnancy.[198,209] Of great interest in this regard is the report by British investigators that this immunologic transition from early to late placental cytokine profiles does not seem to occur in pregnancies characterized by first-trimester oxidant stress and subsequent preeclampsia and IUGR.[209] In these pregnancies, interferon-γ (IFN-γ) R2 protein expression in trophoblasts at the maternal-fetal interface was found to be severely downregulated at 25 to 40 weeks of gestation and was similar to that present in normal placentas at 7 to 10 weeks developing under optimally low oxygen tesions. These findings are supported by those of Swedish investigators, who suggest that maladaptation of immune responses secondary to excessive maternal inflammatory response directed against foreign fetal antigens in the initial stages of pregnancy results in defective trophoblast invasion and a chain of pathologic events leading to clinical preeclampsia.[210]

The current hypothesis is that normal trophoblastic control of maternal immune effectors and cytokine profiles at the fetal-maternal interface is compromised by exposure to abnormal oxidative stress in the initial stages of preeclampsia and may be benefited by treatment directed at maternal-fetal imunologic incompatibilities as well as antioxidant treatment to minimize inflammation.[209,210] In related work,[193] impaired redox regulation was found in umbilical vein endothelial cells and RBCs at 14 to 20 weeks of gestation in pregnancies associated with preeclampsia as compared with those in which preeclampsia did not develop in the study population enrolled in the large VIP trial summarized earlier.[195] Impaired redox regulation was associated with decreased hexokinase and glucose-6-phosphate dehydroxylase (G6PD) activity, suggesting that deficiency in G6PD activity may explain the relative ineffectiveness of vitamin E in preventing preeclampsia in this trial.[193]

Unanswered Questions: Direction of Future Research

As noted in the earlier summary of the paper by Allen and Venkatraaj,[145] the physiologic role of vitamin E in the low-oxygen environment of the normal first trimester may relate to its actions as a cofactor in functions not strictly antioxidant in nature but required for achieving maximum metabolic efficiency for development and differentiation.[145] In excess of this amount, a real concern is that vitamin E, under certain circumstances, may potentially act as an IFN-γ mimic to promote

proinflammatory reactions at the fetal-maternal interface.[198] Investigators are now in general agreement that the importance of vitamin E for reproduction is underestimated and misunderstood if only its antioxidant properties are considered.[191-193] Properties associated with antiinflammation and inhibition of NAD(P)H oxidase activation need to be investigated,[191-193] as do also the role and importance of tocopherol forms other than α-tocopherol, in particular, γ-tocopherol; the role of the tocotrienols (see also under "Non-Antioxidant Functions of Vitamin E," earlier); and the novel mechanisms of antiatherosclerotic and anticarcinogenic properties of vitamin E involving modulation of cellular signaling, transcriptional regulation, and induction of apoptosis.[192]

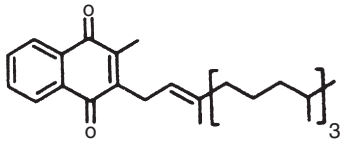
Vitamin K Metabolism in the Fetus and Neonate

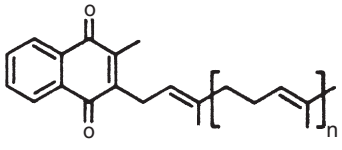
VITAMIN K AND BLOOD COAGULATION

Since the discovery of the pathogenesis of vitamin K deficiency in the 1950s,[1] the importance of prophylactic vitamin K in prevention of hemorrhagic disease in the fetal and neonatal periods has been debated. However, the development of sophisticated high-performance liquid chromatography systems, which can measure low levels of vitamin K and its metabolites in blood and tissues, has provided valuable new information on this subject. These measurements have shown that placental passage of the vitamin from maternal to fetal blood is restricted.[2-5] Thus the fetus can acquire a state of vitamin K deficiency.



It is well documented that premature infants and infants at term are invariably born with reduced levels of many of the essential protein factors of the hemostatic system.[6,7] Among these factors are the vitamin K–dependent clotting factors—prothrombin; factors VII, IX, and X; and protein S and protein C.[7]

Because classic hemorrhagic disease of the newborn has been treated successfully with vitamin K, it has been suggested that neonates begin extrauterine life with a vitamin K deficiency, so that vitamin K administration is necessary to correct the resulting imbalance of the hemostatic system.[4] Several studies contradict this assumption. Using a procedure for blood sampling in utero, Forestier and colleagues[8] found good correlation between procoagulant activity of the vitamin K–dependent clotting factors and the respective antigens in midtrimester fetal blood. Further evidence was the absence of PIVKA (*p*rotein *i*nduced in *v*itamin *K a*bsence) forms of the vitamin K–dependent clotting factors in their samples, arguing against vitamin K deficiency in the fetus.[8] Indeed, in most studies performed on newborns, PIVKA factors have been found in minimal concentrations or are totally absent, even in low-birth-weight infants.[5,8-12] Thus classic hemorrhagic disease of the newborn is likely to result from (1) malnutrition by the mother during pregnancy, (2) use of vitamin K antagonists during pregnancy, (3) exhaustion of the liver stores of vitamin K in the newborn, and (4) undefined causes of vitamin K deficiency.



Production of the vitamin K–dependent clotting factors by the liver is related to gestational age.[7,13-15] The blood concentrations of these factors in the neonate are approximately 30% to 60% of their concentrations in the adult; these low values gradually increase until they reach normal adult values by the age of 6 weeks.[16] Thus the lower concentrations found in the developing neonate apparently result from immaturity in the system that produces these proteins. The hemostatic system requires a fine balance between coagulation on one side and fibrinolysis on the other, so abnormal development of the liver system that produces the vitamin K–dependent clotting factors presumably can contribute to hemorrhagic and thrombotic problems in the fetal and neonatal periods. Because vitamin K metabolism and vitamin K function are linked processes in the liver, this chapter focuses on maturation of the vitamin K–dependent γ-carboxylation system in the fetal and neonatal periods.

FUNCTION AND METABOLISM OF VITAMIN K IN LIVER

The essential steps in vitamin K metabolism and the steps targeted by the anticoagulant drug warfarin were investigated by several laboratories (reviewed by Suttie[17]), including ours,[18-23] in the 1970s and 1980s. Structures of the naturally occurring forms of vitamin K are shown in Figure 40-1. Vitamin K_1, or phylloquinone, is found in plants. The plant vitamin is a naphthoquinone with a saturated polyisoprenoid side chain in the 3 position on the napthoquinone ring system. Vitamin K_2, which comprises the members of the menaquinone family, is found in bacteria and has an unsaturated side chain of variable length in the 3 position. Vitamin K is absorbed in the small intestine and enters the lymphatic system by a process that requires the presence of both bile and pancreatic juice for maximum absorption.[17,24] After uptake, the vitamin is distributed ubiquitously among body tissues, but significant quantitative differences have been noted, the liver being the major organ for uptake. Intracellularly, the vitamin has been found in membranes of mitochondria, the endoplasmic reticulum, and the Golgi apparatus.[25] Although menaquinones have been shown to promote biosynthesis of vitamin K–dependent clotting factors by the liver,[26] the bacterially produced vitamin does not contribute to fetal biosynthesis of vitamin K–dependent clotting factors. Some evidence indicates that the infant is born with essentially no liver stores of menaquinones.[27,28]

Phylloquinone (vitamin K_1)

Menaquinones (vitamin K_2)

Figure 40-1 Chemical structures of phylloquinone, or vitamin K_1, and menaquinones, collectively termed vitamin K_2. Vitamin K_1 is found in plants. Vitamin K_2 is synthesized with a side chain of variable length by bacteria.

Several theories on the biologic action of vitamin K were proposed before the finding that vitamin K was involved in posttribosomal modification of proteins. Stenflo and associates[29] identified the modification as γ-carboxyglutamic acid carried out by an enzyme in the endoplasmic reticulum. Independently, Nelsestuen and co-workers[30] found the modification in a dipeptide (Glu-Ser) from prothrombin. Magnusson and colleagues[31] later showed that the first 10 amino-terminal (N-terminal) glutamic acid (Glu) residues in prothrombin are γ-carboxylated. The new amino acid formed as a result of vitamin K action was called γ-carboxyglutamic acid, abbreviated Gla. Its structure is shown in Figure 40-2. The Gla residues bind calcium, and calcium binding by the fully γ-carboxylated clotting factors is essential for optimal activation or activity of these factors in blood.[32]

Vitamin K–dependent γ-carboxylation has been shown to require molecular oxygen, carbon dioxide, and the fully reduced form of vitamin K, vitamin K hydroquinone[17] (Figures 40-3 and 40-4). Because the normally occurring forms of vitamin K are quinones (see Figure 40-3), the vitamin must be reduced by liver enzymes before the γ-carboxylation reaction is triggered. As illustrated in Figure 40-4, γ-carboxylation of one Glu residue is coupled stoichiometrically to formation of one molecule of the vitamin K metabolite, vitamin K 2,3-epoxide (vitamin K>O). Vitamin K>O is reduced by liver enzymes back to the hydroquinone form, which establishes a redox cycle for vitamin K in liver, known as the vitamin K cycle (see Figure 40-4).[17,18] Two pathways for vitamin K reduction are associated with the cycle. Pathway I

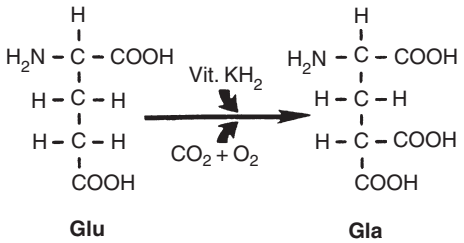


Figure 40-2 Vitamin K–dependent synthesis of γ-carboxyglutamic acid (Gla).

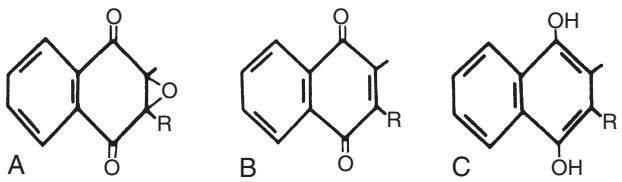

Figure 40-3 Chemical structures of vitamin K metabolites produced by the vitamin K cycle. A, Vitamin K 2,3-epoxide (K>O). **B,** Vitamin K quinone (K). **C,** Vitamin K hydroquinone (KH_2).

is physiologically the more important pathway and operates at normal and low liver concentrations of vitamin K.[22] The enzyme involved, vitamin K epoxide reductase, catalyzes reduction of vitamin K>O and vitamin K to the active vitamin KH_2 cofactor (KH_2). The reduced thiol compound dithiothreitol is an excellent source of electrons for the enzyme-catalyzed reaction (see Figure 40-4). However, the thiol compound, which is active in vivo, has not yet been identified. It has been documented that vitamin K epoxide reductase is the target for the anticoagulant drug warfarin.[17] Thus warfarin mediates its anticoagulant effect by preventing production of reduced vitamin KH_2 by pathway I. Inhibition of pathway I by warfarin is essentially irreversible.[33] However, vitamin K commonly is used clinically as an antidote to overcome intoxication with this drug. The antidotal effect of vitamin K is mediated by pathway II,[22] which is operative only at high liver concentrations of vitamin K. Pathway II, which is insensitive to warfarin, has been shown to consist of more than one dehydrogenase that are dependent on the reduced form of nicotinamide adenine nucleotide (NADH) to reduce the quinone form of the vitamin.[19,20]

Since Bell and Matchiner[34] discovered the warfarin-sensitive vitamin K epoxide reductase (VKOR) of the vitamin K cycle in 1970, much research has focused on this important enzyme. Attempts to purify the enzyme were undertaken by many laboratories (as reviewed by Suttie[33]), but successful research has now been accomplished on the VKOR gene and the VKOR cDNA has been expressed in vitro.[34a] The carboxylase, a 92-kDa membrane protein of the endoplasmic reticulum membrane, has been purified[36,37] and cloned.[38] The successful isolation of the carboxylase has contributed significantly to current understanding of the mechanism by which the carboxylase participates in biosynthesis of vitamin K–dependent clotting factors. Because VKOR has now been purified, knowledge of vitamin K metabolism and the mechanism of action of the anticoagulant warfarin on the vitamin K–dependent γ-carboxylation system and how it is linked to operation of the γ-carboxylase has improved immensely. Our laboratory has provided evidence that VKOR is a multicomponent enzyme complex in the endoplasmic reticulum membrane and that the activity is regulated by the chaperone calumenin.[39]

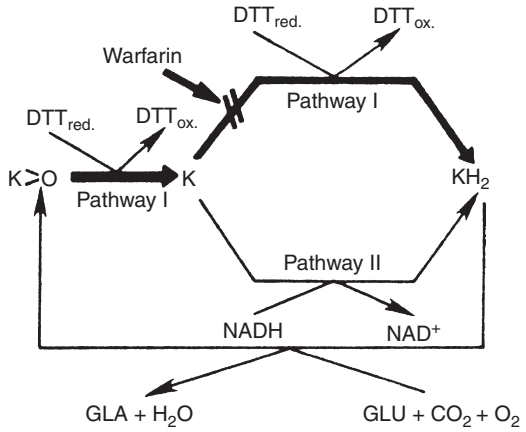

Figure 40-4 Vitamin K metabolism and vitamin K function in liver. Reduction of vitamin K epoxide (K>O) and vitamin K (K) by pathway I is catalyzed by vitamin K epoxide reductase, which requires reduced thiols (dithiothreitol- [DTT]) for the reaction. Pathway I is inhibited by the anticoagulant drug warfarin. Reduction of vitamin K by pathway II is catalyzed by NAD(P)H-dependent dehydrogenases. This pathway is insensitive to warfarin and mediates the antidotal effect of vitamin K. Reduced vitamin K (KH_2) triggers γ-carboxylation of glutamic acid (GLU) residues and converts them to γ-carboxyglutamic acid (GLA) residues. Formation of GLA is coupled to formation of K>O.

MATURATION OF THE VITAMIN K–DEPENDENT γ-CARBOXYLATION SYSTEM IN THE FETAL AND NEONATAL PERIODS

The available data on vitamin K metabolism and γ-carboxylation in the fetal and neonatal periods are derived primarily from the rat model. Nevertheless, in one human study,[5] plasma levels of vitamin K_1 and vitamin Ko were measured in 133 term and 26 preterm neonates. The data indicate that the ratio of epoxide to vitamin K increases with gestational age. One possible explanation for this observation is that maturation of pathway I takes place toward term, potentially leading to underproduction of reduced vitamin KH_2 cofactor and incomplete γ-carboxylation of the vitamin K–dependent clotting factors. Figure 40-5 shows the specific activity profile of the warfarin-sensitive pathway I enzyme, vitamin K epoxide reductase, in 16- to 20-day fetal rats, at birth (day 21), and in 2- and 7-day neonatal rats.[39] As shown, warfarin sensitivity was detected from day 16 in the fetal period, the earliest point in gestation studied. None of the fetal livers had less than 50% of the specific activity measured in 7-day neonatal rats. These studies indicate that in the rat, significant amounts of

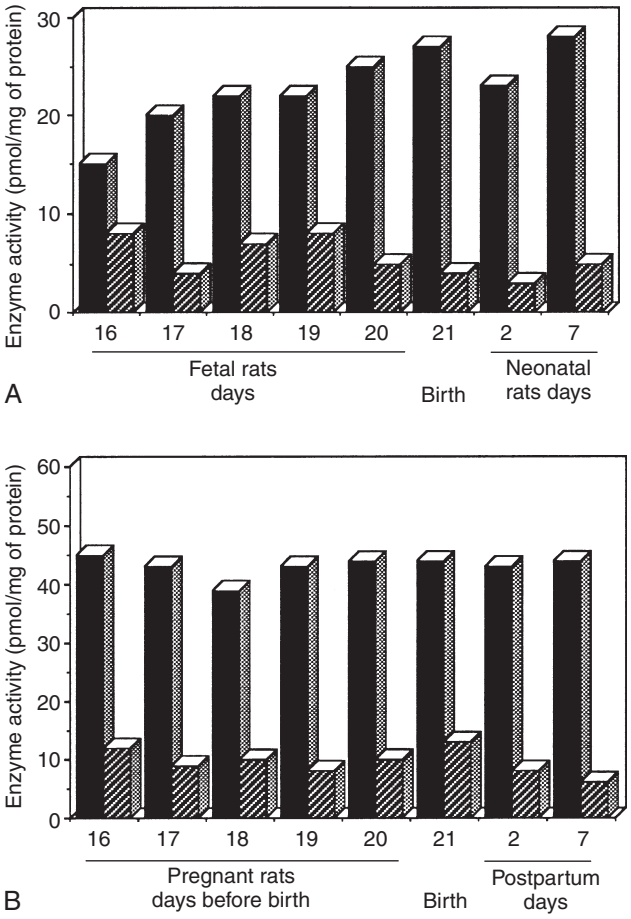

Figure 40-5 Vitamin K epoxide reductase activity in fetal and neonatal **(A)** and maternal **(B)** livers. Before determination of enzyme activity, pregnant rats were injected with saline *(solid bars)* or warfarin *(cross-hatched bars)*. *(From Wallin R: Vitamin K–dependent carboxylation in the developing rat: Evidence for a similar mechanism of action of warfarin in fetal and adult livers,* Pediatr Res *26:370, 1989.)*

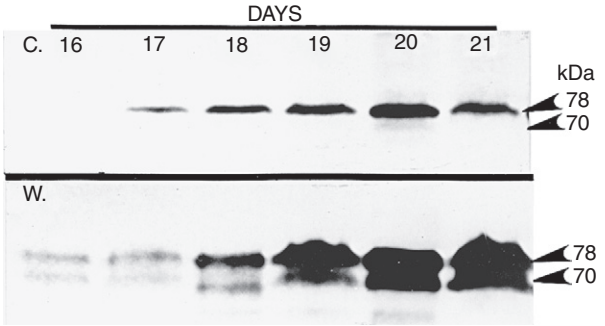

Figure 40-6 Vitamin K–dependent carbon 14 labeling of precursors of prothrombin and factor X in fetal livers. Fetal livers were isolated from day 16 to day 21 in pregnant rats injected with saline (C), and warfarin (W.). The fluorograms show the prothrombin (78 kDa) and the factor X (70 kDa) precursors. *(From Wallin R: Vitamin K–dependent carboxylation in the developing rat: evidence for a similar mechanism of action of warfarin in fetal and adult livers,* Pediatr Res *26:370, 1989.)*

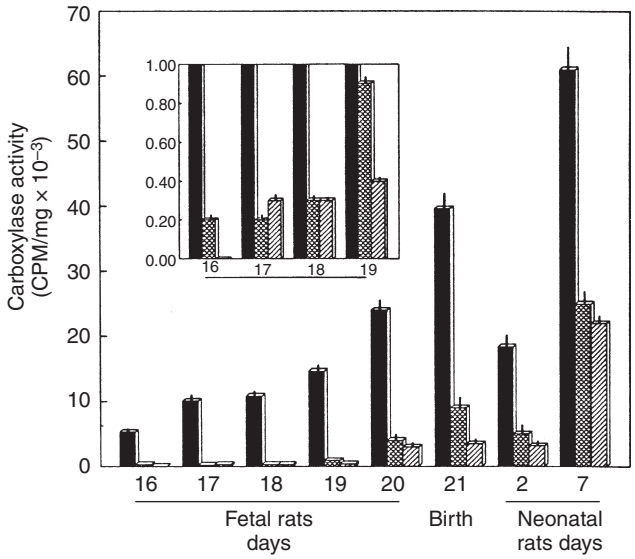

Figure 40-7 Vitamin K–dependent carboxylase activity in fetal and neonatal rat liver. Carboxylase activity, measured in counts per minute (cpm)/mg, was triggered with chemically reduced vitamin K_1H_2 *(solid bars)* or when supported by pathway I *(cross-hatched bars)* and by pathway II *(diagonal bars)*. *(From Wallin R: Vitamin K–dependent carboxylation in the developing rat: evidence for a similar mechanism of action of warfarin in fetal and adult livers,* Pediatr Res *26:370, 1989.)*

vitamin K epoxide reductase are expressed in midterm fetal life (see Figure 40-5, *A*). Figure 40-5, *B*, shows this activity profile in the mothers. The prediction that emerged from the data in Figure 40-5 was that administering warfarin to the mother would affect the developing fetus. This was demonstrated using vitamin K–dependent carbon 14 labeling of prothrombin (78-kDa) and factor X (70-kDa) precursors in fetal rat livers. As shown in Figure 40-6, only the livers of pups from mothers that had been injected with warfarin demonstrated labeling of the factor X precursor (the 70-kDa band on the "W." fluorogram); this observation provides direct evidence for the effect of warfarin on the vitamin K–dependent carboxylation system.[40] Indeed, the data in Figure 40-6 demonstrate that warfarin passes the placental barrier and anticoagulates the fetus. This finding is consistent with its known effect on human fetal development, wherein warfarin intake during pregnancy has been shown to result in an embryopathy characterized by stippled epiphyses, central nervous system abnormalities, optic atrophy, deafness, hypoplasia of the nasal bridge, and distal digital hypoplasia.[41]

Ontogeny of the vitamin K–dependent carboxylase and of its supporting enzymes involved in vitamin K metabolism in the rat is presented in Figure 40-7.[30] A dramatic (12-fold) increase in the specific activity of the vitamin K–dependent carboxylase occurs from day 16 in the fetal period to day 7 in the neonatal period. Of interest, and consistent with our data, Romero and colleagues[42] found, by in situ hybridization, that γ-carboxylase messenger RNA (mRNA) could not be detected before day 16 of fetal life. The activity increases steadily during the fetal period toward birth. At birth, the activity drops, but it increases again to reach adult enzyme activity levels in 7-day neonatal rats. These findings may be of relevance to the prolonged prothrombin time often observed in human neonates 2 to 3 days after birth.[14] Jamison and Degen[43] noted a "dip" in rat prothrombin mRNA at birth. Taken together, these data may reflect the dramatic changes in hormonal control that occur around birth,[44] and they may indeed indicate a critical point in development of the coagulation system. Figure 40-7 also shows the carboxylation "capacity" of the vitamin K–dependent carboxylation system during development, when the system is dependent on vitamin K–metabolizing enzymes to provide the reduced vitamin KH_2 cofactor. The cross-hatched bars in Figure 40-7 show carboxylation activity when triggered by pathway I (the warfarin-sensitive pathway), and the diagonal bars show this activity when triggered by the warfarin-insensitive pathway II. The activity of pathway II, which mediates the antidotal effect of vitamin K, could not be measured in livers from 16-day rat fetuses. This finding is supported by the observations of Wallin and Martin,[18] who demonstrated that the hepatic enzyme DT-diaphorase (Enzyme Commission [EC] number 1.6.99.2), one of the pathway II enzymes, appears late in gestation. These data suggest that vitamin K will not work as efficiently in the fetal liver as in the mature liver for treatment of warfarin intoxication. The vitamin K–dependent carboxylation system has been shown to be similar in rat liver and in human liver.[18]

REGULATION OF DEVELOPMENT OF THE VITAMIN K–DEPENDENT γ-CARBOXYLATION SYSTEM

The stepwise emergence of many enzymes in the developing organism has been shown to be closely related to changes in the hormonal environment, and it is reasonable to assume that the vitamin K–dependent carboxylation system also is under the influence of such control. The appearance of enzymes during late fetal life in the rat is believed to be influenced significantly by glucocorticoid secretion and the appearance of the glucocorticoid receptor on day 18 of gestation.[45] The next profound change in the hormonal milieu takes place around birth. Shortly after birth, the insulin-glucagon ratio, which is high in the fetus, drops significantly; this change induces another cluster of enzymes.[43] Because output of vitamin K–dependent clotting factors from liver to blood is dependent on their γ-carboxylation status in the endoplasmic reticulum,[46] factors that modulate the activities of the carboxylase and the vitamin K–metabolizing enzymes presumably may be used to control development of the hemostatic mechanism. The only information that is available on this issue has been obtained from studies in the rat.[47] As shown in Figure 40-8, fetal rat hepatocytes treated in vitro with dexamethasone express significantly higher carboxylase activity than that noted in untreated cells. An effect of insulin on the activity could not be demonstrated. These cell culture data are supported by in vivo data derived in dexamethasone-injected rats, which documented stimulation of γ-carboxylase activity in both liver[39] and lung.[48]

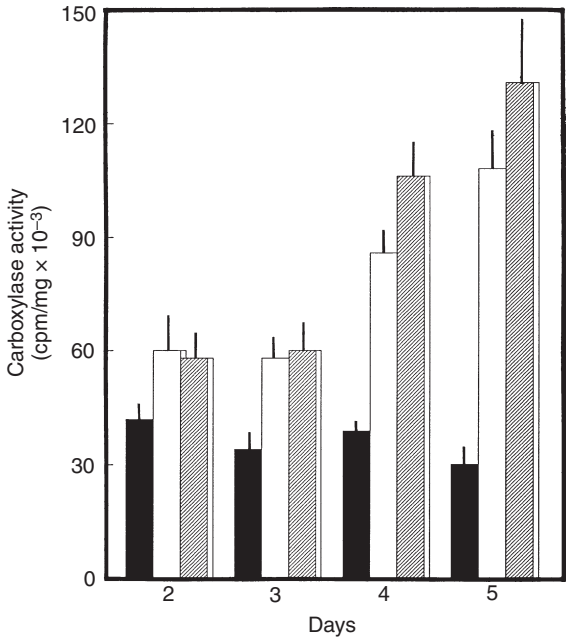

Figure 40-8 Vitamin K–dependent carboxylase activity, measured in counts per minute (cpm)/mg, in cultured fetal hepatocytes treated with dexamethasone. Hepatocytes from day 18 rat fetuses were cultured for 5 days in the absence *(solid bars)* and presence (0.1 μM, *open bars*; 1 μM, *diagonal shaded bars*) of dexamethasone. Fresh medium with hormones was added to the cell each day. *(From Wallin R, Hutson SM: Dexamethasone stimulates vitamin K–dependent carboxylase activity in neonatal rats and cultured fetal hepatocytes,* Pediatr Res *30:281, 1991.)*

Studies demonstrating dexamethasone stimulation of γ-carboxylase activity in fetal life should be extended to include studies on the effect of the drug on the activities of the vitamin K–metabolizing enzymes. The lifesaving effect of dexamethasone on maturation of the lung surfactant system in premature infants (reviewed by Ballard[49]) should stimulate research on the potential use of this agent to control maturation of the vitamin K–dependent γ-carboxylation system in premature neonates with bleeding problems that cannot be corrected by vitamin K administration.

SECTION VI

Lipid Metabolism

41

Emilio Herrera and Miguel Angel Lasunción

Maternal-Fetal Transfer of Lipid Metabolites

Changes in maternal lipid metabolism during gestation control the availability of lipid metabolites to the fetus, even though some components do not directly cross the placental barrier. This is the case with maternal plasma lipoproteins, the profile of which during pregnancy differs markedly from that seen in nonpregnant subjects. Although no evidence exists for their transfer to the fetus, placental cells have lipoprotein receptors that allow the uptake and release of their lipid components to the fetus. Other products of maternal lipid metabolism, however, such as free fatty acids (FFAs), glycerol, and ketone bodies, are able to cross the placenta and become available to the fetus without previous modification. Although the efficiency of transfer across the placenta differs for each of these metabolites, the major force controlling their actual transfer is the maternal-fetal concentration gradient.

HYPERLIPOPROTEINEMIA IN PREGNANCY AND ITS ROLE IN PROVIDING FATTY ACIDS FOR THE FETUS

Maternal hypertriglyceridemia is one of the most striking changes that takes place in lipid metabolism during gestation. The increase in plasma triglycerides during pregnancy is greater than the increases in phospholipids and cholesterol,[1,2] and more triglycerides are found in all of the lipoprotein fractions.[3,4] As shown in Figure 41-1, although both triglycerides and cholesterol in very-low-density lipoproteins (VLDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs) are higher in pregnant women in the third trimester of gestation than in the same women during the postlactation period, the triglyceride-cholesterol ratio remains stable in VLDL despite significant increases in both LDL and HDL. An examination of different HDL subclasses indicates that the rise in triglyceride-enriched HDL_{2b} is mainly responsible for the changes in HDL levels, whereas the small HDL_3 fractions become less abundant.[5] The increase in triglycerides per LDL particle is accompanied by a decrease in cholesterol and phospholipid content,[6] which causes reductions in LDL particle size,[7] although increases in the most buoyant of the LDL subfractions, LDL-1, have been reported with advancing gestation.[6]

The mechanisms responsible for these changes in the maternal lipoprotein profile during pregnancy are summarized in Figure 41-2. The increased adipose tissue lipolytic activity during late gestation[8,9] (which is mediated by an insulin-resistant condition[10]) enhances the availability of substrates for triglyceride synthesis in the liver. This action, together with the stimulating effect of estrogen on VLDL production[11] and the decreased extrahepatic lipoprotein lipase (LPL) activity,[5,12] is responsible in part for the augmented circulating maternal levels of VLDL in late pregnancy. This change in LPL activity corresponds to its decrease in adipose tissue, which in the rat is the body tissue that normally has the highest LPL activity and is the only tissue that shows a marked decrease during late gestation.[13,14] The decreased adipose tissue LPL activity also is a consequence of the insulin-resistant state characteristic of late pregnancy.[10,15] Although the abundance of VLDL could justify an enhanced conversion to lipoproteins of higher density, the specific enrichment in triglycerides of the latter seems to be the result of two additional mechanisms (Figure 41-2): (1) augmented activity of the cholesteryl ester transfer protein (CETP),[5,16] which mediates the transfer of triglycerides from triglyceride-rich lipoproteins such as VLDL to the higher-density lipoproteins LDL and HDL, and (2) decreased activity of hepatic lipase (HL),[5,12] which reduces the conversion of triglyceride-rich HDL_{2b} into the lipid-poor HDL_3. The decreased HL activity also has been proposed to contribute to the reductions in LDL size.[7] In addition, the decreased HL during late gestation may be a response to the increase in estrogens, because these hormones are known to inhibit both HL activity and messenger RNA (mRNA) expression.[12,17,18]

The events just summarized are responsible for the sustained hyperlipoproteinemia in the mother during gestation. Despite the impermeability of the placenta to lipoproteins, their lipidic components become available to the fetus; therefore those changes actively contribute to fetal development. In fact, reductions in maternal hyperlipoproteinemia in animals by treatment with hypolipidemic drugs has negative effects on fetal development.[19,20]

Essential fatty acids (EFAs) and long-chain polyunsaturated fatty acids (LC-PUFAs) derived from maternal diet are transported mainly in their esterified form in maternal plasma lipoproteins, rather than in their FFA form,[21,22] and must become available to the fetus despite the lack of a direct placental transfer of maternal lipoproteins. This transfer occurs thanks to the presence of lipoprotein receptors in the placental trophoblast cells that lie at the interface with maternal blood. These cells are therefore positioned to bind maternal lipoproteins and mediate their metabolism and subsequent transfer of the fatty acids they deliver to the fetal circulation. As described in more detail later, VLDL/apolipoprotein E (apo E) receptor (VLDLR) and LDL, HDL, and scavenger receptors are expressed in human placental tissue.[23-31]

Placental tissue expresses LPL activity[32-34] as well as phospholipase A_2[35-37] and intracellular lipase activities.[38,39] Esterified fatty acids in maternal plasma lipoproteins are therefore hydrolyzed and taken up by the placenta, where their reesterification and intracellular hydrolysis facilitate the diffusion of released fatty acids to the fetus and their subsequent transport to fetal liver. Using cultured placental trophoblast cells, it has been shown that esterified lipids provide a reservoir of fatty acids that can be released into the experimental medium.[40]

Once released into fetal plasma, placental transferred fatty acids bind to a specific oncofetal protein, the alpha

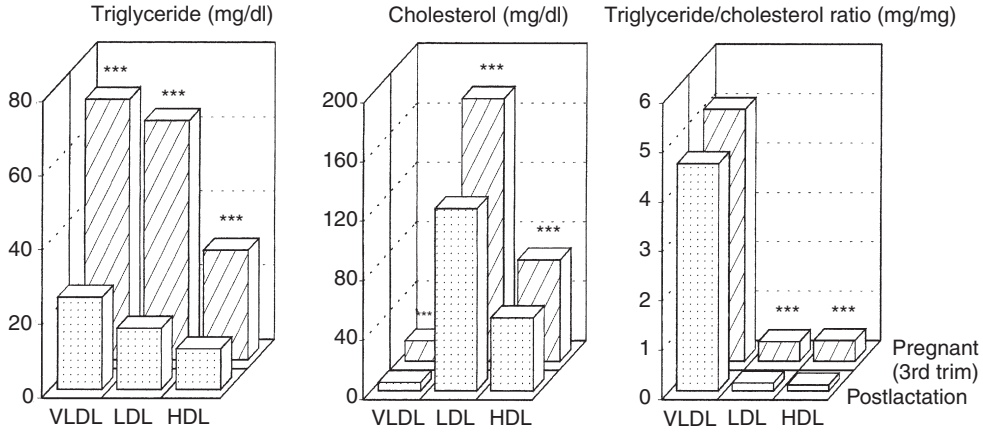

Figure 41-1 Plasma lipoprotein lipids in women in the third trimester of pregnancy and at postlactation. *Asterisks* indicate significant differences between the two groups. *HDL,* High-density lipoprotein; *LDL,* low-density lipoprotein; *VLDL,* very-low-density lipoprotein.

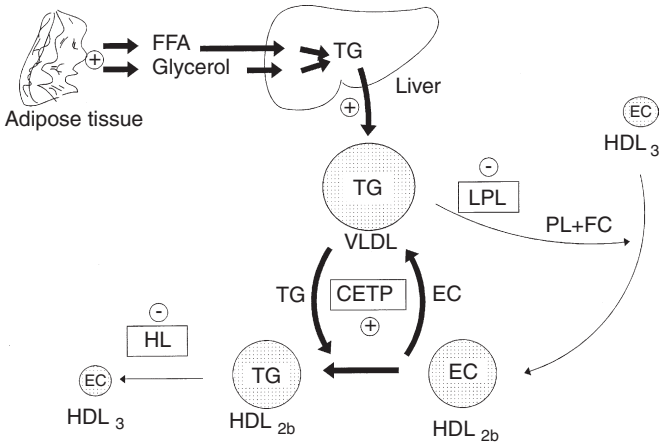

Figure 41-2 Proposed control of major pathways of very-low-density lipoprotein (VLDL) and high-density lipoprotein (HDL) metabolism during late pregnancy. *CETP,* Cholesteryl ester transfer protein; *EC,* esterified cholesterol; *FC,* free cholesterol; *FFA,* free fatty acids; *HL,* hepatic lipase; *LCAT,* lecithin cholesterol acyl transferase; *LPL,* lipoprotein lipase; *PL,* phospholipids; *TG,* triglycerides.

fetoprotein,[41-43] and are rapidly transported to fetal liver. Those fatty acids taken up by fetal liver are esterified and released back into circulation in the form of triglycerides. This observation is consistent with the significant linear correlation found for certain PUFAs between maternal plasma and cord plasma triglycerides during late gestation in humans.[44] A linear correlation also has been found between maternal and fetal plasma triglycerides and PUFAs in the rat.[45,46] This relationship may have important implications for newborn weight, because a direct relationship between maternal triglycerides and newborn weight has been found in humans.[47-49] It has been proposed that the activation of the placental phospholipase A_2, resulting in an accumulation of lipid mediators in the fetoplacental unit, facilitates excess fetal fat accretion, thereby programming in utero obesity.[37]

MATERNAL LIPID METABOLISM AND PLACENTAL TRANSFER OF FREE FATTY ACIDS, GLYCEROL, AND KETONE BODIES TO THE FETUS

During the first part of gestation, the maternal body accumulates fat[50,51] as the result of combined effects of hyperphagia,[52] enhanced lipogenesis,[53] and unmodified or even increased extrahepatic LPL activity.[5,14,54] The tendency to accumulate fat ceases during late gestation[51,55] because maternal lipid metabolism changes to a catabolic condition. This is evidenced by increased adipose tissue lipolysis[9,14] and reduced uptake of circulating triglycerides,[56] secondary to the reduction in adipose tissue LPL activity,[5,12-14] as reviewed earlier. These changes, together with hepatic overproduction of triglycerides[57,58] and the enhanced absorption of dietary lipids,[59] are responsible for the marked progressive increase in maternal circulating triglycerides occurring during late gestation.[3,5] The major changes in the maternal lipid metabolism are summarized in Figure 41-3, which diagrams the changes in adipose tissue, liver, and intestinal activity that are responsible for the physiologic increase in circulating FFAs, glycerol, and triglyceride-rich lipoproteins (VLDL and chylomicrons). Under fed conditions, the frequency of maternal ketosis is no different from that in nonpregnant subjects, but it increases markedly under fasting conditions.[60,61]

With the exception of glycerol used in gluconeogenesis[62,63] and the LPL-mediated circulating triglyceride uptake by the mammary gland before labor,[59,64,65] no part of the increase in circulating lipid components in the fed mother during late gestation seems to benefit her metabolic needs directly. This increase, however, may benefit the fetus because this gestational period coincides with the rate of maximal fetal accretion, a time when the substrate, metabolic fuel, and essential component requirements of the fetus are greatly enhanced. The lipid component also may constitute a "floating" fuel store for both mother and fetus, easily accessible under conditions of food deprivation; this may explain the enhanced ketogenesis in the mother seen under fasting conditions.[60,66]

The enhanced availability of ketone bodies to maternal tissues under fasting conditions allows them to be used as metabolic fuels, with sparing of other, more limited and essential substrates, such as amino acids and glucose, for transport to the fetus. The fetus also receives maternal ketone bodies through the placenta, and their use plays an important role in the fetal metabolic economy under conditions of maternal food deprivation. Augmented lipolytic activity also increases maternal circulating glycerol levels.[13,62] Glycerol can be used as an efficient gluconeogenic substrate,[62,63,67] contributing to the maintenance of glucose production for fetal and maternal tissues. Metabolic adaptations found in the mother during starvation are summarized in Figure 41-4. The transfer of glucose, ketone bodies, and amino acids is emphasized in this figure because quantitatively, they are the major substrates crossing the placenta in this condition.

An understanding of fatty acid, glycerol, and ketone body placental transfer as well as their respective metabolic fates in the fetus provides insight into the effect on the fetus of these

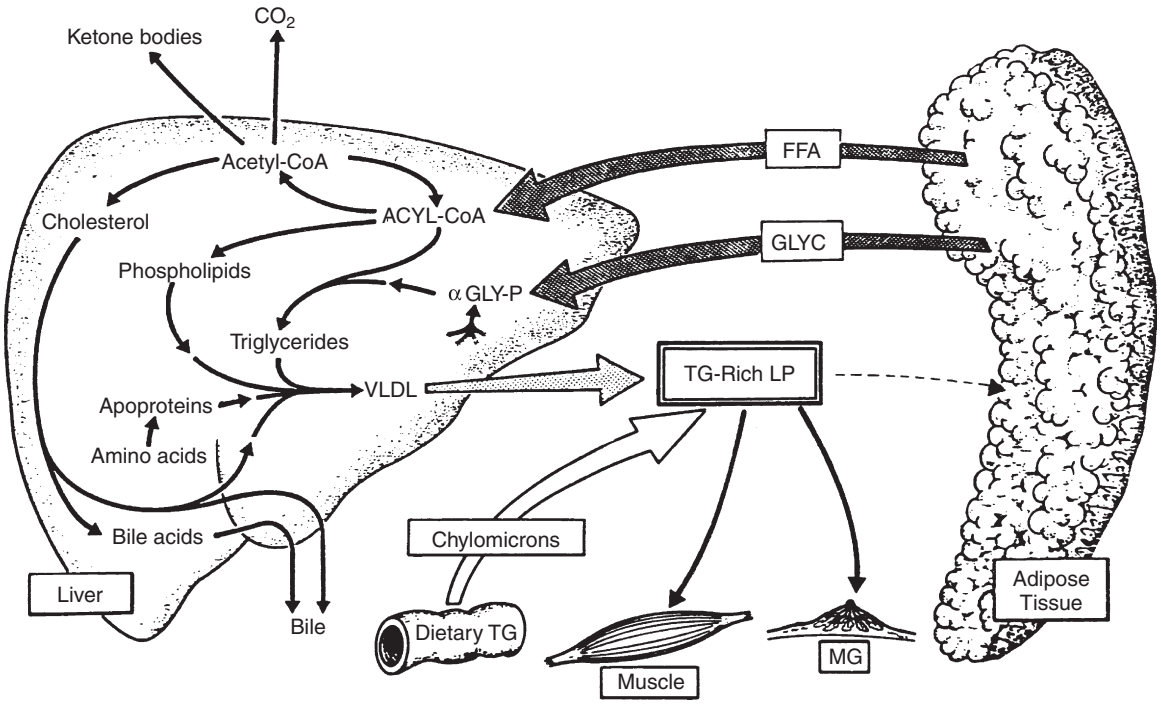

Figure 41-3 Summary of major changes in maternal lipid metabolism at late gestation. *CoA,* Coenzyme A; *FFA,* free fatty acids; α-GLY-P, alpha glycerolphosphate; *Glyc,* glycerol; *MG,* mammary gland; *TG,* triglycerides; *TG-RICH LP,* triglyceride-rich lipoproteins; *VLDL,* very-low-density lipoprotein. *(Modified from Herrera E, Gómez-Coronado D, Lasunción MA: Lipid metabolism in pregnancy,* Biol Neonate *51:70, 1987.)*

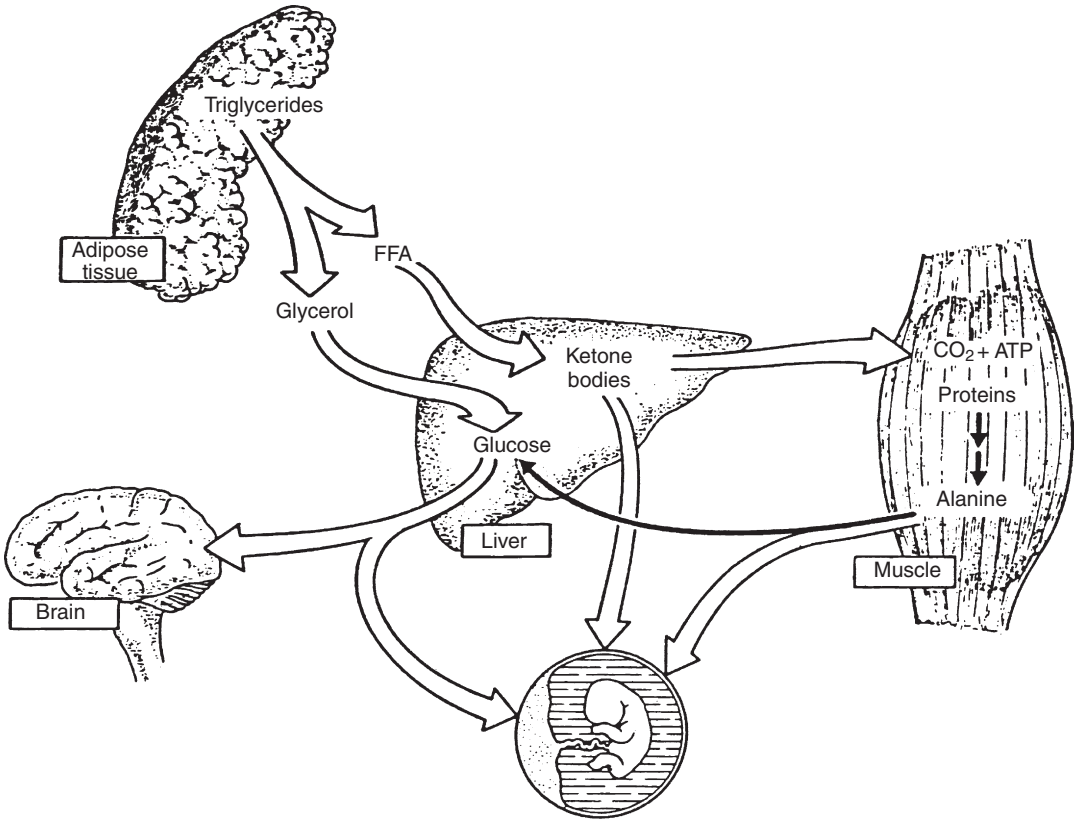

Figure 41-4 Maternal response to starvation. Enhanced adipose tissue lipolysis increases the availability in the liver of glycerol to be used as a preferential substrate for gluconeogenesis and of free fatty acids (FFA) for ketone body synthesis. By this mechanism, the mother conserves other gluconeogenic substrates, such as alanine, and ensures the adequate availability of fuels and metabolites to the fetus. *ATP,* Adenosine triphosphate. *(From Herrera E, Gómez-Coronado D, Lasunción MA: Lipid metabolism in pregnancy,* Biol Neonate *51:70, 1987.)*

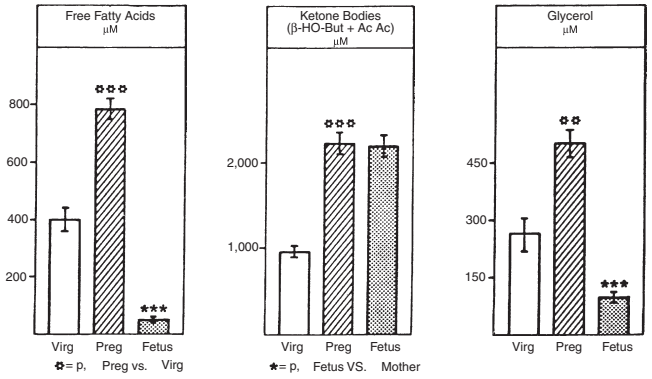

Figure 41-5 Concentrations of free fatty acids, ketone bodies, and glycerol in plasma of starved virgin rats and starved 19-day pregnant rats and their fetuses measured at 48 hours. *AcAc,* Acetoacetate; β-*HO-But,* beta hydroxybutyrate. *(From Herrera E, Gómez-Coronado D, Lasunción MA: Lipid metabolism in pregnancy,* Biol Neonate *51:70, 1987.)*

persistently elevated maternal circulating lipid levels. Figure 41-5 compares plasma levels of these metabolites in virgin and in 48-hour–fasted late-pregnancy rats and their fetuses. It can be seen that although fetal FFA and glycerol levels are much lower in the fetuses than in their mothers, the concentrations of ketone bodies are similar. These maternal-fetal concentration differences probably reflect the efficiency or magnitude of the placental transfer process.

Maternal-fetal nutrient transfer through the placenta may be accomplished by means of different mechanisms, including facilitated diffusion, active transport, and simple diffusion.[68,69] Transfer by simple diffusion seems to be a common mechanism for fatty acids and related moieties. The rate of transfer is a direct function of the concentration gradient and decreases with the molecular size and hydrosolubility.[70] In the case of placental transfer, however, other factors also participate[71,72]: uterine and umbilical blood flows, intrinsic placental metabolism, and structural characteristics. As might be expected, some of these factors, such as blood flow, contribute analogously to the transfer of any nutrient, but other factors differ with each nutrient and require specific consideration.

Free Fatty Acids

The fetus requires not only EFAs from the mother, to support growth[73] and brain development,[74] but also nonessential fatty acids, which, stored in fetal body fat, constitute an important substrate during early postnatal life.[75] This storage pool is especially important in species such as the guinea pig and human, in which body fat at term represents a substantial percentage of body weight (10% in guinea pigs and 16% in humans),[76] and de novo fatty acid synthesis by fetal tissues cannot fulfill fetal requirements.

Either FFAs bound to albumin or esterified fatty acids transported in lipoproteins are the potential sources of the fatty acids in the maternal side that cross to the placenta. Early studies in sheep[77] that measured venous-arterial differences across the umbilical circulation of the fetus in utero and across the maternal uterine circulation showed no significant passage of FFA to the fetus and led to the conclusion that FFAs did not appear to constitute a significant part of the metabolic fuel supplied there by the mother.[77] Later studies demonstrated, however, that the net flux of fatty acids from mother to fetus across the placenta varies greatly among species. For example, in species with both maternal and fetal layers in the placenta, such as the sheep, pig, and cat, the net transfer of fatty acid to the fetus generally is small.[78-80]

In humans, although maternal plasma FFAs are in a smaller proportion than esterified fatty acids in plasma lipoproteins, they are an important source of PUFAs to the fetus.[81,82] Current evidence suggests that cellular uptake of FFA occurs through a process of facilitated membrane translocation involving a plasma membrane fatty acid–binding protein ($FABP_{pm}$).[83,84] It has been shown that $FABP_{pm}$ is present in human placental membranes[85,86] and is responsible for the preferential uptake of LC-PUFAs by the human placenta. The preference for human placental fatty acid transfer from the maternal to the fetal circulation has been reported as docosahexaenoic ⇒ α-linolenic ⇒ linoleic ⇒ oleic ⇒ arachidonic acid.[87] Arachidonic acid was, however, the fatty acid with the highest accumulations in the placenta,[87] and it has been shown that this process of arachidonic uptake by placental syncytiotrophoblast membranes is highly dependent on adenosine triphosphate (ATP) and sodium,[88] implying an active transport mechanism for this fatty acid. A selectivity in the LC-PUFA placental transfer also may be exerted at the level of cellular metabolism: A certain proportion of arachidonic acid is converted to prostaglandins,[82] a selective incorporation of certain fatty acids into phospholipids has been found in the ovine placenta,[89] and even selective placental fatty acid oxidation[90,91] and lipid synthesis[92,93] may occur.

The combination of all of these processes determines the actual rate of placental fatty acid transfer and its selectivity. Through these mechanisms, the placenta selectively transports arachidonic acid and docosahexaenoic acid from the maternal to the fetal compartment, resulting in a proportional enrichment of these LC-PUFAs in circulating lipids in the fetus.[94,95] This transport occurs during the third trimester, when the fetal demands for neural and vascular growth are greatest.[96,97]

Although, as commented on earlier, current evidence indicates that fatty acids are selectively transferred across the placenta, EFAs and nonessential fatty acids also may use a common transfer mechanism. Using in situ perfused guinea pig or rabbit placentas, several investigations have demonstrated that within the physiologic range, the net FFA transfer to the fetus correlates with maternal plasma levels of FFA and that this transfer is regulated by the transplacental concentration gradient.[98,99] Furthermore, during maternal fasting, increased amounts of maternal FFA cross the placenta into fetal circulation and are incorporated into fetal stores.[100] These observations suggest that the transfer of several FFAs across the placenta is mainly by diffusion. Other factors affecting this transfer process are the uterine and umbilical blood flow rates[98,99] and the fetal plasma albumin concentration.[98,101,102] In this respect, the increase in albumin levels throughout the third trimester in the human fetus[103] may increase its FFA supply.

Glycerol

As a result of the enhanced lipolytic activity of maternal adipose tissue, plasmatic glycerol levels are consistently elevated during late gestation.[14,62,63] Values for plasma glycerol therefore generally are higher in the mother than in the fetus (see Figure 41-5), with some interspecies differences: The maternal-fetal glycerol gradient is greater in species with an epitheliochorial placenta (ruminants)[77,104] than in those with a hemochorial placenta.[105,106]

The available experimental data on placental glycerol transfer in any species are very limited. Although the molecular characteristics of glycerol (low weight and uncharged molecule) should facilitate easy placental transfer, its transfer rate is notably lower than for other metabolites with similar molecular characteristics such as glucose or L-alanine.[107-109] In contrast with the carrier-mediated process used for these two metabolites, placental

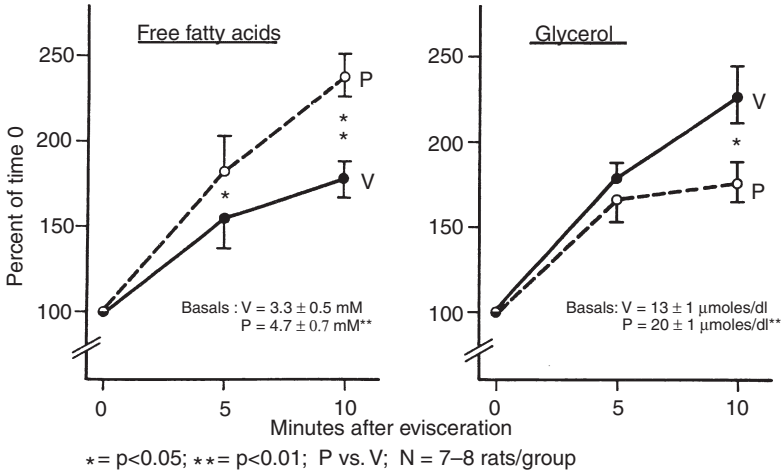

Figure 41-6 Effect of hepatectomy-nephrectomy on plasma free fatty acids and glycerol in virgin (V) and 20-day pregnant (P) rats. Experimental details are described in the original report by Yount and McNamara.[154] *(Data from Yount NY, McNamara DJ: Dietary regulation of maternal and fetal cholesterol metabolism in the guinea pig,* Biochim Biophys Acta *1085:82, 1991.)*

glycerol transfer is accomplished by simple diffusion.[104] In the sheep fetus, glycerol uptake is low, accounting for no more than 1.5% of the total oxygen consumption of the fetus.[77] In humans, it has not been possible to detect a transfer of glycerol from mother to fetus despite its favorable gradient.[110] By comparing different substrates, using the in situ infused placental technique in the rat, the rate of transfer of glycerol has been found to be much lower than that of glucose and alanine and similar to that of FFAs.[107] In addition, the fetal-placental unit has been demonstrated to convert glycerol into lactate and lipids[106]; this rapid use may actively contribute to maintaining the high glycerol gradient consistently found between maternal and fetal blood.[108-110]

Accelerated turnover of maternal glycerol seems to be influenced by the high liver glycerol kinase activity, which facilitates its rapid phosphorylation and subsequent conversion into glucose.[62,63,67] Although this mechanism indirectly benefits the fetus by providing glucose (see Figure 41-4), it may limit the availability of sufficient glycerol molecules for transfer to the fetus. Figure 41-6 summarizes studies that support this hypothesis. Hepatectomy normally results in increased plasma glycerol levels because of a reduction in glycerol use secondary to absence of the liver, the major receptor organ for this metabolite.[111] In pregnant rats, hepatectomy and nephrectomy produce significant but smaller increases in plasma glycerol levels than in nonpregnant animals. This difference cannot be interpreted as reduced lipolytic activity in the pregnant rat because plasma FFA, the other lipolytic product, increases more than in nonpregnant animals. The smaller increase may, however, reflect an augmented transfer of glycerol to the fetus, because glycerol levels in fetal plasma increase significantly after maternal hepatectomy and nephrectomy.[112]

Therefore placental glycerol transfer seems to be limited by the effective, rapid use of this substrate for gluconeogenesis by the liver and kidney cortex of the mother. Although the fetal-placental unit actively uses glycerol (which helps to maintain a favorable transfer gradient), its quantitative and physiologic roles in the fetus, except as a preferential substrate for fetal liver glyceride glycerol synthesis,[106] seem to be limited under normal conditions. Under conditions of markedly elevated maternal glycerol levels, however, the placental transfer of glycerol could become an important mechanism for providing substrates for the fetus.

Ketone Bodies

Although plasma levels of ketone bodies in the fed pregnant mother late in gestation are unchanged under physiologic conditions, under fasting[60,66,113,114] or diabetic[3,115] conditions, they are greatly elevated as a result of increased adipose tissue lipolytic activity and enhanced delivery of FFA to the liver. As noted earlier, when the supply of glucose is limited (e.g., in hypoglycemia or reduced insulin levels or sensitivity, or both), ketone bodies are used by some maternal tissues (e.g., skeletal muscle) as alternative substrates. Ketone bodies also can cross the placental barrier and be used as fuels and lipogenic substrates by the fetus.[116-118]

Maternal ketonemia in the pregnant patient with poorly controlled diabetes, with or without acidosis, has been associated with an increased stillbirth rate, an increased incidence of congenital malformations, and impaired neurophysiologic development in the infant.[117,119,120] These effects are thought to be secondary to placental transfer of maternal ketone bodies to the fetus.[121]

In addition to size and lipid solubility, molecular charge has an important effect on placental membrane permeability. At pH 7.4, most molecules of the two main ketone bodies, β-hydroxybutyrate and acetoacetate, are present in dissociated or ionized form, which retards their diffusion across the placenta. Nevertheless, in all species studied (human,[113,114,122] rat,[66,123] and sheep[121]), increments in maternal ketone bodies are accompanied by increments in fetal plasma levels, indicating efficient placental transfer; fetal liver ketogenesis is practically negligible.[124]

Placental transfer of ketone bodies occurs either by simple diffusion or by a low-specificity carrier-mediated process[104,125]; the efficiency of which varies among species. Although the maternofetal gradient for ketone bodies is higher than 10 in sheep,[121] in humans it is approximately 2,[110] and in rats it is close to 1[66,123] (see Figure 41-5), indicating that the amount of ketone bodies crossing the placenta is much smaller in ruminants than in nonruminant species. It has even been proposed that in the fasting condition, the contribution of ketone bodies to the fetal oxidative metabolism accounts for only 2% to 3% of total oxygen consumption in the case of sheep.[126] In the rat, β-hydroxybutyrate adequately replaces the glucose deficit in the placenta, fetal brain, and liver during fasting hypoglycemia.[118] This finding suggests a much greater contribution of ketone bodies to the fetal oxidative metabolism in the fasted nonruminant.

Key enzymes for ketone body utilization—3-hydroxybutyrate dehydrogenase (Enzyme Commission [EC] 1.1.1.30), 3-oxoacid-CoA transferase (EC 2.8.3.5), and acetyl-CoA acetyltransferase (EC 2.3.1.9)—have been found in the brain and other tissues in both the human and the rat fetus.[116,127] Both the human[117] and the rat brain[128] oxidize β-hydroxybutyrate in vitro in a form that is dependent on substrate concentration and not on the maternal nutritional state. Other fetal tissue

types known to oxidize ketone bodies are kidney, heart, liver, and placenta.[128,129] Some tissues are even known to use ketone bodies as substrates for fatty acid and cholesterol synthesis, as has been shown in the rat brain, liver, placenta, and lung after in vivo administration of ^{14}C-β-hydroxybutyrate to pregnant animals.[130] The activity of ketone body–metabolizing enzymes in fetal tissues (brain, liver, and kidney) can be increased by conditions that result in maternal hyperketonemia, such as starvation during the last days of gestation[131] or high-fat feeding.[132] Such a change is especially evident in the fetal brains from starved late-pregnancy rats[131] and may represent an important fetal adaptation to guarantee brain development under these conditions because fetal brain weight is better preserved than other fetal organ weights.

In conclusion, evidence obtained in nonruminant species is suggestive of efficient placental ketone body transfer, and of fetal use of these materials as substrates for both oxidation and lipogenesis, even in preference to other substrates (glucose, lactate, and amino acids). Because both the placental transfer and the use of ketone bodies are concentration-dependent, the quantitative contribution to fetal metabolism is important only under conditions of maternal hyperketonemia (e.g., starvation, high-fat diet, diabetes).

