The other half of the metabolic equation is the loss of surfactant from the lung. This measurement has three components that include uptake and catabolism of surfactant components from the airspace by type II cells and macrophages and recycling by type II cells. Little surfactant is lost from adult lungs to the lymph or vascular space unless the lung is injured, and minimal amounts of surfactant are lost by suctioning the airways unless edema fluid is present. In the term lamb, a trace dose of surfactant given at birth had a half-life of approximately 6 days, which is longer than values of approximately 10 hours for adult animals.[48] Almost all of a trace dose of surfactant given to preterm lambs with mild RDS was recovered in the lungs after 24 hours of ventilation, demonstrating minimal catabolism[49] (Figure 104-6). However, only 20% of the labeled surfactant was still in the airspaces, and 80% was associated with the lung tissue. Similar measurements in preterm lambs with more severe RDS who were treated with surfactant demonstrated a 30% loss of the surfactant used for treatment by 24 hours and only 14% of the surfactant recovered by alveolar lavage.[50] This rate of loss of surfactant from the lungs yielded a biological half-life of approximately 48 hours. The percent of a treatment dose of surfactant that remained in the airspaces was decreased with high tidal volume ventilation or with high frequency oscillatory ventilation in preterm lambs.[51,52] The amount of surfactant lost from the lungs was increased by ventilator-induced lung injury. Surfactant-treated and ventilated preterm baboons that were developing BPD retained only 4% of the treatment in the airspaces, and approximately 80% of the surfactant was lost from the lungs by 6 days, yielding a half-life of approximately 60 hours.[38] These results indicate that the term and preterm lung degrades surfactant lipids slowly and that injury can increase the loss of surfactant from the lungs.

No information is available in the preterm about where degradation of surfactant occurs. The normal preterm lung at birth contains few macrophages and essentially no granulocytes. However, inflammation and injury will rapidly recruit inflammatory cells to the lung, which may then increase the loss of surfactant. A significant amount of a treatment dose of surfactant that becomes associated with the lung tissue probably is in type II cells. In the term newborn rabbit, more than 90% of

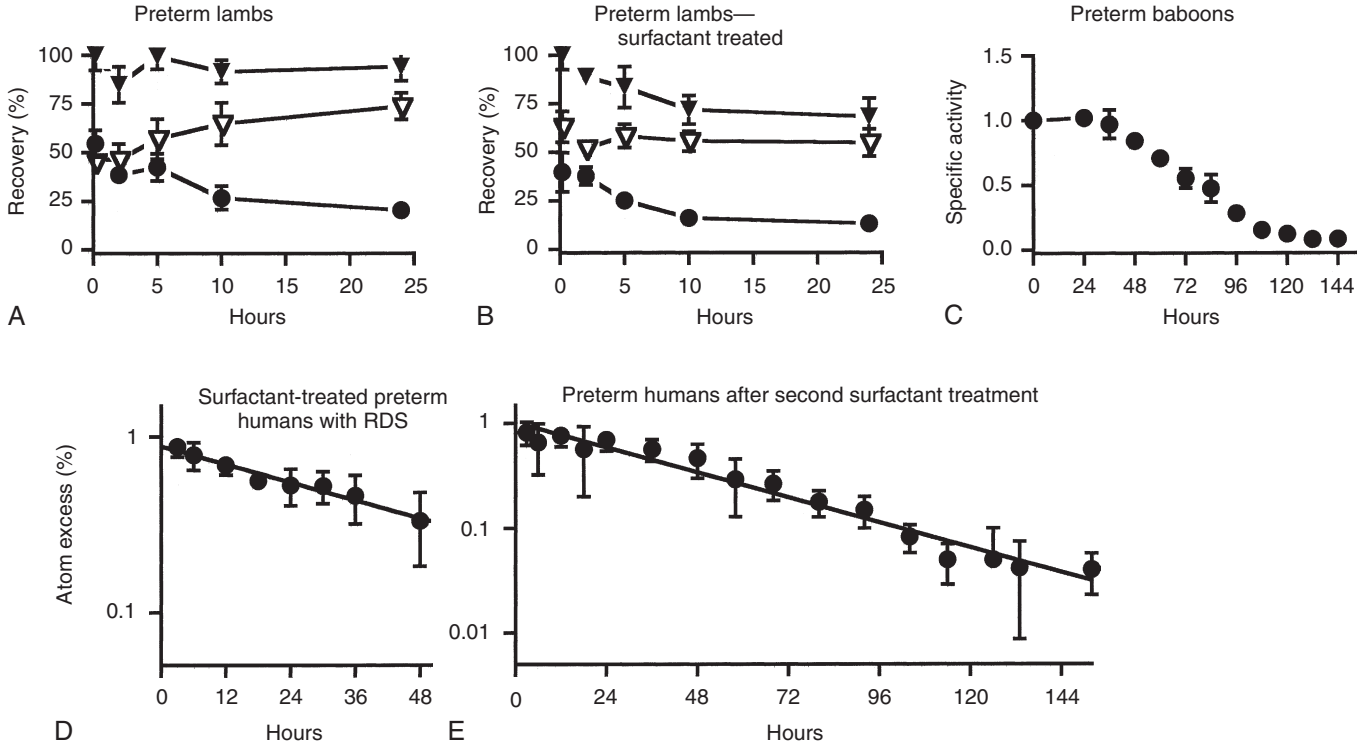

Figure 104-6 Loss of labeled phosphatidylcholine (PC) given into the airways of (A) preterm lambs not treated with surfactant, (B) preterm lambs treated with surfactant, (C) preterm surfactant-treated baboons, and (D and E) surfactant-treated preterm infants. All animals and infants were mechanically ventilated and had respiratory distress syndrome. A, The preterm lambs received a trace dose of natural sheep surfactant labeled with ^{3}H-dipalmitoylphosphatidylcholine. Recoveries in alveolar washes, lung tissue and the total lungs *(alveolar + tissue)* were measured 2 hours, 5 hours, 10 hours, and 24 hours after birth, **B,** Preterm lambs were treated at birth with 100 mg/kg of natural sheep surfactant, containing radiolabeled phosphatidylcholine and the lambs were ventilated for periods to 24 hours for measurements of the percent recovery of the phosphatidylcholine from the surfactant used for treatment. **C,** Curve for specific activity of phosphatidylcholine in airway samples of preterm baboons treated at birth with ^{14}C-dipalmitoylphosphatidylcholine–labeled surfactant.The specific activities were normalized to the values for the surfactant used to treat the baboons. **D,** Curve for atom percent excess in airway samples for ^{13}C-dipalmitoylphosphatidylcholine–labeled surfactant used to treat preterm ventilated infants with RDS.The atom percent excess in the initial surfactant dose given after delivery fell exponentially for 48 hours. **E,** A second dose given at approximately 2 days of age resulted in a similar curve. *(***A,** *Data from Jobe AH, Ikegami M, Seidner SR, et al: Surfactant phosphatidylcholine metabolism and surfactant function in preterm, ventilated lambs,* Am Rev Respir Dis *139:352, 1989.* **B,** *Data from Ikegami M, Jobe A, Yamada T, et al: Surfactant metabolism in surfactant-treated preterm ventilated lambs,* J Appl Physiol *67:429, 1989.* **C,** *Data from Seidner SR, Jobe AH, Coalson JJ, et al: Abnormal surfactant metabolism and function in preterm ventilated baboons,* Am J Respir Crit Care Med *158:1982, 1998.* **D** and **E,** *Data from Torresin M, Zimmermann LJ, Cogo PE, et al: Exogenous surfactant kinetics in infant respiratory distress syndrome: a novel method with stable isotopes,* Am J Respir Crit Care Med *161:1584, 2000.)*

the surfactant phospholipids are recycled back into the type II cells for resecretion.[53] In the only estimate available, ventilated preterm lambs with mild RDS had a turnover time for surfactant phosphatidylcholine of approximately 13 hours.[49] These animals had no measurable surfactant catabolism, indicating efficient recycling.

Measurements of surfactant clearance and biological half-life in animals were estimated from the amount of labeled surfactant remained in the lung tissue and in the airspace after an interval of time. The only practical measurement in the human is to give a trace or treatment dose of surfactant containing a stable isotope and to follow the change in concentration of the label in the surfactant sampled by aspiration of the airspaces. This measurement gives an integrated assessment of the mixing of the exogenous label with the endogenous airspace surfactant and tissue pools of surfactant. A decrease in the concentration of the label in the airway sample represents dilution of the label with surfactant from the lung, but it does not necessarily measure catabolism. Such measurements have been made in surfactant-treated preterm ventilated baboons and infants with RDS[30,38] (see Figure 104-6). In baboons the concentration of labeled lipid (specific activity) did not change for approximately 24 hours, indicating that little endogenous surfactant was present. However, independent information from preterm lambs and baboons indicate that only approximately 20% of the surfactant would have been in the air spaces at 24 hours, and 25% of the surfactant would have been lost from the lung compartment.[49,50] Subsequently the specific activity decreased exponentially, yielding a biological half-life of approximately 30 hours. The biological half-life values for infants with RDS measured with ^{13}C-dipalmitoylphosphatidylcholine were 34 ± 9 hours after surfactant treatment at a mean of 4.6 hours of age and were similar after a second dose of surfactant given at a mean age of 37 hours. The consistency of the indirect measurements in humans and the animals indicates that surfactant catabolism is slow in the preterm with RDS. The treatment dose of surfactant does not remain in the airspace but becomes part of the overall

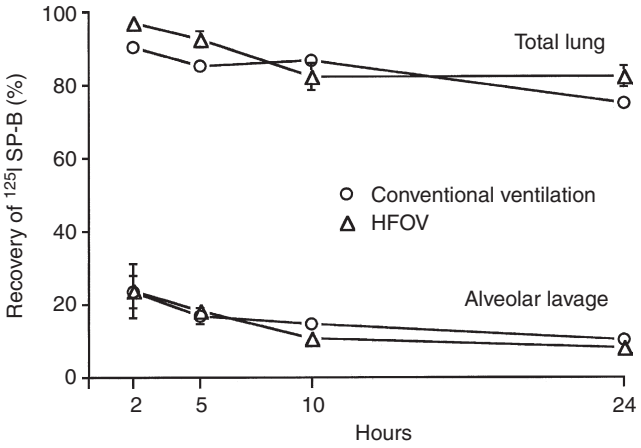

Figure 104-7 Recoveries of ^{125}I-labeled SP-B from the alveolar lavages and total lungs *(alveolar + tissue)* of preterm surfactant treated and ventilated lambs. The lambs were conventionally ventilated or ventilated with high frequency oscillatory ventilation *(HFOV).* Although loss of SP-B from the lungs was minimal, the amount of SP-B recovered by alveolar lavage was low. *(Data from Ikegami M, Wada K, Emerson GA, et al: Effects of ventilation style on surfactant metabolism and treatment response in preterm lambs,* Am J Respir Crit Care Med *157:638, 1998.)*

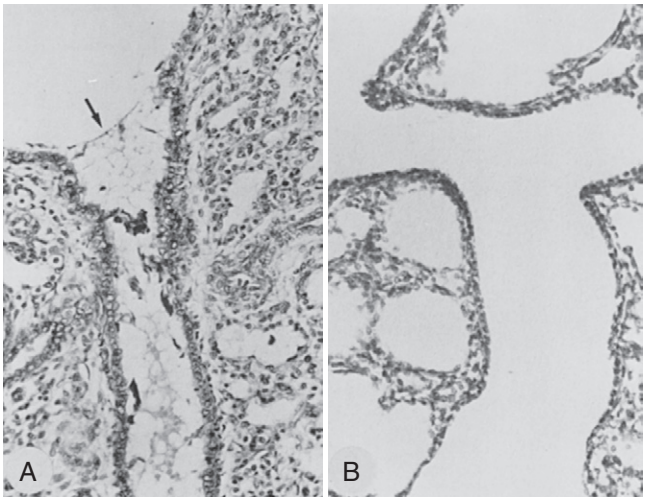

Figure 104-8 Bronchiolar-epithelial injury. A, Lungs from preterm ventilated rabbits had fluid-filled airways with epithelial tears in the absence of surfactant treatment. **B,** With surfactant treatments, the bronchiolar epithelium remained intact, and fluid was cleared from the airways and alveoli. *(From Lachmann B, Berggren P, Curstedt T, et al: Combined effects of surfactant substitution and prolongation of inspiration phase in artificially ventilated premature newborn rabbits,* Pediatr Res *16:921, 1982.)*

metabolic pool of surfactant. Measurements with stable isotopes in preterm infants also indicate that surfactant catabolism is increased and recycling efficiency is decreased with lung injury and with the development of BPD.[54,55]

The surfactant proteins SP-A, SP-B, and SP-C are cleared from the airspaces and the lung compartment of adult animals in parallel with the surfactant lipids.[13] The proteins are recycled with an efficiency slightly lower than the lipids, and degradation of SP-A occurs approximately equally in macrophages and type II cells.[10] The preterm ventilated lamb lung clears SP-A from the airspaces more rapidly than the lipids.[56] The lipophilic proteins SP-B and SP-C are cleared from the airspaces and from the lung compartment similar to saturated phosphatidylcholine in ventilated preterm lamb lungs[37,52] (Figure 104-7). SP-B clearance is similar in lambs ventilated with a conventional style of ventilation or with high frequency oscillatory ventilation. In the only measurement in humans, SP-B secretion paralleled and clearance was somewhat faster than saturated phosphatidylcholine.[57]

Lung Injury With Mechanical Ventilation

The lungs of infants who died from RDS have alveolar atelectasis, alveolar and interstitial edema, and hyaline membranes, primarily in distorted small airways. Hyaline membranes are a coagulum of cell debris, surfactant, and serum proteins that result from epithelial injury and large amounts of soluble and insoluble proteins in the air spaces. The earliest anatomic lesion identified in the lungs of infants who died of RDS shortly after birth was epithelial disruption in the small airways.[58] In preterm surfactant-deficient rabbits, bronchiolar epithelial injury developed within minutes of delivery, and ventilation and this injury was prevented with surfactant treatment[59] (Figure 104-8). The epithelial damage occurs because the small airways of the immature lung are compliant and distort during the ventilation. Lung fluid clearance is not complete and small airways are fluid filled at end expiration. Ventilation requires high peak pressures for the noncompliant lung to achieve relatively normal tidal volumes and carbon dioxide removal.

The ventilated preterm lung has both endothelial and epithelial abnormalities that lead to proteinaceous pulmonary edema after delivery and ventilation.[60] In preterm lambs ventilated for the first 3 hours of life, 11.5% per hour of the labeled albumin mixed with the fetal lung fluid at birth left the lung, and 1.7% per hour of the labeled albumin given intravascularly at birth was recovered from the air spaces, demonstrating the bidirectional movement of albumin across an injured alveolar epithelium.[61] The protein in the alveolar washes increased more than four-fold, indicating that the net protein movement was from the intravascular compartment to the air spaces. The rate of protein accumulation in the air spaces was striking in preterm ventilated rabbits. Approximately 2% to 3% of the intravascularly injected and labeled albumin was recovered from the air spaces within 20 minutes of birth. The leakage was not homogeneous.[62] Leakage involved an increasing number of saccules with time and appeared to occur directly into the alveoli rather than at the bronchiolar level.

Lung gas volumes of infants with RDS can be low because the lung has not yet developed sufficiently to hold much gas or because distal air spaces are uninflated. Another cause of the volume loss in the lungs of infants with RDS is alveolar edema. After 3 hours of ventilation, the total lung capacity was 48 mL/kg in preterm monkeys without RDS and 19 mL/kg for monkeys with RDS.[63] The lungs were flash frozen and evaluated by light and scanning electron microscopy. The lungs of the animals with RDS showed overexpansion of the distal airways and underexpanded and fluid-filled alveolar spaces (Figure 104-9). As seen by scanning electron microscopy, the alveoli of the animals with RDS were filled with proteinaceous liquid, and the interstitium was swollen by edema fluid (Figure 104-10). The monkeys with RDS had alveolar and interstitial edema because of the combination of slow clearance of fetal lung fluid after birth and the entrance of proteinaceous edema into the air spaces.

Four clinical variables are important determinants of the amount of edema formation: gestational age, tidal volume, positive end-expiratory pressure, and surfactant treatment. In preterm animal models, the protein leaks from the vascular space to the alveolar space and from the alveolar space to the vascular space

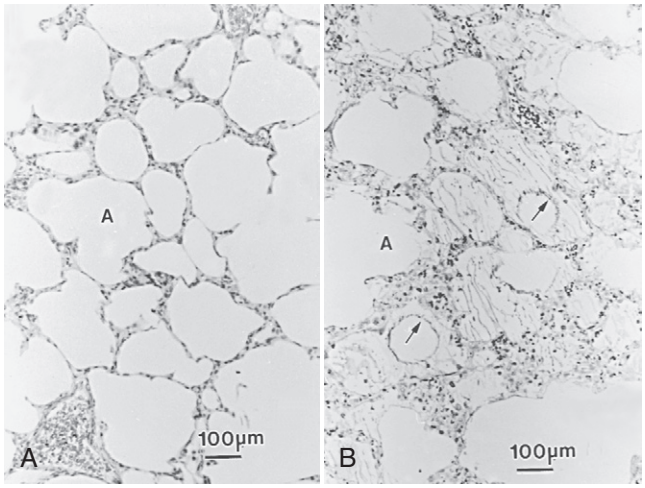

Figure 104-9 Alveolar filling with respiratory distress syndrome. **A,** Light micrograph of lung tissue from a preterm monkey lung without respiratory distress syndrome (RDS). The alveoli and alveolar ducts (indicated by *A*) are air-filled. **B,** In contrast, lung tissue from a monkey with RDS has some air-filled alveoli, and other alveoli are completely or partially filled with proteinaceous material. The *arrows* indicate partially filled alveoli. *(From Jackson JC, Truog WE, Standaert TA, et al: Effect of high-frequency ventilation on the development of alveolar edema in premature monkeys at risk for hyaline membrane disease,* Am Rev Respir Dis *143:865, 1991.)*

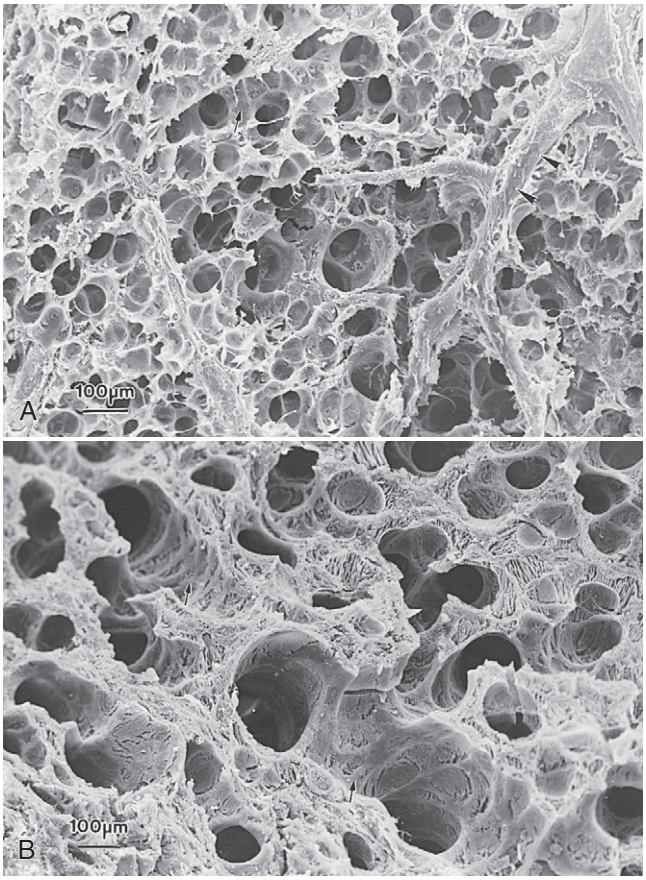

Figure 104-10 Scanning electron micrographs from **(A)** a preterm monkey without respiratory distress syndrome (RDS) and **(B)** a preterm monkey at the same gestational age with RDS. The lung from the RDS animal has dilated alveolar ducts and interstitial and alveolar edema. *(From Jackson JC, Truog WE, Standaert TA, et al: Effect of high-frequency ventilation on the development of alveolar edema in premature monkeys at risk for hyaline membrane disease,* Am Rev Respir Dis *143:865, 1991.)*

increased as gestation decreased[64] (Figure 104-11). The pressure needed to achieve an adequate tidal volume and gas exchange decreased as gestational age increased. Therefore an explanation of the increased leak was the barotrauma caused by the ventilatory requirements needed to support the more immature lung. In the mature lung, pulmonary edema occurred after lung overdistention using high pressures (volutrauma). High pressures were not required to injure the immature surfactant-deficient lung because nonuniform inflation resulted in focal overdistention. Without surfactant treatment, pulmonary edema occurred with relatively low tidal volume ventilation.[51] The end-expiratory volume of the preterm lung also was an important injury variable[65] (Figure 104-12). Ventilation of preterm lambs with the same tidal volume resulted in different amounts of protein recovery from the airways depending on the positive end-expiratory pressure (PEEP) used to support end-expiratory lung volume.[66]

The severity of the surfactant deficiency also influenced the development of pulmonary edema. Surfactant-sufficient preterm lambs and goats did not lose large molecular weight substances from the air spaces, whereas surfactant-deficient animals did.[67] Treatment of premature lambs with surfactant decreased the protein leakage from the vascular space to the airspaces. Surfactant treatment also decreased the endothelial leak of plasma proteins. Surfactant protected the lung from injury caused by high tidal volumes that would otherwise injure the surfactant-deficient lung.[51] A major effect of surfactant is probably by the increased uniformity of lung expansion.[68]

SURFACTANT FUNCTION IN THE ALVEOLUS

Surfactant Forms

Surfactant is present in the alveolus in different structural forms that have different characteristics and functions.[7] After secretion the lamellar bodies unravel to form the elegant structure called *tubular myelin*. This lipoprotein array has SP-A at the corners of the lattice and requires at least SP-A, SP-B, and the phospholipids for its unique structure. Tubular myelin and other loose surfactant lipoprotein arrays in the hypophase generate the surface film within the alveolus and small airways. New surfactant enters the surface film and "used" surfactant leaves as small vesicles, which then are cleared from the air spaces. The major differences in composition between the surface-active tubular myelin and the biophysically inactive small vesicles are that the small forms contain little SP-A, SP-B, or SP-C.

Surfactant is secreted to yield an alveolar pool that is primarily lamellar bodies and tubular myelin. During neonatal transition to air breathing, the percent of surface-active forms falls as the small vesicular forms increase[69] (Figure 104-13). At steady state, approximately 50% of the surfactant in the air spaces is in a surface-active form, and 50% is in the inactive vesicular form. The total surfactant pool size is not equivalent to the amount of active surfactant. The maintenance of surfactant function depends on the preservation of the active forms of surfactant in the air space.

Surfactant Inactivation

Surfactant inactivation or inhibition is a complex concept because it is the integrated result of multiple factors that can alter the alveolar forms and biophysical properties of the surfactant

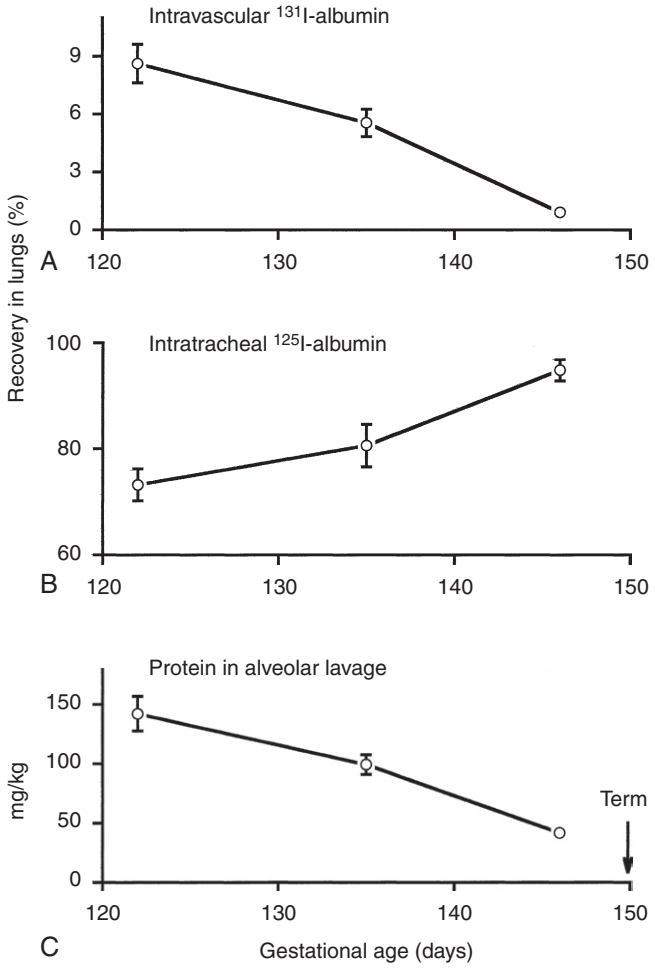

Figure 104-11 Effect of gestational age on the movement of labeled albumin and protein in and out of the air spaces of preterm lambs. Peak ventilatory pressures were held constant at the three gestational ages for 3 hours of ventilation. The more preterm lambs were treated with surfactant to achieve similar ventilatory pressures. **A,** ^{131}I-albumin was given into the vascular space, and the net recovery in alveolar washes and in the total lung (sum of parenchyma plus alveolar wash) decreased as gestational age increased toward term. **B,** ^{125}I-albumin was given into the airways at birth and the amount that was lost from the lungs decreased as gestation increased. **C,** The total amount of protein in alveolar washes decreased as gestation increased. *(Data from Jobe A, Jacobs H, Ikegami M, et al: Lung protein leaks in ventilated lambs: Effects of gestational age,* J Appl Physiol *58:1246, 1985.)*

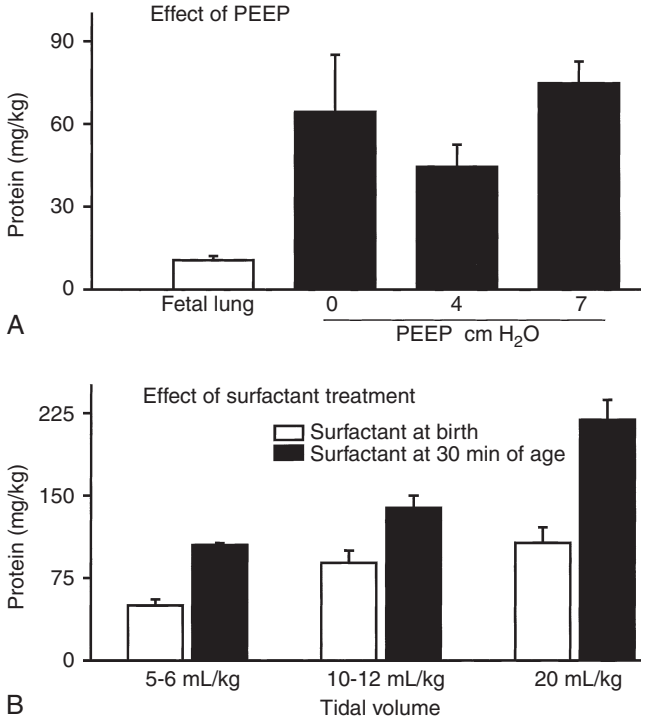

Figure 104-12 Effect of positive end-expiratory pressure (PEEP), tidal volumes, and surfactant on the amount of protein recovered in alveolar lavages of ventilated preterm lambs. **A,** Lambs were ventilated for 7 hours to similar P_{CO_2} values after surfactant treatment with PEEP values of 0, 4 or 7 cm H_2O. In comparison to the protein in the alveolar lavages of unventilated fetal animals, all ventilated animals had increased protein in alveolar lavages. However, the protein was higher with the use of 0 or 7 cm H_2O PEEP than 4 cm H_2O PEEP. **B,** Preterm lambs were ventilated for 30 minutes after birth with different tidal volumes and were then ventilated with a tidal volume of 10 mL/kg until the lambs were 6 hours old. Some lambs were treated with surfactant at birth and others were treated at 30 minutes of age. The high tidal volume of 20 mL/kg increased the protein recovered by alveolar lavage, and surfactant treatment decreased protein recovery at all tidal volumes. *(**A,** Data abstracted from Naik AS, Kallapur SG, Bachurski CJ, et al: Effects of ventilation with different positive end-expiratory pressures on cytokine expression in the preterm lamb lung,* Am J Respir Crit Care Med *164:494, 2001.* **B,** *Data abstracted from Wada K, Jobe AH, Ikegami M: Tidal volume effects on surfactant treatment responses with the initiation of ventilation in preterm lambs,* J Appl Physiol *83:1054, 1997.)*

in the air spaces[70] (Box 104-1). The net effects can be a decrease in the effective pool size, a degradation of the surface tension lowering properties of the surfactant or both. Injury to the alveolar epithelium and edema change the environment where surfactant acts. The mechanisms that contribute to surfactant inactivation will vary with the type of lung injury. The biophysically active surfactant pool can be depleted by an increased rate of conversion to the inactive vesicular forms. This conversion is accelerated by proteinaceous edema and inflammatory products, probably because proteases degrade surfactant proteins.[71] Ventilation styles that use large tidal volumes and no PEEP can deplete the active surfactant pool and high-frequency oscillatory ventilation can preserve the surfactant in adult animal models.[72] However, in surfactant-treated preterm lambs, ventilation with high-frequency oscillation did not have an advantage over conventional ventilation.[52] Meconium and bilirubin can accelerate the conversion to inactive surfactant forms, and surfactant with less surfactant protein will be inactivated more quickly.

Another mechanism of inactivation is the removal of the surfactant by sequestration into clots or hyaline membranes. Surfactant is a thromboplastin and will activate clotting, and in vitro the clot will capture most of the pulmonary surfactant that is in the plasma.[70] Although most soluble proteins can interfere with surface adsorption and film formation, the products of clot lysis are particularly inhibitory.[73] Albumin

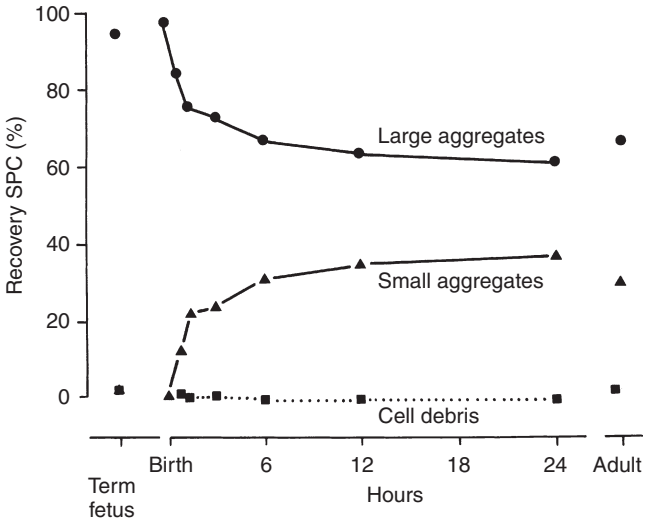

Figure 104-13 Changes in surfactant aggregate size distribution with time after birth. Surfactant suspensions recovered by alveolar wash from term rabbit fetuses and at various ages after birth were fractionated by centrifugation. The large aggregates were recovered by centrifugation, and the small aggregates were the fraction that did not pellet. The distribution of saturated phosphatidylcholine *(SPC)* in fractions is also indicated for alveolar washes from adult rabbits. *(Modified from Bruni R, Baritussio A, Quaglino D, et al: Postnatal transformations of alveolar surfactant in the rabbit: changes in pool size, pool morphology and isoforms of the 32-38 kDa apolipoprotein,* Biochim Biophys Acta *958:255, 1988.)*

BOX 104-1

Mechanisms of Surfactant Inactivation and Substances That Contribute to Inactivation

Form conversions in airspaces

Normal process of alveolar metabolism
Increased conversion with proteinaceous edema (proteases?)
Ventilation, meconium, decreased surfactant protein content

Removal of surfactant from alveolar pool

- Clots and hyaline membranes

Inhibitors of adsorption and film stabilization

- Proteins
  - Edema fluid
  - Plasma
  - Fibrinogen, monomers
  - Albumin
  - Laminin
  - Hemoglobin
- Lipids
  - Lysophosphatidylcholine
  - Cholesterol
  - Red cell membranes
- Other inactivators
  - Meconium
  - Bilirubin
  - Oxidizing agents
  - Amino acids

is not as inhibitory as fibrinogen, although it is the protein that is in the highest concentration in edema and inflammatory fluid. Hemoglobin and other protein products of lung injury also are inhibitors. The phenomenon of interference with film formation by soluble proteins is dependent on both the relative and absolute concentrations of the surfactant and the inhibiting proteins.[74] If surfactant concentrations are high, potent inhibitors at high concentration have little adverse effect when tested in vitro. However, when surfactant concentrations are low, low concentrations of inhibitors can severely degrade surfactant function. Surfactants that contain low amounts of surfactant proteins also are more sensitive to inactivation by soluble proteins.

Lung function will deteriorate when inactivation interferes with enough surfactant to alter the function of the surfactant at the air-fluid interface. Therefore inactivation can be a severe problem when the surfactant pool size is small, as in RDS. Airway samples taken at the time of intubation from infants with RDS had high minimal surface tensions[75] (Figure 104-14). Inhibition of surfactant function contributed to the problem because the airway samples contained surfactant with good function that could be isolated by centrifugation. The soluble proteins from these airway samples inhibited natural surfactant more than did proteins from airway samples from infants without RDS. The importance of surfactant inactivation can be demonstrated using a preterm ventilated lamb model of RDS[76] (Figure 104-15). Lambs at less than 125 days gestation (term is 150 days) have a surfactant pool of less than 1 mg/kg and thus are severely surfactant deficient. Ventilation for 30 minutes caused severe lung injury, and surfactant treatment then resulted in improved oxygenation and a fall in minimal surface tensions of the surfactant in airway samples. However, decreased oxygenation recurred because these animals had progressive lung injury. Most of these adverse effects were avoided by giving the surfactant before ventilating animals with low tidal volumes and a gentle style of ventilation.[51]

These inhibitory effects explain the progressive deterioration in lung function after birth in infants with severe RDS. The infants with RDS have low surfactant pool sizes and with ventilation they develop edema, inflammation, and lung injury. The combination of clot formation (hyaline membranes) and increased soluble inhibitory proteins deplete the functional surfactant pool, which results in progressive respiratory failure.

Inactivation phenomena depend on the type of surfactant being tested. The animal source surfactants in clinical use have in common organic solvent extraction steps that remove nonspecific contaminating proteins, SP-A and SP-D. SP-B and SP-C are retained in the surfactant extract in variable amounts with the phospholipids and neutral lipids. The only functional abnormality in surfactant from mice that lack SP-A is increased sensitivity to inhibition.[77] The addition of SP-A to an organic solvent–extracted surfactant made that surfactant less sensitive to inactivation by albumin and fibrinogen.[78] The potent inactivation of surfactant by fibrinogen was reversed by 0.5% SP-A. Addition of SP-A to a SP-B and SP-C–containing surfactant preserved the in vivo function of the surfactant in the presence of plasma when the mixture was used to treat preterm rabbits.[79,80] These observations may have direct clinical relevance because Hallman and colleagues[28] reported that soluble proteins in airway samples from infants with RDS were much more inhibitory to surfactant samples with low SP-A to saturated phosphatidylcholine ratios than were surfactant samples with higher ratios.

SP-B and SP-C also influence the sensitivity of lipid mixtures to inactivation.[81] Synthetic surfactants that lack these surfactant proteins are sensitive to inactivation by albumin or fibrinogen. Addition of native SP-B and SP-C improved resistance to inactivation.[82] Recombinant SP-C and lipids and mixtures of SP-B and

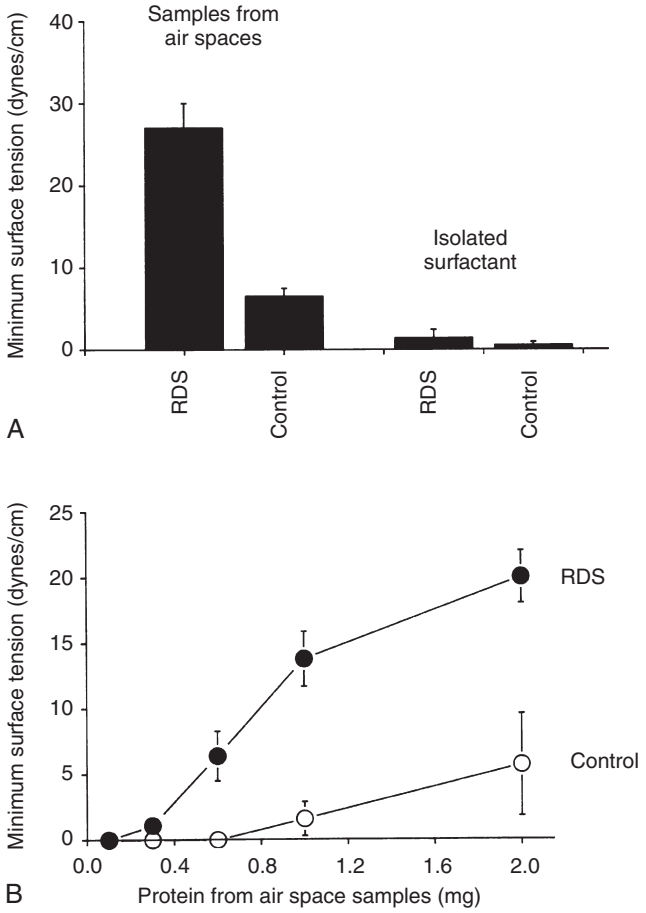

Figure 104-14 Minimum surface tensions of airway samples from (A) infants with respiratory distress syndrome (RDS) and control infants (B) and inhibition of surfactant by proteins. A, Samples from infants with RDS had high minimum surface tensions, whereas control samples had low minimum surface tensions. After isolation of surfactant by centrifugation, the surfactants from RDS and control infants had low minimum surface tensions. **B,** Supernatant protein fractions from airway samples were added to a constant amount of natural sheep surfactant. Protein fractions from infants with RDS had higher inhibitory activity than proteins from the control infants. *(From Ikegami M, Jacobs H, Jobe AH: Surfactant function in the respiratory distress syndrome,* J Pediatr *102:443, 1983.)*

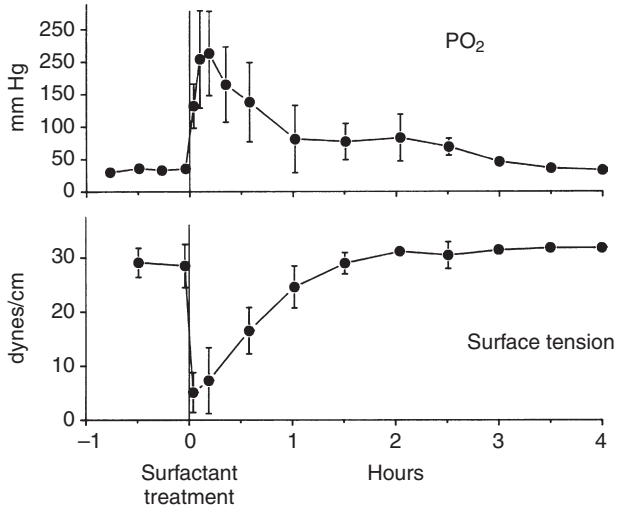

Figure 104-15 Surface tension and clinical response to surfactant treatment. Immature lambs had severe respiratory failure despite ventilatory support and 100% O_2. With surfactant treatment at approximately 45 minutes of age, PO_2 values increased and surface tensions of airway samples decreased. Subsequently the respiratory function of the lambs deteriorated as minimum surface tension values increased in the airway samples. *(From Ikegami M, Jobe A, Jacobs H, et al: A protein from airways of premature lambs that inhibits surfactant function,* J Appl Physiol *57:1134, 1984.)*

SP-C and lipids are less sensitive to protein inactivation than are lipid mixtures alone.

Quality of Surfactant in the Preterm Infant

The preterm infant with RDS has surfactant with properties that are inferior to surfactant from the mature lung, which further compounds the problem of a small pool size of surfactant.[15] Surfactant from the preterm with RDS has a different composition from surfactant from the mature or adult lung. The phosphatidylglycerol content is lower, the phosphatidylinositol content is higher, and the percent saturated phosphatidylcholine is lower. Surfactant from the preterm is less dense than surfactant from term or adult lungs because it contains less SP-A relative to saturated phosphatidylcholine. The alveolar pool from preterm lambs with RDS has a higher percentage of the surfactant in inactive forms than more mature lambs, and in vitro conversion rates from active to inactive forms are more rapid. The surfactant from the preterm also is more sensitive to inactivation in vitro by soluble proteins, most likely because of a lower surfactant protein content. Furthermore, when surfactants from preterm lambs or baboons were tested in preterm surfactant-deficient rabbit lungs, they were less effective at improving compliance than is surfactant from term animals.[15,38] Therefore surfactant from the preterm is intrinsically less effective and more susceptible to inactivation than is surfactant from the mature lung.

Surfactant Function With Surfactant Treatment

The surfactants used clinically are organic solvent extracts of alveolar washes or lung tissue. These surfactants contain no SP-A, the amount of SP-B and SP-C is variable, and processing and sterilization disrupt the lipoprotein structure. The clinical surfactants are more sensitive to inactivation by plasma proteins than is natural surfactant. However, surfactant can have improved function after exposure to the preterm lung. When surfactant is recovered by alveolar wash after surfactant treatment of preterm lambs with RDS, the surfactant has enhanced function.[83] This improved function can be demonstrated by comparing the surfactant used to treat the lambs with the surfactant recovered from the lambs for effects on surfactant-deficient rabbit lungs (Figure 104-16). The very preterm lung cannot improve the function of surfactant used for treatment, whereas the more mature lung can. The mechanism for the enhanced function probably is the mixing of the surfactant used for treatment with small amounts of endogenous surfactant lipids and proteins. Many hours after treatment, the enhanced function of surfactant can occur by recycling of components from the surfactant used for treatment through the type II cells. The sensitivity of the surfactants used clinically to inactivation also can be modulated after exposure to the preterm lung.[84] The surfactants become less susceptible to

inactivation if mixed with 5% or 10% by weight natural surfactant. Therefore small endogenous surfactant pools can interact with the large doses of surfactant used clinically to result in an improved surfactant. This activation phenomenon will not occur if the lung is injured.

Surfactant and Innate Host Defenses

The lung of the infant with RDS is not inflamed at birth unless chorioamnionitis and infection was present before birth. However, the initiation of ventilation in the preterm lung initiates inflammation.[65] The initiation of ventilation results in nonuniform inflation of the surfactant-deficient lung and stretch-mediated injury. If the tidal volume is high or the functional residual capacity is too high or too low, further lung injury will occur. The use of oxygen also may initiate an inflammatory response. Surfactant treatment decreases the severity of this initial inflammation, in part by its mechanical effects on the lungs to make lung inflation more uniform at lower pressures. However, surfactant also can have effects on the inflammatory response because of its multiple innate host defense functions.[85] The preterm lung is severely deficient in SP-A and SP-D. These proteins opsonize a variety of organisms and promote phagocytosis and suppress inflammation in the adult lung. Addition of recombinant SP-D to surfactant prevented the systemic shock caused by intratracheal endotoxin in preterm ventilated sheep.[86] The commercial surfactants do not contain SP-A or SP-D. The hydrophobic proteins SP-B and SP-C also have antiinflammatory properties and can mitigate oxidant-induced injury. The potential for surfactant components to modulate the inflammation that accompanies RDS have not been tested clinically.

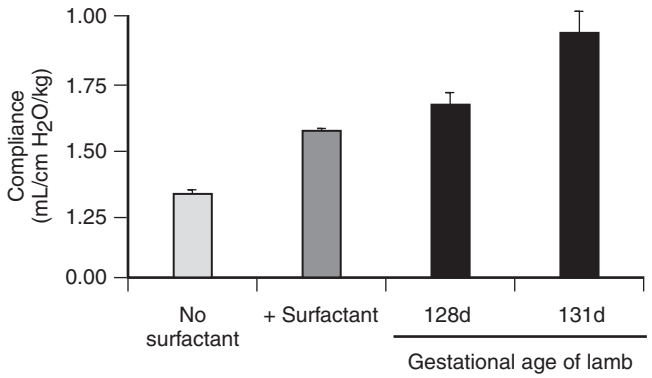

Figure 104-16 Surfactant function after surfactant treatment. Preterm lambs were treated with 100 mg/kg surfactant and ventilated for several hours. Surfactant was recovered by alveolar wash and used to treat preterm surfactant-deficient rabbits. The surfactant from the more mature lambs at 131 days gestation had enhanced function relative to the surfactant used to treat the lambs. *(Modified from Ikegami M, Ueda T, Absolom D, et al: Changes in exogenous surfactant in ventilated preterm lamb lungs,* Am Rev Respir Dis *148:837, 1993.)*

A Model for the Initial Events in Respiratory Distress Syndrome

The preterm infant born at less than 32 weeks gestation and disposed to develop RDS has a saccular lung and a small surfactant pool (Figure 104-17). Antenatal glucocorticoid treatment can increase the surfactant pool and increase the structural potential of the lung for gas exchange.[87] The techniques used for resuscitation and initiating ventilation will influence the initial epithelial and endothelial injury and subsequent ventilation may further aggravate the injury.[88] The small surfactant pool can be inhibited by the products of the injury and initial inflammation that enter the airspaces. Surfactant treatment can decrease the initial lung injury and can increase the surfactant pool size. The surfactant used for treatment becomes substrate for the recycling metabolic pathways. The initial severity of RDS then is a reflection of the reciprocal interactions of surfactant function altered by surfactant inhibition acting on the lung tissue. Surfactant function can be improved with surfactant treatment or by decreasing lung injury. Lung tissue function will be determined by the stage of development and the amount of lung injury. These effects occur at various degrees in different lung regions because the injury that occurs with RDS is not uniformly distributed throughout the lung.

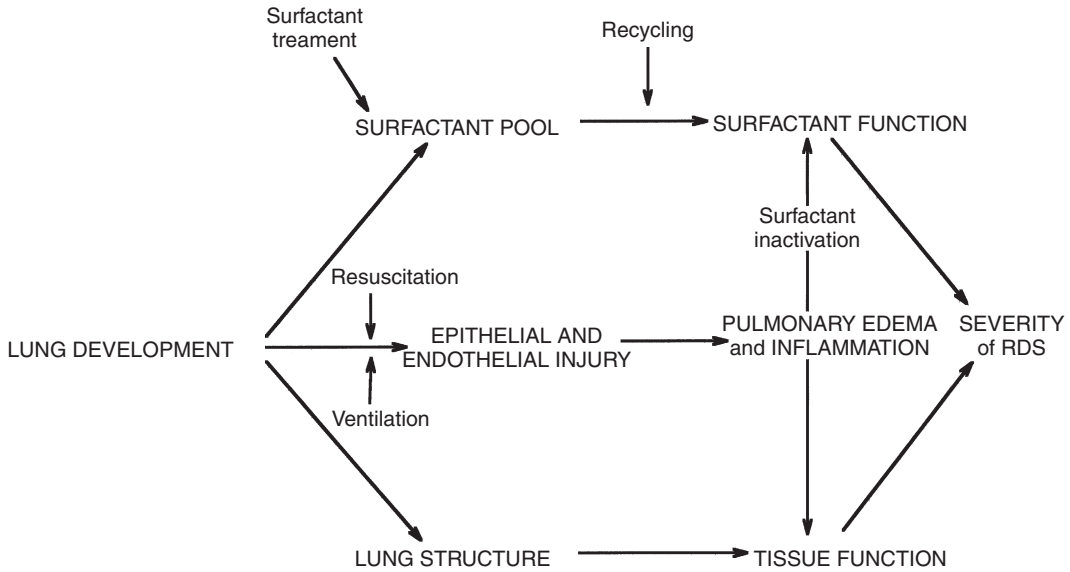

Figure 104-17 Flow diagram of the major variables influencing the clinical course of respiratory distress syndrome (RDS).

Hormonal Therapy for Prevention of Respiratory Distress Syndrome

Over the past 20 years, a multifaceted approach to the prevention of respiratory distress syndrome (RDS) of the newborn has evolved. This approach involves the antenatal prediction of fetal lung maturation by examination of the amniotic fluid, the use of hormones antenatally to accelerate fetal lung maturation, and postnatal surfactant replacement therapy. In this chapter, the clinical evidence that glucocorticoids accelerate fetal lung maturation and act synergistically with postnatal surfactant therapy to decrease the incidence of RDS and other neonatal disorders is reviewed. Guidelines for the use of prenatal glucocorticoid therapy are provided.

BIOLOGIC CONSIDERATIONS

A number of hormones have been shown to influence aspects of fetal lung maturation both in vivo and in vitro[1,2] (Box 105-1).[1,2] Glucocorticoids are the most important of the stimulatory agents; they increase synthesis of all components of surfactant and accelerate morphologic development. Endogenous fetal corticosteroids have a physiologic role in modulating the rate of lung development and likely cause precocious maturation under conditions of in utero stress. Corticoid levels increase in newborn infants who have respiratory disease or other illnesses, and this response may contribute to the resolution of RDS that normally occurs after a few days. Prenatal corticosteroid therapy for prevention of RDS achieves levels of circulating glucocorticoid activity comparable to those during the postnatal surge, and thus antenatal corticosteroid therapy is felt to mimic a physiologic stress response.[3] In the absence of endogenous fetal and maternal corticosteroids (as occurs in homozygous mice genetically engineered with a knockout of either the corticotropin-releasing hormone or glucocorticoid receptor), the lung is structurally and biochemically immature at birth, and the animals die of respiratory failure.[4,5] Effects in the developing lung represent one of many examples of the role of glucocorticoids in modulating tissue differentiation and helping to prepare the fetus for birth.

Glucocorticoids act by binding to specific receptors in lung cells. The receptor-glucocorticoid complex binds to regulatory elements in the promoter of target genes and increases (or in some cases decreases) synthesis of mRNA and protein.[6] Because effects are receptor mediated, responses occur at physiologic levels of glucocorticoid (e.g., 10 to 100 nM cortisol), and higher doses of steroid evoke little additional response. The peak fetal plasma concentration of glucocorticoid after maternal betamethasone treatment (12 mg) is estimated to result in 75% or greater occupancy of receptors.[3] From in vitro studies using both high-resolution gel electrophoresis and DNA microarray profiling of gene expression, it is estimated that 2% to 6% of the proteins in human fetal lung are regulated by glucocorticoids.[7] Glucocorticoids are known to induce the four surfactant-associated proteins, a number of lipogenic enzymes, ion and water transport proteins (Na^+, K^+-ATPase, Na^+ channel, aquaporins), elastin, and a limited number of other proteins; however, the majority of the glucocorticoid-responsive proteins of fetal lung have not been confirmed or characterized.[7,8]

BOX 105-1

Hormones That Influence Fetal Lung Maturation in Animal and Culture Models

Stimulation
- Glucocorticoids
- Cyclic adenosine monophosphate
- Thyroid hormones/thyrotropin-releasing hormone
- Epidermal growth factor
- Retinoic acid
- Bombesin-related peptides
- Parathyroid hormone-related peptide
- Lipopolysaccharide
- ? Estrogen

Inhibition
- Insulin/hyperglycemia/?butyrate
- Tumor-necrosis factor alpha
- Transforming growth factor-β
- Interleukin-1
- Phorbol esters
- Androgen

Although an increase in transcription of responsive genes in cultured lung occurs in 1 to 2 hours of corticosteroid exposure, accumulation of new proteins usually requires 12 to 24 hours. The earliest effect on pulmonary function in the fetal lamb occurred between 8 and 15 hours after treatment; optimal responses were observed at 48 hours and persisted for at least 7 days.[9] Thus a benefit of glucocorticoid administration may not be observable in those situations in which the infant is delivered shortly after therapy is initiated.[10,11] It is known that receptor-bound glucocorticoid is necessary for continuing hormone action[1,2] and that glucocorticoid action in vitro is often reversible on removal of hormone (e.g., induction of surfactant proteins in cultured lung and in fetal sheep).[12,13] Therefore some glucocorticoid responses may be of limited duration in utero. Clinically, reduction of RDS appears to diminish 7 to 10 days after hormone administration is completed.[11] For this reason, retreatment has been used for women with recurring premature labor, and, as will be discussed later, the efficacy and safety of this practice is currently being investigated.

Glucocorticoids also regulate gene expression by an indirect process termed transrepression in which the corticosteroid-receptor complex interacts with transcription factors such as activator protein-1 (jun/fos) and NFκB, regulators of cytokine production. This interaction blocks up-regulation of the cytokine/chemokine cascade in response to various stimuli and is the major mechanism for the antiinflammatory effects of glucocorticoids.[14] Possible involvement of the transrepression mechanism in glucocorticoid effects on fetal lung development are not known but are possible because several cytokines are known to inhibit surfactant production.

The physiologic role and mechanism of other hormones that stimulate lung development (see Box 105-1) have been less extensively studied. An increased endogenous level of the second messenger cyclic adenosine monophosphate stimulates type II cell differentiation and induces surfactant lipids and surfactant-associated proteins (SP)-A and SP-B in cultured fetal lung.[12] Some evidence suggests that treatment of fetal animals with terbutaline or other β-agonists, particularly in combination with glucocorticoid, enhances lung maturation. It is possible that cyclic adenosine monophosphate–mediated effects occur clinically after treatment with β-agonists, prostaglandins or their inhibitors, or agents that inhibit phosphodiesterases (e.g., xanthine derivatives), but possible clinical benefit or harm is not documented. Thyroid hormones stimulate surfactant lipid synthesis in cultured tissue and in fetal lambs, acting in a synergistic manner with glucocorticoids (and prolactin in vivo).[15-17] Nuclear receptors for triiodothyronine (T_3) are present in fetal lung cells, and the properties of thyroid hormone stimulatory effects (e.g., response with physiologic concentrations of hormone) are consistent with a receptor-mediated process.[16] Target proteins for thyroid hormones in fetal lung, except for one lipogenic enzyme (cholinephosphate cytidylyltransferase), are unknown. Clinically, injection of thyroid hormone into amniotic fluid has been reported to cause a slow increase in the lecithin/sphingomyelin ratio, but clinical benefit and safety have not been investigated.[17] Combined glucocorticoid and thyrotropin-releasing hormone (TRH) treatment has been investigated as a potentially useful clinical approach for prevention of newborn lung disease (see later discussion).

Several agents have an inhibitory effect on levels of surfactant components in vitro (see Box 105-1). Tumor necrosis factor-α, transforming growth factor β (TGF-β) and activators of protein kinase C such as phorbol esters and lipopolysaccharide (endotoxin) are of particular interest because they are involved in the etiology of lung inflammation and infection. A negative effect of these agents on levels of SP-A and SP-B has been observed in cultured lung, even when there is combined treatment with glucocorticoids. In cultured fetal lung cells, treatment with glucocorticoid reduces levels of endogenous TGF-β, which likely contributes to type II cell differentiation by relieving suppressed expression of a subset of regulated genes.[18] Thus antenatal glucocorticoid treatment may act both directly (gene induction) and indirectly (up-regulation of TGF-β–suppressed genes) to accelerate lung maturation.

Dysfunction of surfactant occurs in both infants and adults with specific lung diseases. Ventilated premature infants experience episodes of respiratory decompensations that are associated with dysfunctional surfactant and low surfactant content of SP-B.[19] Down-regulation of SP-B may occur secondarily to infection and inflammation with increased production of cytokines. It is possible that down-regulation of surfactant components contributes to the pathobiology of newborn lung diseases such as meconium aspiration, bronchopulmonary dysplasia, and pneumonia.

CLINICAL EVIDENCE FOR THE EFFECTIVENESS OF ANTENATAL GLUCOCORTICOID THERAPY

The effects of glucocorticoids on lung maturation and perinatal outcome have been extensively studied. Liggins and Howie[20] reported in 1972 that a significant reduction in the incidence of RDS and mortality in premature infants occurred after maternal treatment with glucocorticoids. However, despite the positive effects noted in this and many other studies, some obstetricians continued to question the effectiveness and safety of the use of prenatal glucocorticoids for the prevention of RDS. In 1993 it was estimated that only 15% of preterm infants between 500- and 1500-g birth weight were receiving prenatal glucocorticoid therapy in the United States.[21] In 1994, the National Institutes of Health (NIH) convened a Consensus Conference[23] to examine the data and make recommendations relating to glucocorticoid therapy, fetal maturation, and perinatal outcome. The clinical information used was primarily the comprehensive meta-analysis of published randomized trials of Crowley[22,23] and several observational databases. The latter consisted of treatment and outcome information that was prospectively collected from five registries, including multicenter surfactant trials, and involved more than 30,000 low-birth-weight infants. The major findings of these two sources of information will be reviewed

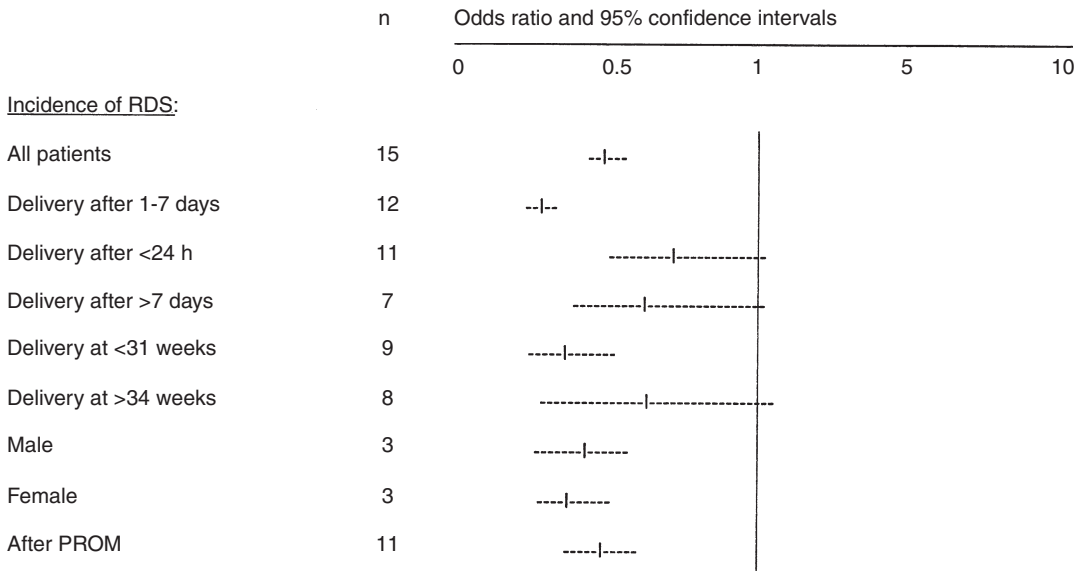

Figure 105-1 Meta-analysis of randomized clinical trials of antenatal glucocorticoid therapy for prevention of respiratory distress syndrome. A significant reduction in the incidence of respiratory distress syndrome is indicated if the mean and 95% confidence interval are less than 1.0 (*n* = number of trials evaluated). *(Data from Crowley P: Promoting pulmonary maturity. In Chalmers IM, Keirse MJNC, editors:* Effective Care in Pregnancy, *vol 1. Oxford, UK, 1989, Oxford University Press, p 746.)*

here, as well as the recommendations of this NIH Consensus Conference.

Impact of Antenatal Glucocorticoids on the Incidence of Respiratory Distress Syndrome

The meta-analysis[22] (Figure 105-1) revealed that glucocorticoid therapy significantly reduced the overall incidence of RDS by approximately 50%. The effect was greatest in those infants who were delivered from 1 to 7 days after the initiation of maternal treatment. A trend toward decreased RDS was observed in babies born less than 24 hours or more than 7 days after the initiation of therapy, but the differences were not statistically significant.

Steroids were effective over a wide gestational age range. A reduction in the incidence of RDS in babies born before 31 weeks of gestation was significant. Babies born after 34 weeks are a heterogeneous group and some have lungs that are almost mature. A trend toward decreased RDS was seen in this age-group. The effectiveness of glucocorticoids in infants born before 28 weeks gestation has been a source of controversy. Although it has been questioned whether the incidence of RDS is decreased,[24] benefit is seen in terms of diminished severity of RDS, decreased mortality, and a lower incidence of intraventricular hemorrhage (IVH).

The U.S. Collaborative Antenatal Steroid Therapy trial[10] found that male fetuses were not responsive to glucocorticoid therapy. However, these data were not appropriately analyzed and this finding has not been replicated in other studies, and the meta-analysis reveals that decrease in RDS is significant in both male and female infants.

Effect of Antenatal Glucocorticoids on Complications Associated With Premature Birth

According to the meta-analysis, as is shown in Figure 105-2, antenatal glucocorticoid therapy results in decreased early neonatal mortality as well as a reduction in two major complications of prematurity, IVH, and necrotizing enterocolitis. The observational database did not support the decrease in necrotizing enterocolitis, but it did find a decreased incidence of IVH, even in infants born less than 24 hours after the first dose of steroid. The decrease in these two complications of prematurity may relate to the fact that steroid-treated babies have a more benign clinical course, but specific maturational effects of glucocorticoids on the gut and brain may also be factors. The intestine, like the lung, arises from the embryonic endodermal tube, and in animals glucocorticoids induce specific enzymes in the developing gut and cause precocious maturation of closure (restricted passage of intact proteins).[3]

When glucocorticoid therapy for the prevention of RDS was first proposed, major concerns arose regarding potential toxicity, particularly to the developing brain. Studies with newborn rats, whose brains are at approximately the same stage of development as a third trimester human, had shown that administration of large doses of glucocorticoid results in a reduction in numbers of brain cells, particularly in the cerebellum, where cells are undergoing rapid mitosis. The doses and relative exposure time in these animal studies, however, far exceeded those used in the clinical trials. Long-term follow-up studies of infants exposed to antenatal glucocorticoids have revealed no adverse effects on developmental outcome. At 12 years of age, no deficits in motor skills, language, cognition, memory, or scholastic achievement were observed, despite greater survival of smaller infants in the steroid-treated group.[25,26] In fact, meta-analysis of three published studies reveals a trend toward decreased neurologic abnormalities at follow-up. There also appear to be no long-term adverse effects on physical growth or health. It should be noted that these studies did not involve repeated weekly courses of glucocorticoids. As will be discussed later, concerns exist relating to fetal toxicity when repeated courses of steroids are administered to pregnant women.

Effects of Antenatal Glucocorticoids on Neonatal and Maternal Infection

One of the concerns regarding glucocorticoid therapy has been its impact on infection. Meta-analysis indicates that a small increase in maternal infection (odds ratio 1.15) and a slight reduction in neonatal infection (odds ratio 0.80) occurs, but

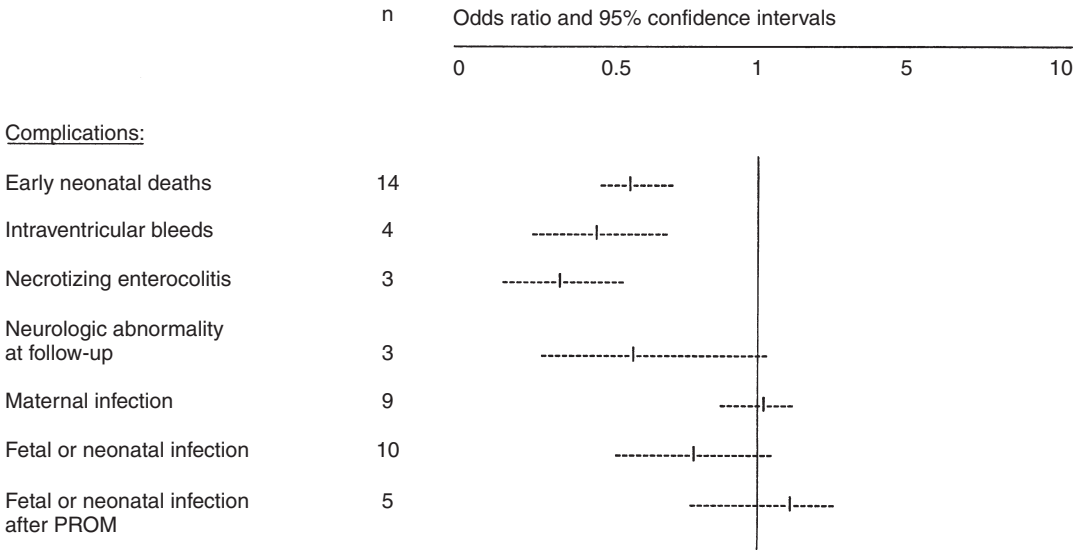

Figure 105-2 Meta-analysis of clinical trials of prenatal glucocorticoids: effects on perinatal complications. Therapy is associated with a significant reduction in deaths, intraventricular hemorrhage, and necrotizing enterocolitis (n = number of trials evaluated). *(Data from Crowley P: Promoting pulmonary maturity. In Chalmers IM, Keirse MJNC, editors:* Effective Care in Pregnancy, *vol 1. Oxford, UK, 1989, Oxford University Press, p 746.)*

neither of these effects is statistically significant. When steroids are administered in the presence of premature rupture of the membranes (PROM), a trend toward an increase in fetal and neonatal infection (odds ratio 1.46) is seen, but this effect is also not statistically significant.

Effects of Antenatal Glucocorticoids in the Presence of Premature Rupture of the Membranes

Although the risk of fetal or neonatal infection may be somewhat increased, analysis of the randomized trials reveals that glucocorticoids decrease the incidence of RDS in the presence of PROM. Evidence from the observational database indicates that glucocorticoid therapy in patients with PROM results in a decrease in IVH and overall mortality. Thus the overall maternal-infant benefit/risk ratio for steroid therapy is also favorable with PROM.

Use of Glucocorticoids in Complicated Pregnancies

Liggins and Howie[22] reported that fetal mortality increased when steroids were administered to women with hypertension and proteinuria. However, this observation was not confirmed in two subsequent trials, and apparently the result arose from mismatched groups in terms of severity of preeclampsia.[10,27]

Glucocorticoid administration may complicate the management of diabetes in pregnancy and the decision to use steroids in this situation is a matter of clinical judgment.

Little information is available on the effectiveness of glucocorticoid therapy in pregnancies complicated by multiple gestation, intrauterine growth restriction, or hydrops fetalis. In these circumstances, fetuses should probably receive routine steroid therapy.

Recommendations of the 1994 NIH Consensus Conference

Antenatal glucocorticoid therapy clearly has several significant benefits for the premature infant. These are summarized in Box 105-2. The recommendations of the 1994 NIH Consensus Conference are listed in Box 105-3. These recommendations were drafted after review and discussion of the relevant data and provide authoritative guidelines. With the publication and dissemination of these guidelines, there appears to be no reason to withhold steroid therapy in patients who meet the recommended criteria.

BOX 105-2

Benefits of Antenatal Glucocorticoid Therapy

From meta-analysis of published studies
- Decreased respiratory distress syndrome
- Decreased incidence of intraventricular hemorrhage
- Decreased incidence of necrotizing enterocolitis
- Decreased mortality
- A trend toward better neurologic and intellectual function at follow-up

From observational database
- Decreased respiratory distress syndrome
- Decreased incidence of intraventricular hemorrhage, even if delivery occurs less than 24 hours after initiation of therapy
- Decreased mortality

From individual studies
- Decreased incidence of clinically significant patent ductus arteriosus
- Decreased duration (and cost) of hospitalization

Since the 1994 NIH Consensus Conference, attention has focused on the question of dexamethasone-specific toxicity, the impact of repeated courses of antenatal glucocorticoids, and the effects of combinations of hormones. A review of these topics follows.

REPEATED COURSES OF ANTENATAL GLUCOCORTICOIDS

Both experimental[12] and clinical studies (see Figure 105-1) suggest that some of the effects of antenatal glucocorticoids on fetal lung development diminish after approximately a week.

BOX 105-3

Summary of Recommendations of the National Institutes of Health (NIH) Consensus Development Conference: The Effect of Corticosteroids for Fetal Maturation on Perinatal Outcomes

- All fetuses between 24 and 34 weeks gestation that are at risk for preterm delivery are candidates for treatment.
- The decision should not be altered by fetal race, sex, or availability of surfactant therapy.
- Prenatal corticosteroids should be given unless immediate delivery is anticipated.
- Tocolytic therapy is not a contraindication.
- *In the absence of clinical chorioamnionitis,* antenatal corticosteroids are recommended in patients with premature rupture of membranes at less than 32 weeks gestation.
- Treatment is recommended in complicated pregnancies, unless evidence suggests that it will have an adverse effect on the mother.

NOTE: Although the Consensus Conference recommended either dexamethasone or betamethasone, the currently recommended regimen is betamethasone, 12 mg q24h × 2 doses intramuscularly.

The question has arisen of what to do if a pregnant mother is given a course of steroids because she is at risk for premature delivery, but the pregnancy then continues without delivery having occurred. It was the practice of some obstetricians to give repeated, even weekly, courses of steroid in this situation until the pregnancy progressed beyond the stage where the infant would have been born prematurely.

Studies in a variety of animal species have shown that multiple courses of antenatal glucocorticoids do result in greater enhancement of lung maturation than a single course, but that associated toxicity, particularly growth restriction, is a risk.[28] A retrospective analysis of the data derived from a multicenter randomized clinical trial of antenatal TRH plus glucocorticoid compared with glucocorticoid alone (both dexamethasone and betamethasone were used)[29,30] revealed that compared with infants who received one course of glucocorticoid, those who were exposed to two courses had lower birth weights, and administration of three courses was associated with increased risk for death and evidence of adrenal suppression. Furthermore, administration of two or three courses did not result in improved outcome in terms of RDS, IVH, or chronic lung disease.

The NIH Consensus Conference in 2000[31] revisited the issue of antenatal steroids and recommended that repeat courses should not be used routinely. The Cochrane review of this subject, which was updated in 2003,[32] was limited by the fact that only three studies were included and many of the analyses involved only one or two trials. This review reported that no decrease in the incidence of RDS was seen after multiple courses of glucocorticoids compared with a single course. One study found that the severity of lung disease was less in the repeated course group and in two studies fewer infants in the repeated dose group received surfactant.

Two larger, multicenter, randomized clinical trials have now examined this issue. The National Institute of Child Health and Human Development (NICHD) Maternal Fetal Units Network enrolled pregnant women with intact membranes between 23 weeks and 32 weeks gestation who had received one course of glucocorticoid.[33] They were then randomized to weekly courses of betamethasone or placebo. The primary end point was the presence of any of the following neonatal conditions: severe RDS, IVH of grade III or IV, periventricular leukomalacia, chronic lung disease, or stillbirth or neonatal death. The study was terminated early because of a tendency to decreased birth weight in the repeat steroid group without a significant reduction in the primary end point. However, decreases were seen in specific neonatal outcomes, including the number of infants who required surfactant therapy, ventilator support, and continuous positive airway pressure (CPAP), and in the incidence of pneumothoraces. The authors commented that a major problem with repeated dose therapy is that the majority (72%) of women who received repeated doses of steroids ended up delivering after 32 weeks gestation, so their newborn infants were not at high risk for RDS. However, a benefit was seen for infants delivering at less than 32 weeks gestation.

The Australasian Collaborative Trial of Repeat Doses of Steroids[34] reported a more positive short-term outcome in infants exposed to repeated courses of antenatal betamethasone. In this trial, women who remained at risk for preterm birth at less than 32 weeks gestation were randomized to placebo or weekly courses of betamethasone. The repeat doses group demonstrated a significant decrease in the primary endpoints, RDS, severe lung disease, need for oxygen therapy, and duration of mechanical ventilation. Mean weight, length, and head circumference at birth and discharge did not differ between the groups. (Z-scores for weight and head circumference at birth, but not at discharge, were lower in the repeated treatment group.) Long-term follow-up of these infants has not been reported yet.

Given the current state of knowledge in this area, we recommend that an initial course of antenatal betamethasone should be administered if concern exists that premature delivery will occur. If the pregnancy continues, one additional course of betamethasone may be considered if threatened premature delivery recurs 10 or more days later.

DEXAMETHASONE-SPECIFIC TOXICITY

In one study antenatal dexamethasone therapy was recently found to result in a higher incidence of periventricular leukomalacia (PVL) than antenatal betamethasone. In a retrospective analysis, Baud and colleagues[35] examined the effects of dexamethasone, betamethasone, or no antenatal steroid therapy on the incidence of RDS, IVH, PVL, and necrotizing enterocolitis. Administration of either of the two glucocorticoids resulted in a decrease in all these complications of prematurity, except PVL. Whereas betamethasone-treated infants had less PVL than non–steroid-treated infants, those that had been exposed to antenatal dexamethasone had more. It was suggested that the sulfites in dexamethasone were responsible for this effect and in vitro studies support this possibility.[36] However, sulfites are present in many medications that are routinely given to neonates. An alternative explanation relates to the method of administration of these two glucocorticoids. Dexamethasone is usually given intravenously, whereas betamethasone is administered intramuscularly as a slowly released mixture of phosphate and acetate forms. The higher peak blood levels of dexamethasone may be responsible for the toxicity, perhaps mediated by a mechanism that does not involve receptor binding to DNA.[37]

The apparent increased central nervous system-related risk associated with antenatal dexamethasone therapy is also supported by recent follow-up observations related to early postnatal use of this corticosteroid. Treatment of infants with dexamethasone to prevent bronchopulmonary dysplasia in the first few days after birth, but not after 7 days, is associated with increased cerebral palsy and other abnormal neuromotor

outcomes. This adverse effect of postnatal dexamethasone may reflect the relatively high doses used, intravenous administration, delayed clearance due to liver immaturity, and prolonged treatment regimens.

SYNERGISM BETWEEN ANTENATAL GLUCOCORTICOID AND POSTNATAL SURFACTANT THERAPIES

Several animal studies have demonstrated the benefit of antenatal glucocorticoid combined with postnatal surfactant therapy. Work by Fiascone and colleagues[38] and Ikegami and colleagues,[39] in which prematurely delivered fetal rabbits were ventilated and lung compliance was measured, found that both prenatal glucocorticoid treatment and postnatal natural surfactant treatment resulted in a significant improvement in lung compliance. However, the combination of steroid and surfactant produced a greater effect than did either therapy alone. These results are consistent with the observations that glucocorticoids increase nonsurfactant components of lung compliance, such as tissue elasticity, in addition to enhancing surfactant production. Glucocorticoids also accelerate the development of lung parenchymal structure, decreasing mesenchymal volume and septal thickness, and these changes per se can increase tissue compliance.[40] It is also possible that the enhanced alveolarization resulting from glucocorticoid treatment provides a better substrate for surfactant therapy.

Clinical data also support the positive interaction between antenatal glucocorticoid and postnatal surfactant therapy. Kari and associates[41] randomized patients with threatened preterm delivery at less than 32 weeks gestation to antenatal glucocorticoid therapy or placebo. All babies born before 33 weeks who required ventilation with greater than 40% oxygen also received postnatal surfactant. As listed in Table 105-1, the infants who were exposed to antenatal steroids had significantly less respiratory disease as well as a lower incidence of IVH and PVL.

COMBINED HORMONAL TREATMENT FOR THE PREVENTION OF RESPIRATORY DISTRESS SYNDROME

Even with optimal glucocorticoid treatment some infants develop RDS. In an effort to further enhance lung maturation, the effects of combinations of hormones have been studied in experimental models.[15-17] Evidence suggests that thyroid hormones stimulate lung development and may act synergistically with glucocorticoid. Triiodothyronine (T_3) is the most active thyroid hormone in terms of surfactant phospholipid production, but it does not cross the placenta well, whereas TRH administered to the mother is transferred to the fetus and increases TSH, T_3, and thyroxine (T_4) levels in cord blood.[42,43] The combination of glucocorticoid and TRH has been evaluated in a number of randomized clinical trials.

A series of trials was completed before the widespread availability of surfactant. These studies generally found that there was a decreased incidence of RDS, chronic lung disease, and mortality in babies who delivered from 1 to 10 days after the initiation of maternal therapy with TRH and glucocorticoid compared with glucocorticoid alone.[44] However, three large trials, which also incorporated postnatal surfactant therapy, were subsequently published.[45-46] These trials, which included an "intention to treat" analysis, indicated that no additional benefit was observed when TRH was added to glucocorticoid therapy. Collectively these findings suggest that a combination of prenatal glucocorticoid and postnatal surfactant is an effective therapy, which is not enhanced by the addition of TRH.[47]

TABLE 105-1

Prenatal Glucocorticoid Effects in the Era of Postnatal Surfactant Therapy

	Dexamethasone (n = 41)	Placebo (n = 38)
Gestational age (wk)	29.9 + 2.0	29.8 + 2.3
Respiratory distress syndrome, incidence	44%	79%*
Received surfactant	22%	53%*
Days ventilated	2.0	5.3*
Days in oxygen	2.0	7.0*
Intraventricular hemorrhage or periventricular leukomalacia	10%	46%*

*$p < .05$.

Infants born 1 to 14 days after glucocorticoid treatment were analyzed.

CONCLUSION

Development of the fetal lung is influenced by a number of hormones and agents that either accelerate or inhibit differentiation. Endogenous and administered corticosteroids modulate the developmental process, acting through glucocorticoid receptors to induce a network of gene products involved in cellular differentiation and production of surfactant. Animal and clinical data demonstrate that the advent of surfactant therapy has further enhanced the benefits of antenatal glucocorticoid administration for lung maturation. Optimal management of premature infants currently consists of prenatal hormone administration followed by postnatal surfactant therapy, if indicated. Betamethasone is the glucocorticoid of choice. The 2000 NIH Consensus Conference[33] recommended that repeat courses should not be used routinely. This approach has had a significant impact on the prevention or amelioration of RDS and other major complications in prematurely born infants.

Surfactant Treatment

A brief history of the development of surfactant for the treatment of respiratory distress syndrome (RDS) provides perspective on how this major therapeutic advance occurred. In 1959, not long after surfactant had been identified as critical to maintaining lung inflation at low transpulmonary pressures,[1,2] Avery and Mead[3] reported that saline extracts from the lungs of preterm infants with RDS lacked the low surface tensions characteristic of pulmonary surfactant. After unsuccessful attempts to treat infants with RDS with aerosolized phospholipids,[4] intratracheal administration of surfactant recovered from the air spaces of mature animal lungs was found to improve lung expansion and ventilation in preterm animals.[5,6] The clinical potential of surfactant treatment for RDS was demonstrated by Fujiwara and colleagues[7] in a nonrandomized study in 1980, using a surfactant prepared from an organic solvent extract of bovine lung. Small, investigator-initiated, randomized, controlled trials testing surfactants prepared from bovine alveolar lavage or human amniotic fluid demonstrated significant decreases in pneumothorax and death by 1985.[8-10] Subsequent multicenter trials demonstrated decreased death rates and complications of RDS.[11] A synthetic surfactant was approved by the Federal Drug Administration (FDA) for the treatment of the syndrome in the United States in 1990, and surfactant from bovine lung was approved in 1991. Surfactants were a new class of drug developed specifically for preterm infants. Current research interests are the optimal timing of surfactant treatments and ventilatory support strategies and the development of synthetic surfactants that contain recombinant surfactant proteins.

SURFACTANTS FOR CLINICAL USE

Surfactants for clinical use were developed empirically by testing surface properties of mixtures of lipids and proteins with the goal to emulate the properties of natural surfactant.[12] Although dipalmitoylphosphatidylcholine is the principal surface active component of surfactant, it is not an effective surfactant because it is a solid at 37° C and does not rapidly spread or adsorb to a surface.[13] Dipalmitoylphosphatidylcholine forms a stable film with an equilibrium surface tension similar to that of natural surfactant, and when spread from an organic solvent, surface tension values approach 0 dynes/cm with surface compression. Surface adsorption can be enhanced by adding other components, such as dioleoylphosphatidylcholine, phosphatidylglycerol, or cholesterol. Simple mixtures of dipalmitoylphosphatidylcholine with other lipids can have surface properties similar to those of a natural surfactant.[14]

Two synthetic surfactants were extensively evaluated in clinical trials and were in clinical use until around the year 2000. A 7:3 weight ratio of dipalmitoylphosphatidylcholine and unsaturated phosphatidylglycerol was used in England.[15] The other synthetic surfactant to be used clinically was a mixture of dipalmitoylphosphatidylcholine, hexadecanol, and tyloxapol. These synthetic surfactants were not as effective as natural surfactants and are no longer used clinically.[16]

Highly surface active surfactants recovered from animal lungs were effective surfactant treatments for preterm surfactant-deficient lungs, demonstrating that formulations for clinical use could come from animal sources.[17] The surfactants from natural sources are of two general types: surfactants recovered from alveolar lavages and surfactants recovered from minced lungs. The surfactant first used clinically by Fujiwara and colleagues[7] was prepared by saline extraction of minced lungs. The saline extract was then further extracted with organic solvents to yield phospholipids, neutral lipids, and small amounts of the hydrophobic surfactant-associated proteins (SP)-B, and SP-C. This lipid extract contains the components of natural surfactant except SP-A. However, it also has increased amounts of unsaturated phospholipids and neutral lipids that interfere with surface properties. Synthetic lipids were added to improve surface properties[12] and enhance clinical effects. Another surfactant for pig lung was developed using the strategy to remove the neutral lipids from the lipid extract that interfere with function by liquid-gel chromatography.[18] This surfactant contains 99% polar lipids, mainly phospholipids, and 1% SP-B plus SP-C, with the neutral lipids removed.

Another approach to making an animal source surfactant is to recover surfactant from alveolar lavages and prepare organic solvent extracts of that material. Several commercial surfactants made from large bovine lungs are in clinical use. The organic solvent extraction step removes nonessential proteins that might be sensitizing. Peptides that mimic the biophysical functions of surfactant proteins also can be combined with lipids to make effective surfactants.[19]

PHYSIOLOGIC EFFECTS OF SURFACTANT TREATMENT ON PRESSURE-VOLUME CURVES

The pressure-volume curve defines the static effects of surfactant on the preterm lung[20] (Figure 106-1). When comparing the lungs of control preterm animals with surfactant-treated animals, surfactant decreased the *opening pressure*, defined as the pressure at which the lung begins to fill above dead space volume. The opening pressure of preterm surfactant deficient rabbit lungs decreased from approximately 20 to 15 cm H_2O with surfactant treatment in this example. The explanation for this effect is that the surfactant-deficient immature lung resists inflation because of the high surface tensions at the interfaces of gas with fluid in small airways. Surfactant decreases the resistance

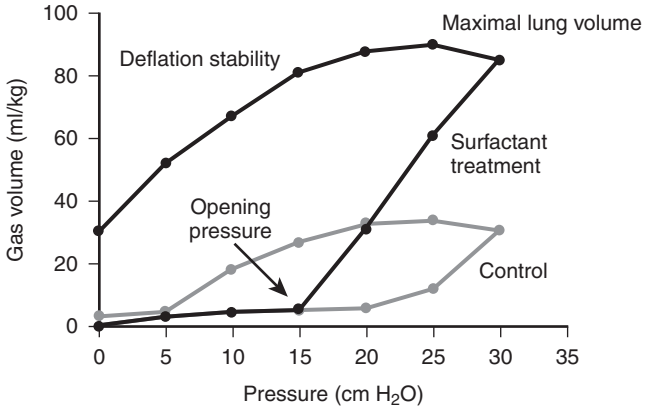

Figure 106-1 Representative pressure-volume curves for 27-day preterm rabbit lungs treated with surfactant in comparison to control lungs.The curves were measured after a 30-minute period of ventilation. Surfactant has pronounced effects on opening pressure, maximal lung volume, and deflation stability relative to the control lungs. *(Modified from Rider ED, Jobe AH, Ikegami M, et al: Different ventilation strategies alter surfactant responses in preterm rabbits,* J Appl Physiol *73:2089, 1992.)*

to fluid movement in the airways and expansion of lung units is facilitated. The major effect of surfactant treatment is the large increase in lung volume at 30 cm H_2O. Because dead space volume will not change with surfactant treatment, this increase in volume represents the recruitment of more surface area for gas exchange. No maximal lung volume (V_{max}) is distinct for the preterm lung. In the mature lung, V_{max} is defined by the limits of expansion of the lung matrix. In contrast the preterm lung will continue to expand with increasing pressure until rupture occurs.[21] For the surfactant-deficient preterm lung, the potential gas volume cannot be achieved because inflation pressures needed to recruit that volume will exceed the rupture pressure. Surfactant also stabilizes the lung during deflation and maintains a lung volume at 5 cm H_2O pressure in excess of the V_{max} achieved in control lungs. The dynamic equivalent to static deflation stability is the functional residual capacity, which will increase with surfactant treatment.

Evaluation of degree and uniformity of inflation is another way to assess surfactant effects on the lung. Based on the simplest model of two alveoli as interconnecting spheres, surfactant deficiency will cause alveolar (or small airway) instability characterized by collapse of units with small radii and dilation of units with large radii. This instability results from Laplace's law: pressure at the surface of an alveolus = 2 × surface tension/radius. Because the alveolus is open to atmospheric pressure, the pressure outside must be balanced by the pressure on the inner surface or the alveolus will collapse. The forces acting on the alveolus are chest wall elasticity, lung tissue elasticity, and surface tensions at the alveolar surface. All alveoli are not the same size. Therefore Laplace's law predicts that the retractive force of surface tension will be greater on the small alveoli than on the large alveoli, with the result being collapse of the small alveoli with further filling of the large alveoli. Surfactant, however, has the unique property of variable surface tension depending on the rate and amount of surface area compression. As alveolar radius decreases, surface tension falls, preventing collapse of the small alveolus. This stabilizing influence is lost in the absence of surfactant.