CHOLESTEROL IN THE FETUS

Role of Cholesterol and Related Compounds in Development

Cholesterol plays an important role in fetal development as well as in the general physiology of the organism. First, it is an essential component of cell membranes. By interacting with phospholipids and sphingolipids, cholesterol contributes to the characteristic physicochemical properties of membranes, mainly fluidity and passive permeability.[133] Cholesterol is not homogeneously distributed in the membrane; rather, it is concentrated in structures such as rafts and caveolae, where it modulates the function of different integral proteins and receptors. Cholesterol is the precursor of both bile acids and steroid hormones; in the fetus, glucocorticoids are intensely synthesized by the adrenal gland in the last part of development. Cholesterol and its oxidized derivatives—oxysterols—are key regulators of different metabolic processes, both by modulating the proteolytic activation of sterol response element–binding protein (SREBP) and by acting as ligands of nuclear receptors, such as LXR (liver X receptor).[134,135] Active SREBP and LXR are transcription factors that regulate the expression of multiple genes implicated in intracellular lipid homeostasis and lipoprotein metabolism.[134,136]

Other important actions of cholesterol also have become apparent; these actions have special relevance for the fetus because they are related to development, embryogenesis, and differentiation. Cholesterol is required for cell proliferation, not only for membrane formation, but also for the activation of regulatory proteins involved in cell cycle progression—specifically, in the transition from the G_2 phase to mitosis.[137,138] Cholesterol plays important roles in differentiation and cell-to-cell communication; in fact, it has been demonstrated to be a key factor in synaptogenesis.[138] Finally, cholesterol is essential in embryonic patterning in both vertebrates and invertebrates.[140] This patterning is attained mainly by activation of hedgehog proteins (i.e., sonic hedgehog [Shh] in humans), which are involved in cell differentiation.[141]

It is thus conceivable that defects affecting cholesterol availability will have deleterious consequences in fetal development. In fact, congenital defects in cholesterol biosynthesis or the reduction of cholesterol synthesis with xenobiotics result in severe malformations and dysfunctions, mainly affecting the craniofacial organs and the central nervous system (CNS), respectively, alterations that are similar to those caused by Shh deficiency.[140,142,143]

It has been observed in pigs that fetal weight is directly correlated with plasma cholesterol concentration in the fetus at late gestation.[144] Similarly, neonatal pigs from lines with genetically low cholesterol levels are smaller at birth and grow more slowly, but the growth rate improved when they were fed with cholesterol.[145,146] An increase in neonatal survival is noted with supplementary dietary fat for the peripartal sow.[147] Thus cholesterol is essential to body growth and the development of the CNS, and fetal requirements must be met either by efficient endogenous cholesterol biosynthesis or transfer from the mother.

Cholesterol Biosynthesis and Congenital Defects

Cholesterol biosynthesis is a multienzymatic pathway that can be separated into three segments according to the type of compounds that are synthesized in each one, that is, mevalonic acid, isoprenoids, and sterols, respectively. In the first, also called the *mevalonate pathway,* three molecules of acetyl-coenzyme A (CoA) are successively condensed by the action of acetyl-CoA acetyltransferase and cytosolic 3-hydroxy-3-methylglutaryl (HMG)-CoA synthase to form HMG-CoA, which is then reduced with the loss of CoA, generating mevalonate, a six-carbon compound[148] (Figure 41-7). This complex reaction is catalyzed by HMG-CoA reductase, which is present in the endoplasmic reticulum and is the rate-limiting enzyme in cholesterol biosynthesis. In the next series of reactions, mevalonate is converted to squalene (see Figure 41-7), which is the immediate precursor of sterols. The first sterol formed is lanosterol, which contains 30 carbons (see Figure 41-7). The transformation of lanosterol into cholesterol occurs in the endoplasmic reticulum and involves at least seven different enzymes (Figure 41-8).

In humans, six different genetic defects in the cholesterol biosynthesis pathway have been identified. Mevalonic aciduria (i.e., Mendelian Inheritance in Man designation [MIM] 251770) is caused by missense mutations in mevalonate kinase, which impair the formation of both isoprenoids and sterols (see Figure 41-7). The patients show dysmorphias and failure to thrive. Milder mutations of the enzyme also underlie hyperimmunoglobulinemia D and periodic fever syndrome (MIM 260920). The rest of the disorders are due to defects in the postsqualene segment of the pathway (see Figure 41-8). Greenberg skeletal dysplasia (MIM 215140), which is associated with short-limb dwarfism, probably is caused by mutations in Δ^{14}-reductase, but confirmation at the molecular level has yet to be achieved. The CHILD (*c*ongenital *h*emidysplasia with *i*chthyosiform erythroderma and *l*imb *d*efects) syndrome (MIM 308050) and Conradi-Hünermann-Happle syndrome (CPDX2; MIM 302960) are caused by deficiencies of C4-demethylase and Δ^8-Δ^7-isomerase, respectively; these two disorders are of X-linked dominant inheritance, so carrier males are lethally affected and females present with several skeletal and skin abnormalities. Desmosterolosis (MIM 602398) is an extremely rare disorder, probably of autosomal recessive inheritance, that is due to the deficiency of Δ^{24}-reductase; the infants affected died shortly after birth and suffered from multiple malformations and dysmorphias. The last of these disorders, and probably the best known and most widely studied, is the Smith-Lemli-Opitz syndrome (SLOS) (MIM 270400), which is caused by mutations in Δ^7-reductase. The phenotypic expression is highly variable; the most prominent anomalies are microcephalia and facial dysmorphias. All affected patients accumulate 7-dehydrocholesterol in plasma and tissues, but the clinical severity of this syndrome correlates best with its relative level to plasma cholesterol. This observation suggests that the availability of cholesterol during development is one of the major determinants of the phenotypic expressions in SLOS. In animals, several experimental models confirm the molecular basis of the aforementioned disorders and extend the current knowledge on the significance

of cholesterol biosynthesis defects on pathogenesis. In this regard, a null mutation of lanosterol synthase and combinations of hypomorphic mutations of lanosterol synthase and farnesyl diphosphate farnesyltransferase-1, both of which conditions lead to decreased cholesterol synthesis, have been associated with cataract formation in the Shumiya rat, a hereditary cataractous strain.[149] In general, these congenital alterations show the important role of cholesterol and its immediate precursors in morphogenesis and fetal development. Excellent reviews on this subject are available.[142,143]

Sources of Fetal Cholesterol

The demands for cholesterol in the fetus are relatively high, especially during the last third of gestation, when fetal growth is extremely rapid. In principle, the fetus may obtain cholesterol from both endogenous biosynthesis and from the yolk sac and placenta. A comprehensive review on this subject has recently been published.[150] By tracking the appearance of radioactivity in the fetus, early experiments demonstrated the placental transfer of maternal cholesterol to the fetus in different species, such as the rat,[151] guinea pig, rabbit,[152] and rhesus monkey.[153] In those studies, the estimated contribution of maternal cholesterol to the fetus varied widely. An accurate approach to estimate the needs for extra sources of cholesterol in the fetus is to compare cholesterol accretion with the absolute rate of cholesterol biosynthesis. Measurements of [^{3}H]water incorporation into cholesterol revealed that cholesterol biosynthesis in fetal tissues is highly active; when calculated per mass unit, the rate of cholesterol synthesis in fetal tissues is several times higher than in maternal tissues in different species.[154-159] This increased level of synthesis is especially high in the fetal brain, which appears almost completely autonomous in cholesterol accretion, and the liver, for which cholesterol biosynthesis proceeds at a rate exceeding the need for cholesterol accretion, resulting in an excess that is secreted into the plasma for uptake by other developing fetal organs.[157,158] These findings are consistent with the near-maximal expression at the level of mRNA of different enzymes involved in cholesterol biosynthesis[159] and the high activity of HMG-CoA reductase—the rate-limiting enzyme of cholesterol biosynthesis—in fetal tissues.[160,161] Important differences among species have been recognized, however.

In the rat, endogenously synthesized cholesterol appears to account for practically all fetal cholesterol,[157,158] meaning that the other potential sources are insignificant, at least during the later stages of gestation. In fact, Belknap and Dietschy[155] found that although the rat placenta did take up ^{125}I-cellobiose–labeled lipoprotein from maternal circulation, none of the apolipoprotein or cholesterol was transferred in any appreciable amount to the fetus. These studies indicate that the rat fetus receives little or no cholesterol from the mother but, rather, satisfies its need for cholesterol during fetal development through local synthesis. Maneuvers directed to modify cholesterol homeostasis in the mother had no significant effects on cholesterol levels or cholesterol synthesis rates in the fetus. Thus feeding pregnant rats with cholesterol, which resulted in an increase in plasma cholesterol concentration and reduced cholesterol synthesis in the maternal compartment, did not affect any of these parameters in the fetus.[154,155,162] Conversely, treatment of pregnant rats with cholestyramine—a bile acid sequestrant that interferes with intestinal cholesterol absorption and consequently stimulates cholesterol biosynthesis in maternal tissues—did not alter cholesterol accretion in the fetus.[163] All of these findings affirm that in the rat, fetal cholesterol originates mainly from endogenous de novo synthesis, rather than from placental transfer.

In the early stages of gestation in the rat, however, maternal cholesterol may make a significant contribution to the fetal cholesterol pool. For instance, treatment of pregnant rats with AY 9944—an inhibitor of Δ^7-reductase—results in fetal teratogenesis, but the simultaneous oral administration of cholesterol early in gestation completely prevents the characteristic holoprosencephalic brain malformations.[140,164,165] By contrast, the anomalies of fetal masculinization caused by AY 9944, when administered late in gestation, are not prevented by the compensatory administration of cholesterol to the mother.[140] These results firmly suggest that maternal cholesterol reaches the fetal compartment at least early in gestation and is of significant physiologic relevance in the rat. In mice, by injecting ^{13}C-cholesterol into the maternal circulation at different stages and following its appearance in fetal tissues, it has been demonstrated that maternal cholesterol is transferred through the yolk sac and the placenta to the embryo and fetus, respectively.[166]

In other species, exogenous cholesterol may constitute an important, quantitative source of cholesterol for the fetus. In the golden Syrian hamster, Woollett found that endogenous biosynthesis accounted for only 40% of the fetal cholesterol, suggesting that the placenta or the yolk sac, or both, contributed the remainder.[156] Actually, in hamsters fed increasing amounts of cholesterol, the cholesterol concentration in the fetal tissues was found to be linearly correlated with the maternal plasma cholesterol concentration, whereas cholesterol synthesis decreased in the reverse way.[166] These studies in hamsters demonstrated that fetal cholesterol homeostasis is affected by maternal plasma cholesterol concentration in gradient fashion.[166] In the guinea pig, fetal cholesterol homeostasis was found to be relatively insensitive to dietary cholesterol manipulations in the mother throughout gestation.[154] Nevertheless, feeding cholestyramine to the mothers, although producing the expected stimulation of [^{3}H]water incorporation into sterols in maternal liver, also resulted in a 1.4-fold increase in fetal carcass cholesterol synthesis at 60 days gestation, which demonstrates that fetal cholesterol homeostasis may respond to induction by maternal hypocholesterolemia during the late gestation period.[154]

Data in humans are more limited, and cholesterol biosynthesis in fetal tissues has not been evaluated for obvious reasons. In deliveries at term, Parker and associates[167] measured cholesterol levels in the umbilical venous and the umbilical arterial plasma and found a highly significant difference between paired HDL, LDL, and total cholesterol concentrations, venous levels being 7.7% to 12.8% higher than those in arterial plasma. These data were suggestive of the delivery of cholesterol from the placenta to the fetus, which could either be synthesized in the placenta or derived from the maternal plasma. The same investigators, however, estimated that the contribution of such cholesterol to the fetal plasma cholesterol pool was of minimal quantitative importance in term newborns of women experiencing uncomplicated pregnancies.[167] Several observational studies have addressed this issue by comparing maternal lipoprotein-cholesterol levels with those in mixed umbilical cord blood, reporting either a positive correlation[168,169] or no correlation between these values.[167,170,171] The gestational stage, however, could influence these results, because cholesterol plasma concentration has been reported to be significantly higher in premature than in full-term newborns.[172,173] In fact, fetal cholesterol levels show a strong inverse correlation with fetal age, being two-fold higher in 5-month than in 7-month fetuses.[174] This finding has been interpreted as an indication of the greater requirements of cholesterol in the younger, more immature fetuses.[174] Of interest, in fetuses younger than 6 months, although not in older fetuses, plasma cholesterol levels are significantly, directly correlated with maternal levels.[174] Therefore available results in humans strongly suggest that maternal cholesterol substantially contributes to fetal cholesterol accretion early in gestation.

Both the placenta and the yolk sac are able to synthesize and remove cholesterol from the maternal circulation and to secrete it into the fetal circulation. In the pregnant rat, it was determined

that placenta takes up LDL at rates approximately one-third those seen in the maternal liver.[155] In the hamster, LDL clearance rates in the placenta and yolk sac were similar to those in the liver and higher than those in the decidua when measured at midgestation (on day 10.5).[175] In the same study, it was found that clearance rates for HDL apo A-I and HDL cholesteryl ether were similar to those for LDL in the placenta and decidua, whereas rates in the yolk sac were dramatically higher. As gestation progressed to day 14.5, LDL and HDL clearance rates decreased in all three tissues.[175]

Regarding the receptors responsible for the uptake of lipoprotein cholesterol, multiple possibilities have been examined. Both the placenta[23-29] and, to a lesser extent, the yolk sac[175] express LDL receptors in their membranes. In correlation with this, several groups of investigators documented the use of LDL cholesterol for progesterone synthesis by trophoblastic cells in vitro.[176,177] Of interest, it was found that HDL-2 cholesterol stimulated placental progesterone secretion to a greater extent than LDL did, by a mechanism that did not involve the LDL receptor.[177] Further evidence on the role of maternal HDL as an exogenous source of fetal cholesterol comes from studies in apolipoprotein A-I (apo A-I)–deficient mice. These animals have markedly reduced HDL cholesterol levels in plasma, and cholesterol accretion in the fetus was diminished, although fetal cholesterol synthesis was not affected.[178] These results were in line with previous observations by Knopp and associates,[179] describing apo A-I concentration in maternal plasma as a significant positive predictor of birth length. It appears that HDL may potentially contribute a significant proportion of the cholesterol required for fetal development.

Several lipoprotein receptors, different from the LDL receptor, that can mediate the uptake of lipoprotein cholesterol have been detected in placental preparations. These include CLA-1/SR-BI (*C*D36 and *L*IMPII *a*nalogous-*1*/*s*cavenger *r*eceptor type *B* class *I*),[175,180-182] an HDL receptor; megalin/glycoprotein 330,[175,183,184] a protein related to the LDL receptor; cubilin,[185] a protein that binds HDL and acts in conjunction with megalin to mediate HDL endocytosis; and LDL receptor–related protein (LRP)[183] and apo ER2,[186,187] which bind to and mediate the uptake of VLDL . Although the yolk sac is vestigial in humans, in rodents it plays an important role in fetal nutrition. Epithelial cells of the visceral yolk sac were shown to express several lipoprotein receptors, including LDL receptor,[175] CLA-1/SR-BI,[175,188] megalin,[183] and cubilin.[189,190]

A final question is how trophoblast or yolk sac cholesterol reaches fetal circulation. One possibility is that these organs synthesize and secrete apo B–containing lipoproteins, similar to the liver or the intestine in the adult. A main issue is the expression of apo B and microsomal triglyceride transfer protein (MTP), which are mandatory for assembly and secretion, respectively, of apo B–containing lipoproteins. In biopsy specimens from human term placentas, both apo B and MTP mRNAs were detected, and on incubation in vitro, secretion of newly formed apo B–containing lipoproteins was demonstrated.[191] Similar findings were reported for the yolk sac in rodents.[192,193] Whether these lipoproteins efficiently reach the fetal circulation is elusive. It is intriguing that no abnormalities of conception and embryonic lethality have been reported in humans who inherit genetic deficiencies of either of these proteins, whereas in homozygous mice bearing knockouts of either apo B[194,195] or MTP,[196] early embryonic lethality is characteristic. This difference may reflect a greater dependence of the mouse embryo on lipoproteins from placental or yolk sac origin for development, in comparison with the human embryo. On the other hand, other mechanisms for the efflux of cholesterol also are present in both the placenta and the yolk sac.[150] Actually, in monolayer cultures of human coriocarcinoma BeWo cells, it has been shown that either radiolabeled free cholesterol or LDL cholesteryl esters given to the apical side are transported to the basolateral surface of the cells and then effluxed to lipid acceptors present in the fetal side.[197] Recently, a transplacental transfer of lipoprotein-derived cholesterol to the fetus, mediated by endothelial ABCA1 and ABCG1, has been proposed.[198]

Taken together, these data confirm the ability of both the placenta and the yolk sac to take up cholesterol from maternal lipoproteins and to deliver it to the fetus, but the extent to which it is exported and the factors that regulate this process remain to be clarified.

SUMMARY

During gestation, both triglyceride and cholesterol increases in all lipoprotein fractions and are associated with an increase in the triglyceride-cholesterol ratio in LDL and HDL. The increase in HDL corresponds mainly to triglyceride-enriched HDL-2. The presence of lipoprotein receptors in the placenta ensures the availability of essential lipoprotein components to the fetus and provides a teleologic reason for maternal hyperlipoproteinemia.

Sustained maternal hyperlipidemia during late pregnancy is of pivotal importance in fetal development, especially during the stage of maximal fetal accretion. Besides using transferred fatty acids, the fetus also benefits from two other products of maternal lipid metabolism: glycerol and ketone bodies. Although only a small proportion of maternally derived glycerol crosses the placenta, it is quantitatively important as a substrate for maternal gluconeogenesis. Because fetal oxidative metabolism is preferentially sustained by maternal glucose crossing the placenta, the use of glycerol for glucose synthesis actively contributes to the fetal glucose supply.

In nonruminant species, maternal ketone bodies are readily transferred to the fetus, where they can be efficiently used as carbon fuels for oxidative metabolism or as lipogenic substrates. Because all of these processes are concentration-dependent, they become relevant only under conditions of maternal hyperketonemia. Under healthy physiologic conditions, they constitute an important support for fetal metabolism when the availability of other substrates is more limited (e.g., during periods of maternal starvation). Under conditions of sustained maternal hyperketonemia, such as high-fat feeding, fetal metabolism also adapts to an enhanced consumption of ketone bodies.

Although the contribution of maternal cholesterol to fetal cholesterol appears to be important during early gestation, it seems to be of minimal quantitative importance during late gestation. This is consistent with the high capacity of all fetal tissues to synthesize cholesterol. In humans, several congenital defects in the cholesterol biosynthesis pathway have been identified, showing the important role of cholesterol in morphogenesis and fetal development.

Accretion of Lipid in the Fetus and Newborn

FETAL FAT METABOLISM

The nutrient and energy requirements of the developing mammalian fetus include the fuels to provide energy for tissue synthesis and the basic nutrients for synthesis of new tissues.[1] From weeks 26 through 40 of gestation, human fetal weight increases more than four-fold. Part of this increase in weight is water, but the rate of accretion of fat and nonfat components is even greater.[2] Between 26 and 30- weeks, nonfat and fat calories contribute equally to the energy content of the body[2]; however, beyond that time, fat accumulation considerably exceeds that of the nonfat components.[3] At 36 weeks of gestation, 1.9 g of fat accumulates for each gram of nonfat daily weight gain, and by term gestation, the deposition of fat accounts for more than 90% of the calories accumulated by the fetus.[1] The rate of fat accretion is approximately linear between 36 and 40 weeks of gestation, and by the end of pregnancy, fat accretion ranges from 1.6 to 3.4 g/kg/day.[1] At 28 weeks, it is slightly less, ranging between 1 and 1.8 g/kg/day.

The main phospholipids of cell membranes contain two of a variety of fatty acids and a substituted (amino) alcohol attached to a glycerol phosphate backbone. The nature of the alcohol head group and that of the attached fatty acids have major effects on the biologic function of that membrane.[4]

The nature and chain length of fatty acidsassociated with complex lipids are of particular significance because they determine the structural and functional roles of these lipids in neural membranes.[5] Fatty acids can be chemically characterized according to presence and number of double bonds: Those with no double bonds are termed *saturated;* those with one double bond, *monounsaturated;* and those with two or more double bonds, *polyunsaturated* fatty acids [PUFAs]). Metabolism of PUFAs results in formation of long-chain PUFAs (LC-PUFAs) (i.e., fatty acids with more than 18 carbon atoms and multiple double bonds), which are incorporated into complex structural membrane lipids or used for production of biologically active substances (eicosanoids). Biosynthetic pathways producing LC-PUFAs consist of a series of desaturation and chain elongation reactions in which there is no direct cross-over between unsaturated metabolites from one sequence to the other. The type and amount of any given unsaturated fatty acid found in tissue lipids are determined by factors that regulate the synthesis of unsaturated fatty acids, as well as by control mechanisms dictating the incorporation of a given fatty acid into a lipid.[6]

Eicosanoids are potent compounds that display many different biologic effects.[7] In response to various stimuli, eicosanoids are generated by de novo synthesis, are not stored, and are quickly inactivated.[8] The precursor fatty acids, predominantly arachidonic acid (AA) (C20:4*n*-6), are esterified in the second position of cellular phospholipids and do not exist as free acids to any significant extent. Thus the generation of free AA from phospholipids is a rate-limiting step for formation of biologically active eicosanoids.[8]

Brain Development

Biochemical Development and Myelination

Brain development is a sequential anatomic process characterized by specific, well-defined stages of growth and maturation.[9] Biochemical development of the brain also appears to be sequential, correlating with anatomic development.[10] The role of lipids during brain development is the subject of a published text.[11] Any defect in the course of brain development can easily result in gross abnormalities of brain function and can cause serious and irreparable damage in the regulation of body activities and expression of behavior.

Lipids are extremely important constituents of the brain. Not only are they essential for the structure and function of the neuronal and glial membranes, but they also constitute the main components of the myelin sheath, which endows the mature axon with its rapid conduction capacity. In myelin, lipids constitute 70% to 75% of dry weight. All of the major lipids found in whole brain also are present in myelin, and no lipid components are present exclusively in myelin. However, cerebroside is the most typical lipid found in myelin, and its concentration in brain is proportional to the myelin content.[12] In the adult brain, lipids are the most abundant compounds, constituting approximately 60% of the total solids or 10% to 20% of the fresh weight of the brain. Significant regional variation in brain lipid composition has been demonstrated: The number of lipid types, as discussed next, is lower in gray matter and higher in white matter. In cortical gray matter, lipids make up only 7.5% of fresh weight, but in the subcortical white matter, they constitute more than 20%.[13]

The major classes of brain lipids are cholesterol, phospholipids, cerebrosides, sulfatides, and gangliosides. Cerebrosides and sulfatides are found primarily in myelin; the gangliosides

are associated with the structure of the external surface of the neuronal membrane, especially in the synaptic region.[14] In myelin, the fatty acids are predominantly saturated or monounsaturated, whereas in neuronal membranes, particularly synaptosomes, the PUFAs predominate. Each neuron in the cerebral cortex gray matter has more than 10,000 discrete areas of membrane responsible for neurotransmission to other nerve cells through the synaptosomes, which have high concentrations of polyunsaturates, particularly docosahexaenoic acid (DHA) (C22:6*n*-3). Phosphatidylcholine is quantitatively the most abundant phospholipid in the immature brain, but the major DHA-containing phospholipids in the synaptosomes are phosphatidylserine and phosphatidylethanolamine.[15] In the developing brain, the lipid composition undergoes very significant qualitative and quantitative changes with maturation. During the early stages of development, only those lipids that are part of the general structure of the cell membrane increase. With the onset of myelination, special lipids accumulate in brain tissue and drastically alter its lipid composition, both qualitatively and quantitatively.

In the human brain, myelination begins during the perinatal period, demonstrates a rapid increase during the first year, and continues into the second decade of life. The first structures in the human brain to be myelinated are the motor and sensory roots; the last ones are the reticular formation, nonspecific thalamic projections, and the neocortex.[16,17] Phylogenetically older structures (e.g., the spinal cord) are myelinated earlier, and the more recently acquired structures follow later.

The total quantity of all classes of lipids increases during brain development. However, not all lipids show the same temporal pattern of increase. For example, phospholipids tend to decrease during brain maturation, whereas others, such as cholesterol, cerebrosides, and sulfatides, are found to increase.[18] These observations reflect the deposition of myelin in the developing brain and also changes in myelin composition at different ages. The relative proportions of different brain phospholipids and the fatty acid composition of phospholipids in gray and white matter also change with age throughout prenatal life, particularly in the last trimester of pregnancy.

Fatty Acid Deficiency

Prenatal and postnatal essential fatty acid deficiency reduces body and brain weights of the developing progeny even though the mothers are asymptomatic. The extent of these changes in the brain depends on the timing of the deficiency. Compositional changes in myelin parallel or even exceed those observed in whole brain[19] and can be manipulated by dietary fatty acid composition.[20,21]

The increasing survival of very-low-birth-weight infants has led to study of the development of accretion of essential fatty acids during the last trimester of fetal development through the early weeks of life. The intrauterine requirements for *n*-6 and *n*-3 fatty acids are estimated to be 400 and 50 mg/kg/day, respectively. For the high-risk, low-birth-weight infant weighing approximately 1300 g, extrauterine tissue synthesis would use approximately 280 mg/kg/day of *n*-6 fatty acids and approximately 35 mg/kg/day of *n*-3 fatty acids (based on a projected growth rate that is similar in composition and amount to the intrauterine rate)[22] (Figure 42-1).

Clandinin and colleagues[23] determined that during the last trimester of fetal growth, accretion of major tissue fatty acids occurs earlier and faster in cervical segments than in lumbar regions. Minimal postnatal accretion of fatty acids occurs in cervical regions of the spinal cord, with the exception of moderate increases in total *n*-9 and saturated fatty acids, reflecting myelination. Postnatal accretion of fatty acids in lumbar regions of the spinal cord occurs for approximately 4 weeks, at rates significantly in excess of in utero rates.

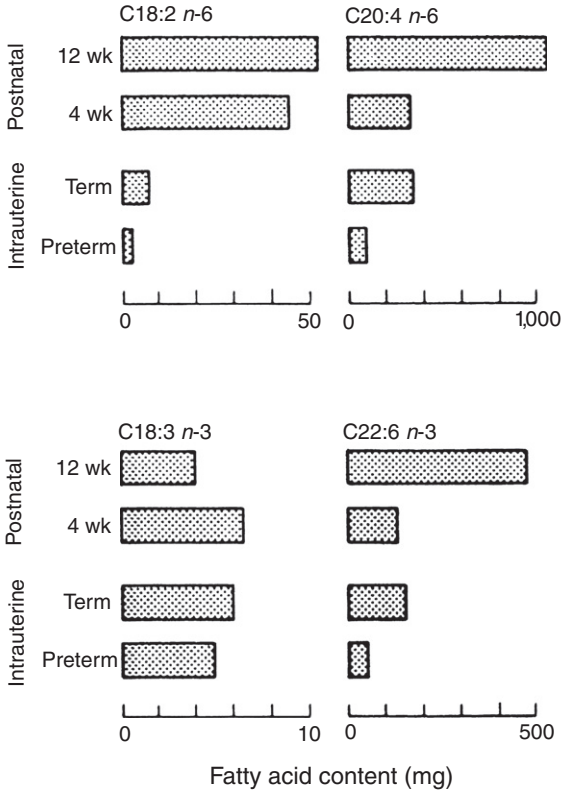

Figure 42-1 Accretion of major essential fatty acids in human brain during intrauterine and early postnatal development.

Changes in Composition of the Brain During Development

Changes in the lipid composition of the brain during development principally reflect accumulation of lipids in myelin sheaths.[24] As a specialized plasma membrane of the myelinating cell, myelin contains large amounts of cholesterol.[25] Cholesterol and sphingolipids (cerebroside, sulfatide, and sphingomyelin) are found mainly in myelin and are the major constituents of total cerebral lipids in the mature brain. On a dry weight basis, approximately 70% of cerebral lipids are contained in myelin. Cerebroside contributes to the stability of the structure of the myelin sheath. In the immature brain, before myelination has occurred, the lipid composition is similar to that in other tissues.[26] At that time, lipid droplets of cholesterol esters are present in glial cell bodies,[27] which rapidly disappear as myelination progresses. Cerebrosides and sulfatides are virtually absent from the brain until myelination begins. At 4 months of gestation, the human fetal brain (which lacks myelin) contains very small amounts of cerebroside and sulfatide, in addition to other glycolipids. The changes in the relative proportions of lipids and the content of individual brain lipids reflect differences in the distribution of lipids in the various cell membranes of the central nervous system. Early in gestation, most cells are devoid of cell processes, and therefore, the lipid content is mainly related to the cell body. Oligodendroglial cells from the mature brain are characterized by high cerebroside and cholesterol concentrations, but neurons and astrocytes do not change in lipid composition during development.[27]

Ethanolamine phospholipids contain most of the PUFAs esterified in cerebral lipids.[28] Essential fatty acid deficiency in the rat, if imposed during pregnancy, results in significant alterations in the content of LC-PUFAs.[29,30] Conservation of essential fatty acids in nervous tissue by recycling processes may contribute to stability of the fatty acid composition of cerebral lipids.

LC-PUFAs with more than 22 carbon atoms are absent from the human fetal brain but appear in sphingomyelin during the late fetal period, when C24:1 predominates.[31] Two classes of sphingomyelin exist: One possesses long-chain fatty acids, with low turnover and localized to myelin; the other is present in non-myelin membranes. The fatty acid composition of cerebroside also changes with development, as does that of individual phospholipids (i.e., phosphatidylcholine) from whole brain and from myelin. Phospholipids exhibit an increase in chain length and a greater proportion of unsaturated fatty acids during maturation. Throughout development, lipid components of the cell membrane undergo continuous turnover, and the lipid components of plasma membranes, including the myelin sheath, are in dynamic equilibrium with intracellular membranes. The enzymes required for lipid biosynthesis exhibit a temporal increase in activity that parallels the rates of accumulation of cerebral lipids.

The ganglioside composition of the brain was reviewed by Ramsey and Nicholas.[24] Gangliosides are important constituents of membranes and are involved in cell differentiation, proliferation, neuritogenesis, growth, inhibition, signaling, and apoptosis.[32-35] The major types of brain gangliosides are fairly consistent across species and include GM_1, GD_3, GD_{1a}, GT_{1a}, GD_{1b}, and GT_{1b}.[36] Gangliosides are present in highest amounts in gray matter and are particularly enriched in synaptic junctions. Rapid changes in the ganglioside composition of the human fetal cortex occur in the latter half of gestation. Vanier and associates[37] revealed that white matter is similar to that of gray matter ganglioside composition of the cerebellum until term, after which GM_1 composition increases to approximately 60% of total gangliosides. Maximal increase in brain ganglioside content, approximately three-fold in the cerebral cortex from fetal week 15 to the age of 6 months, corresponds to rapid increases in development of neuronal connections at these times. This pattern of increase includes increases in GM_1 and GT_1, with GD_{1a} fractions.[37] Severe maternal protein-calorie deficiency that lasts throughout gestation and lactation does not alter prenatal and early postnatal ganglioside accumulation.[38] However, a deficit in postnatal ganglioside accumulation develops after postnatal day 10. Stage of development and thus ganglioside amount and composition may relate to membrane ganglioside function. Research by Park and associates[39] showed that in neonatal rat brain, postnatal ganglioside intake seems to influence ganglioside amount but not composition. Although the ganglioside composition of the diet and enterocyte changed, the plasma and brain composition of the major types of gangliosides measured did not. The functional significance of this preservation of composition is not known.

The fatty acyl-coenzyme A synthetase of cerebral mitochondria is already at maximum activity before birth.[40] A correlation has been found between the main fatty acid changes occurring in the brain and those occurring in the liver during early human development. Linoleic acid (LA) (C18:2*n*-6) and α-linolenic acid (ALA) (C18:3*n*-3) represent a small proportion of the fatty acyl components of the phosphoglycerides of the fetal brain. By contrast, AA and DHA are readily incorporated into the structural lipids of the developing brain.[41]

Intrauterine Fatty Acid Accretion

Development of the infant brain is accompanied by a rapid rise in cellularity and a declining water content.[42] These changes are associated with an increase in the brain and cerebellar content of LC-PUFAs secondary to an increase in the number of plasma membranes.[43] Quantitative analysis of the fatty acid composition of brain lobes indicates rapid accretion of chain elongation and desaturation products during the last trimester of brain growth. Similar analysis of the essential fatty acid composition of cerebrum and cerebellum has demonstrated the vulnerability of the very-low-birth-weight infant to essential fatty acid deficiency at birth.[43] For example, analysis of the chemical composition of the developing fetus indicates that the total fat content of a 1000-g infant is only 28 g.[44] Levels of LA and ALA are consistently low in brain during the last trimester of development, although a marked accretion of long-chain desaturation products, AA and DHA, has occurred by that time (see Figure 42-1).[43]

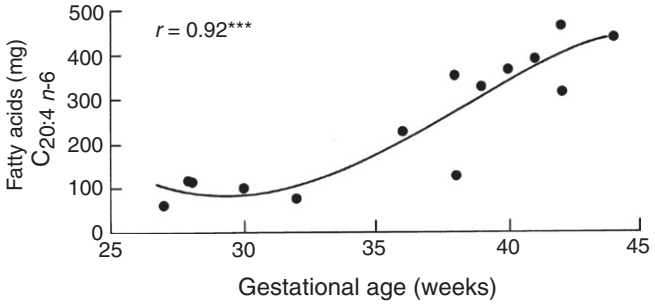

Figure 42-2 Fatty acid content of infant brain expressed as a function of gestational age. Values of *r* and significance levels are indicated (degrees of freedom = 13). Totals for each fatty acid (mg) are calculated for infants of various gestational ages (in weeks).

During the last trimester of pregnancy, a steady increase is seen in the cerebellar content of all fatty acids, reflecting a general increase in fatty acid content. However, *n*-3 fatty acids represent an exception in that absolute accretion rates, particularly DHA, are higher in the antenatal than in the postnatal period. This finding suggests that the accretion of long-chain *n*-3 fatty acids during the third trimester may be particularly important for the normal rise in brain cellularity.[43]

Examination of intrauterine accretion of *n*-6 and *n*-3 LC-PUFAs has indicated rapid accretion of these components in the fetal brain.[43] In the third trimester, accumulation rates are approximately 43 mg of *n*-6 and 22 mg of *n*-3 PUFAs per week[22] (Figure 42-2). Thus, during the last trimester, the major fatty acids to accrue are the chain elongation–desaturation products; only 2.6% of the brain fatty acid content is LA. In term infants during early postnatal brain development, the LA content increases significantly, whereas little increase occurs in brain levels of chain elongation–desaturation products in the first several weeks after birth.[45] In humans, the brain undergoes an accelerated growth phase during the last trimester of pregnancy and the first 18 months of postnatal life (Figure 42-3). During this vulnerable period, essential fatty acids are required for structural expansion of the brain.

PLACENTA

Placental Metabolism and Transport of Lipid

The maternofetal transfer of substances across the placenta involves any of five potential mechanisms (passive diffusion, facilitated diffusion, active transport, ultrafiltration, and pinocytosis); however, fatty acids, some amino acids, and lipid-soluble vitamins are transferred by a passive diffusion process.[46,47] Interspecies comparison of fetal fat accretion, with placental permeability for free fatty acids, demonstrates that the human neonate (who has a high body fat content) has a placenta relatively permeable to free fatty acids. Most observations suggest that embryonic and fetal lipids in early gestation are derived from maternal fatty acids that cross the placenta, followed by a gradual shift to de novo synthesis from glucose in fetal tissue with advancing gestation.[48]

Free fatty acids and cholesterol are the only lipid fractions present in maternal blood that are known to cross the placenta.[49] Free fatty acids are released to the fetus, but the mechanism of

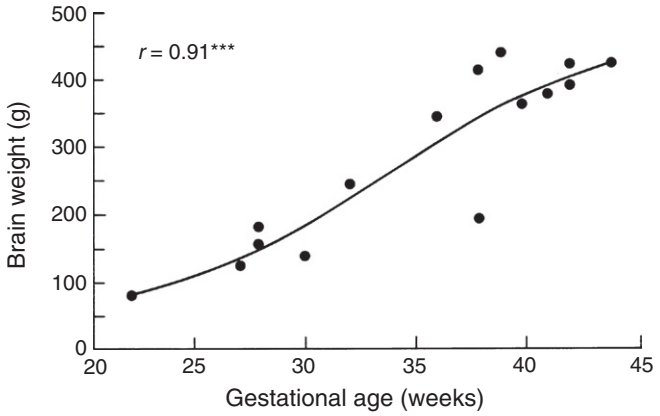

Figure 42-3 Brain weight as a function of gestational age.

release is not known. Maternal free fatty acids enter the placenta and pass into the fetal circulation[47]; however, the placental permeability for free fatty acids is low. Although intact complex maternal lipids may not be transported as triacylglycerol, partial glycerides or phospholipids may be synthesized within the placenta and then released into the fetal circulation.[50] Triglycerides and phospholipids are taken up by the placenta but are metabolized to such an extent that neither can be considered a source of free fatty acids for the fetus.[49] In humans, the levels of free fatty acids are higher in maternal blood than fetal blood, and their concentrations are highly correlated.[49] Under normal circumstances, the fetal/maternal ratio of free fatty acids is less than 0.5.[1] "The fetus appears to obtain [fatty acids] from a combination of de novo synthesis, a passive gradient–dependent transplacental passage of nonesterified [fatty acids] and a selective maternofetal placental transport for certain [fatty acids], such as physiologically important LC-PUFAs."[51] Preferential uptake of LC-PUFAs by the fetal side of the placenta has been suggested as the main mechanism of incorporation of LC-PUFAs in the fetus.[52]

Fatty acids are required by the fetus and the placenta for synthesis of complex lipids.[50] Because fetal tissues can actively synthesize fatty acids, controversy has arisen concerning the relative amounts of fatty acids synthesized by the fetus and the amounts contributed by the mother.[53] An inverse correlation exists between chain length and transfer rate for fatty acids. Interpretation of this information is difficult because many factors change coincident with a reduction in chain length, including a decrease in the association constant of the albumin-free fatty acid complex. Observations in animals and estimates of placental transfer of fatty acids, derived from in vitro studies, suggest that approximately 30% of the daily lipid accumulation by the fetus is transported from the maternal circulation[54]; the remainder is synthesized by the fetus. Thus approximately 1.7 g/day of fatty acids (including essential fatty acids) is transferred each day.

Evidence in humans indicates a placental role in preferential accumulation of LC-PUFAs in fetal tissues.[55] Selective transfer of monounsaturated and polyunsaturated fatty acids into fetal circulation seems to occur as a product of a physiologic mechanism, rather than only as a function of free concentration in the maternal perfusate.[56] Selectivity of placental uptake was proposed previously as the result of brush border and basal membrane concentrations of fatty acid–binding proteins in syncytiotrophoblasts,[57] as well as LC-PUFAs specificity of and competition for fatty acid–binding sites.[55] Human placental tissue lacks both the δ^6 and δ^5 desaturase activities, so any LC-PUFAs in the fetal circulation must come from the maternal plasma.[51,55,58] The presence of desaturase and elongase activity in developing fetal liver[58] makes it more difficult to determine the sources of these fatty acids in the developing fetus. Isotope tracer studies may help to elucidate these processes in vivo.

Examination of intrauterine accretion of *n*-6 and *n*-3 LC-PUFAs has indicated rapid accretion of these components in the fetal brain.[43] In the third trimester, they accumulate at rates of approximately 43 mg of *n*-6 and 22 mg of *n*-3 PUFAs per week.[22] Thus, during the last trimester, the major fatty acids to accrue are the chain elongation–desaturation products; only 2.6% of the brain FA content is LA. In term infants during early postnatal brain development, the LA content increases significantly, whereas little increase occurs in brain levels of chain elongation–desaturation products for several weeks after birth.[45]

The transport of essential fatty acids derived from the maternal diet appears to be affected by maternal nutrition and varies during the course of gestation. Crawford and associates[59] demonstrated that the proportion of LC-PUFA derivatives of parent-essential fatty acids is greatest in fetal brain, less in fetal liver, and further reduced in cord blood. Maternal blood has an even lower proportion of PUFAs. This biomagnification in the fetal brain indicates that the composition of phospholipids in the fetoplacental unit is the result of alterations designed to achieve a high proportion of LC-PUFAs necessary for structural components of the developing brain.[52] Placental prostaglandin synthesis has been assessed in several cellular and subcellular preparations, and it appears that the placenta is capable of producing numerous AA metabolites including prostaglandin D_2, prostaglandin I_2 (i.e., prostacyclin), and several hydroxyacids.[52] Research done with perfused human placentas indicates that the biomagnification of AA may result from fetal synthesis, whereas selective placental transport may be the case for DHA.[56]

Free fatty acids may cross the placenta in either direction, but the movement of phosphoglycerides and triglycerides generally is restricted or absent. This is especially relevant when one considers that maternally derived LA has been found mostly in the free fatty acid fraction of fetal circulating lipids, whereas AA is selectively compartmentalized into phosphoglycerides by the placenta and is exported to the fetus mostly in that form. Thus, the selectivity with which the placenta distributes LC-PUFAs into a lipid fraction impermeable to the placental barrier may allow those fatty acids to be preferentially retained in the fetoplacental unit, in relation to shorter chain homologous essential fatty acids. It also is possible that this mechanism serves to provide the fetus with preformed structural components for inclusion in developing membrane systems.[52] The placenta is able to take up lipids associated with chylomicrons and very-low-density lipid fractions in maternal plasma through the action of lipoprotein lipase. Triacylglycerol hydrolase may be important for releasing free fatty acids from intracellular triacylglycerol stores in the placenta.[55] These lipids are subsequently released into the fetal circulation as both esterified and nonesterified fatty acids.

Although little is known about the processing of fatty acids accumulated in fetal liver, it has been suggested that they are incorporated into lipoprotein for transport to sites of utilization (i.e., adipose tissue).[60] High rates of lipogenesis have been observed in fetal liver (as compared with lipogenesis after birth), suggesting an important role for the liver in the synthesis of endogenous fatty acids and indicating that not all of the fetal need for fatty acids can be met by placental transfer.[61]

Placental Transfer and Cord Polyunsaturated Fatty Acids

Normal growth of infants depends on an adequate supply of essential fatty acids. The human fetus is unable to synthesize essential fatty acids, which must be delivered from the maternal circulation via the placenta.[12] Previous reports indicated that maternal plasma lipids are elevated during pregnancy and that levels of total lipids, triglycerides, cholesterol, and phospholipids

are also significantly higher than those in the neonate.[62] However, the relationship of maternal nutrition during pregnancy with fetal plasma lipid levels remains controversial.

Friedman and colleagues[63] analyzed the phospholipid, cholesterol ester, triglyceride, and free fatty acid levels in maternal plasma and in cord venous and arterial blood of infants at 28 to 44 weeks od gestation. In that study, no difference was found in fatty acid composition of phospholipids, cholesterol esters, triglycerides, and free fatty acids between cord venous and arterial plasma samples obtained at birth.[63] The concentration of LA in cord plasma phospholipid was less than 40% of the maternal value. Lowest values were noted before 34 weeks gestation. By contrast, venous and arterial cord plasma contained a higher concentration of AA than maternal plasma in various lipid fractions (phospholipids, cholesterol esters, triglycerides, and free fatty acids).[62,63] Similarly, the concentration of DHA was higher in cord plasma at term as compared with levels in maternal plasma.[12] The total levels of fatty acids of the ALA and LA series in cord plasma phospholipid increased from 25.5% at 24 to 33 weeks to 33.7% at 34 to 37 weeks and 36% at term. By comparison, the maternal plasma level of these fatty acids was 39.9% at term.[64] Factors that may be responsible for the increased concentrations of AA and DHA in the fetal circulation include preferential transfer of these fatty acids in later gestation and the presence of enzymatic activity in the fetus, resulting in desaturation and elongation of LA to form AA.

Maternal exposure to *trans* fatty acids may be a factor that influences essential fatty acid metabolism in term and preterm infants at birth. Maternal plasma and infant plasma have been found to contain similar percentages of *trans* fatty acids.[65] Humans cannot synthesize *trans* fatty acids; presumably, then, these fatty acids must originate from the maternal diet,[66] and they appear in fetal circulation via placental transport.[55] An inverse relationship has been indicated between *trans*-isomeric fatty acids and LC-PUFAs in cord blood lipids. Research thus far has indicated that total *trans* fatty acids in plasma lipid fractions are not related to LA and ALA but are inversely correlated to *n*-3 and *n*-6 LC-PUFAs and to the product/substrate ratios of long-chain polyunsaturated biosynthesis.[67] *Trans* fatty acids may inhibit the transport of LC-PUFAs to the placenta by competing for fatty acid–binding sites.[55] Existing evidence has not yet shown whether these effects on fatty acid metabolism alter fetal growth or length of gestation.

The fatty acid composition of adipose tissue triglycerides in the newborn infant differs from that of the mother, similar to the observed differences in plasma lipid composition. Body stores of essential fatty acids are particularly low in low-birthweight infants. The concentration of LA in fetal tissue is less than in adults, and the proportion of LA in muscle phospholipids increases with advancing gestational age. Because of the low concentration of LA in fetal adipose tissue, the contribution of LA to the pool of plasma-free fatty acids during lipolysis is also small.[68] Cord plasma levels of LA are also diminished, a finding reflecting the reduced tissue level of this fatty acid. The low plasma concentrations of LA may have a beneficial effect by increasing the maternofetal gradient for LA and facilitating transfer across the placenta. As noted earlier, the relatively high concentration of AA in fetal tissue could result either from preferential transfer of this fatty acid or from desaturation and elongation of LA in the fetus to produce AA. Tissue enrichment in AA plays an important role during fetal life by maintaining the normal function of biologic membranes and perhaps by providing a substrate for prostaglandin biosynthesis. Postnatal brain development is characterized by an increase in LA content; however, chain elongation–desaturation products do not increase for several weeks postnatally. This finding suggests that placental transfer of LC-PUFAs is of primary importance in accretion of these fatty acids in the fetus.[69]

POSTNATAL LIPID ACCRETION

Fatty Acid Utilization

For most mammalian species, birth represents an abrupt transition from a low-fat to a high-fat diet. The endocrine changes that occur at birth, particularly the surge in the plasma concentration of glucagon, favor mobilization of lipids from peripheral tissues. Blood concentrations of free fatty acids and glycerol increase, resulting in a higher rate of fatty acid oxidation and increased ketone body production. After birth, milk provides a relatively high-fat diet compared with that consumed by the fetus, and it is clear that lipids play an important role both as metabolic fuels and in fat deposition. Fat is the main energy source for the newborn infant. In addition to providing 40% to 50% of the total calories in human milk or formula, fats are essential to normal development because they provide fatty acids necessary for brain development; they are an integral part of cell membranes, and they are the sole vehicle for fat-soluble vitamins and hormones in milk.[70]

Using the accretion rate of essential fatty acids during normal growth of the human fetus and newborn as a reference point, Clandinin and associates[43,71,72] demonstrated a lag in accretion of LC-PUFAs in the brain and liver during fetal development and mobilization of PUFA deposits in the liver for a varying period after birth. From these studies, it was concluded that chain elongation products do not accrue in the neonatal brain for several weeks postnatally. In fact, chain elongation products are not synthesized at maximal rates for several weeks after birth in the term infant, further supporting the hypothesis that placental transfer of LC-PUFAs is of primary importance in their accretion.[72]

Although the composition of fatty acids contained in brain total lipids and phosphoglycerides demonstrates a characteristic pattern, small alterations in composition of dietary fat intake change the composition of brain membranes during development. When animals are fed n-3–deficient diets, docosapentaenoic acid (DPA) (C22:5*n*-6) replaces DHA (C22:*n*6*n*-3) in neural membranes.[73] The functional effects of this replacement are not yet clear. Even though DPA is a precursor for AA, this substitution does not seem to affect brain AA levels in *n*-3–deficient rats.[74] The *n*-6–*n*-3 balance also is important; hence, maternal diets providing a high ratio of LA to ALA (10% corn oil) result in higher levels of DPA and lower levels of DHA in the brains of newborn rats.[75] In similar experiments,[76] weanling rats fed diets supplemented with oil rich either in *n*-3 (fish oil) or *n*-6 (safflower oil) fatty acids underwent reciprocal replacement of *n*-6 and *n*-3 families of fatty acids in brain ethanolamine phosphoglycerides according to the dietary levels. Jumpsen and associates[77] examined the effects of feeding ALA, AA, and DHA on brain development in neonatal rats. The *n*-3–*n*-6 ratio at amounts within the recommended limits significantly altered the fatty acid content of the developing rat brain. The amount and rate of AA or DHA accretion into glial and neuronal membranes varied, and ethanolamine phosphoglycerides exhibited the most distinct changes when LC-PUFAs were fed.[77] Thus fatty acid constituents and synthesis of structural lipid in brain membranes that undergo turnover can be altered by changes in the composition of dietary fat intake.[78]

Inclusion of LC-PUFAs is currently implemented in infant formulas. The addition of DHA or AA alone is inappropriate because the balanced addition of both *n*-6 and *n*-3 LC-PUFAs (AA and DHA) is required to achieve optimal accretion. The balance between AA and DHA in the diet is a powerful determinant of the level of these fatty acids in the developing brain. It is becoming increasingly evident that the addition of LA and ALA does not provide optimal *n*-3 and *n*-6 LC-PUFAs, and optimal growth and development require the addition of both AA and DHA. Previous studies had difficulty showing an effect of AA- and DHA-supplemented formulas on growth; however, this difficulty probably was related to a lack of statistical power resulting from insufficient length or size of study

or narrow inclusion criteria that eliminated detection of difference. In a double-blind, controlled multicenter study,[79] Clandinin and associates demonstrated that feeding AA and DHA is essential to enhance growth and neurodevelopment in premature infants (less than 35 weeks of postmenstrual age with a birth weight less than 1500 g). Infants fed standard formula supplemented with 34 mg/100 kcal AA and 17 mg/100 kcal DHA from single-cell oils (n = 95) had significantly greater mean body weights than those of infants in the control group (unsupplemented formula) (n = 98) at every study time point from 66 weeks of postmenstrual age until the study's end, and a length similar to or greater than that in the control group from 40 to 100 weeks; by 118 weeks (n = 72) they also had a mean length and weight comparable with those for a reference term group of infants (n = 97). In addition, mental and psychomotor scores were higher in the supplemented formula group than in the control group. It was concluded that formulas supplemented with DHA and AA at median levels found in human milk are safe for very-low-birth-weight premature infants and are essential for optimal growth and development.

Intake

Human Milk

Many physiologic factors influence milk composition, such as stage of lactation, length of gestation, age of the mother, intrafeed regulation of milk release, and the baby's demand for milk.[80] Throughout early lactation, "preterm" milk is 40% to 50% higher in its total fat content than milk from mothers whose babies were born at term. As the period of gestation increases and approaches term, differences in the nutrient content between preterm and term breast milk diminish. The stage of lactation may also affect lipid content: Colostrum has 1.19% (weight for weight) fat, transitional milk has 3% fat, and mature milk has 3.3% fat.[81] Fat provides approximately 50% of the energy content in human milk.

When compared with cow's milk, the fat content of human milk is characterized by a relatively high proportion of oleic acid, a higher level of essential fatty acids, and a relatively lower level of short-chain fatty acids such as butyric, caproic, caprylic, and capric acids.[80] Also notable are the differences in the ganglioside content of human colostrum, later milk, formula, and cow's milk. Human milk and colostrum contain almost twice the total lipid-bound sialic acid found in cow's milk or formula.[82] The major ganglioside fractions identified in colostrum were GD_3 and GX_1, and later milk also contained a high proportion of GM_3, whereas cow's milk and formula consisted mostly of GD_3.[82] The biologic significance of these differences has not yet been fully delineated.

Limited quantitative information is available on the actual amounts of fatty acids consumed by breast-fed newborn infants. Although better equipment has become available for analysis of fatty acid composition of milk samples, most studies lack basic information, such as lipid content and volume of the milk consumed.[83] Alterations in maternal intake of PUFAs are reflected in milk fatty acid composition; as a consequence, newborn tissue composition is affected by maternal diet in both animals and humans.[84-87] The LC-PUFA status at birth is one of the major determinants of postnatal change in LC-PUFA status, with breast milk the most effective diet for maintaining these levels.[88] Consequently, lower LC-PUFA status in formula-fed infants compared with breast-fed infants may persist at least until the first year of life.[89]

In well-nourished women (who are in energy balance), the fatty acid composition of breast milk shows a strong relationship with the distribution of fat and carbohydrate calories in the diet. For example, a carbohydrate-rich diet providing 75% of energy requirements may result in an increase in the content of saturated fatty acids such as lauric acid (C12:0) and myristic acid (C14:0) and a decrease in the LA content.[80] Maternal diet in well-nourished women affects milk lipid constituents, but not the total amount of fat present in milk. Milk from vegetarian mothers exhibits levels of milk fat similar to those in milk from women who consume an omnivorous diet; however, it has a higher proportion of PUFAs derived from increased consumption of vegetable fats, with the primary effect on the milk LA content.[90] In women who are vegetarians, the higher concentration of LA is accompanied by lower concentrations of DHA in the erythrocyte membranes of their breast-fed infants.[90] It is estimated using isotope tracers that approximately 30% of milk LA is directly transferred from maternal diet, whereas conversion of dietary LA to AA and other longer-chain LA homologues (dihomo-γ-linolenic acid) (20:3n-6) occurs at approximately 1.2% and 11%, respectively.[91] However, the contribution of dietary LA to milk AA may be slightly underestimated because of isotope dilution. Human milk supplies significant amounts of C20 and C22 fatty acids, which are more effective in supporting tissue AA and DHA accretion than are similar amounts of LA and ALA.[92] A review of the research on human milk fatty acid composition of milk lipids detailed the differences in DHA content of human milk between Western and non-Western women, with content averaging 0.45% and 0.88% of total fatty acids, respectively, although a wide variation in Western diet was reported.[93] The largest changes in fatty acid composition occur when maternal diet is supplemented with fish oil.[85] For example, high levels of fish consumption by Inuit women increase the breast milk content of n-3 LC-PUFAs.[94] Levels of DHA in human milk have been reported to range from 0.2% to 1.4% of total fatty acids.[85,94] Supplementation of maternal diet with DHA also results in markedly increased DHA content in human milk, directly attributable to dietary increase rather than to preferential secretion.[95] Levels of AA remain fairly constant despite wide variation in maternal intake of LA or DHA.[85,94,96]

Because maternal diet affects the fatty acid composition of milk so easily, a good question is whether the drastic change in diet over the last few centuries also has modified human milk fatty acid composition. For instance, the dietary n-6/n-3 ratio has changed from 1:1 to 10:1 or 20:1, resulting in a higher ratio of n-6/n-3 than evolution would have allowed without human interference.[97,98] Moreover, the proportion of polyunsaturated to saturated fatty acids present in human milk has been shown to correspond with the ratio of polyunsaturated to saturated fatty acids in the maternal diet.[84] *Trans* consumption also is noteworthy because the *trans* fatty acid content of milk reflects short- and long-term maternal diet.[84]

Fatty acids appear in milk not only as a result of maternal dietary intake but also from factors such as mobilization from maternal fat deposits and endogenous synthesis by the mammary gland.[99] LA and ALA are not synthesized by the mammary gland and are dependent on dietary intake, although their long-chain derivatives may be synthesized partly in the mammary gland, independent of the length of gestation.[100] Long-term maternal diet is important because mobilization of maternal adipose tissue stores is a major source of milk fatty acids, including LA, AA, and DHA.[101,102] Consequently, gestational age and lactational stage influence milk *trans* fatty acid level, but the rate of maternal postpartum weight loss has the most significant effect.[84]

Interest in human milk and the lipid composition of formulas has focused primarily on "humanized" formulas for premature infants, which have been designed to ensure adequate absorption and metabolism of fat and to promote a satisfactory essential fatty acid status. In this regard, the changes in fat content of milk from mothers of term and preterm infants have been investigated. Chappell and colleagues[103] found that milk from mothers who delivered preterm infants has a higher content of LA and ALA and their LC-PUFA derivatives. The prevailing consensus is that early milk produced by women who deliver prematurely is more appropriate for very-low-birth-weight infants than donor

milk from the later stages of lactation.[104] LC-PUFAs are present in the milk of mothers of premature infants. Furthermore, the level of these fatty acids is significantly higher in colostrum and the milk of mothers of premature infants than in the milk of mothers of full-term infants.[105] Finally, whereas the supply of DHA and AA remains fairly constant over 26 weeks of lactation in well-nourished, omnivorous mothers of premature infants, the content of these fatty acids decreases in the milk of mothers of infants born at term. As a result, after 26 weeks of lactation, the relative concentration of AA is 1.5 times higher and that of DHA is twice as high in preterm than in term human milk.[106] Thus human milk apparently can meet the need for LC-PUFAs in preterm infants and can efficiently make up for the diminished supply of fatty acids to the fetus.

Studies of energy metabolism in low-birth-weight infants fed mother's own milk indicate that for a net energy intake of 120 kcal/kg/day, approximately 20 kcal/kg/day of fat will be deposited in tissues (i.e., some 2.2 g fat/kg/day). Because human milk contains 1.08% to 2.65% *n*-6 fatty acids and 1.09% to 1.47% *n*-3 fatty acids synthesized from the C18 precursor, it can be estimated that 23.6 to 58.3 mg of *n*-6 and 23.9 to 32.3 mg of *n*-3 LC-PUFAs will be deposited in tissue each day in a low-birth-weight infant fed adequate amounts of human milk. It also is apparent that human milk contains levels of LC-PUFAs sufficient to meet the requirements of neural tissues for these fatty acids.[45]

Formula for Preterm Infants

Special formulas have been designed to provide adequate intake of calories, fluids, and micronutrients to support the rapid cell division and synthesis of new tissue in the infant.[107,108] The current trend in infant formula preparation is to use a fatty acid profile that more closely reflects the fatty acid composition of human milk, partly owing to its digestibility by the infant. This is the result of many factors, including the fatty acid composition of human milk fat, the triglyceride positional specificity, and complementary enzymatic activities that originate in the breast milk and in the infant's gastrointestinal tract.[107] For instance, the structure of human milk triglyceride is recognized to be unique with regard to the position of saturated and short-chain fatty acids, the presence of phospholipids containing LC-PUFAs, and a triglyceride-to-phospholipid ratio that undergoes a continuous evolution from birth through weaning at 1 year.[109]

Infant formulas and feeding regimens that differ markedly from the composition of human milk fats are prevalent. In some instances, these formulations have been designed to promote utilization of fats with chain lengths of 8 and 10 carbons for maximal absorption.[110] Quantities of each nutrient in formulas for low-birth-weight infants have been adjusted to account for the average absorption of that particular nutrient.[111] Fat accretion in the growing formula-fed premature infant is markedly increased in comparison with that in the fetus of similar weight, rate of weight gain, and postconceptional age. This finding suggests that the weight gain and subsequent body composition of the premature infant differ from those of the comparable placentally nourished fetus.[108]

Interest has focused on the essential fatty acid requirements of preterm infants and the quantities of ALA, AA, and EPA that should be added to formulas in addition to LA. Body stores of essential fatty acids are diminished in low-birth-weight infants, and therefore, they theoretically should be at increased risk of developing clinically apparent essential fatty acid deficiency when they are fed a deficient diet.[112] In that regard, Combes and co-workers[113] did not observe gross abnormalities of the skin in premature infants who were fed milk mixtures low in LA; however, they did note histologic features of the skin compatible with LA deficiency and serum dienoic, trienoic, and tetraenoic acid levels that were significantly different from those in infants fed 4% of their calories as linoleate. Similarly, Hansen and associates[114] demonstrated that many babies younger than who were fed milk diets deficient in LA for 3 months beginning before 6 weeks of age exhibited dry, thick, desquamated skin and retarded growth. Clinical manifestations apparently disappeared after the feeding of diets that provided 1% or more of calories as LA.