The concept of interdependence results from the scaling up of the alveolar model. Each alveolus depends on the position and elasticity of the neighboring alveolar walls to maintain

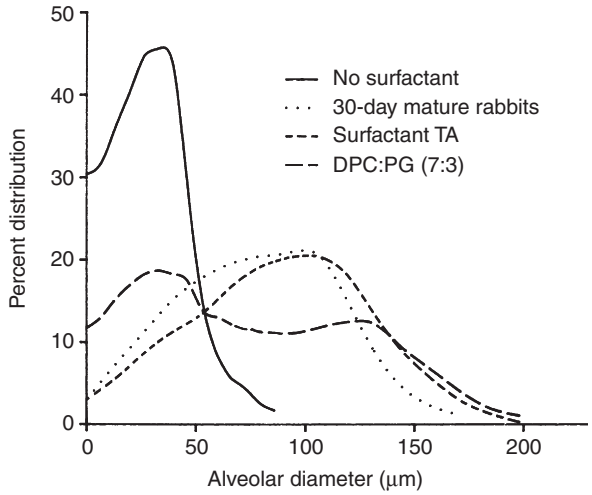

Figure 106-2 Alveolar size distributions for 30-day-gestation mature rabbits, 27-day preterm rabbits receiving no surfactant, and preterm rabbits treated with surfactant TA and a dipalmitoy lphosphatidylcholine:phosphatidylglycerol synthetic surfactant (DPG:PG).The lungs were immersed in formalin at a deflation pressure of 10 cm H_2O for fixation. Surfactant treatment normalized alveolar diameters toward those measured for the mature newborn rabbits. *(From Fujiwara T: Surfactant replacement in neonatal respiratory distress syndrome. In Robertson B, van Golde LM, Battenberg JJ (eds):* Pulmonary Surfactant. *Amsterdam, Elsevier Science Publishers, 1984, pp 480-503.)*

normal shape and volume. If adjacent alveoli collapse, the alveolus either tends to overexpand and distort or collapse. In surfactant-deficient states, the more normal alveoli tend to overexpand as other regional alveoli collapse, generating a nonhomogeneously inflated lung. Surfactant treatment improves uniformity of inflation, minimizes small airway dilation and promotes alveolar inflation. Surfactant treatment of 27-day preterm rabbits resulted in a distribution of alveolar sizes comparable to those of term rabbits[12] (Figure 106-2). Surfactant treatment also resulted in more normal lung morphometry in preterm lambs receiving continuous mechanical ventilation 24 hours after delivery.[22] The alveoli of the lambs not treated with surfactant were shallow, and alveolar ducts were dilated. Most of these abnormalities were prevented with surfactant treatment (Figure 106-3). This surfactant effect on uniformity of lung expansion may be the mechanism that decreases lung injury.

EFFECTS OF SURFACTANT TREATMENT ON DYNAMIC LUNG FUNCTION

If surfactant treatment were to completely normalize lung function, functional residual capacity (FRC) should increase, the time constant for inflation should decrease, and the time constant for expiration should increase. These effects occur to variable degrees, probably depending on factors related to the disease process in each infant, the style of ventilatory management, and the surfactant used to treat the infant. FRC in infants with RDS increased by approximately 150% to approach a normal value after surfactant treatment in one report.[23] In another report, FRC increased from 7.6 mL/kg to 15.4 mL/kg 1 hour after surfactant treatment.[24] The effect of surfactant treatment on FRC depends on the positive end-expiratory pressure (PEEP) used to ventilate the infant. FRC can be too high after surfactant treatment, resulting in CO_2 retention.[25]

Compliance uniformly increased in animal models of surfactant treatment.[26] However, compliance did not increase in infants soon after surfactant treatment in most clinical reports. For example, Davis and associates[27] reported no change in compliance for mechanical breaths with surfactant treatments, although spontaneous breaths after surfactant treatment demonstrated improved compliance. There are several explanations for this inconsistency. The animal models of RDS are ventilated in a standard fashion often with control of tidal volume. In the clinical evaluations of surfactant, tidal volumes were seldom measured. Large tidal volumes or high FRC may mask a "compliance effect" of surfactant treatment. Kelly and associates[28] found no improvement in dynamic compliance after treatment of infants with surfactant, whereas static compliance decreased as a result of lung volume recruitment. However, when the ventilator pressures were lowered, consistent improvements in both static and dynamic compliance occurred. Figure 106-4 illustrates what probably is occurring in infants. Surfactant treatment increases lung volumes at both low and high transpulmonary pressures. Over a range of pressures, the curves are parallel, and the calculated compliance does not change with surfactant treatment. By lowering pressures, mechanical ventilation becomes more efficient, and compliance improves. If peak inspiratory pressures and/or PEEPs are too high, compliance will decrease after surfactant treatment because the lung is overinflated.

Another variable in the compliance response is the type of surfactant used for treatment. A synthetic surfactant without surfactant proteins may not demonstrate improved compliance in the first few hours after treatment. In contrast treatment with animal source surfactants can result in rapid improvements in compliance. These different responses between synthetic surfactants and surfactant from animal lungs have been noted in preterm animal models[29] and in clinical practice.[30] Differences in acute physiologic responses between the surfactants from animal lungs that are now used clinically are not large, and differences in longer term outcomes have not been convincingly demonstrated.

Surfactant treatments also will have effects on the time constants for lung inflation and deflation. The stiff, atelectatic lung of the infant with RDS does not inflate easily, and deflation to low lung volumes is rapid because the elastic recoil properties of the lungs are not counterbalanced by surfactant. With mechanical ventilation, inspiratory times and peak pressures are used empirically to adjust tidal volumes. The time constant for expiration (defined as the time required for the lung to empty two thirds of its volume calculated from the peak tidal volume to FRC) is a passive property of the lung that is not controlled by the clinician. Although measurements of expiratory time constants have not been reported for surfactant-treated infants, the mean expiratory time constant increased from 25 +/− 6 ms for controls to 50 +/− 9 ms for surfactant-treated preterm rabbits.[31] The expiratory time constant increased as the SP-B content of the surfactant increased in preterm rabbits.[32] Increases in expiratory time constants in surfactant-treated infants ventilated at rapid rates could significantly increase expiratory lung volumes to the point of overdistention, resulting in decreased compliance and carbon dioxide retention. The combination of surfactant treatment and a ventilatory style that promotes air trapping may mask surfactant treatment effects.

OXYGENATION RESPONSE TO SURFACTANT

The most consistent response to surfactant treatment is an improvement in oxygenation,[11] which occurs within seconds to minutes after surfactant treatment of preterm animals[26] (Figure 106-5). The rapid improvement in oxygenation results from the acute increase in lung volume and increases in the surface area for gas exchange with surfactant instillation. Surfactant treatments also decrease pulmonary vascular resistance

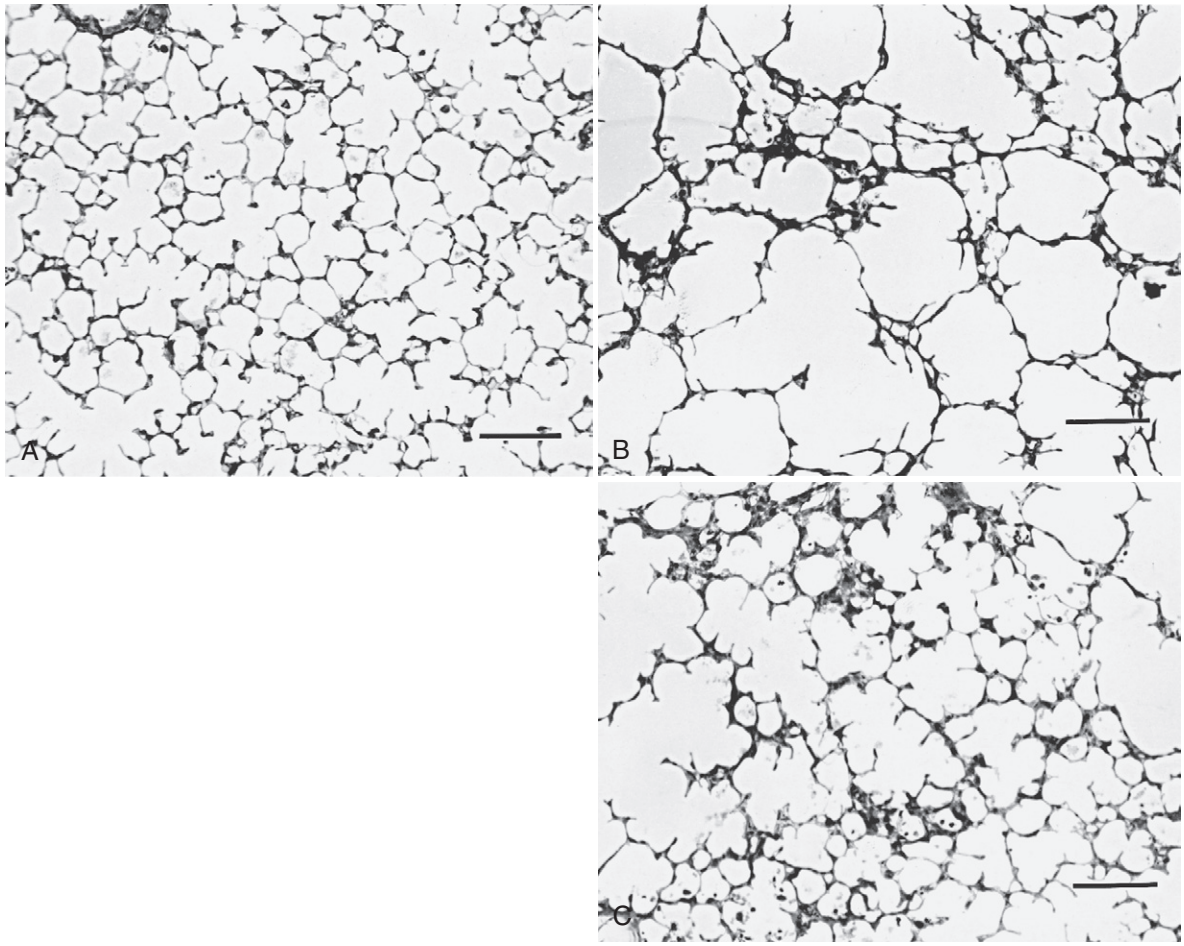

Figure 106-3 Effect of surfactant on uniformity of alveolar expansion. **A,** Light micrograph from a preterm lamb lung fixed at delivery without mechanical ventilation demonstrates uniform alveolar sizes. **B,** After ventilation for 24 hours without surfactant treatment, some alveoli are shallow and alveolar ducts are distended, and other alveoli are collapsed. **C,** After surfactant treatment at birth and ventilation for 24 hours, alveolar sizes are more uniform. Bar is 100 μm in each figure. *(From Pinkerton KE, Lewis JF, Rider ED, et al: Lung parenchyma and type II cell morphometrics: Effect of surfactant treatment on preterm ventilated lamb lungs,* J Appl Physiol *77:1953, 1994.)*

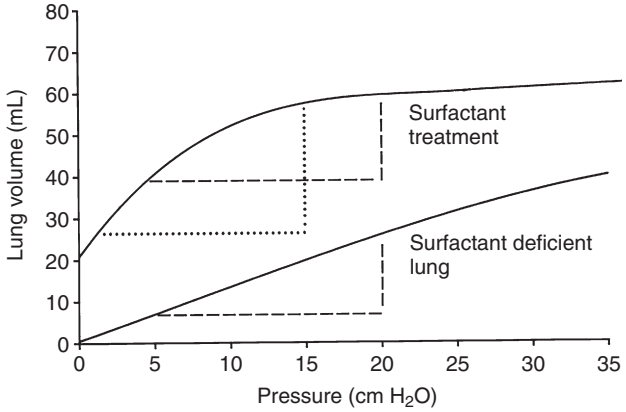

Figure 106-4 Idealized deflation limbs of static pressure-volume curves for a surfactant-deficient lung and surfactant-treated lung. The surfactant treatment has increased lung volume and deflation stability. Compliances calculated over the pressure range of 5 to 20 cm H_2O as indicated by the *dashed lines* are similar despite surfactant treatment. By lowering ventilatory pressures to 15 over 2 cm H_2O, as indicated by the *dotted lines,* compliance has improved with surfactant treatment.

in infants with RDS.[33] Although the fall in pulmonary vascular resistance may reverse the ductal shunt (from right-to-left to left-to-right) and decrease hypoxic shunt,[34] this effect is probably delayed in most clinical situations until after the initial oxygenation response has occurred.[35]

CLINICAL TRIALS OF SURFACTANT FOR RESPIRATORY DISTRESS SYNDROME

The use of surfactant in preterm infants is the most thoroughly studied therapy in neonatal care. The clinical trials have been compiled by Soll[36] in a meta-analysis (Figure 106-6). Two strategies for the use of surfactant have been evaluated: One involves the treatment of infants at high risk of RDS in the delivery room concurrently with the initiation of breathing and resuscitation. The other involves the treatment of infants at 2 to 24 hours of age after a diagnosis of RDS has been made. Treatment in the delivery room is referred to as *prevention* or *prophylactic treatment* because the goal is to prevent both RDS and any injury to the preterm surfactant-deficient lung that might result from mechanical ventilation. The odds ratio for death by 28 days of age was approximately 0.6 for either treatment strategy.[11] With surfactant treatment, the absolute decrease in death from any cause was 30% to 40%.

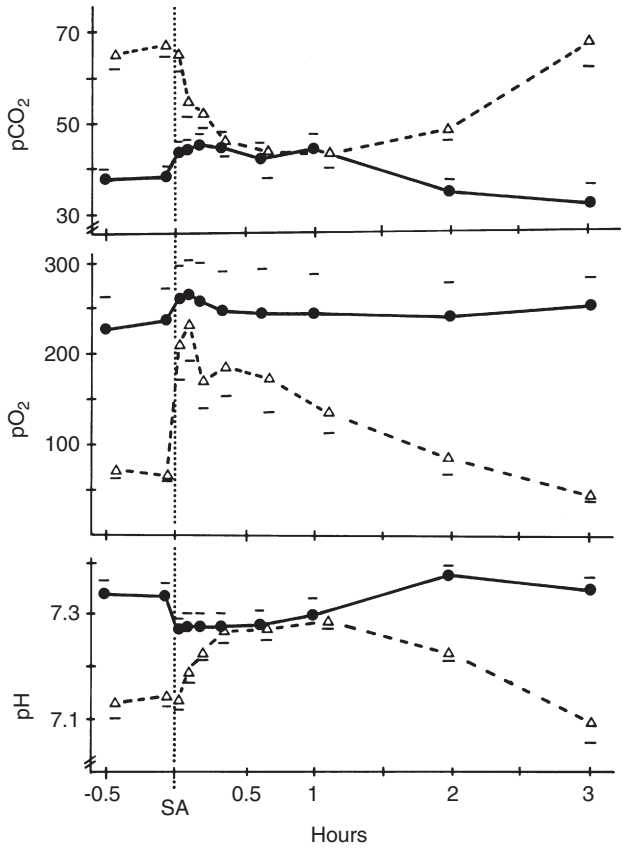

Figure 106-5 Blood gas and pH responses of very preterm lambs to treatment with 100 mg/kg natural sheep surfactant. Preterm lambs were delivered at approximately 121 days gestation (term is 150 days) and treated with surfactant either at birth (•) or after ventilation for approximately 30 minutes (Δ). Oxygenation was good and P_{CO_2} values were normal with surfactant treatment at birth. Oxygenation improved very rapidly after surfactant treatment at 30 minutes of age. *(From Jobe A, Ikegami M, Glatz T, et al: Duration and characteristics of treatment of premature lambs with natural surfactant,* J Clin Invest *67:370, 1981, by copyright permission of The American Society for Clinical Investigation.)*

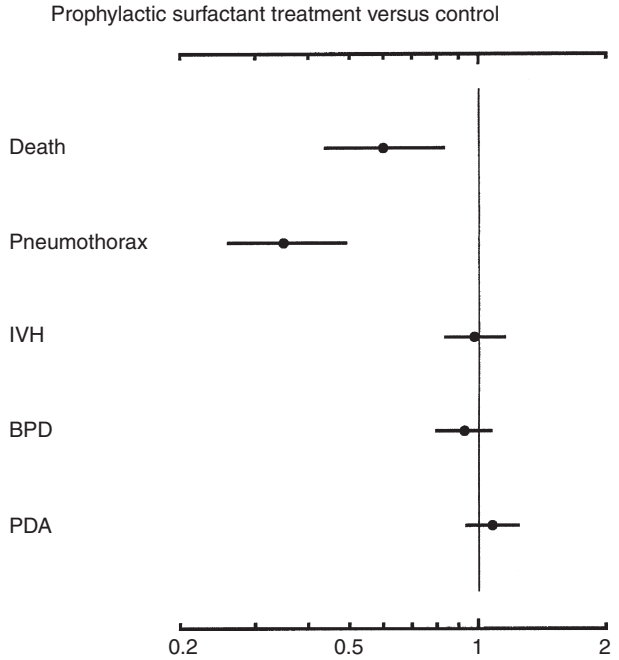

Figure 106-6 Odds ratios and 95% confidence intervals from meta-analysis of clinical trials of natural surfactant treatments given at birth for respiratory distress syndrome (RDS) in comparison to untreated controls. *BPD,* Bronchopulmonary dysplasia; *IVH,* intraventricular hemorrhage; *PDA,* patent ductus arteriosus. *(Data from Soll RF: Prophylactic natural surfactant extract for preventing morbidity and mortality in preterm infants,* Cochrane Database Syst Rev *(2):CD000511, 2000.*

The major pulmonary complications of RDS are acute respiratory failure, air leaks (pneumothorax and pulmonary interstitial emphysema), and the chronic lung disease of infants called *bronchopulmonary dysplasia*. Surfactant treatment results in improved lung function and in a striking decrease in pneumothorax and other air leaks. The incidence of bronchopulmonary dysplasia was not consistently lower, although it was reduced in individual studies. A problem with the reported incidence of bronchopulmonary dysplasia was that the severity of the lung disease was not quantified. Many tiny preterm infants have a supplemental oxygenation requirement and some radiographic abnormalities at 28 days of age, but they do not need oxygen or other treatments for lung disease at discharge.[37] The most frequently used definition for bronchopulmonary dysplasia is the use of oxygen at 36 weeks. Some infants receive oxygen who do not need oxygen when evaluated by objective oxygen saturation criteria.[38] Overall the severity of bronchopulmonary dysplasia has decreased in the very-low-birth-weight population, and surfactant treatments must be contributing to this improved outcome.[39] Surfactant treatment increases survival and these survivors may have the highest risk of bronchopulmonary dysplasia. Egberts and de Winter[40] point out that the incidence of bronchopulmonary dysplasia decreased in the clinical trials if the calculation was based on survivors rather than on infants randomized.

An initial hope was that the improved cardiopulmonary stability and oxygenation resulting from surfactant treatment would protect preterm infants from the nonpulmonary complications of prematurity, such as patent ductus arteriosus, severe intraventricular hemorrhage, and necrotizing enterocolitis. Unfortunately, treatment has not consistently decreased the frequency of patent ductus arteriosus or severe intraventricular hemorrhage. Large decreases in intraventricular hemorrhage in association with surfactant treatment have been reported in individual trials,[41] suggesting that other aspects of neonatal care may be interacting with surfactant therapy to influence the incidence of this complication. A thorough analysis of the available data on the possible association of intraventricular hemorrhage with surfactant treatment did not lead to any direct links.[42] Necrotizing enterocolitis and retinopathy of prematurity were not tabulated for the meta-analyses, but no trends were reported in the individual trials. One study found a decrease in retinopathy of prematurity in the infants treated with surfactant.[43] Infants treated with surfactant generally perform as well as or better than control infants when assessed at long-term follow-up.[44-46] Surfactant-treated infants needed less supplemental oxygen at 6 months and had less wheezing at 12 and 24 months of age relative to control infants.[47] In this study, less cerebral palsy also was diagnosed in surfactant-treated infants.

TIMING OF SURFACTANT TREATMENT

In the initial trials, surfactant was administered 6 to 24 hours after birth when a diagnosis of severe RDS could be made more accurately. In contrast delivery room treatment was considered

to be optimal only if given before the infant breathed or received positive-pressure ventilation.[48] This delivery room strategy was based on information from surfactant treatment of preterm animals that demonstrated airway epithelial damage after very short-term periods of ventilation of the surfactant-deficient lung.[49] The two treatment strategies were compared in eight trials using different surfactants.[50] No differences in the incidences of intraventricular hemorrhage, bronchopulmonary dysplasia, or patent ductus arteriosus were seen. Delivery room treatment decreased pneumothorax, and this outcome would be expected because early treatment protected the infant from pneumothorax for the period before treatment. The important difference was a decrease in death with prophylactic surfactant relative to treatment of RDS.

In the more recent trials, delivery room treatment was delayed until after the infant had stabilized for a few minutes and the treatment of RDS was not delayed for 6 hours. Therefore the two treatment strategies approached each other in time. Treatment of infants at birth has two disadvantages: A number of the infants will be treated unnecessarily because they would not have developed RDS, and instillation of a large volume of surfactant can interfere with normal resuscitative efforts. Kendig and co-workers[48] demonstrated that surfactant treatment within the first 15 minutes after birth was equivalent and perhaps preferable to treatments before the infant was allowed to breathe. Based on the meta-analyses of the initial trials comparing delivery room treatment with treatment of RDS, Horbar and colleagues[51] argued that the standard of care should be delivery room treatment for very-low-birth-weight infants. However, in practice, the majority of infants were not treated in the delivery room. They then performed a collaborative quality improvement initiative and demonstrated that the age at treatment could be reduced from a mean of 78 minutes to 21 minutes, but the intervention had no effect on clinical outcomes.[52] A reasonable approach is to treat most infants as soon as clinical signs of RDS appear. Waiting for the disease to progress to establish the diagnosis more firmly before treatment will minimize the efficacy of the therapy and increase complications. Delivery room treatment is most appropriate for the smallest infants who are at the highest risk of RDS. However, delivery room treatment should be given by a person experienced in neonatal resuscitation.

Decisions about the timing of surfactant treatment are further complicated by the use of continuous positive airway pressure (CPAP) soon after birth to stabilize respiratory function and to avoid intubation and mechanical ventilation. With clinician experience with the use of CPAP, many infants can initially transition from the delivery room and do well on CPAP despite some RDS.[53] The success rate for CPAP management increases as birth weight and gestational age increases, but some infants at gestations of 25 weeks or less do not require surfactant treatment or mechanical ventilation. A management strategy to emphasize CPAP will result in a striking decrease in surfactant use, and reports of clinical experiences suggest a decreased rate of bronchopulmonary dysplasia without increased death or other complications of prematurity.[54] The benefits of avoiding mechanical ventilation for some infants may put other infants at risk for complications that result from delays in surfactant treatment. The compromise to intubate very-low-birth-weight infants at delivery, give surfactant, and then attempt early extubation to CPAP still requires intubation, which may result in injury. Clinical trials for the initial management of very-low-birth-weight infants with surfactant or CPAP are in progress. However, the different management strategies depend on procedural skills, experience, and multiple aspects of the subsequent care, which may confound clear answers to when infants are best treated with surfactant.

REPETITION OF TREATMENT

Multiple doses of surfactant were given in most trials because the response to an individual dose was often transient. In preterm animals, exogenously administered surfactant is not lost from the lungs,[55] but its function can be inhibited by soluble proteins and other factors. Multiple doses of surfactant are thought to be useful because they can overcome this functional inactivation of surfactant. Multiple doses of surfactant have been compared with single-dose treatments. In one trial, second and third doses given 12 and 24 hours after an initial treatment at approximately 6 hours of age reduced the frequency of pneumothorax from 18% with a single dose to 9% with three doses ($p < .01$), and the death rate at 28 days decreased from 21 to 13% ($p < .05$).[56] In another study of 75 large infants with RDS (mean birth weight, 1900 g), those who received multiple doses had better oxygenation during the first several days of life.[57] An unresolved question is whether all infants treated with surfactant would benefit from subsequent treatments. All recent trials have used retreatments. Although most infants respond favorably to treatment, approximately 20% of infants thought to have RDS will have little or no response. These infants may have other diseases, such as pneumonia, pulmonary hypoplasia, or congenital heart disease. Structural immaturity of the lungs and birth asphyxia with decreased cardiovascular performance can also blunt the response to surfactant. It is reasonable to re-treat with surfactant if the initial response to treatment was poor and other causes of respiratory failure have been excluded. Many infants will have such a good response to the first dose that they have minimal residual lung disease. In clinical practice, re-treatment should be individualized and considered for infants with enough residual lung disease to put them at risk for complications such as pneumothorax. The major reason for re-treatment is to overcome inhibition of surfactant resulting from lung injury. If treatment is given early in the clinical course and a gentle approach to ventilation is used, significant lung injury can be avoided. The dose of 100 mg/kg surfactant that is normally used is large relative to the endogenous pool in a normal lung, and it is metabolized slowly.[55] Therefore retreatment with surfactant will not be for inadequate amounts of surfactant, but for inadequate surfactant function. On average, infants with RDS receive less than 2 doses of surfactant. More than two (or perhaps three) doses of surfactant is excessive and is unlikely to improve outcomes.

COMPLICATIONS OF SURFACTANT TREATMENT

The complications associated with the administration of surfactant are listed in Table 106-1. This documentation of treatment complications resulted from an extensive data collection required for the initial clinical use of surfactant in 1990 and 1991.[58] Similar problems associated with surfactant treatments were reported by Horbar and colleagues.[59] The treatment procedures for each surfactant approved for clinical use differ in detail but generally combine positioning of the infant, manipulation of the endotracheal tube, and instillation of suspensions of surfactant in a 3- to 5-mL/kg vehicle. The acute physiologic effects are related to the handling of the infant and the acute effects of the surfactant on the lungs. Manipulation of the head, neck, and endotracheal tube can cause vagal responses resulting in bradycardia and cyanosis. The bolus of fluid can acutely obstruct airways leading to cyanosis, bradycardia, and carbon dioxide retention. If surfactant is rapidly distributed to the distal lung, lung compliance can improve, the Po_2 can increase, and the Pco_2 can decrease. Reflux of some of the surfactant up the endotracheal tube is frequent. These acute effects of surfactant are easily dealt with by adjustments in the ventilator and probably have no long-term effect on outcome. Of more

concern are the reports of transient changes in blood pressure, cerebral blood flow velocities, and electrocortical depression after surfactant treatments.[60-62] The mechanisms and importance of these effects are not known.

The only severe complication consistently associated with surfactant treatment is pulmonary hemorrhage. The overall relative risk for pulmonary hemorrhage after surfactant therapy was 1.47 (95% confidence interval 1.05 to 2.07) in the clinical trails.[63] Incidences ranged from approximately 1% to 5% of treated infants. The presence of a patent ductus arteriosus with a left-to-right shunt resulting in elevated pulmonary vascular pressures was linked to pulmonary hemorrhage in several trials. Although this association has not been identified in other trials, increased pulmonary vascular pressures leading to stress failure of alveolar capillaries is the likely explanation for the pulmonary hemorrhage.[64] The pulmonary hemorrhage after surfactant treatment does not often occur at the time of treatment. Hemorrhage can occur in the smallest infants a number of hours after surfactant treatment has improved lung function. Pulmonary hemorrhage is frequent in autopsies of infants who have died of RDS. The association of pulmonary hemorrhage with surfactant treatment may result from the decreased death rate in tiny preterm infants receiving surfactant, which allows pulmonary hemorrhage to become apparent clinically. Surfactant treatment after pulmonary hemorrhage can improve subsequent lung function.[65] This result is consistent with the concept that pulmonary hemorrhage inactivates surfactant. Although not well documented, pulmonary hemorrhage seems to be less frequent in recent years. Perhaps changes in ventilation style toward the maintenance of better lung inflation, lower tidal volumes, and acceptance of higher carbon dioxide levels have contributed to the decrease in pulmonary hemorrhage.

ROUTINE CLINICAL USE OF SURFACTANT

The randomized, controlled trials demonstrated that surfactant decreased death when used to treat infants with RDS. No assurance, however, is available that general clinical use would result in similar effects. Several reports of the probable effect of surfactant introduction on outcomes for preterm infants have been published. Incidences of death and other major neonatal complications were analyzed for the period before surfactant introduction (before 1989) and after general clinical availability. Horbar and colleagues[66] reported outcomes for 2870 infants weighing 601 to 1300 g before surfactant and 1413 infants after surfactant was available. Mortality decreased from 28% before surfactant to 20% after surfactant was introduced. This decrease in mortality was associated with an increase in the duration of ventilation and length of hospitalization. Of perhaps more importance is the information on secondary outcomes (Figure 106-7). Surfactant treatments were not associated with increased incidences of intraventricular hemorrhage, bronchopulmonary dysplasia, sepsis, or patent ductus arteriosus. Beneficial secondary effects were decreased necrotizing enterocolitis, air leak, and severe retinopathy of prematurity. The increase in apnea probably resulted from the survival of more small infants. This favorable clinical experience was not replicated in a compilation of data for 5629 infants weighing 500 to 1500 g from 14 centers.[67] Although death decreased by 30% after the introduction of surfactant, intraventricular hemorrhage increased from 17% to 23% (adjusted risk ratio, 1.4; 95% confidence interval, 1.2 to 1.6). Nevertheless, the effect of surfactant on death can explain 80% of the decline in infant mortality between 1989 and 1990. The use of surfactant decreased overall costs for both survivors and the infants that died. Palta and co-workers[68] also noted a decrease in death with the introduction of surfactant. Intraventricular hemorrhage also decreased, but this outcome was associated primarily with increased use of antenatal corticosteroids. The incidence of bronchopulmonary dysplasia increased, perhaps because more small infants were surviving. The epidemiology is important for understanding how the introduction of a new therapy affects overall outcomes.

ADMINISTRATION OF SURFACTANT

The instillation procedures used in the trials to treat RDS were selected empirically based on the techniques of treatment for preterm animal models of RDS. Surfactant can be given to infants at risk of developing RDS in the delivery room soon after delivery and intubation as a single bolus into the endotracheal tube followed by mechanical ventilation.[48] For infants with RDS, surfactant has been given by a variety of bolus injection schemes that include positioning the chest of the infant in an effort to optimize distribution. These treatment procedures were standardized for each clinical trial such that each surfactant in current use was given by a somewhat different technique. The essence of each treatment technique is the instillation of surfactant into the proximal or distal trachea with positioning of the chest. The only clinical trial comparing

treatment techniques found that there were no differences in short-term efficacy when the surfactant dose was divided into two or four aliquots for administration or when two or four chest positioning maneuvers were used.[69]

The goal of the treatment technique is to get the surfactant into an infant's lungs with as little physiologic disturbance as possible. This clinical treatment goal may conflict with the goal of an optimal clinical outcome. At the level of the alveolus, the primary goal is to achieve as uniform a distribution of surfactant as possible. If distribution were perfectly uniform, expansion of the lung should be uniform. The physiologic result should be decreased oxygen and pressure needs and less lung injury. In contrast, if the distribution of surfactant were primarily to one lobe or one lung, that lung volume would expand if pressures were not decreased. The inflated lung would tend to overexpand and potentially be injured.[12] If the pressures were decreased, the untreated lung would lose whatever gas volume it was receiving and become more atelectatic. At the alveolar level, alveoli are interdependent in that if a group of alveoli collapse, the adjacent alveoli may overinflate and distort[22] (see Figures 106-2 and 106-3). The frequent occurrence of bronchopulmonary dysplasia after surfactant treatment may result in part from the nonhomogeneous distribution of surfactant, contributing to focal lung injury.

Most experimental studies of surfactant distribution have used radiolabeled surfactant components (primarily dipalmitoylphosphatidylcholine) or other easily measured substances mixed with surfactant.[70] The distribution of surfactant was measured by external scanning of radioactivity,[71] autoradiograms of lung slices,[72] or the content of surfactant in lung pieces of various sizes.[73] Each technique has different strengths and weaknesses, giving only partial information about surfactant distribution. Charon and colleagues[71] measured surfactant distribution in infants. They mixed technetium-sulfur colloid with surfactant and treated eight infants using a four-bolus, four-position treatment technique. They found relatively homogeneous distributions in all infants that did not correlate with clinical response. Subsequently van der Bleek and colleagues[74] reported that microaggregated technetium-albumin mixed with surfactant appeared to be uniformly distributed by external scanning of the lungs of saline lavaged rabbits. When the lungs were divided into 200 pieces and distribution per piece was measured, however, the distribution was not homogeneous. Scanning of whole lungs does not accurately reflect distribution. Analysis of lung pieces also does not provide information about alveolar distribution. For example, if the preterm human lung at 32 weeks gestational age were cut into 200 pieces for a distribution measurement, each piece would contain approximately 200,000 saccules. Therefore, even if distribution to lung pieces were homogeneous, significant inhomogeneity must exist at the alveolar level.

VARIABLES THAT INFLUENCE SURFACTANT DISTRIBUTION

The biophysical properties of surfactant facilitate adsorption to an air-fluid interface and rapid spreading over a surface. Therefore it is logical to anticipate that surfactant will distribute by this spreading behavior. Davis and associates[75] used external scanning to measure the kinetics of surfactant or saline distribution to the lungs of saline lavaged piglets. They found that surfactant began to distribute within 5 seconds of dosing, with substantial distribution to the lung fields within 20 seconds. In contrast, saline did not distribute as rapidly, and multiple filling defects were noted on the scans. These results demonstrate rapid spreading of surfactant with a more uniform ultimate distribution than for saline alone. Surfactant given into single lobes in rabbits did not spread to other lobes even after 10 hours of spontaneous ventilation.[76] Therefore surfactant treatments given into one lung or lobe will not treat other parts of the lung.

The surfactants used clinically are given as suspensions in volumes that range from 2.5 to 5 mL/kg. Intuitively, the larger the volume administered, the more likely multiple bronchi will be filled, and the better the distribution is likely to be. Large volumes, however, are more likely to cause airway obstruction, respiratory distress, cyanosis, and other undesirable side effects. Gilliard and co-workers[77] found that instillation of 1.5-mL/kg surfactant into ventilated rabbits with normal lungs resulted in a nonuniform distribution. Increasing surfactant concentration did not improve the distribution. The same amount of surfactant suspended in 15 mL/kg resulted in a homogeneous distribution. However, with lung injury, the distribution was volume independent and reasonably uniform. This result was interpreted to mean that with severe lung injury, the alveoli were flooded and provided a fluid volume to facilitate surfactant distribution. The residual fetal lung fluid and alveolar edema associated with RDS may help distribute surfactant. Large treatment volumes are not realistic for clinical practice, and some nonhomogeneity of surfactant distribution is an inevitable consequence of present treatment techniques.

Given that surfactant distribution can be improved by increasing the treatment volume, and the administration of large volumes over short treatment intervals results in respiratory complications, it might seem logical to deliver surfactant to the lungs more slowly. This approach has been evaluated in two animal models of RDS. Segerer and associates[78] reported that 4 mL/kg of a surfactant suspension given as a bolus via the endotracheal tube in 10 seconds to saline-lavaged rabbits resulted in a reasonably uniform distribution. In contrast infusion of the same volume of surfactant over 45 minutes through the pressure-monitoring channel in an endotracheal tube resulted in an extremely nonhomogeneous distribution. Ueda and associates[79] compared the four aliquot, four-position technique used clinically with a slow infusion in preterm lambs with RDS. The infusion treated group received 2 mL/kg surfactant in the right lateral position in 15 minutes followed by 2 mL/kg in the left lateral position in 15 minutes. Both groups of lambs had improvements in PO_2 and lung mechanics, although the responses were not as large with surfactant infusion. The bolus treatments delivered surfactant quite uniformly to the different lobes of the sheep lung, whereas infusion resulted primarily in upper lobe localization (Figure 106-8). The animals received a second treatment 2 hours after the initial treatment, and the second treatment localized to the same lung pieces that received the majority of the surfactant with the initial treatments. Therefore the first treatment determined primarily which lung volumes will open, and the second treatment tended to treat the same lung volumes that were initially treated. Pulmonary blood flow was relatively uniform across the lung pieces of the bolus-treated animals. In contrast blood flow decreased to the lung pieces that received the most surfactant by infusion, probably because of overinflation of those lung regions. In the injured lung, instilled surfactant goes preferentially to lung regions that are partially inflated and not to atelectatic or overinflated areas.[80]

Surfactant distributes to the lungs by bulk movement of the suspension down the airways and by spreading. The style of ventilation immediately after treatment could affect the distribution. In clinical practice, conventional volume ventilation is routinely used after surfactant treatments. Walther and colleagues[81] reported that surfactant instilled into the airways of preterm lambs distributed similarly with conventional or high-frequency ventilation. In contrast Heldt and co-workers[82] found that high-frequency ventilation seemed to delay surfactant delivery to distal airspaces of preterm rabbits. The efficacy of surfactant treatment techniques and distribution may be influenced

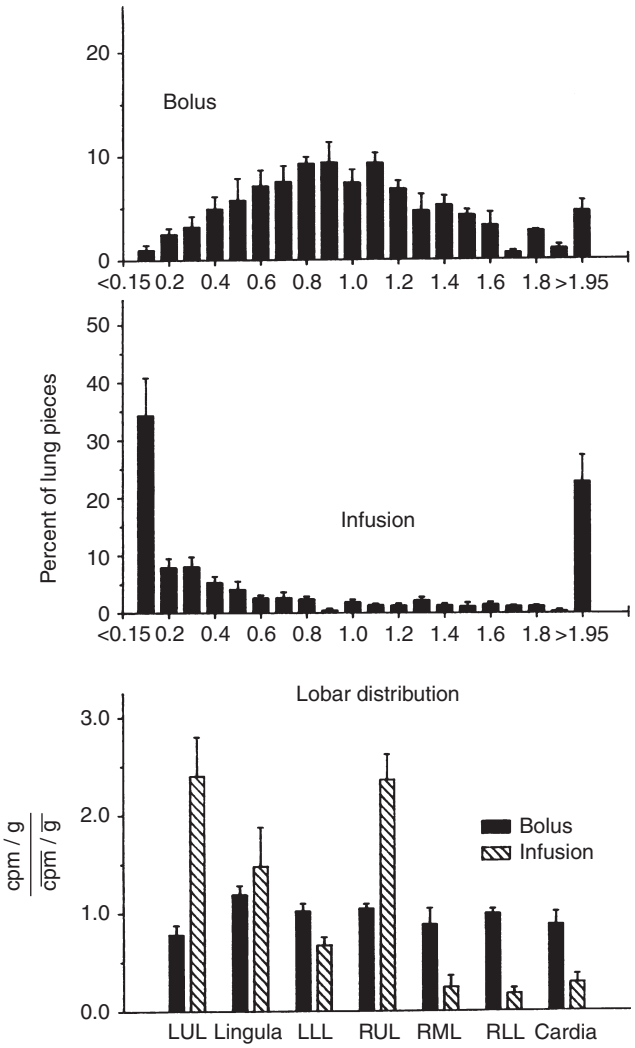

Figure 106-8 Distribution of surfactant by a bolus technique in comparison with a 30-minute infusion to preterm ventilated lamb lungs. The 100 mg/kg dose of surfactant was radiolabeled, and the amounts of surfactant recovered in lung pieces or by lobe were measured. Bolus treatment resulted in approximately 40% of the lung pieces containing within +/− 25% of the mean amount of surfactant. In contrast infusion resulted in 7% of the pieces of lung receiving within +/− 25% of the mean. The majority of the infused surfactant was found in the upper lobes. *(Redrawn from Ueda T, Ikegami M, Rider ED, et al: Distribution of surfactant and ventilation in surfactant-treated preterm lambs,* J Appl Physiol *76:45, 1994.)*

by different ventilation strategies. Surfactant can be delivered to the lungs by aerosol, but the surfactant goes primarily to the ventilated lung regions resulting in a nonuniform distribution.[83] The surfactant dose that can be delivered by aerosol also is low.

VENTILATION EFFECTS ON SURFACTANT TREATMENT RESPONSES

Although mechanical ventilation and the use of PEEP is routine in infants with RDS, multiple ventilatory techniques are in common use. The interaction between ventilatory management and surfactant treatment has not been studied extensively, although in experimental animals the ventilation technique is an important variable in the response of the preterm lung to surfactant treatment.[20] In clinical practice, surfactant does not have equivalent effects in different neonatal units, and the differences may be explained by ventilatory management.[84] Lung injury is induced by ventilation of the normal lung at volumes close to maximal lung volume.[85] With surfactant deficiency, ventilation at low lung volumes (below the normal FRC) also causes progressive injury and pulmonary edema.[86] If alveolar expansion is optimized in the saline-lavaged rabbit model of surfactant deficiency, the effectiveness of surfactant treatments is enhanced. The responses also depend on the type of surfactant used for treatment. Surfactants that contain only lipids are not as effective at improving compliances or pressure volume curves of preterm rabbits.[87] Addition of the surfactant proteins SP-B and SP-C improves function, but the enhanced function is evident only if PEEP is used to ventilate the animals. The use of PEEP in the preterm rabbit model resulted in striking decreases in the leak of albumin from the vasculature to the lungs, indicating less injury.

The equipment used for the mechanical ventilation of preterm infants and the ventilatory goals have changed since surfactant was tested clinically in the 1980s. Most trials of ventilation now focus on very-low-birth-weight infants at highest risk of bronchopulmonary dysplasia. These infants usually have RDS and have been treated with surfactant before trial enrollment. Examples are the trials comparing high-frequency oscillation with conventional ventilation.[88,89] The newer management approaches to keep the FRC relatively high (the open lung strategy) while ventilating with low tidal volumes (4 to 6 mL/kg) to achieve carbon dioxide values higher than the normal range (greater than 50 mm Hg) depend on good surfactant function. If surfactant is deficient, FRC cannot be maintained without excessive PEEP. Surfactant treatment before the initiation of high-frequency oscillation improves respiratory stabilization and allows oscillation at lower mean airway pressures.[90,91] CPAP is also now used commonly as a way to decrease the need for mechanical ventilation and perhaps to decrease the incidence and the severity of bronchopulmonary dysplasia.[53] An advantage of CPAP is the avoidance of intubation, but surfactant cannot be given without intubation. Elective intubation followed surfactant treatment and extubation to CPAP can decrease the need for mechanical ventilation in infants with RDS.[92] The biophysical properties of surfactant will improve lung function in the preterm optimally only when the ventilator support adequately maintains FRC and minimizes injury. Unfortunately no consensus has been achieved on how ventilatory strategies can best be matched to the severity of lung disease in individual infants.

SURFACTANT-MATERNAL CORTICOSTEROID INTERACTIONS

Prenatal corticosteroid therapy decreases the incidence of death and the incidence and severity of RDS as well as other complications of prematurity.[93] Prenatal corticosteroids and postnatal surfactant each decrease RDS or death by similar amounts. The question of clinical relevance is how these two effective therapies interact. The two therapies have additive effects on postnatal lung function in animal models (Figure 106-9). After fetal cortisol exposure, preterm lambs treated with surfactant have improved lung compliance, increased lung volumes, and decreased alveolar edema relative to lambs receiving either treatment.[94] Prenatal corticosteroid treatment of preterm rabbits also resulted in an enhanced postnatal response to surfactant. Corticosteroid-exposed rabbits had larger compliance responses to lower doses of surfactant than did control animals.[95] Prenatal corticosteroid treatments also decreased vascular to alveolar protein leak in the preterm lung and changed the surfactant protein content of surfactant. The net effect was to decrease surfactant inhibition. If the only effects of prenatal corticosteroids on the developing lung were to increase

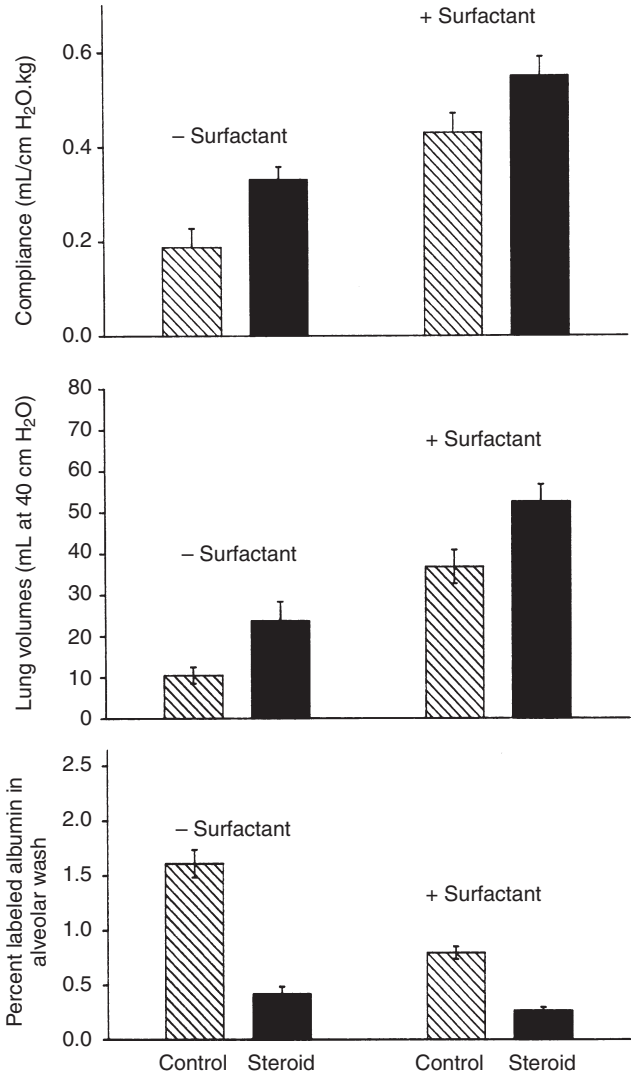

Figure 106-9 Postnatal lung function in preterm lambs randomized to prenatal cortisol and postnatal surfactant treatments. Each treatment increased postnatal compliances, increased lung volumes, and decreased pulmonary edema as measured by the amount of intravascular ^{125}I albumin that was recovered by alveolar wash.The lambs that received both treatments had responses that were approximately the sum of the surfactant and cortisol responses. *(Data from Ikegami M, Polk D, Tabor B, et al: Corticosteroid and thyrotropin-releasing hormone effects on preterm sheep lung function,* J Appl Physiol *70:2268, 1991.)*

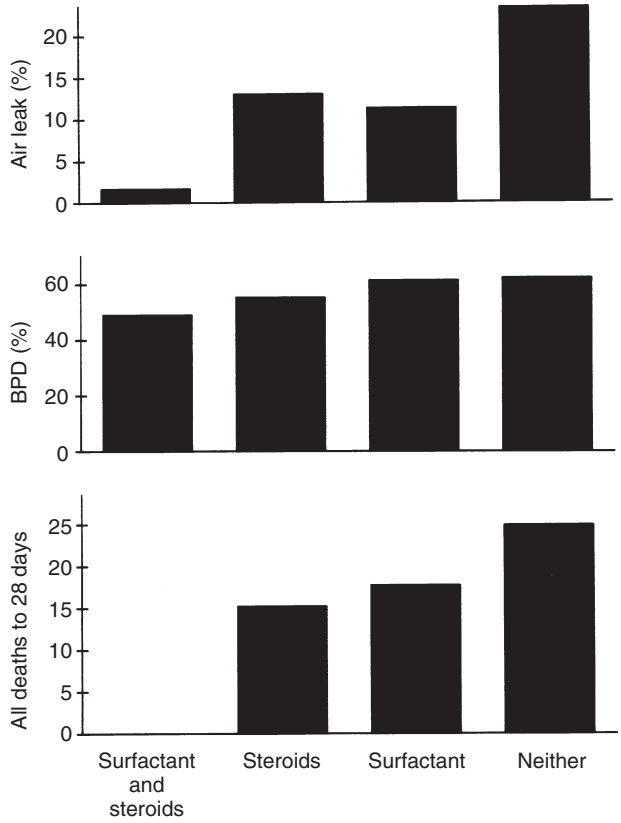

Figure 106-10 Combined effects of prenatal corticosteroids and postnatal surfactant on death, air leaks, and bronchopulmonary dysplasia (BPD) for infants randomized to surfactant or placebo treatment. *(Data from Jobe AH, Mitchell BR, Gunkel JH: Beneficial effects of the combined use of prenatal corticosteroids and postnatal surfactant on preterm infants,* Am J Obstet Gynecol *168:508, 1993.)*

surfactant, prenatal corticosteroids and postnatal surfactant treatments would be acting by the same mechanism. Experiments in developing animals indicate that the primary effects of prenatal corticosteroid treatments are on lung structure, causing increased lung gas volumes that resulted in improved ventilation and better responses to surfactant treatment.

Randomized, controlled trials of the interactions between postnatal surfactant and prenatal corticosteroids are not available because these therapies were developed in different eras. It is no longer ethical to randomize infants to either surfactant or prenatal corticosteroids. Retrospective evaluations of the surfactant trial databases demonstrate a beneficial interaction between prenatal corticosteroids and postnatal surfactant. In one report, treatment with surfactant or prenatal corticosteroids decreased air leak and death similarly (Figure 106-10). However, those infants that received both treatments had the best outcome.[96] Kari and associates[97] also found that infants with RDS randomized to receive maternal corticosteroids had a better response to postnatal surfactant than did infants with RDS not receiving prenatal corticosteroids. The combined use of antenatal corticosteroids and postnatal surfactant are major contributions to the improved outcomes of preterm infants.

THE CHOICE OF SURFACTANTS FOR THE TREATMENT OF RDS

The initial surfactants approved for clinical use by the FDA in 1990 to 1991 were a synthetic surfactant that did not contain surfactant proteins and a surfactant made from bovine lungs. Subsequently other animal lung source surfactants have been approved for clinical use. The clinician who selects a surfactant for clinical use for infants with RDS must sort through claims of product superiority from the pharmaceutical companies. Surfactants have been directly compared in randomized controlled trials, and in general the synthetic surfactants that do not contain surfactant proteins are less effective and are seldom used currently.[16,98] The animal source surfactants do have different characteristics; they are suspended in different volumes, different doses per kilogram are recommended, and treatment techniques vary somewhat. In general, surfactants that contain more of the surfactant proteins SP-B and SP-C have a more rapid onset of action in experimental models. However, in clinical

TABLE 106-2

Comparison of Two Surfactant for Early Treatment of Respiratory Distress Syndrome (BPD)*

	EARLY TREATMENT*	
	Surfactant 1	**Surfactant 2**
Characteristics of Populations		
Number of infants randomized	375	374
Gestational age (weeks, mean)	26.6	26.5
Birth weight (g, mean)	907	910
Age at treatment (minutes)	8	9
Days intubated (median)	3	4
Outcomes		
Died (%)	12	13
BPD; oxygen at 36 weeks (%)	34	33
Severe BPD; ventilator at 36 weeks (%)	4	6
Interventricular hemorrhage; grades III or IV (%)	10	14
Pulmonary interstitial emphysema (%)	5	8
Pneumothorax	7	5

*Data from Bloom BT, Clark RH: Comparison of Infasurf (calfactant) and Survanta (beractant) in the prevention and treatment of respiratory distress syndrome. *Pediatrics* 116:392, 2005.

practice, premature infants with a diagnosis of RDS are much more diverse clinically than experimental animals. The reasons for the preterm delivery (antenatal infection, pre-eclampsia, multiple births, etc.) and prenatal corticosteroids will modulate the severity of RDS and clinical responses to surfactant. Furthermore the ventilation-induced lung injury will change surfactant responses and outcomes. With current management approaches, outcomes other than mild to moderate bronchopulmonary dysplasia are infrequent. In the example listed in Table 106-2, early treatment with two different surfactants resulted in similar and low incidences of complications.[99] Although claims of superiority of one surfactant over another are made, seldom are differences in death, severe bronchopulmonary dysplasia, or neurodevelopmental outcomes compelling. Any differences may result more from management styles than from the different surfactants. Synthetic surfactants that contain the surfactant proteins or peptides that mimic surfactant protein function can be effective in animal models and clinically.[19] New surfactants will need to have cost, ease of use, and safety benefits to replace the effective surfactants that are presently available.

107 Genetics and Physiology of Surfactant Protein Deficiencies

Lawrence M. Nogee

The principal cause of the respiratory distress syndrome (RDS) in prematurely born infants is an inability to produce sufficient amounts of pulmonary surfactant because of immaturity.[1] Surfactant phospholipids in combination with specific proteins help reduce alveolar surface tension at the air-liquid interface and prevent end-expiratory collapse. The risk for RDS is related to gestational age, with more-immature infants being at highest risk, although RDS may also develop in term infants.[2,3] In recent years it has been recognized that RDS in some term infants may result from inherited abnormalities in the genes encoding proteins important in surfactant metabolism. Genetic deficiencies of surfactant protein (SB) B (SP-B) and member A3 of the adenosine triphosphate–binding cassette family (ABCA3) are autosomal recessive causes of neonatal respiratory failure resulting from loss-of-function mutations in the genes encoding these proteins. Mutations in the surfactant protein C (SP-C) gene have been associated with lung disease of more variable onset and severity. Although these conditions are rare, they are associated with significant morbidity and mortality, and it is important that they be recognized in a timely fashion to appropriately counsel families of affected infants. Surfactant protein deficiencies provide insights into the roles of these proteins in normal lung function and surfactant homeostasis and demonstrate how genetic mechanisms may contribute to the development of more common forms of lung disease.

PULMONARY SURFACTANT PROTEINS

The hydrophobic surfactant proteins SP-B and SP-C have important roles in enhancing the surface tension–lowering properties of surfactant phospholipids.[4,5] Both SP-B and SP-C are found in varying amounts in the mammalian-derived surfactant preparations used to treat premature infants with RDS.[4] SP-B and SP-C are both derived from proteolytic processing of precursor proteins that are encoded by single genes on chromosomes 2 and 8 respectively, with the genetic loci referred to as *SFTPB* and *SFTPC*.[6,7] The mature forms of SP-B and SP-C are routed to lamellar bodies, the storage organelles for surfactant in the alveolar type II cell, and secreted along with surfactant phospholipids.[8]

Pulmonary surfactant also contains two larger glycoproteins, surfactant proteins A (SP-A) and D (SP-D), which are members of the collectin family, with both collagenous and carbohydrate-binding lectinlike domains.[9] The principal roles of SP-A and SP-D in the lung are likely related to local host cell defense.[10,11] Both SP-A and SP-D bind to a wide array of microorganisms, facilitate their uptake and/or killing by alveolar macrophages, and also have immunomodulatory functions.[12-15] Genetically engineered SP-A– and SP-D–deficient mice do not develop neonatal respiratory disease but do appear to have an increased susceptibility to infection with a variety of organisms that are relevant to human neonates, including group B streptococcus and respiratory syncytial virus.[16-18] SP-D–deficient mice also develop lung disease as they age, with both emphysema and fibrosis suggesting a role in regulating chronic inflammation, as well as lipoproteinosis suggesting a possible role in surfactant homeostasis.[19-21] Two genes and a pseudogene for SP-A and a single gene for SP-D are located on chromosome 10.[22] Mutations in the SP-A and SP-D genes associated with human lung disease have not yet been reported.

SURFACTANT PROTEIN B DEFICIENCY

Hereditary SP-B deficiency was the first recognized inborn error of surfactant metabolism.[23] The typical presentation is a term infant with symptoms and signs of respiratory distress consistent with surfactant deficiency but without other risk factors for lung disease. The radiographic findings are usually similar to those observed in premature infants with RDS, although this has not been examined systematically.[24,25] Air leak is not uncommon, and affected infants may also have persistent pulmonary hypertension. The lung disease in SP-B–deficient infants is often very severe, and affected infants may require support with extracorporeal membrane oxygenation. However, the initial severity of respiratory disease can be quite variable, and some affected infants have not required mechanical ventilation until well after birth. The factors responsible for the variability in the severity of the initial lung disease in affected infants are unknown, but the lung disease in SP-B deficiency is invariably progressive with escalating need for respiratory support and persistent and worsening alveolar and interstitial infiltrates seen on radiography. An initial positive response to surfactant replacement therapy may be observed but with diminished response to subsequent doses. Glucocorticoids may improve the lung disease in some affected infants, perhaps because they have mutations that allow for some SP-B production.[26] The disease is rapidly fatal, with more than 80% of affected infants dying within 3 months despite aggressive supportive measures.[27,28]

MOLECULAR GENETICS AND EPIDEMIOLOGY

The SP-B gene *(SFTPB)* contains 11 exons, of which the last is untranslated. The gene is transcribed into a 2-kilobase (kb) messenger RNA (mRNA), which directs the synthesis of a 381–amino acid pre-proprotein. The first 23 amino acids comprise a signal peptide that is removed cotranslationally. Mature SP-B corresponds to codons 201 (encoding phenylalanine) to 279 (encoding methionine) of the mRNA and is encoded in exons 6 and 7 of the gene[29] (Figure 107-1). The first and most common mutation identified involves a substitution of three bases (GAA) for one (C) in codon 121 of the SP-B mRNA, located in exon 4 of the SP-B gene, leading to a net insertion of two bases, and is termed 121ins2. The 121ins2 mutation causes a frameshift and introduces a premature codon for the termination of translation in exon 6, thus completely precluding production of mature SP-B; the resulting transcript is also unstable, accounting for the lack of SP-B mRNA.[30]

Many other disease-causing mutations and a sizable deletion in *SFTPB* have subsequently been identified[26,27,31-37] (see Figure 107-1). All are loss-of-function mutations that result in markedly

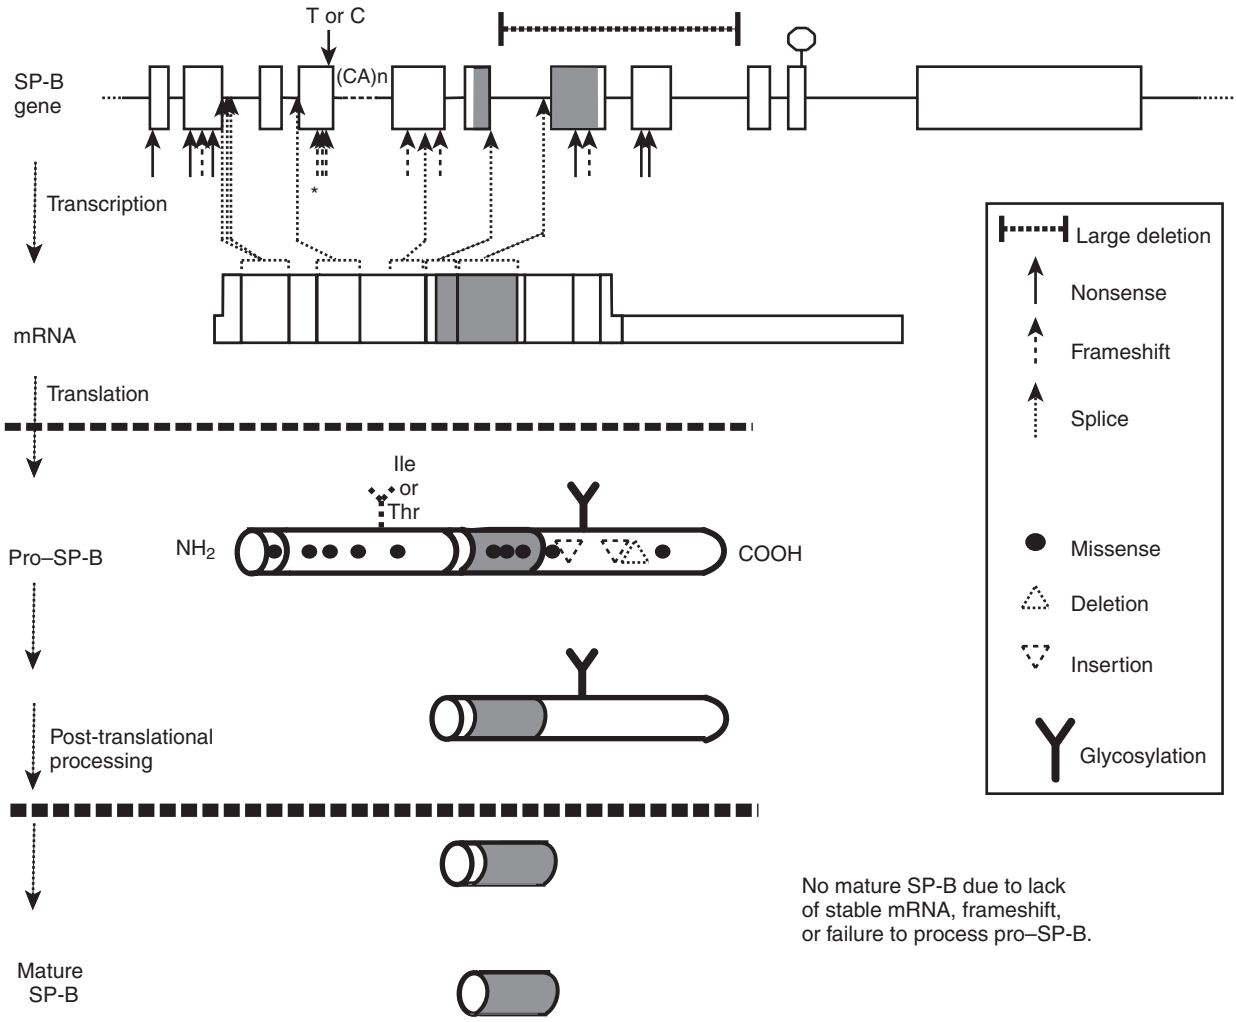

Figure 107-1 SP-B gene, protein synthesis, and postranslational processing of SP-B and mutations in the SP-B gene. The normal transcription, translation, and processing of SP-B are outlined with the SP-B gene at the top. The 11 exons are represented by *boxes,* and the introns are represented by *lines*. The locations of a coding polymorphism resulting in either isoleucine *(Ile)* or threonine *(Thr)* in exon 4 and variable nucleotide repeat sequences (CA_n) in intron IV are indicated. Untranslated regions of the mRNA are indicated by the *narrower rectangles*. Regions corresponding to mature SP-B are *shaded. Arrows* indicate the locations of known nonsense and frameshift mutations in the SP-B gene, which result in absent SP-B mRNA and protein. The location of the 121ins2 mutation is indicated with an *asterisk*. Nonsense and frameshift mutations often result in an unstable mRNA, interfering with SP-B production at a pretranslational level *(thin dashed line).* Mutations that interfere with normal SP-B mRNA splicing are indicated by *arrows* pointing to the location in the gene and indicating the affected exon on the mRNA. Missense mutations or in-frame deletions or insertions, which are indicated by their location in the SP-B proprotein, interfere with the processing of pro–SP-B to mature SP-B as indicated by the *thick dashed line.*

reduced or absent amounts of mature SP-B. Some mutations allow production of pro–SP-B, but its processing to mature SP-B is hindered, resulting in the lack of mature SP-B in lung tissue and tracheal secretions of affected infants.[27] Mutations on both *SFTPB* alleles in affected infants are consistent with the autosomal recessive inheritance pattern.

Pro–SP-B contains three tandem domains with structural homology to the saposins, lysosomal proteins that bind lipids and activate lysosomal hydrolases.[38] Mature SP-B corresponds to the middle domain of the proprotein,[39] and mutations in this region could theoretically result in the production of an SP-B protein with abnormal surface properties. However, a synthetic peptide containing one such mutation (R236C) was able to augment surface tension lowering normally in an in vitro system,[40] suggesting that the disease in infants with this mutation also resulted from impaired processing of pro–SP-B containing the mutation. Mature SP-B forms higher-order oligomers dependent on sulfhydryl-bond formation and ionic interactions.[41,42] Mutations that prevent oligomerization of SP-B could also in theory result in an SP-B with decreased activity, and possibly even act in a dominant negative fashion to interfere with SP-B from a normal allele. Such a mechanism for SP-B deficiency has not been recognized to date.

The exact incidence of SP-B deficiency is unknown. The number of reported cases is relatively small,* and population-based studies to determine the incidence of disease have not been performed. A carrier frequency of approximately 1 in 1000 individuals has been reported for the 121ins2 mutation.[49,50] Because this mutation has accounted for approximately two thirds of the mutant alleles identified, this implies that the frequency of

*References 26, 27, 31, 33-36, 43-48.

any SP-B gene mutation in the population is approximately 1 in 600. Because SP-B deficiency is an autosomal recessive disorder, if both parents have a mutation they have a 25% chance of having an affected child. The predicted incidence of disease would thus be approximately 1 in 1.4 million (600 × 600 × 4), indicating that SP-B deficiency is a very rare disease. This is probably an underestimate, because most studies to date have focused on children with either the 121ins2 mutation and/or very severe lung disease, whereas children with mutations resulting in milder disease may have been underrecognized.

The 121ins2 mutation has been found mainly in individuals of Northern European descent and likely results from a common ancestral origin ("founder effect").[51] Two other SP-B gene mutations (122delC, 122delT) have been identified within five nucleotides of the site of the common mutation, and a single nucleotide polymorphism is located within 30 base pairs (bp) of the site of the 121ins2 mutation, suggesting that this region of the SP-B gene could also be a "hot spot" for mutation.[33,47] Clusters of mutations have also been identified in exons 2 and 9. Other mutations that have been observed in more than one unrelated individual include the 122delT mutation in individuals of Middle Eastern descent, the 1043ins3 mutation in Asians, the R295X mutation in individuals of Hispanic descent, and a splicing mutation (c.479G>T) in French-Canadians. The frequencies of these mutations and incidence of the disease in these populations have not been determined.

Rare children with *SFTPB* mutations and a relatively milder phenotype have been identified. The mutations in these children allow for the production of some SP-B and thus result in "partial deficiency."[26,31] Whether the small amount of mature SP-B (approximately 8%-10% of control levels) or some retained function of pro–SP-B accounts for the milder phenotype is unclear. These observations suggest that there is a critical level of SP-B needed for normal lung function. This hypothesis is further supported by studies in which mice genetically engineered so that their production of SP-B could be shut off developed respiratory failure when their SP-B levels fell to 20% to 30% of that of SP-B levels observed in controls.[52]

SP-B production increases with advancing gestational age and is down-regulated with inflammation.[53-55] Lung disease could develop in individuals with loss-of-function mutations on one *SFTPB* allele (haploinsufficiency) if other factors, such as prematurity or infection, further delay or reduce SP-B expression below a critical level. Severe neonatal lung disease was observed in a child who had undetectable amounts of SP-B in bronchoalveolar lavage fluid (BALF) during his acute illness and an *SFTPB* mutation on only one allele with an apparently normal second *SFTPB* allele. The child's lung disease gradually improved in association with increased amounts of SP-B detected in subsequent BALF samples, suggesting that the mutation on one allele contributed to transient SP-B deficiency.[32] In addition, genetically engineered mice heterozygous for a null *sftpb* allele have half normal levels of SP-B protein and do not have neonatal respiratory disease but were more susceptible to pulmonary oxygen toxicity than their wild-type littermates.[56-58] In contrast to these observations, pulmonary function test results in seven human adult carriers for the 121ins2 mutations did not differ from those in controls, nor do the parents of affected infants generally have a history of neonatal lung disease.[59] Larger, population-based studies will be necessary to determine whether carrying one abnormal *SFTPB* allele is a risk factor for lung disease.

OTHER SURFACTANT PROTEIN B GENE VARIANTS AND LUNG DISEASE

Although rare, SP-B deficiency demonstrates the essential role of SP-B in normal surfactant metabolism. Given this critical role, *SFTPB* is a reasonable candidate gene to account for possible genetic variation observed in more common lung diseases such as RDS. A number of variants in the *SFTPB* have been identified that could potentially affect SP-B expression. A single nucleotide polymorphism has been identified in codon 131, which encodes either threonine (Thr) or isoleucine (Ile).[27,29,47,60,61] The 131Thr allele, but not 131Ile, has a potential additional recognition site for N-linked glycosylation.[62] Whether glycosylation at this site significantly affects pro–SP-B structure or its routing through the cell is unknown. However, the 131Thr allele was associated with an increased risk for acute RDS in adults and an increased risk for neonatal RDS in premature infants.[63-65] *SFTPB* variants that result in small differences in SP-B function or metabolism could thus be important in the pathogenesis of other lung diseases. Multiple other single nucleotide polymorphisms have also been identified in both coding and noncoding regions of *SFTPB*, including one in the promoter region that affects gene transcription and protein levels.[47,63,66-69] Exon 8 contains an alternative splice site, the utilization of which would result in an SP-B proprotein with four amino acids deleted from the carboxyl terminus domain.[48,70] This splice variant has been detected in normal human lung tissue and in increased in amounts in lung tissue from patients with various lung diseases.[70] It is not known whether this alternative transcript is translated and whether the resulting proprotein would be processed normally. Further studies are needed to address these questions, as well as whether the increase in the use of the alternative splice site is a consequence of or contributes to lung disease.

The fourth intron of *SFTPB* also contains a variable nucleotide tandem repeat sequence, and allelic variants containing different numbers of repeats have been characterized.[71,72] An increased risk for RDS in infants with alleles that differ from the predominant allele alone or in association with polymorphic variants in the SP-A gene loci has been observed in some studies.[64,71,73-76] The mechanisms by which these intron IV allelic variants would affect RDS risk are unclear because these variants have not been shown to directly affect SP-B expression or function, although they may be related to alterations in mRNA splicing or alterations in transcription factor binding.[77,78] They could also be in linkage with other variations in the SP-B gene with direct functional importance.[79]

Surfactant isolated from BALF of SP-B–deficient infants does not lower surface tension effectively, which is not surprising given the apparent importance of SP-B in surfactant function.[30,80-82] Tubular myelin, the latticelike extracellular form of surfactant the formation of which requires SP-B (as well as SP-A and calcium), is also not found in lung tissue of affected infants.[83,84] However, additional disturbances in surfactant metabolism also contribute to the pathophysiology of the lung disease in SP-B–deficient infants. These include abnormal surfactant phospholipid composition, particularly a marked reduction in phosphatidylglycerol content, abnormal lamellar body formation, and an apparent block in posttranslation processing of the SP-C precursor protein (pro–SP-C).[30,85,86] These latter changes result primarily from the loss of SP-B and not from treatments used to sustain SP-B–deficient infants, because abnormal lamellar body formation and impaired pro–SP-C processing were also observed in the lungs of genetically engineered mice that were unable to produce SP-B and that died within minutes of birth because of respiratory insufficiency.[87,88] These observations indicate a fundamental intracellular role for SP-B (or pro–SP-B) in surfactant metabolism in addition to its extracellular role in lowering surface tension.

Lung tissue from SP-B–deficient infants contains proteins that are immunoreactive with antisera directed against the amino-terminal domain of pro–SP-C, intermediate in size between pro–SP-C and mature SP-C, and which contain amino-terminal epitopes by protein sequence analysis.[86,89] These observations are consistent with a block in the final processing steps of pro–SP-C to

mature SP-C. This would result in a relative deficiency of mature SP-C, further contributing to surfactant dysfunction.[90] These peptides are found in BALF from affected infants, and intense immunostaining of intraalveolar material using antisera directed against pro–SP-C is observed in lung tissue from SP-B–deficient infants, indicating that they are secreted. However, they are not very surface active and likely to inhibit surfactant function. The precise mechanisms underlying this block in SP-C processing are unknown. Ultrastructural examination of the lungs of SP-B–deficient infants reveals a lack of normally formed lamellar bodies, the intracellular storage organelles of surfactant, with abundant, abnormal-appearing lipid vesicles, indicating that intracellular expression of SP-B (or pro–SPB) is needed for normal lamellar body biogenesis. The final steps in processing of pro–SP-C to mature SP-C occur late in the secretory pathway, either in lamellar bodies or in their immediate precursors.[91-94] Thus the inability to form these organelles because of the lack of SP-B results in incompletely processed pro–SP-C, as well as inadequate packaging of surfactant components for secretion. SP-B also facilitates membrane fusion, and an explanation for these observations is that without SP-B, transport vesicles containing incompletely processed pro–SP-C are unable to fuse with developing lamellar bodies, thus exposing the amino-terminal epitopes of pro–SP-C to the necessary processing enzymes.[92,95]

Other mechanisms that impair SP-B production, such as mutations in genes for the enzymes needed for the proper processing of pro–SP-B to mature SP-B, or accelerate SP-B catabolism, could result in deficiency of SP-B and similar lung disease. Fatal neonatal lung disease inherited in an autosomal recessive fashion, associated with reduced or undetectable amounts of SP-B in the BALF or lung tissue of affected children, but without *SFTPB* mutations identified to account for the lack of SP-B, has been reported.[67] Many, but not all, of these cases were due to mutations in the gene encoding ABCA3, which may also interfere with SP-B metabolism (discussed in more detail later). A comprehensive approach to the evaluation of children with severe neonatal lung disease of unclear etiology, including ultrastructural examination and collection of frozen, as well as fixed, tissue from biopsy and autopsy studies, will be essential to elucidating novel mechanisms of lung disease.

ADENOSINE TRIPHOSPHATE–BINDING CASSETTE FAMILY A3 DEFICIENCY

ABCA3 is a 1704–amino acid transmembrane protein that is highly expressed in alveolar type II cells where it is localized to the limiting membrane of lamellar bodies.[96-99] It is a member of the adenosine triphosphate–binding cassette family of proteins, which hydrolyze adenosine triphosphate to translocate a wide variety of substrates across biologic membranes.[100] The gene encoding ABCA3 *(ABCA3)* is large, spanning some 80,000 bases on the short arm of chromosome 16, and contains 33 exons.[101] ABCA3 contains 12 membrane-spanning domains and two nucleotide-binding domains (Figure 107-2). Although the function of ABCA3 is unknown, its localization in type II cells and the findings that other members of the ABCA

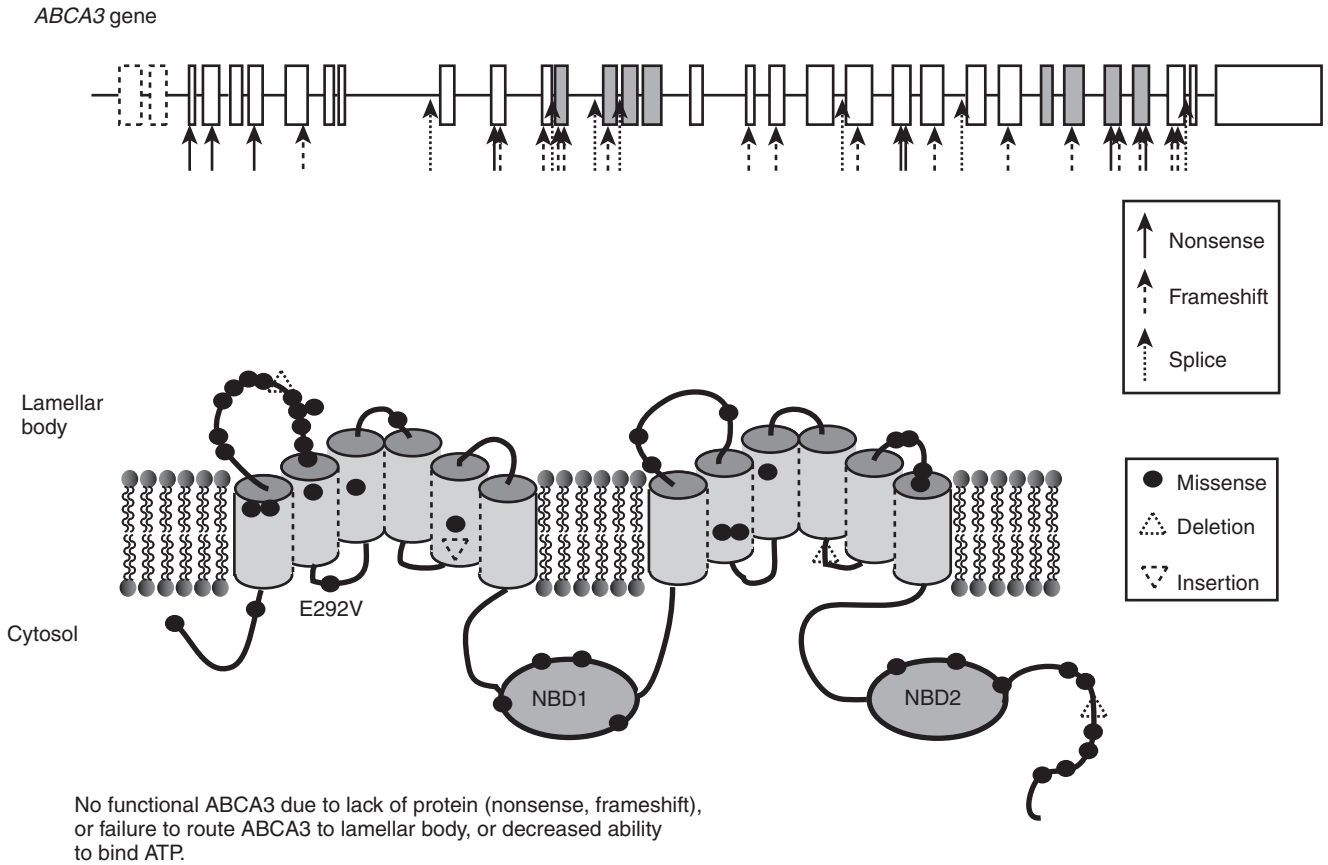

Figure 107-2 ABCA3 gene, predicted protein structure, and location of mutations. The 30 coding exons of the *ABCA3* gene are indicated by *solid boxes* and two 5′ untranslated exons indicated by *dashed boxes.* The locations of known nonsense, frameshift, and splice-site mutations in the gene are indicated by *arrows.* The structure of the ABCA3 protein is predicted by homology with other ABCA proteins, with 12 membrane-spanning domains *(cylinders)* and two nucleotide-binding domains *(NBD)* indicated by *ellipses.* The locations of known missense mutations or small in-frame insertions or deletions are indicated on the protein structure.

subfamily transport lipids are consistent with a role for ABCA3 in importing lipids needed for surfactant function into lamellar bodies.[96-98] These properties also suggested ABCA3 as a possible candidate gene for genetic surfactant deficiency.

ABCA3 deficiency was recognized as a cause of lung disease when *ABCA3* mutations were found in 16 of 21 term newborns with severe lung disease who all had clinical and radiographic features of surfactant deficiency and no other cause for their lung disease identified.[102] Both the clinical and lung pathologic features of these infants were similar to those of infants with SP-B deficiency. Ultrastructural examination of lung tissue from infants with *ABCA3* mutations demonstrated absence of normal lamellar bodies in their alveolar type II cells, which instead contained many small dense organelles with very tightly packed membranes and eccentrically placed electron-dense inclusions, giving them a "fried egg" appearance.[103] These findings thus supported a role for ABCA3 in both surfactant metabolism and lamellar body biogenesis.

Subsequent studies confirmed and extended these findings. *ABCA3* mutations were identified in 8 of 12 infants who had undergone lung transplantation within the first year of life for respiratory failure of unknown cause that had its onset in the neonatal period. Surfactant isolated from BALF of these children had significantly reduced phosphatidylcholine content and a markedly reduced ability to lower surface tension.[80] In another series of infants with fatal neonatal lung disease of unknown etiology, *ABCA3* mutations were found in 8 of 14 patients studied, and decreased or absent ABCA3 protein was demonstrated in lung tissue of patients with mutations. SP-B and SP-C were also decreased in amount in BALF from some patients, which may have further contributed to impaired surfactant function.[104] In vitro studies support both a role for ABCA3 in surfactant lipid metabolism and that the mutations observed in patients with fatal lung disease were functionally significant. ABCA3 containing missense mutations that had been identified in patients with lung disease were either abnormally trafficked when expressed in cells in tissue culture, had reduced binding of adenosine triphosphate, or resulted in reduced uptake of lipids into lysosomes compared with wild-type ABCA3.[105,106] Genetically engineered mice homozygous for null ABCA3 alleles have been generated, and these animals have a phenotype identical to that of human infants with loss-of-function *ABCA3* mutations, with perinatal lethal respiratory disease, abnormal lamellar body formation, and abnormal lung phospholipid profiles.[107-110] Collectively these observations indicate that loss-of-function mutations in *ABCA3* result in altered surfactant lipid metabolism and impaired lamellar body biogenesis, although the exact substrates transported by ABCA3 remain to be determined.

ABCA3-deficient infants often present with severe neonatal lung disease similar to that observed in SP-B–deficient infants.[80,102,104,111,112] However, infants with *ABCA3* mutations on both alleles and either transient or even no apparent neonatal lung disease have been observed, and long-term survival with chronic interstitial lung disease (ILD) is possible.[113-116] No predominant *ABCA3* mutation has been identified, and a wide range of different mutations, including nonsense, frameshift, splice-site, and missense mutations scattered throughout the gene have been reported, indicating considerable allelic heterogeneity.[80,102,104,112-118] The most frequently identified *ABCA3* mutation consists of a substitution of valine for glutamine in codon 292 (E292V), and the population frequency of this mutation was approximately 1 in 300 individuals depending on ethnic background.[119] Because *ABCA3* E292V has been found mainly in patients with relatively milder disease, genotype may be important in predicting phenotype, although additional studies are needed to evaluate this possibility.[113]

The overall frequency of *ABCA3* mutations in the general population and the incidence and prevalence of lung disease caused by ABCA3 deficiency are currently unknown. It is likely that the disease is rare, because death resulting from unexplained neonatal respiratory failure is unusual, and the types of pediatric ILD associated with *ABCA3* mutations are also unusual.[120,121] The high ascertainment rate for *ABCA3* mutations in studies that have examined the cause of unexplained severe lung disease in neonates or young infants suggests that *ABCA3* mutations are a more frequent cause of this phenotype than SP-B deficiency.[112] As with SP-B deficiency, the finding of patients with a milder phenotype suggests that there is a critical level of ABCA3 expression needed for normal lung function, and *ABCA3* genetic variants could thus contribute to the pathogenesis of other lung diseases, including RDS in premature infants.[119,122]

SFTPC MUTATIONS AND LUNG DISEASE

SP-C is a 35–amino acid extremely hydrophobic protein that also enhances the surface tension–lowering properties of surfactant phospholipids. SP-C is encoded by a small (<3.5 kb) gene *(SFTPC)* on human chromosome 8 that contains six exons, the last of which is untranslated. The gene directs the synthesis of a proprotein (pro–SP-C) of either 191 or 197 amino acids, depending on alternative splicing at the beginning of the fifth exon. SP-C is extensively posttranslationally modified, including the palmitoylation of cysteine residues at positions 5 and 6 of mature SP-C, such that it is a proteolipid.[6,123] Pro–SP-C is proteolytically processed at both the amino and carboxyl termini to yield the 35–amino acid mature SP-C that is secreted into the airspaces. Pro–SP-C does not contain a signal peptide, and the domain corresponding to mature SP-C is thought to anchor it in the membrane such that pro–SP-C is an integral membrane protein (Figure 107-3). Because of its importance in surfactant function, it was anticipated that SP-C deficiency caused by loss-of-function mutations could also result in neonatal lung disease resembling RDS. However, no patients with such mutations and RDS have been reported to date. Moreover, genetically engineered mice with an inability to produce SP-C do not develop neonatal lung disease but instead develop ILD and emphysema with aging (depending on their genetic background).[124,125] Thus SP-C does not appear to be essential for normal neonatal lung function.

Mutations in *SFTPC* cause human lung disease of variable severity and onset of symptoms, with some patients remaining free of symptoms well into adulthood.[90,126-133] Severe and even fatal neonatal disease has been observed, although the majority of reported patients with *SFTPC* mutations have not had neonatal lung disease, and *SFTPC* mutations are an unusual cause of neonatal respiratory failure.[102,134] The most commonly reported clinical presentation is that of ILD in young infants. Clinical symptoms have included tachypnea, retractions, and hypoxemia in room air; failure to thrive and digital clubbing have also been observed in affected infants. The mechanisms responsible for the variability in disease severity remain largely unknown, although heterozygosity for an *ABCA3* mutation may exacerbate the severity of the pulmonary symptoms.[135]

As opposed to SP-B and ABCA3 deficiencies where loss-of-function mutations on both alleles result in loss of protein expression or function and lung disease is inherited in a recessive fashion, the lung disease caused by *SFTPC* mutations generally results from a mutation on only one *SFTPC* allele; lung disease is transmitted as an autosomal dominant with a high degree of penetrance in familial cases, or sporadically caused by a de novo mutation.[127,128,130,132] All identified mutations are predicted to result in an abnormal form of pro–SP-C, including missense mutations, in-frame insertions or deletions, or distal frameshift mutations that are likely associated with stable transcripts. Nonsense mutations, early frameshifts (likely to be associated with

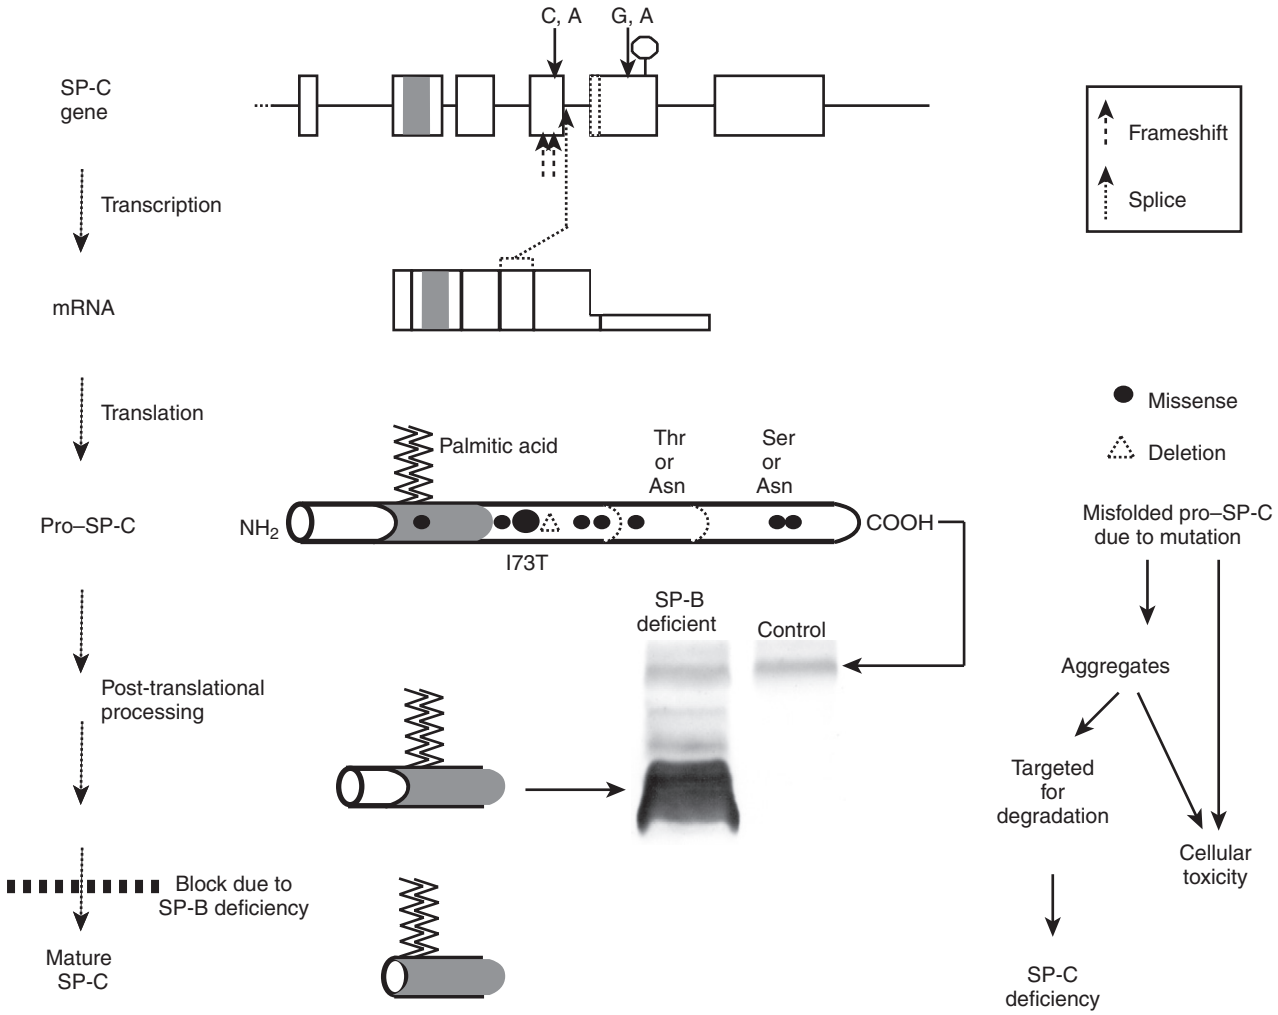

Figure 107-3 SP-C gene, processing, and effects of mutations. The normal transcription, translation, and processing of SP-C are outlined with the SP-C gene at the top. The six exons are represented by *boxes,* and the introns are represented by *lines.* The locations of two coding polymorphisms resulting in either threonine *(Thr)* or asparagine *(Asn)* in exon 4 and serine *(Ser)* or asparagine *(Asn)* in exon 5 are indicated. The normal processing of pro–SP-C to mature SP-C is shown on the *left,* with the portion corresponding to mature SP-C *shaded.* A *dashed line* indicates the site of the block in pro–SP-C processing that occurs in the absence of SP-B. The accumulation of immunoreactive peptides in the lung tissue from an SP-B–deficient infant are shown in the Western blot *(inset)* and are not present in lung tissue from a control infant. *Arrows* indicate the locations of frameshift or splicing mutations in the SP-C gene, and the locations of missense mutations or an in-frame deletion are indicated on the proprotein. SP-C gene mutations result in an abnormal form of pro–SP-C, with SP-C deficiency and/or toxicity resulting from misfolded pro–SP-C caused by the mutations.