For term infant formula, the American Academy of Pediatrics recommends a minimum of 3.3 g of fat per 100 kcal (30% of calories) and 300 mg of LA (approximately 2.7% of calories).[115] For preterm infants, the consensus among Europe, the United States, and Canada is 4.4 to 6.0 g of fat per 100 kcal.[116] Several of the most widely used formulas are based on cow's milk protein and also contain lactose. All contain vegetable oils of one type or another, and most contain more LA than human milk. In these vegetable fat blends, palmitic acid is esterified predominantly to the *sn*-1 and *sn*-3 positions of the triglycerides, resulting in the release of free palmitic acid after intraluminal hydrolysis by lipases. The absorption of palmitic and stearic acids is low, and their presence in the intestinal lumen results in the formation of soaps with calcium and other divalent cations.[117,118] To minimize this problem, medium-chain triglycerides (MCTs) or coconut oils sometimes are used to replace part of the oils containing a large amount of palmitic and stearic acids. Oleo oils are used to simulate the saturated and monounsaturated fatty acid content of human milk. In this type of oil, most of the palmitic and stearic acids are esterified in *sn*-1,3 of the oleo triglycerides. The long-term effects of these varied dietary fatty acid regimens used in feeding infants are unknown, but in animal models, physiologic variations in dietary fat intake are known to alter membrane structure and many related membrane functions.

Research has focused on the requirements for LC-PUFAs.[4,83,119,120] Preterm and term infants fed formula without AA and DHA have lower levels of those fatty acids in plasma and erythrocyte phospholipids than do infants fed human milk.[92,121] A clear dose response is evident in the levels of AA and DHA found in erythrocyte membrane phospholipids when infant formula is supplemented with increasing levels of AA and DHA.[122] The dietary intake of LA and ALA in infant formulas lacking longer-chain homologues of these fatty acids results in reduced levels of AA and DHA in membrane phospholipids compared with those of infants fed human milk.[121] The currently available formulas with high concentrations of LA or high LA-ALA ratios may be contributing to the low incorporation of DHA, both by providing insufficient substrate (i.e., ALA) and by inhibiting the incorporation of endogenously formed DHA into the membrane. ALA does not seem to act as a competitive inhibitor of the incorporation of AA into membranes,[123] unless the content of ALA is increased to unphysiologic levels.[124,125] Energy intake may also be an important variable because erythrocyte phosphatidylethanolamine DHA decreases rapidly in preterm infants who receive less than 100 kcal/kg/day, and a similar decrease is seen for AA in erythrocyte phosphatidylethanolamine and phosphatidylcholine.[92] When preterm infants receiving human milk are in energy balance, the levels of erythrocyte DHA remain constant, but they decline in premature infants fed vegetable oil formulas containing ALA but no DHA.[121,126,127] This decline is rapid and is associated with electroretinographic changes when the formula contains less than 0.37% kcal of ALA; however, both the visual development and the DHA levels in plasma and erythrocytes are comparable to those of breast-fed preterm infants if the formula contains at least 1% kcal of ALA.[121,126,127] Evidence from autopsy material indicates that formula-fed infants experience a similar decrease in DHA content in the brain cortex, and this correlates with a similar decrease in the erythrocyte DHA content.[128] Similarly, results in term infants indicate that the lower DHA level in erythrocytes in formula-fed as compared with breast-fed infants correlates with decrease in visual acuity.[129] As in preterm infants, a higher intake of ALA (1% kcal or greater) should result in visual acuity similar to that in breast-fed infants.[130]

Supplementing marine oil in formula-fed infants also alters visual acuity, as compared with nonsupplemented formula-fed infants.[131] Weak clinical evidence supports a higher intelligence test score in breast-fed than in formula-fed infants. In a nonrandomized study, the advantage in intelligence quotient with human milk feeding at 7 to 8 years of age was 8 points, which is half of one standard deviation in the sample of infants studied.[132] These results, however, also could be explained by group differences in parenting skills and genetic potential.[133] Feeding preterm infants formulas with DHA and arachidonic (ARA) from algal and fungal oils resulted in enhanced growth and provided better developmental outcomes than those documented with unsupplemented formula feeding.[134] The clinical evidence regarding factors such as fatty acid status, growth, and visual and cognitive functions on dietary PUFAs for preterm and term infants has been reviewed by Fleith and Clandinin.[135]

In the foregoing discussion, several aspects of fatty acid metabolism and functional implications were compared for breast milk and several types of commercial formula. Until recently, however, no commercial formula with essential fatty acids of chain length designation greater than C20 was available in North America. For premature (and term) infants fed synthetic formulations in place of human milk fats, it is important to establish whether such formulas possess the enzymes capable of elongating and desaturating LA and ALA and whether they are capable of producing sufficient amounts of LC-PUFAs for optimal synthesis of neural tissues and prostaglandins. This is an especially important question because these infants possess adipose tissue stores adequate for only a few days before essential fatty acid deprivation occurs.[136] Synthesis of AA and DHA therefore depends on adequate desaturase-elongase activity, as well as an adequate supply of dietary LA and ALA and energy. Because specific information on desaturase activity in infants is lacking and because human milk contains a significant amount of AA and DHA, formulas probably need to be supplemented with those fatty acids as well. Some evidence indicates that term infants fed formulas without LC-PUFAs synthesize sufficient AA and DHA from dietary precursors, although the consensus is that this process may not provide enough DHA to meet accretion demands during rapid brain development.[137-139] Furthermore, in preterm infants, evidence indicates that formula supplemented with AA and DHA is essential for optimal long-term growth and development.

MCTs make up half the fat content of many formulas for preterm infants. These nutrients have been added because it is thought they are better absorbed by the premature gut than long-chain triglycerides. Although earlier studies reported improved growth, further studies did not demonstrate an increased gain in weight, head circumference, or linear growth in preterm infants fed a formula containing medium- rather than long-chain fatty acids.[140-143] Energy wastage associated with oxidation followed by biosynthesis, compared with direct tissue incorporation of long-chain fatty acids, may explain the absence of improved energy or weight gain in infants fed formulas with MCTs.[144,145] At higher dietary levels of MCTs, the essential fatty acid balance in the infant may possibly be adversely affected. Lower plasma levels of AA and DHA associated with formula feeding may be exacerbated when MCTs rather than palmitic acid are used as the source of saturated fatty acids in formula.[146] Although high doses of MCTs do not seem desirable, no overwhelmingly clear evidence has shown that they are harmful. Accordingly, more extensive studies are needed to determine the optimal fat blend to use in formulas for low-birth-weight infants.

In summary, the fat in commercial infant formula is different in many aspects from that in human milk: The content of monounsaturated fatty acids, LA, and ALA varies with the oil blend used, the absence of C20/C22 *n*-6/*n*-3 fatty acids, the abundance of MCTs, and the triglyceride fatty acid stereoconfiguration. High levels of LC-PUFAs are present in milk produced by mothers of low-birth-weight infants, whereas current "humanized" formulas are devoid of essential fatty acids with greater than 20 carbons in chain length.[72] Supplementation of infant formulas with very-long-chain PUFAs at levels and ratios similar to those of human milk increases the incorporation of these components into membrane lipids in the developing infant,[119] in a dose-dependent manner.[147] At these physiologic levels, AA and DHA from marine oil sources[148,149] and from single-cell oils[147] maintain AA and DHA status in formula-fed infants similar to that in breast-fed infants.

Absorption

Physiologic Phases

Fat absorption improves with gestational age. Most of the dietary fats are triglycerides, and approximately 2% are phospholipids, free fatty acids, monoglycerides and diglycerides, cholesterol, and other substances.[150] The absorption of triglycerides is dependent on fatty acid chain length. MCTs can be absorbed directly into the circulation without being hydrolyzed by pancreatic lipase. All other fats, however, are hydrolyzed and are then reesterified to form triglycerides within the mucosa. Absorption coefficients for unsaturated fats have been demonstrated.[151]

In the newborn infant, pancreatic lipase and bile salt concentrations are diminished, thus impairing emulsification and breakdown of triglyceride.[152] Efficient fat absorption in the newborn depends on lingual and gastric lipases. These have a special role in the hydrolysis of milk fat and can account for hydrolysis of 60% of the ingested fat. Lingual lipase hydrolyzes medium- and short-chain triglycerides,[152] as well as monounsaturated and polyunsaturated, but not saturated, long-chain triglycerides.[100,153,154] Animal studies have shown that short- and medium-chain fatty acids can be absorbed directly through the gastric mucosa, suggesting that these products of intragastric lipolysis appear rapidly in the circulation. Free fatty acids and monoglycerides, the products of intragastric lipolysis, are relatively polar. Therefore they can locate in the surface layer of the fat globule (dislocating phospholipids and proteins), making the core triglyceride more accessible to pancreatic lipase and human milk bile salt–stimulated lipase. The latter enzyme hydrolyzes milk fat at pH 7.0 to 8.0, in the presence of bile salts, thereby acting in the intestine to complete the digestive process initiated in the stomach by lingual and gastric lipases.[152]

The breast-fed newborn infant depends on an additional compensatory enzyme, the bile salt–stimulated lipase of human milk.[152] This lipase is present in milk beginning at 26 weeks of gestation, has no positional specificity for triglycerides, and hydrolyzes various triglycerides to free fatty acids and glycerol in the presence of bile salts.[155,156] The major differentiating characteristics of milk lipase and other lipases in gastric aspirates are shown in Table 42-1. It is estimated that milk bile salt–stimulated lipase concentrations are sufficient to hydrolyze 30 to 40% of available triglyceride in 2 hours.[157] Addition of this lipase to formula for preterm infants may be feasible.[158] Because bile salt–stimulated lipase does not discriminate between fatty acids and completely hydrolyzes triglycerides, this modification may aid in efficient release of LC-PUFAs, especially in the presence of pancreatic colipase-dependent lipase.[158] The combined action of intragastric lipolysis and intestinal hydrolysis of fat by the bile salt–stimulated lipase of human milk can effectively substitute for low pancreatic lipase activity and low levels of bile salts in the newborn.[152]

It is apparent that a dynamic interrelationship must exist among the products of lipid digestion. The triglyceride emulsion particle, stabilized by the products of intragastric lipolysis and phospholipids, undergoes hydrolysis by pancreatic lipase-colipase and phospholipase A_2. The accumulated lipolytic products are then extruded as unilamellar liposomal vesicles that are in

TABLE 42-1

Compensatory Digestive Lipases Versus Pancreatic Lipase in the Newborn

Feature	Lingual	Gastric	Milk (BSSL)	Pancreatic
Origin	Serous glands	Gastric mucosa	Mammary gland	Acinar cells
TG site (sn)	sn-3	sn-3	sn-1,2,3	sn-1,3
End products	FFA, DG, MG	FFA, DG, MG	FFA, glycerol	FFA, MG
pH optimum	2.2-6.0	3.5-6.5	7.0-8.5	6.5-8.0
Bile salts	No	No	Obligatory	Obligatory
Stability (at pH 2.5-3.0)	Yes	Yes	Yes	No

equilibrium with large bile salt mixed micelles. The mechanism of lipid exchange between these phases, particularly for lipids of differing aqueous solubility or chemical composition, is not completely known.[157] (Chapter 115 describes digestive and absorptive processes in infants in further detail.)

Medium- and Long-Chain Triglycerides

The efficiency of fat absorption in preterm infants is determined not only by maturity of the gastrointestinal tract and pancreas but also by the dietary fat composition. Preterm infants fed fresh human milk can absorb fat as well as term infants, at an efficiency of 90% to 95% of intake.[159] Only 85% to 92% of the fat in formulas that do not contain MCTs is absorbed by preterm infants.[155] Feeding breast milk also has been shown to promote better fat absorption than that observed in formula-fed infants,[151] not only because of the presence of bile salt–stimulated lipase, but also because of differences in the structure of the milk fat globule and the stereoconfiguration of triglycerides. Feeding of pasteurized or stored human milk eliminates some of these factors.[160] For instance, lipases are completely destroyed by pasteurization, whereas fatty acid levels seem to be unaffected.[161] The stereoconfiguration of triglyceride is important in piglets, in which palmitic acid is absorbed from sow's milk and from formula with rearranged triacylglycerols as an *sn*-2 monoacylglycerol.[162] Similarly, in full-term infants who receive human milk, palmitic acid is absorbed as *sn*-2 monopalmityl-glycerol.[163] Positional distribution seems to affect digestion, absorption, and chylomicron triglycerides and has an effect on infant lipoprotein metabolism.[164] However, in preterm infants, randomizing palmitic acid in infant formula triglycerides to improve absorption of fat remains controversial, and no net physiologic benefit may result from an increased level of palmitic acid in the *sn*-2 position of the triglyceride. Previous observations indicated that the coefficient for absorption of palmitic and stearic acids is 20% to 30% lower for premature infants fed formula versus infants fed human milk.[151] Some findings suggest that a palmitic acid configuration similar to that of human milk (with C16:0 esterified in the *sn*-2 position) confers better absorption than when C16:0 is esterified in the *sn*-1 or *sn*-3 position.[165] Thus it is reasonable to expect that if the presence of palmitic acid in the *sn*-2 position confers improved absorption of palmitic acid, then increasing the content of saturated fatty acid in the *sn*-2 position of the fed triglyceride could significantly improve absorption of palmitic acid by up to 10%.

Significant improvement of net absorption of total fatty acid probably would be difficult to demonstrate, because total fat absorption would be likely to increase by only a small amount. In a feeding experiment, the proportion of saturated fatty acids in the *sn*-2 position of palm oil was randomized to simulate the positional distribution of fatty acids in human milk triglyceride closely. Fatty acid absorption was assessed in preterm infants fed a commercial formula or a similar formula in which the palmitic acid was randomized into all positions of the triglyceride molecule. Incorporation of approximately one third of the palmitic acid into the *sn*-2 position of the fed triglyceride improved absorption of fat, but no effect of this triglyceride structure on the net absorption of palmitic acid was observed. Alternatively, other modifications in the triglyceride structure may occur during randomization.[166]

The MCTs are relatively more water-soluble and are more completely hydrolyzed by pancreatic lipase. They also can be absorbed directly into mucosal cells. C8:0 and C10:0 are almost 100% absorbed, despite the low lipase and bile salt concentrations. Efficiency of fat absorption increases with the degree of unsaturation, so fatty acids with more double bonds are absorbed more efficiently (C18:3 > C18:2 > C18:1).[151,167] Several previous studies[168] demonstrated improved fat absorption but only small differences in weight gain with infant formulas containing MCTs.[169] The effect of MCT diet on energy and macronutrient utilization in very-low-birth-weight infants was studied by Van Aerde,[145] who concluded that the growth of infants fed a formula containing 50% MCTs (at an energy intake of 124 kcal/kg/day) will mirror the intrauterine gain in length, head circumference, and weight. Body composition cannot be simulated because of the higher rate of fat deposition. Further studies could not demonstrate an increased gain in weight, head circumference, or linear growth of preterm infants fed a formula containing medium-chain rather than long-chain fatty acids.[140-143] Energy wastage associated with oxidation followed by biosynthesis, compared with direct tissue incorporation of long-chain fatty acids, may explain the absence of improved energy or weight gain in infants fed formulas with MCTs. Premature infants oxidize one third to two thirds of the medium-chain fatty acids, indicating that the remaining medium-chain fatty acids are chain-elongated.[144,145] Production of ketones and dicarboxylic acid increases with an increasing amount of MCTs in the preterm infant formula.[170,171] The rapid oxidation of medium-chain fatty acids probably leads to accumulation of acetylcoenzyme A, exceeding the capacity of the tricarboxylic acid cycle. Dicarboxylic acids are the products of ω-oxidation of C8:0 and C10:0.

The absorption coefficient of oleic and LA from vegetable triglycerides is greater than 90%.[118,151] (For myristic acid, it is only 89%; for palmitic acid, it is 75%; and for stearic acid, it is 62%.) The absorption of oleate and linoleate (unsaturated C18 fatty acids) is highest in infants fed a formula with a linoleate-to-oleate ratio similar to the ratio provided by human milk. Therefore some infant formulas have been designed to provide high linoleate-oleate ratios.[172] In general, agreement in the literature that infant formulas containing cow's milk fat as the sole or principal form of fat also are less well digested by the preterm infant than those containing vegetable oils or MCTs.

Gastric lipolysis,[173] nonnutritive sucking,[174] and a "humanized" lipid formulation for infant feeding can partially compensate for the low-birth-weight infant's intraluminal immaturity.[151] Human milk triglyceride structure,[175] fat globule integrity,[176] inherent lipase activity,[177] and a substance stimulating expansion of the bile salt pool[178] have been suggested as additional factors responsible for relative efficiency of fat absorption in infants fed human milk. The influence of the free fatty acid composition of human milk on fat absorption also should be considered a variable that contributes to efficient absorption of milk fat.[151] Total absorption of fatty acids and the coefficient of fatty acid absorption are significantly higher in very-low-birth-weight infants fed their mothers' milk than in infants receiving formula.[119]

In the premature infant, the fecal fatty acid pattern generally resembles the fatty acid profile fed; however, an inverse relationship has been found between increasing chain length in

saturated fatty acids and absorption.[151] The marked difference in absorption of C18:0 in preterm mothers' milk and formula-fed infants may indicate that factors in addition to position of fatty acids on the triglyceride molecule are responsible for the efficient absorption of fatty acids from preterm mothers' milk.[151] The absorption of specific saturated fats may be low and decreased by the form or perhaps by the method of mineral supplementation.[151] Clandinin and colleagues[119] demonstrated that the overall distribution of individual fatty acids within an insoluble bound fraction is similar for infants fed breast milk and those fed formula. Insoluble bound C16:0 and C18:0 account for more than 65% of fatty acids. Calcium supplementation resulted in an unexpected relative increase in fecal C12:0 and C14:0 in formula-fed and breast milk–fed infants and a decrease in C18:0 in the feces of a breast milk–fed group. Providing palmitic acid appropriately esterified in *sn*-2 of the infant formula triglycerides seemed to improve mineral balance in formula-fed infants.[179]

It is apparent that some fatty acids (i.e., PUFAs) are readily and efficiently absorbed[119]; however, as much as 25% of dietary LC-PUFAs can be lost in the feces of formula-fed and breast-fed preterm infants.[180] In general, longer-chain fatty acids are less well absorbed, possibly because of solubilization and rate limitations of uptake and processing in the enterocyte.[181] Supplementation of formula with AA and DHA has resulted in decreased absorption of these fatty acids,[182] possibly resulting in variable results in clinical supplementation studies. As previously mentioned, human milk bile salt–stimulated lipase has a role in the utilization of LC-PUFAs,[158] so its absence in infant formula also may have an effect. However, it appears that a single-cell oil source AA and DHA in formula may be as efficiently absorbed as these fatty acids are from breast milk.[180] This evidence indicates that the absorption coefficients are not identical for all fatty acids, with a documented difference between human milk–fed and formula-fed very-low-birth-weight infants.[119]

Metabolism

Oxidation

Current understanding of the utilization of individual dietary fatty acids for energy is vague.[119] Because more than 50% of dietary calories of the newborn are derived from fat, metabolic adaptation in the oxidation of long-chain fatty acids and ketone body utilization must occur at the time of birth.[183] It is evident that infants deprived of sufficient fat stores at birth (i.e., premature or growth-restricted infants) lack an important fuel source.[184] In the immediate postnatal period, serum levels of free fatty acids rise dramatically, indicating active lipolysis of adipose tissue.[185] After 12 to 24 hours, the rate of lipolysis falls rapidly as feeding or intravenous nourishment is initiated. Rates of lipolysis in the first few hours of life appear to be regulated by catecholamine release, resulting in production of cyclic adenosine monophosphate and increased protein kinase C activity. Ultimately, this process leads to activation of adipose tissue lipoprotein lipase.[185,186] Lipolysis in neonatal adipose tissues may depend more on mobilization of glycogen stores than on catecholamine stimulation. Insulin, growth hormone, thyroxine, sex hormones, and glucagon also have a role in stimulating free fatty acid production in the neonate by increasing lipogenesis.[187] With typical fecal fat losses of approximately 10% to 15%, some 40% to 50% of the fatty acids consumed would be expected to be available for new tissue synthesis. However, selective β-oxidation of individual dietary acids has been shown in adults.[119] Whether or not this selective β-oxidation of PUFAs also occurs in infants is unknown. Therefore it is difficult quantitatively to assess or estimate the net oxidation rate for dietary LC-PUFAs on the basis of available data.[119]

Relative proportions of major dietary fatty acids consumed may potentially affect the net contribution of fat oxidation to total energy production. The metabolizable energy of saturated triglycerides has long been known to be less than that observed for unsaturated fats.[188] Studies in animals and humans suggest that the degree of unsaturation of dietary LC-PUFAs influences the partitioning of fat between oxidation and storage. Several reports have indicated that LC-PUFAs undergo faster oxidation as compared with their saturated counterparts. Thus, as expressed earlier, human metabolism of dietary fat is not independent of the long-chain fatty acid composition of the fat consumed.[189-191] From nutrient balance and energy balance studies, it appears that only a small amount of the absorbed fat is oxidized, and most fat is stored. A faster clearance and a higher rate of oxidation of fats have been observed in hypermetabolic patients than in physiologically normal subjects. By contrast, fat clearance is faster in patients receiving total parenteral nutrition (TPN), but the rate of oxidation is much lower.[192]

In the past, it was generally assumed that medium-chain fatty acids are preferentially oxidized, but more recent studies estimated that preterm infants oxidize only one third to two thirds of dietary C8:0.[144] Medium-chain fatty acids, particularly C12:0, are incorporated into adipose tissue of preterm infants in proportion to the formula content.[193] It is unclear whether this is of clinical benefit.

Accretion

The lipid content of the brain is fairly constant until 7 months of gestation, when lipid deposition gradually increases, reaching a peak in gray matter at 3 months of postnatal age. In white matter, the process is slower. By 2 years of age, 90% of the adult lipid content has been deposited, and by 10 years of age, 100% has been deposited. White matter accounts for most of the brain lipid, mainly in the form of myelin. Myelin itself contains 50% of the total lipid content and represents 25% of the weight of the mature brain.[194]

Preterm infants born at a weight appropriate for gestational age (AGA) (approximately 1300 g) have a total-body fatty acid content of approximately 30 g, whereas term AGA infants have a total-body fatty acid content more than 10 times greater (340 g). Quantitative analyses of the fatty acid content of liver and neural tissues have demonstrated a combined fatty acid content of 1.55 g in preterm infants and 4.63 g in term infants. Based on dissection data, the total amount of fatty acids in white adipose tissue of preterm and term infants can be estimated at approximately 3.45 g and 255.6 g, respectively.[119] During the first 5 weeks of postnatal life, an apparent mobilization of total fatty acids from the liver is seen. Of the essential fatty acids, only LA and ALA accrue during the initial weeks of life. Significant postnatal accretion of chain elongation–desaturation products does not occur immediately after birth. This finding suggests that early on, either synthesis in the liver may be limiting or mobilization of LC-PUFA homologues of LA and ALA exceeds the capacity of liver to synthesize them from dietary LA and ALA.[119]

Mammalian tissues contain *n*-3 fatty acids primarily in the form of DHA and are mostly concentrated in phospholipids.[195] Although DHA accounts for a small percentage of the fatty acid content of most tissues, very high levels are found in the retina, cerebral cortex, testes, and sperm.[196] Across mammalian species, the levels of DHA in brain and retina phospholipids are remarkably similar despite wide variations in dietary intake. This comparative constancy suggests an important role for DHA in brain and retinal function.[197] DHA occurs almost entirely in the 2-position of phospholipids. The 1-position is characteristically occupied by saturated fatty acids (stearic and palmitic acids). The specific role of DHA is not understood, but its chain length and uniquely high degree of unsaturation may help to create a membrane with high fluidity, flexibility, and permeability. However, some studies of model membranes fail to support the long-standing hypothesis that DHA increases membrane fluidity.[198] The role of DHA may

be more specific in that it may involve modulation of the kinetics of carrier-mediated transport systems, the activity of membrane-bound enzymes, or the properties of membrane receptors.[195]

These characteristics of DHA seem to be necessary for the dynamic behavior of rhodopsin (the photosensitive pigment of rod photoreceptors) in the photoreceptive process.[198] Within the retina, DHA is concentrated in specialized membranes, which make up the photoreceptor outer segments. However, it has been shown that visual cell membrane fatty acid composition and thus early retinal development are influenced by small dietary changes in DHA and AA. A diet containing a balanced mixture of both fatty acids within the physiologic intake range is required to support an *n*-3–*n*-6 balance necessary for developing the highest rhodopsin content in the rod outer segments, with potentially important functional implications.[199] Research has begun to delineate a possible role of DHA in promoting optimal G-protein–coupled signaling systems in visual transduction.[200] It has been suggested that early visual experience and input during infancy may be critical to later visual function and may result in lasting consequences.[201] "More generally, delays in the early stages of visual, cognitive, and motor development can have a cascade of effects on later-maturing processes."[201]

In summary, high levels of DHA are found in the photoreceptor outer segment membranes of the retina and in the gray matter of the cerebral cortex. Some evidence, discussed extensively in Chapter 44, suggests a relationship between essential fatty acid intake and the development of visual functions.[127,130,131,202,203] Therefore, it is important to determine whether optimal extrauterine accretion of LC-PUFAs requires dietary supply of these fatty acids (perhaps originating as normal constituents of human milk) or arises sufficiently in vivo from chain elongation–desaturation of shorter-chain precursors (i.e., LA and ALA). Important research on this aspect of lipid metabolism, along with its clinical implications, is reviewed next.

APPROPRIATE BALANCE OF DIETARY FATTY ACID INTAKE FOR PRETERM INFANTS

Fat Requirements

"The human neonate and its mammalian counterparts have for millions of years received balanced nutrition during early infancy exclusively through breast-feeding."[204] Unfortunately, with replacement of human milk by cow's milk or formula, the nutritional requirements of the infant have become less clear.[205] The caloric requirement of the full-term infant younger than 1 year of age is 100 to 120 kcal/kg/day. For each 100 kcal of energy intake, the term infant requires a minimum of 1.8 g protein, 3.3 to 6 g of fat, 300 mg of essential fatty acid, and 11 to 17 g of carbohydrate.[206] The fat content of preterm infant formulas should be 4.0 to 6.0 g/100 kcal, which would provide 4.8 to 7.2 g/kg/day to infants fed 120 kcal/kg/day.[207] Regardless of the fat content of a particular formula, the fat intake of the infant is generous. A premature infant who receives 180 mL/kg/day of 20 kcal/oz formula will consume 6.2 to 6.8 g/kg/day of fat. By contrast, only 2 g/kg/day of fat must be deposited to simulate the intrauterine fat accretion rate. Some of the excess fat is subjected to oxidation and fecal excretion.[205] Studies of energy requirements indicate that the low-birth-weight infant requires approximately 80 kcal/kg/day for maintenance. Thus, in the low-birth-weight infant with an energy intake of 120 kcal/kg/day, some 34% of the calories fed will be used for tissue synthesis or growth. Because approximately half of the available calories in human milk are fat, then 36% of fat intake will be used for growth in the preterm infant (assuming 67 kcal/100 mL of milk and 90% fat absorption). Under these metabolic conditions (if all fatty acids are used for energy to a similar degree, if fat absorption coefficients are greater than 0.9, and if adipose tissue is synthesized in amounts and composition similar to those of intrauterine growth), the maximum requirements for essential fatty acids in infants weighing less than 1300 g can be estimated at 1100 mg for *n*-6 fatty acids and 140 mg for *n*-3 fatty acids per day.[208]

In human milk, *n*-6 and *n*-3 fatty acids normally represent a consistent percentage by weight of total fatty acids. Therefore it has been recommended that these values should be used as a guideline for the composition of infant formulas.[119] Quantitative and qualitative analyses of the composition of milk from mothers of preterm infants indicate that it provides levels of *n*-6 and *n*-3 essential fatty acids approximating the predicted requirements for day 16 of life, at intake levels of 120 kcal/kg/day. As the infant's body weight and milk intake increase, the net intake of essential fatty acid will approach and rapidly exceed the predicted requirements.[208] Levels of LC-PUFAs in human milk suggest that adequate intakes of mother's own milk also provide quantities of these membrane structural precursors in excess of their reported intrauterine rates of accretion in neural and liver tissues. If the rate of adipose tissue synthesis is projected for the extrauterine growth of a 1300-g low-birth-weight infant gaining 17 g of body weight per day, it can be estimated that synthesis of adipose tissues would use 185 mg/day of C20*n*-6 and C22*n*-6 fatty acids and 30.8 mg/day of C20*n*-3 and C22*n*-3 fatty acids. An adequate intake of mother's own milk provides 90 to 130 mg of C20*n*-6 and C22*n*-6 fatty acids per day and 55 to 75 mg of C20*n*-3 and C22*n*-3 fatty acids per day.[208] It thus seems prudent to feed the preterm infant human milk or formulas with a fatty acid balance similar to that of human milk, containing longer-chain homologues of LA and ALA.[171,209] Liu and colleagues,[210] using fish oil as a source of DHA (in a dose of 11 mg/kg/day), maintained red blood cell DHA concentrations in phospholipid in the range observed for human milk–fed infants. The effect of adding marine oil to infant formula has since been investigated in several species and under many different test conditions.[127,211-213] In general, this dietary maneuver causes a reduction of plasma and membrane levels of AA.[213,214] Supplementation of premature infants with long-chain homologues of ALA in the absence of long-chain homologues of LA not only leads to membrane abnormalities[215] but also decreases circulating levels of AA, resulting in a reduction in growth potential during the first year of life.[216,217]

Clandinin and co-workers[119,147] recommended that formulas for premature infants contain the appropriate balance of *n*-6 and *n*-3 metabolites of LA and ALA at concentrations that reflect normal human milk levels of these constituents and that will provide a ratio of *n*-6 to *n*-3 (C20 and C22) fatty acids of 1 to 1.4:1.[119] A clear dose response is produced in the levels of AA and DHA found in erythrocyte membrane phospholipids when preterm infant formula is supplemented with increasing levels of AA and DHA. It appears that a formula with 0.32% to 1.1% AA and 0.24% to 0.76% DHA provides sufficient levels of these fatty acids to achieve a membrane phospholipid fatty acid composition similar to that of infants fed human milk. Approximately 0.6% AA and 0.4% DHA provide sufficient and perhaps optimum levels of these fatty acids in formula-fed preterm infants.[147]

Composition of Fat

Postnatal growth seems to differ from fetal growth, especially with respect to fat deposition, and net absorption of fat improves with increasing gestational age. In animal models, the brain is sensitive to alteration of dietary lipid intake, even with a nutritionally complete diet. It is therefore reasonable to postulate that dietary lipids fed during the early postnatal period are important determinants of structural and functional components of developing brain tissues.[218]

Although the overall fat content of human milk and that of cow's milk appear to be similar, detailed analyses show marked differences in lipid composition and fatty acid pattern. Compared with human milk, cow's milk contains more saturated

fatty acids and many fewer essential fatty acids. Human milk contains somewhat more monounsaturated fatty acids and LC-PUFAs.[205] Current formulations have attempted to simulate the energy and fat content of human milk, resulting in various calorie-dense and fat-dense formulas on the market.[205] To correct dissimilarities in fatty acid composition, bovine milk fat must be augmented or replaced with various vegetable oils to provide mixtures that offer a low saturated fatty acid content and a higher unsaturated fatty acid content, including LA and ALA.

Formulas for premature infants have been further modified by incorporation of MCTs. The result has been that some formulas have fatty acid profiles that are very dissimilar to that of human milk, especially with respect to medium-chain fatty acids (considerably increased) and long-chain saturated fatty acids (decreased). In the newborn infant, synthesis of AA and DHA depends not only on adequate desaturase and sufficient supply of dietary LA and ALA but also on calories to support energy metabolism. Based on the composition of human milk, changes in blood fatty acid levels in preterm infants in energy balance, and studies of other species, it is possible to estimate fatty acid requirements for preterm and term infants. The European Society of Pediatric Gastroenterology and Nutrition (ESPGAN) committee recommended an LA-ALA ratio ranging from 5:1 to 15:1,[219] which is similar to the Canadian recommendation (which ranges from 4:1 to 16:1) when no C20 and C22 fatty acids are added.[220] This ratio probably should be closer to the lower than to the upper limit, and this goal can be accomplished by increasing the ALA and decreasing the LA content of commercial formulas.[214] For LA, the recommended intake is 4% to 6% of energy, and for ALA, a minimum of 1% of energy for preterm and term infants fed formulas not containing any AA or DHA.[214] Although the addition of 0.25% to 0.5% kcal of long-chain *n*-3 fatty acids is sufficient to maintain DHA levels and to keep activities such as retinal function at the same level as observed in breast-fed infants, it also reduces the accretion of AA. Therefore, when *n*-3 LC-PUFAs are added, *n*-6 LC-PUFAs should be added simultaneously.[72,119,214,219,221] Preliminary evidence suggests that the long-chain *n*-6–*n*-3 ratio should be approximately 1.1:1.4.[148,159] The Child Health Foundation Expert Consensus Workshop[222] recommended that infant formulas for term infants should contain at least 0.2% of total fatty acids as DHA and 0.35% as AA. For preterm infants, because of their lower body stores, formulas should include at least 0.35% DHA and 0.4% AA.

The inclusion of high amounts of medium-chain fatty acids in formulas may not be as important as was previously indicated, because use of such formulas, while conferring no benefit on energy balance and growth, may be associated with abnormal fatty acid metabolism.[140-143,146] Although high doses of MCTs do not seem desirable, no convincing evidence has emerged to show that they are harmful. Consequently, more extensive studies are needed to determine the optimal fat blend to use in formulas for low-birth-weight infants.

Previous assessments of the essential fatty acid status of the neonate focused on measures of visual function that are different and do not enable analysis of the site of the functional deficit or mechanism involved. Measures of immune function have similar difficulties; however, in neonates, the peripheral immune system is available for analysis. Human milk is known to contain many immunologic factors that reduce the incidence of infection and aid in immune development and maturation. One review[223] briefly outlined some of the effects of *n*-3 fatty acids on the immune system, involving the suppression of inflammatory response through effects on eicosanoids, although it is suggested that *n*-3 PUFAs have many noneicosanoid effects on the immune system as well. In rats, dietary saturated fatty acids have little effect on cytokine production, whereas *n*-3 PUFAs are potent inhibitors of the T_H1-type (proinflammatory) cytokines.[224,225] As determined by Field and colleagues,[226,227] feeding infants with or without AA and DHA alters the composition of functional cells related to maturity of the immune system. By linking changes in the specific cell types with release of subcellular messages (exocytokines) and their receptors, it is possible to develop dynamic measures of cell function that can be used to link known physiologic functions through biochemical mechanisms altered by changes in the essential fatty acid status. The addition of AA and DHA to preterm formula, at levels similar to those in human milk, can influence the proportion, maturation, and cytokine production of peripheral blood lymphocytes. Improvement of the ability of peripheral mononuclear cells to produce interleukin-10 by supplemented preterm infants as compared with standard formula–fed infants suggests that these dietary modifications may aid induction of tolerance to oral antigens. Further studies will elucidate other aspects of immune development, including antigenic response.[227]

Parenteral Lipid Emulsions and Potential Complicating Factors

TPN frequently is considered when the gastrointestinal tract is not capable of digesting and absorbing nutrients. The basis for calculating nutrient requirements in infants receiving TPN is similar to that for the enterally fed neonate, except malabsorption and the energy cost of the digestion and absorption of food need not be considered. Current research, however, indicates that the enterocyte possesses significant fatty acid desaturation activity.[228] Thus parenteral feeding of fats may bypass this physiologic control over fatty acid metabolism.

The fat particles in emulsions are similar in size to chylomicrons and, like the latter, are cleared from the circulation by lipoprotein lipase[229] and by hepatic lipase.[230] As compared with the use of 10% lipid emulsions, the use of a 20% lipid emulsion does offer the advantage of more efficient triglyceride clearance with lower cholesterol and phospholipids in low-density lipoproteins.[231,232] This finding suggests that excessive phospholipid liposomes in 10% lipid emulsions, as opposed to the liposome-poor 20% emulsion, impede the removal of triglycerides from plasma. Friedman and colleagues[233] studied sick newborns who were maintained on fat-free intravenous alimentation. These infants demonstrated very rapid biochemical changes in plasma that were compatible with essential fatty acid deficiency during the first week of life and were reversible with oral feedings containing essential fatty acids. Infusion of lipid emulsions rapidly reversed clinical symptoms of essential fatty acid deficiency and returned plasma phospholipid *n*-6 fatty acid levels to normal. However, the erythrocyte and liver phospholipid *n*-6 fatty acid content and adipose tissue reserves of *n*-6 fatty acids normalized more slowly. Similar findings have been observed in experimental animals.[234] Innis[235] studied the effect of TPN with LA-rich emulsions on tissue *n*-6 and *n*-3 fatty acids in the rat and concluded that intravenous administration of large amounts of LA in parenteral lipid reduces desaturation and elongation of essential fatty acids but does not competitively inhibit esterification of other fatty acids into phospholipid. Innis also reported that after 3 days of fat-free parenteral nutrition, not only are DHA and AA both diminished in the red cell membrane phospholipids,[236] but some biochemical signs of essential fatty acid deficiency develop as well.[237] Essential fatty acid deficiency is avoided by intravenous lipid infusions of 0.5 to 1.0 g/kg/day.[238]

Energy metabolism, fat accretion, and oxidation in parenterally fed infants are determined not only by total energy intake[239] but also by the composition of the nonprotein calories.[240-243] The proportion of nonprotein calories supplied as intravenous fat probably should range between 30% and 50%. Commercial lipid emulsions contain excessive amounts of LA and no long-chain derivatives of either LA or ALA in the triglyceride fraction. In adults, the use of medium- and long-chain triglyceride mixtures may alter LC-PUFA synthesis, but no similar evidence is available

for neonates.[244] It also is not known whether this alteration in long-chain fatty acid metabolism results from a reduction in LA content or from the addition of MCTs to the intravenous lipid emulsion. Research involving structured lipid emulsions in which both medium- and long-chain fatty acids are esterified to the same glycerol backbone indicates that use of such emulsions could be a safe and well-tolerated approach to TPN.[245]

Delineation of the physiologic and pharmacologic effects of the LC-PUFAs in disease states may lead to development of therapeutic modalities directed at inflammation, endotoxin effects, liver cholestasis, and pulmonary hypertension.[246-248] Some concern has been raised regarding the occurrence of hepatic injury with intravenous lipid administration. The current belief is that TPN-associated cholestasis is increased in infants receiving fat emulsions.[250,251] The inclusion of *n*-3 PUFAs in intravenous lipid emulsions may be a way to decrease the incidence of TPN-induced cholestasis by improving the bile flow, which is reduced by intravenous soybean oil emulsions.[248] Very significant changes have been found in the fatty acid composition of liver ethanolamine phosphoglycerides and choline phosphoglycerides in infants receiving TPN with a soybean oil emulsion as the lipid source. These alterations have included an increase in LA, a decrease in linoleate elongation-desaturation products, and a decrease in the level of DHA in liver phosphatidylethanolamine and phosphatidylcholine. In the brain, an increase in the LA content of choline phosphoglyceride has been observed; however, it has not been accompanied by any increase in the *n*-6 LC-PUFAs. These findings demonstrate a potential for adverse effects of high doses of LA on the tissue levels of LC-PUFAs.[252] Conversely, fish oil–enriched emulsions reduced the impairment of bile flow seen in a newborn piglet model of TPN cholestasis.[253] Although feeding the fish oil emulsion resulted in alterations in canalicular and sinusoidal fatty acid composition of membrane phospholipids, the mechanism responsible for the prevention of cholestasis is not known. Changes in eicosanoid metabolites may be partly responsible. More research is required to determine clinical applications of fish oil–enriched emulsions in human neonate TPN.[253]

The necessity of carnitine supplementation for the metabolism of intravenous lipid metabolism remains uncertain, because some studies have demonstrated beneficial effects, which could not be confirmed by others. Comparisons are difficult to make, however, because the studies used different doses of carnitine.[254] Carnitine is present in human milk[255,256] and is essential for fatty acid metabolism, but high doses may have an undesirable effect.[257] No convincing data have documented physiologic or metabolic benefit of giving carnitine to infants receiving intravenous lipid. If carnitine is given, the dose should not exceed the amount a breast-fed infant receives (i.e., 15 μmol/100 kcal).

In summary, the fatty acid composition of commercial lipid emulsions is inappropriate in that it is unphysiologic and results in abnormal composition of circulating and tissue membrane lipids. For prevention of essential fatty acid deficiency, 0.5 to 1 g/kg/day of intravenous lipid is required, preferably as a 20% emulsion. To maintain an acceptable energy balance, 0.5 to 1 g/kg/day of intravenous lipid as part of the TPN solution should be introduced by the postnatal age of 24 to 48 hours. This dose can be progressively increased (by 0.5 to 1 g/kg/day) in incremental daily or alternate-day steps, as tolerated, up to 3 to 4 g/kg/day, while triglyceride clearance is monitored.

Brown Adipose Tissue: Development and Function

Mammals such as humans are exposed to their greatest temperature-related shock at birth. Coming from a protected and thermoneutral environment, the newborn infant is suddenly exposed to "cool" surroundings, where survival depends on self-generation of sufficient heat to keep warm.

The development of the ability to regulate body temperature regardless of the temperature of the surroundings (and through this to ensure that the activity of the organism is constant and high) apparently was a necessary step in the evolution of so-called higher animals. A requirement for this development was that newborns be endowed with a physiologic ability to produce the heat essential for survival. To accomplish this, an organ was developed without parallel in cold-blooded animals, an organ endowed with the function of producing heat exactly when required, especially around the time of birth. This organ is brown adipose tissue.

Thus, in evolutionary terms, brown adipose tissue is a rather new organ. Even within the scientific community, brown adipose tissue is rather "new." Its function as a heat producer in the cold[1] and in newborns[2,3] was first described less than 50 years ago. However, during subsequent years, understanding has grown about the events responsible for the heat production in that tissue,[4-10] and at present, researchers are actively elucidating mechanisms underlying the recruitment processes in brown adipose tissue (i.e., those processes that, during perinatal development, are responsible for the growth and differentiation of the tissue).

One of the most important accomplishments in research on brown adipose tissue thermogenesis has been the recognition that the ability to produce heat resides in the fact that brown adipose tissue mitochondria are endowed with a unique protein—the original uncoupling protein (i.e., UCP1), thermogenin. This protein functions as a regulated protonophore through the mitochondrial membrane. The identification of this protein has in many ways consolidated brown adipose tissue research, so a description of the function and fate of this protein must be a central issue in a review on the perinatal recruitment of brown adipose tissue.

DEVELOPMENT OF BROWN ADIPOSE TISSUE IN HUMAN INFANTS AND OTHER NEWBORNS

Significant differences in perinatal development of brown fat (and many other characteristics) have been documented among newborns of different species.[11-15] Broadly speaking, three different groups of newborns can be distinguished: altricial newborns, so-called true immature newborns, and precocial newborns.[11]

The *altricial* (literally, nest-dependent) newborns often are whelped as members of litters of more than five pups. They are poorly developed at birth, have no fur, are blind, and move poorly if at all. To keep warm, they huddle together. As discussed later on, development of brown adipose tissue in these newborns is a slow process that starts just before birth and reaches its

maximum some days after birth. The main driving force for this recruitment is probably the (comparatively) low environmental temperature coupled with the attempt by these newborns to activate processes to oppose hypothermia. Rat and mouse pups belong to this group. The morphologic and ultrastructural development of the tissue in these animals has been described in several papers.[16-21]

The *immatures* (not to be confused with prematures) are not able to respond to the environmental temperature at birth and are truly poikilothermic. In species with immature newborns, the recruitment process in brown adipose tissue starts only when the central control system has developed, after which processes occur that seem similar to those elicited immediately after birth in the altricial newborns. Hamster pups[22] belong to this group.

The *precocial* newborns normally are born singly or in small litters. They are very well developed, their eyes are open, they are furred, and they can walk around shortly after birth. These newborns are born with well-developed brown adipose tissue, which tends to atrophy postnatally. It is unknown how this uterine recruitment of brown adipose tissue is accomplished. Certain small newborns, such as the guinea pig,[25] belong to this group, but more obvious members are the newborns of many larger species, such as lambs,[26,27,28] goats,[29] calves,[30,31] and musk oxen.[32]

Classification of the human infant (or other primate infants[33]) as either altricial or precocial is not self-evident. Although born in a somewhat developed state, the human infant has several traits of immaturity and probably is most akin to the altricial newborns—specifically, human perinatal brown adipose tissue development has similarities to that found in the newborn rat pup.

HOW MANY ADIPOSE TISSUES EXIST?

Experiments concerning the function of most body organs are helped from a practical standpoint by the fact that most organs are anatomically well-defined entities with a single localization in the body and with structurally homogeneous and stable cells. Unfortunately, such characteristics do not pertain to brown adipose tissue.

In the human infant, the major depots are in the neck, under the clavicles, around the intercostal arteries, and around the kidneys and adrenals. Only a thin sheet of interscapular brown adipose tissue is found.[34,35,35a]

Distinguishing between white and brown fat is not straightforward. When activated, brown adipose tissue can be distinguished from white by its ability to express UCP1. However, because the potential ability to express UCP1 in a given cell (in a given physiologic situation) may not have been invoked at the moment of study, it is likely that each anatomically defined depot contains cells that are genuinely "white," as well as cells that are only visually disguised as white but that still carry the potential to be brown. Leptin is well expressed in white adipose tissue, but it is not expressed in recruited (i.e., activated) brown adipose tissue.[36] It is, however, expressed in nonactive brown adipose tissue, and its expression in both adipose tissues is inhibited by sympathetic stimulation.[37]

Morphologically, even epididymal white adipose tissue can be altered by an intense cold stress to visually resemble brown adipose tissue and to have brown fat–like mitochondria.[38,39] Not even under these extreme circumstances, however, has it been possible to detect UCP1 as a protein immunologically or to identify UCP1 messenger RNA (mRNA) in this tissue.[39] Thus, within this depot, apparently only truly white fat cells are present. By contrast, in the parallel female tissue, the parametrial fat pad, good evidence has emerged for the presence of genuine brown fat cells (i.e., those containing UCP1).[40] Additionally, UCPI may be detected in small amounts in other depots of seemingly white adipose tissue.[40a,40b]

In certain species, even the subcutaneous adipose tissue (which generally is believed to have storage and insulatory properties) can be brown. As indicated by a functional analysis of the mitochondria in the subcutaneous adipose tissue of newborn seals[41] and in dog pups treated with sympathomimetics,[42] the presence of UCP1 in subcutaneous tissue can be discerned.[43] In these species, the subcutaneous adipose tissue works not only as a blanket but also as an "electric blanket." Thus, although certain fat depots apparently lack any capacity for conversion to brown fat, most depots have this potential, and UCP1 may be expressed under certain physiologic or pharmacologic circumstances.

As a general rule, more visible brown adipose tissue depots are present in the newborn than in the adult, even the cold-acclimated adult. It has been stated that in some newborn species, all adipose tissue is brown, and these depots are converted to white adipose tissue in the adult. In cell biology, however, the meaning of this statement is vague,[44] and no strict lineage relationship between brown and white adipose cells has been clarified. Recent studies indicate that brown and white adipose tissues are of distinct lineages, with the brown having a close relation with a skeletal muscle lineage.[40b,45,46,] Certainly, the behavior of certain depots that look white in the adult is functionally close to that of brown adipose tissue in the newborn, and the fat in these depots retains some potential to again become brown.[47]

UCP1 AND THERMOGENESIS

Heat production may result from shivering or nonshivering thermogenesis. In the newborn infant and in the adult animal, the first resource used for extra heat production is nonshivering thermogenesis. Only after this capacity is fully utilized does shivering begin. In an adult living in a warm environment, with little active brown adipose tissue, shivering is the dominant source of extra heat production initially. In the infant, however, the ability to shiver sufficiently and intensively enough to produce substantial amounts of heat does not seem to be fully developed, so brown adipose tissue is the sole source of heat production.

Heat produced during nonshivering thermogenesis results directly from the activity in brown adipose tissue of the unique mitochondrial UCP1; in the absence of this protein, no heat is produced in brown fat cells.[48,49] Heat production is governed by signals from the hypothalamus. These signals are relayed through the sympathetic nervous system and transmitted to the cell as a norepinephrine stimulus leading to a series of events within the cell (for overview, Figure 43-1). Sympathetic innervation to the tissue is dense. One system of fibers, which contains the costored neuropeptide Y (NPY), innervates the numerous blood vessels entering the tissue, and another system innervates the adipocytes.[50] The neuropeptides calcitonin gene–related peptide (CGRP) and substance P also are found in the tissue, the latter in afferent nerves; however, the localization of CGRP currently is not completely clarified, and the functions of these neuropeptides are unknown.[51]

THE UNCOUPLING PROTEIN UCP1 (THERMOGENIN)

Considerable research by several groups of investigators led to the identification of UCP1 as the key enzyme in nonshivering heat production. Much is known today about this protein (Figure 43-2, *A*). It has been sequenced both as a protein and from complementary DNA (cDNA) clones corresponding to the UCP1 mRNA. The amino acid sequence is known for many species of mammals.[52-55] The amino acid sequence of the human protein is 79% homologous to that of the rat protein, allowing considerable immunologic cross-reactivity between human UCP1 and rodent UCP1.[56] The human UCP1 gene has been isolated[57,58] and its organization analyzed.

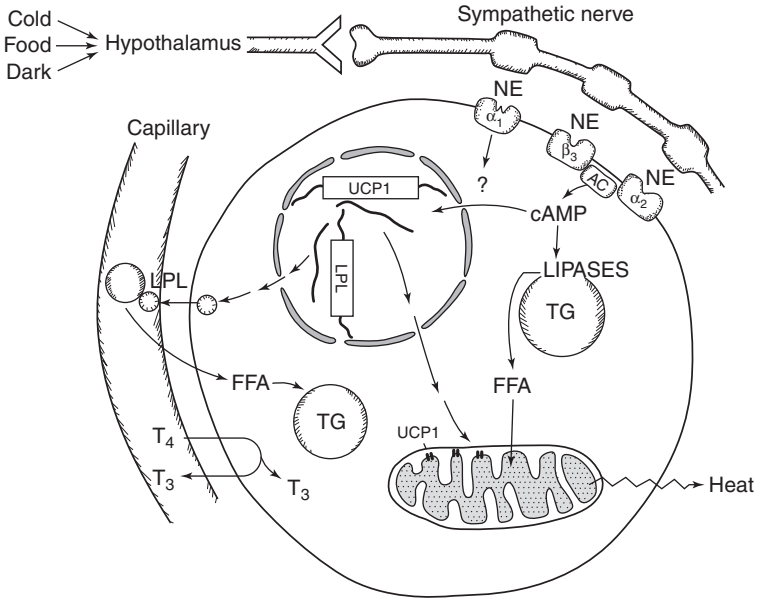

Figure 43-1 Function of the brown fat cell: An overview. When postnatal cold is perceived, the sympathetic nervous system is activated. Norepinephrine (NE) is released and interacts with adrenergic receptors, leading to release of fatty acids, which undergo combustion in the mitochondria. This combustion is possible as a result of the presence of uncoupling protein-1 (UCP1). Further substrate is provided by the action of lipoprotein lipase. Brown adipose tissue also may produce triiodothyronine (T_3) from thyroxine (T_4), leading to local and systemic effects. Dietary factors and darkness also activate centers in the hypothalamus in a manner analogous to that of norepinephrine. *AC,* Adenylyl cyclase; *cAMP,* cyclic adenosine monophosphate; *FFAs,* free fatty acids; *LPL,* lipoprotein lipase; *TG,* triglycerides.

UCP1 is a member of the superfamily of mitochondrial carrier proteins (see Figure 43-2, *B*).[59-61] Most closely related to UCP1 are two more recently identified but evolutionarily more ancient proteins known as UCP2 and UCP3 because of their extensive homology with UCP1.[62] The functions of these proteins remain unclear. They are, however, not responsible for any thermoregulatory thermogenesis.[49] Other proteins (e.g., those termed UCP4, UCP5) are not closely related to UCP1; therefore functional relationships cannot be expected.

From analysis of the amino acid sequence, it has been proposed that UCP1 may constitute three membrane-spanning Us, as shown in Figure 43-2, *A*. When functionally inserted into the brown fat mitochondrial inner membrane, UCP1 endows these mitochondria with a series of unique properties, including a high rate of respiration in the absence of adenosine diphosphate (ADP) or uncoupler addition, a high proton conductivity, and a high Cl^- conductivity.

THE *UCP* GENE

The *UCP1* gene is found on chromosome 8 in mice[63] and on chromosome 4 in humans.[64] Only one copy of the gene is present.[57]

An interesting functional and evolutionary connection between the exon-intron pattern of the *UCP1* gene and the suggested transmembrane structure of the protein has been described: Each of the six proposed membrane-spanning segments is represented by one exon.[55,64,65] This pattern also is found in the other *UCP* genes. A gene for a proto UCP1 exists in fish,[65a] and a rapid evolution led to this proto UCP1 gaining its thermogenic function in mammals.[65b]

ACUTE REGULATION OF UCP1 ACTIVITY

The function of UCP1 in the mitochondrial membrane is depicted in simplified form in Figure 43-3. UCP1 acts as the equivalent of a proton translocator, allowing dissipation of the proton gradient that has arisen from the functioning of the respiratory chain.

UCP1 cannot be constantly active, because such activity would lead to constant high heat production in the tissue, irrespective of the environmental (or ambient) temperature. In experiments with isolated mitochondria, it has been observed that the activity of UCP1 can be inhibited by the addition of purine nucleotides.[66,67] Traditionally, GDP has been the nucleotide of choice for such experiments, and thus, UCP1 has been known as the GDP-binding protein. This protein is not related to the G-proteins in signal transduction, nor to the ribosomal guanosine triphosphate (GTP)-binding proteins, and the term may be considered to be physiologically misleading, because adenosine triphosphate (ATP) is as good as or better than GDP both for binding and in inhibiting respiration.[68,69] Because ATP is present in much higher concentrations in the cytosol of brown fat cells than is GDP,[70] ATP is the physiologically relevant nucleotide that binds to UCP1 and inhibits thermogenesis when thermogenesis is not physiologically required.

The affinity of UCP1 for ATP is so high that the binding site would probably always be saturated with ATP and thermogenesis inhibited if this were the only agent that interacted with UCP1. Thus it is necessary to postulate the existence of a physiologic activator of UCP1.[67] The nature of this "positive" modulator continues to be investigated. A detailed analysis of the problem is outside the scope of this chapter, but a few main points can be summarized here.

Among the many suggestions, the most simple hypothesis for the nature of this modulator is that it is produced during the release of fatty acids, occurring as an effect of stimulation of the cell. Within this framework, several alternatives have been proposed. The positive modulator could be the free fatty acids themselves.[67,71,72] The most telling experiments that indicate a direct effect of free fatty acids are those of Rial and colleagues.[73] More recent experiments support this theory.[74] Alternatively, the fatty acids have been suggested to have a catalytic function, although in this case a positive modulator may be involved.[75,76] Another hypothesis along the same line has suggested that palmitoyl-coenzyme A (CoA) may interact directly with UCP1.[77,78] Each proposal has advantages and problems. Although conclusive experiments have been published that the modulator is downstream of lipolysis, general agreement on the mechanism has not yet been reached.

POSSIBLE SEMIACUTE REGULATION OF UCP1 ACTIVITY

Under certain conditions, apparently no direct correlation has been established between the amount of UCP1 (e.g., as measured immunologically) and the activity of UCP1 (as estimated by GDP binding or proton or Cl^- translocation). When the level

of activity is found to be lower than expected, the phenomenon has been termed *masking* of UCP1.[79] UCP1 thus typically is masked when it is inactive (as is probably the case in utero) but becomes *unmasked* when called into function. Accordingly, it is reasonable to speculate that the rapid increase in GDP-binding capacity seen shortly after birth in guinea pigs[25] may be due to this unmasking mechanism.[80]

ADAPTIVE REGULATION OF UCP1 AMOUNT

The total amount of UCP1 in the newborn is expected to be the rate-limiting factor for nonshivering thermogenesis. In newborns and adults, the amount of UCP1 is under precise regulation. Although a significant temporal delay between a change in UCP1 mRNA and the ensuing increase in amount of UCP1 has been documented,[81] the simplest explanation is that the mRNA level determines the protein level.

Receptors Involved

The major stimulus for UCP1 gene expression is from the sympathetic nervous system through the release of norepinephrine. β-Adrenergic receptors are well recognized to be involved in this regulation.[82-84] Furthermore, some evidence indicates that simultaneous α-stimulation is necessary in vivo.[83] Perhaps this α-stimulation is of a permissive nature.

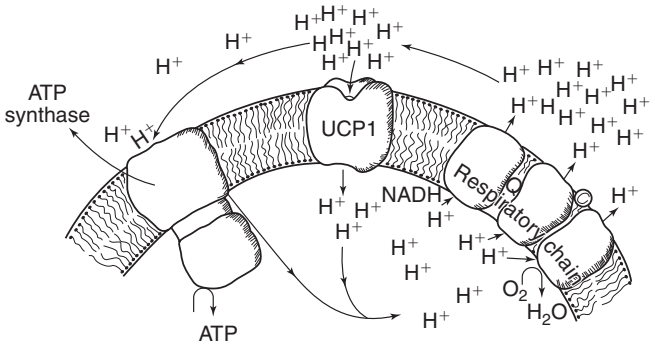

Figure 43-3 Suggested function of uncoupling protein 1 (UCP1) in the brown fat cell. UCP1 functions as a regulated translocator of protons (or proton equivalents) through the mitochondrial membrane, thereby allowing dissipation of the proton gradient built up by the respiratory chain, as a consequence of the oxidation of substrate, such as nicotinamide adenine dinucleotide *(NADH).* Thus respiration can proceed unlimited by the turnover of adenosine triphosphate *(ATP). (Based on descriptions in Nicholls DG: The bioenergetics of brown adipose tissue mitochondria,* FEBS Lett *61:103, 1976.)*

Perinatal UCP1 Expression

Altricial Species

The amount of UCP1 increases around the time of birth (in mice and rats).[21,85] This increase is caused by a concomitant increase in the amount of UCP1 mRNA[84,86,87] (Figure 43-4, *A* and *B*). The cause of the postnatal recruitment in brown adipose tissue (and increase in UCP1 mRNA) could be either ontogenic or an effect of the cold stress experienced by the pups at birth.[11] No postnatal increase in UCP1 mRNA occurs in the absence of a postnatal cold stress (see Figure 43-4, *C*); presumably, therefore, in these species, the postnatal brown adipose tissue recruitment is a response to the cold stress experienced by the newborn.[87] This correlation indicates that the increase is mediated by sympathetic activation as in adults.