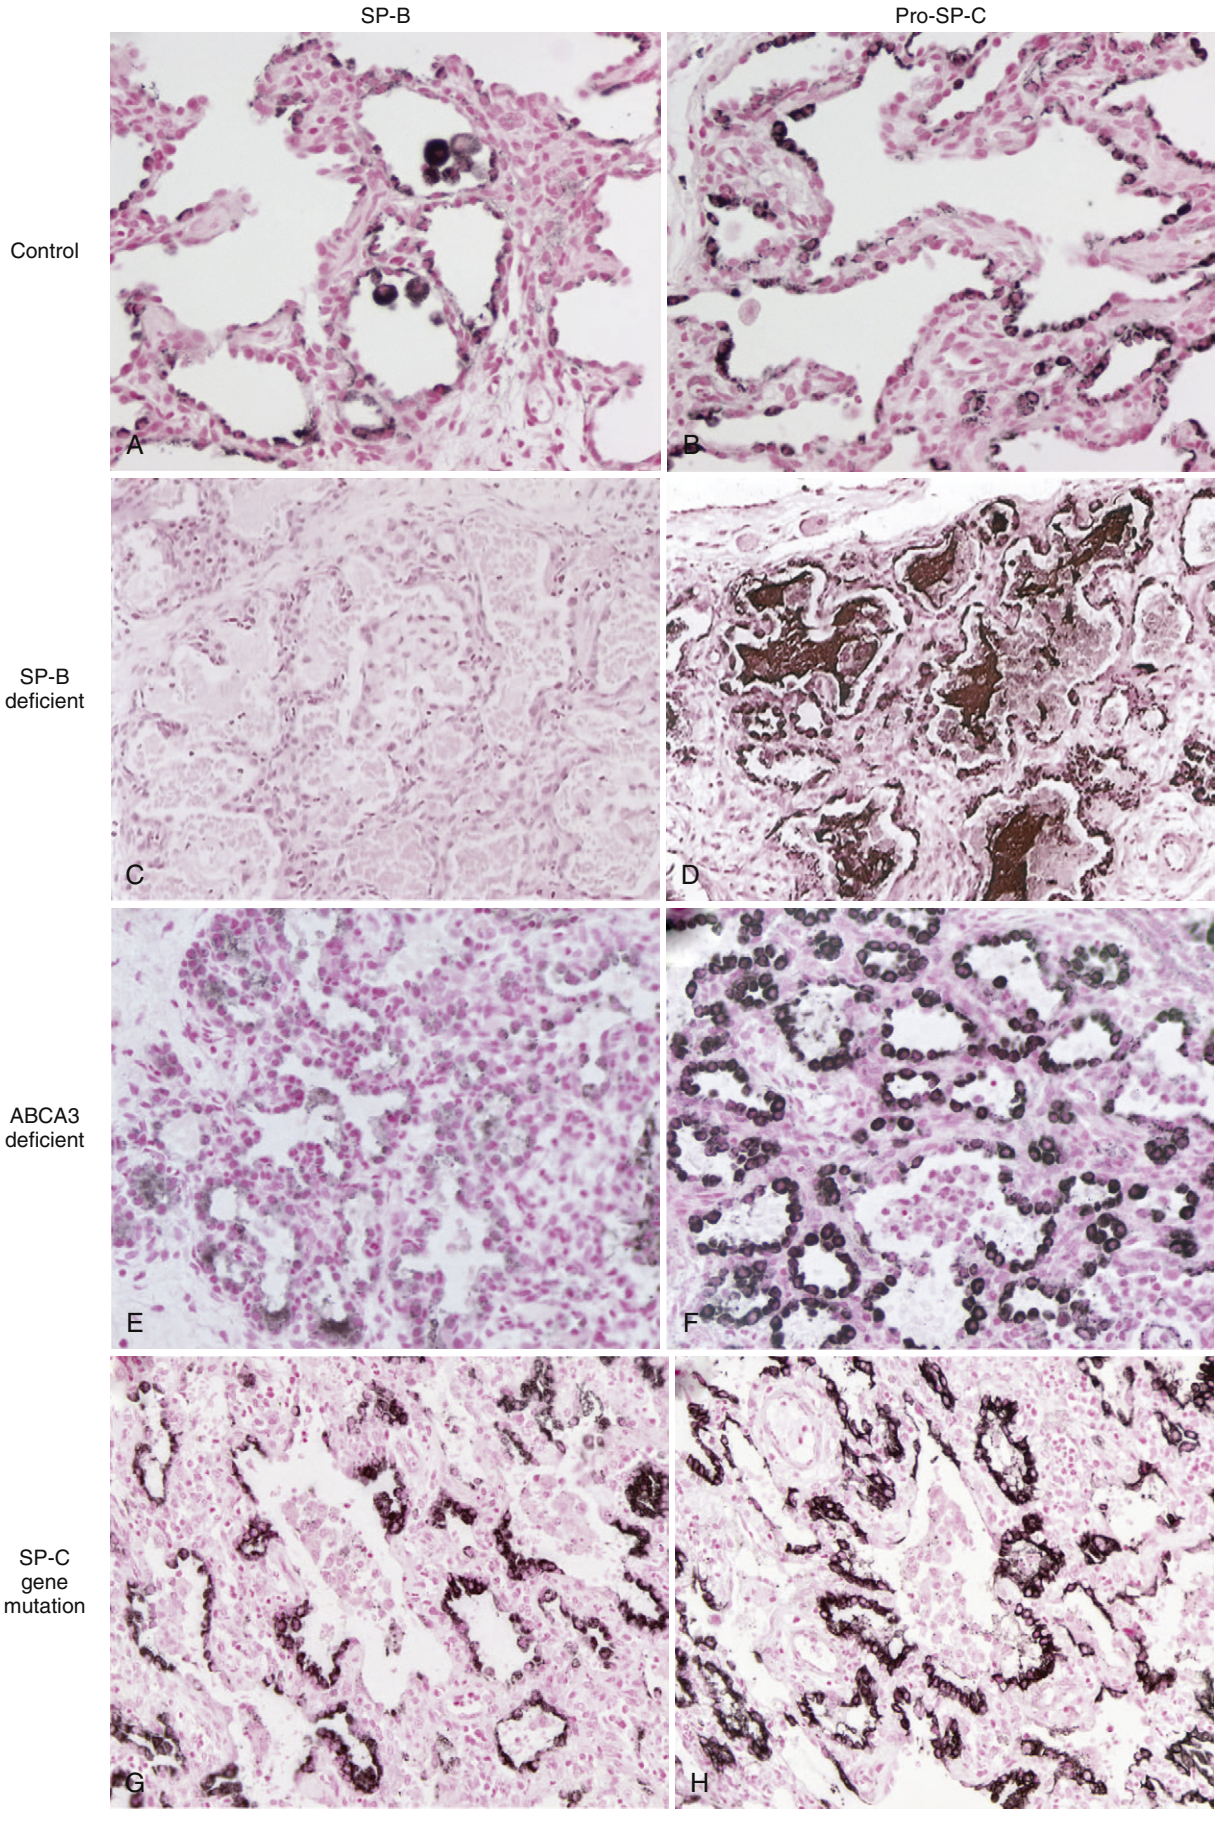
unstable SP-C transcripts), or major deletions that would preclude SP-C production have not been reported, suggesting that haploinsufficiency is unlikely to be the mechanism for lung disease. One specific *SFTPC* mutation resulting in the substitution of threonine for isoleucine in codon 73 (I73T) has been found in multiple unrelated families and associated with both familial and sporadic lung disease.[126,128,130] The finding of a common mutation may be useful in population-based studies to determine the incidence and prevalence of lung disease associated with *SFTPC* mutations, which are currently unknown.

SFTPC mutations could result in lung disease either by causing SP-C deficiency because of a dominant-negative mechanism, or through a toxic gain-of-function mechanism because of the presence of abnormal pro–SP-C within alveolar type II cells. Pro–SP-C containing a mutation (Δexon4) identified in human subjects with ILD was rapidly degraded in vitro in the absence of inhibitors of proteosome-mediated degradation.[136] Pro–SP-C self-associates in the secretory pathway, and mutated pro–SP-C that is targeted for degradation could interact with normal pro–SP-C, leading to its degradation as well, and thus SP-C deficiency.[137,138] Decreased expression of both pro–SP-C and mature SP-C were observed in patients with the *SFTPC* Δexon4 mutation, supporting such a mechanism.[90] Mature SP-C was also markedly reduced in a patient with a different *SFTPC* mutation who had normal to increased pro–SP-C expression by immunohistochemical analysis[132] but was present in BALF from a child with yet a different *SFTPC* mutation,[129] indicating that different mutations may cause lung disease through different mechanisms. Precisely how deficiency of mature SP-C eventually results in ILD is unknown.

The carboxyl-terminal domain of pro–SP-C, in which the majority of known pathogenic mutations are located, has homology with other proteins in what has been termed the Brichos family (membrane proteins in which abnormal aggregates have been implicated in the pathophysiology of familial dementia and neoplasia).[139] The Brichos domain of pro–SP-C



may be important in binding to and stabilizing the mature SP-C domain in a conformation that is less prone to forming amyloid-like aggregates.[140,141] *SFTPC* mutations may induce misfolding of pro–SP-C with exposure of hydrophobic epitopes, resulting in accumulation of misfolded protein aggregates early in the secretory pathway. Therefore lung disease caused by *SFTPC* mutations could represent a conformational disease.[142] The presence of misfolded protein in the endoplasmic reticulum could result in endoplasmic reticulum stress, triggering the unfolded protein response, resulting in up-regulation of chaperone proteins and other downstream pathways, eventually leading to apoptosis and/or inflammation. In support of such a toxic gain-of-function mechanism, robust rather than reduced or absent staining for pro–SP-C has been observed in the lung tissue of some patients with *SFTPC* mutations,[127-130,132] and aggregates of pro–SP-C caused by mutations have been observed both in vitro and in lung tissue from an infants with *SFTPC* mutations.[129,132,143] The potential toxicity of mutated SP-C to lung epithelial cells has been demonstrated in vitro[127,144,145] and by the observations that transgenic animals that overexpressed either mature SP-C without the flanking domains of the proprotein or the *SFTPC* exon 4 mutation died of a marked disruption of lung development.[136,146] This impairment of normal lung development associated with high levels of SP-C expression in utero also suggests a potential mechanism whereby some *SFTPC* mutations could result in severe neonatal lung disease. Finally, another mechanism for disease has been proposed in which abnormal routing of mutated pro–SP-C leads to accumulation within the endosomal pathway, inhibiting recycling of surfactant components.[129]

LUNG PATHOLOGIC FINDINGS OF INBORN ERRORS OF SURFACTANT METABOLISM

The histopathologic findings in the lungs of infants with mutations in *SFTPB, ABCA3,* or *SFTPC* are similar and overlapping. Prominent findings in all three disorders include alveolar type II cell hyperplasia, prominent collections of foamy macrophages in the airspaces, and interstitial thickening. Cholesterol clefts may be found in airspaces or within cells; nonspecific findings including diffuse alveolar damage and interstitial fibrosis may also be present. Variable amounts of granular eosinophilic material within entrapped foamy macrophages may be seen in distal airspaces. This finding may be so prominent that the pathologic findings are labeled as pulmonary alveolar proteinosis because of the similarity to the findings in adults with that disorder, where there is accumulation of surfactant phospholipids and proteins in the airspaces. Other diagnostic terms that were also originally used to describe lung pathologic conditions in adults have been applied to children with these disorders, including desquamative interstitial pneumonitis and nonspecific interstitial pneumonia. Although these pathologic features were similar to those seen in adults, the clinical features of children with these lung diseases differed from those in adults, often with the onset of disease in infancy and a more severe course, associated with a positive family history.[147,148] The term "congenital alveolar proteinosis" was used to distinguish neonatal onset and fatal disease in infants from the adult disorder in which the onset and progression of disease are more gradual.[149-152] SP-B deficiency was the cause for lung disease in one of the kindreds reported in one of these studies and ABCA3 deficiency in the other (Nogee and colleagues,[48] Moulton and colleagues,[151] and unpublished data). Findings of pulmonary alveolar proteinosis have also been reported in association with *SFTPC* mutations.[129,130] Chronic pneumonitis of infancy is a more recently described condition specific to young infants that encompasses the pathologic findings observed in children with mutations in *SFTPB*, *ABCA3,* or *SFTPC* but is also nonspecific because mutations in any one of the three genes have been reported in children with this disease.[27,102,128,153] Recently the term "surfactant dysfunction mutation" has been proposed to encompass the pathologic findings related to all of these conditions,[154,155] reflecting the nonspecific nature of the pathology at the level of light microscopy.

Specific immunostaining for surfactant proteins may be helpful in distinguishing between SP-B deficiency and other genetic mechanisms, although such analyses are currently confined to research laboratories (Figure 107-4). Immunostaining can be performed on archived lung specimens, allowing for retrospective diagnosis in children who died years earlier. In SP-B deficiency, staining for mature SP-B is usually absent or markedly reduced; staining for pro–SP-B may be also absent depending on the responsible *SFTPB* mutation.[27] In contrast, robust staining for pro–SP-C is observed in both the alveolar epithelium and extracellular material. The extracellular pro–SP-C–positive staining is likely due to the secreted, incompletely processed pro–SP-C and has correlated very well with the finding of mutations in *SFTPB*.[27] Surfactant protein immunostaining patterns associated with *SFTPC* or *ABCA3* mutations are less specific. Reduced epithelial staining for pro–SP-C has been seen in some patients with *SFTPC* mutations but may be robust in others, with pro–SP-C staining confined to the alveolar epithelium.[90,128] Reduced staining for mature SP-B had also been observed in some, but not all, children with *ABCA3* mutations.[104,113] Pro–SP-B staining in these children is generally robust, as is staining for pro–SP-C, which is confined to the alveolar epithelium, thereby distinguishing it from SP-B deficiency. Antibodies to ABCA3 have recently been generated, and in one study ABCA3 mutations were identified in all children with neonatal respiratory failure in whom ABCA3 expression was not detected or was markedly reduced compared with controls, which included children with *SFTPB* or *SFTPC* mutations.[104] These findings suggest that specific immunostaining for ABCA3 will be helpful in discriminating between these disorders. However, because some *ABCA3* missense mutations result in protein that is appropriately routed but not functional,[105,106] it is likely that positive staining for ABCA3 will not be able to exclude the disease.

Figure 107-4 Immunohistochemical staining of lung tissue. Lung tissue was immunostained for mature SP-B *(left)* and pro–SP-C *(right).* Lung tissue from a control infant who died of chronic lung disease demonstrates positive staining for both mature SP-B **(A)** and pro–SP-C **(B)** observed in alveolar epithelial cells *(top row).* In contrast, absent staining for mature SP-B **(C)** but intense staining for pro–SP-C in the alveolar epithelium and extracellular proteinaceous material **(D)** is observed in lung tissue from an SP-B–deficient infant who was homozygous for the 121ins2 mutation *(second row).* Staining for mature SP-B is also markedly reduced **(E)** in lung tissue from a patient who was a compound heterozygote for two ABCA3 mutations, with robust staining for pro–SP-C that is confined to the alveolar epithelium **(F).** Staining for mature SP-B **(G)** and for pro–SP-C **(H)** is robust in tissue from a patient with the most frequently found SP-C gene mutation (I73T) on one allele *(bottom). EVALUATION OF INFANTS WITH SUSPECTED INBORN ERRORS OF SURFACTANT METABOLISM

Clinical features that distinguish SP-B or ABCA3 deficiency from reversible causes of neonatal respiratory failure have not been identified. Term infants with respiratory distress that is not explained by history and does not improve after the first week of life, or infants who died of lung disease of unclear etiology should be suspected of having one of these disorders. Although a family history of lung disease may prompt suspicion for a genetic disorder, a positive family history is often absent given the autosomal recessive inheritance patterns. The differential diagnosis includes RDS, transient tachypnea of the newborn, pneumonia (both bacterial and viral), persistent pulmonary hypertension, pulmonary hypoplasia, unrecognized cardiac malformations, and developmental anomalies of the lung such as alveolar capillary dysplasia. Because the initial lung disease in some children with *ABCA3* mutations may be very mild, these children may be discharged from the neonatal intensive care unit and be seen later with signs and symptoms of persistent diffuse lung disease without a clear cause.

Routine laboratory findings in SP-B– and ABCA3–deficient infants are nonspecific. Tracheal aspirate samples for lecithin-sphingomyelin ratios have been reported as low and within the normal range but have not been systematically evaluated because such testing is not routinely done in term infants.[46,151] Analysis of tracheal aspirate or BALF samples for surfactant protein levels remains a research tool but is unlikely to provide a definitive result. SP-B levels are usually undetectable in SP-B–deficient infants but may also be undetectable or very low in children with ABCA3 deficiency.[27,104] Children with diffuse alveolar injury and more global surfactant deficiency not caused by genetic mechanisms may also have undetectable or very low levels of SP-B. Conversely, the presence of normal levels of SP-B in tracheal aspirate or BALF does not exclude the possibility of ABCA3 deficiency.[80]

A definitive diagnosis may be made through genetic testing. Such testing is noninvasive, and sequenced-based analysis of all of the coding exons of *SFTPB*, *ABCA3*, and *SFTPC* is available through certified diagnostic laboratories. A finding of likely disease-causing mutations on both alleles of either *SFTPB* or *ABCA3* is diagnostic for SP-B or ABCA3 deficiency, respectively. The interpretation of genetic testing may not always be straightforward. It may be difficult or impossible to distinguish whether a newly identified missense mutation represents a functionally significant or benign variant, because functional assays for such mutations are not readily available. Such testing is not 100% sensitive, because functionally significant mutations in the unexamined regions of the gene will be missed, as might be major deletions or rearrangements. Children with only one identifiable *ABCA3* mutation yet who have a clinical phenotype and lung pathologic findings consistent with ABCA3 deficiency have been reported, indicating that some *ABCA3* mutations have gone undetected.[102,112,113] Other limitations to genetic testing include cost and the length of time needed for results to be reported, particularly for a child with rapidly progressive disease.

Tissue examination may be helpful if lung biopsy is deemed necessary for proper diagnosis or on autopsy tissue when no suitable material is available for genetic studies. Lung histologic findings may be suggestive of an inborn error of surfactant metabolism, although not specific for a given genetic disorder. Because there are characteristic ultrastructural findings associated with both ABCA3 and SP-B deficiency, tissue should be prepared for electron microscopy with proper fixatives if an inborn error of surfactant metabolism is a possibility.[156,157] Strong consideration should also be given to snap freezing tissue in liquid nitrogen because such studies may facilitate future investigations.

Term infants with the nonspecific phenotype of severe RDS and without any identifiable mutations in *SFTPB*, *ABCA3,* or *SFTPC* have been reported, and it is thus likely that other inherited disorders resulting in abnormal surfactant production remain to be discovered.[102,104,112] Candidate genes could include those encoding other important enzymes and factors needed for the proper production, posttranslational processing, intracellular routing and packaging, or secretion of surfactant components. For example, haploinsufficiency for thyroid transcription factor 1 (TTF-1, also known as NKX2.1) because of loss-of-function mutations on one allele or a gene deletion has been associated with neonatal respiratory disease in term infants.[158-160] Similar to the nonspecific appearance of a sepsis-like illness and metabolic disturbances in children with inborn errors of intermediary metabolism, children with inborn errors of lung cell metabolism may present with a nonspecific picture of neonatal respiratory distress and radiographically diffuse lung disease. Elucidation of these inborn errors should enhance our understanding of normal surfactant metabolism and may provide clues to the pathogenesis of lung diseases outside the neonatal period.

TREATMENT

There are no specific therapies for inborn errors of surfactant metabolism. Whole lung lavage was ineffective in treating neonates with findings of alveolar proteinosis now known to have resulted from SP-B or ABCA3 deficiency.[151] SP-B deficiency is generally a fatal disease with the majority of reported infants having died within the first 6 months of life despite maximal medical therapy. Purified preparations of SP-B are not available for replacement therapy. Replacement therapy with exogenous surfactants containing SP-B has been attempted but did not alter the course in an infant in whom diagnosis was made before birth and treatment given from birth with more than 80 doses of surfactant.[46] Because exogenous replacement surfactants contain variable amounts of SP-B, as well as other surfactant components, the amount of SP-B administered may have been insufficient or repeated treatment with surfactant lipids and SP-C may have been toxic. Even if a preparation of purified SP-B were available, exogenous replacement therapy might be ineffective because exogenously administered SP-B might not reach the intracellular compartments needed to correct the intracellular deficits, or endogenous pro–SP-B synthesis might be necessary. Viral vectors capable of directing SP-B expression have been generated and tested in vitro and in animal systems, although multiple obstacles need to be overcome before gene therapy may be considered for human infants.[161-163]

The clinical course of infants with ABCA3 deficiency is more variable. Although most affected infants reported to date have had a course similar to that of infants with SP-B deficiency and died within the first 6 months of life, an increasing number of children with milder disease have been recognized. These children are usually treated with agents commonly used to treat forms of ILD, including corticosteroids and hydroxychloroquine, although data supporting the efficacy of these therapies in this condition are lacking. Infants with severe disease have received exogenous surfactant, with anecdotal reports of transient responses, but this has not been examined critically. Even if infants were to respond, the practical considerations of dosing and route of delivery for long-term therapy are considerable. Because many children with *ABCA3* mutations have missense mutations that result in inappropriate intracellular routing of ABCA3,[105,106] chemical chaperones to facilitate routing that may eventually be useful in this condition.[164-166]

Patients with *SFTPC* mutations are also often treated with agents such as steroids and hydroxychloroquine, but there are only anecdotal reports to support their efficacy.[167] Because of

the findings of pulmonary alveolar proteinosis in some of these patients, whole lung lavage has been attempted, but because this will not correct the underlying genetic defect it seems unlikely to result in sustained improvement. Anecdotal reports of clinical improvement in patients with *SFTPC* mutations after either whole lung lavage or treatment with other therapeutic agents must be interpreted in light of the natural variable history of the disorder.[130,167,168]

Lung transplantation has been performed for all three disorders with outcomes that are similar to those in infants with other pulmonary conditions.[80,85,132,169] Lung transplantation requires long-term immunosuppressive therapy with continued risks of infection and rejection. The procedure is costly and available only at a limited number of medical centers, potentially requiring a long-distance transport of a critically ill child in unstable condition. The availability of donor lungs is also limited, and death may occur before donor lungs become available. Compassionate care is an appropriate option for infants with SP-B deficiency given its bleak prognosis. The more variable courses associated with ABCA3 deficiency and especially with *SFTPC* mutations make decisions regarding lung transplantation or cessation of care more difficult for patients with these disorders. Finally, the parents of affected children should be referred for formal genetic counseling, because there is a 25% recurrence risk with SP-B and ABCA3 deficiency for subsequent pregnancies, and prenatal diagnosis may be an option if the mutation(s) responsible for disease in a family is identified.[170] Counseling of families of patients with *SFTPC* mutations is more difficult given the dominant inheritance and variable penetrance, because parents or other family members may be asymptomatic carriers of the mutation found in the proband, yet be at risk for development of lung disease.

SUMMARY

Hereditary SP-B deficiency is a rare disorder that causes fatal lung disease in term infants and demonstrates an essential role for SP-B in normal lung metabolism. Children with ABCA3 deficiency may have a clinical picture similar to that of infants with SP-B deficiency or may have milder, chronic lung disease. Mutations in the SP-C gene are associated with sporadic and familial lung disease of variable severity and age of onset. The pathophysiology of the lung diseases resulting from the lack of SP-B, ABCA3, and SP-C or from abnormally folded pro–SP-C is incompletely understood. Environmental factors and other genes that may have roles in modifying the course of these diseases need to be identified, and more effective treatments are needed.

Trophic Factors and Regulation of Gastrointestinal Tract and Liver Development

FETAL AND NEONATAL GASTROINTESTINAL AND LIVER GROWTH

Nature of Growth

To understand the role of trophic factors in fetal and neonatal gastrointestinal (GI) and liver growth it is important to first consider the nature of growth. The fetal and neonatal period is the most dynamic period of postconceptual growth and includes critical developmental milestones, such as gastrulation, organogenesis, morphogenesis, cellular differentiation, and functional maturation, all of which are described in detail in other chapters in this section. In the case of the intestine, this includes formation of the gut tube, the appearance of villi and digestive enzymes, and the development of swallowing and mature motility patterns.[1] Growth at the tissue and cellular level is characterized by increased cell numbers, that is, hyperplasia, and increased cellular size, that is, hypertrophy. Intestinal growth also involves expansion of the number and size of crypt and villus units.[2] Moreover, the timing and characteristics of fetal and neonatal GI and liver growth are exquisitely coordinated with the events of birth and weaning to ensure survival of the organism. The regulation of the timing and nature of GI and liver growth is complex and involves multiple and often redundant factors. Among these factors are intrinsic cell programs or signals arising from gene expression, as well as extracellular signals, such as peptide growth factors, hormones, nutrients, and microbes, which originate from surrounding cells, the blood, and the gut lumen.

The application of molecular biologic techniques in model organisms such as the mouse, zebrafish, fruit fly, and nematode have revealed that genetic regulatory factors have a critical influence on early organogenesis and morphologic development of the gut, pancreas, and liver.[3-6] These types of studies have identified a group of key homeodomain transcription factor genes, including *box, pdx1, cdx2,* and *GATA*, and signaling pathways, including Wnt/β-Catenin, Hedgehog, and Notch.[7,8] Another important aspect of growth in the gut is the continual proliferation, migration, and loss of epithelial cells along the mucosal surface. In the small intestine, this process involves four cell lineages (absorptive enterocyte, goblet, Paneth, endocrine) that differentiate from one pluripotent stem cell located in the crypt[9] (Figure 108-1). Recent studies have identified several genes that play a key role in the determination of lineage cell commitment in the intestine, including *atoh1, notch, hes1,* and *neurogenin3*.[10-12] The homeodomain transcription factors are also involved in the anterior-posterior pattern formation of demarcations in muscular sphincters and regional epithelial morphology along the length of the gut.[1,5] Genetic regulation via homeodomain factors also influences function maturation of the intestinal tract that occurs during the late gestation and neonatal period. For example, the expression of lactase-phlorizin hydrolase, a key enzyme involved in digestion of milk lactose, is up-regulated by a synergistic interaction between Cdx2 and HNF1 transcription factors.[13]

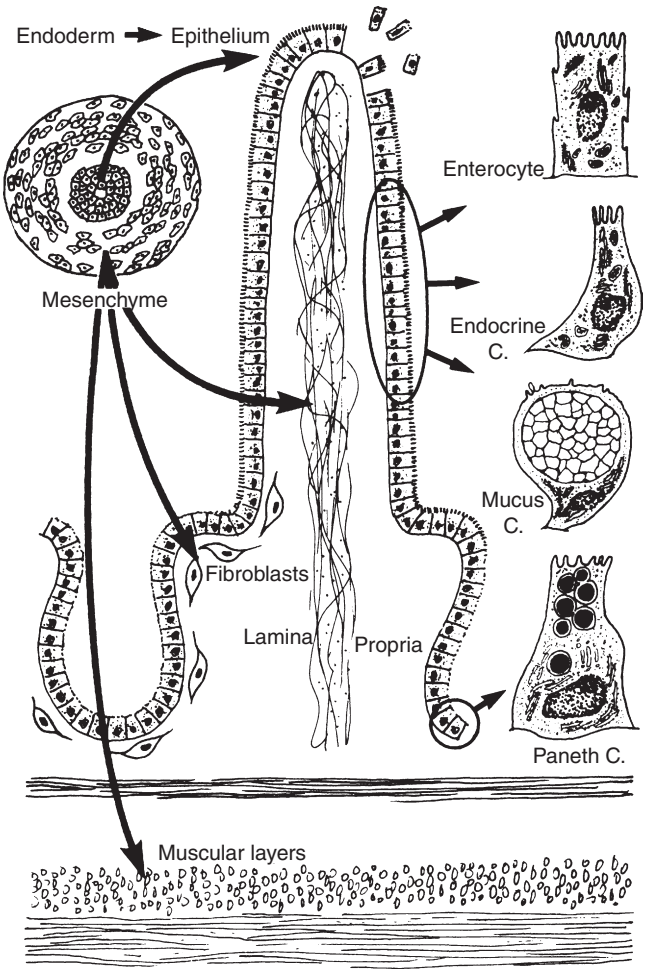

Figure 108-1 Description and localization of the four intestinal epithelial cell lineages within the crypt-villus region. The stem cells located in the lower crypt area differentiate into absorptive enterocytes, mucin-secreting goblet cells, endocrine cells, and Paneth cells. *(From Haffen K, Kedinger M, Simon-Assmann P: Cell contact dependent regulation of enterocytic differentiation. In Lebenthal E [ed]:* Human Gastrointestinal Development, *New York, 1989, Raven Press, p. 20.)*

Environmental Influences

Normal GI growth and development during fetal life are critical to facilitate the successful adaptation from nutritional support via the umbilical circulation to that of oral ingestion of breast milk by the neonate. An increase in circulating fetal glucocorticoid concentration just before and during vaginal birth is an important trigger of gut functional development.[14] In the neonatal period, growth of the GI tract is influenced by multiple physiologic factors that serve to prepare the developing neonate for separation from maternal nutritional support (i.e., weaning). In addition, a number of important environmental cues signal adaptive changes in GI function to facilitate postweaning survival. For example, the microbial colonization of the gut may serve to prime intestinal lymphoid cell development for normal innate immune function.[15-17] During these processes, extracellular signals, such as peptide growth factors, are often considered to be the major trophic factors that influence growth. However, the term *trophic* actually means "of or pertaining to nutrition," and, in the case of the gut, nutrients present in amniotic fluid and breast milk are a major trophic influence. There are numerous extracellular trophic signals including foods, nutrients, peptide growth factors, gut peptide hormones, steroid and thyroid hormones, microbes, and neural inputs. The cells in the fetal and neonatal GI tract and liver are influenced by extracellular signals from multiple sources including (1) blood-borne factors in the circulation such as hormones that act via endocrine mechanisms; (2) luminal factors derived from amniotic fluid, mammary secretions, or microbes; and (3) local factors secreted via autocrine or paracrine mechanisms from surrounding cells (Figure 108-2).

Recent studies have revealed novel insights into the role of mesenchymal cells, especially myofibroblasts,[18-20] and luminal microbes on intestinal epithelial growth and differentiation. Mesenchymal cell interactions are mediated via local secretion of tissue growth factors (e.g., fibroblast growth factor [FGF], hepatocyte growth factor [HGF], keratocyte growth factor [KGF], insulin-like growth factor [IGF]) and basement membrane proteins (laminins, collagens, proteoglycans).[21] The extracellular matrix protein, laminin, may be particularly critical for expression of *cdx2* and induction of epithelial differentiation genes, such as lactase-phlorizin hydrolase. Interaction between the integrin receptors on the basal surface of epithelial cells with basement membrane proteins can also affect differentiation and cell death. Studies have shown that disruption of the integrin-receptor binding via protease degradation leads to detachment of epithelial cells from the basement membrane and activation of anoikis-mediated apoptotic signaling pathways.[22-24] Symbiotic relationships between commensal microorganisms and their mammalian host, such as ruminants, are well known. Yet there is a rapidly growing appreciation for how these environmental influences also affect the health and disease of the human gut. Studies in conventional and germ-free animals demonstrated that the presence of intestinal microbes exerts a trophic effect on the gut, as evidenced by increased epithelial cell proliferation, mucosal thickness, and lymphoid cell density. Studies with germ-free mice monoassociated with specific bacterial species (e.g., *Bacteroides thetaiotaomicron*) have shown how microbes can alter particular pathways of intestinal differentiation.[3,25] The neonatal gut is sterile, but colonization occurs rapidly during early postnatal life and plays a critical role in development of mucosal immune function. Microbes also produce bioactive molecules and substrates, including toxins and short-chain fatty acids (SCFAs) that influence the proliferation and function of mucosal epithelial and immune cells. The aim of this chapter is to provide a brief overview of some of the major trophic factors in these categories and discuss their relevance to the growth and development of the fetal and neonatal gut and liver. Most of the references cited in this chapter are review articles, and the number of original articles listed is limited because of space.

MAJOR TROPHIC FACTORS

Nutrients

Enteral Versus Parenteral

Nutrition is perhaps the most potent trophic stimulus of GI tract growth. The diet acts directly by supplying nutrients for growth and oxidative metabolism of the mucosal epithelial cells, but it also acts indirectly by triggering the release of local growth factors, gut hormones, and activating neural pathways. It has been shown that the trophic actions of several nutrients are mediated by specialized enteroendocrine cells within the mucosal epithelium that literally sense the amount and chemical composition

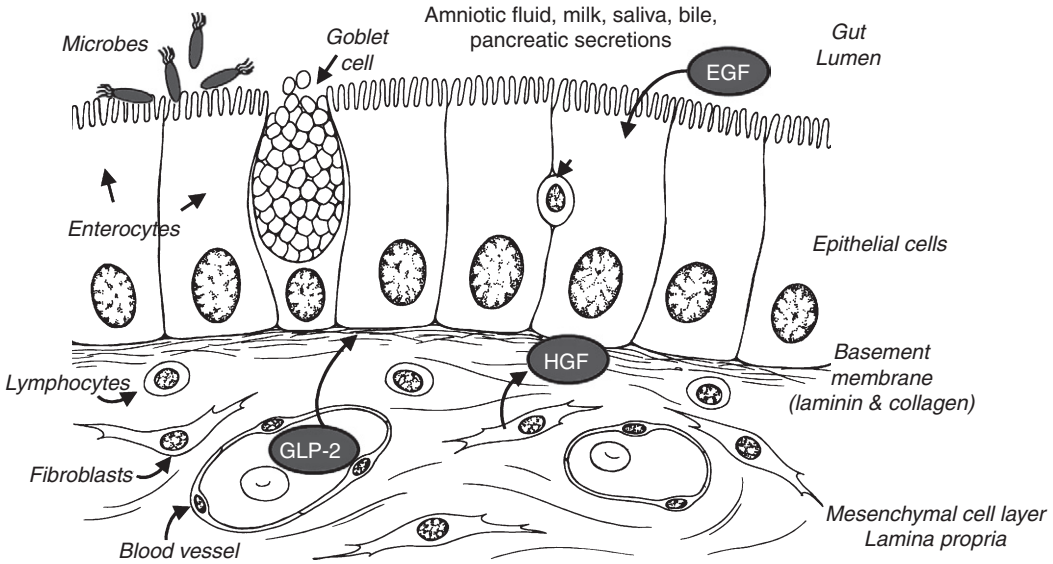

Figure 108-2 Spatial organization of various cell types and structural architecture of intestinal mucosa. Also shown are the sites of input and expression of selected extracellular factors within the intestinal mucosa. *EGF,* Epidermal growth factor; *GLP-2,* glucagon-like peptide 2; *HGF,* hepatocyte growth factor; *IEL,* intraepithelial lymphocyte.

of luminal nutrients.[26] The molecular mechanisms for these responses are emerging and show that membrane receptors and transport proteins act as chemical sensors that signal the presence of nutrients via enteric nerves to mediate local GI function but also peripheral responses via the extrinsic nervous system. Maternal malnutrition and neonatal starvation cause reduced gut tissue mass, shortened villi, and generalized increased catabolism and decreased protein synthesis.[27,28] However, the route of nutrient input, either enteral or parenteral, has a critical impact on the trophic response. In the late-gestation fetus, the onset of amniotic fluid swallowing coincides with increased intestinal growth and development. Studies in fetal sheep and pigs have shown that preventing this process by esophageal ligation suppresses intestinal growth.[14,29] In the neonate, total parenteral nutrition (TPN) leads to significantly reduced growth and atrophy of the intestinal mucosa.[30] The TPN-induced intestinal atrophy is associated with reduced gut DNA and protein mass, cell proliferation, villus height, and protein synthesis and increased apoptosis and proteolysis. Studies with neonatal animals and human infants show that the lack of enteral nutrition is also associated with reduced secretion of many gut peptide hormones and growth factors.[30] Animal studies have shown that several growth factors and gut peptides can prevent intestinal atrophy when coinfused with TPN, yet few of these studies have been done with neonatal animals. The practice of feeding small volumes of enteral nutrition, known as minimal enteral feeding or trophic feeding, has been shown to enhance GI motility and other functions.[31,32] The precise relationship between enteral feeding level and gut function has not been established; however, studies in neonatal piglets suggest that an enteral intake of between 20% and 40% of the total nutrient intake is necessary to maintain normal growth.[33] An additional consideration is whether to provide enteral nutrition orally, intragastrically, intraduodenally, as a bolus, or continuously. Studies in piglets suggest that, in comparison with continuous feeding, bolus feeding resulted in increased gut growth; however, this does not appear to be linked to secretion of trophic gut peptides.[30]

Breast Milk Versus Formula

The relative significance of milk-borne trophic factors has been one of the most intensely studied areas of pediatric nutrition and gastroenterology.[17,34-36] Many of the trophic peptide growth factors discussed in this chapter are present in breast milk, but not infant formulas, and have been implicated in the beneficial outcomes of breast-fed infants. Studies have assessed the relative trophic effect of colostrum and mature milk compared with formula in neonatal animal studies in which macronutrient intake was controlled. These studies have largely confirmed the idea that breast milk has a greater trophic effect on the GI tract than formula, as measured by typical indices of structural and cellular growth. However, the most significant advantage of breast milk in the neonatal intestine may be related not to growth but rather to mucosal barrier and immune function. Considerable evidence suggests that immunoprotective factors in breast milk (e.g., secretory immunoglobulin A, lactoferrin, oligosaccharides) act to modulate mucosal immune function and bacterial colonization, thereby limiting the incidence of infection, sepsis, and necrotizing enterocolitis.[34,37-40] Many of the trophic factors in milk are polypeptides that survive digestion, retain their biologic activity, and interact with specific receptors present on the mucosal epithelium of neonates. A number of studies have shown that these milk-borne growth factors stimulate neonatal intestinal growth when given in purified and recombinant forms either orally or systemically. Moreover, in preterm neonates the presence of increased intestinal permeability could facilitate the intestinal absorption of milk-borne peptide growth factors; however, there are limited instances where this process has been found to be physiologically significant.

Macronutrients

The chemical form and nutrient composition can also influence the impact of enteral nutrition on GI growth and function.[27,28] Some studies indicate that enteral nutrition in a complex, polymeric form is more trophic to the small intestine than in a simpler, elemental form. The dietary restriction of protein and energy generally suppresses gut growth and mucosal immune function. The enteral infusion of individual nutrients, by themselves, can have a trophic stimulus on the gut if administered in a sufficient large amount. However, a number of specific nutrients have trophic actions when supplemented to a complete diet; among those are glutamine, arginine, threonine, leucine, nucleotides, SCFAs, long-chain polyunsaturated fatty acids (LC-PUFAs), and retinoic acid.

Glutamine is a key intestinal oxidative fuel that is extensively metabolized and oxidized to CO_2 by intestinal tissues when fed either enterally or parenterally.[41] However, several studies have shown that enteral and parenteral glutamine also stimulates intestinal growth and enhances function in healthy and diseased conditions.[42,43] Studies in cultured intestinal epithelial cells indicate that glutamine, arginine, and leucine directly stimulate cell proliferation, activate mitogenic intracellular signaling pathways,[44] and may be a critical precursor for glucosamine and arginine synthesis.[45-47] Arginine is an essential amino acid for neonates and may be an especially important substrate for maintenance of intestinal nitric oxide synthesis, blood flow, and immune function. Some studies have shown that enteral arginine supplementation can reduce the incidence of necrotizing enterocolitis in neonates.[48,49] Other nonessential amino acids, including glutamate, proline, and ornithine have been shown to have stimulatory actions on the gut, perhaps because they are precursors for glutamine and arginine synthesis. Threonine is also a key nutrient for the intestine, because it is used for the synthesis of threonine-rich mucins by goblet cells; the intestinal threonine use by goblet cells appears to be dependent on the enteral rather than parenteral route.[50,51]

Nucleotides are ubiquitous, low-molecular-weight, intracellular compounds that are integral to numerous biochemical processes and are especially important as precursors for nucleic acid synthesis in rapidly dividing cells, such as epithelial and lymphoid cells in the mucosa.[52,53] Nucleotides consist of a purine or pyrimidine base, which can be synthesized within cells de novo from glutamine, aspartic acid, glycine, formate, and carbon dioxide as precursors, or they can be salvaged from the degradation of nucleic acids and nucleotides. Human milk is an excellent source of dietary nucleotides for infants during the first months of life, and its nucleotide content is markedly higher than that of cow's milk and most infant formulas, although several commercial formulas now include nucleotides. Numerous reports show that dietary supplementation with nucleosides, nucleotides, or nucleic acids supports small intestinal mucosal function, growth, and morphology.

SCFAs, largely in the form of acetate, propionate, and butyrate, are produced by microbial fermentation of carbohydrates in the large bowel.[16,38,54] Colonic epithelial cells derive most (60% to 70%) of their energy from SCFAs, and butyrate is the preferred oxidative fuel compared with glucose, glutamine, or ketone bodies. The diet of the human neonate is largely devoid of fiber, yet the production of SCFAs from large-bowel microbial fermentation increases with the degree of microbial colonization and postnatal age. Normal substrates for colonic SCFA production in neonates include endogenous secretions and malabsorbed dietary carbohydrates, such as lactose and oligosaccharides.[55] Oligosaccharides are the second most abundant carbohydrate in human milk, but cow's milk and infant formulas are substantially devoid of them.[34,56] Considerable evidence exists for the specific intestinal trophic effects of SCFAs. Intraluminal and systemic infusions of SCFAs have a stimulatory effect on intestinal mucosal proliferation, gene expression, blood flow, and gut hormone

secretion, yet studies with cultured colonic tumor cell lines indicate that butyrate induces differentiation and apoptosis, thereby suppressing neoplasia.[57-59]

There is considerable interest in dietary long-chain fatty acids, because breast milk generally contains higher concentrations of *n*-3 LC-PUFAs than do formulas. As a result, many infant formulas are now formulated with these fatty acids. Interest in the *n*-3 LC-PUFAs or omega-3 fatty acids, particularly docosahexanoic acid, eicosapentaenoic acid, and arachidonic acid, has been heightened by recent studies showing that supplementing these fatty acids can lower the incidence and inflammatory effects of necrotizing enterocolitis in neonatal infants and rats.[60-62] Information is limited regarding the intestinal trophic effects of either *n*-3 LC-PUFAs or other long-chain fatty acids in developing animals. However, a series of studies have demonstrated that *n*-3 LC-PUFAs enhance intestinal adaptation after small-bowel resection, and their effects were greater than those of less-saturated oils; they also found that medium-chain triglycerides are less trophic than long-chain triglycerides. In contrast, studies with neonatal piglets indicated that the long-chain fatty acid, oleic acid, can cause significant mucosal injury and increased permeability and that this effect is more severe in newborn than in 1-month-old piglets.[63,64]

Gastrointestinal Hormones

The gut is one of the largest endocrine organs in body and secretes numerous peptide hormones primarily in response to nutrient ingestion but also by stage of development and disease. Many of these gut hormones discussed in this section have been implicated in the stimulation of gut and liver growth in response to enteral nutrition. Gastrin is secreted from the G cells within the antrum of the stomach and acts primarily to stimulate proliferation of parietal and enterochromaffin-like cells within the gastric mucosa.[65] Cholecystokinin (CCK) is expressed in endocrine cells of the gut and in neurons within the gut and brain, and its primary target tissues are the pancreas and gallbladder. Structural homology exists between gastrin and CCK with respect to both the peptide sequence and receptor function. Studies have shown that hypogastrinemia, produced by antrectomy and targeted disruption of the gastrin gene, leads to atrophy of the gastric mucosal cells. CCK stimulates pancreatic growth and cell proliferation, and these trophic effects have been attributed exclusively to interaction via the CCK-A receptor. The neonate exhibits hypergastrinemia and comparatively high gastric pH, yet gastrin secretion is induced by feeding.[31] The development of pentagastrin-responsive gastric acid secretion occurs within 1 week in neonatal piglets and can be prematurely induced with glucocorticoids, consistent with up-regulation of gastrin receptor expression with age.[66] The trophic effects of gastrin are most evident in the stomach and are mediated by increased ornithine decarboxylase activity and cell proliferation. Gastrin-releasing peptide is a 27–amino acid peptide with a carboxyl-terminus region that is structurally related to bombesin, a 14–amino acid neuropeptide found in amphibian skin.[67] Gastrin-releasing peptide is secreted from neurons located throughout the GI tract in response to vagal stimulation. Bombesin is also found in milk, and both oral and systemic administration to suckling animals stimulates intestinal growth.[68]

Glucagon-like peptide 2 (GLP-2) is a product of the intestinal proglucagon gene expressed in the enteroendocrine L cells located predominantly in the distal intestine.[69,70] GLP-2 is secreted in response to feeding, especially carbohydrate, and studies in fetal and neonatal piglets suggest an ontogenic increase in GLP-2 secretion. GLP-2 has significant trophic effects on the neonatal and adult gut that are mediated by increased cell proliferation, protein synthesis, blood flow, and glucose transport. The trophic actions of GLP-2 are mediated by paracrine signals that are believed to originate from enteric neurons and subepithelial myofibroblasts.[69] GLP-2 has also been shown to possess antiinflammatory effects in conditions of bowel injury, resulting from colitis and chemotherapy.[71] Peptide YY is secreted from the same enteroendocrine cell as the glucagon-like peptides, GLP-1 and GLP-2, and together these hormones have been implicated as factors responsible for the "ileal-brake" phenomenon. Studies indicate that peptide YY stimulates gut growth in some, but not all, cases and does not stimulate proliferation of cultured epithelial cells. Neurotensin is a 13–amino acid peptide secreted from the enteroendocrine N cells located exclusively in the gut within the distal small intestine.[72,73] Neurotensin expression is markedly increased during the neonatal period, and secretion is stimulated specifically by ingestion of fat. Administration of neurotensin stimulates gut growth in animals after small-bowel resection even in the absence of enteral nutrients.

Tissue Growth Factors

Tissue growth factors can be generally categorized as polypeptides that are secreted locally and act via paracrine or autocrine mechanism to affect cellular growth and function.[74] However, a number of the tissue growth factors are also present in the blood and GI secretions and thus may act via endocrine mechanism, for example, insulin-like growth factor I. Moreover, many of these growth factors are present in breast milk and thought to influence neonatal gut growth.[36,39,68,75] Among the best known of these is epidermal growth factor (EGF), a member of a family of peptides that includes transforming growth factor-α (TGF-α), heparin-binding EGF, amphiregulin, epiregulin, betacellulin, neuregulin, and neuregulin 2. These factors act as ligands for membrane-bound EGF receptor and other EGF-related (ErbB family) receptors that become activated via phosphorylation on binding. EGF is widely distributed in most body fluids (notably mammary, salivary, biliary, and pancreatic secretions) but is not produced in the epithelial cells, in contrast to its homologue, TGF-α. Most of the EGF family peptides are trophic to the gut, stimulating cell proliferation and suppressing apoptosis; however, they also modulate a number of other physiologic functions including enhanced tooth eruption, decreased gastric acid secretion, increased mucus secretion and gastric blood flow, reduced gastric emptying, and increased sodium and glucose transport.[76-79] EGF also has been found to increase mucosal growth and functional adaptation after intestinal resection, diarrhea, and TPN and to prevent the incidence of necrotizing enterocolitis.[80-83] Enteral nutrition stimulates GI secretion, resulting in the release of EGF into the gut lumen where it is postulated to play a protective role, whereas TGF-α functions in the maintenance of epithelial cell proliferation and migration in the healthy gut. EGF appears to be more trophic to the gut when it is given intravenously than when given enterally, perhaps because the EGF receptor is localized to the basolateral membrane. However, many neonatal animal studies have shown that oral EGF administration does indeed augment gut growth and functional development. These findings combined with recent evidence from transgenic mice support the idea that both local expression and milk-borne ingestion of EGF and TGF-α play a physiologic role in neonatal gut growth and development.

The IGF family of peptides includes insulin, IGF-I, and IGF-II.[36,74,84-87] The biologic actions of insulin are mediated via the insulin receptor, whereas the actions of both IGF-I and IGF-II are largely mediated through the type I IGF receptor. The insulin and type I IGF receptors are present in epithelial cells; they are more abundant on the basolateral than the apical membrane and more abundant in proliferating crypt cells than in differentiated enterocytes. Although insulin secretion is confined to the pancreas, both IGF-I and IGF-II are expressed throughout the body, including the gut. However, within the intestinal mucosa,

expression of both IGF-I and II appears to be localized to mesenchymal cells in the lamina propria, although epithelial cells may also produce IGF-II. The expression of IGF-I and II in the gut is highest in the fetal and neonatal period and declines with age. In addition, insulin, IGF-I, and IGF-II are present in milk, and IGF-I is found in salivary, biliary, and pancreatic secretions and amniotic fluid. Numerous studies have shown that either administering IGF systemically or increasing its expression locally (as in transgenic mice) stimulates intestinal growth and function in normal animals and under conditions of TPN, gut resection, dexamethasone treatment, sepsis, and radiation therapy.[88-90] The expression of IGF-binding proteins has been shown to inhibit IGF action in gut tissues. Some studies with fetal and neonatal animals given pharmacologic oral doses of insulin and IGF-I have demonstrated a stimulation of gut growth, disaccharidase activity, and glucose transport.[85,86] Yet others have shown only limited effects of oral IGF on the neonatal gut suggesting that the IGFs may not have a physiologic role in the neonate. Growth hormone (GH) has a major influence on IGF-I expression during postnatal growth, and studies in postweanling rodents indicate that hypophysectomy results in gut atrophy, whereas transgenic overexpression of GH in mice increases gut growth.[30,87,91-93] However, the significance of GH in neonatal gut and liver growth may be limited by the abundance and responsiveness of the GH receptor. Studies with hypophysectomized neonatal rats suggest some degree of pituitary-dependent intestinal growth and development. Other studies in rats demonstrate that GH treatment does not prevent TPN-induced intestinal atrophy but may augment intestinal growth after massive small-bowel resection.

Transforming growth factor-β (TGF-β) is structurally unrelated to TGF-α and is found in three major forms (TGF-β-1 through 3) in mammalian tissues.[74,94] TGF-β expression has been found throughout the small intestine in both lamina propria and epithelial cells; the levels are low in neonates and increase with age. In contrast, the levels of TGF-β-2 are high in early milk and decline as lactation progresses. At least five receptors (types I-V) have been found to bind one or more of the various TGF-β ligands, although the type I and II receptors appear to mediate the effects on cell proliferation. TGF-β is a potent inhibitor of epithelial cell proliferation and may also induce differentiation. TGF-β has been implicated as an intermediate signal whereby butyrate suppresses proliferation and induces differentiation of colonic epithelial cells. TGF-β also stimulates epithelial cell migration and production of extracellular matrix proteins such as collagen via induction of connective tissue growth factor, thus making it a critical factor in the process of restitution of the epithelium after mucosal damage.[95] This latter function of TGF-β may play an important role in the intestinal inflammatory response, as evidenced by the fact that its expression is up-regulated in inflammatory bowel disease and that TGF-β–deficient transgenic mice develop inflammatory disease.

HGF, vascular endothelial growth factor (VEGF), FGF, and KGF are expressed in the gut tissues and may play a role in mucosal growth and repair.[30] HGF is expressed by mesenchymal, but not epithelial cells, whereas the HGF receptor *(c-met)* is found in epithelial cells; the c-*met* receptor is localized on the basolateral membrane. Studies with cultured intestinal epithelial cells demonstrate that HGF stimulates cell proliferation and wound closure proliferation but decreases transepithelial resistance.[77,96,97] Hepatocyte growth factor is found in human milk mononuclear cells and partially accounts for the stimulatory effect of human milk on intestinal cell proliferation. Studies in rats have shown that HGF, given either systemically or orally, increased gut growth and nutrient transport after massive small-bowel resection and colitis.[98,99]

VEGF is expressed in the small intestine, predominantly in the lamina propria mast cells.[30,77,100,101] A recent report indicates that the receptor (flt-1) for the VEGF 165–amino acid isoform is present in intestinal epithelial cells; however, VEGF did not stimulate cell proliferation of these cells. A recent report in mice demonstrated that VEGF and FGF-2 reduce the rate of crypt cell apoptosis after total body irradiation treatment. FGF and the FGF receptors have been found in intestinal tissues, yet their function remains poorly understood. Both VEGF and FGF-2 have been implicated in angiogenesis during intestinal repair.[102] Increased local expression of KGF has been found in patients with inflammatory bowel disease, and administration of KGF enhanced mucosal healing in rats after induction of colitis.[103] The trefoil factors (TFFs) are a family of peptides (TFF1-TFF3) that play an important protective role in the gut.[104] TFF3 is expressed and secreted from goblet cells of the small and large intestine and interacts with mucins on the apical cell surface. Trefoil peptides have been shown to promote cell migration and suppress apoptosis via activation of intracellular signaling pathways linked to mitogen-activated kinase and the EGF receptor; however, TFF receptors have not been identified.

Glucocorticoids

The role of glucocorticoids in neonatal intestinal development has been studied extensively, especially in rodents.[105] The impact of glucocorticoids, particularly dexamethasone, on human intestinal growth and development has received considerable attention in the past decade because of their use in treatment of pulmonary function in premature infants.[106] Results of studies in fetal animals suggest that increased endogenous glucocorticoid levels are critical signals that stimulate GI development and growth.[23] The prenatal cortisol surge is an important signal for development of the neonate, and premature birth precludes the exposure to this key intestinal maturation signal. This idea is supported by studies in infants and piglets showing that premature birth results in insufficient intestinal maturation of intestinal lactase and lactose digestive capacity.[14,29] Numerous studies demonstrate how glucocorticoids stimulate neonatal intestinal development and maturation, especially with regard to disaccharidase expression. However, their effects on neonatal mucosal growth, per se, as indicated by cell proliferation, cell cycle, protein turnover, and apoptosis are not completely understood. Studies in vivo and in vitro suggest that glucocorticoids inhibit intestinal mucosal growth by suppressing cell proliferation and increasing protein catabolism.[30]

ESOPHAGUS

Organogenesis

At 22 to 23 days gestation, a median ventral diverticulum is first noted within the region of the posterior confines of the developing foregut. This diverticulum, which is destined to become the cranial end of the fetus's esophagus and trachea, is termed the *tracheal diverticulum*. The diverticulum becomes groovelike as it elongates concurrently with the proliferation of endodermal cells at its lateral aspect. This phenomenon forms lateral ridges, which themselves ultimately create a division between the trachea and the esophagus occurring at 34 to 36 days gestation. Muscular and submucosal layers are present at this time point, and it is at this stage in development that tracheoesophageal anomalies such as the relatively common tracheoesophageal fistula occur. As these tracheoesophageal folds continue to develop, a spindle-shaped dilation occurs along the caudal aspect of the foregut—this structure ultimately becomes the stomach. The foregut between this dilation and the tracheal diverticulum is the *developing esophagus.* Elongation of the developing esophagus occurs first craniad and then caudad so that it is ascent of the pharynx rather than descent of the stomach that accounts for most esophageal growth. By 7 weeks gestation, the final, relative length of esophagus is achieved. In addition, any tracheoesophageal anomalies are present and, theoretically, identifiable at this stage of development.[1]

Anomalies of Embryogenesis

Esophageal atresia and *tracheoesophageal fistula* are commonly found in association. In the most common form of this anomaly, there is a blind proximal esophageal pouch associated with a distal tracheoesophageal fistula. As shown in Figure 109-1, other less-common configurations can be observed. Interruption of the events responsible for elongation and separation of the esophageal and tracheal tubes during the fourth fetal week is thought to lead to the development of this anomaly. The most full-blown manifestation of this disease of embryogenesis is a complete communication between the esophagus and trachea, or *laryngotracheoesophageal cleft.*

Most presentations of *esophageal stenosis* in children and adults result from an acquired anomaly rather than a congenital defect. However, a narrowing of the esophagus is occasionally found in the middle to distal third of the esophagus and presents as either a web or a long segment of narrowed esophagus. This anomaly likely results from incomplete recanalization of the esophagus. Another form of esophageal stenosis is one created by the presence of abnormal tissue rests within the esophageal wall. Often called an *esophageal ring,* this is commonly respiratory tissue and often contains cartilage, as well as ciliated epithelium.[2] This lesion is generally found within the lower third of the esophagus.

Esophageal duplications may be in direct communication with the esophagus or they may lie within the mediastinum completely separate from the esophagus. It is generally thought that intramural duplications or those that communicate directly with the esophagus are examples of faulty recanalization of the esophageal lumen (as suggested by the Bremer theory of duplications), whereas the cause of those duplications lying free within the mediastinum-thorax is not so easily understood.[3] Results of separate studies by Bentley and Smith[4] and by McLetchie and partners[5] have suggested that the developmental error underlying the formation of these cysts occurs during the formation of the notochord (at 18 to 19 days gestation) before development of the foregut itself has begun. Attachment of endodermal cells to the developing notochord permits formation of such enterogenous cysts.

As already noted, during the development of the esophagus the lining is initially columnar epithelium, which later becomes ciliated as the transition is made to the final stratified squamous epithelium. As this differentiation proceeds, if glandular columnar epithelium develops instead of the stratified squamous epithelium, gastric-type epithelium can occur within the esophagus. Termed *heterotopic mucosa,* this is a particularly common finding, and as many as 70% of clinically normal people are known to have such ectopic mucosa at some point within their esophagus.[6] Intraesophageal thyroid tissue has also been described[7]; the embryogenesis of this phenomenon is obscure.

Because it is known that the elongation of the esophagus is a phenomenon that creates the "descent" of the stomach, one can conceptualize that cessation of the elongation before the time that the stomach has reached the appropriate level would result in a situation in which a portion of the stomach remains in the thorax. This is a true *congenital short esophagus,* and the fact that a portion of the stomach remains supradiaphragmatic needs to be distinguished from a similar condition in which the supradiaphragmatic stomach is the result of a hiatal hernia.

STOMACH

Organogenesis

At 4 to 5 weeks gestation, a fusiform dilation at the caudal region of the foregut is first noted. Disagreement within the literature remains about whether the initial fusiform dilation destined to become the stomach occurs before or after the initial appearance of the tracheal diverticulum; however, it is known that the initial enlargement of the stomach is in a ventrodorsal direction.[1] The stomach begins its development at the C3 to C5 level. Because of the marked cephalic growth of the foregut, "descent" of the stomach occurs so that its eventual final location is in the region between T10 and L3. Although still unproved, it is generally thought that, as the stomach develops, its dorsal border grows more rapidly than the ventral border does so that a 90-degree clockwise rotation occurs on its

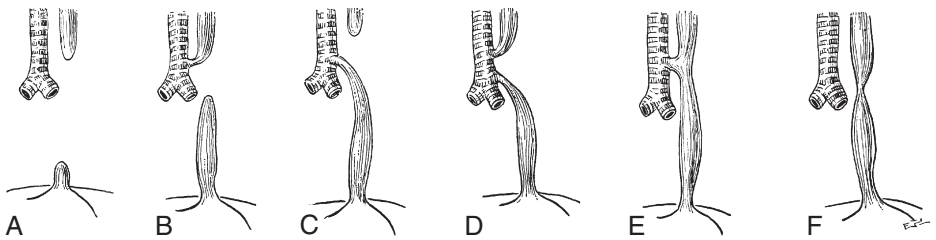

Figure 109-1 A-F, Types of esophageal atresia and tracheoesophageal fistula. Type **C,** with a blind proximal esophageal pouch and distal tracheoesophageal fistula, is the most common presentation (85%) of this anomaly. Type **A,** isolated esophageal atresia, and type **E,** isolated (H-type) tracheoesophageal fistula, constitute about 10% of this entity. *(From Gross RE:* The Surgery of Infancy and Childhood, *Philadelphia, 1953, WB Saunders, p 76.)*

longitudinal axis. As a result of this leftward rotation, the dorsal border of the stomach becomes the greater curvature of the organ, whereas the ventral border rotates toward the right and becomes the lesser curvature. The end result is that the original left side of the stomach becomes its ventral surface and the original right side of the stomach becomes its dorsal surface; the pylorus rotates upward and to the right and the cardia rotates downward and to the left. Studies have challenged this classic hypothesis, and the suggestion has been made that the left side of the stomach becomes the greater curvature (this anatomic orientation could result from accelerated growth only, with no actual rotation).[1] Although both hypotheses have solid foundations, it seems that the rotational hypothesis better explains why the left vagus supplies the anterior portion of the stomach and the right vagus innervates the posterior wall. Regardless, it is known that the final position of the longitudinal axis of the stomach is transverse to the longitudinal axis of the body itself and that this process is completed by approximately 8 weeks gestation.

Anomalies of Embryogenesis

Total agenesis of the stomach is an anomaly not encountered in otherwise viable infants. *Microgastria* is not uncommonly encountered and is thought to be the result of a failure or arrest of appropriate development of the caudal portion of the embryologic foregut. It is almost always associated with an enlarged esophagus and incomplete gastric rotation.[8] Although the mucosa of the gastric wall is normal, there may be other associated gastrointestinal anomalies—most frequently, incomplete rotation. Asplenia is a common concurrent finding, which is not unexpected because embryologically the spleen is derived from the dorsal mesogastrium, which has an intimate relationship with the developing stomach. *Gastric atresias,* almost always partial and in the form of membranous diaphragms, have been encountered, as have been complete, solid atresias of a portion of the stomach. Discontinuity of the stomach may occur in cases of such solid atresias. These atresias tend to be located within the antral and pyloric regions, and infants present as newborns with complete gastric outlet obstruction. Incomplete prepyloric membranes also occur. The embryologic characteristics of gastric atresias are considered to be different from those encountered within the duodenum, because there is no solid phase of epithelial occlusion of the stomach during development. It has been suggested that areas of endodermal redundancy may be the origin of small, weblike membranous diaphragms, whereas the larger zones of atresia are thought to be due to local attenuation of the developing endodermal tube during the formation of the pylorus. In this instance, endodermal proliferation fails to keep up with the elongating foregut.[1] Others have suggested that an in utero vascular accident (as occurs with other small and large intestinal atresias) is the cause of the solid atresias found within the gastric region; however, most clinicians favor the former theory.[9]

Pyloric stenosis results from hypertrophy of the muscularis of the pyloric channel, especially the circular muscle. It was for a long period considered to be a developmental defect of the pyloric musculature and thus congenital. Because this anomaly generally occurs at about 3 weeks of life and has not been known to occur earlier than the 4th or 5th day of life, it is no longer considered to be a true congenital defect. Its pathogenesis remains, essentially, unexplained.

Most *gastric duplications* occur along the greater curvature or on the anteroposterior walls of the stomach. Communications to the stomach are not always present, and the mucosal lining is generally gastric. Several embryologic theories have been suggested, which include the persistence of vacuoles within the primitive foregut epithelium[3] and the persistence of embryonic diverticula.[10] However, as with the esophagus, larger duplications, as well as those that lie completely outside the normal gastric wall, are likely the result of faulty separation of the notochord and endoderm.[5]

Acute gastric *volvulus* in children is a rare condition. Chronic gastric volvulus is encountered more frequently. Gastric volvulus is the result of errors in gastric rotation that lead to laxity or lack of the normal attachments of the stomach to the body. These attachments include the gastrophrenic ligaments, the gastrocolic ligament, the short gastric vessels, and the retroperitoneal fixation of the duodenum. The volvulus itself is classified according to the plane of rotation. If the stomach rotates on its long axis, it is called an *organoaxial volvulus*. In this situation, the greater curvature generally passes anteriorly but can be displaced posteriorly. A less common volvulus is mesenteroaxial volvulus, and rotation here is on an axis from the greater to the lesser curvature. In this instance, the pylorus and cardia commonly rotate anteriorly, although rotation in the opposite direction is also possible.

The most common *heterotopic mucosal tissue* found within the stomach is pancreatic; it is most frequently found within the antral region. Heterotopic tissue often presents as a 1- to 2-cm–diameter mass within the submucosal layers. Both translocation of the embryonic pancreatic cells and metaplasia in situ have been postulated as the cause of this anomaly. On rare occasions, heterotopic intestinal epithelium has been observed. Some have suggested that the presence of such epithelium (generally columnar epithelial cells with a striated border and interspersed goblet cells) is due to metaplasia induced by gastritis.[11] Conversely, there is clearly some embryologic basis for this phenomenon, because such cells are found in abundance within the pylorus and cardia of fetuses and newborn infants.[12] It is thought that this heterotopic tissue results from the persistence of a primitive form of gut epithelium.

DUODENUM

Organogenesis

Although the histogenesis of the duodenum is not significantly different from that of the rest of the small bowel, the organogenesis is quite different in many regards. The duodenum's development begins early in the fourth week of gestation, at which time it is the most caudal portion of the foregut and the most cranial portion of the midgut. This junction of the foregut and midgut is at a region just distal to the entry of the bile duct. The duodenal loop, which is convex throughout organogenesis and later life, is originally oriented in an anterior fashion. However, when gastric rotation takes place, the duodenal loop also rotates to the right so that the duodenum ends up lying with its loop convex to the right. The duodenum's rotation results in movement of the duodenum and pancreas to the right upper quadrant, at which point they are pressed against the posterior abdominal wall so that fusion of peritoneal structures with the posterior abdominal wall results in the duodenum becoming retroperitoneal. Because it represents a watershed between the foregut and the midgut, its blood supply is derived from both the celiac and superior mesenteric arterial trees. Unlike the rest of the midgut, the duodenum is not herniated into the extracoelomic cavity because of mesenteric-retroperitoneal attachments that anchor it in the right upper quadrant.

Duodenal mucosal proliferation begins around the 4th week of gestation, and an exuberant amount of duodenal epithelial proliferation occurs through the 10th week of gestation. The cellular proliferation is so abundant that at 5 to 6 weeks gestation complete duodenal occlusion routinely occurs. This occlusion is an epithelial proliferative formation rather than a stage of anatomic "narrowing" during the gut's development. Epithelial proliferation is the basis for most current theories

of duodenal atresia-stenosis, as well as the basis for the Bremer theory of duplications.[3] Furthermore, at this time, the proliferating epithelia bulge into the antimesenteric mesenchyme so that budlike diverticula appear in the embryo. These diverticula also appear in other regions of the small bowel but to a lesser extent. Such diverticula resorb into the gut wall at a later time during development, but they may play a role in the pathogenesis of duplications (the Lewis and Thyng theory of gastrointestinal duplications).[10]

Anomalies of Embryogenesis

The duodenum may be involved in many different manifestations of disordered embryogenesis. *Duodenal atresia* results from a failure of recanalization during the solid stage of duodenal development. If the lumen does not re-form as a result of revacuolization of the epithelial plug, an atresia will result. Atresias commonly occur in the second or third portion of the duodenum, with the site of atresia located just distal to the opening of the bile duct. The duodenum may or may not be in continuity (Figure 109-2). Similarly, if the vacuolization process has been incomplete, a *duodenal stenosis* may exist. Although duodenal atresia may often be a solid phenomenon, webs, either partial or complete, may also create obstruction within the duodenal region. Duodenal webs are also thought to result from a failure of recanalization. Duodenal obstruction of a partial or complete nature may occur because of an *annular pancreas* or *incomplete intestinal rotation.* In this anomaly, the cecum overlies the second portion of the duodenum, and obstruction results from peritoneal attachments (Ladd bands), which run from the cecum to the lateral body wall. Obstruction of the duodenum can also be created by a *preduodenal portal vein* that arises from abnormal development of vitelline vein anastomoses. This anomaly is commonly associated with other serious malformations that are often of a rotational variety.

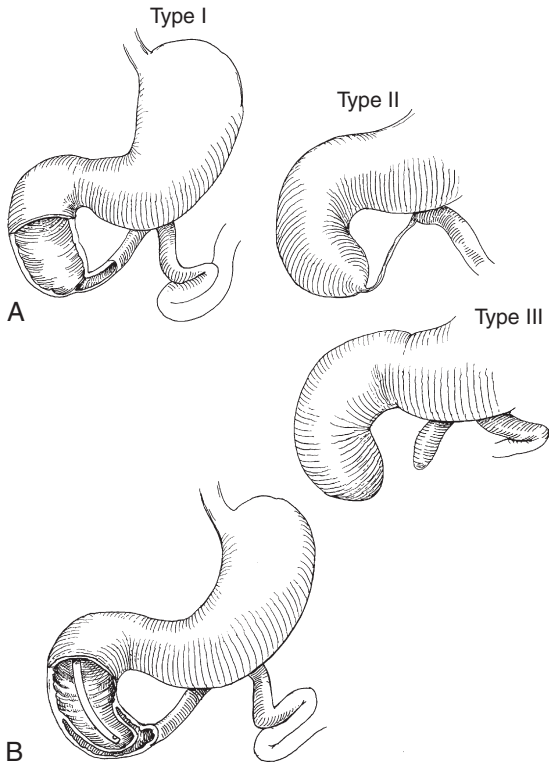

Figure 109-2 A and **B,** Duodenal atresia-stenosis, an anomaly of failure of duodenal recanalization, may be seen in several ways. *Type I* may be either a complete or an incomplete membrane, and the membrane may be more proximally based (so-called windsock anomaly) as seen in **B.** *(From Ross AJ III: Intestinal atresia. In Nora PF (editor):* Operative Surgery, *ed 3, Philadelphia, 1990, WB Saunders, p 1042.)*

PANCREAS

Organogenesis

Organogenesis of the pancreas is very closely related to that of the duodenum. During the 5th week of gestation, two buds appear as diverticula of endodermal cells emanating from the more caudal region of the foregut. The two endodermal buds are termed the *dorsal* and *ventral pancreatic anlagen*, and their eventual fusion creates the pancreas. The ventral anlage normally develops at the site of entry of the bile duct into the duodenum, and during the duodenum's rotation to the right this ventral anlage is carried dorsally along with the bile duct. Although initially this ventral anlage lies on the same side and below the dorsal primordium, this rotation permits the ventral anlage to fuse with the proximal portion of the dorsal anlage by the 7th week of gestation. The course of the ventral pancreatic anlage may be widely variable; errors in this rotation commonly lead to pancreatic anomalies.

Most of the pancreas is derived from the dorsal bud; the ventral bud is responsible for forming only the uncinate process in the inferior portion of the head of the pancreas. The pancreatic ducts normally anastomose as the two anlagen fuse. The main pancreatic duct (duct of Wirsung) is derived from the former duct of the ventral bud and the distal portion of the dorsal bud. The portion of the duct more proximal to the dorsal bud eventually becomes the accessory pancreatic duct (duct of Santorini), lying approximately 2 cm cranial to the main duct (Figure 109-3).

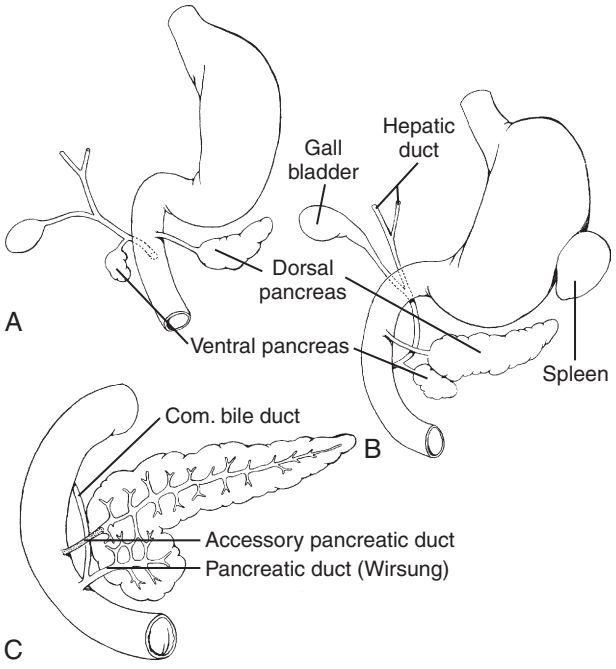

Figure 109-3 A-C, The migration of the ventral pancreatic anlage and subsequent relationship of the dorsal and ventral anlagen and pancreatic ducts are depicted. *(From Allan FD:* Essentials of Human Embryology, *New York, 1969, Oxford University Press.)*

Anomalies of Embryogenesis

Annular pancreas is a well-known cause of duodenal obstruction and a commonly encountered error in development (Figure 109-4). One finds a thin, flat band of tissue surrounding the second portion of the duodenum. The tissue of this band is histologically normal, and it is noted to be continuous with the head of the pancreas. The annular pancreas need not be complete and, as such, may manifest as a duodenal stenosis rather than a complete duodenal obstruction. Furthermore, intrinsic duodenal stenosis or atresia, or both, have been noted to occur in addition to the annular pancreas itself. A number of theories regarding the embryogenesis of this anomaly have been proposed. Although none completely explains all the intricacies involved in the embryogenesis of annular pancreas, there is no question that an aberration in the rotation of the ventral anlage has a key role.

Another common pancreatic anomaly is that of *variations of the pancreatic ducts.* Normally, the main duct (duct of Wirsung) and accessory duct (duct of Santorini) open into the duodenum and are interconnected. Obliteration of one or the other duct or the complete separation of one from the other is not at all uncommon so that the main drainage occurs through the accessory duct. *Complete agenesis* of the pancreas has not been reported in otherwise viable newborns, and *partial agenesis* of the pancreas is an exceedingly rare anomaly.

MIDGUT

Organogenesis

The midgut consists of small bowel beginning with the duodenum distal to the point of entry of the ampulla of Vater. It also includes the cecum and appendix, as well as the ascending colon and right one half to two thirds of the transverse colon. The midgut is supplied by the superior mesenteric artery and is thus also defined as that portion of bowel supplied by the superior mesenteric artery. The midgut is also defined from an embryologic standpoint as that portion of gut that opens ventrally into the yolk sac. The organogenesis of the midgut is one of the most fascinating aspects of development and was first described in 1923 by Dott, whose sketches remain the standard index for understanding the development of the appropriate intraabdominal rotational anatomy.[13]

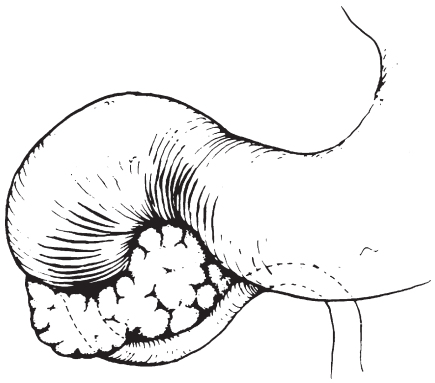

Figure 109-4 Failure of appropriate migration of the ventral pancreatic anlage leads to anomalies such as annular pancreas with resultant duodenal obstruction. *(From Schnaufer L: Duodenal atresia, stenosis, and annular pancreas. In Welch KJ, Randolph JG, Ravitch MM, et al, editors:* Pediatric Surgery, *ed 4, Chicago, 1986, Year Book Medical Publishers.)*

By the beginning of the 6th week of development, elongation of the midgut occurs at a rate faster than that of the elongation of the embryonic body itself. This is seen especially at the cranial end of the midgut. The result is a U-shaped ventral loop of gut (the midgut loop), which projects anteriorly and enters the extraembryonic coelom of the developing body stalk. Conceptually, one could consider this a huge physiologic umbilical hernia. The apex of this loop entering the extraembryonic coelom (marked by the yolk stalk) is directly in line with the superior mesenteric arterial axis and is termed the *omphalomesenteric duct*. The midgut proximal to this point is termed the *prearterial segment* (signifying that it is proximal to the superior mesenteric artery), whereas bowel distal to this point is the *postarterial segment.* Developmentally, the prearterial segment of bowel is small bowel, whereas the postarterial segment is mostly colon. After the appearance of the U-shaped ventral loop of the midgut, a counterclockwise (approximately 90 degree) rotation begins. During the time that the bowel is herniated into the extraembryonic coelom, most growth occurs within the prearterial segment so that jejunum and ileum develop at a rate proportionately greater than that of the colon. Within the postarterial segment, a cecal bud forms at 6 to 7 weeks gestation. Beginning at approximately 10 weeks development, the bowel begins to return to the embryonic abdominal cavity. The return of the bowel to the abdomen occurs rather suddenly and rapidly; the forces that dictate this phenomenon remain unknown. It has been postulated that external pressure forces the mass of bowel back through the umbilical ring, but this has not been substantiated. Both the prearterial and postarterial bowel segments rotate a total of 270 degrees counterclockwise before their rotation is completed. Although much of the rotation of the postarterial segment occurs during the time of its return into the body cavity, it is thought that the prearterial segment rotates 180 degrees while it remains herniated. It is the prearterial segment that enters first, passing posteriorly to the superior mesenteric artery during its return. This segment is followed by the cecum and colon (postarterial), which come to lie in front of the superior mesenteric artery. The terminal prearterial segment enters last (Figure 109-5).

Formal fixation begins after the midgut has returned to the abdominal cavity (approximately the 12th gestational week). The cecum and developing appendix lie in the subhepatic region at this time point, but further growth of the ascending colon forces the cecum down into the right lower quadrant. The force of the mesenteries of the ascending and descending colons against the posterior abdominal wall fuses these surfaces. As a result, the ascending and descending colons come to lie in the retroperitoneal space. The attachments of the fascial fusion planes of the right and left colon are termed the *fascial fusion planes of Toldt*.

The apex of the cecum does not grow as rapidly as the rest of the cecal pouch, which ultimately results in the development of the appendix. The appendix generally lies on the medial aspect of the cecum. During rotation and fixation of the cecum, however, the appendix can become retrocecal or retrocolic. A similar form of fusion occurs in the midgut portion of the duodenum, which attaches to the retroperitoneum in the left upper quadrant, termed the *ligament of Treitz*. As a result of the attachments of the right and left colon and the midgut duodenum, the small bowel mesentery becomes fan shaped with a very broad oblique line of attachment from the left upper quadrant to the right lower quadrant (Figure 109-6). This broad-based attachment limits the mobility of the mesentery and prevents midgut volvulus from occurring around the superior mesenteric artery. When the intestinal rotation is incomplete (i.e., malrotated), mesenteric attachment may not be sufficient to prevent the development of midgut volvulus. Errors in rotational development need operative correction to avoid this potentially lethal problem (Figure 109-7).