Immature Newborn Species

In immature-type newborns, the increase in UCP1 occurs rather late.[22,23] It is conjectured that when the ability to react to environmental cues has developed in these animals, the recruitment of brown adipose tissue takes place in the same way as already described for altricial species.

Precocial Newborn Species

In species with precocial newborns, UCP1 is expressed in the fetal state.[25,30,88] Because fetal production of excessive heat would be potentially lethal, it follows that a uterine inhibitor of thermogenesis must exist, which still allows transmission of the signal for gene expression to occur but inhibits a thermogenic response. Without such an inhibitor, the activation signal presumably would trigger fetal heat production in utero. In experiments in which the umbilical cord has been sectioned, some indications for the existence of such an inhibitor have been observed.[89-92]

The central signal that leads to sympathetic stimulation of the tissue in utero is unknown. It cannot be a cold stimulus and could hardly be a food stimulus. The only other documented pathway for sympathetic stimulation of brown fat recruitment is through short day length,[93] probably mediated by the pineal gland and melatonin. It could be argued that the fetus lives its life in darkness, and that newborns are more sensitive to the day's elapsed length.[94] Whether such a mechanism could function in precocial species is doubtful, and most available data indicate that it is merely the dam's level of melatonin that is reflected in the fetal blood level.

Alternatively, another mechanism of recruitment, independent of sympathetic stimulation, may be postulated: Specifically, it is possible that activators of peroxisome proliferator–activated receptor-gamma (PPAR-γ) are formed and stimulate UCP1 expression without concomitant thermogenesis.[94a]

The Human Newborn

Because the classification of the human newborn as precocial or altricial is not fully clear, it is not evident which animal neonate is the best for experimental models to make determinations that may be considered applicable to the human infant. Human brown adipose tissue is present in considerable quantities at term gestation but also demonstrates a postnatal increase.[95] The amount of UCP1 is high in children, and brown adipose tissue containing UCP1 is found in a significant fraction of adults.[96-100,100a-100f]

SUBSTRATES FOR THERMOGENESIS

Intracellularly Derived Fatty Acids

During the initial acute phase of thermogenesis, the supply of fatty acids for combustion comes from triglyceride droplets found within the tissue. The release of fatty acids for combustion is caused by a series of events similar to those known to occur in white fat cells, leading to a release of fatty acids in the circulation. Thus stimulation of β-receptors leads to an increase in intracellular levels of cyclic adenosine monophosphate (cAMP),[101] which in turn leads to activation of the cAMP-dependent protein kinase (see Figure 43-1). Both of these events can be observed during postnatal development: cAMP is elevated in brown adipose tissue,[102,103] and the activity ratio of cAMP-dependent protein kinase increases, from 0.3 in fetal tissue to 0.7 after birth.[104]

Different Adrenergic Receptors

A β-adrenergic receptor is the adrenergic receptor type involved in the increase in cAMP in fully differentiated brown adipocytes. In rodents, it is the β_3-receptor that is predominantly involved, but the situation in human brown fat is less clearly understood.[105-110] The effects of β-receptor activation on cAMP levels may be counteracted by α_2-adrenergic receptors, which also are found in brown adipose tissue of fetuses and newborns.[111-113] Adenosine receptors also may counteract β-stimulation.[114]

Brown fat cells also are endowed with α_1-adrenergic receptors.[115] Although some of their intracellular actions are known,[116-118] their significance for thermogenesis is not fully understood. In in vitro experiments, only a small fraction of thermogenesis resulting from adrenergic stimulation can be

demonstrated to result from stimulation of α_1-adrenergic processes. Nonetheless, a large fraction of nonshivering thermogenesis can be inhibited in vivo by α_1-blockade[119] in the newborn rabbit. This effect may be secondary to cardiovascular phenomena. In isolated cells, α_1-adrenergic stimulation may enhance the effectiveness of cAMP.[120]

Protein Kinase and Hormone-Sensitive Lipase

One substrate for the activated cAMP-dependent protein kinase is the hormone-sensitive lipase found in brown adipose tissue.[121] Activation of this lipase leads to the breakdown of diglycerides formed by the action of adipose tissue triglyceride lipase (ATGL) on the stored triglycerides; how ATGL is stimulated is still unclear.[121a] The fatty acids released probably undergo immediate combustion in the mitochondria, whereas glycerol probably is released to the circulation. The decrease in triglyceride droplet size after birth can be seen on electron micrographs.[18]

Whether a physiologically significant release of fatty acids from brown adipose tissue into the circulation occurs is still unconfirmed. It originally was suggested that brown fat (unlike white fat) did not release any fatty acids to the circulation,[122] but isolated brown fat cells break down more triglycerides to fatty acids than can be subject to combustion within the cells and release fatty acids in vitro.[123] Investigations of the effluent blood from brown adipose tissue have yielded somewhat variable results,[124,125] but a capacity for export is likely.

Also unknown is whether increases in plasma levels of fatty acids observed in cold-stressed animals may be due to an increased release from brown fat and thus reflect the activity of this tissue. Tissue ablation experiments have indicated that this may be the case,[126] especially in newborns in whom a large fraction of the adipose tissue found is in the form of brown adipose tissue.

Fatty Acids From the Circulation

The brown fat cell is endowed with a store of triglycerides that can be used in any situation in which thermogenesis is required. This store is limited, however; in newborn rabbits, the amount of stored triglycerides is sufficient for only 3 days of heat production. After this time, unfed rabbits die as a result of hypothermia.[127] Similar observations can be made in premature human infants.[128] To ensure a constant supply of substrate for combustion, additional substrate must be supplied by the circulation. Only under conditions of starvation before cold stress has it been reported that the uptake of circulating free fatty acids is significant.[129] The quantitatively most important source of lipid substrate is that found in chylomicrons, which are formed from ingested food. Fatty acids in chylomicron triglycerides are released to the brown fat cells by the enzyme lipoprotein lipase.

Regulation of Lipoprotein Lipase

In contrast with the situation in white adipose tissue, brown adipose tissue lipoprotein lipase activity is increased by adrenergic stimulation.[130,131] (In this respect, the tissue is similar to that of the heart.) This stimulation is mediated by β-adrenergic receptors, resulting in an increase in cAMP and an ensuing increase in the expression of the gene for lipoprotein lipase.[131-134] This is a comparatively slow process, requiring several hours to reach full effect, because the lipase must be synthesized and transported to the capillaries. Thus the tissue cannot rely on this process to generate an acute thermogenic response.

Insulin also can stimulate lipoprotein lipase activity.[135-137] This insulin stimulation does not seem to be mediated through central effects and the sympathetic nervous system; instead, it seems to be a direct effect of insulin on tissue in states of proper nutrition. Insulin stimulation also is mediated through an increased expression of the lipoprotein lipase gene.[133,134]

Perinatal Recruitment of Lipoprotein Lipase

Lipoprotein lipase activity is low in the fetus but increases postnatally[138] (Figure 43-5, *A*). This postnatal increase also can be seen in premature pups. It is not known whether the increased activity is an effect of suckling, temperature change, or release of an inhibitor transferred through the umbilical cord.

When this "birth-induced" increase in activity is evaluated in the context of measurements of lipoprotein lipase mRNA, an

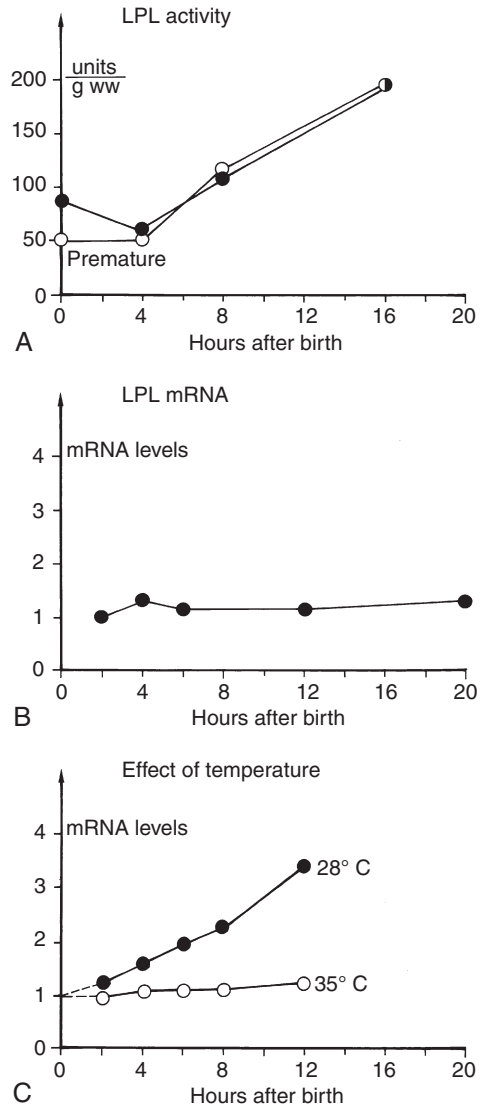

Figure 43-5 Lipoprotein lipase *(LPL)* activity and gene expression. enigma arises, however (see Figure 43-5, *B*): Lipoprotein lipase mRNA is not increased (possibly owing to an inhibitory factor in the colostrum).[139] To explain the discrepancy between lipoprotein lipase mRNA level and lipoprotein lipase activity, a transfer of lipoprotein lipase across gut membranes has been suggested.[87] This hypothesis requires further investigation. Under conditions of mild cold stress in the absence of the dam, however, lipoprotein lipase mRNA level within brown adipose tissue increases, apparently through processes similar to those described in the adult (see Figure 43-5, *C*).

One effect of this postnatal activation of lipoprotein lipase on the fatty acid composition of tissue triglycerides is that fatty acids become more unsaturated and in this respect reflect the composition of the diet (i.e., the mother's milk).[140-142]

Pathology

No pathologic state that involves activity of lipoprotein lipase in human brown adipose tissue is known, but a fatal genetic disease in mice, combined lipase deficiency (the mutation is therefore designated cld/cld), leads to the synthesis of an inefficient lipoprotein lipase.[143] The absence of lipoprotein lipase activity has the expected effect of reducing the amount of fat droplets in brown adipose tissue.[144]

Glucose

Uptake of glucose was early documented in brown adipose tissue in the newborn rabbit,[129] but the identification of brown adipose tissue through intense glucose uptake in adult man demonstrates that this is a general process.[100,100a-100d,100f] The glucose probably is used mainly as a substrate for thermogenesis, but on the basis of in vitro experiments, it may be envisaged that this uptake of glucose may also function to increase the catabolic capacity of the citric acid cycle through the action of pyruvate carboxylase.[145] Brown adipose tissue also shows insulin-sensitive glucose transport through redistribution of the GLUT4 glucose transporter from intracellular vesicles to the plasma membrane.[146] Glucose uptake in brown adipose tissue is markedly stimulated by cold exposure; this stimulation is mediated through norepinephrine rather than insulin. Although it apparently does not alter GLUT4 distribution, norepinephrine may increase either GLUT1 or GLUT4 activity and, correspondingly, glucose uptake rates.[147-149]

Fatty Acid Synthesis

The significance of lipogenesis in brown adipose tissue has been discussed. The capacity for lipogenesis in brown adipose tissue is high.[150,151] Lipogenesis also has been observed in human infants.[152] However, strong evidence suggests that this lipogenesis is not of quantitative or qualitative significance for thermogenesis. Rather, it could be considered to represent a "refilling" reaction that occurs in tissue after cessation of the thermogenic stimulus. Thus, during the perinatal period, the activity of lipogenesis is low when thermogenesis is high. This inverse correlation probably is due to the effect of suckling (i.e., a change from a high-carbohydrate "diet" in the fetal state to a high-lipid diet). A direct inhibitory effect of increased sympathetic stimulation on lipogenesis also has been postulated.[11] Weaning, which reintroduces a high-carbohydrate diet but also coincides with a reduced demand for thermogenesis, is associated with an increase in lipogenesis.

The so-called lipogenic enzymes (in addition to the fatty acid synthase complex) include pyruvate dehydrogenase, the citrate cleavage enzyme (ATP citrate lyase), acetyl-CoA carboxylase, glucose-6-phosphate dehydrogenase, 6-phosphogluconate dehydrogenase, and malic enzymes.

All of these enzymes generally follow the same perinatal pattern: Levels are high in the fetal state and much reduced during suckling, returning toward high fetal values as suckling ends.[11] For malic enzyme, it has been demonstrated that this phasic pattern is due to a change in the amount of enzyme (not a change in activity of existing enzyme).[153]

The activities of the glycolytic enzymes increase after weaning,[154] indicating that during the time when the diet consists of milk alone, it is those fatty acids that supply brown adipose tissue and are spent in combustion. Only after weaning to a diet rich in carbohydrates does glycolysis contribute to fatty acid synthesis.

Amino Acid Uptake

The possibility that amino acid uptake occurs has been investigated. It generally is believed that this pathway is of minor importance for the functioning of brown adipose tissue.[155] Amino acid uptake could account for approximately one third of the uptake of glucose. Several amino acids have propionyl-CoA as the end product of oxidation. This three-carbon fatty acid cannot be degraded through the normal β-oxidation pathway for fatty acid derivatives, so detrimental levels of this fatty acid could accumulate, resulting in a sequestration of all mitochondrial CoA, with consequent inhibition of thermogenesis. This effect may explain why the mitochondria have a high activity level of a propionyl-CoA hydrolase with unusual regulatory properties.[156-158] This hydrolase also could function to recover the CoA otherwise bound up in the propionyl-CoA.

5′-DEIODINASE AND THYROID

In brown adipose tissue, high activity of thyroxine 5′-deiodinase, which produces the active thyroid hormone triiodothyronine (T_3), has been described[129] (Figure 43-6). The 5′-deiodinase found in brown adipose tissue has been classified as a type II deiodinase (distinguished from type I by its insensitivity to propylthiouracil in vitro[159] and by its being induced by hypothyroidism in vivo[160]). The gene has been cloned.[161] The enzyme probably is localized to the endoplasmic reticulum. The presence of 5′-deiodinase has been demonstrated in human, lamb, and rodent brown fat.[159,162,163]

Internal Action

It is thought that the activity of the 5′-deiodinase is important both for the normal development of brown adipose tissue and for the rapid increase in brown fat during the perinatal period. The T_3 produced probably binds to T_3 receptors found within the tissue[164,165] (Figure 43-6) and in this way influences expression of the *UCP1* gene through binding to sequences in the promoter region.[166] Indeed, hypothyroidism leads to a decreased expression of UCP1 in both rats and lambs (see Figure 43-4, *A*).[86,162] However, in mice in which the nuclear thyroid hormone–binding receptors are ablated, UCP1 expression is high, confirming that the hormone is required primarily to relieve a repression, rather than to cause activation.[167,168]

Systemic Action

The possibility also has been considered that brown adipose tissue 5′-deiodinase is of systemic physiologic significance in that it could release T_3 from brown fat into the circulation.[169] Indeed, such release has been substantiated in the newborn rat.[170]

T_3 could be responsible for the small increase in basal metabolism sometimes found in conditions in which brown fat is stimulated, but no experiments have been performed in which brown fat has been removed to investigate this possibility.

In addition to the metabolic effects of T_3, thyroid hormone also may have an important role in promoting differentiation. Some interesting but as-yet unconfirmed observations suggest that

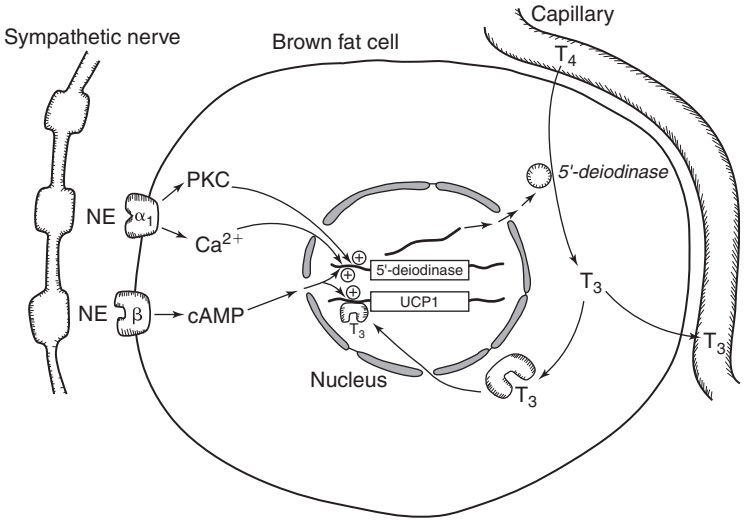

Figure 43-6 The regulation and action of 5′-deiodinase in brown adipose tissue. *cAMP,* Cyclic adenosine monophosphate; *NE,* norepinephrine; *PKC,* protein kinase C; T_3, triiodothyronine; T_4, thyroxine; *UCP1,* uncoupling protein-1.

removal of brown adipose tissue at a young age affects development of other bodily functions in later life. Thus, in several studies, Jankovic and colleagues have implied the presence of such a brown adipose tissue effect on the development of the immune response,[171-173] but so far these observations have not been independently verified.

Regulation of Deiodinase Activity

The activity of 5′-deiodinase is rapidly induced under conditions in which brown adipose tissue is recruited. This increase in activity is due to an increased synthesis of the enzyme.[174,175]

Adrenergic Regulation

It originally was suggested that the increase in deiodinase activity was mediated through an α_1-adrenergic mechanism.[176] Apparently, although an α_1-stimulus presumably is necessary to produce a significant stimulation, α- and β-adrenergic stimulation interact synergistically to induce maximal induction of 5′-deiodinase activity. From in vitro experiments with isolated cells, it has been suggested that this interaction occurs at the cellular level, apparently at a post-cAMP step in the activation pathway.[177,178]

Insulin

Insulin can increase 5′-deiodinase activity when injected into animals[175] and when added to isolated brown fat cells.[179] Neither the physiologic significance of this phenomenon nor the specific intracellular pathways involved in the gene activation events have been characterized.

Perinatal Recruitment of 5′-Deiodinase

The perinatal pattern of development of 5′-deiodinase is unusual: The deiodinase activity rises markedly before birth, after which it spontaneously declines[180-182] (Figure 43-7). The regulation of this activity and its significance for brown fat recruitment are of interest, but no experimental evidence concerning these questions is available at present.

REGULATION OF RECRUITMENT OF THE TISSUE

The capacity of brown adipose tissue thermogenesis is limited by the amount of UCP1 in the tissue, and this level is governed by the activity of the sympathetic nervous system and norepinephrine. To increase the amount of UCP1 in the tissue, two principal

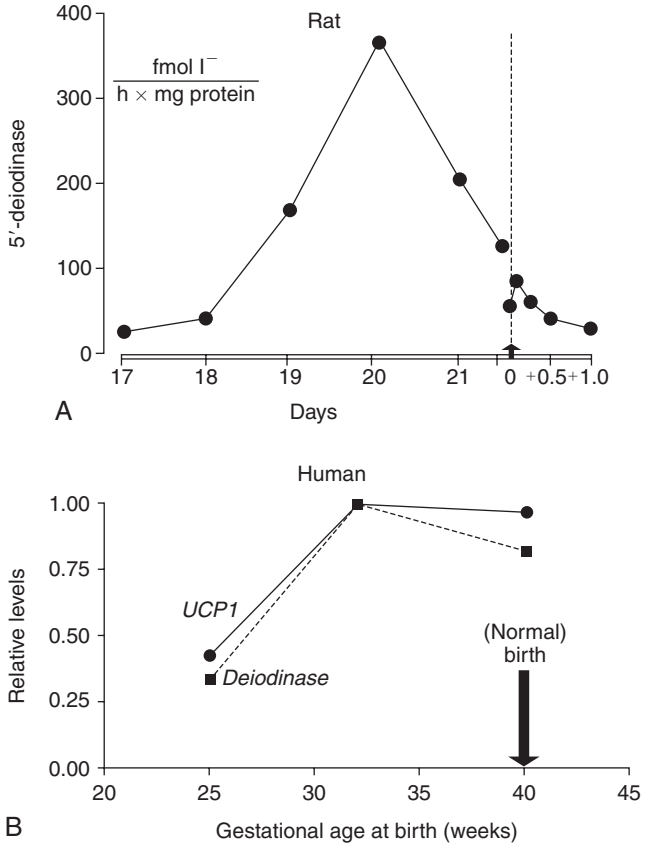

Figure 43-7 5′-Deiodinase activity in the perinatal period. *(Data based on rat studies from Giralt M, Martin I, Mampel T, et al: Evidence for a differential physiological modulation of brown fat iodothyronine 5′-deiodinase activity in the perinatal period; supported by similar data from Obregón MJ, Ruiz de Oña C, Hernandez A, et al: Thyroid hormones and 5′-deiodinase in rat brown adipose tissue during fetal life,* Am J Physiol *257:E625, 1989. Human data from Houstěk J, Vízek K, Pavelka S, et al: Type II iodothyronine 5′-deiodinase and uncoupling protein in brown adipose tissue of human newborns,* J Clin Endocrinol Metab *77:383, 1993.)*

strategies may be used. In the first, the amount of UCP1 per brown adipocyte is increased. In the second, an increase in cell proliferation (i.e., in the number of adipocytes) occurs, but each individual adipocyte maintains an unchanged capacity. Although different species appear to use more or less of either the first or the second modality, both seem to be operative in all species studied. The situation has not been studied for the human neonate.

The tissue retains a potential proliferative capacity, even in adulthood. Preadipocytes in culture can be stimulated to increase their proliferation by the addition of norepinephrine, and the stimulation is through β_1-receptors and cAMP-coupled mechanisms.[183] This mechanism is in contrast with the norepinephrine stimulation of *UCP1* gene expression in mature brown adipocytes, which, while also using cAMP as the intracellular messenger, couples to the adenylyl cyclase through β_3-receptors.[184]

Various transcription factors might be expected to be involved in the control of cell proliferation, and many are currently being studied. Of note, an important adipose-related factor, CCAAT/enhancer binding protein alpha (C/EBPα), is transiently decreased as proliferation begins.[185] Other fat-related transcription factors, such as members of the PPAR family, and the coactivator PGC1α (PPAR-gamma coactivator 1 alpha), also appear to be of importance.[186] A more comprehensive study of the roles of these transcription factors is required to elucidate the complex control of cell proliferation, both in utero and postnatally. It is evident that in the fetal state, growth factors such as insulin-like growth factor-I (IGF-I)[187,188] are important for cell growth.

CLINICAL IMPLICATIONS

Considerable evidence suggests that one of the major problems with temperature regulation in small premature infants is that the lipid supply to brown adipose tissue and its mechanism of recruitment are not sufficiently developed. This deficiency, combined with the larger surface-to-volume ratio characteristic of the small premature infant promoting rapid heat loss, places them at increased risk for hypothermia. Therefore the main problem resulting from the incomplete development of brown adipose tissue in premature newborns was solved through the introduction of the incubator.[189]

Effects of Environmental Temperature

Convincing evidence from animal experiments indicates that the postnatal environmental temperature has a substantial effect on brown adipose tissue development (see Figures 43-4 and 43-5).[11] Indeed, some anecdotal evidence suggests that children who live in relatively cold environments will acquire or maintain an improved cold tolerance, probably through persistent brown adipose tissue function.

Anesthesia in Infants

During general anesthesia, body temperature regulation is disturbed, and this effect is more marked in young infants. Although effects on central mechanisms controlling body temperature also may be observed, it is now apparent that the commonly used inhalation anesthetic halothane and its derivatives are potent inhibitors of brown adipose tissue thermogenesis.[190-193] This effect is of particular significance in young infants, in whom the activity of brown adipose tissue is very important for body temperature regulation.

Effects of Malnutrition

The effects of prenatal or postnatal malnutrition have been investigated in experimental animals. In general, food restriction reduces the function of brown adipose tissue,[194,195] although paradoxical observations have been reported.[196] Adverse effects of more specific dietary restrictions (e.g., riboflavin, protein) also have been reported.[197,198] In scattered reports in the literature, malnutrition has been implicated as a cause of hypothermia in human newborn infants, presumably owing to a lack of substrate being available for thermogenesis.[199]

Overfeeding

The presentation of a palatable, so-called cafeteria diet to adult rats results in overfeeding. However, these animals do not gain weight to the extent anticipated by the degree of overfeeding. The brown adipose tissue of such animals is markedly recruited, and it has been suggested that the decrease in the animals' whole-body efficiency (as indicated by lower weight gain than anticipated) could result from increased thermogenesis in brown adipose tissue.[200,201] Postnatal overfeeding in rats (induced by a reduction in the number of pups per litter) also leads to activation of brown adipose tissue.[202,203] Postnatal overfeeding leading in the adult to decreased brown fat thermogenesis may have long-lasting efects.[204]

It can be posited that in the human infant, overfeeding may cause an activation of brown adipose tissue, leading to an increased thermogenesis, which could counteract the effect of the increased food intake.

Genetically Obese Animals

In genetically obese animals (the fa/fa rat and the ob/ob and db/db mice, all of which have problems in the leptin system), the postnatal recruitment process in brown adipose tissue is blunted, before any signs of obesity become evident.[205-207] This inactivity of brown adipose tissue appears to constitute at least one cause of developing obesity. This correlation was apparently confirmed by studies in which brown adipocytes were molecularly ablated from mice.[58] For these experiments, transgenic animals were produced in which the UCP1 promoter region was coupled to the gene for the diphtheria toxin A chain. This A chain inhibits protein synthesis, thereby killing the cells in which it is expressed (e.g., primarily brown adipocytes). The transgenic animals developed obesity and other manifestations of pathophysiology associated with obesity, such as insulin resistance. However, mice with an ablation in the UCP1 gene and thus possessing thermogenically incompetent brown fat initially did not appear to become manifestly obese.[208] However, if animals are kept at thermoneutral temperatures, at which thermogenesis is not needed to defend body temperature, the absence of UCP1 leads to increased adiposity.[209,209a]

It is unclear whether some humans may be subject to the same forces as in these genetically obese animals. Although the potential to develop obesity is known to have a strong genetic component, to what extent brown adipose tissue inactivity contributes to the development of obesity in children remains undetermined.

Diseases Affecting Brown Adipose Tissue

In fever, some of the heat necessary for the increase in body temperature comes from brown adipose tissue, at least in young experimental animals.[210,211] It also is clear that brown adipocytes not only are responsive to cytokines released during infections that cause fever but also can synthesize such cytokines.[212] A relatively rare benign tumor, the hibernoma, can occur, even in neonates.[213] Also of note is that treatment with prostaglandin E_1 for palliation of neonatal congenital heart disease results in calcific brown fat necrosis, which can resolve over time.[214,215] In a number of relatively rare diseases such as Duchenne progressive muscular dystrophy,[216] subcutaneous fat necrosis of the

newborn,[217] and sudden infant death syndrome (SIDS),[218-220] a role for brown adipose tissue has been suggested. In the case of SIDS, a link with gestational magnesium deficiency has been proposed.[221] At present, however, no direct evidence has emerged to show causative involvement of brown adipose tissue in any of these syndromes.[222]

44 Lipids as an Energy Source for the Premature and Full-Term Neonate

Sudha Kashyap and Guy Putet

Lipids and carbohydrates are the major sources of energy for the neonate. Together with carbohydrates, lipids provide the dietary energy necessary for optimal utilization of protein. Lipids also supply the essential omega-6 and omega-3 fatty acids and are a vehicle for fat-soluble vitamins. In human milk and in formulas designed for preterm and full-term infants, fat provides approximately 40% to 50% of the total calories and accounts for more than 50% of nonprotein energy. Most dietary lipids are triglycerides. Long-chain triglycerides provide about 9 kcal of energy per gram; medium-chain triglycerides (MCTs), because of the shorter chain length, have been reported to have an energy value of 8.3 kcal per gram as determined by bomb calorimeter[1] and a net (usable) energy value of 6.8 kcal per gram as determined from animal studies and calculations of molecular composition.[2] The quantity and quality of dietary lipids have an effect on the absorption, metabolism, and tissue deposition of fat. When fed currently available formulas and human milk, very-low-birth-weight (VLBW) infants are reported to have efficiency of fat absorption greater than 85% and that of carbohydrate exceeding 95%.[3]

Substrate oxidation in neonates receiving enteral and parental nutrition has been estimated from gaseous metabolism as measured by indirect calorimetry and by stable isotope methodology. Concentrations of plasma metabolites have also been used in determining the type of substrate being oxidized in the infants. In this chapter the importance of lipids as a fuel for oxidative metabolism in term and preterm infants is discussed. This review is followed by a brief discussion of effects of quality of energy (fat versus carbohydrate) on substrate oxidation.

LIPIDS AS A FUEL FOR OXIDATIVE METABOLISM IN UTERO AND AT BIRTH

Glucose is the major energy source for the human fetus. Other substrates available for oxidative metabolism are amino acids, lactate, and free fatty acids (FFAs). Although triglycerides do not cross the placenta, FFAs cross by facilitated diffusion.[4,5] During fetal life approximately 80% of the energy expended is derived from carbohydrate oxidation.[6-9] If one assumes that energy expenditure of a fetus averages 50 kcal/kg/day,[10] the fetus should oxidize about 10 g/kg of carbohydrate each day. The major portion of the remaining energy needs is derived from amino acid oxidation. Thus, in the human fetus, lipids do not seem to be a major source of energy; however, they do play an important role in fetal development.

At birth, an abrupt change occurs in the nutrient supply after the umbilical cord is clamped and divided. In newborn term infants who have not received any feedings, the respiratory quotient (RQ) has been reported to drop from approximately 0.9 to less than 0.8 in the first 12 hours of life,[11] indicating increasing use of lipids as energy source. At the low RQ, the contribution of energy from fat is approximately 60% to 70% of the energy expenditure. During the first few hours after birth, an increase in plasma FFAs, glycerol, and ketone bodies has also been reported, indicating that lipolysis is actively occurring.[12,13] In the next few days, the RQ of infants increases as enteral feedings increase.[11]

Preterm infants are provided with glucose immediately after birth. On the first day of life, contribution of energy from the various substrates to the energy expenditure of these infants can be calculated from substrate oxidation rates that have been determined by stable isotope methodology. The energy derived from glucose oxidation has been reported to be approximately 16.4 kcal/kg/day[14] and that from protein oxidation, 6.7 kcal/kg/day.[15] With an estimated energy expenditure in these infants of approximately 30 to 45 kcal/kg/day on day 1 of life,[16] the contribution of energy from glucose is approximately 35% to 50% of the energy expenditure, that of protein approximately 15% to 20%, and the remaining energy is provided from fat oxidation.

LIPID AS A FUEL FOR OXIDATIVE METABOLISM FOR GROWING INFANTS

For full-term infants with adequate enteral intakes after the first week of life, fat is provided in abundance. Minimal data, however, are available on the RQ and substrate utilization in the normally fed and growing full-term infant between weeks 1 and 4 of postnatal life. The most careful estimates of RQ place it at around 0.85 or greater.[11] Based on those estimates and an oxygen consumption that has been measured at between 7 and 8 mL/kg/min, one can calculate that between 2 and 3 g/kg/day of fat is oxidized. This means that between 40% and 50% of calories oxidized after the first week of life in term infants are derived from fat. (This percentage would range between 30% and 40% for an RQ estimated at 0.9.)

For the growing preterm infant fed either human milk or a preterm formula, considerably more data on energy balance are available. Lipids provided 40% to 50% of total energy intake in these diets. Table 44-1 summarizes studies from the literature, in which data on metabolizable energy (energy intake minus losses in stools), energy expenditure, nutrient balances, and RQ have been precisely determined. Few published reports have provided sufficient data to permit a calculation of the amount of fat oxidized[17-23]; however, several conclusions can be reached based on the data in Table 44-1:

1. Almost all the studies listed in Table 44-1 have an observed RQ greater than 0.9. These values for RQ are similar to values from other studies[24-28] from which data were not precise enough to be included in this table, but the RQ values were measured in growing infants receiving full oral feedings (lower RQ values have been reported in nongrowing infants.[29]
2. The amount of fat oxidized averages 1.5 g/kg/day (i.e., approximately 14 kcal/kg/day). This represents approximately 30% of the fat absorbed and 20% (range, 10% to 35%) of the calories oxidized.
3. As listed in the table, although the values for RQ are noted to be high, they are slightly lower with human milk than with preterm formula. A high RQ can result from either a high rate of carbohydrate oxidation (fat being almost

nonutilized as a source of energy) or increased storage of carbohydrate as triglyceride.[30,31] With human milk, 30% to 35% of the calories oxidized are derived from fat (1.6 to 1.9 g/kg/day) compared with 10% to 25% with preterm formula (0.6 to 1.6 g/kg/day). It is difficult to assess whether this difference in fat oxidation rate is the consequence of a lower total metabolizable energy intake or of differences in the quality of the human milk. However, if studies that have used only preterm formula are analyzed, it appears that the highest RQ values are consistently observed in infants with the highest metabolizable energy intakes. Thus the lower oxidation rate of fat seen with formula is more likely to be due to the higher caloric intake provided as carbohydrate rather than a difference in the quality of milk. The higher carbohydrate intake in infants receiving formula could also explain the higher urinary C-peptide levels observed in formula-fed infants.[32]

Relatively few studies in the literature have made repeated measurements of energy expenditure in infants. Of interest is the observation by Gudinchet and colleagues[33] who demonstrated an increased participation of fat in oxidative metabolism with advancing age in the premature infant fed a constant energy intake of 130 kcal/kg/day (Table 44-2). Decreasing RQ, indicating increasing fat oxidation, has also been reported in extremely LBW infants in the first 5 weeks of life.[34]

Medium-Chain Triglycerides as Fuel

MCTs (C8 and C10) were introduced in premature infant nutrition to enhance fat absorption. Several studies[28,35,36] demonstrated an improved total fat absorption rate when part of the long-chain triglycerides are replaced by MCTs, but others[37] have not. Formulas designed specifically for preterm infants contain 25% to 50% of total fatty acids as MCT. In human milk, approximately 8% to 10% of the total fatty acids is available as MCT.[38] Although no evidence shows that MCTs are harmful, storage or incorporation of MCTs into structural lipids may be of concern.

In the adult, MCTs appear to be entirely oxidized, but little is known about the metabolism (oxidation and storage) of MCTs in premature infants. Increases in the plasma concentrations of β-hydroxybutyrate and acetoacetate in infants receiving formula containing these fats[39,40] demonstrates that oxidation of MCTs does occur. However, when the total amount of fat oxidized by a preterm infant (range 1.3 to 1.5 g/kg/day, see Table 44-1) is calculated, it appears that an infant fed 160 mL/kg/day of a formula containing more than 20% of its fat as MCTs has either to oxidize all the MCTs and no other fat, or store some of the MCTs if longer-chain fatty acids are to be oxidized simultaneously.

Quantitation of MCT oxidation in preterm infants fed formula containing 40% of its fat content as MCTs has been determined by stable isotope tracer methodology with simultaneous determination of substrate utilization using indirect calorimetry.[41,42] The results of the energy expenditure, RQ, and fat oxidation as determined by indirect calorimetry and MCT oxidation as determined by isotopic measurement of expired CO_2 of the labeled octanoic acid are shown in Table 44-3. The MCT oxidation was more than 80% of the calories derived from fat oxidation, indicating a preferential utilization of C8 and C10 triglycerides. The high rate of utilization of these fatty acids is likely to be related to their fast absorption; they are the first fats available for oxidation after a meal. MCTs that are not oxidized can either be stored as such in adipose tissue or be elongated to longer-chain fatty acids. Sarda and associates[43] have reported C8:0, C10:0, and C12:0 storage in adipose tissue in association with MCT dietary intake in infants.

No difference has been observed in carbohydrate utilization by preterm infants fed formulas containing 38% MCTs compared with 6% MCTs in the fat blend. However, the glucose oxidation in infants fed the high MCT formula was reported to

TABLE 44-3

Energy and Fat Oxidation Values*

Component	DATA SOURCE	
	Putet et al (n = 7)	Sulkers et al (n = 8)
Intake (kg/day)		
Energy (kcal)	116	120
Total fat (g)	5.4	6.7
MCTs (g)	2.2	2.7
Other fat (g)	3.2	4.0
Oxidized (kg/day)		
Energy (kcal)	62	58
Total fat (g)	1.3	1.4
MCTs (g)	1.2	1.2
Other fat (g)	0.1	0.2

Data from Putet G, Thelin A, Philippossian G, et al: Medium-chain triglycerides as a source of energy in premature infants. In Horisberger M, Bracco U (eds): *Lipids in Modern Nutrition,* New York, Raven Press, 1987, pp 43-49; and Sulkers EJ, Lafeber HN, Sauer PJ: Quantitation of oxidation of medium-chain triglycerides in preterm infants, *Pediatr Res* 26:294, 1989.

*According to the oxidation rate of the labeled octanoic acid, 1.2 g/kg/day of the ingested medium-chain triglycerides (MCTs) is oxidized; because indirect calorimetry measurements give a total fat oxidation of 1.3 and 1.4 g/kg/day, the amount of long-chain fatty acids oxidized is assumed to be the difference (i.e., 0.1 and 0.2 g/kg/day).

TABLE 44-4

Difference in Intravenous Fat Oxidation Rates in Neonates (Preterm and Term) on Total Parenteral Nutrition at Two Different Levels of Energy Intake*

Total Nonprotein Energy Intake (kcal/kg/day)	Fat Intake (g/kg/day)	Energy Expenditure (kcal/kg/day)	Fat Oxidation (g/kg/day)	% Energy Expenditure Derived from Fat
102 ± 12 (n = 9)	4.6 ± 1.6	63 ± 12	1.4 ± 0.9	21
73 ± 4 (n = 8)	2.5 ± 0.5	52 ± 3	1.7 ± 0.5	30

*Note that an increase in fat intake (which accounts for almost 70% of the increase of the nonprotein energy intake) is not followed by an increase in fat oxidation rate.

Calculated from data of Putet G, Verellen G, Heim T, et al: Energy intake and substrate utilisation during total parenteral nutrition in newborn. In Wesdorp RIC, Soeters PB (eds): *Clinical nutrition '81,* Edinburgh, Churchill Livingstone, 1982, pp 63-70.

be significantly decreased,[44] suggesting that a larger portion of carbohydrate was used in the nonoxidative pathway (i.e., lipogenesis). MCTs have also been reported to effectively reduce polyunsaturated fatty acids and long-chain polyunsaturated fatty acids oxidation in enterally[45] and parenterally[46] fed preterm infants.

A consequence of MCT oxidation is an increased urinary excretion of dicarboxylic acids.[47] The clinical significance of this remains to be determined. No evidence, however, suggests that the presence of these oxidation products is harmful.

FAT AND TOTAL PARENTERAL NUTRITION

Intravenous fat emulsions have been given to newborn infants for several years. Some of the intravenously administered fats are used as a source of energy, as manifested by changes in the concentrations of FFAs and ketone bodies[48,49] and alterations in the RQ.[49-51] Even when lipoprotein lipase activity is impaired during the first days of life (especially in VLBW and small-for-gestational-age infants), the increase in ketone bodies[48] indicates that fat oxidation occurs during total parenteral nutrition. Currently it is recommended that intravenous fat be administered initially at a dose of 1 to 2 g/kg/day given continuously during 18 to 24 hours and increased as tolerated to a maximum of 3 g/kg/day.[52] Providing neonates approximately 30% of energy intake as lipids in total parenteral nutrition (TPN) regimens has been reported to improve their nitrogen utilization.[53,54]

Some evidence shows that oxidation of intravenous lipids may be correlated with total energy intake. The portion of energy expenditure derived from fat oxidation and the net amount of fat oxidized are reported to decrease with increasing energy (even as fat) intake.[54] (Table 44-4) This observation also correlates with data from adults, demonstrating that an increased oxidation rate of glucose is followed by a decreased oxidation rate of concomitantly infused lipids.[55] When an important part of energy intake is given as glucose, it is likely that glucose oxidation will impair utilization of lipid as a fuel during TPN. Similar observations have been made in enterally fed preterm infants[56] and in adults.[57]

The observation that an increase in fat intake is not followed by a higher rate of fat oxidation when total energy intake is high means that it may not be appropriate to increase the amount of intravenous lipid during total parenteral nutrition (at least when nonprotein energy intake exceeds 80 to 90 kcal/kg/day). When the total nonprotein energy intake is lower, it is possible that more fat will be oxidized and, therefore, more energy will be provided. Indeed, Rubecz and colleagues[51] have demonstrated a higher rate of fat oxidation when intravenous fat was the only energy provided, and in this experimental design 85% of the fat infused was oxidized.

EFFECTS OF QUALITY OF ENERGY (FAT VERSUS CARBOHYDRATE) ON PROTEIN ACCRETION AND SUBSTRATE OXIDATION

The effect of energy intake on protein utilization has been studied in animals,[58] human adults,[59,60] and human infants.[61-63] Although greater nitrogen retention with increasing energy intake has been reported in enterally fed[62,63] and parenterally fed[64] preterm infants, little is known about the differential effects of carbohydrate versus fat on substrate utilization in these infants. In adults substrate oxidation is dependent on the relative proportions of carbohydrate and fat in the diet.[57,65] Evidence shows that, calorie for calorie, carbohydrate used as an energy source is more effective than fat in supporting protein accretion.[59,66-68] Increased protein retention has been observed when carbohydrate is the primary energy source in adults with both enteral[65,66] and parenteral[67] diets and in preterm infants on enteral[69] and parenteral[68] diets. Although protein oxidation has been reported to decrease with increasing carbohydrate oxidation in preterm infants, no correlation was observed with fat oxidation.[69] Increasing carbohydrate intakes has been associated with increasing carbohydrate oxidation in adults[65,70] and in enterally[56] and parenterally fed infants.[71,72] Decreasing fat oxidation has also been associated with increasing carbohydrate intake.[56,57] Although the association of increasing fat intake with increasing fat oxidation has been reported by some investigators,[53,57] others have not observed this association.[54,73,74]

Because de novo lipogenesis from carbohydrate is an energy-consuming process, metabolic efficiency is improved if the nonprotein energy is provided as a mixture of carbohydrate and lipids rather than predominantly carbohydrate. Although the recommendation for enteral lipid intake of at least 30% of total energy intake has been made,[75] it is unclear if this intake would be adequate for neonates. Some evidence supports that preterm infants fed diets providing 35% of nonprotein energy as fat grow normally.[69] Various committees and expert panels have recommended that the total fat energy intake be 36% to 55% of the total energy intake for a preterm infant.[52,76-79]

Ketone Body Production and Metabolism in the Fetus and Neonate

AVAILABILITY OF KETONE BODIES

Under physiologic conditions, the rate of utilization of ketone bodies is directly proportional to their concentration in the circulation, which in turn represents a balance between production (ketogenesis) by the liver and removal by peripheral tissues. Ketone bodies are excreted in the urine (ketonuria) when the renal threshold is exceeded. The relationship between production and utilization can be disturbed if the utilization of ketone bodies is inhibited by drugs,[1,2] with congenital absence of key enzymes required for ketone body utilization (e.g., 3-oxoacid–coenzyme A [CoA] transferase),[3] or in insulin-deficient states secondary to a metabolic defect in utilization.[4]

The concentration of ketone bodies in the blood is extremely sensitive to alterations in the physiologic state. *Normoketonemia* in humans has been defined as a blood ketone body concentration less than 0.2 mmol/L; *hyperketonemia,* greater than 0.2 mmol/L; and *ketoacidosis* (by analogy to the definition of lactic acidosis), greater than 7 mmol/L.[5] In adult humans, small but characteristic diurnal changes in blood ketone body concentrations have been noted.[6] Larger increases in concentration occur with fasting (in both humans and rats), with consumption of a high-fat diet, after exercise, in late pregnancy, and during suckling (Table 45-1). In pregnancy, blood ketone bodies will be available to the fetus in prevailing concentrations, because the placenta appears to be freely permeable to acetoacetate and 3-hydroxybutyrate.[7,8]

Ketonemia in Pregnancy

The major substrate of the mammalian fetus is considered to be glucose supplied by the mother.[8] However, the concentration of ketone bodies in maternal blood is increased in the last trimester of pregnancy,[5,7] and high concentrations are attained during delivery, particularly if it is prolonged (ketosis of labor).[7,8] This increase in blood ketone bodies may be related in part to the decrease in food intake around parturition, because hyperketonemia develops more rapidly with fasting in women in the second trimester of pregnancy than in nonpregnant control subjects.[9,10] Poorly controlled diabetes during pregnancy (including gestational diabetes) also is likely to lead to wide fluctuations in blood ketone bodies.[11]

Ketonemia in the Neonatal Period

During the suckling period, the neonate is presented with a relatively high-fat and low-carbohydrate diet. Both humans and rats have marked hyperketonemia in the early suckling period, compared with the respective adult fed values (see Table 45-1). By contrast, ketone bodies are not increased to the same extent in the blood of puppies,[12] piglets,[13] and lambs.[14] Nonesterified fatty acids (both long- and medium-chain) are the major precursors of ketone bodies, and a possible reason for the species differences in neonatal ketonemia may be the fat content of the maternal milk (rat milk contains 14.8 g fat/100 g; sheep milk contains 5.3 g fat/100 g). In addition, the brains of sheep and dogs have a low rate of ketone body utilization, so the demand for ketone bodies may be less than that in humans or rats.

The hyperketonemia of the neonatal period in humans is a physiologic event; therefore any change in blood ketone body concentration (decrease or increase) is likely to indicate a pathologic process. Increased ketone bodies may accompany the hypoglycemia associated with certain inborn errors of metabolism, and a decrease may occur in hyperinsulinism. It is therefore advisable to measure blood ketone bodies by a specific enzymatic method[15] in neonates presenting with hypoglycemia or any other abnormality in the concentration of circulating substrates.

†Deceased

TABLE 45-1

Range of Blood Ketone Body Concentrations in Humans and Rats

	KETONE BODY CONCENTRATION (mmol/l)*	
Clinical/Experimental Condition	**Human**	**Rat**
Fed normal diet	~0.1	Up to 0.3
Fed high-fat diet	Up to 3	4-5
Fasted: 12-24 hours	Up to 0.3	1-2
Fasted: 48-72 hours	2-3	2-3
Postexercise	Up to 2	Up to 2
Late pregnancy	Up to 1	Up to 0.3
Late pregnancy after 48-hour fast	4-6	6-15
Neonate: 0-1 days	0.2-0.5	0.2
Neonate: 5-10 days	0.7-1.0	0.5-1.1
Hypoglycemia	1.5-5	—
Untreated diabetes mellitus	Up to 25	Up to 10

*Concentrations of total ketone bodies (acetoacetate + 3-hydroxybutyrate measured by enzyme assay) in whole blood.

For example, infants born small for gestational age (SGA) have increased blood concentrations of gluconeogenic substrates, in association with decreased blood ketone body concentrations.[16] The latter may be a result of defective development of the ketogenic capacity of the liver.

REGULATION OF KETOGENESIS

Current understanding of the regulation of ketogenesis is based mainly on studies in rats—in particular, during the fed-to-starved transition, when a large increase (three- to four-fold) in ketogenesis occurs. In addition, a high proportion of the experimental evidence comes from work on perfused livers or isolated hepatocytes from adult rats. Consequently, in the review of regulation of ketogenesis in the adult presented in this section, comparison is made with the neonate or fetus whenever information is available. Further details are available in more comprehensive reviews.[17-21]

Extrahepatic Regulation

It is convenient to discuss the regulation of ketogenesis in two parts: extrahepatic and intrahepatic. The major precursors of ketone bodies in the postabsorptive state are long-chain fatty acids (LCFAs), and in all physiologic situations associated with hyperketonemia, including those of the neonatal period, the plasma concentrations of LCFAs are increased (see Table 45-1).[22-25] Extraction of LCFAs by the liver is concentration-dependent, and a direct relationship between their concentration and the rate of ketogenesis has been shown in rat and human.[26]

Adipose Tissue Lipolysis

In the adult, a key factor in determining the supply of LCFAs to the liver is their rate of release (lipolysis) from adipose tissue triacylglycerol stores. Lipolysis is initiated by activation of hormone-sensitive lipase; glucagon, epinephrine, norepinephrine, and thyroxine increase enzyme activity, whereas insulin (as well as some prostaglandins) has the opposite effect.[27] Isolated human adipocytes from neonates are very sensitive to the lipolytic effects of thyrotropin,[28] which increases in concentration immediately after birth and may therefore be involved in the regulation of lipolysis in the perinatal period. A decrease in blood glucose (e.g., in starvation, fat feeding) along with a concomitant decrease in plasma insulin leads to an increase in lipolysis and efflux of nonesterified fatty acids from adipose tissue. When carbohydrate is then supplied, the increases in glucose and insulin inhibit

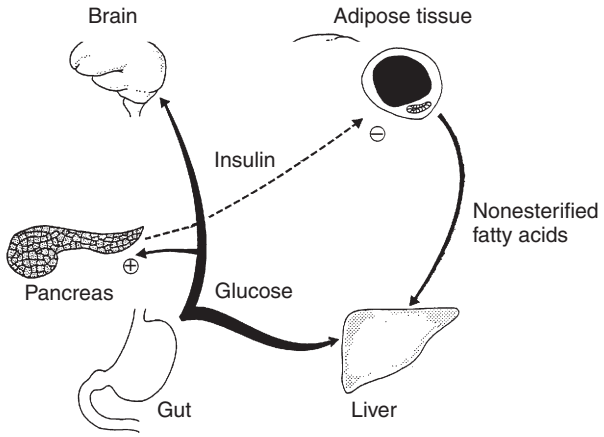

Figure 45-1 Intertissue fluxes in the fed state. Relative rates of flux are reflected in thickness of *arrows*.

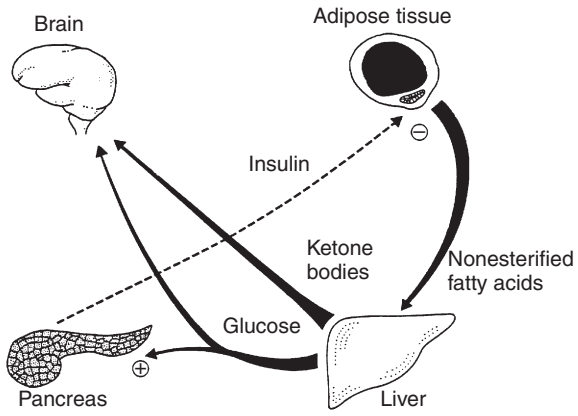

Figure 45-2 Intertissue fluxes in the starved state. Relative rates of flux are reflected in thickness of *arrows*.

lipolysis. The rate of ketogenesis can therefore respond in a reciprocal way to the availability of glucose in the circulation, so that an alternative fuel for the brain is provided when needed (Figures 45-1 and 45-2). During suckling in the rat, the plasma insulin-to-glucagon ratio is decreased, thereby favoring lipolysis.[29,30]

Ketone bodies apparently can regulate their own formation by feedback mechanisms on adipose tissue (Figure 45-3) to decrease lipolysis. Current evidence suggests two mechanisms: direct inhibition of lipolysis by ketone bodies and an indirect effect mediated by stimulation of insulin secretion[31,32] (see Figure 45-3). Work with the perfused rat pancreas suggests that ketone bodies increase insulin secretion only at concentrations above 1 mM.[33] These feedback mechanisms have not been investigated in neonates.

In the suckling neonate, another important source of precursors for ketogenesis is the medium-chain fatty acids (MCFAs) (12 or fewer carbons) of maternal milk.[34] These are in the form of triacylglycerols (one MCFA and two LCFAs per triacylglycerol) and are hydrolyzed by the action of lingual lipase. They are rapidly absorbed from the stomach into the portal venous system[35] and are therefore directly available to the liver, unlike LCFAs derived from milk lipids, which are transported as triacylglycerols (chylomicrons) by way of the lymphatic system and initially enter the peripheral circulation (Figure 45-4).

In the neonatal period, chylomicrons may provide a direct source of LCFAs for the liver, as suggested by the presence of lipoprotein lipase (responsible for the hydrolysis of triacylglycerols contained in chylomicrons to LCFAs) in neonatal rat liver[36] (see Figure 45-4). However, the total activity in liver constitutes

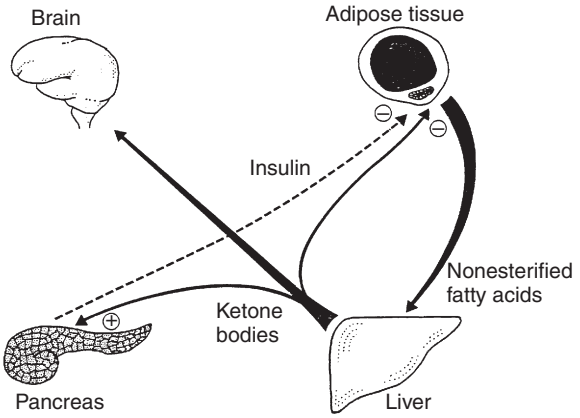

Figure 45-3 Role of ketone bodies as feedback regulators. Relative rates of flux are reflected in thickness of *arrows.*

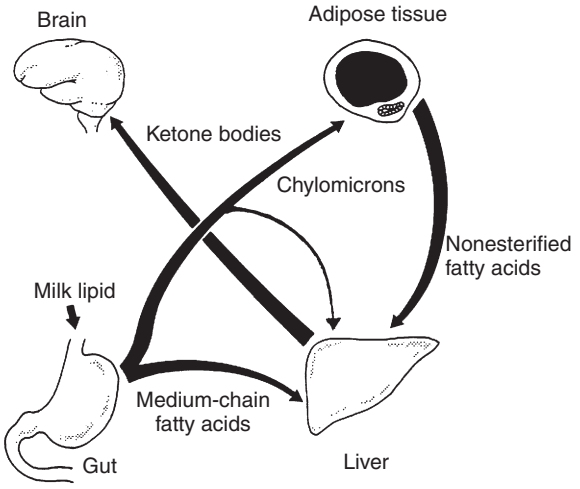

Figure 45-4 Intertissue fluxes in the suckling neonate. Relative rates of flux are reflected in thickness of *arrows.*

only a small percentage (3%) of that in the carcass,[34] presumably mainly muscle and adipose tissue.

Intrahepatic Regulation

It is generally considered that liver is the sole tissue capable of synthesis and release of ketone bodies to the circulation. However, ketone bodies can be formed by the intestinal mucosa of neonatal rats; this is due to the presence of an active hydroxymethylglutaryl (HMG)-CoA pathway (Figure 45-5) during suckling.[37,38] Research has shown that the expression of the key enzyme, HMG-CoA synthase, in intestinal mucosa is suppressed in weaning suckling rats.[39,40] The rate of intestinal ketogenesis is less than 10% of that in suckling liver, but this mechanism does provide an additional strategy for supplying ketone bodies to developing tissues.[34]

Pathway of Fatty Acid Catabolism

LCFAs derived from adipose tissue are transported in the plasma bound to albumin, cross the cell membrane as free fatty acids, and then bind again to cytosolic binding proteins.[32] Within the liver, the LCFAs either can be reesterified to form triacylglycerols (for subsequent secretion as very-low-density lipoprotein) and phospholipids or can enter the mitochondria by way of the carnitine acyltransferase system to undergo β-oxidation. The resultant acetyl-CoA can be converted to ketone bodies (acetoacetate and 3-hydroxybutyrate) by the (HMG-CoA pathway, or it can undergo complete oxidation in the tricarboxylic acid cycle (see Figure 45-5). By contrast, MCFAs are not converted to triacylglycerols in mammalian liver and can directly cross the inner mitochondrial membrane, thereby bypassing the carnitine acyltransferase system. Within the mitochondrial matrix, the MCFAs are converted to the corresponding acyl-CoA derivatives by acyl-CoA synthetases and then undergo β-oxidation (see Figure 45-5).

Changes in Neonatal Liver

As might be expected because of the relative impermeability of the placenta to LCFAs,[41] the concentration of the cytosolic fatty acid–binding protein is very low in fetal liver and gradually increases (approximately 20-fold) to reach adult values; evidence is lacking for a peak concentration of the protein in livers from suckling rats.[42]

Liver of fetal rats has a low capacity for fatty acid catabolism and ketogenesis, and this is rapidly increased after birth. The signals and mechanisms regulating the maturation of ketogenesis in the perinatal period are not completely understood[43] (as reviewed by Girard and colleagues[44]). Available evidence indicates that the capacity of the liver for LCFA catabolism is increased in the suckling period. A number of the key enzymes show higher activities,[45-47] particularly carnitine acyltransferase I [Enzyme Commission (EC) number 2.3.1.21], which increases at birth and attains values three to six times higher than those of the adult within a few days of parturition; it then declines rapidly on weaning.[47] These increases in enzyme activity[45-47] are paralleled by higher rates of ketogenesis from LCFAs in isolated hepatocytes from suckling rats than in cells from adult rats.[48,49]

The rate of ketogenesis from MCFAs is not increased in hepatocytes from suckling rats compared with that in cells from adult animals.[48] Presumably, then, the increased ketogenesis from LCFAs during the neonatal period is connected with either their esterification or entry into the mitochondria by way of the carnitine acyltransferase transport system.

Role of Malonyl Coenzyme A

In adult liver, carnitine acyltransferase I is regulated by short-term changes in the concentration of carnitine (a co-substrate) and malonyl coenzyme A (malonyl-CoA), which is a potent inhibitor of carnitine acyltransferase I.[17] Malonyl-CoA is a key intermediate in the conversion of carbohydrate into fat, and the hepatic concentration is directly correlated with the rate of lipogenesis (de novo fatty acid synthesis).[50] In liver, the major lipogenic precursor is pyruvate, formed from lactate returning to the liver as a product of glycolysis in peripheral tissues, or from hepatic glycogen through glycogenolysis and glycolysis (Figure 45-6). Therefore the rate of lipogenesis and the concentration of malonyl-CoA indicate the carbohydrate status of the liver: A high rate of lipogenesis is associated with an elevated malonyl-CoA, inhibition of carnitine acyltransferase I, and a decreased rate of ketogenesis. Conversely, a decrease in lipogenesis secondary to lack of substrate or hormonal inactivation of the key enzyme[51] acetyl-CoA carboxylase [EC 6.4.1.2] results in a decrease in malonyl-CoA and a stimulation of ketogenesis owing to increased entry of long-chain acyl-CoA into the mitochondria (see Figure 43-6). In addition, it appears that the sensitivity of carnitine acyltransferase I to inhibition by malonyl-CoA is affected by change in the physiologic state[52,53]; it decreases during suckling.[54,55]

In suckling liver, the rate of lipogenesis in isolated hepatocytes[48] and in vivo[56] is low, owing mainly to the decrease in the activities of key lipogenic enzymes (e.g., acetyl-CoA carboxylase,[57] fatty acid synthetase[58]); this pattern is rapidly reversed on weaning. It is therefore reasonable to assume that hepatic malonyl-CoA concentration is very low during suckling and cannot be altered acutely. This fact, together with the decreased sensitivity of carnitine acyltransferase I to inhibition by malonyl-CoA,[54,55]

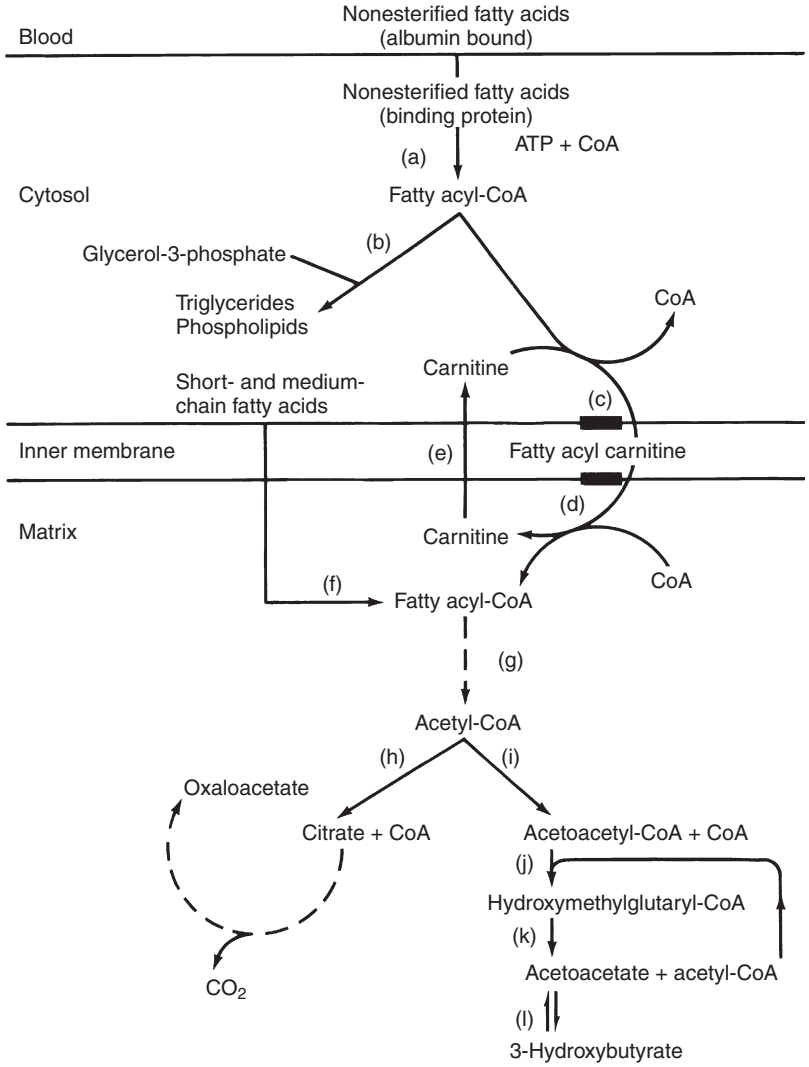

Figure 45-5 Pathway of fatty acid catabolism in liver. Enzymes involved: *(a)* long-chain fatty acyl-CoA synthetase; *(b)* glycerol-3-phosphate acyltransferase; *(c)* carnitine acyltransferase I; *(d)* carnitine acyltransferase II; *(e)* carnitine exchange; *(f)* short- and medium-chain fatty acyl-CoA synthetase; *(g)* fatty acid oxidation complex; *(h)* citrate synthase; *(i)* acetoacetyl-CoA thiolase; *(j)* hydroxymethylglutaryl-CoA synthase; *(k)* hydroxymethylglutaryl-CoA lyase; *(l)* hydroxybutyrate dehydrogenase. *ATP,* Adenosine triphosphate; *CoA,* coenzyme A.

suggests that in the suckling neonate, regulation of ketogenesis (once maturation has occurred) depends on both substrate supply and the increased capacity of the mitochondria for fatty acid catabolism, particularly the entry of long-chain acyl-CoA. Still to be determined is the nature of the signal or signals that bring about the stimulation of ketogenesis immediately after birth.[43,44,59] One possibility is the acute decrease in the insulin-glucagon ratio.[30,44]

Role of Insulin and Glucagon

The role of hormones in regulating the supply of LCFAs to the liver has already been discussed. It might be expected that insulin and glucagon also would act directly on the liver. Glucagon or dibutyryl cyclic adenine monophosphate (cAMP)—the so-called second messenger—stimulates ketogenesis from LCFAs in perfused livers[60,61] and isolated hepatocytes[48] from adult rats. Dibutyryl cAMP or glucagon does not increase ketogenesis from MCFAs,[62,63] suggesting that the site of action of glucagon is at the disposition of long-chain acyl-CoA between the pathways of esterification and β-oxidation (see Figure 45-6). A possible mechanism for the effects of glucagon on ketogenesis is suggested by the finding that the hormone (or cAMP) inhibits hepatic lipogenesis in vivo[64] and in vitro[64,65] and, consequently, decreases the concentration of malonyl-CoA.[50] The site of inhibition is acetyl-CoA carboxylase, which is inactivated by glucagon through increased phosphorylation of the protein.[51] Other sites of action of glucagon cannot be ruled out, however, because cAMP still stimulates ketogenesis and decreases esterification of LCFAs in isolated hepatocytes when an inhibitor of lipogenesis is present,[48] and malonyl-CoA presumably is low.

Decreased esterification of LCFAs by microsomal fractions isolated from livers of fed rats perfused with dibutyryl cAMP has been reported.[66] Activation of carnitine acyltransferase I by glucagon (or cAMP) has been described.[67] In hepatocytes from suckling rats, dibutyryl cAMP has no effect on ketogenesis.[48] This lack of effect may be a result of the elevation of cAMP in neonatal hepatocytes[8] and the consequent maximal stimulation of ketogenesis. Alternatively, it can be argued that because of the low rate of lipogenesis in neonatal hepatocytes, glucagon (cAMP) addition does not lead to a further decrease in the already low concentration of malonyl-CoA. Additional evidence that hepatocytes from neonatal rats are maximally stimulated is the finding that starvation of neonatal rats, in contrast with adult rats, does not further increase the rate of ketogenesis from LCFA in vitro.[49]

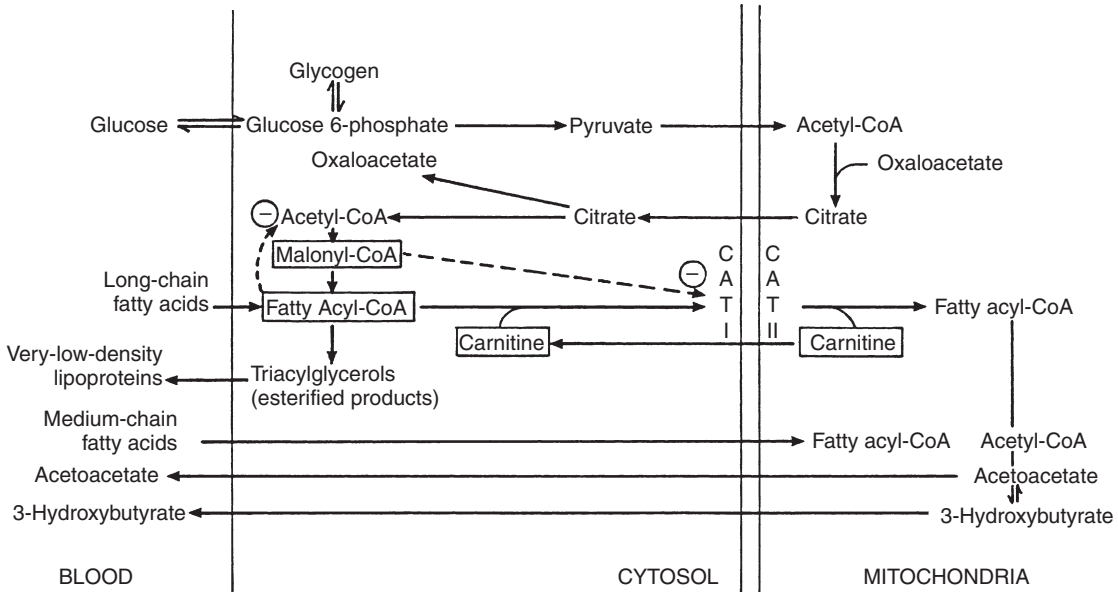

Figure 45-6 Interrelationship of hepatic carbohydrate metabolism, lipogenesis, and ketogenesis. *Circled minus signs* indicate sites of inhibition by metabolite. *CAT-I, CAT-II,* Carnitine acyltransferase I and II; *CoA,* coenzyme A.

By analogy to its potent antilipolytic effect on adipocytes, insulin might be expected to exert a direct antiketogenic effect on the liver. However, unlike with glucagon, demonstration of direct hepatic effects of insulin has proved comparatively elusive.[63] The general view is that in adult liver, insulin stimulates the de novo synthesis of fatty acids, in part by activation of acetyl-CoA carboxylase,[51] which in turn increases malonyl-CoA. It is therefore not surprising that in perfused livers of adult rats, insulin decreases the oxidation of LCFA and increases the rate of their esterification.[68] Investigation of the effects of insulin on LCFA catabolism in neonatal liver has been limited. Administration of insulin to suckling rat pups decreases blood ketone body concentrations without altering the concentration of plasma LCFAs, suggesting a direct antiketogenic effect of the hormone not mediated by a change in LCFA supply to the liver.[69] Livers of suckling rats[31] and human neonates[70] are resistant to the suppressive effects of insulin on glucose production, and this resistance also may extend to its effects on lipid metabolism. Of note, none of the putative direct hepatic actions of glucagon or insulin discussed earlier are likely to affect MCFA metabolism, which appears to be favored over LCFA metabolism in suckling liver.[71] This predilection may be important in the formulation of infant feedings.[72]

Thus a number of changes favor a high rate of ketogenesis in the suckling neonate (Table 45-2). All of these changes are reversed on weaning to a high-carbohydrate diet.

Fatty Acid Catabolism in Fetal Liver

LCFAs cannot readily cross the placental barrier,[41] and the capacity of fetal liver to oxidize them and form ketone bodies is very limited.[45,73] Ketone body formation by the liver in early human fetuses has been demonstrated.[74]

KETONE BODY UTILIZATION

With availability of sufficient ketone bodies in the circulation, their rate of utilization is to a large extent regulated by the prevailing concentration.[75] Transport of ketone bodies through the plasma membrane or mitochondrial inner membranes is not considered to limit their utilization in muscle, because the tissue concentration is linearly related to the plasma concentration.[76]

TABLE 45-2

Changes That Favor Ketogenesis in Suckling Rats

Factor	Change*
Plasma insulin[29,30,44]	Decreased
Plasma glucagon[29,30,44]	Increased
Insulin-glucagon ratio[29,30,4 4]	Decreased
Plasma LCFAs[24]	Increased
Hepatic carnitine acyltransferase I activity[47]	Increased
Sensitivity of carnitine acyltransferase I to malonyl-CoA inhibition[54,55]	Decreased
Hepatic [carnitine][143]	Increased
Hepatic lipogenesis[48,56]	Decreased
Hepatic [malonyl-CoA]	Decreased†

*Reported changes are relative to determinations in the adult fed rat, which has a low rate of ketogenesis.

†Malonyl-CoA has not been measured in neonatal rat liver, but a reasonable assumption is that it is low.

CoA, Coenzyme A; *LCFAs,* long-chain fatty acids.

Data from cited references.

This may not be true for brain, however, because the ketone body concentrations in rat brain[77] and human cerebrospinal fluid[78] are considerably less than those in blood in hyperketonemic states. Within the cell, the metabolism of ketone bodies depends on the activities of the "initiating" enzymes, which allow their entry into the metabolic pathways of the cell. The acetyl-CoA formed from ketone bodies either is completely oxidized in the tricarboxylic acid cycle to provide energy (adenosine triphosphate [ATP]) or is used as a precursor of fatty acid or sterol (cholesterol) synthesis. The pathways of ketone body utilization are shown in Figure 45-7. (A more detailed review of ketone body metabolism in peripheral tissues is available.[32])

Pathways of Ketone Body Utilization

Mitochondrial Pathway

As might be expected in view of its role as an energy-yielding substrate, the major site of ketone body utilization is the mitochondria. The initiating enzyme for acetoacetate metabolism is

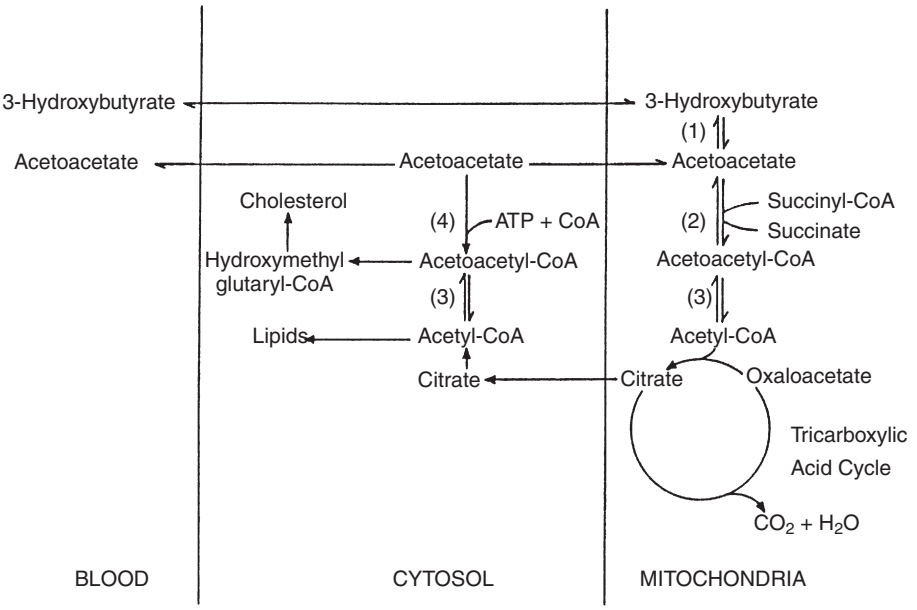

Figure 45-7 Pathways of ketone body utilization in peripheral tissues: *1,* hydroxybutyrate dehydrogenase; *2,* 3-oxoacid–CoA transferase; *3,* acetoacetyl–CoA thiolase; *4,* acetoacetyl–CoA synthetase. *ATP,* Adenosine triphosphate; *CoA,* coenzyme A.

3-oxoacid–CoA transferase [EC 2.8.3.5], which carries out the following reversible reaction:

$$\text{Acetoacetate} + \text{succinyl-CoA} \rightleftharpoons \text{acetoacetyl-CoA} + \text{succinate}$$

The succinyl-CoA is derived from the tricarboxylic acid cycle and as succinate is returned to the cycle; no loss of cycle intermediates occurs. The equilibrium of the reaction is in favor of acetoacetate formation. The K_m value (around 0.2 mM) of 3-oxoacid–CoA transferase for acetoacetate and its kinetic properties are similar in different rat tissues.[79] The transferase of rat tissues is inhibited by acetoacetate at concentrations in excess of 5 mM; this inhibition may depress ketone body utilization in severe hyperketonemic situations.[80]

The acetoacetyl-CoA formed is cleaved by acetoacetyl-CoA thiolase [EC 2.3.1.9] to yield two molecules of acetyl-CoA:

$$\text{Acetoacetyl-CoA} + \text{CoA} \rightleftharpoons 2 \text{ acetyl-CoA}$$

The equilibrium of this reaction is strongly in favor of acetyl-CoA formation, and when this reaction is coupled with that of the 3-oxoacid–CoA transferase, utilization of acetoacetate is favored. Acetoacetyl-CoA thiolase, unlike the transferase, is present in both the mitochondrial matrix and the cytosol.[81]

D(–)-3-Hydroxybutyrate is oxidized to acetoacetate by 3-hydroxybutyrate dehydrogenase [EC 1.1.1.30].

$$\text{D(–)-3-Hydroxybutyrate} + \text{NAD}^+ \rightleftharpoons \text{acetoacetate} + \text{NADH} + \text{H}^+$$

where NAD^+ is nicotinamide adenine dinucleotide and NADH is its reduced form. The reaction is reversible, but the equilibrium is in favor of acetoacetate reduction. The dehydrogenase is tightly bound to the inner mitochondrial membrane.

Unlike the hepatic HMG-CoA pathway for synthesis of ketone bodies (see Figure 45-5), the mitochondrial utilization pathway is freely reversible. So long as the cell contains sufficient activity of the three enzymes to catalyze near-equilibrium among the three reactions, the utilization of ketone bodies depends on the prevailing concentrations of 3-hydroxybutyrate and acetoacetate and the rate of removal of acetyl-CoA. The latter depends on the activity of the tricarboxylic acid cycle and on the rate of acetyl-CoA formation from other substrates, mainly, oxidation of fatty acids. This alternative acetyl-CoA source explains why it is possible to demonstrate net formation of ketone bodies in vitro when kidney slices are incubated with fatty acids.[82] Thus, in certain tissues, the free reversibility of the pathway can be viewed as means of "buffering" the mitochondrial acetyl-CoA pool. Of course, the concentrations of co-substrates (succinyl-CoA, succinate) and cofactors (CoA, NAD^+, NADH) also may influence the utilization of ketone bodies.

As already stated, the major role of the mitochondrial pathway is to allow complete oxidation of ketone bodies for energy supply. in tissues with active lipogenesis, however, a portion of the acetyl-CoA is transported to the cytosol in the form of citrate to act as a precursor for lipid synthesis (see Figure 45-7).

Cytosolic Pathway

The cytosol of all lipogenic tissues—brown and white adipose tissue, developing brain, lactating mammary gland, and liver—contains an enzyme, acetoacetyl-CoA synthetase, that converts acetoacetate into acetoacetyl-CoA[83-85]:

$$\text{Acetoacetate} + \text{ATP} + \text{CoA} \rightarrow \text{acetoacetyl-CoA} + \text{AMP} + \text{pyrophosphate}$$

This reaction is virtually irreversible, and its activity is, at most, 10% of that of the 3-oxoacid–CoA transferase. However, the enzyme has a high affinity (K_m = 50 μM) for acetoacetate and is therefore probably saturated with substrate even in the fed state.

The presence of 3-hydroxy-3-methylglutaryl-CoA synthase [EC.4.1.3.5] and acetoacetyl-CoA thiolase in the cytosol of the lipogenic tissues allows the acetoacetyl-CoA from acetoacetate to enter the pathway of sterol synthesis (see Figure 45-7). Experiments in suckling rat brain in vivo[86,87] and in adult rat liver in vitro[88] have yielded evidence for the preferential conversion of acetoacetate to sterols rather than lipids The activity of acetoacetyl–CoA synthetase is very low in suckling rat liver and increases on weaning.[84,85] Although of relatively low activity compared with that of the mitochondrial pathway, the cytosolic pathway allows the specific direction of acetoacetate to lipid or sterol synthesis (see Figure 45-7). The fact that the cytosolic pathway is irreversible means that the flux is unidirectional—which, together with the delivery of acetoacetyl-CoA and acetyl-CoA at the site of utilization, may be the physiologic advantage of this pathway over the mitochondrial pathway.

Utilization of L(+)-3-Hydroxybutyrate

It is generally accepted that D(−)-3-hydroxybutyrate, the isomer present in biologic fluids, is the physiologic substrate. However, the L(+) isomer also can be used by mammalian tissues,[88-91] although its presence in the circulation has not yet been demonstrated. A comprehensive study of the enzymes of L(+)-3-hydroxybutyrate metabolism in the adult rat has been reported.[92] In suckling rat brain, the L(+) isomer can be effectively used for synthesis of fatty acids and sterols.[91,92] These findings may be important when DL-3-hydroxybutyrate is administered to humans.

Acetone as a Gluconeogenic Precursor

Acetone is produced by decarboxylation of acetoacetate:

$$\text{Acetoacetate} \rightarrow \text{acetone} + CO_2$$

and it can reach high concentrations in blood in states of prolonged hyperketonemia (starvation, diabetic ketoacidosis). The rate of chemical decarboxylation is insufficient to explain the rate of acetone formation; therefore tissue acetoacetate decarboxylases have been implicated.[93] A rat kidney enzyme has been studied that has a K_m for acetone around 1 mM and is competitively inhibited by its substrate.[93]

Although early radioactive tracer experiments demonstrated that [2-^{14}C]-acetone can be converted to liver glycogen,[94] only recently has this mechanism been investigated in detail,[93,95] and net conversion of acetone to glucose has been measured in rat hepatocytes.[96] The pathways for acetone conversion to glucose are shown in Figure 45-8. Current evidence suggests that at low acetone concentrations (physiologic conditions), most of the acetone is converted to glucose, but that at high concentrations (hyperketonemia), the acetone is converted mainly to acetate[95] (see Figure 45-8). A study in human diabetic ketoacidosis with [2-^{14}C]acetone indicated that some 10% of the newly gained glucose carbon atoms were derived from acetone.[97] This rate of conversion of fat to carbohydrate (fatty acid oxidation → acetoacetate → acetone → glucose) is not insignificant and merits investigation in neonatal liver.

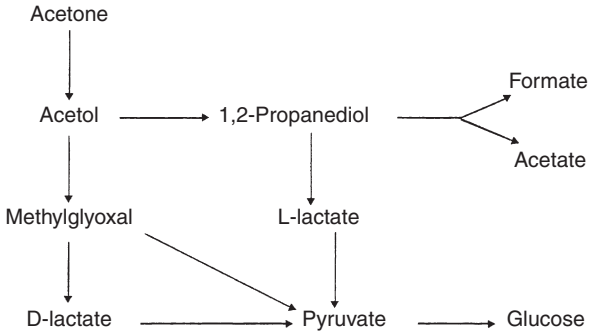

Figure 45-8 Pathways in the conversion of acetone to glucose.

Enzyme Activity

Adult Tissues

The relative activities of the enzymes of ketone body utilization in adult rat tissues are given in Table 45-3. The mitochondrial pathway is most active in kidney, heart, brown adipose tissue, and adrenal gland, followed by submaxillary gland, lactating mammary gland, and brain (see Table 45-3). The activities do not change appreciably during short-term fat feeding, starvation, or alloxan-induced diabetes.[22,98,99] By contrast, the cytosolic pathway enzyme acetoacetyl-CoA synthetase is more sensitive to alterations of hormonal and nutritional status.[83,85,100]

Neonatal Tissues

In contrast with those in the adult, the enzymes of ketone body utilization show marked changes in activity during development of the rat, and the pattern is tissue-specific. The activities of 3-hydroxybutyrate dehydrogenase and 3-oxoacid–transferase increase after birth to reach adult levels by approximately 5 days post partum and then continue to rise until just before weaning, when the values are two to three times higher than those in the adult.[22,24,47,101-103] Experiments indicate that the amount of 3-oxoacid–CoA transferase mRNA is three times higher in suckling rat brain than in fetal or adult brain.[104] Experiments with a modified milk formula low in fat have shown that the physiologic hyperketonemia in the neonatal period is not essential for the normal development of 3-oxoacid–CoA transferase in rat brain.[105]

By contrast, in the two adult tissues that have the highest activity of these enzymes, namely, kidney and heart (see Table 45-3), the activities remain below the adult values throughout the suckling period. If the changes in tissue mass during development also are taken into account, it is clear that neonatal brain is the major site for ketone body utilization.

The activities of the cytosolic pathway enzymes (see Figure 45-7) also are higher in neonatal rat brain.[84,106] These findings support their postulated role in lipogenesis (myelinization).

This pattern of increased capacity for utilization of ketone bodies in neonatal rat brain is not shown in other species. In neonatal pigs, the concentration of blood ketone bodies is low,[13,107] and the brain activity of 3-oxoacid–CoA transferase is barely detectable.[108] In contrast with the findings in rat, the transferase activity in neonatal pig heart and kidney is considerably higher than that in neonatal pig brain.[108] Similarly, the activities of 3-oxoacid–CoA transferase and 3-hydroxybutyrate dehydrogenase remain low throughout the neonatal period in guinea pig brain.[109] Data are lacking on the activities of the enzymes of ketone body utilization in human neonatal tissues. The available information derived from postmortem material suggests that in brain, the activities of the mitochondrial pathway enzymes remain comparatively constant throughout the postnatal period.[110,111]

Effects of Ketone Bodies on Glucose Metabolism

Glucose Utilization

It is well established that physiologic concentrations of acetoacetate and 3-hydroxybutyrate decrease glucose utilization in a number of adult rat tissues, including heart, soleus muscle, kidney, brain, and lactating mammary gland.[32] These tissues all exhibit high rates of glycolysis and utilization of the pyruvate formed from glucose-6-phosphate. Consequently, if glucose metabolism was not inhibited in situations associated with carbohydrate lack, the animal would rapidly become hypoglycemic. The mechanism for the inhibition of glucose metabolism by ketone bodies was established in studies by Randle and colleagues[112] and involves inhibition of the enzymes phosphofructokinase [EC 2.7.1.11] and hexokinase [EC 2.7.1.1] and inactivation of pyruvate dehydrogenase [EC 1.2.4.1]. The overall effect is decreased glucose utilization. In addition, a higher proportion of any glucose that still undergoes glycolysis leaves the tissue as lactate and pyruvate and returns to the liver for gluconeogenesis. No systematic investigation of this "sparing" of glucose by ketone bodies appears to have been made in neonatal tissues. In normal children, however, an inverse correlation has been noted between glucose flux and the degree of ketonemia.[113] This observation supports the view that glucose and ketone body interactions operate at the whole-body level.

Glucose Production

Ketone bodies can alter hepatic glucose production by their effects on the supply of two important precursors, glycerol and alanine. Ketone bodies decrease flux of glycerol to the liver by

TABLE 45-3

Relative Activities of Enzymes of Ketone Body Utilization in Adult Rat Tissues

Tissue	RELATIVE ENZYME ACTIVITY*			
	3-Oxoacid-CoA Transferase	Acetoacetyl-CoA Thiolase	3-Hydroxybutyrate Dehydrogenase	Acetoacetyl-CoA Synthetase
Adipose tissue—white	0.14	0.05	—	1.0
Adipose tissue—brown	6.9	10.0	—	—

Muscle (hind limb)	0.4	0.3	1.0	—
Submaxillary gland	3.2	1.1	—	—

*The respective enzyme activities (in mol/min per g fresh wt. at 25° C) for adult rat brain were set at unity (transferase: 2.1; thiolase: 2.1; dehydrogenase: 0.6; synthetase: 0.01). For further details, see references 32, 141, 142, 144.

†Higher values are reported during dark phase.[48]

their antilipolytic action on adipose tissue and apparently also on muscle triacylglycerol stores.[114] Hypoalaninemia is present in a number of conditions associated with hyperketonemia, including starvation, diabetes, and ketotic hypoglycemia of childhood, and can be induced by infusion of 3-hydroxybutyrate.[115] The mechanism by which ketone bodies decrease muscle release of alanine has not yet been established. Two possibilities are recognized: (1) inhibition of muscle glycolysis decreases pyruvate availability to form alanine by transamination or (2) a direct inhibition of muscle proteolysis.

Roles of Ketone Bodies in Neonatal Tissues

Only three neonatal tissues of the rat—brain, lung, and brown adipose tissue—have been examined in any detail with regard to ketone body metabolism. The findings are briefly discussed next.

Brain

Arteriovenous difference measurements across the brain of adult and suckling rats have shown that for a given arterial concentration of ketone bodies, the extraction by suckling brain is three to four times higher than by adult brain.[77,116] This finding is in agreement with the higher activities of the enzymes of ketone body utilization in suckling brain. A similar increase in ketone body extraction by brain has been demonstrated when human neonates and adults have been compared.[117,118] However, no appreciable increase in the activities of the enzymes of ketone body utilization has been demonstrated in human neonatal brain.[110,118] Therefore the increased utilization in the human neonatal brain is likely to be due to another factor. A possibility is increased cerebral permeability to ketone bodies, as demonstrated in neonatal rat brain.[119]

The major portion (90%) of the ketone bodies used by suckling brain is likely to be completely oxidized to provide energy,[120] thereby sparing glucose. However, it is now well established that a portion of the carbon (5% to 10%) is converted to fatty acids and cholesterol.[86,106,111,120,121]

Ketone bodies inhibit glucose utilization in a number of rat tissues, but such inhibition does not occur in brain.[122,123] They do, however, decrease glucose oxidation and its conversion to lipid,[122,124] suggesting inhibition of pyruvate dehydrogenase. Support for this hypothesis is the correlation between ketone body extraction by the brain and the proportion of extracted glucose released as lactate and pyruvate in rat[123] and humans.[125]

A point worthy of emphasis is that measurements of arteriovenous differences or enzyme activities in whole brain give no information on the regional utilization of ketone bodies within the brain. This question has been addressed in some elegant experiments,[126] and it appears that the telencephalon uses the most ketone bodies and the hind brain the least.[126,127]

Lung

Like neonatal brain, the developing lung has a specific requirement for the synthesis of complex lipids, that is, pulmonary surfactant. In vivo synthesis of lipids is more rapid from acetoacetate than from glucose, and the incorporation of ketone bodies appears to occur through direct generation of cytosolic acetyl-CoA.[128] The presence of cytoplasmic acetoacetyl-CoA synthetase and acetoacetyl-CoA thiolase and their developmental pattern, which parallels that of acetoacetate incorporation into fatty acids, indicates that the cytoplasmic pathway (see Figure 45-7) is as important in this tissue in the immediate postnatal period[129] as it is in developing brain.

Fetal Tissues

As already discussed, the fetus is exposed to the concentrations of ketone bodies present in maternal blood. The utilization of ketone bodies as oxidizable substrates has been demonstrated in the fetal human brain[130] and in several tissues of the fetal rat,[131] including liver.[132] The interpretation of these findings is not clear, however, because in some experiments, the tracer used was DL-[3-^{14}C]hydroxybutyrate, so the metabolism of the nonphysiologic L isomer may have made a contribution to $^{14}CO_2$ production. Ketone bodies also can act as lipogenic substrates in the fetus.[133] Injection of D-[3-^{14}C]hydroxybutyrate into the femoral vein of pregnant rats in late gestation results in significant incorporation into the lipids of a number of tissues,[133] the greatest relative incorporation on a per gram basis being into brown adipose tissue.

Ketone Bodies and the Embryo

In contrast with fetal and neonatal tissues, the rates of $^{14}CO_2$ production by mouse conceptuses in vitro from DL-[3-^{14}C]hydroxybutyrate are higher than those from the D isomer, suggesting that utilization of the L isomer is greater.[134] Of some concern is the finding that DL-3-hydroxybutyrate has a teratogenic effect on rodent embryos in culture[135-137]; the malformations are similar to those observed in offspring of human diabetics.[138] One potential pathogenic mechanism appears to be inhibition of the

oxidative pentose phosphate pathway of glucose metabolism,[139] which supplies ribose moieties for pyrimidine synthesis. It may be relevant that DL-3-hydroxybutyrate also inhibits the synthesis of pyrimidines in fetal brain slices.[139] Ribose supplementation will maintain the rate of DNA synthesis in embryos exposed to DL-3-hydroxybutyrate,[140] which is consistent with the proposed mechanism of action of the hydroxybutyrate.

It thus appears that increased maternal blood concentrations of ketone bodies in the first weeks of pregnancy secondary to malnutrition or insulin deficiency (diabetes mellitus) may lead to malformations in the embryo and subsequent abortion. This sequence of events can be viewed as a mechanism for terminating pregnancy in adverse conditions.

Long-Chain Fatty Acids in the Developing Retina and Brain

The brain and retina contain large quantities of long-chain (20 and 22 carbon) n-3 and n-6 polyunsaturated fatty acids (LCPUFAs), particularly docosahexaenoic acid (DHA; 22:6n-3) and arachidonic acid (AA; 20:4n-6).[1,2] During the last intrauterine trimester[3,4] and the first 18 months of postnatal life, DHA and AA accumulate in neural tissue at a high rate supported by selective placental transfer of DHA and AA from mother to fetus[5,6]; transfer from human milk consumption to breast-fed infants[7,8]; and synthesis from the dietary essential fatty acids, α-linolenic acid (18:3n-3), and linoleic acid (18:2n-6),[9-12] respectively. In 2002, DHA and AA were added to infant formulas in the United States. (For a more extensive treatment of these topics, see Chapter 41[13] and Chapter 42.[14])

In animal studies, diets deficient in α-linolenic acid result in lower brain DHA level and a reciprocal increase in docosapentaenoic acid (DPA; 22:5n-6 or n-6 DPA) (Figure 46-1),[15] which has been related to atypical retinal physiology[16-18] and development of visual acuity,[19] as well as atypical learning abilities.[20-28] As first observed in the late 1970s and now well established, infants fed formulas without DHA have lower levels of DHA in red blood cell and plasma lipids than do breast-fed infants.[7,8] Even though early infant formulas contained essential fatty acids, these formulas lacked DHA or AA. It was hypothesized that lower DHA in the lipid profiles of formula-fed infants could indicate limited DHA accumulation in the brain and retina, thereby resulting in less than optimal sensory and cognitive function.

Randomized studies of DHA supplementation in infants were necessary to determine whether functional outcomes such as visual acuity could be improved by adding DHA to infant formula. The first small studies focused on infants born preterm because they were considered more likely than infants born at term to need supplemental dietary DHA; that is, they are born before maternofetal DHA transfer is complete[3,4] and before lactation is possible. The first preliminary reports of higher visual acuity[29] and more mature retinal physiology[30] as a function of supplementation were followed by full reports in 1992 and 1993.[31,32]

After Makrides and associates[33] reported an association between higher DHA status and visual acuity in breast-fed infants born at term, the first randomized trials in preterm infants were conducted to determine the potential benefits of adding DHA to all infant formulas.[34,35] Subsequently researchers have conducted a number of randomized trials to compare the growth and development of term and preterm infants fed formulas with varying levels of DHA and sources of DHA, as well as of infants born to mothers who received DHA supplementation during pregnancy or lactation. These randomized trials have been reviewed and reported elsewhere.[36-41]

Dietary sources of AA were not available for addition to infant formulas when the first randomized studies were conducted; when early studies showed slower growth in infants born preterm who were fed DHA and not AA,[42,43] it was speculated that this could be due to an imbalance of the n-3 and n-6 LCPUFA. On the basis of findings that AA is important for typical growth,[44] that dietary n-3 LCPUFA reduces red blood cell phospholipid AA,[45] and that the concentration of AA in circulating lipids is related to size at birth[46] and first-year growth achievement,[47] subsequent study formulas have included AA and DHA to provide a balance of n-3 and n-6 LCPUFA. A review of the randomized studies in which growth was assessed, however, failed to reveal any physiologically relevant difference between the growth rates of infants fed formulas containing both DHA and AA and growth rates of infants fed control formulas.[48] Nonetheless, it can be argued that AA should be a component of early milk because it is present in all human milk. As well, AA is a major component of brain phospholipids, which accumulate rapidly after birth.[4]

Both DHA and AA were added to commercially available term and preterm formulas in the United States in 2002 after the Food and Drug Administration gave generally recognized as safe (GRAS) status to specific single-cell oil sources of DHA and AA *(Federal Register).* After the addition of DHA and AA to infant formula, research in this area has focused on questions of the proper timing of supplementation for effective accumulation of DHA and the optimal level of supplementation. Work on animal models has continued to focus on the mechanisms in the retina and brain by which DHA influences functional performance.

HISTORICAL PERSPECTIVE

DHA constitutes 30% to 45% of the total fatty acids in some phospholipid classes (specifically ethanolamine and serine phosphoglycerides) in brain gray matter and the retina, respectively. In the

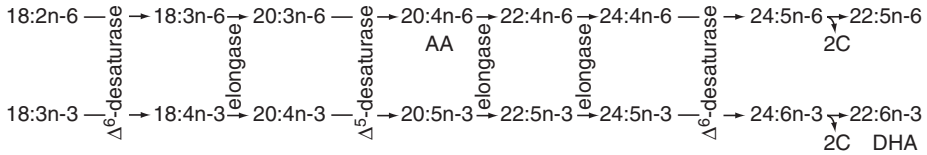

Figure 46-1 Elongation and desaturation of the essential fatty acids linoleic acid (18:2n-6) and linolenic acid (18:3n-3).

brain, DHA is especially concentrated in membranes surrounding synapses.[1] In the retina, DHA is concentrated in the synaptic regions and in the disk membranes of photoreceptors.[2] During the last intrauterine trimester, brain DHA increases exponentially and AA decreases linearly, such that the ratio of DHA to AA in the retina doubles between 24 and 40 weeks of gestation and increases further after birth.[49]

Sanders and Naismith[7] and Putnam and colleagues[8] were the first to show, in infants born at term, that those who were formula fed had lower erythrocyte phospholipid DHA and AA levels compared with breast-fed infants. Infants fed a formula that contained 5% of total fatty acids as α-linolenic acid had similar amounts of DHA in red blood cell phospholipids when compared with infants fed a formula with 1.2% α-linolenic acid, suggesting that α-linolenic acid intake was not the cause of lower levels of circulating DHA.[8] This observation was consistent with the observation of Sinclair and Crawford[50,51] that DHA and AA were more efficiently incorporated into rat brain than were their essential fatty acid precursors.

A study of rats fed an α-linolenic acid–deficient diet during development demonstrated that lower DHA accumulation in the brain was reflected in lower red blood cell phospholipid DHA.[52] From the human and rat studies,[7,8,52] it was inferred that DHA intake was the most likely reason for higher red blood cell DHA in breast-fed compared with formula-fed infants and that it was reasonable to conclude that red blood cell DHA accurately reflected brain DHA accumulation.

Clandinin and colleagues[3] first demonstrated that fetal brain DHA and AA accumulate during the third intrauterine trimester and that this accumulation continued after birth. A later report by Martinez[4] confirmed this finding of rapid postnatal DHA accumulation with a larger sample. Infants born preterm could miss as many as 18 weeks of intrauterine DHA transfer. Formula-fed compared with human milk–fed infants born preterm also had lower levels of erythrocyte phospholipid DHA and AA.[53] This finding was similar to α-linolenic acid–deficient rodents and nonhuman primates that exhibited behavioral effects of deficiency. It was hypothesized that formulas containing DHA relative to formulas containing α-linolenic acid as the only n-3 fatty acid could improve early visual and neural development of infants born at the beginning of the last trimester. As will be detailed, the experimental human studies compared outcomes in infants fed formulas that contained α-linolenic acid with or without a source of DHA. Later, infant and child development was studied for the effects of providing variable amounts of DHA during fetal or postnatal life by experimentally altering maternal DHA intake.

FACTORS INFLUENCING ACCUMULATION OF LONG-CHAIN POLYUNSATURATED FATTY ACIDS DURING DEVELOPMENT

The timing of brain fatty acid accumulation varies considerably among mammalian species. Humans can receive a preformed supply of DHA from the mother both before and after birth,[7,8,53-56] whereas guinea pigs receive most maternal LCPUFA during fetal life[57] and rats receive most maternal LCPUFA after birth.[50] Researchers have used these differences to create models for studying the temporal effects of low brain DHA levels on brain development. For example, newborn rats may be a model for human DHA accretion beginning with the third intrauterine trimester, whereas in newborn pigs postnatal DHA accretion resembles that in postnatal humans. We will describe the processes through which LCPUFA is accumulated by the body. Research in this area is necessarily reliant on animal models, and it is with caution that we extend results from the animal literature to the human.

Maternal Influences on Accumulation of Arachidonic Acid and Docosahexaenoic Acid in the Fetus and Infant

Arbuckle and Innis[58] found that feeding fish oil to pigs increased DHA levels in sow milk, as well as in the tissues of piglets. Connor and colleagues[59] and Harris and associates[60] published the first direct evidence in humans that consumption of fish oil by lactating women increased the amount of postnatal DHA transfer to their infants in milk and increased the DHA status of their infants: fish oil consumption by breast-feeding women increased erythrocyte and plasma phospholipid DHA in their offspring.

Researchers have shown that maternal DHA status is highly variable during pregnancy and lactation,[61-66] and maternal DHA status is related to the DHA status of the infant.[61,62,65,67] Two independent research groups showed that infants fed human milk compared with infants fed formulas without DHA had more brain DHA at autopsy.[68,69] Other observational studies associated higher maternal DHA status during pregnancy with higher infant development status.[33,70-73] This evidence suggests that prenatal and postnatal transfer of DHA can influence infant brain biochemistry and subsequent development.

Indeed, experimental studies have shown that maternal DHA status during pregnancy or lactation can enhance development.[74,75] Jensen and colleagues[74] randomly assigned women to consume DHA as single-cell oil during lactation. The toddlers of the women who received supplements had higher scores on a standardized test of motor function at 30 months of age. Similarly, Helland and colleagues[75] randomly assigned women to consume DHA in the form of fish oil with the goal of increasing DHA during pregnancy and lactation. They reported a higher intelligence quotient (IQ) at 4 years of age. Notably, no accelerated development was evident in either the Helland or Jensen samples during infancy (for discussion see Specific Measures of Cognitive Development section later in this chapter).[76,77]

Pregnancy itself alters the amount of DHA in circulating blood lipids and red blood cell phospholipids. Otto and colleagues[63] observed that phospholipid DHA in maternal plasma and red blood cells increased in early pregnancy, regardless of the initial levels of red blood cell DHA. These data suggest that DHA is mobilized during pregnancy for transfer to the fetus. However, the same group of investigators reported increased maternal n-6 DPA relative to DHA, from which they concluded that pregnant women's systems lag behind with respect to DHA production and transfer to the fetus.[64] Van Houwelingen and colleagues[78] observed similar relative increases in the ratio of n-6 DPA to DHA in infants born preterm, providing further evidence that an increase in n-6 DPA/DHA may be an indicator of inadequate DHA synthesis or accumulation. Thus, even though DHA is mobilized during pregnancy, it may not be sufficient for fetal development.

Several factors affect the amount of DHA available for mobilization. In a comparative study in pregnant women from the Netherlands, Hungary, Finland, England, and Ecuador, large differences were found in the percentage of fatty acids present in the blood as DHA.[61] These national differences most likely reflect differences in dietary DHA intake. The number of prior pregnancies has been shown to be inversely related to maternal DHA as well.[55] To our knowledge, no work has been undertaken to explore maternal DHA levels in women carrying multiple fetuses, but one might predict that multiple births would reduce maternal DHA transfer to each fetus.

Just as a woman's DHA status during pregnancy affects transfer of DHA to her fetus, a woman's DHA status also influences DHA transfer to her newborn in human milk. DHA content of human milk is quite variable within and among populations. The extremes of milk DHA that have been reported are, as a percentage of total fatty acids, 0.02% in vegans[79] and 2.4% in women from China who consume a diet high in fish.[80] Human milk DHA in most populations falls between 0.1% and 0.5% of total fatty acids.[55,56] In general, DHA content of human milk in the United States is within this range.[7,81-83] In a case study, the DHA content in the milk of a given woman consuming an American diet was relatively stable across two periods of lactation 9 months apart.[84] However, in a study in 12 fish-eating women, it was shown that DHA content in breast milk can vary 10-fold from day to day and is directly related to the timing of fish consumption.[85] As has been observed in other nutrients, some day-to-day variation would be expected. However, it is unlikely that such variability would be sufficient to have much impact on infant status, particularly among women whose DHA consumption is low.

As with DHA, the reported average amount of AA in human milk encompasses a wide range among cultural groups, from 0.2% to 1.2%.[83] However, the average AA in the milk of most populations falls within the range of 0.4% to 0.6%, and the linoleic acid content ranges from 10% to 17% of total fatty acids.[55,56,83]

Synthesis as a Source of Long-Chain Polyunsaturated Fatty Acids

Infants who do not receive dietary DHA must synthesize their DHA from α-linolenic acid (see Figure 46-1). Many clinical studies have asked whether infants who consume α-linolenic acid are able to accumulate enough brain DHA for optimal function or whether they would benefit from receiving additional dietary DHA. In a later section, the evidence of functional benefits of DHA is discussed. This section provides a brief review of DHA synthesis and the relative role that synthesis plays in tissue accumulation of DHA.

Voss and colleagues[86] followed stable isotope–labeled fatty acids and demonstrated that the likely pathway for conversion of α-linolenic acid to DHA involves two successive additions of two-carbon units to 20:5n-3 (20:5n-3 to 22:5n-3 to 24:5n-3) followed by a δ6-desaturation (24:5n-3 to 24:6n-3) and the subsequent removal of a two-carbon segment (24:6n-3 to DHA or 22:6n-3) (see Figure 46-1). Synthesis of DHA from 22:5n-3 by frog retinal pigment epithelium also generated 24:5n-3 and 24:6n-3.[87] The final step in synthesis of DHA occurs in peroxisomes. Important supporting evidence of the importance of peroxisomes in the supply of DHA comes from Martinez's studies in patients with peroxisomal disorders.[88,89]

DHA can be synthesized from α-linolenic acid by the liver, retina, and brain.[87,90-94] Synthesis in the retina has been localized to the retinal pigment epithelium,[87] and synthesis in the brain has been localized to astrocytes and cerebral endothelium.[93-95] Retinal photoreceptor cells and neurons do not synthesize DHA.[92-94] Chen and Anderson[96] found that DHA was preferentially incorporated into triglycerides in retinal pigment epithelium. Their observation suggests a role for triglycerides in the DHA enrichment of the retina or recycling of photoreceptor DHA between the retina and the retinal pigment epithelium. Electron microscopic studies of retinal DHA accumulation suggest that DHA is stored in lipid droplets of the pigment epithelium and is transferred to photoreceptors.[97] Moore and co-workers[93] suggested an analogous model for uptake of DHA by neurons. Either preformed DHA or n-3 fatty acid precursors of DHA could be taken up by the cerebral endothelium and incorporated into astrocytes, which could synthesize DHA and transfer it as well as preformed DHA to neurons. Innis and Dyer[95] showed that astrocytes release fatty acids in cholesterol esters.

Uauy and associates[30] generated early evidence that infants born preterm had the capacity to synthesize DHA from α-linolenic acid. These researchers showed that infants born preterm and fed formulas containing soybean oil had higher erythrocyte DHA levels than those fed formulas containing corn oil (a fat with much less α-linolenic acid than soybean oil). An early study showed δ6- and δ5-desaturase activity in the human liver at midgestation, suggesting that the fetus could metabolize essential fatty acids to more polyunsaturated forms.[98] Stable isotope studies in human infants born preterm and at term demonstrated whole body synthesis of DHA,[9-12] as well as high variability among infants.[11]

Only recently have stable isotope studies in humans permitted quantification of DHA accumulation from new synthesis relative to preformed DHA.[99] Using isotope ratios, Carnielli and colleagues[100] determined that whole body DHA synthesis of 1-month-old preterm infants was only 12.6 mg × kg^{-1} × day^{-1} of DHA, and DHA synthesis fell dramatically with time reaching only 3.2 mg × kg^{-1} × day^{-1} at 3 months of age. Not surprisingly, synthesis was also reduced by DHA feeding. Studies with nonhuman primate neonates are helpful for assessing the relative contribution to tissue DHA of newly synthesized versus preformed DHA. Studies with neonatal monkeys suggested that the amount of DHA derived from synthesis was relatively minor compared with the amount received from mother's milk.[101] Newborn baboons synthesized DHA from α-linolenic acid[102]; however, preformed DHA was eight times more likely than α-linolenic acid to accumulate in the brain. It has been estimated that the third-trimester fetus accumulates approximately 40 to 60 mg × kg^{-1} × day^{-1} of n-3 LCPUFA.[103] On the basis of the results of Carnielli and colleagues,[100] it is unlikely that synthesis of DHA from α-linolenic acid can meet the neonate's need for optimal brain DHA accumulation.

Although pigs[104,105] and possibly other species may have different relative capacities for synthesis of DHA compared with humans, studies with animals are valuable as a means of understanding the relative effects of different tissues and physiologic effects on DHA synthesis. In the rat, the activity of hepatic δ6- and δ5-desaturases falls after birth and then peaks after weaning, and brain activities are also maximal at birth and fall steadily through the first several weeks of life when animals are suckled.[106] Rat milk, like all mammalian milk, contains DHA. These changes in enzyme activity suggest a classic feedback inhibition of DHA on LCPUFA biosynthesis. The mouse exhibits a postnatal decline in brain δ6-desaturase activity similar to that in the rat.[107] After 3 months of age, mouse brain activity of this enzyme is extremely low, but hepatic activity remains fairly high through 9 months of age and then decreases dramatically at later ages.[107] In the fetal pig, δ5-desaturase activity increases by seven-fold in the brain and by 23-fold in the liver during the last half of gestation.[104,105]

Effects of Dietary Influences on Accumulation of Long-Chain Polyunsaturated Fatty Acids

From fatty acid analyses, it is known that diets deficient in α-linolenic acid decrease tissue DHA and increase n-6 DPA. Because of the recognized importance of retinal and neural DHA accumulation, most recent infant formulas in the United States

have contained a ratio of linoleic to α-linolenic acid of less than 10 and have provided at least 1.5% of total fatty acids (0.75% energy) as α-linolenic acid. Now that DHA and AA have been added to infant formulas in the United States, it may be time to reassess the high amount of linoleic acid and α-linolenic acid in some formulas. High levels of 24:2 have been reported to replace 24:1 in red blood cell sphingomyelin, especially in infants born preterm.[108] Transfer of essential fatty acids directly to the fetus during gestation appears to be limited, on the basis of low linoleic acid levels in circulating phospholipids of cord blood.[53] Maternal linoleic acid intake was inversely related to infant head circumference in one published study.[65]

A diet containing α-linolenic acid does not compensate for the DHA accumulation that occurs in red blood cells, plasma, and the brain of infants fed even small amounts of DHA.[32,45,68,69] In the months after birth, infants fed formulas that contain α-linolenic acid but not DHA have progressively lower amounts of circulating DHA.[45] Infants fed formulas with DHA have higher concentrations of red blood cell phospholipid DHA, an indicator of infant DHA status, than infants fed formulas with more than 0.75% energy from α-linolenic acid.[32,45]

Breast-fed human infants have higher brain,[68,69] but not retinal,[69] DHA accumulation compared with infants who were fed formulas without DHA. A functional study by Uauy and coworkers[109] found normal electroretinogram responses in infants at 4 months corrected age who were born preterm, even though they had been fed a formula low in α-linolenic acid from birth. Thus, although diets deficient in α-linolenic acid lead to reduced retinal DHA in monkeys[110] and piglets,[111] it appears that formulas that contain α-linolenic acid and no DHA may provide for sufficient retinal DHA.[112]

The many remaining questions include whether brain DHA in formula-fed infants eventually catches up to that of milk-fed animals, whether there is a critical period for accumulating retinal and brain DHA, whether there is a threshold of DHA accumulation in retina and brain for optimal function, and whether there is a level of DHA intake that might be harmful to the developing infant. In addition, it remains uncertain whether any of the answers to these questions interacts with gestational age, size at birth, or other maternal or infant factors.

EFFECTS OF ESSENTIAL FATTY ACID DEFICIENCY ON BEHAVIOR

The kinds of behavior in animals subjected to toxic insult or nutrient variation during development can provide useful information about affected behavioral domains, which, in turn, reflect neural function. Behavioral domains include sensory, motivational or arousal, learning, cognitive, and motor. Wainwright[113,114] has reviewed the principles governing animal models of behavior and the evidence from these models that lipids influence behavior. Carlson[115] and Mostofsky[116] have reviewed models and methods for studying behavior that have been or could be applied to studies of n-3 fatty acid–deficient animals.

The earliest studies of essential fatty acid deficiency restricted intake of dietary fat, thereby producing deficiency in both linoleic and α-linolenic acids. Diets deficient in both essential fatty acids led to reduced number of brain cells; lower LCPUFAs in the brain; and poor growth, probably from AA deficiency.[117] Diets containing linoleic acid but little α-linolenic acid (e.g., made with safflower oil or sunflower oil) reduce DHA accumulation in the retina and brain, with a proportional increase in n-6 DPA compared with diets that contain α-linolenic acid. Animals fed α-linolenic acid–deficient diets grow normally and have no evidence of disease; however, they have atypical retinal responses to light,[16,17,110] visual acuity,[19] and behavior.[20-28,36,118,119] Behavioral studies of α-linolenic acid–deficient animals differ from studies of DHA adequacy that have been done in human infants. In the animal models, DHA is low because dietary α-linolenic acid is deficient. In the infant studies, α-linolenic acid is not deficient. However, as noted above (and supported by the evidence from stable isotope studies), synthesis of DHA from α-linolenic acid may appear sufficient to support optimal brain DHA accumulation and function. Studies of n-3 fatty acid–deficient animals provide clues to the effects of lower brain DHA on behavior, regardless of why brain DHA is reduced. However, given that infants can synthesize DHA from its essential fatty acid precursor,[9-12] any effects of inadequate conversion would likely be less severe than those found in animal models of n-3 fatty acid deficiency.

Evidence of the Sensory Effects of n-3 Fatty Acid Deficiency

The physiologic response of the retina evoked by a brief flash of light (electroretinogram [ERG]) has components determined by the photoreceptor outer segments and the synaptic regions of the retina, the a wave and b wave, respectively. Diets deficient in n-3 fatty acid have a negative effect on the ERG in rats and monkeys. Wheeler and colleagues[17] reported a higher a-wave amplitude in rats fed α-linolenic acid compared with linoleic acid. Feeding α-linolenic acid to depleted animals only partially normalized the a-wave amplitude, evidence that the effects of n-3 fatty acid depletion on retinal physiology were not completely reversible.[16] Other investigators have also reported lower a-wave and b-wave amplitudes in n-3 fatty acid–deficient rats[24,120] compared with controls, but reports to the contrary exist in the rat and guinea pig.[121] Among ERG studies, the variability in results may be caused by differences in the duration of light stimulus, interstimulus interval, stimulus intensity, and the degree of n-3 fatty acid deficiency. For example, an effect on amplitude would be suggested in n-3 fatty acid–deficient animals with a long recovery latency if the retinas were not allowed to recover fully between stimuli.

In n-3 fatty acid–deficient monkeys, the ERG responses of retinal rods and cones are delayed compared with controls, and the time required for the dark-adapted retina to recover from an initial bright flash of light is significantly increased.[110,122] Monkeys deficient in n-3 fatty acid have also been found to have transiently lower a-wave and b-wave amplitudes compared with controls.[122] When n-3 fatty acid–deficient monkeys were fed fish oil, brain DHA increased to normal levels in both young and adult animals. However, the ERG peak latencies did not return to normative values.[122] In fact, even when n-3 fatty acid repletion was started at birth, membrane DHA was reduced, and recovery of the dark-adapted ERG was prolonged relative to controls. These results may be attributable to the finding that, at birth, the monkey retina is more developed than the human retina, and thus some critical developmental period and the opportunity for repleting the deficiency may have passed.[122]

Visual acuity requires a functional retina and a functional brain. Monkey infants whose mothers were fed an n-3 fatty acid–deficient diet made with safflower oil during pregnancy had only half as much DHA in phospholipids as those whose mothers were fed a diet with soybean oil.[19] The n-3 fatty acid–deficient animals had lower visual acuity (determined by forced choice preferential looking) at 4, 8, and 12 weeks of age compared with controls. Bogener and associates[123] and Radel and associates[124] studied brain cortical responses evoked by visual and auditory stimuli in a rat model, and the brain DHA depletion was observed to be similar to that occurring in human infants fed α-linolenic acid without DHA. In adult rats, visual and auditory brain cortical responses showed increased amplitudes in deficient animals[123,124] compared with controls, a finding suggesting decreased ability to inhibit responses to these stimuli. Evidence that the responses were cortical was suggested by the finding that both the ERG and auditory brain responses were within typical ranges. Half of

the animals in each litter were given a diet with DHA beginning at weaning, and their visual, but not auditory, cortical responses returned to normative levels as adults.[124] In addition, a lowered pain threshold with n-3 fatty acid deficiency has been demonstrated and may reflect an effect on sensory function.[125,126]

Evidence of the Cognitive Effects of n-3 Fatty Acid Deficiency

Some studies in rodents suggest that n-3 fatty acid–deficient animals may learn more slowly than n-3 fatty acid–sufficient animals. Differences in performance on tasks generally thought to reflect learning could be evidence of effects on cognition. However, as Wainwright[113,114] has pointed out, many studies did not control for what are known to be effects of n-3 fatty acid deficiency on visual function, reflex development, and exploratory activity, all of which could influence performance even if the ability to learn were unaffected by n-3 fatty acid deficiency.

Lamptey and Walker[20] noted that the offspring of rats fed safflower oil compared with soybean oil had diminished ability to discriminate in a black and white Y-maze that used food as reinforcement. Similarly, Yamamoto and colleagues[21,22] demonstrated that n-3–deficient animals had difficulty discriminating between levels of light intensity to obtain food and required longer to extinguish previously reinforced behavior in a new task. Yehuda and Carasso[126] also reported poorer ability to extinguish a previously learned behavior in n-3–deficient rats. These studies and many more provide the basis for the hypothesis that n-3 fatty acids have an effect on cognitive processes.

Further work with monkeys revealed an inverse relationship between brain DHA accumulation and look duration during a visual recognition task.[28] The observation could be interpreted as evidence of an effect of higher brain DHA on the speed of learning visual stimuli, because the duration of looking generally declines over age during infancy, and shorter look durations are generally associated with faster perceptual learning.[127] Alternative explanations for shorter look durations include increased ability to disengage attention[128] and lower reactivity.[129] Nevertheless, each of these possible explanations suggests a positive effect on cognition of higher brain DHA during development.[130]

Using mice, Frances and colleagues[131] studied the effects of n-3 deficiency on habituation, a form of learning, and found that habituation occurred more slowly in deficient mice relative to repleted mice. In a brightness discrimination task, n-3–deficient mice exhibited inferior learning that was not rectified by practice.[132] However, it has been shown that altered learning behavior in n-3 fatty acid–deficient mice can be reversed by supplementing with DHA after weaning,[133] and the altered learning patterns seen in deficient mice are not associated with substantial changes in the rate of protein synthesis in the brain.[134] Researchers who measured learning through tasks that did not require visual function, but rather tested olfactory function, found higher performance in rats fed α-linolenic acid compared with an n-3 fatty acid–deficient diet.[135-138] Thus, because olfactory function is not thought to be affected by DHA deficiency, these studies are indicative of an effect of DHA on cognition independent of sensory processes.

Evidence of the Effects of n-3 Fatty Acid Deficiency on Motivation and Arousal

Rats fed n-3 fatty acid–deficient diets were reported to have increased exploratory activity in a novel environment,[139] which Wainwright[113] suggested may reflect greater arousal. Differences in arousal may also explain the polydipsia and polyuria that have been observed in n-3 fatty acid–deficient monkeys that have normal renal function, growth, and physical health.[140] Reisbick and associates[119] reported evidence of a higher frequency of stereotyped behavior, higher locomotor activity, and higher general behavioral reactivity in n-3 fatty acid–deficient monkeys. Moreover, it has been reported that DHA and AA supplementation in the diets of infant rhesus monkeys markedly increased heart rate variability that persisted into adolescence.[141] According to these authors, dysregulation of behavior resulting in, for example, aggression, is related to a concomitant dysregulation of sympathetic responses such as heart rate variability. Thus proper levels of fatty acids are important for arousal and behavior regulation.