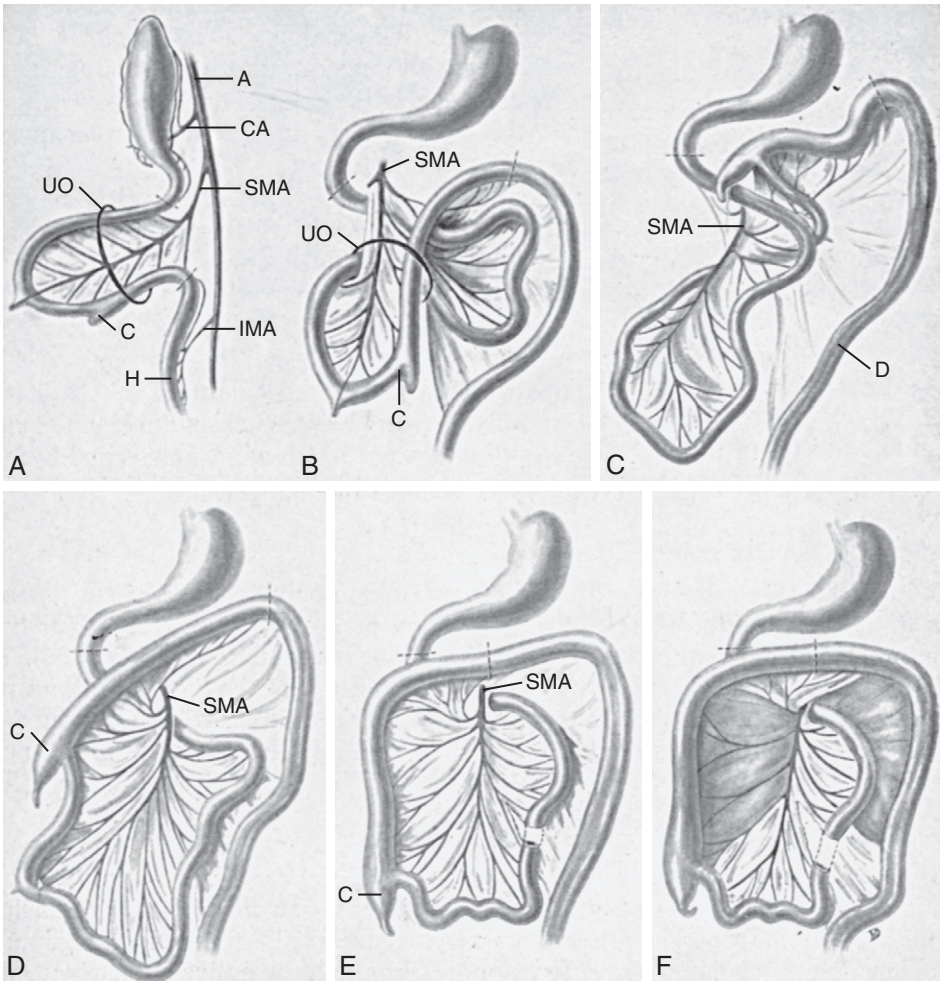

Figure 109-5 The normal rotation and fixation of the developing midgut. A, Herniation into the extraembryonic coelom at week 5. **B,** At week 10, initial rotation has taken place, and the midgut begins its return into the abdominal cavity. **C-E,** Completion of the 270-degree counterclockwise rotation of the prearterial and postarterial segments. **F,** Final fixation. *(From Gross RE:* The Surgery of Infancy and Childhood, *Philadelphia, 1953, WB Saunders, p 131.)*

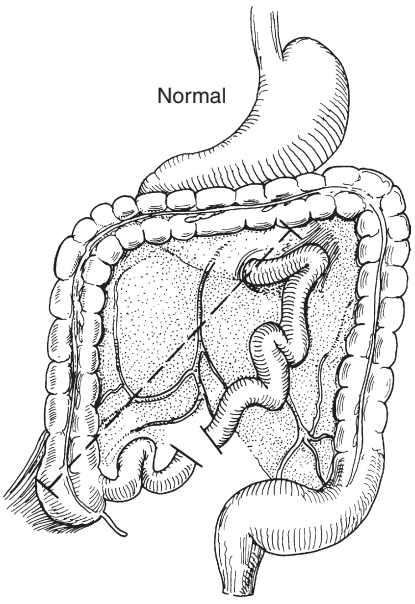

Figure 109-6 Normal rotation and fixation of the midgut. Note the broad-based fixation between the left upper and right lower quadrants, which fixes the superior mesenteric artery such that it cannot be the "root" of a volvulus. *(From Ross AJ III: Malrotation of the intestine. In Nora PF, editor:* Operative Surgery, *ed 3, Philadelphia, 1990, WB Saunders, p 1048.)*

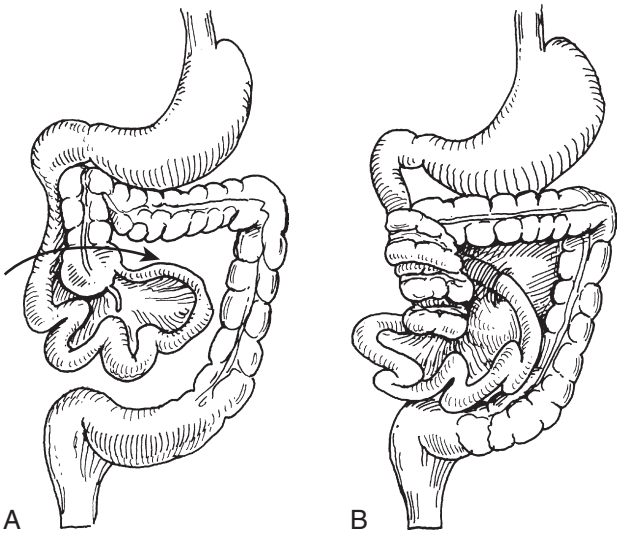

Figure 109-7 A, Malrotated bowel with the cecum overlying the duodenum. Bands from the cecum to the right upper quadrant could obstruct the duodenum. **B,** The lack of fixation in **A** permits the bowel to volvulize; note how the entire axis of the superior mesenteric artery is compromised. *(From Ross AJ III: Malrotation of the intestine. In Nora PF, editor:* Operative Surgery, *ed 3, Philadelphia, 1990, WB Saunders, p 1048.)*

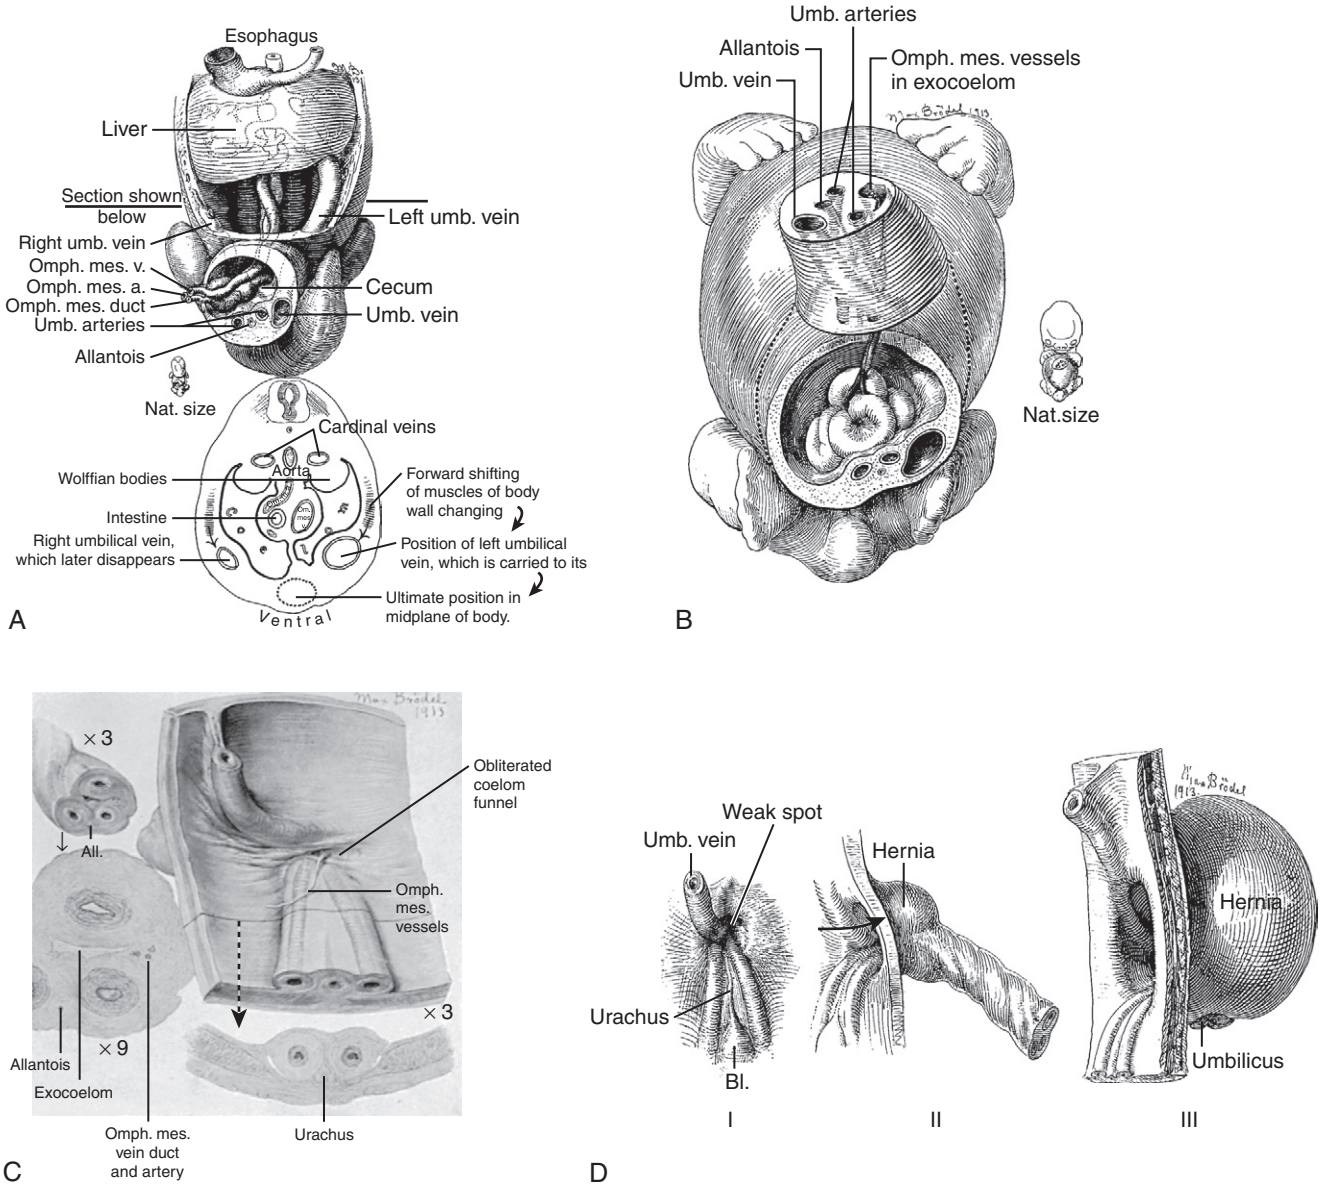

Figure 109-8 A-D, Max Brodel's drawings depicting the embryology of the umbilicus. Note the disappearance of the right umbilical vein and the resultant weak spot to the right side of the umbilicus. It is proposed that rupture at this weak spot is the cause of gas troschisis, thus explaining the usual finding of the defect occurring to the right of an infant's umbilical cord. *(From Cullen TS:* The Umbilicus and its Diseases, *Philadelphia, 1916, WB Saunders, p 745.)*

Anomalies of Embryogenesis

Failure of the midgut to return to the abdominal cavity is a frequently encountered congenital anomaly known as *omphalocele.* This developmental arrest is associated with a small abdominal cavity. It is unclear whether the small abdominal cavity is due to failure of the development of the body wall by appropriate migration of the lateral body folds medially or to failure of the return of the intestinal contents, or both. The amount of intestine herniated varies from a small amount that is barely distinguishable from an umbilical hernia to a massive anomaly containing the entire midgut and liver. Unless ruptured, the omphalocele is covered by a sac consisting of both peritoneum and amnion, and the umbilical cord is seen to enter the large exomphalos. In this anomaly, because midgut rotation does not occur, all children with omphalocele have an incompletely rotated intestine. Omphalocele needs to be distinguished from *gastroschisis,* in which there is an abdominal wall defect lateral (usually to the right) to the intact umbilical cord. Gastroschisis is thought to be due to a rupture of the lateral umbilical ring at the site of regression of the right umbilical vein during development (Figure 109-8). In this situation, in addition to the intact umbilical cord, there is no membrane covering the herniated bowel, which is generally thick, matted, and leathery. Rotation in this anomaly is similarly incomplete (Figure 109-9). Meckel diverticulum is another commonly noted embryologic anomaly that arises from the remains of the vitelline *(omphalomesenteric)* duct or embryonic yolk stalk. This anomaly is a fingerlike pouch approximately 5 cm long arising from the antimesenteric border of the ileum some 40 to 50 cm proximal to the ileocecal junction. It is found in approximately 2% to 3% of the normal population. As many as 24 variations of persistent vitelline duct anomalies have been

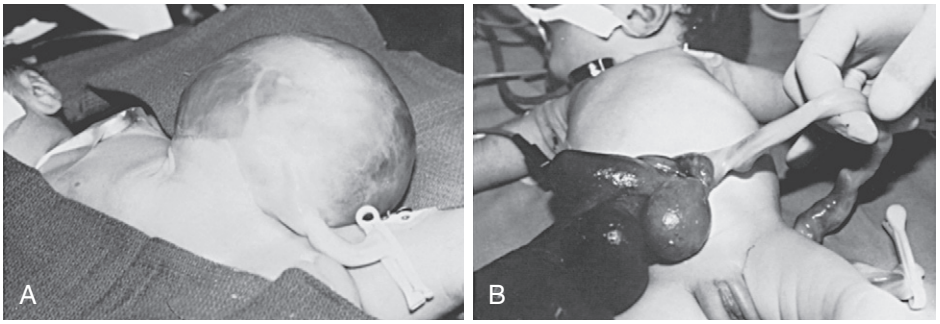

Figure 109-9 A, An infant with a large hepatoomphalocele. Note that the defect includes an intact sac and that the umbilical cord enters the sac. **B,** An infant with gastroschisis. Note that the defect is to the right of an intact umbilical cord normally situated on the abdominal wall. Also note the absence of a sac and the thick, matted bowel.

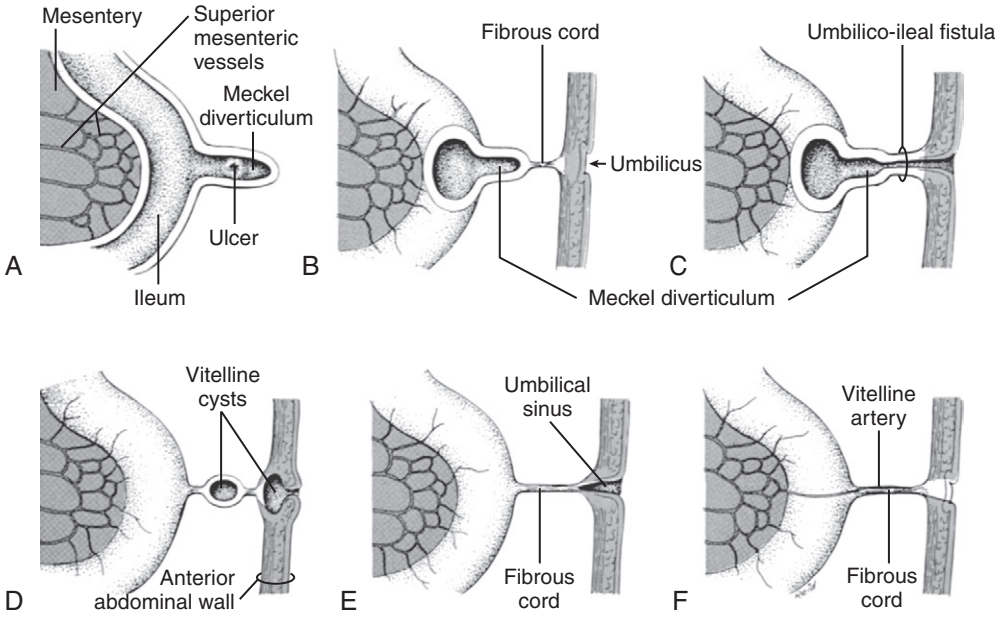

Figure 109-10 A-F, Meckel diverticulum and other anomalies of a persistent omphalomesenteric duct are shown. It is easily appreciated how **B** through **F** can be the focus of either volvulus or obstruction from an adhesive band. *(From Moore KL:* The Developing Human*, ed 4, Philadelphia, 1988, WB Saunders, p 236.)*

described. In addition to the uncomplicated variety of Meckel diverticulum, the tip of the vitelline duct remnant can be attached to the body wall or another intraabdominal structure. Volvulus or obstruction, or both, can occur at this site. In addition, this diverticulum may be patent, creating an *omphaloileal fistula* (connecting the ileum with the umbilicus). A mucosal remnant may persist, creating either an *umbilical sinus* or *polyp.* Furthermore, cystic remnants may persist along the length of the vitelline duct lying within the body wall or within the abdominal cavity itself (Figure 109-10).

Anomalies of midgut rotation are generally referred to as *malrotations.* If the extent of midgut rotation is less than the full 270 degrees, the mesentery may be incompletely based, allowing the bowel to rotate on the superior mesenteric artery axis, creating a volvulus-type picture. The number of possible anomalies of rotation is bewildering; however, all intestinal malrotations have the risk of volvulus.

Congenital intestinal atresia and *stenosis* are common anomalies. The observations of Louw and Barnard[14] have clearly demonstrated that such atresias are due to late intrauterine mesenteric vascular accidents. On rare occasions, jejunoileal atresia may be due to a failure of recanalization of the intestinal lumen occluded by epithelial cells. Atresia of the colon is far less common than atresia of the ileum or jejunum. Its cause is generally accepted as being similar to that of jejunoileal stenosis-atresia.

Duplications of the intestinal tract have been broadly categorized as cystic duplications and tubular duplications.[15] Cystic duplications are far more common and generally do not communicate with the intestinal tract, whereas tubular duplications communicate with the intestinal lumen. Duplications are almost invariably located on the mesenteric side of the bowel. When duplications enlarge, they can compress (and possibly obstruct) adjacent bowel or create a mass effect, or both. Most duplications are located within the small intestine, most commonly within the ileum. Most have mucosa resembling that of the adjoining gut. Duplications are generally thought to arise from (1) a failure of normal regression of the known embryonic diverticula with persistence of the transitory diverticula noted during embryogenesis (Lewis and Thyng theory); (2) traction between endoderm and overlying structures during early embryogenesis (Bentley and McLetchie theory; Figure 109-11); (3) errors of recanalization of epithelial plugs within the small intestine (Bremer theory); or

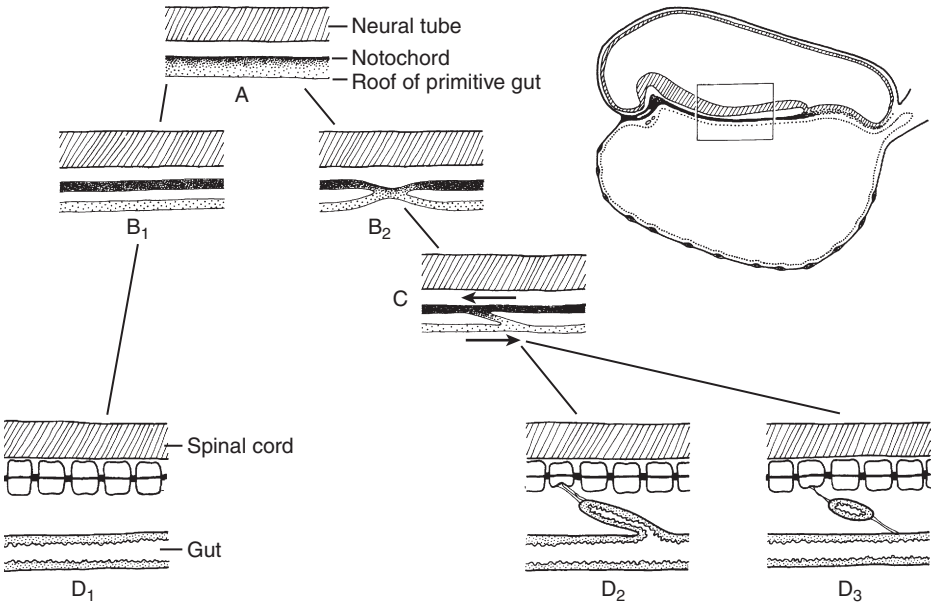

Figure 109-11 Abnormal separations of the notochord from the endoderm at week 4 *(A, B_2, C)* can result in the formation of an enteric duplication, either cystic *(D_3)* or diverticular *(D_2).* Normal is depicted in *A, B_1, D_1.* It can be appreciated why a vertebral malformation is often seen concurrent to the enteric duplication. *(From Gray SW, Skandalakis JE:* Embryology for Surgeons, *Philadelphia, 1972, WB Saunders, p 173.)*

(4) adherence of the endodermal walls lining the developing gut to create a double lumen.[3-5,10]

HINDGUT

Organogenesis

The hindgut comprises that region of the digestive tube that is supplied by the inferior mesenteric artery. The watershed region between the superior and inferior mesenteric arteries is located in the mid to distal transverse colon. This region, as well as the descending colon, sigmoid colon, rectum, and superior portion of the anal canal, is a derivative of the hindgut. The epithelium of the urinary bladder and most of the urethra are derivatives of the hindgut as well.

It is well known that the growth of the postarterial limb lags behind that of the prearterial limb so that at 10 weeks gestation, when the intestines return to the abdominal cavity, the caliber of the large intestine is much smaller than that of the small intestine. Transient occlusion of the colon by a solid epithelial plug probably occurs between 5 and 8 weeks gestation.[1]

Developmentally, the most complex region of the hindgut is its most terminal portion, the cloaca. At approximately day 13 of development, a ventral diverticulum, the *allantois*, forms. The future cloacal region is located at the junction of the allantoic stalk and the hindgut. The gut posterior to the allantois (tailgut) remains small and disappears by about the 6th week of development. Although the cloaca is lined with endoderm, it is in direct contact with an ectodermally lined structure termed the *proctodeum* (anal pit). The area of contact between the ectodermal and endodermal surfaces is termed the *cloacal membrane*. Thus the cloaca proper has the allantois ventrally and the cloacal membrane, an ectodermal-endodermal interface, posteriorly.

As organogenesis proceeds, the cloaca becomes partitioned by a mesenchymal-mesodermal wedge termed the *urorectal septum*. This structure begins development in the angle between the allantois and the hindgut and proceeds in a cephalic to caudal direction moving toward the cloacal membrane (Figure 109-12). The septum stimulates lateral cloacal ridge development and fusion, and by week 7 of development it reaches and fuses with the cloacal membrane. This results in the formation of a perineal body, which divides the cloacal membrane into a caudal anal membrane and a larger ventral urogenital membrane.

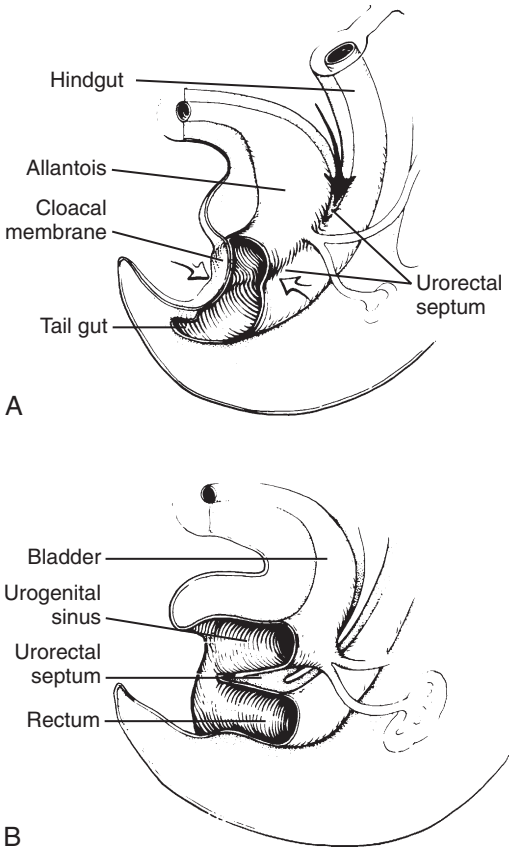

Figure 109-12 **A** and **B,** Descent of the urorectal septum is demonstrated. This results in the partitioning of the distal hindgut, or cloaca, into a urogenital sinus and rectum. It can be appreciated how deviations in the descent of this septum can lead to anorectal malformations, which often include urogenital anomalies as well. *(From Ziegler MM, Duckett JW, Howell CG, et al: Cloacal exstrophy. In Welch KJ, Randolph JG, Ravitch MM, et al, editors:* Pediatric Surgery, *ed 4, Chicago, 1986, Year Book Medical Publishers.)*

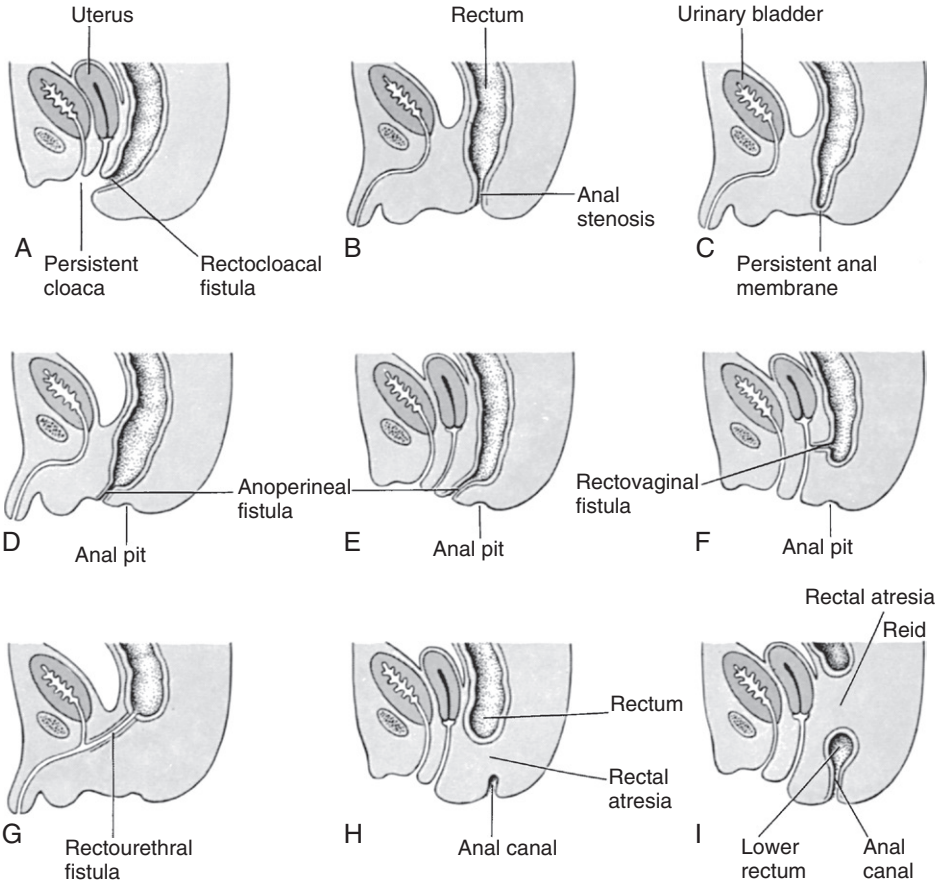

Figure 109-13 Various anorectal anomalies. A, Persistent cloaca, a common confluence of the intestinal, urinary, and reproductive tracts, results from failure of descent of the urorectal septum. **B-E,** Manifestations of low-type imperforate anus. **F-H,** Manifestations of high-type imperforate anus. **I,** Rectal atresia (rare). *(From Moore KL:* The Developing Human, *ed 4, Philadelphia, 1988, WB Saunders, p 241.)*

Anatomically, this creates a rectum and upper anal canal dorsally and a urogenital sinus ventrally. At approximately 8 weeks of development, the anal membrane (proctodeum) ruptures. The caudal portion of the digestive tract (the anal canal) is now in communication with the amniotic cavity. The superior two thirds of the anal canal is derived from the hindgut and the inferior third from the proctodeum. The junction is noted by the pectinate line. This pectinate line represents not only the junction of the proctodeum's ectoderm and the hindgut's endoderm but also the region of vascular watershed between these two structures. The superior rectal artery supplies the upper portion of the anal canal (from the inferior mesenteric artery), and the inferior rectal artery supplies the lower third (from the internal pudendal artery). The urorectal septum descent also defines a cloacal sphincter, the posterior aspect of which develops into the external anal sphincter, and the anterior aspect becomes part of the transversus perinei superficialis, the bulbospongiosus, the ischiocavernosus, and the urogenital diaphragm. In females, the fusion of the müllerian ducts (to form the uterus and vagina) moves down the urorectal septum and reaches the urogenital sinus at week 16 of development. In the male, the urogenital diaphragm is eventually obliterated by the fusion of the genital folds, and the sinus itself becomes incorporated into the urethra.

The obvious complex development of the cloacal region makes it easy to understand why anorectal malformations are common. Most arise from abnormal partitioning of the cloaca by the urorectal septum and its descent to create anorectal and urogenital structures. More often than not, it would seem that many of the anomalies can be explained by a dorsal (posterior) deviation of this septum, which leads to anomalies such as imperforate anus with rectourethral fistula. These anomalies would develop at approximately 6 to 8 weeks gestation (Figure 109-13).

Anomalies of Embryogenesis

The most common disorder of embryogenesis involving the hindgut is generally referred to as *imperforate anus.* Found more commonly in males, anorectal malformations result from the abnormal development of the urorectal septum so that there is incomplete separation of the cloaca into its urogenital and anorectal components. As a result, the anal canal may end blindly or there may be an ectopic opening on the perineum, almost always directed anteriorly toward or into the vulva in females or into the scrotum or urethra in males (see Figure 109-13). The anorectal malformations are commonly categorized as either low or high, determined by whether the blind end of the rectum is above or below, respectively, the level of the levator musculature. The high type of lesion is more common than the low and, generally, more complex. In its most complete form (usually encountered in females) one is left with a *persistent cloaca.* In this anomaly, only a single perineal hole is present, which functions as a common outlet for the intestinal, urinary, and reproductive tracts.

The congenital lack of ganglion cells within the myenteric plexus of the bowel is termed *congenital aganglionic megacolon*, or *Hirschsprung disease.* Congenital megacolon results from the failure of neuromyenteric cells to migrate normally into the wall of the colon and, in most cases, the rectosigmoid is the only bowel involved. This anomaly probably arises between the 6th and 8th weeks of gestation. The "normal" bowel is the proximal dilated bowel that results from the aganglionic bowel's inability to undergo parasympathetic-mediated relaxation. Total colonic and total intestinal aganglionosis have been reported. The aberrant developmental stimulus leading to the lack of the parasympathetic ganglion cells is unclear.

Development of the Enteric Nervous System

Multiple maturational milestones, including coordination of sucking and swallowing, effective gastric emptying, propagation of small intestinal contents, and colonic elimination, are necessary for successful enteral feeding of the infant. Symptoms consistent with poor gastrointestinal (GI) motility, such as vomiting, abdominal distention, and constipation, are common in the preterm infant. Developmental patterns of GI motility have been described in both animals and humans. This chapter reviews the physiology of GI movements, the extrinsic innervation of the gut, and the development of the intrinsic neural tissue of the gut, the enteric nervous system (ENS).

PHYSIOLOGY OF GASTROINTESTINAL CONTRACTIONS

Myogenic Control

Neurochemical, humoral, and mechanical stimuli control smooth muscle contractile activity. Smooth muscle cells generate spontaneous electrical activity through a fluctuation in resting membrane potential. These periodic depolarizations are below the membrane potential necessary to initiate a contraction and are known as *slow waves, electrical control activity, basic electrical rhythm*, or *pacesetter potentials*. Contractions occur only when a slow wave, after neural or chemical stimulation, exceeds the excitation threshold necessary for an action potential. After depolarization of a smooth muscle cell, an increase occurs in intracellular calcium. Calcium binds to calmodulin, a regulatory protein, and permits binding of the contractile proteins actin and myosin, resulting in a contraction. Therefore the action potential, referred to as *electrical response activity* or *spike potential*, occurs against the background of the slow wave (Figure 110-1).[1] Slow waves control the timing, speed, and direction of intestinal contractions.[2]

Neural Control

Central Nervous System

The central nervous system (CNS) and neural tissue within the intestinal wall, known as the ENS, control GI motor, secretory, and vascular activities. The CNS and ENS consist of afferent (sensory) neurons, efferent (motor) neurons that synapse directly with effector cells (muscle secretory cells, blood vessels), and interneurons, which integrate messages from the afferent neurons and program the efferent neurons. The sensory fibers travel closely with parasympathetic preganglionic fibers in the vagus nerve and sympathetic postganglionic fibers in the splanchnic nerves. Their neuronal cell bodies are located in the nodose and dorsal root ganglia, respectively. Vagal afferents terminate in the mucosal and muscular layers of the GI tract from the soft palate to the descending colon, as well as the liver, gallbladder, and pancreas.[3-5] Splanchnic afferents innervate the serosal surface and the bowel mesentery, as well as its mucosal and muscular layers.[6]

GI motor innervation is provided by the sympathetic and parasympathetic divisions of the autonomic nervous system (Figure 110-2). Postganglionic neurons of the sympathetic division are located in the prevertebral position on either side of the spinal cord, and the ganglia of the parasympathetic division are within the GI tract. Preganglionic sympathetic and parasympathetic neurons are located in spinal cord segments T2 through L2 (sympathetic) and in the medulla and sacral spinal cord (parasympathetic).

Most parasympathetic innervation of the gut is supplied by the vagus; the sacral nerves innervate only from the middle of the transverse colon to the rectum. Vagal efferents terminate primarily within the enteric ganglia.[7,8] Because the vagus nerve innervates most of the gut, organization of its projections within the brain stem has been studied extensively. Neural tracer studies have demonstrated a viscerotropic organization of afferent projections within the vagal sensory nucleus and the nucleus tractus solitarii (NTS), as well as efferent fibers within the motor nuclei, the dorsal motor nucleus of the vagus nerve, and the nucleus ambiguus (NA) of the rat.[3,4,9-13]

The NTS is the first synaptic site for vagal afferent fibers of the alimentary tract through cranial nerves IX and X. Within the NTS are interneurons involved in the coordination of afferent and efferent information to control esophageal and GI motor activity. Afferent fibers, depending on their site of origin with the rat GI tract, project to the distinct subnuclei within the NTS. For example, the central subnucleus (NTS_{cen}) has been implicated in

Development of the Enteric Nervous System

Multiple maturational milestones, including coordination of sucking and swallowing, effective gastric emptying, propagation of small intestinal contents, and colonic elimination, are necessary for successful enteral feeding of the infant. Symptoms consistent with poor gastrointestinal (GI) motility, such as vomiting, abdominal distention, and constipation, are common in the preterm infant. Developmental patterns of GI motility have been described in both animals and humans. This chapter reviews the physiology of GI movements, the extrinsic innervation of the gut, and the development of the intrinsic neural tissue of the gut, the enteric nervous system (ENS).

PHYSIOLOGY OF GASTROINTESTINAL CONTRACTIONS

Myogenic Control

Neurochemical, humoral, and mechanical stimuli control smooth muscle contractile activity. Smooth muscle cells generate spontaneous electrical activity through a fluctuation in resting membrane potential. These periodic depolarizations are below the membrane potential necessary to initiate a contraction and are known as *slow waves, electrical control activity, basic electrical rhythm*, or *pacesetter potentials*. Contractions occur only when a slow wave, after neural or chemical stimulation, exceeds the excitation threshold necessary for an action potential. After depolarization of a smooth muscle cell, an increase occurs in intracellular calcium. Calcium binds to calmodulin, a regulatory protein, and permits binding of the contractile proteins actin and myosin, resulting in a contraction. Therefore the action potential, referred to as *electrical response activity* or *spike potential*, occurs against the background of the slow wave (Figure 110-1).[1] Slow waves control the timing, speed, and direction of intestinal contractions.[2]

Neural Control

Central Nervous System

The central nervous system (CNS) and neural tissue within the intestinal wall, known as the ENS, control GI motor, secretory, and vascular activities. The CNS and ENS consist of afferent (sensory) neurons, efferent (motor) neurons that synapse directly with effector cells (muscle secretory cells, blood vessels), and interneurons, which integrate messages from the afferent neurons and program the efferent neurons. The sensory fibers travel closely with parasympathetic preganglionic fibers in the vagus nerve and sympathetic postganglionic fibers in the splanchnic nerves. Their neuronal cell bodies are located in the nodose and dorsal root ganglia, respectively. Vagal afferents terminate in the mucosal and muscular layers of the GI tract from the soft palate to the descending colon, as well as the liver, gallbladder, and pancreas.[3-5] Splanchnic afferents innervate the serosal surface and the bowel mesentery, as well as its mucosal and muscular layers.[6]

GI motor innervation is provided by the sympathetic and parasympathetic divisions of the autonomic nervous system (Figure 110-2). Postganglionic neurons of the sympathetic division are located in the prevertebral position on either side of the spinal cord, and the ganglia of the parasympathetic division are within the GI tract. Preganglionic sympathetic and parasympathetic neurons are located in spinal cord segments T2 through L2 (sympathetic) and in the medulla and sacral spinal cord (parasympathetic).

Most parasympathetic innervation of the gut is supplied by the vagus; the sacral nerves innervate only from the middle of the transverse colon to the rectum. Vagal efferents terminate primarily within the enteric ganglia.[7,8] Because the vagus nerve innervates most of the gut, organization of its projections within the brain stem has been studied extensively. Neural tracer studies have demonstrated a viscerotropic organization of afferent projections within the vagal sensory nucleus and the nucleus tractus solitarii (NTS), as well as efferent fibers within the motor nuclei, the dorsal motor nucleus of the vagus nerve, and the nucleus ambiguus (NA) of the rat.[3,4,9-13]

The NTS is the first synaptic site for vagal afferent fibers of the alimentary tract through cranial nerves IX and X. Within the NTS are interneurons involved in the coordination of afferent and efferent information to control esophageal and GI motor activity. Afferent fibers, depending on their site of origin with the rat GI tract, project to the distinct subnuclei within the NTS. For example, the central subnucleus (NTS_{cen}) has been implicated in

the coordination of esophageal peristalsis with use of organ-specific injections of neural tracers.[3,14-16] In the rat, esophageal vagal afferents terminate in the NTS_{cen}, and its neurons (esophageal premotor neurons) project directly to esophageal motoneurons located in the compact formation of the NA (NA_c).[17,18] The efferent neurons for the striated muscle of the esophagus are located in the NA, and the smooth muscle efferents originate in the dorsal motor nucleus of the vagus nerve in the rat.

Identification of anatomic circuits that project to specific bowel segments has enabled investigation of neurotransmitters, which may be involved in the control of esophageal and other GI motor activities in animal models. Pseudorabies virus, a swine neurotropic herpesvirus that undergoes retrograde axonal transport, has been instrumental in the colocalization of neurotransmitters within the brain stem neurons involved in esophageal peristalsis.[16] After injection of the virus into an end organ, active infection develops within a neuronal cell body following retrograde transport. The virus replicates and subsequently undergoes retrograde transport to the synapsing afferent terminals. (Specific transsynaptic retrograde transport to first-, second-, and third-order neurons is a function of postinjection time.) The virus can be localized immunohistochemically by using specific pseudorabies virus antisera.

Several neurotransmitters have been implicated as mediators of synaptic transmission in the brain stem–esophageal swallowing circuit, including the excitory amino acid glutamate (GLU).[19-21] GLU binds to a family of receptors that includes the *N*-methyl-D-aspartate (NMDA) receptor (NMDAR) class. Pharmacologic studies demonstrate that the application of GLU-agonist NMDA to the rat NTS_{cen}[20-22] and NA_c[23] stimulates esophageal motor activity. NMDA is a heteromeric protein composed of several subunits, of which NMDAR1 is a subunit necessary for a functional receptor. The demonstration of the colocalization of NMDAR1 messenger RNA and pseudorabies virus immunoreactive neurons in the esophageal premotor neurons (NTS_{cen}) and esophageal motoneurons (NA_c)[24] adds further support to this hypothesis.

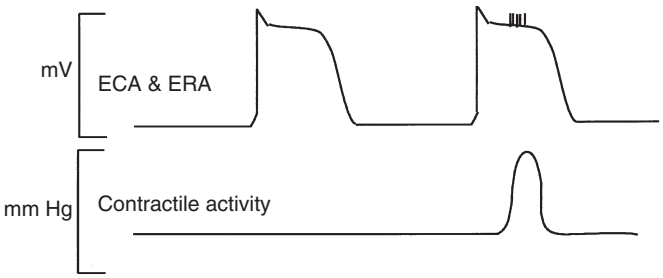

Figure 110-1 Schematic of pacemaker electrical control activity *(ECA)* with electrical response activity *(ERA)* in the second cycle. The ERA results from depolarization of the ECA beyond a threshold potential and produces a smooth muscle contraction. *(Modified from Sarna SK, Otterson ME: Small intestinal physiology and pathophysiology,* Gastroenterol Clin North Am *18:383, 1989.)*

Enteric Nervous System

Although the CNS plays a significant role in the control of GI movements, central innervation of the GI tract is relatively sparse when compared with the large number of ENS neuronal fibers. The ENS is unique, compared with other peripheral nervous system ganglia, because of its ability to mediate reflex activity independent of the CNS. The ENS is a complex system of neurons, which integrates extrinsic neuronal and humoral stimuli to produce stereotypic patterns that regulate motility, secretion, and vascular flow. For example, contraction of an orad segment of bowel to a food bolus is coordinated with relaxation of a caudad segment to attain peristalsis. Consequently, the ENS has been referred to as the "little brain" in the gut (Figure 110-3).[25]

The ENS consists of two major plexuses—the myenteric (Auerbach), located between the external circular and longitudinal muscle layers, and the submucosal (Meissner); it also includes six relatively minor plexuses, occupying different layers of the bowel wall (Figure 110-4).[26] The density of each plexus varies according to location in the GI tract and by animal species.[27-29]

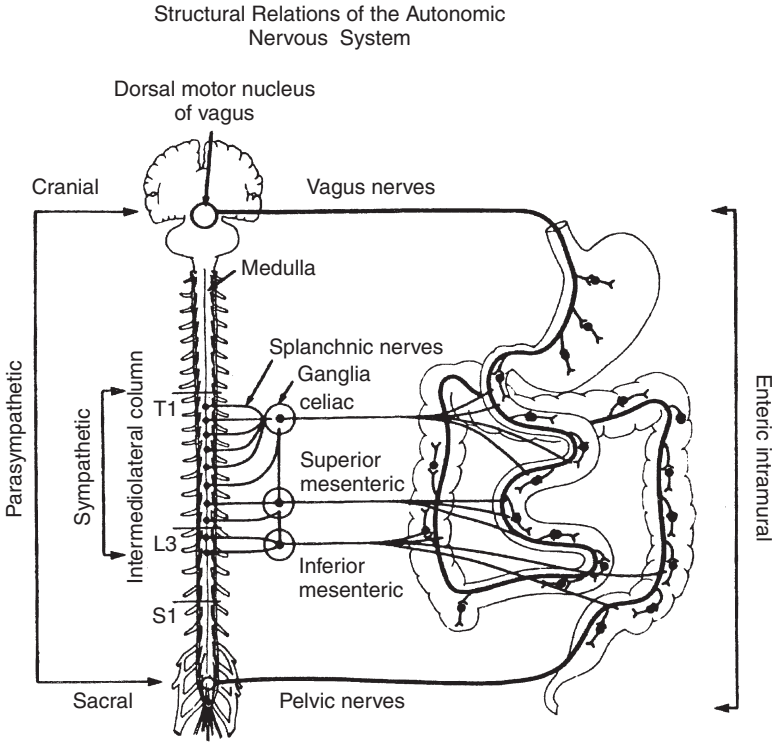

Figure 110-2 Organization of the projections of the autonomic nervous system to the gut. The enteric nervous system is within the bowel wall. *(Modified from Wood JD, Wingate DL: Gastrointestinal neurobiology: the little brain in the gut. In* American Gastroenterological Association Undergraduate Teaching Project in Gastroenterology and Liver Disease, *Timonium, Md, 1988, Milner-Fenwich, p 1.)*

The importance of the ENS is supported by abnormal myoelectrical recordings from the small intestine after chemical ablation of the myenteric neurons.[30] In addition, extrinsically denervated bowel can still mix and propel foodstuffs, and an autotransplanted small-bowel segment does not cause obstruction.[31]

The ENS and CNS ganglia share ultrastructural and neurochemical similarities. Neither the enteric ganglia nor the CNS ganglia contain connective tissue or blood vessels.[32,33] The enteric glia, support cells of enteric neurons, have processes that abut the basal lamina surrounding the myenteric plexus, analogous to the pia-astroglial border of the brain.[34] The internal structure of the enteric glia consists of high concentrations of cytoskeletal protein glial fibrillary acidic protein, which is also a marker for astroglia.[35] The functions of enteric glia are not clear; however, selective destruction of enteric glia in niacin-deficient mice results in diarrhea.[36] The anatomic, structural, and chemical similarities of enteric glia and astroglia support the hypothesis that their roles are analogous.[34]

Neurotransmitters

Many CNS neurotransmitters are also found in the ENS. Acetylcholine is the most abundant excitatory neurotransmitter mediating smooth muscle contractions in the ENS. Although many other enteric neurotransmitters have been suggested by immunocytochemical, pharmacologic, and electrophysiologic studies, not all have met the criteria for a neurotransmitter. These criteria are (1) a pharmacologic response to exogenous application of the potential neurotransmitter, (2) a mechanism for transmitter uptake and synthesis, (3) storage in presynaptic vesicles, and (4) a physiologic action following the neurotransmitter release by nerve stimulation.

Nitric oxide (NO), which is a gas, has been shown to mediate nonadrenergic noncholinergic relaxation in GI smooth muscle. There are several proposed mechanisms for the effects of NO. NO mediates relaxation through an increase in 5′-cyclic guanosine monophosphate.[37,38] Other studies suggest that NO does not act alone but may interact with other inhibitory neurotransmitters such as vasoactive intestinal peptide to mediate its effects.[39] NO synthase, the enzyme responsible for NO synthesis, has been demonstrated in the ENS of several animal species.[40-44] There is also electrophysiologic evidence for NO in the human GI tract,[45-47] as well as immunocytochemical labeling of NO-containing enteric neurons in the developing human intestine.[48]

Pyloric stenosis is the most common cause of gastroduodenal obstruction in infancy. The pathophysiology of antropyloric muscle hypertrophy and decreased neuronal fibers is not known. Animal and human studies have suggested that NO may play a role in pyloric stenosis. NO,[49] vasoactive intestinal peptide,[50] and substance P[51] fibers have been found to be decreased in the circular muscle layer of infants with hypertrophic pyloric stenosis. Although several neurotransmitters are decreased in the circular muscle layer of infants with pyloric stenosis, a transgenic neuronal NO synthase gene–deficient mouse phenotypically expresses hypertrophy of the circular muscle of the pylorus and marked enlargement of the stomach as its only phenotypic abnormalities.[52] Unlike the ubiquitous distribution of NO in wild-type mice, homozygous mutant mice do not have NO-positive fibers

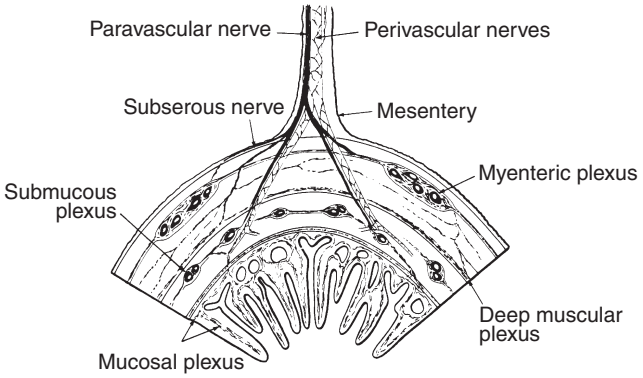

Figure 110-4 Arrangement of enteric plexuses in whole mounts of intestine. In addition to the large myenteric and submucosal plexuses, several smaller plexuses are shown. *(From Furness JB, Costa M: Arrangement of enteric plexuses. in the myenteric plexus or circular muscle of the stomach or pylorus. NO deficiency has also been described in aganglionic segments of patients with Hirschsprung disease.[53]

Intestinal guinea pig muscle tension studies have implicated GLU as a potential excitatory neurotransmitter in the gut. Longitudinal muscle strips associated with the myenteric plexus contract in the presence of exogenous GLU, an abundant excitatory amino acid neurotransmitter in the CNS.[54-57] This contraction can be inhibited by agents that antagonize the CNS GLU receptor NMDA and by drugs that block cholinergic receptors. GLU can be synthesized from exogenous L-glutamine in myenteric neurons and released from myenteric neurons after neuronal depolarization in vitro.[58] These data support an excitatory GLU neural pathway in the myenteric plexus through NMDA-type receptors and suggest that glutamatergic neurons are interneurons initiating contraction through cholinergic motoneurons. In situ hybridization studies have localized the NMDAR gene to the neurons of the guinea pig taenia coli myenteric plexus[59] and rat intestine.[60] The NMDAR has also been implicated in colonic peristalsis.[61] These studies support the concept that GLU is a neurotransmitter in the ENS that mediates its effects through NMDARs, but further studies are necessary to confirm a functional NMDAR. CNS astroglia take up neuronally released GLU and convert it to glutamine, through the enzyme glutamine synthetase.[62] Our laboratory[63] and that of Jessen and Mirsky[35] have demonstrated the presence of glutamine synthetase in enteric glia, the support cells of enteric neurons. However, further studies are needed to confirm the uptake of GLU by enteric glia.