Changes in arousal and motivation may be related to catecholaminergic systems.[142] Levant and colleagues[143] used a model of physiologically relevant reduction in brain DHA content (i.e., modeled after reductions that have been observed in human infants[68,69]) to explore behavioral changes reflective of dopaminergic tone, in particular hyperactivity of the mesolimbic dopamine system.[144] They found higher basal locomotor activity in n-3 fatty acid–deficient adult rats that did not normalize in deficient rats fed a fish-oil source of DHA starting at 21 days of age. Rats that were n-3 deficient through adulthood exhibited significantly higher activity levels relative to controls in a novel environment consistent with dysregulation of the dopamine systems. Wainwright[114] showed that n-3 fatty acid–deficient rats had delayed matching-to-place abilities in the water maze compared with controls, a task associated with prefrontal dopamine function. As discussed later in this chapter, this finding suggests negative effects of n-3 fatty acid deficiency on higher order cognitions but also reflects altered states of motivation.

Possible Mechanisms for Changes in Behavior With Lower Brain Docosahexaenoic Acid Accumulation

Although it is clear from numerous studies that variations in brain DHA influence behavior, the underlying mechanism by which this occurs has not yet been definitively explained. It was hypothesized early on that a cyclooxygenase or lipoxygenase metabolite of DHA, but not n-6 DPA, played an important role in the function of the central nervous system, but a review by Salem and associates[145] found insufficient evidence to support this idea.

Another hypothesis, for which there is now good evidence, was that phospholipids containing DHA compared with those containing n-6 DPA affected cellular functions. Using a specific example of visual signaling, Salem and associates[145] reported evidence that the signaling pathways depended on the acyl side chains of phospholipids. Cellular studies demonstrated the importance of DHA for the synthesis and accumulation of phosphatidylserine, an aminophospholipid enriched in DHA. Other cellular studies showed that phosphatidylserine accumulation is related to the antiapoptotic effect of DHA.[145] Finally, biophysical studies of membranes constituted with DHA or DPA n-6 in the sn-2 position by these authors showed that membranes with DHA compared with DPA n-6 have lower-order parameters, a finding reflecting a change in bond geometry and an increase in chain dynamics.

The combined evidence for the effects of variations in DHA accumulation in membrane phospholipids suggests a unifying mechanism that could account for the effects reported for n-3 fatty acid deficiency on neurotransmitters and their receptors. DHA affected the neural *N*-methyl-D-aspartate response that relates to calcium influx into postsynaptic neurons.[146] Chalon and colleagues[144] and Delion and colleagues[142] reported an increase in dopaminergic function in the mesolimbic area of the brain and a decrease in the frontal cortex in adult rats. De la Presa Owens and Innis[147] also observed regional differences in piglet brain monoaminergic neurotransmitters after dietary variations that influenced brain DHA and AA accumulated during development. Presumably, all membrane proteins could be influenced by the DHA/DPA n-6 ratio of the membrane phospholipids, in which case functional effects would probably not be limited to effects on neurotransmitters.

LONG-CHAIN POLYUNSATURATED FATTY ACIDS AND THE DEVELOPING HUMAN INFANT

Human fetuses accumulate DHA during the last intrauterine trimester by maternal transfer of DHA across the placenta.[5,6] The process of maternal transfer continues after birth through breast-feeding: all human milk contains DHA, albeit in variable amounts.[7,8,54-56] With medical advances, infants born as early as 20 weeks of gestation, and thus before in utero brain DHA accumulation, now have a good chance of survival. Before the addition of DHA and AA to preterm formulas, these infants had to rely on synthesis for any additional postnatal DHA accumulation.

Breast-fed infants have more DHA and AA in red blood cells than do formula-fed term infants.[7,8,35] Regardless of gestational age at birth or diet (human milk or formula), mean red blood cell phospholipid DHA is higher at birth than in the months after birth in U.S. infants. The apparent "physiologic" decline in red blood cell DHA in breast-fed infants raises several questions, such as whether mothers transfer less DHA to their infants in milk than in utero, whether DHA decreases because of enhanced utilization by other tissues, and whether this postnatal decline is unique to infants in the United States, whose mothers have been shown to have milk DHA content among the lowest in the world.[8,53-56,83]

Differences in maternal DHA status reflected by milk DHA content also likely influence an infant's DHA accumulation in utero. The evidence of variable intrauterine DHA accumulation includes (1) the large range of normative values for DHA in cord red blood cell phospholipids of infants born preterm,[53] (2) the progressive increase in phospholipid DHA throughout the last intrauterine trimester,[148] (3) the decline in cord red blood cell phospholipid DHA with successive pregnancies,[84] and (4) the variability in brain DHA among infants born at the same gestational age.[3]

The addition of DHA to infant formula can prevent declines in red blood cell and plasma phospholipid DHA after birth compared with formulas without DHA. DHA from fish oil,[32,45,149,150] egg phospholipids,[35] and single-cell oils[151] has been shown to increase DHA in circulating phospholipids, a finding suggesting that these sources could increase DHA supply available for the brain. Conversely, infant formulas with α-linolenic acid but no DHA did not prevent the postnatal decline in DHA over several months, and DHA in circulating phospholipids remained low through follow-up to 12 months corrected age.[45,152]

After birth, AA declines in plasma and red blood cell phospholipids. To some degree, the decline appears to be physiologic. For example, AA is higher in preterm than in term cord blood, and even after 4 to 6 months of breast-feeding, infants born at term have much lower red blood cell AA than is seen at preterm delivery (8.8% vs. 15.7%).[8,12] AA in the brain and liver also declines during the last intrauterine trimester.[153] However, breast-fed infants have more AA in red blood cell and plasma phospholipids than do infants fed formulas without LCPUFAs, and those fed formulas with n-3 LCPUFAs have still lower phospholipid AA levels.[154]

AA is the source of metabolically important prostaglandins and leukotrienes. Researchers report significant correlations between AA levels with both intrauterine growth[46,148] and growth in the first year of life of infants born preterm.[47] DHA or total n-3 LCPUFAs added to infant formula reduces AA and alters the balance of n-3 and n-6 LCPUFAs in red blood cell phospholipids.[154] In three randomized trials, scientists found some reduction in growth of infants born preterm with the addition of fish oil DHA and no AA to infant formula.[42,43,155] In one study, the effect was limited to a lower weight for length at several ages in the first year.[155] In another study, the growth effects were found only in male infants.[43] Researchers have not found slower growth in either term infants fed formula containing DHA or in infants born preterm and fed formula containing AA as well as DHA (for review, see Lapillone and Carlson[48]). A recent meta-analysis concluded that the effects of DHA supplementation on growth were not clinically meaningful in term infants.[156]

Still, it is possible that long-term feeding of n-3 LCPUFAs without AA could decrease brain AA accumulation and thus affect the developing central nervous system. High concentrations of α-linolenate[157] and n-3 LCPUFAs from fish oil[158] decreased brain AA accumulation in rats. Arbuckle and associates[159] reported that piglets fed a diet with 4% of fatty acids as α-linolenic acid (but not one with 1% α-linolenic acid) had lower brain weights and lower levels of AA in membranes of synaptosomes compared with controls. Although experimental evidence for adding AA to the diet of formula-fed infants is lacking, it seems prudent to balance the addition of DHA to infant formulas with AA, as has happened with LCPUFA-supplemented formulas in the United States. This is a defensible practice because both these fatty acids are found in all human milk, albeit in variable amounts.

FUNCTIONAL EFFECTS OF DOCOSAHEXAENOIC ACID STATUS: OBSERVATIONAL AND EXPERIMENTAL STUDIES

Retinal and Visual Effects of Feeding Docosahexaenoic Acid to Preterm and Term Infants

Outcomes measured in infant studies of DHA supplementation were modeled after those found to be affected by n-3 fatty acid deficiency in nonhuman primates. Lower retinal and visual development were noted first in n-3 fatty acid–deficient primates,[19] and some aspect of visual development has been measured in most infant studies.[30-35] Retinal physiology is measured by ERG. Visual acuity has been assessed by both a behavioral procedure (Teller Acuity Card) and an electrophysiologic procedure (visual evoked potential [VEP]).[160] Although studies using both procedures have shown higher acuity with higher DHA status, two studies that used both procedures found significant effects only with the electrophysiologic procedure.[32,161]

The first interventions in which DHA was added to infant formula were designed for infants born preterm because, in the absence of in utero maternal transfer, these infants were the most likely to benefit from supplementation. Preliminary reports of higher visual and retinal function, respectively, with DHA supplementation were published in 1989,[29,30] and full reports soon followed.[31,32] Most of the trials of DHA supplementation in preterm formula were relatively small (number per group approximately 20 to 30). However, all the randomized studies of DHA-supplemented preterm formula that measured visual acuity found higher visual acuity with DHA at some age in the first year of life.[31,32,155,161,162] Unfortunately, one quite large study of DHA and AA supplementation did not include any measure of visual development.[163] Systematic reviews by SanGiovanni and associates[164] and by Simmer and Patole[39] concluded that supplementing formulas with DHA improves visual development of infants born preterm but noted the absence of long-term evidence. However, as discussed later, positive effects of an intervention at one age may be manifest in other outcomes at later ages. Relevant to the existence of continued higher grating visual acuity, several studies in term infants using electrophysiologic procedures for measuring visual acuity find persistent effects after postnatal DHA supplementation is discontinued.[151,165,166]

Compared with infants born preterm, the supplemental DHA need of infants born at term for optimal visual development has been more difficult to ascertain, because the results of the published studies are mixed.[37,38,167] The first suggestion that DHA status played a role in visual development of term infants came from a study by Makrides and colleagues,[33] who found higher blood levels of DHA in breast-fed infants to be associated with higher visual acuity. Observational studies by Jorgensen and

colleagues[70] and by Innis and colleagues[71] also showed associations between DHA status of lactating women and the visual acuity of their infants. Finally, results of a population-based cohort study suggested that maternal prenatal and postnatal intake of oily fish, a source of both DHA and eicosapentaenoic acid (EPA), was related to higher stereoacuity in their children at 3.5 years of age.[168]

Only experimental studies that increase DHA transfer to the infant can determine a causal relationship between DHA and optimal visual function in infancy. There have been several published intervention studies with some source of DHA (high-EPA fish oil, low-EPA fish oil, egg phospholipid, single-cell oils) with or without AA that measured some aspect of visual development in formula-fed infants born at term.* Makrides and colleagues found higher VEP acuity in one study but not in another.[34,169] Higher visual acuity with use of the Teller Acuity Card procedure has been observed at 2 months of age but not at 4, 6, 9, and 12 months of age.[35] Jorgensen and colleagues[170] did not find a significant difference between formula groups, although the visual acuity in the group fed formula without DHA was significantly less than in the breast-fed group, with use of the Teller Acuity Card procedure.

In a study of infants randomly assigned at birth to receive a DHA-supplemented formula until 4 months of age, Birch and colleagues[151] found higher VEP acuity at 6, 17, and 52 weeks of age but not at 26 weeks. More recently, the same group of investigators reported higher VEP acuity at 17, 26, and 52 weeks of age in infants randomly assigned to consume formula with, compared to without, DHA and AA after they were weaned from human milk at 6 weeks,[171] or approximately 6 months of age.[172] On the other hand, two large multicenter trials conducted in term infants by Ross Laboratories found no effect of DHA supplementation on visual acuity.[173,174] However, the formulas used in these studies contained much less DHA than the formulas used by Birch and co-workers[151] in their term studies. Recent systematic reviews[38,175] included all but the most recent Ross Laboratories study. Simmer and colleagues[38] concluded that there was little evidence that LCPUFAs conferred any visual development advantage in term infants. SanGiovanni and colleagues[175] concluded that significantly higher visual function was associated with LCPUFA intake at 2 and 4 months in both randomized and unrandomized studies.

Even though DHA and AA were added to term formulas in the United States in 2002, the report from the American Society for Nutritional Sciences Life Sciences Research Office did not recommend a minimum intake of DHA and AA for infants born preterm and cited some of the positive effects noted as being small or transient. The report did recommend a maximum concentration of 0.6% AA and 0.35% DHA and cited no adverse effects at these intakes and the possibility that functional changes noted in studies "may be important on a population basis or important for subsequent visual and/or cognitive function."[176]

Although it is true that only about half of the studies showed higher visual acuity in term infants with the addition of DHA to infant formula, it is difficult to draw any definitive conclusions because of the wide variation in the age and environments of the populations assessed and wide variation in the source and amount of fatty acids in the formulas studied. One review of these studies led to the conclusion that many lack sufficient statistical power to reject the null hypothesis because of uncontrolled variability.[177] Failure to control for variables other than background diet that potentially influence visual acuity could inflate or mask the effectiveness of an intervention. Factors such as DHA status at enrollment, head circumference at birth, paternal smoking, postconceptual age at assessment, and even paternal social status should be considered potential covariates of visual acuity.[178]

*References 34, 37, 38, 151, 165, 166.

Indeed, groups of researchers who controlled for gestational age at birth reported statistically significant differences in visual acuity, favoring DHA-supplemented groups.[35,154] Thus, with careful control of environmental variables, the results may more consistently show improved visual acuity with DHA supplementation.

Early increases in visual acuity with DHA may contribute to or be independent of accelerated maturation of other aspects of development over time. In two studies, infants born preterm and fed formulas with DHA had shorter duration looks to visual stimuli at 6, 9, and 12 months compared with infants fed formula without DHA. These results emerged even though differences in visual acuity that favored the supplemented group earlier in infancy did not persist at these later ages.[179,180] Another study found that higher reported intakes of oily fish during pregnancy were related to higher stereoacuity in childhood.[168] These observations suggest a possible effect of early differences in visual development on more complex tasks later in infancy and childhood.

Reviews by both Wainwright[114] and Colombo[181] include arguments against a static interpretation of development and suggest the consideration of developmental systems theory[182] in the interpretation of behavioral data arising from studies that vary LCPUFA status. The developmental systems perspective is transactional in nature: development occurs as a result of biologic and environmental bidirectional influences on the individual across time. Thus investigators need to consider environmental and metabolic factors that may interact with altered LCPUFA status.

Arousal in Infants

Cheruku and associates[72] reported an association between maternal plasma phospholipid DHA (another indicator of maternal status) and brain maturation in newborn infants based on differences in sleep patterns at birth. With maturation, there is an increase in quiet sleep, a decrease in active sleep, increased wakefulness, and a decrease in the transition from sleep to wake. These authors noted inverse relationships between maternal DHA status and both active sleep and the ratio of active sleep to quiet sleep. They also found that maternal DHA status was associated with more time awake and less time in transition between sleep and wake in the infants. This observation is evidence of more mature function with higher DHA status and adds to the evidence that intrauterine exposure to DHA affects development.

Docosahexaenoic Acid Effects on Language Development

The development of vocabulary proceeds concomitantly with motor, cognitive, and social development, and therefore it is reasonable to posit that a direct relation may exist between language development and supplementation with DHA. Innis and colleagues found that several indicators of DHA status (plasma phospholipid DHA, red blood cell phosphatidylcholine DHA, and phosphatidylethanolamine DHA) in breast-fed infants were significantly correlated with the ability to discriminate a nonnative language consonant at 9 months[71] and with a parent-report measure of vocabulary comprehension and production at 14 months of age.[183] O'Connor and colleagues[161] found higher vocabulary comprehension at 14 months in infants born preterm from English-speaking families who received formulas with versus without AA and DHA.

However, other researchers have reported apparent negative effects of DHA on vocabulary. In one study,[184] lower scores on a parent-report language inventory were observed at 14 months of age in a DHA-supplemented group relative to a control group. This may be attributed to an imbalance in the DHA to AA ratio.[185] Moreover, those differences were not detected in a follow-up at 3 years of age when language was assessed with use of an

age-appropriate standardized expressive language assessment (i.e., not parent report).[186] Similarly, Lauritzen and colleagues[187] found a lower language ability at 12 months of age in breast-fed infants whose mothers had received supplements, but this difference was no longer evident at 2 years of age. It is unclear how one would correctly interpret these findings. It may lie with the nature of the assessment of language comprehension and production at 12 to 14 months of age (i.e., parent report vs. a more objectively administered standardized test). More research is clearly needed to determine what variables are exacting an effect on language, whether or not that effect is transient, and what meaning it may have for future outcomes.

Visual Attention: Novelty Preference and Attention Duration in Preterm and Term Infants

Several studies compared novelty preference and attention duration in infants born preterm and receiving supplementation with DHA. Both novelty preference and shorter look duration in infancy were modestly correlated with higher cognitive function later in childhood in one study (for review see Carlson and Neuringer[130]). Compared with controls, DHA-supplemented infants had a greater number of discrete looks[188] and a significantly shorter look duration at 6, 9, and 12 months.[179] A replication confirmed these results at 12 months of age, when most infants were tested.[180] These data are analogous to those reported in n-3–sufficient compared with n-3–deficient monkeys (i.e., higher membrane DHA level correlated with shorter look duration).[28] As in the monkey studies, the results of the human studies suggest that DHA supplementation enhances either the speed of visual processing or the ability of the infant to disengage from the stimulus.

Other support for a relationship between DHA status and visual attention comes from observational studies. Look duration is a robust indicator of the development of attention, as it declines sharply across the first year of life. This decline was reported to have been accelerated in term infants whose mothers had red blood cell phospholipid DHA higher than the median level of the sample, relative to those whose mothers' levels fell below the median. This difference in look duration disappeared by 8 months of age but then reemerged at 12 months of age with the administration of a more sophisticated task.[73] Given that infants were not provided DHA supplementation after birth and background diets in the United States contain only small amounts of DHA, the data suggest that variable DHA accumulation during intrauterine life was the influential factor. Experimental studies that manipulate maternal DHA status during pregnancy are needed to test this hypothesis, and ongoing clinical trials should provide some information related to this question within the next few years.

Physiologically normal infants prefer novel stimuli; this is commonly used to assay visual recognition memory early in life. In two randomized trials, the Fagan Infantest (Infantest Corporation, Cleveland, OH) was used to measure visual novelty preference at 6, 9, and 12 months of corrected age of infants born preterm. Here, infants fed control and DHA-supplemented formulas had a similar novelty preferences.[179,180] In contrast, O'Connor[161] found a higher novelty preference but no effect on look duration in one group of infants fed AA and DHA (egg triglyceride and fish oil) compared with the control group at 6 months of age. In studies of term infants,[77,171,173] including one that provided supplemental DHA to women during pregnancy and lactation,[77] no effect on recognition memory was found.

Global Measures of Cognitive Development

Two tests of global neurodevelopment have been used in studies of DHA supplementation: the Bayley Scales of Infant Development (BSID-II),[189] which was developed in the United States, and the Brunet-Lezine Test,[190] which was developed in France. Both tests are standardized procedures that provide indices of mental and motor age relative to group norms. Standardized tests tend to be less-ambiguously interpreted and are familiar to pediatricians. As such, their use as outcome measures in studies of children receiving DHA supplementation has been encouraged.

However, researchers who have used global assessments of development have reported mixed results. Some found that supplementation with DHA resulted in higher standardized scores,[191-195] whereas others, including several larger and appropriately powered trials, found none.* Many explanations for these mixed results may be viable; differences in samples, supplementation, and administration could confound the results. Most important, the primary purpose of such standardized global assessments is to identify infants and children at risk for developmental delays or disabilities. Most are not sensitive enough to detect slightly different rates of development in typically developing infants and children. Thus caution should be exercised when interpreting the results of interventions by using these global assessments.

Specific Measures of Cognitive Development

Functional aspects of DHA suggest that its effects would be manifest in specific processes of cognitive development. Two specific processes underlie cognitive development: the acquisition of information (memory) and the speed with which that information is acquired (speed of processing).[199] DHA is concentrated at the synapses[200] and may act to improve synaptic efficiency and neuronal transmission speed. Moreover, DHA is implicated in processes that are integral to the laying down of a memory trace, such as long-term potentiation in the hippocampus.[201] Thus measurement of specific cognitive processes such as attention, processing speed, and memory is warranted in studies of the effects of DHA supplementation on the development of the child.

Researchers who have used specific measures of development have shown more consistent results relative to those who have used the global measures. Infants who have been fed formula supplemented with DHA reportedly are better able to detect novelty,[161] have faster processing abilities,[179,180,202] and are better problem solvers[203,204] relative to those fed unsupplemented control formula. As previously mentioned, infants whose mothers had DHA levels above the sample median at the time of their births are reported to have had enhanced information processing performance, as well as more mature orienting and attentional abilities.[73] Certainly, given these results, further research into the effects of DHA supplementation on specific cognitive abilities would be important.

We have argued elsewhere that the integration of memory and attention underlie and drive the development of the higher-order cognitions known as executive functions.[205] Executive functions include cognitive processes such as working memory, inhibitory control, and planning. It is likely that these developments are attributed to the development of the frontal lobes, which mature at a more protracted rate. Whereas such integrated cognition is initiated at the end of the first year, these abilities are not reliably evident until the early preschool period (e.g., 3-4 years of age).

Fatty acids are implicated in the higher-order cognitions. Frontal lobes accumulate significant amounts of DHA during their development.[206] Moreover, dopamine is an important modulator of the executive functions, specifically working memory and attentional control.[207] Dopamine has been shown to decrease in the frontal area in DHA-depleted rats,[208] and, relative to DHA-adequate rats, the DHA-depleted rats do not do as well on executive function types of tasks[26] (for review, see Wainright[114]). Thus it seems reasonable that the effects of DHA supplementation in infancy may also be apparent in the development of executive function.

As children from the supplementation trials age, researchers are beginning to assess their developmental status. In a follow-up of 2½-year-olds whose mothers received supplementation with DHA during pregnancy, hand-eye coordination scores from a global assessment were significantly related to n-3 PUFA levels in cord blood erythrocytes.[209] Helland and colleagues[75] reported differential results on a global assessment of cognitive abilities at age 4 years in children whose mothers received supplementation during pregnancy and lactation, even though the infant assessments revealed no group differences: children of mothers who received DHA supplementation scored higher at 4 years of age on a standardized IQ test than those of mothers who did not receive supplementation. A multiple regression analysis showed that maternal DHA intake during pregnancy was the only variable related to IQ at 4 years of age. Similarly, in a small study of breast-fed infants, Gustafsson and colleagues[210] found that DHA levels in colostrum were significantly related to IQ at 6.5 years of age, further attesting to the importance of maternal DHA levels at birth.

SUMMARY

DHA and AA were added in 2002 to formulas for term infants and infants born preterm in the United States. The levels of DHA added to study formulas vary. Although the importance of DHA in infant development is becoming increasingly obvious from human and animal work, the optimal and maximum levels of DHA intake for pregnant women and infants have not yet been determined. Progress in these areas is to be expected in the future, because a number of large trials are currently ongoing around the world. However, it is clear that these studies are taking place at the same time as DHA intake from supplements, supplemented food, and formula may be changing the background DHA exposure of women, infants, and children. Variable DHA exposure in control groups will be a potential confounder of new studies of DHA supplementation. Studies of infant behavior will need to control for maternal prenatal and background diet postnatal DHA intake or use some biochemical measure of DHA exposure such as red blood cell or plasma DHA concentration.

Animal models continue to be used to answer questions about the effects of lower brain DHA accumulation on neural development. It seems likely that the results of these studies will aid in targeting new developmental outcomes, as well as explicate the effects of DHA on other aspects of physiology. Still other research is being directed toward understanding the mechanisms through which lower DHA accumulation in membranes affects physiologic functions. Readers wishing to have a more extensive treatment of the neural mechanisms of DHA are referred to a review by Salem and colleagues.[145]

As noted above, ongoing research is addressing maternal DHA status during pregnancy and its influence on development of the infant and child. Some experimental and observational studies report associations between more mature patterns of sleep, language, peak look duration, and global neurodevelopment scores with higher maternal DHA status. Experimental studies of infants whose mothers were provided different amounts of DHA during pregnancy are now in progress. It is hoped that, in addition to aiding our understanding of the timing and amount of DHA needed for the developing brain, these studies can incorporate novel outcomes that target specific behavioral domains. A positive effect of intervening with DHA during pregnancy and lactation has been found in children as old as 4 years of age, and DHA levels in breast milk have been related to positive outcomes in children at 6.5 years of age. The relation of DHA levels in infancy to child outcomes is not surprising given the involvement of polyunsaturated fatty acids in brain growth, neuroprotection, and neurotransmission. Thus research is needed to assess childhood outcomes in those who received supplementation in utero and/or in infancy. As supplemented populations grow, we can expect to see research in this area grow also.

Glen E. Mott

Lipoprotein Metabolism and Nutritional Programming in the Fetus and Neonate

Studies of cholesterol and lipoprotein metabolism in the fetus and infant have dramatically expanded in the past few decades because of their relevance to the etiology and pathogenesis of atherosclerosis. Atherosclerosis, the process leading to coronary heart disease in adult life, is common in young adults and probably has its origins in the arterial fatty streaks found in infants and children. Plasma cholesterol and lipoprotein concentrations, which are associated with the rate of development of these arterial lesions, often track from infancy to adulthood. Furthermore, fetal undernutrition and the type of prenatal and postnatal nutrition can lead to metabolic "programming" for an increased risk of diabetes, the metabolic syndrome, and coronary heart disease in adulthood. Therefore prenatal and early postnatal nutrition has become the focus of intense investigation in preventive medicine. Because intervention can considerably slow the progression of atherosclerosis in adult life, identifying children at risk and providing follow-up and family counseling are important research goals.

All lipid and lipoprotein cholesterol values are given in milligrams per deciliter (mg/dL). In some instances, use of units of millimoles per liter (mmol/L) may be more convenient.

To convert *cholesterol* values from mg/dL to mmol/L, multiply by 0.02586.
To convert *triglyceride* concentrations from mg/dL to mmol/L, multiply by 0.01129.

Representative conversions are given in Table 47–1.

PRENATAL (FETAL) DEVELOPMENT

Serum Cholesterol, Triglyceride, and Lipoprotein Concentrations

Humans

Early in gestation, serum cholesterol concentrations average 85 ± 31 (SD) mg/dL[1] and decrease cyclically to 50 to 75 mg/dL in cord blood of normal term infants,[2-14] which is less than half the normal adult concentration (Figure 47-1). Serum cholesterol concentrations of preterm infants frequently are elevated and commonly exceed 100 mg/dL,[1,14-16] possibly because of a second serum cholesterol peak early in the third trimester.[1] Term babies who are small for gestational age (SGA) at birth may have slightly higher peak serum cholesterol levels[16]; those who are born near term with growth restriction have lower values.[17] Infants with familial hypercholesterolemia have cord blood cholesterol concentrations from 100 to 200 mg/dL.[18] Cord serum triglyceride concentrations average 30 to 50 mg/dL,* which are much lower than normal adult values. Some newborns infants, however, will have triglyceride levels above 200 mg/dL.[19] Most of the variation in plasma lipids at birth is due to genetic factors, gestational age, or disease.

Low-density lipoprotein (LDL) cholesterol (LDL-C) concentrations also decrease during gestation in the human fetus, from approximately 65 mg/dL in the first trimester[2] to 25 to 30 mg/dL at term,[2,3,6,25] which is approximately one-fifth the adult level (see Figure 47-1). Compared with serum cholesterol and LDL-C, high-density lipoprotein (HDL) cholesterol (HDL-C) concentrations in humans are stable during gestation,[2,3] although a decrease in HDL-C concentration was reported in premature infants.[9] The HDL-C concentration at term gestation is approximately 25 mg/dL (see Figure 47-1), compared with adult values of 40 to 50 mg/dL.[2,7,9,25,27-29] In contrast with the HDL in adults, HDL in cord blood contains higher levels of large HDL_2[30-32] and a broader range of particle sizes.[32-34] The very-low-density lipoprotein (VLDL) of cord blood carries less than one third of the total serum triglyceride concentration,[35,36] and its cholesterol content averages less than 10 mg/dL,[30,31,36] whereas in the adult, VLDL is the principal transport vehicle for triglycerides in fasting plasma. Although lipoprotein(a) concentrations at birth may be as high as 20 mg/dL, the average is 4 mg/dL,[8,37-39] compared with average adult values of 15 mg/dL.

The low serum cholesterol and lipoprotein concentrations in the human fetus and neonate compared with those in adults are consistent with the low apolipoprotein B (apo B)[23,25,28] and apolipoprotein A-I (apo A-I)[9,24,25,29,40] concentrations at birth. Although HDL-C concentrations in the human fetus are relatively stable, apo A-I concentrations double between 20 and 40 weeks of gestation and increase the apo A-I–HDL-C ratio.[40] Levels of cord serum apo E, which is principally associated with the lighter-density HDL classes,[32,36] are near or above adult concentrations of approximately 10 mg/dL.† Apo E polymorphisms affect the metabolism of apo B–containing lipoproteins such that infants with phenotype apo E 2/2 have lower apo B concentrations compared with other apo E phenotypes.[42] At birth, apo C-I and apo C-II levels also approach adult concentrations,[23] but apo C-III and apo A-II are only 40% to 60% of the adult level[23,25,43] (Table 47-2).

Ethnic and racial differences in serum cholesterol, lipoprotein cholesterol, and triglyceride concentrations at birth are small in contrast with those observed later in childhood.‡ It is not clear whether the reported ranges of cord serum cholesterol concentration (50 to 100 mg/dL) among different ethnic groups reflect methodologic variation, maternal diet, or genetic effects. Female infants have slightly higher cord serum cholesterol and lipoprotein concentrations than those reported for males[4,11,23,25,49] but similar triglyceride levels.[5,11]

Experimental Animals

As in humans, serum cholesterol, LDL-C, and apo B levels are low and decrease during gestation in fetal calves[50,51] and pigs.[52] HDL-C concentrations are low in fetal calves and do not change with fetal age. In contrast with other large animals, the fetal pig carries less than 1% of the total cholesterol in HDL early in gestation; HDL-C increases gradually until term gestation, when it reaches approximately 35% to 50% of the adult value.[52,53]

TABLE 47-1

Corresponding Levels of Lipids in Milligrams per Deciliter and Millimoles per Liter

CHOLESTEROL		TRIGLYCERIDES	
mg/dL	mmol/L	mg/dL	mmol/L
35	0.9	150	1.7
50	1.3	250	2.8
110	2.8	400	4.5
130	3.4	500	5.6
170	4.4	1000	11.3
200	5.2		
240	6.2		

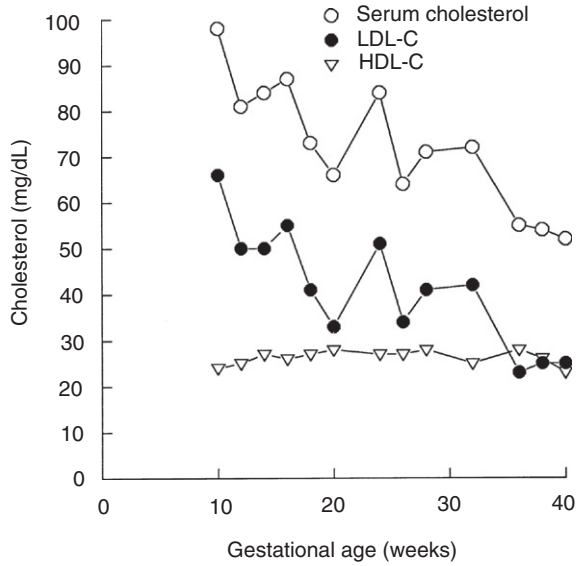

Figure 47-1 Serum cholesterol, low-density lipoprotein cholesterol (LDL-C), and high-density lipoprotein cholesterol (HDL-C) concentrations in 17 human fetuses by gestational age. *(Modified from Cai HJ, Xie CL, Chen Q, et al: The relationship between hepatic low-density lipoprotein receptor activity and serum cholesterol level in the human fetus,* Hepatology *13:852, 1991.)*

As in humans, the serum cholesterol concentration in newborn baboons averages 75 mg/dL,[54,55] but the ratio of LDL to HDL cholesterol[55] is 0.5, compared with approximately 1.0 in humans at birth.[2] As observed in newborn humans, apo A-I and apo B concentrations of neonatal baboons are only approximately half of adult values.[55]

In the rat, serum cholesterol measured late in gestation is higher than in the adult animal.[56] LDL is the principal carrier of cholesterol in the rat fetus, whereas in the adult rat, HDL is the major lipoprotein class.[15,56] HDL-C concentrations in fetal rats are approximately 60% and VLDL-C levels are approximately 10% of adult values.[57] In contrast with the neonatal rat, the adult rat has high concentrations of apo E–rich HDL, with low levels of LDL.[58] At birth, serum triglyceride levels in the rat are below adult values.[59] As in the rat, LDL predominates in the fetal rabbit, and HDL is the major lipoprotein class in the adult.[60] The guinea pig fetus has similar HDL-C and LDL-C levels, but in the adult animal, LDL predominates.[15] Newborn rabbits and guinea pigs have higher serum cholesterol levels than their dams unless the dams are fed a high-cholesterol diet.[61-64]

Lipoprotein Metabolism: Humans and Experimental Animals

The development of the LDL receptor in humans has a major role in lowering LDL concentrations during gestation.[2] By midgestation, LDL receptor activity is higher in human fetal liver than in adult liver[2] (Figure 47-2), as in the fetal calf compared with the adult cow.[50] In the newborn infant, LDL receptor activity is suppressed by the absorption of biliary and dietary cholesterol and by the uptake of bile acids during fat digestion. In the fetus, the absence of these negative regulatory processes probably contributes to the sustained elevation of LDL receptor activity and low plasma cholesterol and LDL-C levels in humans during the third trimester. The inverse correlation of LDL receptor activity and serum cholesterol concentration during gestation is consistent with that rationale.[2] The lower level of plasma cholesterol esterification[24] (secondary to reduced lecithin-cholesterol acyltransferase activity [LCAT] in the fetus and newborn[9,41,65-67]) also may contribute to differences in lipoprotein composition in the neonate.

In the human fetus, hepatic and intestinal genes[68,69] that are essential for cholesterol and apolipoprotein synthesis are transcribed at high levels by 8 to 20 weeks of development.[69] Most cholesterol in tissues probably is derived from endogenous synthesis rather than from the maternal circulation. The placenta, however, contains the necessary cholesterol uptake and transport mechanisms for its transfer to the fetus, and a high cholesterol content in the yolk sac has been documented.[70] The positive association of serum cholesterol in human fetuses with the level of hypercholesterolemia in their mothers through the second trimester also suggests that maternal-fetal transfer of cholesterol occurs in humans, at least early in gestation.[71]

In pregnant rabbits, dietary-induced hypercholesterolemia increased neonatal serum cholesterol concentrations over levels in non–cholesterol-fed control animals by approximately 50% in one study[72] and minimally in several others.[73,74] Considerable maternal-fetal transfer of cholesterol occurs in both the rabbit and the guinea pig.[62] In the hamster, tissue cholesterol concentrations of the fetus increase with maternal cholesterol intake, but only with very-high-cholesterol diets.[75]

In fetal rats, LDL metabolism differs considerably from that in the adult. Late in gestation, the rat fetus greatly increases LDL production, leading to higher LDL-C levels and an LDL turnover rate more than 15 times that in the adult.[76] In contrast with that in humans, lipoprotein binding to hepatic LDL receptors in the rat fetus is reduced compared with that of the newborn or adult.[77] In the rat fetus, hepatic cholesterol synthesis[78] and hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase activity,[79] the

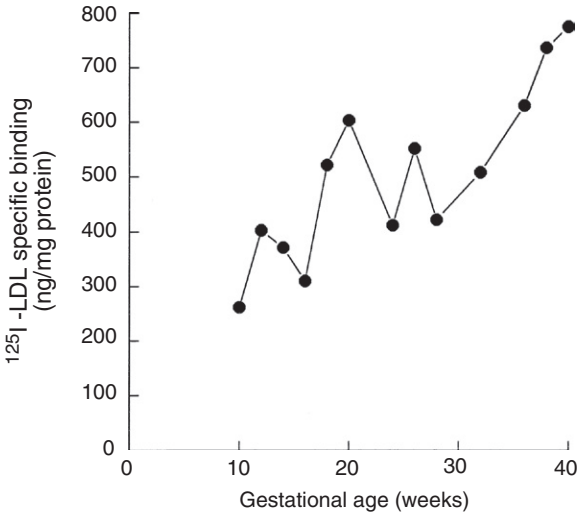

Figure 47-2 Specific binding of ^{125}I-labeled low-density lipoprotein (LDL) by hepatic LDL receptor preparations from 17 human fetuses by gestational age. *(Modified from Cai HJ, Xie CL, Chen Q, et al: The relationship between hepatic low-density lipoprotein receptor activity and serum cholesterol level in the human fetus,* Hepatology *13:852, 1991.)*

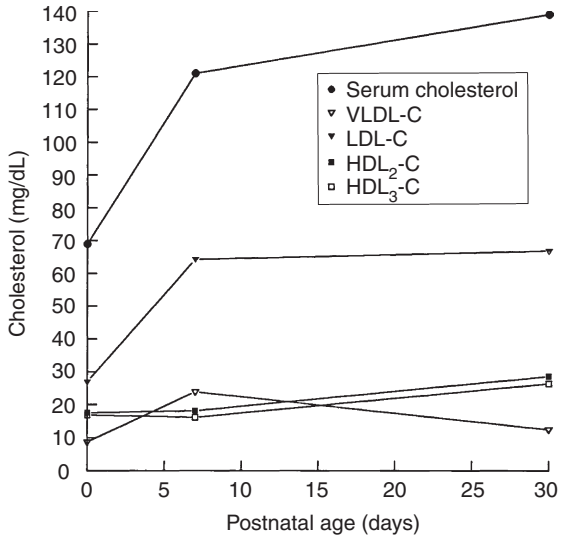

Figure 47-3 Serum cholesterol and lipoprotein cholesterol response of normal human infants who were exclusively breast-fed from birth to 30 days of age. *HDL_2-C, HDL_3-C,* High-density lipoprotein cholesterol subfractions 2 and 3; *LDL-C,* low-density lipoprotein cholesterol; *VLDL-C,* very-low-density lipoprotein cholesterol. *(Modified from Rosseneu M, Van Biervliet JP, Bury J, Vinaimont N: Isolation and characterization of lipoprotein profiles in newborns by density gradient ultracentrifugation,* Pediatr Res *17:788, 1983.)*

latter representing the rate-limiting step in cholesterol biosynthesis, markedly increase during the week before parturition but decrease somewhat before birth.[79,80] The fetal rat increases hepatic and intestinal messenger RNA (mRNA) concentrations for cholesterol metabolism or transport genes a few days before birth or at parturition.[69,81,82]

Summary of Fetal Lipoproteins

In the human fetus, the enzymes for cholesterol and lipoprotein metabolism develop early in gestation. As expression of the LDL receptor increases in gestation, serum cholesterol and LDL-C concentrations decrease to levels much lower than those observed in early postnatal life and adulthood. In the rat, the pathways for cholesterol and lipoprotein production develop rapidly late in gestation and are associated with higher serum cholesterol and LDL-C concentrations in the fetus than in the adult.

POSTNATAL DEVELOPMENT

Serum Cholesterol and Lipoprotein Concentrations

Humans

Serum cholesterol, LDL-C, VLDL-C, and triglyceride concentrations increase rapidly in normal breast-fed infants within a few days after birth.[30,31,66,83,84] Serum cholesterol concentration increases from an average of 50 to 60 mg/dL on day 1 to greater than 100 mg/dL by 1 week of age, and LDL-C from 25 mg/dL on day 1 to greater than 50 mg/dL by 1 week[36] (Figure 47-3). Serum cholesterol and LDL-C concentrations are approximately half the adult level.[28,36] At 1 month of age, serum cholesterol and LDL-C concentrations[30,83] are more than double the birth values but decrease after weaning to a typical Western diet.[13,85] By contrast, HDL-C concentrations increase only slightly during the first week of life[28] and thereafter increase to near adult levels (40 to 50 mg/dL) by the age of 1 month.[30] Throughout the first month of life, the ratio of the HDL subfractions HDL_2-C and HDL_3-C[31] remains approximately 1.0 (see Figure 47-3) but decreases to less than 0.5 later in childhood.[86] Apo B and apo A-I levels rise in association with increasing LDL-C and HDL-C concentrations during the first weeks of life[8] and then stabilize. By contrast, lipoprotein(a) concentrations increase steadily from low levels at birth and reach adult levels by the age of 1 year.[37,39] At birth, more than 80% of serum apo E is in the HDL fraction, but by 30 days of age, apo E decreases in HDL to approximately 60% of the total.[36] The apo E–enriched HDL-C is taken up rapidly by the LDL receptor, which may facilitate efficient delivery of cholesterol to tissues in the rapidly growing neonate.[87]

Part of the increase in serum cholesterol after birth is attributed to both cholesterol and saturated fat present in breast milk, although hemoconcentration during the first 24 hours may account for 10% of the increase.[88] Some of the postnatal increase in serum cholesterol is attributed to other, unidentified dietary factors or to metabolic maturation, because serum cholesterol and lipoprotein concentrations increase regardless of the diet composition.

Serum cholesterol, LDL-C, HDL-C, and apo B concentrations usually are higher in breast-fed infants than in those fed typical formulas low in cholesterol and containing fat with a higher ratio of polyunsaturated to saturated fatty acids (the P/S ratio) than that found in breast milk.* Feeding infant formulas prepared from cow's milk or evaporated milk that contain levels of cholesterol and saturated fat similar to those of human milk also increases serum cholesterol concentrations to levels comparable to those with breast-feeding.[4,44,95-100] The relative importance of cholesterol versus fat in breast milk in elevating the serum cholesterol concentration is not known, because most studies of neonatal dietary cholesterol intake in humans are confounded by differences in fat composition or other factors. Formulas high in saturated fat with half to three-fourths the level of cholesterol found in breast milk raise the serum cholesterol and apo B levels but have little effect on HDL-C or apo A-I concentrations compared

*References 13, 28, 43, 89, 90-94.

with the same formula low in cholesterol.[30,101,102] Infants fed formula containing cholesterol at twice the level in breast milk have slightly higher LDL-C concentrations but equivalent levels of HDL-C compared with those in infants fed a similar formula without cholesterol.[103] Generally, more of the lipoprotein response to a preweaning diet is attributed to the type of fat than to the cholesterol content. Serum cholesterol is inversely related to the dietary P/S ratio but is not significantly correlated with cholesterol intake among infants after weaning.[104]

The independent effects of types of fat in diets of the newborn infant have been more thoroughly studied than those of dietary cholesterol. Feeding a formula low in cholesterol with a fatty acid composition similar to that of breast milk increases the serum cholesterol and LDL-C concentrations to approximately two-thirds those levels in infants who are breast-fed.[90,105] Feeding low-cholesterol formulas containing higher proportions of coconut oil (and therefore more lauric [$C_{12:0}$] and myristic acids [$C_{14:0}$]) increases serum cholesterol,[106] LDL-C, and HDL-C concentrations to nearly the same levels as those observed with breast-feeding.[107] Infants fed formulas containing higher concentrations of corn or soy oil (P/S ratio greater than 3) have approximately 25% to 35% lower serum cholesterol and LDL-C concentrations[43,108] compared with those fed breast milk. Feeding formulas with more moderate P/S ratios (i.e., less than 2.0) lowers serum cholesterol and LDL-C concentrations by lesser amounts.[90,105,109] The HDL-C level is decreased very slightly with use of high or moderately high-P/S-ratio formulas.[43,107-109] Strong evidence indicates that dietary supplementation with long-chain polyunsaturated fatty acids is necessary for optimal growth and development, particularly for preterm infants, and that such supplementation of formulas possibly is indicated for to all infants.[110]

Experimental Animals

The serum cholesterol and lipoprotein responses of neonatal nonhuman primates are similar to those described for humans. Breast-fed rhesus monkeys[111] and baboons[54,55] have higher serum cholesterol concentrations than those in animals fed low-cholesterol formulas. In the rhesus monkey, however, breast-feeding principally increases the serum LDL-C fraction, whereas in the baboon, it increases HDL_1-C and HDL_2-C (and therefore HDL-C) levels.[55,112] In the infant rhesus monkey fed a low-P/S-ratio formula with a cholesterol content similar to that of breast milk, serum cholesterol levels increased to approximately 100 mg/dL higher than in breast-feeding.[113] In baboons, a high-P/S-ratio infant formula with a cholesterol content similar to that of breast milk increased the serum cholesterol concentration to the same extent as with breast-feeding.[54] Baboons fed formula with a low P/S ratio (similar to that of breast milk) had a higher LDL-C but lower HDL-C level compared with breast-fed baboons.[55] In the suckling pig, serum cholesterol levels increase to approximately 200 mg/dL by 1 month of age, primarily because HDL levels are more than two-fold higher than in the adult.[52,53] Breast-fed piglets have higher serum cholesterol and VLDL plus LDL-C concentrations than those measured in piglets fed low-cholesterol[114-116] or high-cholesterol formulas with unsaturated fat.[117] A palm oil–containing, low-cholesterol formula that was similar to sow milk in fatty acid composition raised the serum cholesterol in the piglet only to approximately 80 mg/dL, nearly half that in piglets fed sow milk; the serum VLDL plus LDL-C concentration increased to only 27 mg/dL, or approximately 25% of that in piglets fed sow milk.[116] In pigs, neither level of dietary cholesterol nor type of fat accounts for the serum cholesterol or lipoprotein differences between breast-feeding and formula-feeding.[118]

Suckling rabbits have serum cholesterol levels of 300 to 400 mg/dL,[61] predominantly as a result of greatly elevated VLDL-C and intermediate-density lipoprotein (IDL) concentrations.[119] In the suckling rat, total cholesterol increases from approximately 60 mg/dL at birth to 100 mg/dL at 10 days[120] and to 170 mg/dL at 3 weeks of age.[121] LDL is the principal carrier of cholesterol in the newborn rat,[122] and its concentration decreases after 2 to 3 weeks of age.[121-123] By contrast, serum HDL-C concentrations increase from approximately 20 mg/dL at birth in the neonatal rat to 40 mg/dL by 2 weeks of age.[121,123]

Lipoprotein Metabolism: Humans and Experimental Animals

Breast-feeding increases serum LDL-C concentration and decreases by three-fold the cholesterol synthetic rate in human infants[92,93] and by two-fold in piglets,[114] compared with rates observed in those fed low-cholesterol formulas. Consistent with those observations is a lower hepatic HMG-CoA reductase activity in the suckling rat[79,124] than that observed in the fetus.[79,80] The postpartum increase in serum LDL-C levels is associated with a rapid decrease in the number of LDL receptors during the suckling period in cattle,[50] but a similar decrease in the LDL receptor–binding capacity is not observed among suckling piglets compared with those fed a high-cholesterol versus a low-cholesterol formula.[118] The enzyme that controls the rate-limiting step in cholesterol degradation to bile acids (cholesterol 7α-hydroxylase) develops slowly in the fetus, but its activity increases rapidly and the bile acid pool size expands markedly late in gestation and in the early postnatal period (reviewed by various investigators[125-128]). The role of bile acid metabolism in the lipoprotein responses to early diet is not well understood.

Summary of Postnatal Lipoproteins

In most breast-fed animals, serum cholesterol and lipoprotein concentrations increase rapidly after birth. Although serum cholesterol and lipoprotein concentrations respond to the high cholesterol and saturated fat contents of breast milk, the particular lipoprotein that increases and the timing are species-specific. The biochemical and molecular mechanisms responsible for the dramatic neonatal increases in lipoprotein concentrations are only partially understood.

Perinatal Disease and Lipoprotein Concentrations

Familial hypercholesterolemia is associated with a several-fold increase in LDL-C concentrations in the newborn infant.[18,129] Most neonates with this disorder can be identified by a cut-off value for LDL-C of 41 mg/dL (95th percentile in control infants). Although no treatment for hypercholesterolemia generally is recommended for infants younger than 2 years of age, screening cord blood from infants at risk for the disorder should be done selectively in anticipation of later follow-up.[130] Aggressive treatment may be indicated for affected children.[131] Maternal diabetes,[132] hypertension,[133] or prenatal treatment with glucocorticoids[134] increases fetal serum cholesterol, LDL-C, HDL-C, or triglyceride levels. Fetal stress and hypoxia may elevate triglyceride and free glycerol concentrations, implying triglyceride mobilization and lipolysis in these conditions.[20] Premature infants with respiratory distress syndrome (RDS) and birth weight between 1 and 2 kg have lower levels of serum apolipoprotein B and arachidonic acid than in similar-sized neonates without RDS.[135] A causal relationship among these factors has not been demonstrated. In contrast with adult-onset hypothyroidism, congenital hypothyroidism has only small effects on serum cholesterol or lipoprotein concentrations during the first month of life,[136,137] but nevertheless an inverse association between triodothyronine (T_3) and LDL-C concentrations has been reported.[138]

LONG-TERM CONSEQUENCES OF FETAL AND NEONATAL NUTRITION ON LIPOPROTEIN CONCENTRATIONS

Humans and Experimental Animals

Human fetal undernutrition and low birth weight are associated with type 2 diabetes and the metabolic syndrome (syndrome X) in adulthood and result in hyperlipidemia.[139,140] The newborn infant with a birth weight less than 6.5 pounds has a 10-fold greater risk of developing the metabolic syndrome as an adult than that in an infant whose birth weight is greater than 9.5 pounds.[139] Furthermore, persons with a perinatal history of low birth weight have higher apo B and lower HDL-C concentrations as adults.[139] Maternal malnutrition in early gestation is associated with a higher LDL-C–HDL-C ratio in adult offspring at midlife.[141] Poor maternal nutrition late in gestation results in a smaller abdominal circumference in the neonate, a condition that may reflect impaired hepatic growth and, correspondingly, altered lipoprotein metabolism. For each 1-inch decrease in abdominal circumference at birth, serum cholesterol and LDL-C concentrations in older adults are increased by approximately 10 mg/dL.[142] Therefore body proportions at birth may reflect differential timing of gestational malnutrition, resulting in diverse metabolic consequences.

Restricted fetal growth without catch-up growth in 8- to 10-year-old children is associated with increased LDL-C levels over those in children who grow normally after intrauterine growth restriction.[143] Maternal hypercholesterolemia in humans has been positively associated with serum cholesterol concentration in the fetus through the second trimester,[71] and with the extent of arterial lesions (fatty streaks) in the fetus and also in children who died of multiple causes before the age of 13 years.[144] A surprising observation is that the small differences in serum cholesterol levels of children from mothers who were hyper- or normocholesterolemic do not explain the differences in atherosclerosis.The study investigators speculated that unidentified "atherogenes" may be programmed by gestational elevation of serum cholesterol concentration.[144]

In guinea pigs, maternal undernutrition lowered the birth weight and also resulted in a higher serum cholesterol and LDL-C in adult male offspring after a dietary cholesterol challenge.[145] Similarly, pregnant rats that are food-restricted produce progeny with higher levels of serum cholesterol than in offspring of normally fed mothers.[146] In rats, dietary protein restriction during either gestation or lactation produced offspring with lower serum cholesterol, HDL-C, and triglyceride concentrations than in control animals.[147] In pregnant rabbits, diet-induced maternal hypercholesterolemia does not increase serum cholesterol concentrations in the offspring at birth up to 1 year.[73] However, the frequency of arterial lesion development, which is possibly mediated by oxidative mechanisms, is significantly greater in the offspring of hypercholesterolemic dams than in those of normocholesterolemic dams studied during gestation.[73,74] These findings in humans and experimental animals support the concept that fetal growth restriction, perinatal malnutrition, and hypercholesterolemia during gestation permanently program plasma lipoprotein concentrations or enhance the risks of diseases that cause dyslipoproteinemia. The lipoprotein changes frequently are associated with an increased risk of cardiovascular disease in adult life.[148,149]

The type of neonatal nutrition also programs or imprints adult lipoprotein concentrations. Among elderly men who as infants were breast-fed or fed cow's milk–based formulas, serum cholesterol, LDL-C, and apo B concentrations were higher than among those who as infants were weaned before 1 year.[150] By contrast, women at 32 years of age who had been breast-fed had lower plasma cholesterol than those who were bottle-fed.[151] In a study of 6-year-old children, serum cholesterol and LDL-C concentrations increased with the duration of breast-feeding up to 6 months of age.[85] Similarly, breast-feeding duration was related to serum cholesterol and the apo B–apo A-1 ratio in adolescents.[152] Short-term prospective studies in children usually have not detected deferred effects of neonatal diet on total serum cholesterol concentrations.[153,154]

Studies of breast-fed versus formula-fed experimental animals also have reported long-term differences in serum cholesterol responses to a high-cholesterol challenge diet.[155-158] Juvenile and adult baboons that were breast-fed exhibited lower HDL-C levels and higher ratios of VLDL plus LDL-C to HDL-C than those in animals fed formulas as infants.[55,112,159-161] Variation in the type of dietary fat or the cholesterol content of formulas fed to infant baboons does not affect serum cholesterol or lipoprotein concentrations after weaning.[160,161] Therefore the long-term effects of breast-feeding versus formula-feeding on serum cholesterol and lipoprotein concentrations must be elicited by factors other than the level of cholesterol or the type of fat in the infant diet.

Many of the studies in humans and nonhuman primates were stimulated by results of experiments with rodents in which differences in neonatal diet or premature weaning permanently affected the serum cholesterol response of the adult animal.[155,154] The early studies with experimental animals tested the hypothesis that high cholesterol levels in breast milk affect development of cholesterol homeostasis in adult life (i.e., the cholesterol challenge hypothesis).[155,162,163] Most experiments, however, do not support that supposition.[154] No long-term studies of humans have been performed in which cholesterol intake in the newborn infant was controlled. One recent study of infants fed formulas with or without cholesterol for 6 months does not report a significant difference in serum cholesterol or LDL-C levels before or after a cholesterol challenge at 11 to 12 months. In a parallel study, cholesterol synthesis rates of both formula groups at 4 months of age were approximately four-fold higher than in a breast-fed group.[164]

Summary: Early Nutritional Programming

These studies provide compelling evidence that nutritional deficiencies during fetal life and the types of newborn feeding program plasma lipoprotein responses and other risk factors affecting the progression of coronary artery disease in the adult. However, the molecular or metabolic basis of these nutritional programming effects on lipoprotein concentrations has not been elucidated.

Metabolism of Glucose and Methods of Investigation in the Fetus and Newborn

The metabolism of glucose in the fetus and newborn has been studied extensively, both in animal species and in humans, and several reviews have been published. Our ability to study glucose metabolism has improved significantly because of the following: (1) the availability of the chronic fetal preparation in sheep, in which fetal blood sampling can be done without causing major changes in the physiologic state of the fetus; (2) the availability of stable, nonradioactive isotopic tracers; and, more recently, (3) the application of molecular biology techniques and transgenic animals. In this chapter, the metabolism of glucose in the fetus and newborn is discussed, and recent developments are emphasized. Throughout the chapter, emphasis is placed on the available information in humans, supplemented when necessary by animal data.

Since the early 1980s, numerous improvements in the synthesis of stable isotopically labeled tracers and sensitive mass spectrometric methods have allowed investigators to examine glucose metabolism in the human fetus and newborn. Such studies could not be performed in the past because of the lack of availability of these tracers and the risk associated with radioactive tracers. In addition, the development of newer synthetic techniques has increased the number of isotopic tracers, which can be used simultaneously to answer complex questions. By combining these tracer methods along with the measurements of energy consumption, the metabolic fate of substrates and their contribution to overall fuel economy can be quantified.

ISOTOPIC TRACER

Atoms, other than hydrogen, are made of protons (+), electrons (−), and neutrons. Atomic number (Z) represents the number of protons or the number of electrons in an atom; that is, the number of electrons is equal to the number of protons, and the atomic weight is equal to the sum of protons and neutrons. Isotopes are atoms of an element differing from each other only in the number of neutrons. Thus, for a given atomic number (Z), more than one value of atomic weight can exist. The stability of the nucleus of the atom is related to the ratio of neutrons and protons. If neutrons are too many or too few for the number of protons, the nucleus becomes unstable. To become stable, the nucleus may undergo rearrangement that involves the release of radiation—radioactive nuclei.

The stable, nonradioactive isotopes, by virtue of the lack of radioactivity, have been particularly useful for the study of metabolism in the mother and newborn infant. However, these isotopes also have limitations.

Cost

Initially, because of limited availability, the cost was prohibitive. At the same time, the instruments for their detection, mass spectrometers, were not easily available and were expensive. Now, with relatively easy accessibility and improved sensitivity of the instruments, and with changing attitudes of society toward radioactivity, the use of stable isotopic tracers has become popular, and the cost has continued to decrease.

Natural Abundance

The stable isotopes are naturally occurring nuclides and therefore have a certain background or natural abundance. This is in contrast to the radionuclides, the natural abundance of which is negligible. Because of this background abundance, and also in part related to the sensitivity of the mass spectrometry, the amount of tracer required for the study of metabolism is more than that used with radioactive tracer.

IDEAL TRACER

Although one could define an ideal tracer in many different ways, the following are some of the most important considerations. Its biologic behavior should be the same as that of the parent compound; that is, it is used in the same manner as the compound traced. This is important for both radioactive and nonradioactive stable tracers. Radioactive-labeled proteins, such as iodine-125 (^{125}I)–labeled albumin, are not necessarily metabolized in the same manner as for the native protein. In fact, the labeling may damage or denature the protein.

Stable isotopes, conversely, have their own chemical differences described as isotopic fractionation or isotopic effect. In this process, the isotope behaves differently from the native atom. Two types of isotopic fractionation are important:

1. Temperature: These fractionations are significant in geologic studies in which the changes in the carbon-13 (^{13}C)/^{12}C and oxygen-18 (^{18}O)/^{16}O ratio have been used to study the changes in the earth's temperature.
2. Kinetic and chemical fractionation: These fractionations are the result of isotopic discrimination by various enzyme systems; that is, the labeled compound is not as rapidly metabolized as the unlabeled compound. Such fractionation will result in the accumulation of the labeled compound in the metabolic pool and will potentially result in errors in measurements. In nature, isotopic fractionation results in differing isotopic composition of nutrients; for example, glucose obtained from sugar cane has different ^{13}C enrichment compared with glucose obtained from beet sugar.[1,2] The ^{13}C abundance of lipid fractions in several organisms is lower than that of carbohydrates and proteins.[3,4] The basis for these differences has been attributed to isotopic discrimination at certain key enzymatic steps involved in the synthesis of these compounds.[1] DeNiro and Epstein[5] showed that the low ratio of ^{13}C/^{12}C of lipids synthesized

by *Escherichia coli* grown in minimal media is the result of isotopic fractionation during the oxidation of pyruvate to acetyl coenzyme A.[5] It is important to recognize these isotopic fractionations when isotopic tracers are used to study metabolism. In general, it is accepted that more heavily labeled tracers such as those labeled with multiple isotopes are likely to be discriminated more than the lightly labeled tracers. In relation to stable isotopes, isotopic fractionation is probably more common with deuterium than with ^{13}C and nitrogen-15 (^{15}N).

The quantity of tracer used should be negligible; therefore it should have no or minimal pharmacologic effects. This requirement is easily met by the radiolabeled tracers, in which the background radioactivity is essentially zero. In contrast, stable isotope tracers that have a significant background natural abundance have to be infused in somewhat larger quantities that are not negligible. The amount of tracer infused is determined by the ability of the analytic instrument to measure the isotopic enrichment above the background in biologic samples. With the newer instruments and better analytic techniques, several of these problems have been resolved; therefore, in most instances, enrichments in the range of 0.5% to 1% above the background can be easily measured. Therefore the isotopic tracer can be infused at rates approximating 1% of the turnover rate of the "tracee." With multiple labeled compounds, in which the background abundance is much lower, even lower rates of tracer infusion can be used and still achieve excellent results.

Isotopic tracers are used in vivo to quantify the rate of appearance and disappearance of a substrate, such as glucose and amino acids, or to quantify the utilization and metabolic fate of the substrate, such as oxidation, or the contribution of a substrate to another compound: precursor-product relation.

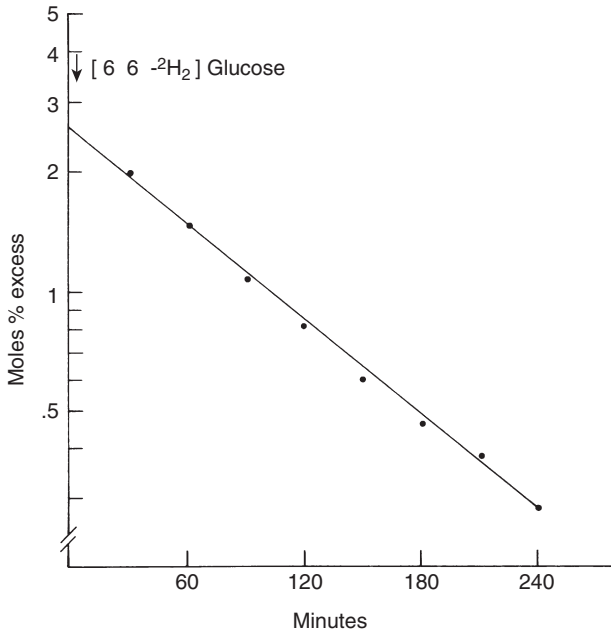

Figure 48-1 Changes in deuterium enrichment of plasma glucose after a single bolus injection of [6,6-$^2H_2$]glucose in a physiologically healthy man. The rate of glucose appearance is quantified from the rate of decrease (dilution) in the plasma glucose enrichment and the pool size. The latter is quantified from the concentration of glucose, and the volume of distribution is measured by extrapolating the disappearance curve to time zero.

Quantification of the Rate of Appearance and Disappearance of a Substrate

The usual methods involve the administration of the isotopically labeled tracer either as a single bolus (Figure 48-1) or as a constant-rate infusion (Figure 48-2). In both instances, the dilution of the tracer in the blood is estimated by measuring the enrichment or specific activity (in case of radioactive tracers) in the blood or plasma. The dilution of the tracer is the function of appearance of the substrate, and the disappearance or utilization of the substrate has no impact on the enrichment because the same proportion of the tracer and tracee will be used. This is a fundamental concept in the tracer studies. The following are the definitions of certain terms used in tracer studies.

Concentration: Amount of substrate per unit of blood or plasma, micromoles per milliliter or milligrams per milliliter.

V: Volume of distribution of the substrate or the space in which the substrate is distributed, milliliters per kilogram of body weight.

Q: Quantity (moles or grams) of the substrate in the system (body), that is, the size of the substrate pool or pool size, which is equal to the concentration of the substrate times

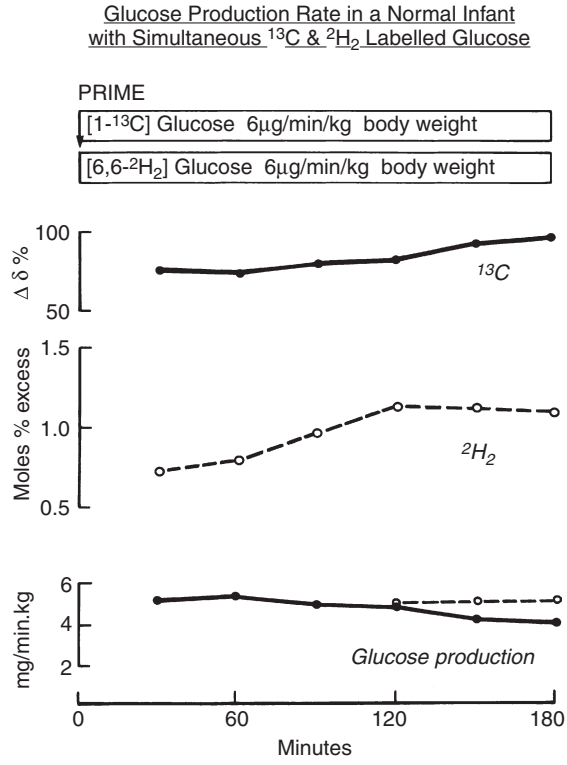

Figure 48-2 The constant-rate tracer infusion method. As shown, the deuterium-labeled glucose was infused at a constant rate whereas [1-^{13}C]glucose was administered as a prime–constant-rate infusion. Because of the tracer prime, an early plateau plasma glucose ^{13}C enrichment was achieved. However, a slow continuous increase in enrichment was also seen because of tracer carbon recycling. As shown, the measured rate of glucose production will decrease as the tracer recycling becomes more evident later in the study. *(From Kalhan SC, Bier DM, Savin SM, Adam PA: Estimation of glucose turnover and ^{13}C recycling in the human newborn by simultaneous [1-^{13}C]glucose and [6,6-$^2H_2$]glucose tracers,* J Clin Endocrinol Metab *50:456, 1980. Copyright The Endocrine Society.)*

volume of distribution, that is, moles (or grams)/milliliter × milliliters/kilogram = moles (or grams)/kilogram.

Ra: Rate of appearance of the substrate (tracee) in the compartment under study. In most instances, it is the plasma or extracellular fluid compartment, micromoles or milligrams per minute.

Rd: Rate of disappearance of the substrate from the compartment under study, micromoles or milligrams per minute. Disappearance is often used as synonymous with utilization. However, utilization is implied in the broad sense of overall utilization and does not necessarily imply a specific pathway.

Steady-state system: The system is said to be in a steady state when the input Ra is equal to output Rd and the concentration remains constant. Conversely, when these parameters are changing, it is called nonsteady state.

Turnover: Rate of turnover of the pool under steady-state conditions, that is, when the concentration is constant: Ra = Rd = Turnover, micromoles per minute or milligrams per minute.

Turnover time: Time it takes for the entire pool to turn over, which depends on the size of the pool and the turnover rate: Q (moles)/Rate of turnover.

MCR: Metabolic clearance rate, that is, the volume of plasma that is completely cleared of the substrate in a unit time: Rate of disappearance Rd (micromoles per minute)/Concentration (micromoles per milliliter) = Milliliters per minute. It should be called plasma clearance rate rather than metabolic clearance rate. It does not necessarily mean that the substrate has been *metabolized.*

Two more terms need to be known in relation to tracers:

Specific activity (SA): Radioactivity that is specific to a compound or substrate, expressed in relation to the weight or molecules of the substrate, that is, Radioactivity (disintegrations per minute, or dpm) per mole or gram of substrate = dpm/mole or gram.

Enrichment: Used in relation to stable isotopic tracers to describe the magnitude by which that particular isotope has been increased (enriched) above the background. Enrichment has also been used as synonymous with atom percent excess, that is, how many labeled atoms are present in excess of the background. For practical purposes, enrichment corresponds to specific activity with certain limitations. In relation to stable isotopic tracer, often the tracers are measured as molecules rather than atoms, and therefore they are described as moles percent excess, that is, the percentage of labeled molecules in excess of the background.

Further, the labeled molecules are designated by the number of labeled atoms added to the parent molecules (m), such as m+1, m+2, and m+3 (or m_0, m_1, m_2, m_3). Therefore enrichment is described as moles percent excess of these labeled molecules (m+3) enrichment or (m+1) enrichment.

Finally, a tracer is called a *reversible* or *recycling tracer* when, after its disappearance or utilization, it reappears in the plasma. The reappearance results in a second, not easily measurable, source of tracer, and it leads to higher enrichments and underestimation of kinetics. In contrast, when a tracer is lost during its utilization, it is called a *nonrecycling tracer*. In general, when the tracers are labeled with carbon, whether ^{13}C or ^{14}C, the carbon atoms are likely to be reincorporated (recycle) into newly synthesized substrate; in contrast, when the tracers are labeled with hydrogen ^{2}H, ^{3}H, the hydrogen atoms are lost mostly into water (H_2O) during the metabolism of the substrate and are termed *nonrecycling tracers*. Before selecting a tracer to study the kinetics of a tracee, a knowledge of the pathways of metabolism of the tracee can help in the selection of a particular type of label.

During a bolus injection technique, the labeled tracer is administered at zero time, and the rate of change in enrichment or specific activity is measured (see Figure 48-1). Extrapolation of the decay curve to zero time gives an estimate of the pool size and the volume of distribution of the tracer, and the turnover time is calculated from the rate constant of the disappearance curve.

The constant-infusion technique (see Figure 48-2), evaluated in detail by Altszuler and associates,[6] is a commonly used method to quantify tracee kinetics. Altszuler and colleagues further improved the technique by administering the priming dose of the tracers to achieve early plateau. Thus it should be called the prime–constant-rate technique. After a priming dose, the tracer is administered at a constant rate throughout the experiment. The size of priming dose depends on the pool size of the tracee and the rate of administration of the tracer. This relation is expressed as follows:

$$\begin{aligned}(\text{Prime}/\text{Pool}) &= (\text{Rate of infusion of tracer} \\ &\quad /\text{Rate of appearance of tracee Ra}) \\ &= \text{Enrichment or specific activity}\end{aligned}$$

The turnover rate or the rate of appearance and disappearance is calculated from the final asymptote of the enrichment curve and the rate of infusion of the tracer.[6,7]

The methods described earlier assume that the tracer mixes with the tracee in a single compartment instantaneously. Although such an assumption may hold true for a system that is turning over rapidly, it is not necessarily true for slow turnover systems, such as body bicarbonate pool, and it may lead to significant errors. Numerous multiple compartment systems have been used to fit the data most precisely under these circumstances.[8-10] However, at times the physiologic significance of such compartments is not easily understood.

Another problem studied in detail relates to the site of tracer administration and sampling in turnover studies.[11-14] This is particularly true in relation to compounds that are produced by multiple organs and tissues, such as lactate. Thus a venous sample obtained from a particular vein will not only represent the mixed blood from the body but will also be influenced by the metabolism of the tissues drained by that particular vein. Certain modifications have been proposed, such as retrograde venous sampling, arterial blood, or arterialized venous blood.[12,13] All these have their own limitations and must be recognized during data reduction and interpretation.

Finally, when the concentration of substrate is changing as a result of perturbations, the system is described as being in a *nonsteady state*. Under these conditions, a different set of assumptions and a different data reduction method are employed. The most commonly used method of data reduction is that described by Steele.[15] These equations have been subsequently modified and validated by several investigators.[16,17]

Quantification of Metabolic Fate of the Substrate

Oxidation to carbon dioxide (CO_2) and the contribution of a substrate to another: precursor-product relationship are two examples of reactions that can help quantify the metabolic fate of the substrate. This is estimated by the appearance of tracer isotope, usually carbon, in the product. However, the mere appearance of the isotope in the product does not necessarily imply net conversion of the precursor into the product.[18] It may simply represent an exchange of the isotope during biochemical reactions. Second, during the sojourn of the tracer from the precursor to the product, the tracer may be diluted by intermediary compounds. Thus there would be an underestimation of the contribution of the precursor to the product. The precursor-product relationship is quantified by measuring the turnover of the precursor and product by separate isotopically labeled tracers and by measuring the rate of appearance of the tracer in the product.[9] These

concepts of precursor-product relationship are best illustrated with use of glucose as a model system.

Glucose (precursor) is oxidized to CO_2 (product) by first conversion to pyruvate, which enters the tricarboxylic acid (TCA) cycle via acetyl coenzyme A. During oxidation of pyruvate to CO_2, the three carbons of pyruvate do not appear in CO_2 to the same magnitude. Carbon-1 of pyruvate appears in CO_2 100% during pyruvate's conversion to acetyl coenzyme A by pyruvate dehydrogenase. Carbon-2 and carbon-3 of pyruvate, which form carbon-1 and carbon-2 of acetyl coenzyme A, enter the TCA cycle, and neither of these carbons appears in CO_2 during the first spin of the cycle. It is only in the subsequent turns of the TCA cycle that carbon-2 and carbon-3 appear in CO_2 but not in equal amounts.[19,20] Wolfe and Jahoor[21] showed, in normal healthy adults by infusing labeled acetate, that only 80% of carbon-1 and 50% of carbon-2 of acetate appeared in CO_2 during isotopic steady state. On the basis of this and other studies, it can be concluded that during glucose-pyruvate oxidation, only 80% of the tracer carbon will appear in CO_2, whereas the remainder is lost via exchange in the TCA cycle. This loss of tracer or the lower appearance of tracer in CO_2 will result in underestimation of oxidation of glucose.

Another example of the loss or exchange of tracer is the synthesis of glucose from pyruvate via gluconeogenesis. During gluconeogenesis, pyruvate is first converted to oxaloacetate, a common intermediate between gluconeogenesis and the TCA cycle. Therefore when carbon-labeled precursor is administered for the estimation of gluconeogenesis, some of the tracer will be lost by exchange in the TCA cycle at the oxaloacetate level. Thus the enrichment or the specific activity of the immediate precursor of glucose, that is, phospho*enol*pyruvate, will be less than that of pyruvate, and it will result in a lower estimate of gluconeogenesis.[22] This problem was resolved by Landau and colleagues[23] by using deuterium-labeled H_2O, which, in turn, labels the pyruvate pool. Because this method results in constant labeling of pyruvate, and phospho*enol*pyruvate without loss of tracer, the appearance of deuterium in glucose can be used to quantify the contribution of gluconeogenesis to total glucose production accurately.

Finally, all these methods of quantification have their own limitations and are near approximations of the actual turnover rates. The assumptions involved in each experimental technique should be recognized when such estimations are done in biologic systems.

MEASUREMENTS OF ENERGY CONSUMPTION

Measurements of energy consumption rate and CO_2 production have become integral components of metabolic studies. Estimation of energy consumption and CO_2 production rate help in the partitioning of the contribution of various substrates to the overall energy utilization. In addition, most studies using carbon-labeled tracers also estimate the isotopic enrichment of CO_2 either in the blood or in the expired CO_2 to quantify the oxidation rate of the labeled substrate.[24,25] The major contribution of these estimates has been the ability to accurately quantify as many components of oxidative metabolism as possible and to develop as complete a picture as possible of the fuel metabolism in vivo. Two commonly used methods are briefly discussed here: open-circuit indirect respiratory calorimetry and the doubly labeled H_2O method.

Open-Circuit Indirect Respiratory Calorimetry

In this system, as shown in Figure 48-3, a plastic hood or canopy is placed over the subject's head, and a suction pump is used to draw air through the hood. The air exiting from the hood is mixed by passing through a baffled mixing chamber. The concentration of O_2 and CO_2 is measured in the mixed air by an appropriate device, either an O_2 and CO_2 analyzer or a mass spectrometer, such as the PerkinElmer medical gas analyzer MGA-1100 (PerkinElmer, Pomona, CA). The flow of air through the system is regulated by flow controllers and is measured by a flowmeter. Commercially available servocontrolled flow regulators are appropriate. The rate of O_2 consumption and CO_2 production is measured by multiplying the gradient of these gases across the face with the rate of flow of air and applying Haldane transformations.[26-29] The latter is based on the finding that the volume of air expired is less than the volume of air inspired and that nitrogen is not used or produced by the body. The transformations therefore use the concentration of nitrogen in the inspired and expired air to estimate the inflow of air into the system. The outflow is measured by the flowmeter. The open-circuit method has been validated over many years in large numbers of studies in adults, children, and newborn infants,[30-32] and its limitations have been examined.[33]

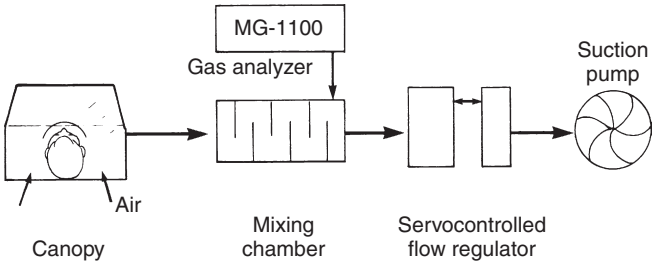

Figure 48-3 Open-circuit indirect respiratory calorimetry. A canopy is placed over the subject's head, and air is drawn through it by a suction pump. Between the canopy and the pump are placed a mixing chamber, a gas analyzer to measure the O_2 and CO_2 concentrations, and a flowmeter and regulator to measure and control the flow rate. For details, see text.

Doubly Labeled ($^2H_2{}^{18}O$) Water Method

The doubly labeled water method of measuring energy consumption is based on the estimation of the rate of CO_2 elimination from the body. It has become a popular method because of several distinct advantages:

1. It can be applied to free-living individuals; that is, the subject need not be restrained or confined to bed.
2. CO_2 elimination is measured over a prolonged period, hours to days, and thus it includes a composite measure of energy consumption throughout the entire period.
3. The method is simple and noninvasive. It requires administration of a single dose of labeled H_2O and obtaining a few samples of urine, or saliva, or blood to measure the changes in isotopic enrichment over several days. It can be used in adults, children, and infants with ease, without requiring any major modifications in equipment.

This technique was first described by Lifson and associates[34] to study energy metabolism in small animals and was extensively evaluated in humans, both adults and newborns, by Schoeller and colleagues[35-38] and by other investigators.[39-42] The method is based on the following principles: When H_2O labeled with deuterium (^2H) and ^{18}O is administered to a subject, it equilibrates in all the body H_2O compartments. Then the tracer is eliminated at the same rate as the body H_2O. The deuterium is eliminated from the body as H_2O (^2H_2O). Because oxygen (as well as the tracer ^{18}O) equilibrates rapidly between H_2O and CO_2 in the presence of carbonic anhydrase, the ^{18}O is eliminated both by CO_2 and H_2O:

$$CO_2 + H_2^{18}O \rightleftharpoons H_2CO^{18}O \rightleftharpoons H_2O + C^{18}O$$

Thus the rate of loss of ^{18}O represents the elimination rate of CO_2 plus H_2O, whereas the rate of loss of deuterium from body water represents only the loss of H_2O. Therefore the difference in the turnover rates of oxygen and hydrogen of H_2O is equal to the CO_2 elimination rate. The mathematical calculations, the limitation of the technique, and related analytic problems were described by Schoeller, and the reader is referred to the excellent review by him.[38]

The partitioning of fuel oxidation is estimated from the stoichiometry of the three oxidative reactions.[26,27]

$$1\ \text{Glucose} + 6\ O_2 = 6\ CO_2 + H_2O + 673\ \text{kcal}$$

$$\text{Respiratory quotient} = \frac{6\ CO_2}{6\ O_2} = 1.0$$

$$1\ \text{Palmitate} + 23\ O_2 = 16\ CO_2 + 16\ H_2O + 2398\ \text{kcal}$$

$$\text{Respiratory quotient} = \frac{16\ CO_2}{23\ O_2} = 0.70$$

$$1\ \text{Amino acid} + 5.1\ O_2 = 4.1\ CO_2 + 0.7\ \text{urea} + 2.8\ H_2O + 475\ \text{kcal}$$

$$\text{Respiratory quotient} = \frac{4.1\ CO_2}{5.1\ O_2} = 0.8$$

Because nitrogen is approximately 16% protein by weight, the amount of protein oxidized can be estimated from the urinary nitrogen excretion:

$$\text{Protein oxidized} = 6.25 \times \text{Urinary nitrogen}$$

The contribution of glucose and fat to oxidative metabolism can be estimated from the measured respiratory quotient corrected for protein oxidation.

The limitations in estimation of substrate oxidation by respiratory gas exchange have been discussed by numerous investigators.[20,26,27,43,44] Respiratory gas exchange measures net utilization or oxidation of the substrates, such as glucose or fat, irrespective of the intermediate steps. For example, if glucose is converted to fatty acids and the fatty acids are oxidized, it will be estimated as glucose oxidation only.[44] Respiratory gas exchange as commonly used and as described earlier does not include other metabolic processes such as gluconeogenesis and lipogenesis.[26,27] In addition, no net oxidation of fat is assumed to occur at respiratory quotients of less than 1.0.[44] At respiratory quotients greater than 1.0, a calculated negative rate of lipid oxidation is assumed to represent lipid synthesis.[44] Finally, respiratory gas exchange also assumes substrate homogeneity, that is, all fatty acids are represented by palmitate with a respiratory quotient of 0.72, and similarly all amino acids and proteins are assumed to have the same respiratory quotient. These limitations should be recognized when data from respiratory calorimetry measurements are interpreted.[19,20]

GLUCOSE METABOLISM IN THE FETUS

Maternal-Fetal Glucose Relationship

In most species studied, including humans, the fetal plasma glucose concentration has been observed to be significantly lower than that observed in a simultaneously obtained blood sample from the mother.[45,46] In addition, a significant linear relationship has been observed between the prevailing glucose levels in the mother and those in the fetus.[47,48] In humans, the fetal blood samples had been obtained mostly at term gestation from fetal scalp blood or at the time of delivery, by cesarean section, from a segment of doubly clamped cord.[47-49] However, because of the effects of labor and delivery on maternal and fetal circulation, these data had been questioned in regard to their representation of fetal metabolism. The technique of percutaneous umbilical blood sampling permits access to fetal circulation without causing any significant perturbations to the physiology of the fetus. Fetal blood samples have been obtained in midgestation (18 to 21 weeks) by fetoscopy or late in gestation by ultrasound visualization of the umbilical vessels.[45,46] Some interesting observations have been made. Bozzetti and colleagues[46] observed a significant correlation between maternal arterialized venous blood glucose and fetal umbilical venous glucose concentrations in 14 fetuses examined between 17 and 21 weeks gestation, with the fetal glucose concentration lower than that in the mother. Of interest were the findings that in 7 cases, the maternal glucose concentration was less than 4.4 mmol/L (79 mg/dL). These investigators found that, at maternal glucose concentrations lower than 4.4 mmol/L (4.12 ± 0.11 mmol/L), fetal umbilical venous glucose concentration may exceed the maternal glucose concentration (4.4 ± 0.06 mmol/L) and may be independent of it. Similar suggestions have been made by other investigators when fetal blood samples have been obtained early in gestation.[45] The significance of these findings remains to be defined. However, the higher levels observed were in the umbilical venous sample, whereas the umbilical arterial levels may have been much lower. Later in gestation, and as shown in Figure 48-4, most investigators have observed a close linear relationship between maternal and fetal glucose whether the samples were obtained by percutaneous umbilical blood sampling, by scalp sampling during labor, or from umbilical vessels at the time of elective cesarean section.[47-51] This linear relationship between maternal and fetal glucose concentrations has been observed during euglycemia, during hyperglycemia induced by glucose infusion to the mother, and during hypoglycemia induced by insulin infusion to the mother.

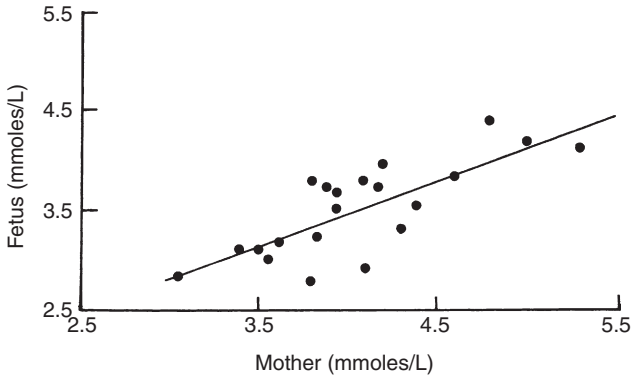

Figure 48-4 Relationship between maternal and fetal glucose concentrations. Simultaneous maternal venous and umbilical venous blood samples (via percutaneous umbilical blood sample) were obtained in the third trimester of pregnancy. *(Data from Ashmead GG, Kalhan SC, Lazebnik N, et al: Maternal-fetal substrate relationships in the third trimester in human pregnancy,* Gynecol Obstet Invest *35:18, 1993.)*

Glucose Transport Across the Placenta

On the basis of data of in vivo studies in animals and isolated perfused placenta, it can be concluded that glucose is transported across the placenta along a concentration gradient by a facilitated, carrier-mediated diffusion.[52,53] Furthermore, this process is stereospecific. Although the net transfer is from the mother to fetus, tracer isotope studies have demonstrated a bidirectional diffusion of glucose, that is, from the mother to the fetus and vice versa.[54] Studies of human placenta perfused in vitro have shown that the placental glucose uptake from the maternal perfusate and glucose transfer to the fetal perfusate is linearly correlated with maternal glucose concentration up to 20 mmol/L. Beyond this level, glucose is transferred to the fetal perfusate by simple diffusion.[55] Metabolically, the placenta is a very active organ, and glucose transfer to the fetus represents only 40% to 50% of the total glucose uptake by the placenta.[56] The remaining glucose is used by the placental tissue for oxidation, stored as glycogen, or

converted to lactate, which is then used by the mother and the fetus.[56-59] As gestation advances, an increase in uterine blood flow results in an increased delivery of glucose to the fetus.[60] Wilkening and colleagues[61] showed that, in the presence of a constant blood glucose concentration in the pregnant sheep, a reduction of uterine blood flow (from 600 to 300 mL/minute per kilogram of fetus) did not have any effect on fetal glucose uptake or fetal arterial glucose concentration. However, any further decrease in uterine blood flow resulted in decreased fetal glucose uptake and variable fetal arterial glucose concentration. Conversely, a reduction in umbilical blood flow by ligation of one of the umbilical arteries resulted in a decrease in fetal glucose uptake and fetal growth restriction.[62]

Sources of Glucose for the Fetus in Utero

Although simultaneous changes in fetal glucose concentration correspond to changes in maternal glucose concentration and are suggestive of fetal dependence on maternal glucose pool, they do not unequivocally indicate that the fetus in utero cannot mobilize hepatic glycogen; that is, the fetus does not release glucose from the glycogen stores. To determine whether the fetus in utero can regulate glucose metabolism independent of the mother under circumstances in which the maternal metabolism is compromised, two different methods have been applied. The first involves the infusion of glucose labeled with isotopic tracers, to either the mother or the fetus, and examines the isotopic enrichment or specific activity in the maternal and the fetal compartments.[50,54] In humans, this approach could be applied only in women undergoing elective cesarean section (and therefore minimal maternofetal perturbation) and examining the fetal compartment by obtaining an umbilical arterial and venous blood sample at the time of birth.[50] The second approach, commonly used in animal studies, combines the isotopic tracers with placement of catheters in fetal circulation. Using these techniques, in large as well as small animals, several groups have measured the umbilical blood flow, fetal glucose uptake, fetal glucose utilization, and oxidation.[54,63-68]

Studies in Humans

Only one study has examined the sources of glucose for the human fetus at term gestation.[50] Glucose labeled with ^{13}C was infused at a constant rate into pregnant women undergoing elective cesarean section for clinical indications after an overnight fast. At delivery, simultaneous blood samples were obtained from the maternal vein, cord artery, and cord vein. As shown in Figure 48-5, the ^{13}C enrichment of maternal vein, cord vein, and cord artery was similar in healthy women and women with gestational diabetes. These data indicate that the fetal glucose pool was in equilibrium with the maternal glucose pool and that maternal glucose was the only source of glucose for the human fetus at term gestation after a brief overnight fast. If the fetus had been producing (releasing) glucose, a lower [^{13}C]glucose enrichment would have been seen in the fetal blood. Whether such a relationship is also present early in gestation is not known. However, combining isotopic tracer infusion with percutaneous umbilical blood sampling permits an answer to this question at different gestations.

Marconi and colleagues[69] examined whether the fetus could produce glucose in nine patients with pregnancy complicated by intrauterine growth restriction between 29 and 35 weeks gestation. They administered glucose ^{13}C (ul) tracer to the mother and measured the isotopic enrichment in the maternal blood and in fetal blood obtained by cordocentesis. They observed no difference in tracer enrichment in the maternal and fetal compartments, again confirming that even in pregnancies with fetal growth restriction, the maternal glucose is the only source of glucose for the fetus.

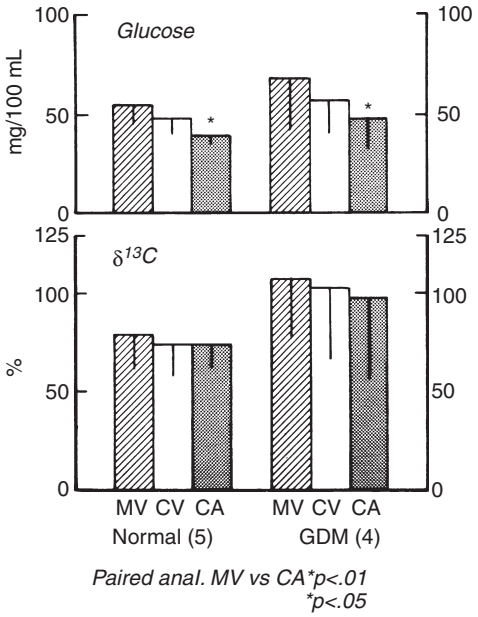

Figure 48-5 Plasma glucose and glucose ^{13}C enrichment (^{13}C) during [1-^{13}C]glucose infusion in maternal venous *(MV),* cord arterial *(CA),* and cord venous *(CV)* blood. Five healthy mothers and four mothers with gestational diabetes *(GDM)* were infused with [1-^{13}C]glucose tracer for at least 2 hours before elective cesarean section. Simultaneous maternal venous and umbilical blood samples were obtained at delivery. *(Reproduced from the* Journal of Clinical Investigation, *1979;63:388, by copyright permission of the American Society for Clinical Investigation.)*

Studies in Animals

Examination of the relationship between maternal and fetal glucose pool by measuring maternal and fetal blood glucose concentrations and by infusing isotopic tracer solely in the maternal compartment (as was done in human studies described earlier) provides only qualitative information regarding maternal and fetal glucose pools. To quantify the magnitude of glucose flux from the mother to the fetus, that is, umbilical glucose uptake and fetal glucose utilization and simultaneous tracer isotopic infusion to the mother and the fetus, measurements of umbilical arterial and venous gradient along with quantification of umbilical blood flow are required. The details of these techniques were described by Krauer and co-workers,[57] Anand and colleagues,[66] and Hay and associates.[67] Because acute perturbations, such as placement of vascular catheters, surgery, or anesthesia, result in major alterations in fetal metabolism, sufficient time must be allowed for the fetus to recover and return to a "normal" basal state. Such studies are not ethically possible in humans.

The sources of fetal glucose have been examined in animal species. The most commonly used animals have been the rat and the sheep. In the pregnant rat examined during the last 3 days of pregnancy (normal rat pregnancy is 21 days) and after a 16-hour fast and with the animal under anesthesia, the fetal glucose specific activity during a constant-rate maternal [^{14}C]glucose tracer infusion was consistently lower than that in the mother, a finding suggesting a fetal source of blood glucose.[63-65] However, such studies should be interpreted with caution because a 16-hour fast in a pregnant rat may be equivalent to a prolonged fast in larger animals.

In contrast to studies in rats, studies in sheep fetuses have shown that, under basal conditions during maternal euglycemia, maternal glucose is the only source of fetal glucose, and fetal

glucose production under these circumstances either does not occur or is negligible.[66,67] The only exception is the study of Hodgson and colleagues,[68] done with the animals in a fed state, which showed that the fetal uptake of glucose from the mother accounted for only approximately 70% of the fetal glucose pool. The reason for this discrepancy is not clear and may be related to feeding in a ruminant mammal. However, it is now accepted that, in most species during basal state, the fetal glucose pool is entirely derived from the maternal glucose pool, and, under these circumstances, the fetus late in gestation does not release endogenous glucose.

Gluconeogenesis in Utero

Because in certain animal studies, as stated earlier, the fetus appears to be producing endogenous glucose, and because fetal utilization of placentally produced lactate appears to be a significant component of fetal carbohydrate metabolism, some investigators examined the quantitative contribution of fetal gluconeogenesis. The key gluconeogenesis enzymes, pyruvate carboxylase (PC), phospho*enol*pyruvate carboxykinase (PEPCK), and fructose diphosphatase, are present from early fetal life onward in humans (discussed in the following section).[70,71] Hepatic cytosolic PEPCK appears for the first time after birth in the rat.[72] In humans, isolated liver tissue (explants) early in gestation can incorporate [^{14}C]alanine and [^{14}C]pyruvate into glucose.[73,74] The recycling of the glucose carbon in isolated human fetal liver preparation, however, is negligible.[75] These observations in humans are similar to those seen in guinea pigs and sheep.[76-80] Gleason and associates[81,82] and Levitsky and colleagues[83] quantified gluconeogenesis from [^{14}C] lactate in chronically catheterized sheep and baboon fetus. In sheep, although a significant amount of [^{14}C]lactate was taken up by the liver, only a negligible quantity of the tracer was incorporated into glucose, and the lactate to O_2 quotient was 2:1. These studies suggest that lactate in sheep fetal liver is probably used for nonoxidative metabolic processes, such as a source for glycogen.[81,82] In contrast to sheep, the baboon fetus had slightly greater incorporation of tracer lactate into glucose.[83] Finally, Palacin and colleagues[84] demonstrated that, even after 48 hours of maternal food deprivation, no gluconeogenesis was demonstrable from radioactively labeled glycerol or alanine in the rat fetus at 21.5 days gestation. Thus, in the mammalian species studied, even though the potential for hepatic gluconeogenesis exists, the gluconeogenic capacity is not expressed in utero under unperturbed circumstances, and the contribution of gluconeogenesis from lactate, pyruvate, or alanine to glucose is quantitatively negligible.

Expression and Regulation of Gluconeogenic Enzymes

The initiation of gluconeogenesis after birth is the result of a number of orchestrated events such as expression of key regulatory enzymes as a result of changes in hormonal and cytokine concentration and changes in hepatic redox state. The gluconeogenic pathway involves both the mitochondrial and cytosolic enzymes. Among these, four enzymes, PC, PEPCK, fructose-1,6-diphosphatase, and glucose-6-phosphatase (G-6-pase) catalyze irreversible reactions in the pathway. The developmental expression and regulation of these enzymes are discussed in the following section.

Pyruvate carboxylase: PC, a biotin-dependent mitochondrial enzyme, catalyzes the initial step in the gluconeogenic pathway, the adenosine triphosphate–dependent carboxylation of pyruvate to form oxaloacetate. The developmental expression of PC during the perinatal period in the rat liver and kidney have been quantitated by using enzymatic reverse transcriptase polymerase chain reaction and by immunologic methods. The data show that the activity of PC in the fetal rat liver is undetectable on day 20 of gestation (gestation in rat approximately 21 days), but increases to 8.23 ± 0.40 mU • mg^{-1} protein a day before birth. A further increase occurs in the activity in the immediate postnatal period, reaching a peak at 12 hours after birth (59.95 ± 9.17 mU • mg^{-1} protein). Thereafter a decline in the activity takes place followed by a further increase over the next few days, reaching a maximal activity on the sixth postnatal day (254 ± 16 mU • mg^{-1} protein). The activity of PC decreases to the adult values (86 ± 2.9 mU • mg^{-1} protein) after weaning. The in vitro activity of PC correlates with the amount of protein detected by the Western blot method. The transcription of PC gene parallels its activity during the perinatal period. In contrast to the developmental pattern in the liver, the PC activity in the fetal kidney is undetectable until the sixth postnatal day, suggesting a minimal or no contribution of kidney to gluconeogenesis in the perinatal period. PC activity in the kidney remains at low levels until after weaning, when it reaches the adult values. The rise in glucagon and catecholamines and decline in the levels of insulin in the immediate period after birth further increase the expression of the PC gene after birth.[85] Biotinylation of carboxylases is important for their action. Biotin deficiency during pregnancy in the mice has been shown to reduce the activity of PC in both the maternal and the fetal liver.[86]

Phosphoenolpyruvate carboxykinase catalyzes the guanosine triphosphate–dependent decarboxylation of oxaloacetate to phospho*enol*pyruvate. Two forms of PEPCK have been identified in mammalian species: the mitochondrial form (PECPK-M) and the cytosolic form (PEPCK-C). The mitochondrial form, present in larger proportion in certain species, (e.g., guinea pigs and humans) may be important in gluconeogenesis and lipogenesis particularly in the fetus in utero. The cytosolic PEPCK is the predominant form in the rat. The perinatal development of PEPCK-C in the rat shows that the messenger RNA (mRNA) levels are undetectable in the fetal liver. The gene is induced for the first time at birth, and the activity of PEPCK-C increases to 2.61 units • g^{-1} of liver within 2 to 3 hours after birth. A number of transcription factors, glucoregulatory hormones, and hepatic redox state in concert regulate the transcription of the gene for PEPCK-C.

An extensive analysis of the PEPCK-C gene promoter showed a number of binding sites for the transcription factors. Among these binding sites, CRE-1 region (cyclic adenosine monophosphate [cAMP] response element) is crucial for the expression of PEPCK-C gene during the perinatal period. The transcription factors–CAAT/enhancer binding proteins (C/EBP) bind to the CRE region of the PEPCK-C promoter. The developmental expression of C/EBPs (C/EBPα and C/EBPβ) follows closely with the expression of PEPCK-C gene. The important role of C/EBPα in the cAMP induction of PEPCK-C gene expression in the liver was demonstrated by undetectable PEPCK-C mRNA levels in the mice homozygous for a deletion in the C/EBPα gene. These data suggest that C/EBPα is required for the induction of the dormant PEPCK-C gene at birth. In addition to the transcription factors, hormonal changes associated with birth, that is, an increase in glucagon and catecholamines and decline in insulin levels, and increase in the intracellular concentration of cAMP induce PEPCK-C gene transcription. The inhibitory effect of insulin on PEPCK-C has been shown to be mediated by the transcription factor, SREBP-1c (sterol regulatory element binding protein 1c). Finally, the expression of PEPCK-C gene in the oxygen-rich periportal area of the liver, and its induction at birth associated with a change in the hepatic redox state, also suggests an oxygen-dependent modulation of PEPCK-C gene transcription. Putative sites in the CRE region of the PEPCK-C promoter were identified, indicating the role of oxygen in the PEPCK-C gene transcription.[87,88]

Fructose-1,6-diphosphatase catalyzes the hydrolysis of fructose-1,6-diphosphate to fructose-6-phosphate and inorganic phosphate. It is expressed in the liver, kidney, and pancreatic

beta cells. In the liver, fructose-1,6-diphosphatase is involved in both glycolysis and gluconeogenesis, and it has been suggested to participate as a component of metabolic sensing mechanism in the pancreas.The activity of fructose-1,6-diphosphatase is very low in the fetal period (less than 1 unit), increases after birth, peaks between 8 and 10 days after birth (10 units), and declines to reach the adult values at 25 to 30 days.[89]

Southern blotting of the rat genomic DNA showed a single copy of the fructose-1,6-diphosphatase gene. Three consensus cAMP regulatory elements have been identified in the 5′ flanking region of the gene. Studies in primary adult hepatocyte culture system demonstrated that cAMP increases the abundance of fructose-1,6-diphosphatase mRNA and insulin reduces the mRNA levels. The response to insulin occurs independent of the changes in cAMP levels.[90] Recent in vitro data show that insulin inhibits fructose-1,6-diphosphatase gene expression via activation of the c-Jun amino terminus kinase pathway.[91] Administration of glucagon intravenously has been shown to increase the activity of hepatic fructose-1,6-diphosphatase activity in humans.[92] The regulation of fructose-1,6-diphosphatase gene has not been examined in the perinatal period. However, the preceding in vitro and in vivo data support the role of glucagon and insulin in the expression of fructose-1,6-diphosphatase gene at birth.

Glucose-6-phosphatase is a membrane-bound, endoplasmic reticulum–associated enzyme found mainly in the liver and kidney cortex, the two important gluconeogenic tissues. In addition, G-6-pase is expressed in pancreatic beta cells and jejunum. G-6-pase catalyzes the terminal step in gluconeogenesis and glycogenolysis. Glucose-6-phosphate is transported into the microsomes by the glucose-6-phosphate transporter, where G-6-pase converts glucose-6-phosphate to glucose and inorganic phosphate. The products are then exported out of the vesicles by specific glucose and pyrophosphate transporters. The developmental expression of G-6-pase is tissue specific. Hepatic G-6-pase mRNA is present in significant amount in the fetal liver. Highest levels of hepatic G-6-pase mRNA are observed at birth and at weaning. In the human fetal liver, the pyrophosphate protein and transport capacity appears 2 to 3 weeks after the expression of G-6-pase mRNA. Its level increases by 20-fold in the first 3 days after birth in conjunction with an increase in the G-6-pase mRNA. In contrast to the developmental pattern in the liver, the intestinal G-6-pase mRNA levels are low in the fetal period and increase steadily during the first 2 weeks after birth.[93]

A number of regulatory elements have been identified in the G-6-pase promoter.The data show that higher levels of cAMP and long-chain fatty acids up-regulate the transcription of G-6-pase gene, whereas insulin represses its expression. Long-chain fatty acids have been proposed to enhance the expression of G-6-pase gene transcription via peroxisome proliferator activated receptor (PPAR) dependent pathway.[87] Little is known about the regulation of microsomal phosphate–pyrophosphate transport. In contrast to findings in term infants, persistence of low activity of G-6-pase beyond the immediate neonatal period is common in preterm infants.[94] As a consequence, preterm infants are more prone to have hypoglycemia during periods of starvation.

Fetal Glucose Utilization

The quantitative aspects of fetal glucose utilization have been studied extensively in large animals, such as sheep, by several investigators.[66-68,87,95,96] These data suggest that, because the fetus of a fed normoglycemic sheep, late in gestation, takes up approximately 5 mg/kg per minute of glucose and uses a similar amount, fetal hepatic glucose production approaches zero.[58,67,95] The only exception has been the study by Hodgson and colleagues,[68] which showed a higher utilization rate compared with umbilical uptake, suggesting fetal production of glucose.This difference may be related to the isotopic tracer method used in which the loss of tracer from the fetal to maternal compartment was not taken into account.[90] In humans, no such estimation of fetal glucose utilization has been possible. The only approximation has been based on the increase in total maternal glucose production, measured in late gestation, and it suggests a fetoplacental glucose utilization rate of 5 to 6 mg/kg per minute.[50] Whether such a magnitude of glucose uptake can account for the oxidative metabolism of the fetus has been examined by calculating glucose/O_2 quotient.[97,98] The glucose/O_2 quotient represents the fraction of the total fetal O_2 consumption required to metabolize aerobically and completely the glucose acquired by the fetus across the placental circulation and is calculated as follows: Glucose/O_2 quotient = 6 × [Umbilical vein − Umbilical artery difference of glucose (millimoles)]/[Umbilical vein − Umbilical artery difference of O_2 (millimoles)]. The fetal glucose/O_2 quotient in the fed sheep[98] has been estimated to be approximately 0.5 and in humans approximately 0.8.[97] These data suggest that the maternally acquired glucose could not provide for the entire oxidative metabolism of the fetus and that other substrates, such as lactate and amino acids, may also be used by the fetus in utero for its energy needs.

The role of insulin in fetal glucose use and fetal glucose production was further evaluated by the following means: (1) infusion of somatostatin, resulting in insulin and glucagon withdrawal from the fetus; (2) infusion of insulin directly to the fetus; and (3) injection of streptozocin to the fetus, to produce chronic fetal hypoinsulinemia. Acute infusion of somatostatin to the sheep fetus caused a decrease in plasma insulin and glucose concentration without any change in glucagon concentration.[99] Under these circumstances, fetal glucose utilization and umbilical glucose uptake did not change. Exogenous infusion of glucose did not elicit an insulin response; however, glucose utilization increased even though insulin secretion had been suppressed by somatostatin infusion. These data suggest that acute withdrawal of insulin does not affect fetal glucose utilization and that fetal glucose utilization can be increased even in the absence of a significant insulin stimulation.[99] Chronic withdrawal of insulin by streptozocin injection to the fetus resulted in fetal hypoinsulinism, fetal hyperglycemia, and a decrease in fetal glucose utilization and glucose carbon oxidation.[100-102] An associated decrease also occurred in umbilical uptake of glucose, probably as a result of fetal hyperglycemia.[101] Finally, direct infusion of insulin to the fetus increased fetal glucose utilization in both sheep and rat fetus.[103-106] In addition, acute insulin infusion also increased the glucose/O_2 quotient across the hind limb of fetal lamb.[107] These data are important in the context of human infants of mothers with diabetes in whom intrauterine hyperinsulinemia results in increased fetal glucose utilization, increased accretion of carbon in insulin-sensitive tissue, and increased growth and fetal macrosomia.[108] Such a change in fetal body composition, that is, increased fat deposition and increased hepatic lipogenesis in response to fetal insulin infusion, has been demonstrated in the sheep, monkey, and rat.[109-115] The role of other glucose-regulatory hormones, such as glucagon, cortisol, and catecholamine, in fetal glucose production, utilization, and umbilical glucose uptake needs to be evaluated.

Utilization of Other Substrates by the Fetus

Because glucose could not account for the total O_2 uptake by the fetus, attention has been focused on the utilization of other substrates such as lactate and amino acids by the fetus. Studies of quantitative aspects of lactic acid metabolism by the fetus are confounded by the rapid changes in the concentration of lactic acid in response to small perturbations in the fetus. Therefore, particularly in humans in whom previous blood samples had been obtained only at the time of vaginal or elective cesarean delivery, the umbilical arterial concentration of lactate has

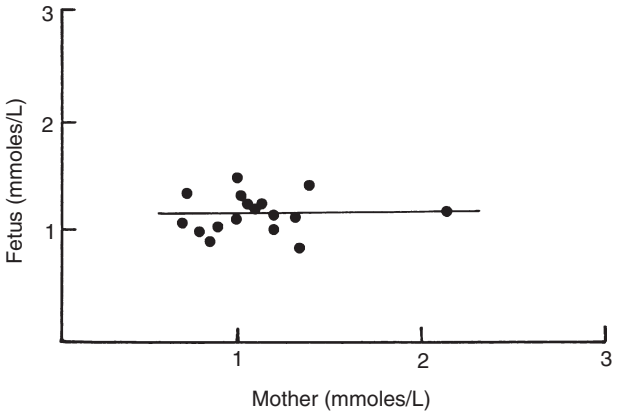

Figure 48-6 Lack of relationship between maternal and fetal blood lactate concentrations. The fetal samples were obtained by percutaneous umbilical blood sampling late in gestation. *(Data from Ashmead GG, Kalhan SC, Lazebnik N, et al: Maternal-fetal substrate relationships in the third trimester in human pregnancy,* Gynecol Obstet Invest *35:18, 1993).*

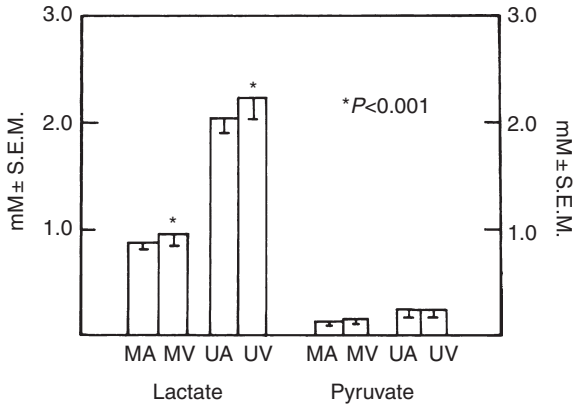

Figure 48-7 Maternal-fetal lactate and pyruvate gradients in the sheep, late in gestation. *MA,* Maternal artery; *MV,* uterine vein; *UA,* umbilical artery; *UV,* umbilical vein. *(Reprinted by permission from* Nature*, vol 254, p 710. Copyright 1975, Macmillan Magazines Ltd.)*

been observed to be higher than the simultaneously obtained umbilical venous and maternal venous blood concentrations.[116] These data would suggest fetal production and placental clearance of lactate but are subject to criticism because of a lack of steady state and the effect of labor on fetal metabolism. Even in a relatively unperturbed state in which percutaneous umbilical blood samples have been obtained from the fetus in utero, the fetal blood lactate concentrations were found to be similar to the simultaneously obtained maternal venous blood concentrations.[45] However, in a more recent study in which fetal blood samples were obtained by cordocentesis late in gestation, no correlation between maternal and fetal blood lactate concentrations was observed (Figure 48-6).[51]

In contrast to the data in humans, stable chronic preparations in the sheep fetus provide near-optimal conditions to study the maternal-fetal lactate relationship. As shown in Figure 48-7, the umbilical venous and uterine venous concentrations of lactate have been shown to be higher than the simultaneously measured umbilical arterial and uterine arterial lactate concentrations.[58] These data, which have been confirmed by Char and Creasy,[59] indicate uteroplacental production and maternal and fetal utilization of lactate. The metabolic fate of the lactate produced by the uteroplacenta and used by the fetus was not examined in these studies. However, estimation of the lactate/O_2 quotient suggested that complete oxidation of lactate could account for 25% of fetal O_2 consumption.[58] These studies are of interest in that the lactate derived from the placenta could potentially be used by the fetus for both oxidative and nonoxidative purposes such as glycogen synthesis.

In addition to glucose and lactate, amino acids actively transported from the mother to the fetus are an important potential source of energy as well as substrates for glycogen synthesis. Amino acids are actively transported across the human placenta from the mother to the fetus.[117] Lemons and colleagues[118,119] examined the fetal uptake of amino acids in the unstressed sheep and observed that the fetal uptake of amino acids was far in excess of that found in the carcass. These investigators suggested that a significant amount of amino acids taken up by the fetus was oxidized. Gresham and colleagues[120] estimated that up to 25% of the total fetal O_2 consumption in the sheep fetus could be accounted for by the oxidation of amino acids. In the human, on the basis of urea concentration gradients across the umbilical circulation, it can be assumed that the human fetus in utero catabolizes amino acids and synthesizes urea.[121] Using stable isotopic tracer methods, Gilfillan and colleagues[122] demonstrated synthesis of alanine by the human fetus at term gestation. They estimated that endogenous alanine synthesis could account for approximately 44% of alanine flux in the fetus. Because alanine is a major glucogenic precursor and because alanine nitrogen is a major precursor of urea nitrogen, the major oxidation product of amino acids, these data are consistent with utilization of amino acids by the human fetus for energy metabolism.

Regulation of Umbilical Glucose Uptake and Fetal Glucose Utilization

The fetal uptake of glucose appears to be closely regulated by the maternal plasma glucose concentration. As cited earlier, in human studies, the fetal glucose concentration closely follows maternal glucose concentration. In studies of fetal sheep, when the maternal glucose concentration was decreased by fasting[123] or by acute insulin infusion,[66] the umbilical uptake of glucose also decreased. During acute hypoglycemia produced by insulin infusion, the glucose-specific activity in the maternal and fetal compartment was identical, a finding suggesting no compensatory glucose production by the fetus and hence an associated decrease in fetal glucose utilization.[66] In contrast, in the experiments on fasted sheep, the fetal glucose utilization measured by isotopic tracer did not decline as much as the decrease in umbilical uptake, a finding suggesting a compensatory fetal glucose production.[123] The reason for the difference in these two studies may be that, in the former, hypoglycemia was produced acutely by insulin infusion, whereas, in the latter, the hypoglycemia was produced slowly after 5 to 7 days of fasting, which probably permitted the fetus to mount a compensatory response. DiGiacomo and Hay[124] showed that, during chronic maternal hypoglycemia produced by up to 3 weeks of insulin infusion, the sheep fetus increases glucose production and thus maintains glucose utilization. Whether such compensation also occurs in humans is not known. Nevertheless, isolated perfused human liver early in gestation is capable of release and autoregulation of uptake of glucose.[75] In this context, during acute umbilical cord compression in the sheep fetus that resulted in decreased umbilical glucose delivery to the fetus, Rudolph and associates[125] also showed an increase in net glucose production by the fetal liver. However, under these circumstances, a decrease in O_2 delivery to the fetus and a decrease in fetal arterial O_2 content also occurred, even

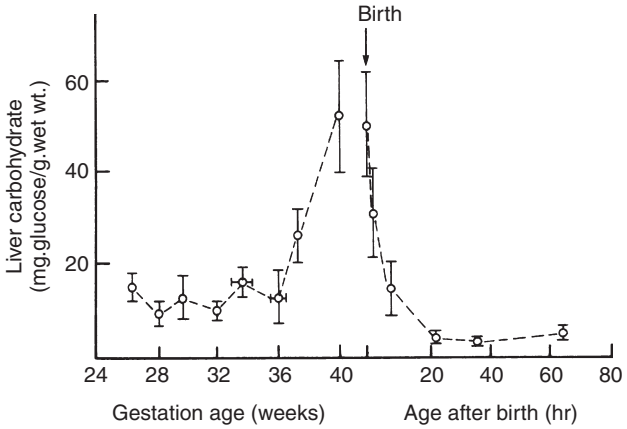

Figure 48-8 Changes in liver glycogen concentration in the human during fetal life and after birth. *(Modified from Shelley HJ, Nelligan GA: Neonatal hypoglycaemia,* Br Med Bull *22:34, 1966.)*

though umbilical O_2 uptake was maintained. Therefore the mechanism of compensatory glucose production during these conditions may be different from that seen during sustained hypoglycemia.

Glycogen Metabolism and Sources of Glycogen in the Fetus

The hepatic glycogen content in the human fetus is low early in gestation. As measured by Capkova and Jirasek,[126] the glycogen content of the fetal liver between 51 and 60 days (average, 8 weeks) gestation was 3.4 mg/g. A slow continuous increase in hepatic glycogen took place, so that between 121 and 130 days gestation it had reached 24.6 mg/g. In preparation for birth, a rapid steep increase appears to occur at around 36 weeks gestation. As shown by Shelley and Neligan,[127] in the human fetus at 40 weeks gestation, the hepatic glycogen content approaches 50 mg/g net weight (Figure 48-8). Soon after birth, hepatic glycogen decreases rapidly, so that by 24 hours of age it has reached a very low concentration. The human data have been obtained from abortions, fresh stillbirths, or infants who died soon after birth. Therefore the consequences of the events responsible for death should be considered when interpreting these data. It is likely that these estimates are lower than the actual levels in the liver. Similar changes in hepatic glycogen in relation to development have been observed in other animal species.

The fetal liver contains the full complement of enzymes required for the synthesis and breakdown of glycogen.[128] The potential for the synthesis of glucose from three carbon substrates has been demonstrated from early on in gestation in most mammalian species, except the rat. Evidence has been presented in mature animals and in humans suggesting that glucose may not be the immediate precursor of hepatic glycogen and that three carbon substrates—lactate, pyruvate, and alanine—derived from glucose in the periphery are likely to be the precursors for hepatic glycogen.[129-131] Whether a similar "indirect" pathway is also operative in the fetus was examined by Levitsky and associates[132] in chronically catheterized sheep fetuses late in gestation. By simultaneously infusing [^{14}C]lactate and [3-^{3}H]glucose in the fetal circulation and measuring ^{14}C- and ^{3}H-specific activity of glycogen, these investigators showed that glycogenesis from glucose, in the ovine fetus, is partly through the "indirect" gluconeogenic route, and lactate may be an important glycogenic precursor. These data are consistent with high lactate turnover rates observed in the sheep fetus.[133,134]

GLUCOSE METABOLISM IN THE NEWBORN

As discussed in the preceding section, the fetus in utero under normal circumstances is entirely dependent on the mother for glucose, and negligible amounts, if any, of fetal glucose production have been observed in most mammalian species studied. At birth, with the discontinuation of the maternal supply of substrates and nutrients as a result of cutting the umbilical cord, the newborn has to mobilize glucose and other substrates to meet energy needs. Therefore the process of birth involves certain well-orchestrated endocrine and metabolic events that result in adaptive responses for independent existence. Studies in newborn humans and in newborn animals have shown major changes in circulating glucoregulatory hormones, in association with birth and cutting of the umbilical cord. The plasma concentration of epinephrine, norepinephrine, and glucagon has been shown to increase rapidly, whereas the concentration of insulin decreases.[134-139] The net effect of these changes is mobilization of glycogen[140] and fatty acids.[135,136] After birth in the human newborn, the plasma glucose concentration declines, reaching a nadir by 1 hour of age and then rising spontaneously so that plateau levels are reached between 2 and 4 hours.[141-144] The lowest level of glucose observed and the speed with which stable levels are reached are in part dependent on whether the mother received glucose during labor and delivery.[145] With the current obstetric management of the mother and the nutritional practices for the neonate, low blood glucose levels are not seen as often as in the past. In addition, the average glucose levels observed in the nursery are higher than those in the past.[142-144] At present, a term healthy neonate in the first 6 hours of life maintains plasma glucose between 40 and 80 mg/dL. The glucose levels increase slightly with the initiation of feeding; therefore, after 24 hours of birth, the normal infant's plasma glucose levels range between 45 and 90 mg/dL. Of course, these data vary with the individual institution's clinical practice regarding nutritional management of the newborn. The data in animal studies are variable depending on the individual species differences. Suffice it to say that most newborn animals go through a brief period of transient hypoglycemia with spontaneous recovery.

Glucose Kinetics in the Newborn

By using an isotopic tracer dilution method, radioactive tracers in animals, and nonradioactive (stable) tracers in humans, the rates of glucose production and utilization have been quantified in several studies.[146-150] Although these measurements fit within a certain range, these quantitations are influenced by the following factors:

1. The type of tracer used, that is, recycling versus nonrecycling. In general terms, labeled carbon tracers are recycling tracers and result in underestimation of glucose production rate, the only exception being the use of uniformly labeled [^{13}C]glucose and quantitation of only the masses representing the whole molecule of glucose that is uniformly labeled.[149,151] In contrast to labeled carbon tracers, labeled hydrogen tracers are nonrecycling.[147] However, in some of the later tracers, an excessive loss or exchange of label may occur, resulting in an overestimation of the rate of turnover.
2. The clinical condition of the subject. Although it has been described that the subjects were "well," in many of these studies, the infants were receiving intravenous fluids or were completing a course in antibiotics. In one study, the infants were receiving intravenous glucose, which was discontinued before initiation of isotopic tracers.[147] These infants should not be considered "well" in the strict sense, and their underlying problems may have contributed to

the variance in measurements. Similarly, the earlier animal studies were performed by either tying the animals down or administering anesthesia to them.[150] Anesthesia has been documented to have significant effect on glucose metabolism.[152]

3. The blood-sampling technique, such as with repeated venipuncture or heelsticks versus indwelling needles, may influence glucose measurements. It has been well recognized and confirmed that the newborn infant can respond to pain by mounting a "stress"-hormone response, which can result in changes in glucose kinetics.[153]

Glucose Kinetics During Fasting

The rates of glucose production and utilization in the human newborn during fasting, that is, 3 to 4 hours after birth, before feeding, or after 8 to 9 hours after the last feeding, have been estimated to be between 4 and 6 mg/kg per minute.[146-149] These rates are higher than those measured by recycling tracers.[148] The rate of glucose production in the newborn human is somewhat lower than that observed in newborn dog, lamb, or pig,[150,154] and this situation probably is caused by species differences or by experimental conditions.

The rates of glucose production estimated in the newborn are significantly higher than those observed in adult humans and animals and reflect the higher metabolic rate and the higher brain–body weight ratio of the newborn, the brain being the major glucose-using organ. As the newborn grows, the rate of glucose production per unit body weight decreases; therefore, by adolescence, the rates of glucose production approximate the rates in adults, which are one half to one third those seen in the newborn.[147]

During steady state, in the presence of a constant blood glucose concentration, the rates of glucose production and utilization are equal. The fate of used glucose and its contribution to oxidative metabolism was quantified in human newborns by Denne and Kalhan.[149] By infusing glucose labeled uniformly with ^{13}C in combination with indirect respiratory calorimetry, these investigators showed that only 53% (range, 40.9% to 68.1%) of glucose produced was oxidized to CO_2, and oxidation of plasma glucose contributed up to 38% of the total calorie expenditure. Another interesting finding of this study was the small discrepancy (approximately 20%) between the estimation of total carbohydrate oxidation by respiratory calorimetry and that measured by tracer isotope studies. A similar discrepancy was shown by Sauer and colleagues[155] in their study in glucose-infused newborn infants. This difference has been postulated to result from the inclusion of local glycogen mobilization and oxidation, not included in the tracer isotope estimations.[149] However, this does not explain the observed discrepancy during prolonged fasting conditions.[19]

The study of Denne and Kalhan[149] raises an important question regarding the energy metabolism of the brain in newborn humans during fasting. As demonstrated by studies in adult humans, the brain derives almost all its energy from glucose.[156,157] The calculated amount of glucose necessary to supply the energy for the brain correlates well with the measured oxidation rates of glucose.[158,159] The O_2 consumption rate of the brain in the newborn human has been determined to be 104 μmol/100 g brain tissue per minute.[160] If the average weight of brain in newborn infants is estimated to be 360 g,[161] approximately 3.7 mg/kg per minute of glucose would be required to meet the metabolic needs of the brain. Thus, as shown by Denne and Kalhan,[149] the measured rates of glucose oxidation in the human newborn will supply only approximately 70% of energy needs of the brain. These data suggest that in the human newborn during fasting, the energy requirements of the brain are supported in part by fuels other than glucose.

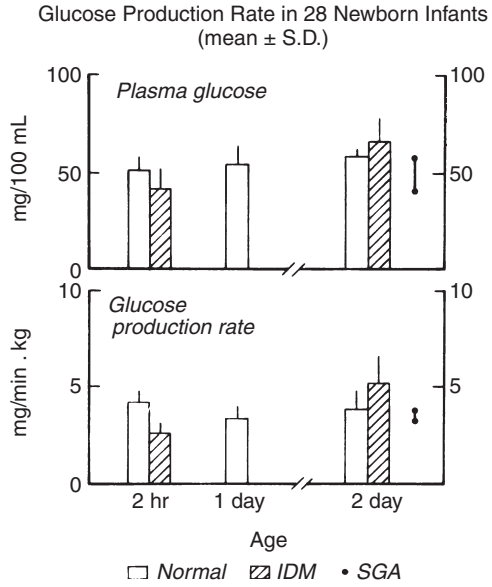

Figure 48-9 Changes in the rate of glucose production and blood glucose concentration in the first 2 days in physiologically normal infants, infants of mothers with diabetes *(IDM),* and small-for-gestational age infants *(SGA).*

Effect of Age

The data presented earlier were obtained in the first 48 hours after birth. Over the next few days, with the introduction of feeding, the normal infant maintains the plasma glucose level between 40 and 70 mg/dL during fasting.[162] The endogenous rate of glucose production and utilization, as measured by [1-^{13}C]glucose tracer dilution, also either remains unchanged or decreases slightly (Figure 48-9). Thus the glucose production rate in seven infants older than 2 days was 4.1 mg/kg per minute. As shown, in contrast to the finding in physiologically healthy infants, in the infant of a mother with diabetes the plasma glucose concentration and endogenous glucose production rate increased and reached those observed in the normal infants. In the infant with intrauterine growth restriction, the endogenous glucose production rate expressed per kilogram of body weight had been noted to be either the same as in healthy infants or slightly increased, a finding reflecting the higher brain weight–body weight ratio in these infants.

Regulation of Glucose Production in the Newborn

Interest in the regulation of hepatic glucose production in the newborn stems from the observation of marked fluctuation in glucose homeostasis during this period. Both in human and in animal models, hypoglycemia and hyperglycemia have been observed and constitute a significant problem in the clinical management of the infant. The problem is further compounded in the premature newborn and in the presence of intrauterine growth restriction. These responses in the newborn led some investigators to suggest that glucose homeostasis in the newborn is "transitional" as a result of immaturity of the regulatory mechanisms.[154] Evaluation of regulation of glucose homeostasis is rather difficult because of the small size of the newborn infant and animal, the prolonged nature of the experiments, and, finally, the rapid changes in the physiologic state as the newborn adapts to the extrauterine environment.

The role of glucose and the pancreatic hormones insulin and glucagon in the regulation of glucose production has been examined in both adults and newborns. During the basal state

in normal adult humans and animals, the hepatic glucose output is regulated by the interaction of insulin and glucagon. An unopposed action of insulin causes a decrease in hepatic glucose output, whereas glucose output increases in the presence of unopposed action of glucagon.[163,164] When glucose is infused in normal adults, the endogenous glucose production is suppressed as a result of the autoregulatory effect of glucose and the action of insulin on the liver.[165,166] At low rates of glucose infusion, when the insulin concentrations are similar to those in the basal state, 70% to 90% inhibition of endogenous glucose production occurs.[164,167,168] However, at higher rates of glucose infusion, with higher levels of circulating insulin, endogenous glucose production is completely suppressed.[155,159] Thus endogenous glucose production in adult animals and humans appears to be regulated by both glucose and insulin. Glucose alone appears to have its effect in suppressing endogenous glucose production on an insulinized liver via its effect on glycogen metabolism.[169-172]

Whether such mechanism of glucose regulation is functional in the newborn infant and animals has been a subject of study for some time. Numerous studies have examined the newborn human's and animal's response to exogenous glucose infusion. Varma and associates[173] observed a continuous increase in plasma glucose concentration during a constant-rate glucose infusion in newborn dogs, while at the same time the rate of endogenous glucose production decreased to a lesser degree than in adult dogs. In this study, the animals were anesthetized with sodium pentobarbital (Nembutal), which may have affected their glucose metabolism; these investigators used [2-^{3}H]glucose tracer, which is lost in excess as compared with other tracers because of futile cycling; and finally, because the newborn dogs had fasted for a very short time, as compared with adults, they were not in a true fasted state and may have been absorbing glucose from the gut. Sherwood and associates,[174] in a study of rhesus monkey neonates, showed a marked reduction of endogenous glucose output in response to glucose. However, in a group of "sick" newborns, possibly as a result of counterregulatory hormonal responses, marked hyperglycemia developed with no suppression of endogenous glucose output. Finally, in a study of newborn lambs, Cowett and colleagues[154] observed persisting endogenous glucose production until glucose was infused at high rates. However, in this study, the animals had consistently high glucose concentrations, a finding suggesting some influence of counterregulatory hormones, possibly as a result of experiment-related "stress."

In human studies, data have been variable. King and associates[175] observed 80% suppression of endogenous glucose production in term newborn infants. In contrast, Cowett and colleagues[176,177] observed a variable response—complete suppression in some and incomplete in others. The latter was seen more often in preterm infants. In another study, Kalhan and colleagues[178] examined the role of plasma glucose concentration in the regulation of endogenous glucose production by infusing glucose at 2.6 to 4.6 mg/kg per minute as a continuous infusion to term, preterm, and small-for-gestational age infants. Because of the different rates of exogenous glucose infusion, the measured endogenous glucose production rate was variable. However, the peak glucose concentration was related to the rate of glucose infusion, and a negative correlation between peak glucose concentration and the rate of endogenous glucose production was seen (Figure 48-10). All infants in this study mounted a significant insulin response, yet the hepatic response in terms of glucose production rate was variable, a finding suggesting that insulin alone does not appear to be the dominant factor in the regulation of hepatic glucose production. The inverse relationship between plateau glucose concentration and the endogenous glucose production (Re) supports the hypothesis that, in the presence of insulin, plasma glucose concentration appears to be the major regulator of hepatic glucose output in the human neonate. Such a regulatory effect of glucose level on hepatic release and uptake

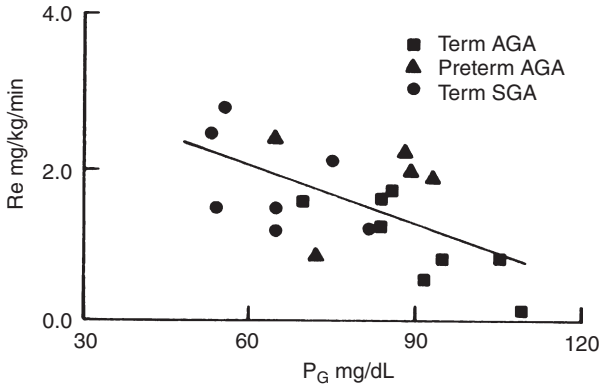

Figure 48-10 Relationship between peak glucose concentration *(P_G)* and endogenous glucose production rate *(Re)* in newborn infants during intravenous glucose infusion at varying rates. The rate of glucose production was measured by [6,6-$^2H_2$]glucose tracer as a prime–constant-rate infusion. A negative correlation between P_G and Re is shown. *AGA,* Appropriate for gestational age; *SGA,* small for gestational age. $Y = 3.56 - 0.03x$; $r = 0.59$; $p = .006$. *(From Kalhan SC, Oliven A, King KC, et al: Role of glucose in the regulation of endogenous glucose production in the human newborn,* Pediatr Res *20:49, 1986.)*

of glucose has been demonstrated in the isolated liver from the midterm human fetus.[75] In that study, insulin in physiologic concentration had no detectable effect on hepatic glucose output.

The role of other regulatory hormones, glucagon and catecholamines, in neonatal glucose homeostasis was evaluated in dogs and lambs. As discussed previously, an increase in glucagon concentration and a decrease in insulin are important in the establishment of hepatic glucose production after birth. However, when the role of glucagon was further evaluated in the neonatal dog and lamb by infusing somatostatin (an inhibitor of insulin and glucagon secretion), a variable response was observed.[179-181] This variability was in part the result of "resistance" to somatostatin action on the pancreas; therefore neonatal pancreas does not show a magnitude of inhibition of insulin and glucagon secretion similar to that seen in adults.[179,181] Thus these data remain subject to ambiguity in interpretation. Finally, studies by Cowett[182,183] suggest that, under normal physiologic conditions, the neonatal liver is more responsive to β-adrenergic stimulation than to α-adrenergic stimulation. The role of hepatic adrenergic receptors in glucose production in vivo in the newborn needs further examination.

Gluconeogenesis in the Newborn

Although the capacity for gluconeogenesis is present in the fetal liver with the exception of the rat, and even though the fetus in utero as well as the isolated fetal liver preparation can synthesize glucose via gluconeogenesis under certain circumstances, gluconeogenesis, that is, synthesis of new glucose and release in circulation, is a postnatal event in most mammalian species. In the case of rat liver, the key gluconeogenesis enzyme PEPCK appears only after birth, and hence the rat fetus is incapable of gluconeogenesis in utero.[87]

In the human newborn, a steady plasma glucose concentration maintained by systemic glucose production is evident soon after birth. Although glucose production most likely is initiated at birth, because of technical problems such as infusion of isotopic tracers, the earliest time of measurement has been 2 to 3 hours after birth. The contributors to systemic glucose production are glycogenolysis and various glucogenic substrates—glycerol,

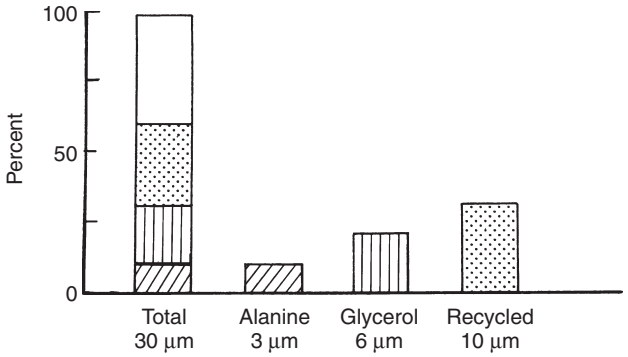

Figure 48-11 Sources of glucose in the human newborn. As measured by tracer isotopes, the major sources of glucose during fasting in the human newborn are glycogen *(unshaded area in the bar),* alanine, glycerol, and recycled glucose carbon.

lactate, and alanine via gluconeogenesis (Figure 48-11). Using various isotopic tracer methods, investigators have quantified the kinetics of these gluconeogenic substrates and their contribution to systemic glucose production in healthy newborn infants.

Gluconeogenesis from glycerol has been quantified in healthy term infants by simultaneous infusion of carbon-labeled glycerol along with labeled glucose. The appearance of tracer carbon in glucose is used to quantify the contribution of glycerol to glucose.[184-186] Data from two such studies in healthy newborn infants are displayed in Table 48-1. As shown, the rate of appearance of glycerol in healthy term infants during the first 48 hours after birth was approximately 9 μmol/kg per minute. Glycerol's contribution to glucose accounted for 10% to 20% of glucose produced. The wide range in estimates of glycerol's contribution to glucose may simply reflect the characteristics of the study population, their time since birth, and relation to the last feeding. Nonetheless, these data show that gluconeogenesis from glycerol is active in the healthy term infant immediately after birth, and approximately 10% to 20% of plasma glucose is derived from glycerol. Finally, these data show that lipolysis in adipose tissue is also active at a high rate in the neonate, because adipose tissue triglyceride depots are the primary source of plasma glycerol.

Because all other gluconeogenic substrates enter the gluconeogenesis pathway via pyruvate, some investigators have examined the contribution of alanine and lactate to glucose production,[87] by using carbon-labeled tracers. As discussed previously, all these methods result in an underestimation of the contribution of gluconeogenesis to glucose production because of the loss of tracer carbon via exchange in the TCA cycle. The data on lactate kinetics from one such study[187] are displayed in Table 48-2. The rate of appearance of glucose and lactate were quantified by using [6,6-$^2H_2$]glucose and [$^{13}C_3$]lactate, respectively. As shown, newborn infants have a relatively high rate of lactate turnover when compared with adults, and approximately 18% of glucose was derived from lactate. However, this estimate of gluconeogenesis from lactate did not correct for the loss of tracer. When corrected for the loss of tracer carbon (correction factor, approximately 1.5),[188] the lactate's contribution to glucose would be approximately 27%.

Newer techniques have been developed to avoid the errors associated with the loss of tracer carbon in the TCA cycle. These include the deuterium labeling of the body H_2O and mass isotopomer distribution method. These techniques have been applied to quantify gluconeogenesis in term and preterm infants.[187,189,190] Using the deuterium labeling of body H_2O method, Kalhan and colleagues[187] showed that the contribution of pyruvate to glucose production in healthy term infants amounted to 31% or 9.30 ± 1.96 μmol/kg per minute (mean ± SD). These estimates of gluconeogenesis via pyruvate are similar to the estimate of glucose carbon recycling, approximately 35%,[149] and the measurements of lactate contribution to glucose (see earlier). If the contribution of glycerol (10% to 20%) is also included, then the total gluconeogenesis in a healthy newborn infant will amount to approximately 50% or approximately 15 μmol/kg per minute of the total glucose Ra of 30 μmol/kg per minute. This is significant and implies an important role of gluconeogenesis, even after a brief fast. These data show that gluconeogenesis from pyruvate, and possibly from glycerol, is occurring at all times, although its contribution to glucose varies with feeding and fasting.

TABLE 48-1

Glycerol Metabolism in Healthy Newborn Infants

No.	Glycerol Ra (μmol/kg/min)	Glucose Ra (μmol/kg/min)	Fraction, glucose from glycerol	Quantity, glucose from glycerol (μmol/kg/min)	Reference
6	9.47 ± 2.11	21.09 ± 1.71	0.20 ± 0.06	4.34 ± 1.30	Patel and Kalhan[185]
8	8.7 ± 1.2	25.0 ± 3.5	0.11 ± 0.02	2.75 ± 0.59	Sunehag et al.[186]

Values are expressed as mean ± SD.
Ra, Rate of appearance.

These data also suggest that gluconeogenesis is one of the several substrate cycles in the body, like the triglyceride fatty acid cycle and protein turnover, which are active at all times and can be rapidly accelerated at the time of acute demand.[187] The regulation of gluconeogenesis in the human newborn has not been examined, and the reader is referred to a review by Girard for a discussion of regulation in the rat.[72]

Very-Low-Birth-Weight Infant

Low-birth-weight infants have become the largest clinical population in the neonatal intensive care unit as a result of improved clinical care and enhanced survival.[191] Studies in this population using isotopic tracer methods have shown that low-birth-weight infants can produce glucose at an appropriate weight-specific rate to meet their metabolic needs, and they respond appropriately to exogenous glucose and amino acid infusions.[178,192,193] Because several of the studies reported in these infants were performed while the babies were receiving intensive support, the hepatic response to glucose and insulin has been reported to be variable, that is, complete suppression of glucose production in some infants and incomplete in others.[178,193-197] However, such a response may be related to the stress response in these infants, as documented by persistent increase in circulating catecholamine levels.[198] In relation to glucose production, provision of exogenous lipids (i.e., a source of energy for gluconeogenesis) caused an increase in glucose levels but did not cause an increase in hepatic glucose production.[199,200] The utilization of glucose by low-birth-weight infants has been examined both during fasting and in response to intravenous glucose. These data suggest that healthy low-birth-weight infants can dispose of infused glucose appropriately without the development of glycosuria and osmotic diuresis, and glucose disposal is related to both plasma insulin levels and plasma glucose concentrations.[201,202] Finally, very-low-birth-weight infants less than 28 weeks gestation show that even this population can regulate endogenous glucose production in response to an infusion of glucose.[203,204]

Quantification of gluconeogenesis in very-low-birth-weight infants has also been done with use of more newly developed tracer techniques.[187-189] Because the data on low-birth-weight infants cannot be obtained during fasting, these studies have

TABLE 48-2

Glucose and Lactate Kinetics in Newborn Infants

	Glucose (mmol/L)	Lactate (mmol/L)	Glucose Ra (μmol/kg/min)	Lactate Ra (μmol/kg/min)	Glucose from lactate (%)
Healthy infants (n = 10)	2.96 ± 0.51	1.83 ± 0.29	20.66 ± 3.28	38.3 ± 11.90	17.9 ± 5.2
SGA infants (n = 4)	3.46 ± 0.43	2.22 ± 0.36	17.71 ± 3.34	32.5 ± 5.74	18.0 ± 9.4
Infants of IDDM (n = 6)	3.42 ± 1.12	2.14 ± 0.43	25.74 ± 8.92	48.6 ± 10.40	18.4 ± 4.1

Values are expresssed as mean ± SD.

Glucose Ra, Rate of appearance of glucose quantified by [6,6-$^2H_2$]glucose tracer dilution; *IDDM,* mothers with insulin-dependent diabetes; *Lactate Ra,* rate of appearance of lactate measured by [$^{13}C_3$]lactate tracer dilution; *SGA,* small for gestational age.

been performed while the infants were receiving parenteral glucose, glucose plus amino acids with or without lipids. Therefore these data should be interpreted in view of the specific metabolic and physiologic state. In addition, low-birth-weight infants are also receiving other clinical support that may confound the data obtained. These studies in low-birth-weight infants show that gluconeogenesis is active in these infants, even when they are receiving parenteral nutrients, and it contributes as much as 30% to 70% to endogenous glucose production. Because of the study conditions, that is, parenteral glucose infusion, endogenous glucose production is significantly suppressed. Thus, even under these circumstances with a low rate of appearance of glucose, gluconeogenesis makes a significant contribution to endogenous glucose production.

Carbohydrate Metabolism During Pregnancy

The effects of pregnancy on maternal glucose metabolism should be considered as two epochs. The first half of gestation is a period of sustained maternal anabolism. During this time, the increased calories ingested by the mother not only sustain fetal growth but also are stored as maternal fat. Normally expected maternal insulin secretion drives this period of anabolism.[1,2]

The increase in maternal metabolic energy stores is important for the second half of gestation, a period of logarithmic fetal growth. The substrate and energy demands of the rapidly growing fetus require not only a greater fraction of maternal food intake but also utilization of the maternal energy stores laid down during the first half of pregnancy. Alterations in maternal sensitivity to insulin are central to this process.[3] The development of insulin resistance can unmask a tendency toward diabetes mellitus (gestational diabetes mellitus).[4,5] The conceptus is responsible for these adaptations. Indeed, these changes parallel the growth of the conceptus.[1] These alterations become increasingly apparent as the conceptus rapidly increases in mass from 20 to 24 weeks of pregnancy onward, and they are promptly reversed after delivery.[1] In the immediate postpartum period, normal glucose tolerance returns, even in those women with gestational diabetes mellitus.

EFFECT OF THE CONCEPTUS ON MATERNAL INSULIN METABOLISM

The fetus and placenta exert multiple metabolic effects. With respect to insulin, maternal insulin does not cross the placenta,[6] although some insulin may be bound there. The placenta clears some maternal insulin by directly degrading it.[7]

Changes in maternal insulin secretion and action are dramatic during the second half of pregnancy.[8] During the first half, basal insulin secretion is normal, and insulin secretion mediates the laying down of metabolic fuels.[9] In the second half of gestation, insulin secretion is greatly exaggerated.[9-11] Intravenous glucose tolerance testing indicates that, by the third trimester, physiologically normal pregnant women secrete three times the insulin that they do in the nonpregnant state.[1]

The development of insulin resistance during the second half of pregnancy is responsible for this exaggerated insulin secretion. Insulin sensitivity is reduced 40% to 60% during the second half of gestation.[9,12] This insulin resistance is caused in part by the generation of human placental lactogen, progesterone, and estrogen, which become available in ever-increasing amounts as gestation progresses.[13-15] These hormones directly antagonize the effect of maternal insulin. Insulin resistance increases in liver, adipose tissue, and skeletal muscle.[16] Insulin binding appears to be normal during late gestation, a finding indicating that insulin resistance is mediated by events distal to receptor and insulin binding. It is possible that tyrosine kinase inhibition may also contribute to insulin resistance.[17,18] Increased insulin clearance may also add to the impact of insulin resistance.[19] This possibility remains to be confirmed.[20]

EFFECT OF THE CONCEPTUS ON MATERNAL GLUCOSE AVAILABILITY

These changes in maternal endocrine controls ensure the availability of glucose, amino acids, and lipids to meet the ever-increasing needs of the fetus during the second half of gestation.

This is not trivial, because the energy and substrate needs of the fetus are considerable. Glucose utilization by the human fetus is estimated to be three times that of the adult. Growth of the human fetus during the third trimester requires the net transplacental transfer of 54 mmol of nitrogen per day.[21] The blunted response to insulin ensures that, during the postprandial state, glucose and amino acids are made available to the fetus at the mother's expense.

During maternal fasting, the ongoing insulin resistance allows a rapid and profound mobilization of maternal fat stores and stimulates ketogenesis. This also causes a decrease in maternal blood glucose and amino acid concentrations despite increased hepatic gluconeogenesis.[22] The reduction in maternal blood glucose may result in hypoglycemia. This fasting hypoglycemia of pregnancy is a result of a failure of amino acid mobilization to keep up with rates of glucose removal. This "accelerated starvation" of the mother ensures fuel availability to the fetus at the mother's expense during pregnancy.[23,24]

CONSEQUENCES OF PROLONGED MATERNAL FASTING

If maternal fasting is prolonged, maternal ketogenesis as a result of these endocrine changes will be prolonged and exaggerated. Ketone bodies readily cross the placenta, and the fetal brain can use ketones as early as 10 to 12 weeks gestation.[23] Although the capability to use an alternative fuel to glucose may be beneficial for the fetus, limited data suggest that the children of mothers who had ketosis during pregnancy are at risk for cognitive and psychomotor delays during childhood. The mechanisms responsible for this potential association between ketone body oxidation and impaired brain function are unclear.[25]

Oxygen Consumption and General Carbohydrate Metabolism of the Fetus

This chapter covers those factors related to general fetal metabolism, with specific reference to fetal energy balance and substrate uptake. Although some direct information regarding human fetal energy metabolism and balance is available, much of the information presented here relies heavily on data obtained from animal experiments and theoretic considerations. Because human fetuses of less than 30 weeks gestation are common in newborn intensive care units, an understanding of those factors involved in determining fetal metabolic needs may be of use in such settings. The word "metabolism" has been used here to describe a variety of biochemical reactions that either require or produce energy. This term is used here in a general sense to illustrate chemical processes in the fetus that alter carbon-containing substrates in order to synthesize tissue (accretion/growth), or provide the organism with energy needed for basic homeostasis (fuel/energy).

FETAL ENERGY REQUIREMENTS

For many years after the discovery of oxygen by Lavoisier,[1,2] it was assumed that the fetus had no metabolism of its own. John Hunter had, however, demonstrated in 1786 that fetal and maternal circulations within the placenta were distinct from each other[3] and Erasmus Darwin, Charles Darwin's grandfather, surmised correctly in his text *Zoonomia* (1794) that at least some of the function of the placenta was to supply oxygen for fetal demands. However, it was not until the late 1800s that fetal blood was demonstrated to contain oxygen[4,5] derived from mother's blood and in the 1930s that fetal blood oxygen content and hemoglobin saturation could be accurately measured.[5] Even so, mammalian fetuses were thought to live in hypoxic environments[5,6] because human and animal umbilical venous blood had a lower partial pressure than adult blood. The normal fetal umbilical venous pO_2 at term was found to be 25 mm Hg or less. This finding led to the "Mount Everest in utero" concept attributed to Sir Joseph Barcroft,[5] and attempts were then made to understand how the fetus adapted to such conditions. Because of the leftward shift in the oxyhemoglobin dissociation curve and elevated levels of fetal (versus adult) hemoglobin, normal umbilical venous oxygen content, measured by the standard of mL or mmol of oxygen per mL of blood, was found to be the rule.

Interestingly, more recently it has also been demonstrated that acquiring hemoglobin concentrations of 16 to 18 g/dL, similar to those found in the fetus, also appears to confer significant survival advantage for some adults living at high altitude (i.e., 3800 m),[7] another condition placing constraints on arterial blood oxygen tension. This is also likely to spare cardiac work (i.e., obviating the need to increase cardiac output, which would be limited in the fetus). Oxygen delivery to tissues in the fetus due to fetal hemoglobin, when studied in 5 mammalian species[8] (for a variety of reasons), was found to be more efficient than that of adult hemoglobin, as was the ability of hemoglobin to load oxygen at the placental level, due to the Bohr pH effect (Figure 50-1). Overall, therefore, in both human cord blood and umbilical venous samples from fetuses of a number of species, fetal oxygen delivery as measured by blood oxygen content (not pO_2) is adequate for aerobic metabolic needs.[9]

It follows that fetal mammals, under steady-state, or unstressed, conditions, ought to achieve adequate oxygen delivery (the product of umbilical venous blood oxygen content and umbilical venous blood flow) and should not exhibit evidence of hypoxia (low tissue oxygen availability), unless specific organ or total blood flow falls dramatically or fetal blood oxygen content declines below a critical level. Studies of fetal acid-base or lactate balance indirectly test this hypothesis. The consensus is that no evidence exists to support a hypoxic fetal milieu because (1) umbilical cord blood pH values of unstressed fetal humans, pigs, monkeys, and sheep are all similar to each other and to the normal adult range of 7.35 to 7.45; (2) venoarterial $[H^+]$ concentration differences in cord blood of these species are only modest, suggesting relatively small fetomaternal $[H^+]$ transfer, inconsistent with hypoxia-induced lactic acid production; (3) both in vitro and in vivo, the placenta has been shown to deliver lactate into the fetal circulation, where it is taken up, particularly by the fetal liver, for purposes of accretion and oxidation[10,11]; and (4) experimental production of maternal and therefore relative fetal hyperoxia in the sheep is not associated with an increase in fetal oxygen consumption.

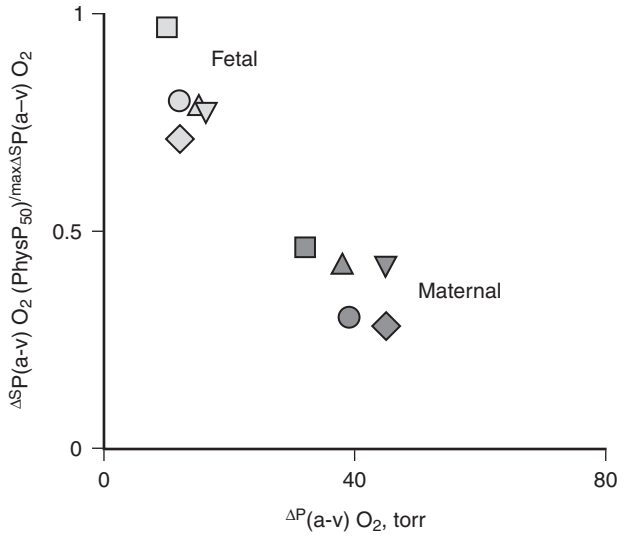

Figure 50-1 Enhanced efficiency of oxygen delivery of fetal vs maternal blood in five mammalian species. Efficiency calculated as $\Delta S_{(P(a\text{-}v)\ O2)PhysP50}/Max\Delta S_{(P(a\text{-}v)\ O_2}$ and plotted as a function of the arteriovenous (a-v) O_2 partial pressure difference of oxygen $(P(a\text{-}v)\ O_2)$. The term $\Delta S_{(P(a\text{-}v)\ O2)PhysP50}/Max\Delta S_{(P(a\text{-}v)\ O_2}$ represents the change in hemoglobin (Hb) saturation at any given a-v po_2 value at physiologic P50 (partial pressure at which Hb is 50% saturated) relative to a theoretically derived "optimal" Hb saturation at the same a-v pO_2 difference. (Open symbols: fetal; closed symbols: maternal; human ◇; cow ○; sheep △; pig □; horse ▽) *(From Zhang Y, et al:* Zool Sci *23:49, 2006)*

Thus in the unstressed fetus, energy processes appear to operate for the most part through oxidative pathways, and estimation of fetal oxygen consumption may be used as a direct indicator of the fetal metabolic rate.[9,12] Although rates of substrate uptake and carbon dioxide production provide alternate measurements of fetal metabolic activity, the calculation of each requires a significant number of assumptions. In the case of substrate utilization, the relative partitioning of carbon uptake by the fetus for use as fuel (oxidative needs) or growth (accretion needs) must be considered. In the case of carbon dioxide production measurements, the overall respiratory quotient (RQ) must be estimated (i.e., the relative contributions of carbon from the oxidative metabolism of carbohydrates, amino acids, and fats toward carbon dioxide production must be taken into account).[9,13]

FETAL OXYGEN CONSUMPTION

Measurement

Fetal oxygen consumption (Vo_2) has been estimated using a variety of techniques. Two methods have been used to gauge fetal oxygen consumption in vivo. Because the fetus has little stored oxygen, the vast majority of fetal requirement for oxidative metabolism of substrate is met by transfer of oxygen to the fetus via the placenta and umbilical venous circulation. Little, if any, transfer is thought to occur across the fetal membranes. The earliest known method for measuring fetal VO_2 accurately in the intact animal was that derived by Christian Bohr (circa 1900). By measuring VO_2 before and after intermittent umbilical occlusion in pregnant guinea pigs (or in subsequent studies by others before and after delivery of the fetus), fetal VO_2 could be calculated as follows:

$$\text{Fetal } VO_2 = \text{Predelivery maternal } VO_2 - \text{Postdelivery maternal } VO_2 \quad (1)$$

Fetal VO_2 is usually expressed as either mL or mmol o_2/kg or g/minute. As shown in Table 50-1, estimates for fetuses of several species, including humans, are available.

The major assumption in such studies is that the act of delivery (or cord occlusion) does not measurably alter maternal, uterine, or placental VO_2. Such assumptions may not be entirely true because of parturition-induced changes in fetal, placental, and maternal rates of metabolism, but the results of these studies provide a framework for estimates obtained using other methods.

The second technique for measuring fetal VO_2 relies on the principle derived by Adolf Fick (circa 1870), whereby uptake of substrates or oxygen for the whole organism can be calculated as the product of cardiac output and the arteriovenous difference in substrate or oxygen content. In the case of specific fetal organ uptake (or in this case, the whole fetus), the product then can be transposed as that of the organ or whole fetal blood flow multiplied by the arteriovenous or venoarterial concentration difference of the substance in question across the organ or umbilical circulation, respectively. Thus for oxygen consumption of the mammalian fetus, the principle may be restated according to Equation 2:

$$\text{Fetal } VO_2 = \text{Fumb} \times (V - A)\, O_2 \quad (2)$$

where Fumb = umbilical blood flow (mL/minute or mL/kg/minute) and (V – A) O_2 = the venoarterial difference in O_2 content (mL or mmol of O_2/100 mL blood) across the umbilical circulation.

Noninvasive methods for determination of human fetal VO_2 are being developed, such as magnetic resonance imaging (MRI)[14,15,15a] and near infrared spectroscopy (NIRS)[16] (Figure 50-2). Both techniques make use of the differences observed in either image density or spectroscopic patterns between saturated and desaturated hemoglobin and may be particularly useful for assessing specific organ (i.e., liver, brain) oxygen requirements or abnormalities of metabolic function due to maternal or fetal disease states.[17]

TABLE 50-1

Fetal Oxygen Consumption in Various Species

Species	Measurement	VO_2 (mL/kg/min)
Human at term[19,19a]	B	6.0-6.8
Human <28 wk[135]	F	5.4
Rhesus monkey[136]	F	7.0
Sheep[115]	F	8.0
Cow[137]	F	6.7
Horse[138]	F	7.0
Guinea pig[139]	B	8.8

B, Bohr principle measurement; *F,* Fick principle measurement.

Experimental Data

The difficulties involved in obtaining Fick principle estimates of fetal VO_2 include the necessity of obtaining samples of umbilical venous and distal aortic blood for oxygen content analysis, which requires use of a relatively large fetus (i.e., sheep, cow, pig) for catheter placement, and the requirement of a reliable estimate of umbilical blood flow. The former problem has been overcome either by sampling at these sites acutely in anesthetized animals or by the implantation of fetal catheters[9] for serial measurements under nonstressed conditions. The latter problem has been overcome by the development of several methods for the accurate measurement of umbilical blood flow, which include the use of laser-Doppler, ultrasonic, or electromagnetic flow transducers; radiolabeled microspheres; or steady-state diffusion of substances such as antipyrine, ethanol, or tritiated water across the placenta. The advantages of the Fick method over the original Bohr technique include (1) the ability to perform serial studies in the same animal during late gestation, (2) the ability to measure uptake and excretion of potential fetal metabolites simultaneously with the uptake of oxygen, and (3) the ability to observe changes in metabolic rate before and after experimental manipulation. As noted, other noninvasive methods are being developed that are hoped to allow for diagnostic as well as research use in humans, such as blood oxygenation–level dependent (BOLD) MRI[14-15a] and optical methods such as NIRS and a modification of NIRS, intensity-modulated optical spectroscopy (IMOS).[16] These latter two techniques estimate with significant accuracy differences in hemoglobin saturation in intra-organ circulations. Other noninvasive methods, such as the doubly labeled water technique,[18] have been used to estimate long-term oxygen consumption or oxygenation in humans, but significant obstacles in estimating human fetal VO_2 preclude their use at this time.

As can be seen in Table 50-1, when corrected for fetal weight, fetal VO_2 as measured in a variety of species is remarkably consistent, with a range of 6.5 to 8.5 mL $O_2 \times kg^{-1}$/ minute. In studies of fetal VO_2 in term human fetuses using the Bohr or modified Fick methods,[19,19a] values of 6.0 to 6.8 mL/kg/minute obtained fit well within the range observed for other species.

Determining Factors

As stated, fetal requirements for energy may be estimated from measured fetal VO_2 or by measuring uptake of a variety of fetal substrates to gauge both fuel and accretion requirements. The factors that control fetal energy expenditure are not fully understood but one main tenet is that a relatively constant relationship exists between mass and metabolic rate across species in the adult. Kleiber[20] originally formulated the allometric scaling relationship:

$$\text{Metabolic rate} = (\text{Mass})^{3/4} \quad (3)$$

In this relationship, however, it is important to point out that metabolic rate is expressed in kcal/day and so the total daily

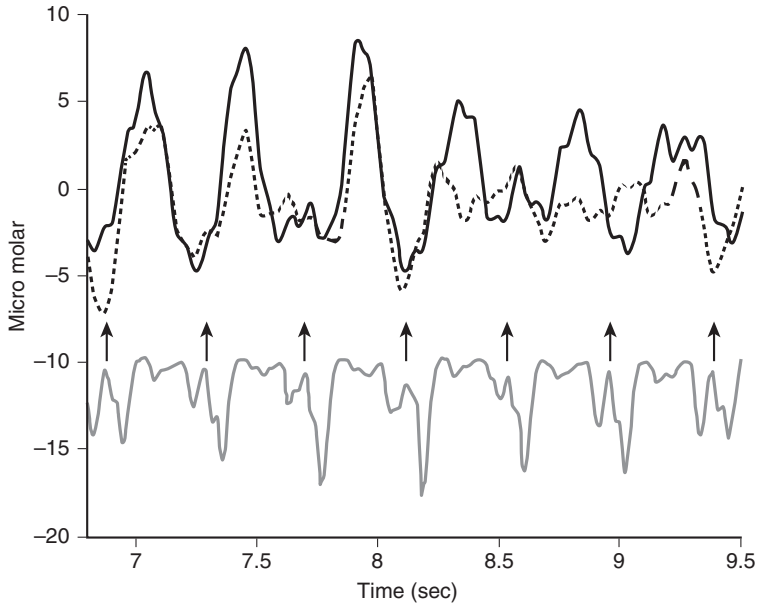

Figure 50-2 Near infrared spectroscopic (NIRS) analysis of blood volume *(solid line)* and saturated oxyhemoglobin *(dashed line)* changes in a human fetus measured transabdominally along with the fetal heart rate *(bottom dotted line). Arrows* represent fetal heart rate signals. *(From Vinzileos A, et al:* Am J Obstet Gynecol*192:129, 2005.)*

energy expenditure (not mass specific) rises in proportion to $(mass)^{3/4}$. As shown by Singer and others,[21] if mass-specific (non-allometric) basal metabolic rate (kcal/kg/time unit) is used instead, the relationship becomes an inverse one, with smaller animals having relatively larger mass-specific metabolic rates. It has been suggested that as mammalian species evolved, there was a general tendency for metabolic rate to increase directly in proportion to body mass (i.e., to $mass^{1.0}$). However, given that, geometrically speaking, surface area changes (which also must be taken into account relative to such factors as heat dissipation) are only proportional to $mass^{2/3}$,[22,23] an incongruity existed and the three-fourths power relationship may represent a basic biologic compromise. Alternatively it has also been recently argued[24,24a] that in living systems a variety of scaling relationships relative to mass are all based on multiples of 1/4 (life span, 1/4; heart rate, 1/4; mitochondrial density, 1/4; whole body RNA and DNA content, 1/4; cardiac output, 3/4). Over the 70 years since Equation 3 was first formulated, this basic principle has been extended and is reasonably predictive of the aerobic metabolic rates not only for a variety of mammals and other vertebrates, but also for the metabolic rates of single cells, mitochondria, and even for the turnover rate for substrates in the respiratory enzyme chain within mitochondria[25] (Figure 50-3).

The general relationship above may be predicted theoretically due to the basic limitations of nutrient and oxygen transport placed on respiring cells that relates to the geometry of branching networks, such as blood vessels or mitochondrial cristae. Subsequently this scaling relationship has been corroborated by a number of observers.[12,22,23] The theory requires that three basic factors be present for the scaling rule to be accurate: (1) a space-occupying branching network for transport purposes that extends throughout, (2) a "final" size-invariate end branch (such as a capillary), and (3) a requirement for minimization of the energy needed for substrate or oxygen transport purposes.[24,25] The caveats in such a relationship are that the metabolic rate is measured (classically as VO_2) (1) in the resting state as opposed to a "field" metabolic rate (i.e., during normal physical activity and changing milieu), and (2) in non-growing adults (i.e., does not include subjects that are actively growing, such as the fetus).

Although the basic three quarters rule would otherwise probably also apply in fetal and early neonatal life, the additional metabolic needs for growth and development clearly increase the demand for energy. At this point it may be more instructive to examine the nonallometric relationship between mass and energy as noted previously for the fetus and newborn. As it turns out, mass-specific metabolic rate is relatively constant from fertilization through the morula stage,[23] and increases (three- to four-fold) thereafter for the fetus. However, probably because of the diminished needs for such metabolic functions as heat control, VO_2 in late fetal life more clearly matches the weight-specific metabolic rate for the adult (Figure 50-4). According to recent work,[21] metabolic rate then rises above that of the adult postnatally, with a slow decline thereafter.[21,23] In fact, studies in human infants by a variety of investigators concluded that the relationship between body mass and VO_2 falls back to "adult" levels by about 18 months of age, or at roughly 12 kg.[26] Some of the differences noted relate to growth and changes in mass-specific surface area and some also to a poorly understood increment in cellular sodium pump activity in the newborn.[27] At the cellular level, the control of metabolic rate has not been clearly elucidated but involves complex interactions between a number of factors, including (1) the concentration of adenosine triphosphate (ATP), the product of mitochondrial oxidative phosphorylation; (2) the ratio of intracellular adenosine diphosphate (ADP) to ATP; (3) rates of intracellular protein synthesis; and (4) the generation of proton ($[H^+]$) gradients by respiratory enzymes across the mitochondrial and cell membranes.[12,28] For example, it has been estimated that approximately 15% of VO_2 of the term fetus might be spent on total active transport processes. One emerging factor related to regulation of metabolic rate (and potential changes during development)[29] is that polyunsaturated fatty acid (PUFA) composition of cellular phospholipid bilayers is directly related to the activity of the Na^+,K^+-ATPase pump, whereby increasing PUFA concentration is associated with increased metabolic activity. Whether this has significant applicability to the human fetus and newborn is unknown.

It has been assumed that at the organ or tissue level, metabolic rate is not influenced by oxygen availability unless the diffusion of oxygen is severely limited. Justification for this view stems from

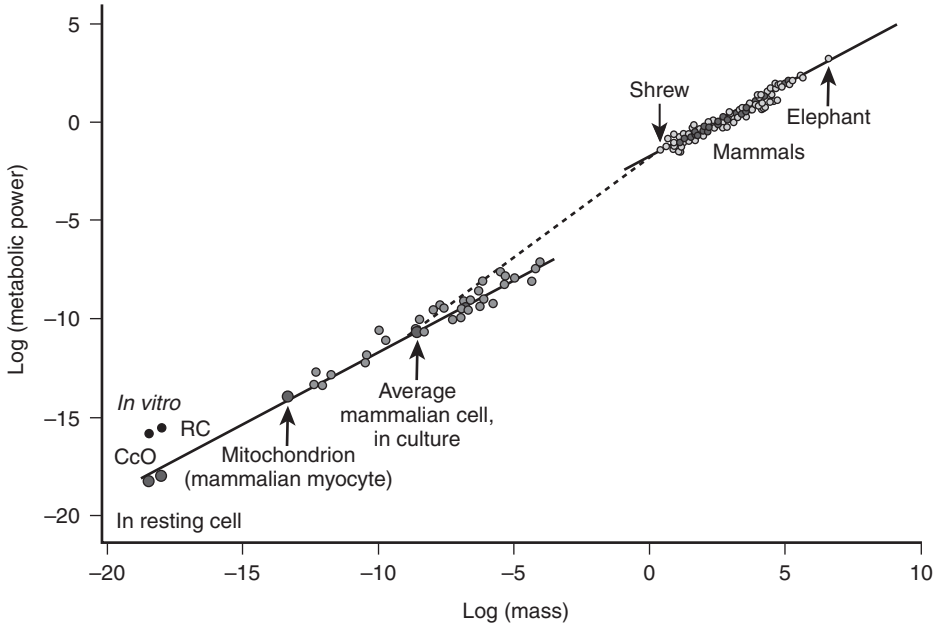

Figure 50-3 Basal metabolic rate as a function of mass using a logarithmic scale. The solid line is representative of the mass$^{3/4}$ relationship in mammals over 27 orders of magnitude from individuals, and extrapolated to unicellular organisms and uncoupled mammalian cells, mitochondria, cytochrome oxidase molecules (CoC) and the respiratory chain (RC) complex. *(From West GB, et al:* PNAS *99(Suppl 1):2473, 2002;West GB, et al:* J Exp Biol *208:1575, 2005.)*

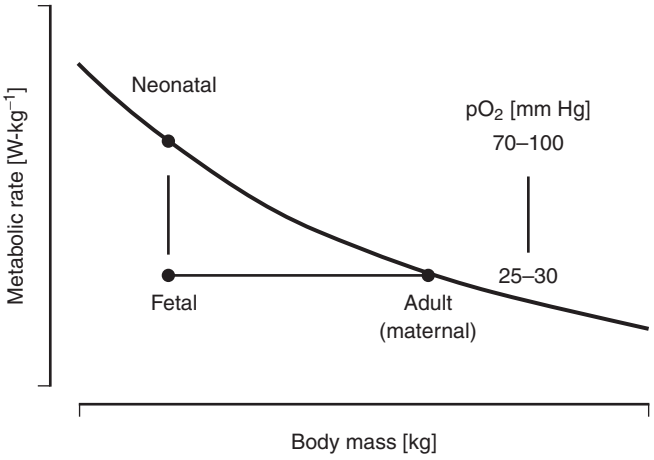

Figure 50-4 Change in relationship between body mass and metabolic rate (mass-specific, or nonallometric) from fetus to newborn. *(From Singer D, Mühlfeld C: Perinatal adaptation in mammals: The impact of metabolic rate.* Comp Biochem Physiol *Part A 148:780, 2007.)*

the observation that several mammalian tissues (liver, kidney) have similar in vivo and in vitro rates of VO_2, suggesting an intrinsic regulatory mechanism, perhaps related to genetically defined tissue-specific respiratory enzyme activities. However, some contradictory in vivo studies in mammals genetically adapted to living at high altitude (the South American Andean llama, family Camilidae)[30-31a] and in sheep recently acclimatized to high altitude[32] have shown that chronic exposure to relative fetal hypoxemia can, in addition to increasing hemoglobin concentration, induce significant depression of cerebral Na^+, K^+-ATPase pump activity, reduced expression of at least two Na channel proteins and decreased cerebral heat production, as well as decreased cerebral VO_2 without apparent biochemical or histologic evidence of brain damage.[30] At least some of these changes appear to be mediated by endothelin-1 and intrinsic nitric oxide, (NO) both potent mediators of vascular tone.

At sea level, however, classic studies have shown the characteristic fetal blood flow (and consequent oxygen) redistribution during graded maternal hypoxia, in which blood flow and oxygen delivery are preferentially shunted to brain and away from carcass.[33] Interestingly, in vitro studies have shown that tissues such as fetal muscle[34] do decrease VO_2 in response to change in media pO_2. Similar findings have been observed in other fetal organs such as liver and kidney.[35] A series of studies have shown that several oxygen-sensitive factors, most notably, hypoxia-inducible factor-1 (HIF-1),[36] a potent gene transcriptional factor, and calcium channel receptors[37] such as RyR1 may act to stimulate local organ intravascular synthesis of the intrinsic vasodilator NO, thereby increasing local blood flow and therefore oxygen delivery during times of relative hypoxemia. Expression of HIF-1, as well as several other hypoxia-inducible factors, appears to be developmentally and evolutionarily regulated.[38,38a] Studies of two distinct human populations living at high altitude for many centuries (Andeans and Tibetans) suggest divergent HIF-1 responses have evolved to deal with the problem of oxygen delivery.[19a,38a] Such studies have important implications for understanding the manner in which the fetus might be protected against sudden changes in oxygen delivery

INTEGRATION OF FETAL METABOLIC RATE

In terms of integrated metabolic rate of the whole fetus, most data available are from animals studied under steady-state conditions. Under a wide variety of circumstances, changes in O_2 delivery to the fetus are met by fetal changes in O_2 extraction to meet metabolic demands.[39] In the fetal sheep, O_2 extraction may be measured as the ratio between O_2 consumption (as in Equation 2) and O_2 delivery (the product of umbilical blood flow and umbilical venous O_2 content). In the steady state, this ratio

Muscle[9,141*]	20	50 (1.1)	14.0
Other growth[4,9]	—	20 (0.45)	5.6
Activity[49*]	—	54 (1.2)*	15.0
Total	—	296 (6.6)	83

*Data for muscle (in vitro) and activity (in vivo) must reflect both sedentary and active states of striated muscle respiration.

is usually roughly 0.4 in the fetal sheep, meaning that only 40% of the oxygen delivered to the fetus via the placental circulation is actually extracted. The ratio during experimental hypoxemia may rise to some extent (to 0.5 to 0.6). Studies in healthy human fetuses during delivery found extraction ratios of 0.62 to 0.64.[11,40] Interestingly, even in fetuses with intrauterine growth restriction that were excreting significant amounts of lactate (and presumably had relative fetal hypoxia), no increase in extraction was observed, suggesting a relative maximum in extraction efficiency had been reached.[9,11] Of interest is the relative constancy of fetal VO_2 across species lines when corrected for fetal weight. In species whose fetal weights differ by as much as a factor of 300, weight-specific fetal VO_2 estimates (ml/kg/minute) differ by only 15% with a mean value of 7.4 mL/kg/minute (see Table 50-1).[9] Corroboration of these observations is apparent when resting fetal heart rates of a number of species are compared. Fetal and neonatal heart rates (and therefore cardiac output) have been used as reliable indicators of the metabolic rate.[41] Meier and co-workers[42] have observed that fetal heart rate differs little across species lines, in contrast to the adult, in whom heart rate is universally related to body weight. The reasons for such constancy of metabolic rate between various species are unclear but may relate to the previously mentioned allometric scaling principles,[25] the rapid rate of growth in late perinatal life, and changes in membrane lipid composition.[29] In addition, it has been hypothesized that the fetus is relatively free from the "adult" oxidative demands of temperature homeostasis and, to a lesser extent, gravity and muscular activity, all of which are somewhat dependent on body mass and surface area.

Of those factors influencing fetal VO_2, several are particularly prominent (Box 50-1). "Specific organ metabolism" refers to those various cellular processes common to most tissues. Under basal conditions a certain minimal level of VO_2 is necessary to maintain cellular homeostasis. Virtually all mitochondrial and plasma membrane ion pumps, vital for maintenance of intracellular and intraorganelle homeostatic reactions, require energy in the form of ATP for their activity and are thus heavily dependent on cellular respiratory activity. Such pumps consist of F-type H^+ pumps (mitochondria), V-type H^+ pumps (lysosomes, storage granules), or P-type Na^+,K^+, or H^+ pumps (plasma membranes).[43] The degree of mitochondrial proton leak is also allometrically related to body mass among different species.[23] In the adult, overall pump activity has been estimated at approximately 20% of the basal metabolic rate.[44] Although it has thus far been difficult to estimate the contribution of such processes to the overall demand on the fetus for oxygen, it is likely that for many tissues, pump activity is important in determining tissue VO_2. For example, in one estimate,[45] ouabain (via inhibition of Na^+,K^+-ATPase pump activity) caused a decline in fetal sheep liver and placental VO_2, which accounted for 20% and 34% of whole organ VO_2, respectively. Similarly in the newborn rat, approximately 50% of liver metabolism was due to activity of the sodium pump, with a significant decline in infancy.[27]

Other metabolic processes, such as protein synthesis and attendant energy-dependent chemical reactions such as transamination and decarboxylation have metabolic costs, but the contributions of these to fetal VO_2 have not been determined. Such processes that are common to all cells must make up a significant fraction of what is estimated when whole-organ or cellular VO_2 is measured. It is clear that fetal work (i.e., muscle oxidative requirements to perform such activities as fetal breathing movements, limb movements, etc) also accounts for a significant fraction of the total fetal VO_2. For example, striated muscle activity (excluding cardiac work), as assessed in the in vivo fetal sheep, has been estimated to account for as much as 15% of the total fetal VO_2, which agrees with an in vitro measurement of approximately 20 μmol/100 g/minute, assuming muscle mass in the term fetal lamb of 25% fetal wet weight. If specific cardiac VO_2, as also measured in the lamb, is added, slightly greater than 20% of the fetal requirement for oxygen is necessary for normal striated muscle activity.

Unfortunately further information of tissue-specific oxygen needs in the fetus is limited to several accessible organs in the sheep fetus although some in vitro tissue data from premature humans is available for comparison.[46] From estimates in Table 50-2, however, it can be seen that approximately 50% of the fetal VO_2 is attributable to fetal brain, liver, kidney, and intestine. Lastly, the energy cost of growth (i.e., the energy necessary to synthesize new tissue as opposed to the energy stored in new tissue) has been estimated to be approximately 10% of the caloric value of new tissue, which is equivalent to about 6% of the fetal VO_2. Thus in the sheep fetus, approximately 83% of the fetal VO_2 can be accounted for in the resting state. It is assumed that measurement of VO_2 in other tissues (e.g., bone marrow, lung, adrenal gland, cartilage, skin, etc.) will provide for the remaining 17% of whole fetus oxygen needs.

Several factors may influence the fetal metabolic rate (see Box 50-1). Interestingly, other than active fetal cooling, such adverse stimuli such as mild hypoxemia, manipulations such as mild hypoxemia, maternal exercise,[47] or severe maternal starvation[48] do not appear to depress overall fetal metabolic activity. Although not well studied, those maternally administered drugs that cross

the placenta and have a depressive effect on fetal activity would be expected to decrease fetal VO_2 as well. For example, skeletal muscle paralysis in the fetal lamb causes a 10% to 15% decrease in fetal VO_2.[49] Significant depression of fetal respiratory or body movement has been noted after maternal exposure to ethanol, antidepressants, cigarette smoking, hypoxemia, or steroids.[50,51] The fetal metabolic rate can be stimulated by such factors as change in fetal sleep state,[50,52] excessive fetal muscular activity, maternal fever, and possibly external stimuli such as sound.[53] Studies regarding changes in fetal behavior are possible using fetal ultrasound to gauge fetal movement and breathing. Using these techniques, it has been shown that fetal breathing is more prominent after maternal food intake[50] or glucose infusion[54] and appears to be stimulated by maternal drug abuse (cocaine, methadone).[51]

The hormonal milieu also plays a significant role in setting the background for the fetal metabolic rate at rest and when changes occur in the fetal environment. The interplay between the hypothalamic-pituitary-adrenal axis, catecholamines, and other fetal hormones influence cellular respiration and metabolic rate. In the adult, changes in both sympathetic and parasympathetic nervous activity during meals may be partially responsible for the well-known postprandial increase in metabolic rate. In the steady state, fetal insulin deficiency has not been shown to cause a change in resting umbilical VO_2,[55] although maternal and therefore fetal hypoglycemia has been shown to lower VO_2 by as much as 30%.[56] As noted in the following text, both fetal hyperinsulinemia and hyperglycemia appear to have independent effects upon accelerating fetal VO_2.[56] Fetal thyroid ablation has been shown to cause a 20% to 30% reduction in fetal metabolic rate[57] and exogenous thyroxine can be shown to reverse these metabolic changes. These observations may have important implications for such disease states as fetal thyrotoxicosis or maternal diabetes.

FETAL ENERGY SUBSTRATES

As noted in the previous sections, fetal VO_2 in most species, including humans, has been measured to be approximately 7 to 8 mL/kg/minute or roughly 11.5 L of oxygen per kg body weight per day. Assuming a "fetal diet" (see later) relatively low in fat intake for most species and a conversion factor of approximately 4.8 to 4.9 kcal energy liberated per liter oxygen consumed, the energy requirement (caloric value of substrate used for oxidation) by the fetus would be equivalent to approximately 55 kcal × kg^{-1} × day^{-1}. Because fetal energy requirements dictate a significant source of carbon uptake, it has been of interest to determine the relative uptakes of potential substrates across the fetal circulation. This has been accomplished both by classic Fick principle physiologic methods in ruminant species and by isotope infusion studies (e.g., radioactive carbon [^{14}C]-labeled glucose, lactate). Although the latter method has been more completely defined in fetal sheep, transfer studies are also available in small mammals such as the guinea pig, rabbit, and rat,[58,59] as well as in human fetuses to a limited extent.[60]

METHODS AND TERMINOLOGY

Uptake

Uptake of a substrate such as glucose may be calculated using the equation derived for fetal VO_2:

$$U_{substrate} = Fumb \times (v - a)_{substrate} \quad (4)$$

where $U_{substrate}$ = the umbilical uptake of a particular substrate in mmol or mg/kg/minute and $(v - a)_{substrate}$ = the umbilical vein–distal aortic concentration difference of substrate in mmol or mg/mL. Note that U does not necessarily measure fetal uptake because, theoretically, endogenous production of a particular substrate (such as glucose or lactate) from other substrates must be taken into account. U, therefore, measures net umbilical uptake and provides only a minimum estimate of fetal uptake. Another limitation of this method for estimating fetal substrate utilization is the sensitivity of the method used to assay substrate concentration (usually colorimetric or spectrophotometric methods) relative to the percent extracted from the circulation. For example, in the fetal sheep, the umbilical venous concentration of glucose is approximately 30 mg/dL (1.7 mmol/L), and the extraction coefficient ([uptake/delivery] × 100) ranges from 10% to 15%. The coefficient of variation of the glucose assay is approximately 3%, and thus it is possible to measure umbilical glucose uptake with accuracy. By contrast, the umbilical venous concentration for the amino acid serine is 700 μmol/L with a coefficient of variation of the assay of 1%.[61] In this case, however, the extraction coefficient of serine is only 0.6% of the delivery rate. It is therefore obvious that for substances with small extraction coefficients, accuracy in measuring umbilical uptake using the Fick principle is problematic.

Oxygen Quotient

Previously it was difficult to determine directly whether specific fetal substrates were taken up by the umbilical circulation and oxidized completely. The concept of substrate-oxygen quotient was adapted for the fetus,[9] predominantly using sheep to address this question. To estimate the maximum fraction of fetal oxygen consumption accounted for by the oxidation of any given substrate, the following equation is applied:

$$\text{Substrate}/O_2 \text{ quotient} = \frac{F_{umb} \times (v - a)_{substrate}}{F_{umb} \times (v - a)\ O_2} \times n \quad (5)$$