Development of the Enteric Nervous System

Enteric neurons and glial elements are derived from the migration of neural crest cells.[64-66] Early investigations of the origin of the ENS, using quail-chick chimeras, demonstrated that vagally derived neural crest cells migrated throughout the entire bowel, but sacral émigrés were found only in the postumbilical hindgut.[67] Because the neural crest émigrés are not recognized as neurons or glia as they first enter the bowel, novel labeling methods have been developed to more specifically trace the migration of neural crest cells. Fluorescent dye 1,1-dioctadecyl-3,3,3,3′-tetramethylindocarbocyanine perchlorate (DiI) or retrovirus LZ10, constructed with *lac Z* reporter gene and detected with β-galactosidase immunoreactivity, was injected by Pomeranz and colleagues[68] into the neural tube of chick embryos before neural crest migration. Injections into the vagal crest level resulted in labeled cells in the avian stomach and duodenum. Injections into the sacral crest resulted in labeled cells in the postumbilical bowel; however, injections into the truncal crest localized to the sympathetic ganglia and not to the bowel wall. DiI tracer experiments have also demonstrated that the murine gut is colonized by the vagal and sacral regions of the neural crest.[69,70]

The premigratory neural crest cells are multipotent; therefore, factors that determine their differentiation have been of interest.[71] Premigratory chick crest cells replaced with those of quails (or the reverse) in younger embryos demonstrate that the phenotypic expression of the grafted crest cells is independent of the site of origin and determined by the migration pathway of the host embryo.[66,67,72] Phenotypic expression of the neural crest cells is dictated by the enteric microenvironment at the site of terminal differentiation. This is illustrated by the transient expression of the catecholaminergic neuronal phenotype by crest-derived cells that colonize the rodent bowel.[73] Transiently catecholaminergic cells are found in the murine and rat foregut at embryo days 9.5 and 11, respectively. During their migration through the vagal nerve pathway, transiently catecholaminergic cells express tyrosine hydroxylase, aromatic L-amino acid decarboxylase, dopamine β-hydroxylase, catecholamine storage, and norepinephrine transport as is seen in other sympathetic neurons. When these cells reach the bowel, they no longer express the catecholaminergic phenotype. Differentiated neurons express serotonergic and peptidergic neurotransmitters (e.g., serotonin, substance P, and neuropeptide Y).

Hirschsprung Disease

Hirschsprung disease is a GI disorder manifested by intestinal obstruction, as a result of the absence of neural crest–derived enteric ganglia in the terminal hindgut. It is a common disease occurring in 1 in 5000 live births. Patients with Hirschsprung disease commonly present with partial or complete obstruction during the first year of life. The cellular mechanisms for this disease are not known, but animal models such as the lethal spotted (*ls/ls*) mouse, in which congenital aganglionosis is an autosomal recessive trait, have suggested possible mechanisms.[74] As is seen in association with Hirschsprung disease, the colon of the *ls/ls* mouse is dilated proximal to the aganglionic segment, which acts as a functional obstruction. The aganglionosis develops as a result of failure of precursors of enteric neurons[75] and enteric glia[76] to colonize the bowel wall. Neurotropins[77] and laminin,[78] in addition to other molecules, may play a role in the control of enteric neuron migration and differentiation. After reaching the gut, neural crest cells express a 110-kDa cell-surface laminin-binding protein, which is not detected in ENS precursor cells.[78] It has been hypothesized that laminin interacts with the laminin-binding protein to cause neural crest cells to terminate migration. Neural crest cells from the *ls/ls* mouse can colonize the colonic walls of normal mice but not the distal colon of *ls/ls* mice.[79] Examination of the aganglionic segment of *ls/ls* bowel reveals that there is an overabundance of laminin and other components of the extracellular matrix in the gut wall.[80] It has been hypothesized that the accumulation of laminin could result in premature cessation of migration of crest-derived cells and, therefore, the absence of ganglionic cell bodies in the distal colonic segments of *ls/ls* mice. The 110-kDa laminin-binding protein may promote neurite extension.[78] The inhibition of cranial-to-caudal migration of vagal enteric neuroblasts to the large intestine of *ls/ls* mice suggests that a defect in the mesenchyme of the large intestine prevents colonization.[81] In vitro studies of the effects of neuronal development on smooth muscle cells from normal and aganglionic human bowel have suggested that the aganglionic colon is a less-favorable environment for neuronal growth because of a membrane-linked factor.[82]

Genetic and molecular studies in both animals and humans have proposed that specific genes may be responsible for regulating the migration of enteric neurons. In the mouse, the homeobox-containing gene, *Hoxa-4*, is expressed in various developing tissues, including the mesodermal layer of the gut. Exploration of the function of *Hoxa-4* has used a transgenic mouse expressing multiple copies of the *Hoxa-4* gene, which demonstrates congenital megacolon as its phenotype.[83] However, the pathogenesis of the bowel lesions of transgenic and lethal spotted mice is different. In this transgenic mouse model, crest-derived cells can enter the terminal colon, but their development is abnormal, resulting in hypoganglionosis. The *ls/ls* mouse has an abnormality of the extracellular matrix that prevents normal migration into the terminal bowel.

Pedigree studies have demonstrated that Hirschsprung disease is a heterogenous genetic disorder with autosomal dominant, autosomal recessive, and polygenic forms, as well as a few cases that result from environmental factors.[84] One autosomal dominant form has been mapped to human chromosome 10q11.1.[85] This region contains the *RET* proto-oncogene, a protein tyrosine kinase gene expressed in the cells derived from the neural crest. Mutations in the *RET* gene of Hirschsprung disease in both sporadic and familial cases have now been identified.[86,87] These data suggest that *RET* plays a critical role in the development

of the mammalian ENS. However, the existence of families with Hirschsprung disease without linkage to the *RET* gene suggests that there are additional genes affected in patients with Hirschsprung disease.[88]

Another susceptible chromosome in an inbred Mennonite kindred with Hirschsprung disease is chromosome 13q22.[89] Extensive molecular and genetic studies have implicated the endothelin-B (ET_B) receptor gene *(EDNRB)* as a gene candidate for Hirschsprung disease susceptibility within a subset of this family. Endothelins are a group of peptides that bind to two receptors, including ET_B. The ET_B receptor is expressed in the human colon, particularly in the myenteric plexus, mucosa, ganglia, and blood vessels of the submucosa,[90] areas that may be abnormal in Hirschsprung disease. Targeted disruption of the *EDNRB* gene in the mouse results in aganglionic megacolon.[91] After the transfection of a mutant *EDNRB* haplotype (identified in this pedigree) into a cell line, the resulting mutant did not demonstrate a normal ET_B-induced intracellular Ca^{2+} response, further supporting the susceptibility of this gene in Hirschsprung disease. These data suggest that *EDNRB* is important in the normal development of enteric ganglion in some patients with Hirschsprung disease.

Intestinal Motor Activity

The stomach and small intestine exhibit periodic motor activity during fasting. A migrating band of contractions of maximum spiking frequency and pressures is observed throughout the fasting small intestine. This is known as the migrating motor complex (MMC) or interdigestive motor complex (Figure 110-5).[92] The MMC is a recognizable pattern of cyclic groups of caudally migrating contractions or myoelectric activity of the antrum and small intestine that occurs in mammals in the fasted state.[92,93] The MMC consists of four phases: phase I, a period of quiescence, characterized by an absence of action potentials; phase II, a period of irregular contractile and myoelectric activity; phase III, maximal-amplitude regular contractions occurring at the frequency of the slow wave; and phase IV, a brief period of contractile activity before the start of phase I.[93-95] The MMC is thought to sweep residual products of digestion toward the colon, serving as a housekeeper.[96]

The MMC is primarily controlled by local enteric mechanisms.[2] Denervation of the extrinsic nerves to the gut does not stop initiation of the MMC cycle,[97-101] but the MMC cycle's duration becomes more variable, suggesting that the extrinsic nerves modulate periodicity. It is hypothesized that the MMC is under local control by the ENS, which has a neuronal circuit that periodically activates smooth muscle cells to contract at their maximal frequency.[99,102] Intraluminal calories disrupt MMC activity at all levels of the bowel and initiate generalized irregular contractions—the fed pattern—in the stomach and small intestine (Figure 110-6).[93] Introduction of nutrients into the bowel lumen results in a fed pattern in all areas of the bowel, including a noncontiguous bowel loop. The fed pattern does not occur, however, if the noncontiguous bowel is extrinsically denervated.[103] This suggests that initiation of the fed motor pattern requires regulation by extrinsic nerves or humoral factors. The caloric content of the ingested nutrient influences GI motility. Fats reduce spiking amplitude and intestinal transit[104] to a greater extent than do carbohydrates and protein.[105]

Development of Intestinal Motility

Animal studies of the fetal development of small intestinal motility, using long-term implanted electrodes, have demonstrated a progressive increase in the duration of spiking activity in dogs and sheep to a well-defined propulsive motor pattern.[106] Three stages of development of intestinal myoelectrical activity in the fetuses of several species have been identified. Stage 1 is characterized by unorganized spiking activity. In stage 1, there is a high percentage of retrograde propagation of low-amplitude spike bursts, suggesting that its main motor function is to mix intestinal contents. Stage 2, the fetal pattern, exhibits occasional cyclic spike bursts superimposed on slow waves that propagate aborally or orally. When stage 2 is associated with distally propagated phases of spiking activity recurring at short intervals,

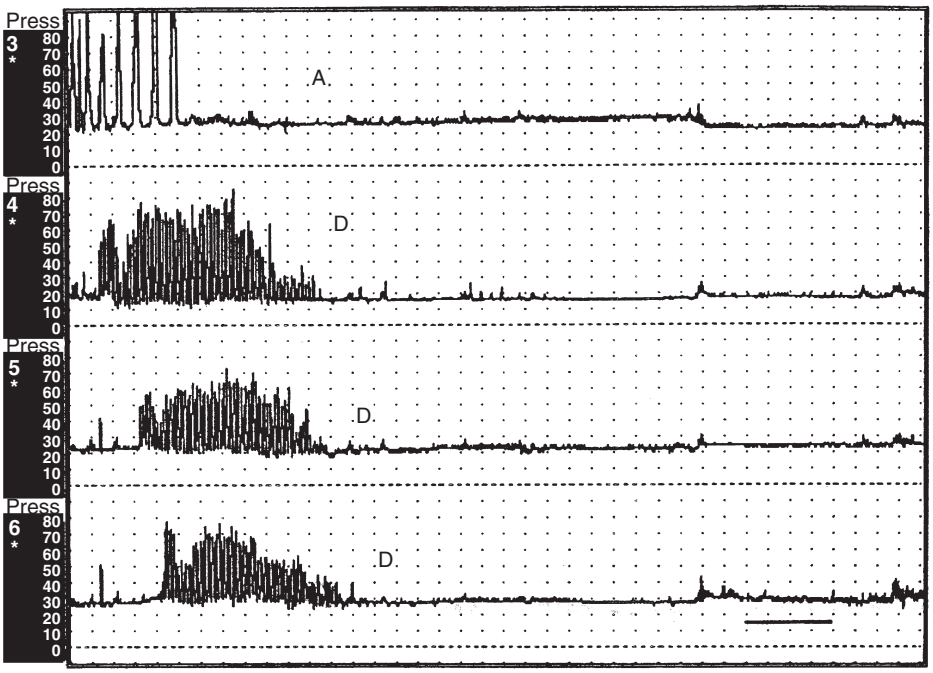

Figure 110-5 A normal MMC during fasting in a human subject. The recording was obtained with intraluminal miniature pressure transducers spaced 8 cm apart in the antrum *(A)* and duodenum *(D)*. High-amplitude contractions are distally propagated. (Scale bar = 2 min.) *(From Broussard DL: Gastrointestinal motility in the neonate,* Clin Perinatol *22:39, 1995.)*

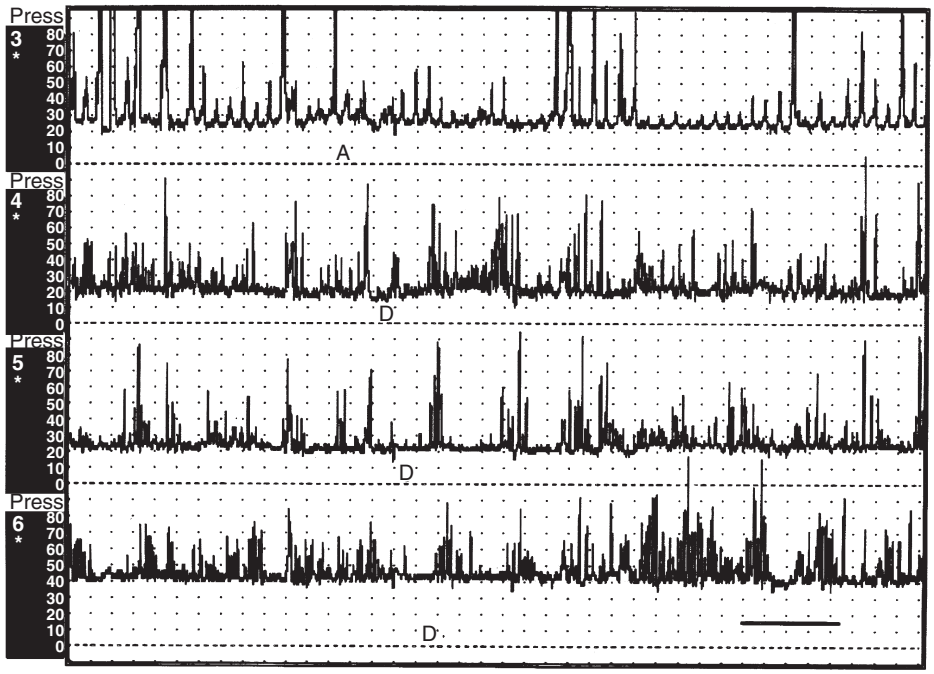

Figure 110-6 Antroduodenal motility pattern after a meal. Generalized spiking activity in the antrum *(A)* and duodenum *(D)* observed with miniature pressure transducer catheter. (Scale bar = 2 min.) *(From Broussard DL: Gastrointestinal motility in the neonate,* Clin Perinatol *22:39, 1995.)*

intraluminal contents may be propelled slowly for storage in the ileum and colon. Stage 3 resembles the adult MMC pattern.

Comparison of small-bowel motility patterns of ungulates (the GI motility patterns of which mature prenatally) and species with small intestinal motility patterns that develop after birth demonstrate parallel development of the ENS and CNS. Ungulates have full CNS maturity at the time of birth, which allows them to run with the herd soon after birth. In dog and rat pups that are born blind, deaf, and poikilothermic, maturation of the CNS and ENS is mainly postnatal.[107] Intestinal motor activity develops according to a species-specific, gestation-dependent pattern and is independent of birth.

The first studies in human fetuses to investigate intestinal transit used amniography. McLain[108] showed there was no transit of contrast down the intestine until 30 weeks gestation. Thereafter, an increasing aboral transit and propagation rate was seen as the pregnancy progressed. Subsequent manometric studies in infants illustrated a gestationally dependent pattern of development of small-intestinal motility, with developmental stages similar to those of dogs and sheep.[109,110] Increasing gestational age resulted in an increase in both duration and propagation of phase II contractions before the development of the MMC pattern.[110,111] The amplitude of contractions is also increased with gestational age.[110-112] The cycle time of the MMC is shorter in the term infant than in the adult,[111,113] suggesting that further maturation of the MMC occurs in infancy.

Development of Gastric Secretory Function*

The development of the human stomach is complex because of the many roles it plays in the digestive process. The stomach serves as a reservoir for food and regulates the flow of nutrients into the small bowel. In addition, the stomach is a secretory organ that continues digestive processes that were initiated in the mouth. Although hydrochloric acid is the major gastric secretory product, the stomach also secretes mucus, pepsinogen, bicarbonate, intrinsic factor, prostaglandins, and regulatory peptides. This chapter outlines gastric organogenesis and gives an overview of the regulation of gastric secretion, with emphasis on developmental studies in humans and animal models.

In interpreting the data currently available regarding the development of gastric secretory capability, several points should be kept in mind. First, although the mechanisms regulating gastric acid secretion are consistent across species, the relative contribution of individual components is quite variable. Second, considerable gaps remain in understanding the development of gastric secretory processes in humans. Third, although there have been numerous advances in understanding the molecular mechanisms that regulate the development of the small intestine and the digestive enzymes (e.g., sucrase-isomaltase and lactase), much less is known regarding the development of gastric secretory function.

ORGANOGENESIS AND CELL DIFFERENTIATION

The human stomach derives from the endoderm of the foregut at about 4 weeks gestation. As the gastric pouch continues to grow, the dorsal portion of the stomach enlarges at a more rapid rate than does the ventral border, producing the greater curvature. As this disproportionate growth continues, the stomach eventually undergoes a 90-degree rotation clockwise to assume the adult position by 8 weeks. The final J shape of the human stomach is not seen until 22 weeks.[1] Fetal ultrasound studies have greatly refined this process and can be used to detect abnormalities in gut function very early in gestation.[2] Histologically, the stomach is initially lined with stratified or pseudostratified epithelium.[3,4] At 6 to 9 weeks, the first gastric pits appear,[5,6] followed by the development of glands at approximately 12 weeks gestation, when the first primitive parietal cells can be recognized. The antral glands develop slightly later than those of the fundus but are present by 13 weeks gestation. At 12 to 13 weeks, the glands contain virtually no parietal cells but an abundance of mucous and endocrine cells. The gastric glands then expand toward the fully developed mature structures. In the hamster, the glands

*This chapter is reprinted from ed 3 of *Fetal and Neonatal Physiology.*

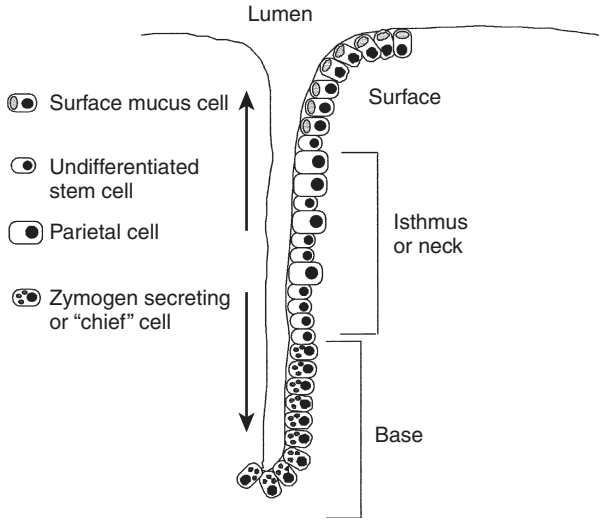

Figure 111-1 Representation of a gastric gland. The gastric gland is divided into three contiguous and overlapping areas: surface, isthmus or neck, and base. Unlike in the small intestine, gastric stem cells are located in the middle of the gland. As differentiation progresses, the three main cell types migrate to different areas.

appear to multiply by dichotomous branching.[7,8] In humans, the gastric glands appear to mature in a similar fashion and are very convoluted during this process, which is complete by 5 to 6 months of gestation.[6]

For many years it was unclear whether the various secretory cells of the stomach (mucous, acid-secreting parietal, pepsin-secreting chief, and endocrine cells) arose from a common progenitor cell or whether there were multiple stem cells. It is now known that a multipotent stem cell (known as the isthmus) is located in the middle region of the gastric pit.[9-14] Investigators also know that neck cells of neonatal mice can be grafted into the subcutaneous tissue of nude mice and it will differentiate into all four cell types.[15] This is consistent with a multipotent stem cell model analogous to that of the small intestinal crypt (Figure 111-1). It is interesting that grafts from embryonic day 14 mice maintain the axial patterning of gastric glands despite being in a different endocrine environment. Although these grafts do develop parietal and chief cells, there is a delay in the appearance of differentiated endocrine cells, suggesting that extragastric factors may be required for their development.

These data have led investigators to search for genes that might regulate gastric differentiation. Unfortunately, no such gene has yet been identified, but several things are known. First, the *N-myc* gene is necessary for development of the stomach, because *n-myc* knockout mice have a poorly developed gut.[16] Second, GATA-4 is known to be expressed first in primitive endoderm and then in definitive gastric endoderm. GATA-4–null blastocysts develop an abnormal gastric epithelium that has a squamous morphology.[17] Third, sonic hedgehog, an endoderm-derived signaling molecule, is overexpressed in the GATA-4–deficient cells.[17] Fourth, the nuclear transcription factor SP-1 is expressed in large quantities in the developing gut and is responsible for basal and gastrin-mediated transcription of some important genes, such as the proton pump H^+/K^+–adenosine triphosphatase (ATPase).[18,19] It is likely that over the coming years other important transcription factors necessary for gastric development will be identified in mouse models.

The regulation of gastric development took a leap forward when the human fetal stomach was studied in organ culture.[20] Overall, cell division decreased after 12 to 17 weeks gestation and became concentrated in the neck region. Unlike the mature human stomach, the fetal stomach can grow in serum-free media, suggesting that the fetal stomach contains all the growth factors necessary for growth.

Other studies have confirmed that all the epithelial cells of the gastric gland (mucous, parietal, chief or zymogenic, and so on) arise from stem cells in the neck region. A stem cell in the neck gives rise to prepit or premucous, preparietal, and prezymogen cells.[11-13] These premucous cells then migrate up the gland to the surface, where they eventually are shed into the lumen. The prezymogen cells migrate down into the base of the gland, where they differentiate into pepsin-secreting chief cells and eventually undergo apoptosis. These cells also secrete intrinsic factor in rodents but not humans. Preparietal cells differentiate in the neck and migrate only a very short distance into the large, acid-secreting mature parietal cell. Transgenic experiments confirm that all three cell types are monoclonal and thus arise from a common precursor.[21] Parietal cell ablation experiments demonstrate a block in the differentiation of the other two cell types, suggesting that a balance between the cell types is maintained by interactions among the cells.[22]

REGULATION OF ACID SECRETION IN ADULTS

Since the discovery of the acidic nature of gastric secretions by Beaumont in 1826, investigators have sought to determine the regulation of their release in humans.[23] It is now known that the parietal cell uses H^+/K^+-ATPase to secrete hydrochloric acid into the lumen of the stomach. Furthermore, several stimuli regulate acid secretion in mammals. These include neurogenic input (primarily via the vagus) and endocrine or paracrine effects from somatostatin-producing D cells, gastrin-producing G cells, histamine-containing enterochromaffin-like (ECL) cells, and other peptide hormones. An overview of the regulation of gastric acid secretion is necessary to understand the developmental changes seen in humans and animal models (Figure 111-2). It should be noted that although these regulatory mechanisms are seen in a wide variety of mammalian species, the relative contribution of individual components has intraspecies variation. Thus animal models may not entirely reflect human physiology. Moreover, it has also been shown that the contribution of these inputs can vary during development.

As shown in Figure 111-2, the regulation of gastric acid secretion is quite complex. Excellent reviews of this topic have been published elsewhere, but an overview is provided here.[24] As noted by Beaumont and Pavlov,[23,25] the central nervous system during the cephalic phase of gastric acid secretion can stimulate acid secretion via specific sites in the medulla and the vagus nerve.[26,27] The predominant vagal effect is mediated by acetylcholine released from postganglionic fibers and muscarinic receptors. Acetylcholine has multiple effects, including a direct stimulatory effect on the parietal cell. Acetylcholine also stimulates the release of somatostatin from D cells, which provides a brake on acid secretion via multiple pathways. In addition to acetylcholine, gastrin-releasing peptide (GRP) is secreted from postganglionic vagal nerve fibers and directly stimulates gastrin release[28] via GRP receptors on G cells.[29,30] Vasoactive intestinal polypeptide (VIP) is also released from vagal postganglionic fibers, but, unlike GRP, VIP does not have a direct effect on the G cell. VIP stimulates somatostatin release[31] from D cells, which, in turn, inhibits gastrin secretion. Other candidate peptides regulating the cephalic phase of acid secretion include calcitonin gene–related peptide and corticotropin-releasing hormone.

During the gastric phase of a meal, antral distention evokes low levels of gastrin release that is inhibited by low doses of the muscarinic antagonist atropine but enhanced by atropine at higher doses.[32] Other studies show that low-dose atropine depresses gastrin release in response to feeding in both intact and vagotomized dogs, suggesting that this effect is mediated by local neural reflexes.[33] Gastrin is also released by the presence of food in

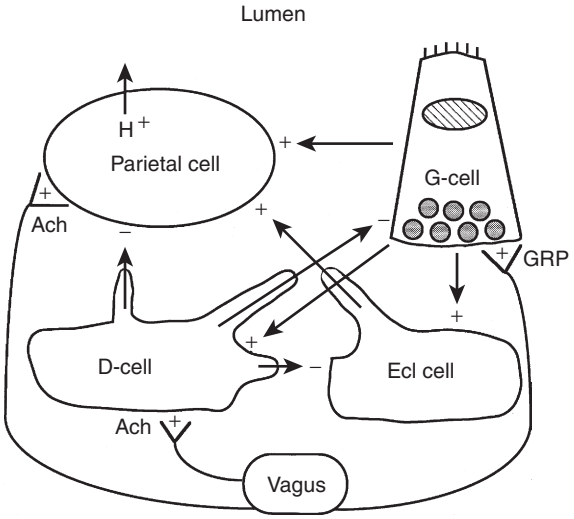

Figure 111-2 Regulation of gastric acid secretion. See also text. The acid-secreting parietal cell is regulated by inputs from the vagus nerve and three main cell types found in gastric mucosa: gastrin-secreting G cells, somatostatin-secreting D cells, and ECL cells that secrete histamine. Vagal postganglionic fibers release acetylcholine *(ACh)* that directly stimulates acid secretion from parietal cells and somatostatin release from D cells. Other vagal GRP-containing fibers stimulate gastrin secretion from G cells. Gastrin is posttranslationally processed to its biologically active forms within secretory granules that release their contents into the circulation. Increases in plasma gastrin enhance acid secretion from parietal cells, histamine release from ECL cells, and somatostatin release from D cells. Unlike gastrin, which acts in an endocrine fashion, somatostatin and histamine are released from D and ECL cells in a paracrine manner. Histamine stimulates acid secretion from parietal cells, whereas somatostatin inhibits secretion of acid from parietal cells and inhibits the release of gastrin from G cells and histamine from ECL cells.

the stomach. Neurotoxins, such as tetrodotoxin, GRP antagonists, and atropine, abolish both stimulation of gastrin release and inhibition of somatostatin release, indicating that peptone-induced gastrin release is mediated, in part, by both cholinergic and GRP neurons. However, other groups have shown that amino acids and amines also stimulate gastrin release from isolated canine G cells.[34] Circulating gastrin is the principal mediator of postprandial gastric acid secretion in adult humans.[35] Gastrin stimulates acid secretion by a direct effect on the parietal cell or by stimulating the release of histamine from ECL cells, which, in turn, enhances acid secretion.

The entry of chyme into the small intestine initiates the intestinal phase of the acid secretory process. The primary stimulatory factors in the small bowel are distention and the products of protein digestion, and these contribute relatively little to overall gastric acid secretion. The presence of food, especially fat, does initiate several inhibitory mechanisms. Duodenal fat releases intestinal cholecystokinin (CCK), which stimulates the release of somatostatin from gastric D cells.[36] Somatostatin has several inhibitory effects on gastric acid secretion, including suppression of release of gastrin from G cells, histamine release from ECL cells, and acid secretion from parietal cells. Although many other peptides released during the intestinal phase of digestion can inhibit gastric acid secretion, it appears that many of their effects are mediated by gastric D cells.[37] As the stomach empties, the continued secretion of acid is no longer buffered by the presence of food, and luminal pH drops. This lower pH has no direct effects on the G cell, parietal cell, or ECL cell but does cause a release of somatostatin from D cells to provide an inhibitory feedback loop for acid secretion.

NEONATAL PARIETAL CELL SECRETION

At birth, the gastric pH is greater than 2, probably because of the alkaline nature of swallowed amniotic fluid.[38,39] However, by several hours of age the stomach begins to secrete acid, and the pH falls. Unfortunately, the amount of acid produced in the human neonatal stomach has been difficult to determine because many studies have not included important parameters to quantify acid secretion accurately, such as body weight.[38,39] Most studies agree that acid secretion increases from birth to day 10 and then declines again over the next 20 days.[40,41] Acid production then slowly increases toward adult levels by about 3 months of age.[42] To examine gastric acid secretion more thoroughly, investigators have examined acid secretion in the absence (basal acid output [BAO]) or presence of secretagogues such as gastrin (maximal acid output [MAO]). As with previous studies, Euler and associates[43,44] demonstrated that the BAO of term infants was very low during the first 5 hours of life when compared with basal values of infants 4 to 14 hours of age. Basal acid secretion then increased in the infants from 6 to 8 hours of life. It is interesting that administration of pentagastrin did not increase acid production over basal levels. The investigators concluded that either acid secretion was already at maximal levels or the acid secretory apparatus was insensitive to gastrin at this stage of development. Euler and associates found that infants had elevated levels of serum gastrin that did not fall despite the increase in acid secretion. This suggested that the normal inhibitory effect of acid on gastrin release mediated by somatostatin was also not fully functional. Recent studies in neonates demonstrate that the proton pump H^+,K^+-ATPase is expressed at low levels as early as 25 weeks gestation. H^+,K^+-ATPase gene expression increases in concert with gastric acid secretion, gestational age, and postnatal age.[45]

Hyman and others investigated acid secretion in 34 healthy 7-day-old preterm infants of less than 37 weeks gestation and found that BAO was proportional to body weight but less than that of term infants.[46,47] BAO then gradually increased from 1 to 4 weeks of age and varied with postgestational but not postconceptual age, suggesting that extrauterine factors were involved. Hyman has suggested that feeding may play a primary role in this effect, but this has not been experimentally confirmed. Although there is no acid secretory response to pentagastrin in term infants at birth, preterm infants demonstrate this effect at 1 week of age. Unlike the effect of age on BAO, MAO in preterm infants increases with postgestational age and postconceptual age but remains far below that seen in older children and adults.[48-50]

To investigate the acid secretory capacity of the neonatal stomach in response to other stimuli, investigators examined MAO in response to the histamine analogue betazole.[51] They noted that BAO was low within the first 24 hours of life but that there was a twofold to threefold increase in acid output in response to betazole, which is consistent with findings in other studies. Betazole-stimulated MAO, however, was much lower than that seen in older infants, suggesting that the acid secretory apparatus was not functionally mature at this early stage in development.

MECHANISMS FOR DIMINISHED PARIETAL CELL FUNCTION IN THE NEONATE: ANIMAL MODELS

To explore the mechanisms that regulate the development of gastric acid secretory capacity, investigators have turned to animal models to examine each of the individual components in the

acid secretory apparatus. In human neonates, BAO is quite low at birth but rises shortly thereafter. Moreover, the acid secretory response is sensitive to meals but not to exogenous gastrin stimulation despite high plasma gastrin levels. Johnson[52] has extensively studied the development of acid secretion in the rat and noted a similar pattern in the ontogeny of gastric acid secretion. One theme common to all animal models is that the development of gastric acid secretion depends on the maturation of the parietal cell and those cells important for the regulation of acid secretion (outlined earlier).

PARIETAL CELL

In the mouse, gastric glands are first seen on fetal day 18, at which time there is no ultrastructural evidence of distinct parietal cells or alpha or beta H^+,K^+-ATPase subunit expression.[53,54] On fetal day 19 in the mouse, parietal cells can be identified, and both subunits of H^+,K^+-ATPase are now associated with apical membranes. Marino and colleagues[18] examined H^+,K^+-ATPase expression as well as expression of a second enzyme, carbonic anhydrase II, that generates a H^+ within the parietal cell in the rat. They noted that H^+,K^+-ATPase expression was present in 1-week-old pups, slowly increased over the next 7 weeks of development, and was limited to parietal cells. Conversely, carbonic anhydrase II was expressed in many cell types within the gastric mucosa at high levels shortly after birth. Carbonic anhydrase expression then declined slowly over the next several weeks but maintained high levels of expression in parietal cells. Hervatin and colleagues[55] examined H^+,K^+-ATPase activity in the developing rat and detected enzymatic activity on fetal day 19 although most of the enzyme was in the inactive state. H^+,K^+-ATPase activity rose from fetal day 19 to birth and then fell to almost zero by day 12 of life. Activity then rose over the next several weeks to adult levels, and the enzyme was found primarily in the active state. Other studies in the mouse[53,54] and rabbit[56] also detect the presence of functional H^+,K^+-ATPase early in gestation. Unlike in the rat, basal acid secretion in pigs is present at birth, but there is little response to secretagogues until 1 week of age.[57] In summary, it appears that the parietal cells are present at birth and contain the machinery necessary to secrete acid, albeit at diminished levels when compared with mature parietal cells.

Other investigators have examined the ability of the parietal cell to respond to gastrin, histamine, and acetylcholine. The receptors and postreceptor mechanisms for these secretagogues appear to develop with age; however, their patterns of development are both cell and species specific.[58-62] Despite the presence of parietal cells and functional H^+,K^+-ATPase at birth, basal acid secretion is very low at birth.[58,59] In the adult, basal acid secretion is controlled largely by vagal cholinergic inputs. Thus the low level of basal acid secretion suggests that these animals lack muscarinic receptors shortly after birth. However, muscarinic receptors are found at 70% to 80% of adult levels from birth onward and are functional, in that they can stimulate the release of pepsin from chief cells.[58] Investigators have hypothesized that this may reflect a low level of receptors on parietal cells or a failure of the parietal cell to develop postreceptor mechanisms that mediate the response. It is interesting that histamine and gastrin do not stimulate acid or pepsin secretion until day 20 of life.[59] Nevertheless, in neonates, protein hydrolysate formulas can stimulate gastric acid secretion twofold via unknown mechanisms.[63] Injection of corticosterone into 8-day-old pups before the natural steroid burst seen at weaning around day 21 prematurely induces basal acid secretion and the acid secretory response to all three secretagogues.

In other studies in the developing rat, investigators measured the binding of gastrin to its receptor and found no specific binding until day 20 of life; the receptor number was increased by treatment with corticosteroids.[64-66] The parietal cell response to histamine is more variable in its time of presentation but is documented to occur between 14 and 20 days of life in rats.[51,59] Although investigators can describe the presence of receptors in developing gastric mucosa and note the effects of secretagogues on acid secretion, it has been very difficult to examine postreceptor mechanisms in the developing animal. To determine that the changes in second messengers reflect changes in a particular cell type requires the use of isolated cell systems and large quantities of tissue. Thus this important area remains relatively unexplored.

INTRINSIC FACTOR SECRETION FROM PARIETAL CELLS

In humans, the parietal cell secretes intrinsic factor,[67] and investigators have examined its ontogeny to gain insight into the development of the parietal cell. Marino and associates[47] found that basal intrinsic factor production was similar in term and preterm infants. Conversely, term infants had much higher gastric acid secretion than preterm infants, suggesting that the development of these processes in human parietal cells was not linked. Other investigators have examined histamine-stimulated intrinsic factor secretion and noted low levels at birth that increase to normal adult values by 2 weeks of age.[51] Again, a dissociation was seen between the maturation of intrinsic factor secretion and gastric acid secretion—histamine-stimulated acid secretion did not reach adult levels even at 2 to 3 months of age. In the rat, intrinsic factor is a product of the chief cell, and thus it is difficult to use the rat as a suitable model for human development.[67,68]

G-CELL FUNCTION

Gastrin-producing G cells can be detected in the human fetus as early as 12 weeks of gestation.[69] It is interesting that most of these early G cells also express thyroid-releasing hormone (TRH), and the number of TRH-positive G cells increases to reach a maximum between 26 and 36 weeks gestation.[69] Thereafter, the number of TRH-positive G cells decreases, and none are found in the mature human stomach. Moreover, there is no known physiologic role for TRH in the developing stomach, and TRH is not found in G cells of other developing animals. In the rat, gastrin immunoreactivity is detected in the pancreatic islets before it is seen in the gastric antrum.[70] As fetal development proceeds, gastrin expression increases in the antrum and decreases in the islets. It appears that fetal pancreatic gastrin, in combination with transforming growth factor α, plays an important role in islet neogenesis.[71]

Human plasma gastrin levels in the neonate are approximately three times higher than those found in adults and pregnant women.[42] Unfortunately, the physiologic significance of neonatal hypergastrinemia is not known. It has been suggested that these elevated levels may play a role in the growth and development of the gastrointestinal tract.[72] To explore the role of gastrin in gut development, two groups have developed gastrin-deficient mice.[73-75] These mice are viable and develop normally with normal weight gain. This suggests that gastrin is not a vital hormone. However, both basal and stimulated gastric acid secretions are severely impaired in homozygous animals. Furthermore, there is a reduction in gastric mucosal thickness, with reductions in all three cell types. Although CCK can bind to the gastrin receptor, CCK does not substitute for gastrin because both gastrin-deficient and gastrin receptor–deficient mice have a similar gastric phenotype.[76]

Antral gastrin content increases in the developing rat until weaning. Early weaning or administration of corticosteroids or thyroid hormone increases antral gastrin content and promotes

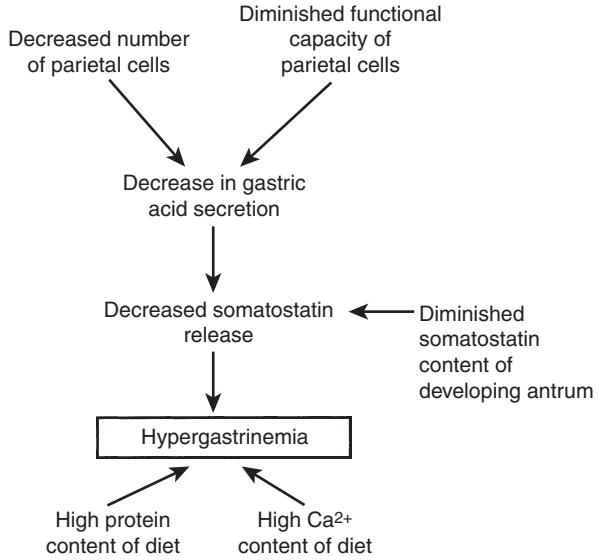

Figure 111-3 Mechanism(s) of neonatal hypergastrinemia.

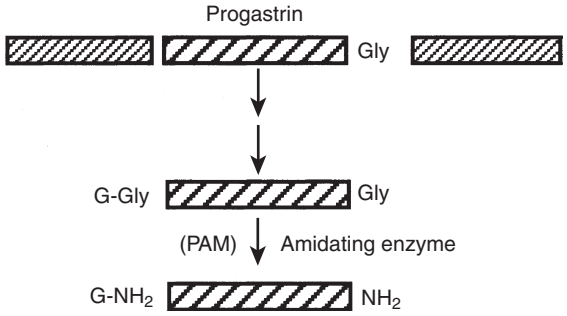

Figure 111-4 Progastrin posttranslational processing. Progastrin *(top)* is sequentially processed to a glycine-extended form of gastrin *(G-Gly).* G-Gly then serves as a substrate for the amidation enzyme *(PAM),* which catalyzes the formation of amidated gastrin *(G-NH_2).* The C-terminal amide moiety is necessary for G-NH_2 binding to the gastrin-CCK_B receptor. Developing tissues often contain more G-Gly than G-NH_2 before maturation of PAM.

the maturation of the gastric mucosal gastrin receptors.[52,55,65] It is unknown whether a similar phenomenon also occurs in the human stomach with a change in diet, but human plasma gastrin levels do remain elevated for several months after birth while infants are primarily milk fed.[77] The cause of neonatal hypergastrinemia is multifactorial, and the rat seems to provide a suitable model for study (Figure 111-3). A milk-based diet that is high in known gastrin secretagogues such as amino acids and calcium[78] may account for some of the hypergastrinemia. In both rats and humans there is diminished gastric acid secretion because of a diminished number of functional parietal cells. In mature humans this inhibits somatostatin secretion, which increases gastrin secretion. Consistent with this is the finding that the somatostatin content of the rat gastric antrum is low at birth and increases gradually until weaning at around day 21.[79] Moreover, infusion of somatostatin does not inhibit gastrin release in newborn rat pups until day 18 of life, suggesting that somatostatin receptor or postreceptor mechanisms are functionally mature until weaning.[80] The combined effect of low somatostatin content and diminished response to exogenous somatostatin before weaning suggests that somatostatin plays a major role in neonatal hypergastrinemia.

The exact nature of the role that gastrin plays in neonatal gastric acid secretion also is not fully elucidated. For example, gastrin is the primary mediator of gastric acid secretion during a meal in mature humans.[35] However, it has been unclear whether this is a direct effect on the parietal cell, because H_2 receptor antagonists block much of this response. This suggests that gastrin's effects on acid secretion are mediated via histamine release from ECL cells. In other species, it appears that gastrin has a more direct effect on the parietal cell. In the developing rat, gastrin-stimulated acid secretion is not blocked by H_2 receptor antagonists but is partially attenuated in mature animals.[81] It is currently unknown whether gastrin exerts its effects directly on the parietal cell of human infants or whether its effects are mediated by histamine release.

Gastrin, as is the case with other regulatory neuropeptides, is initially synthesized as a large, biologically inactive precursor termed *progastrin* (Figure 111-4). Endoproteolytic processing of progastrin within G cells results in the formation of a glycine-extended form of gastrin (G-Gly) that is found in high concentrations in the developing rat gastric antrum.[82] G-Gly serves as a substrate for the amidation enzyme, peptidylglycine α-amidating monooxygenase, that catalyzes the formation of fully processed, mature, amidated gastrin.[83] Gastrin (G-NH_2) requires its carboxyl-terminal amide moiety for full biologic activity mediated by gastrin-CCK_B receptors. Indeed, removal of the carboxyl-terminal amide in gastrin completely abolishes its acid stimulatory effects mediated by standard gastrin-CCK_B receptors, and the immediate precursor of amidated gastrins, G-Gly, is at least four orders of magnitude less potent than G-NH_2 in stimulating acid secretion from gastric parietal cells.[84] Nevertheless, interest in the physiologic effects of G-Gly has been fueled by the observations that G-Gly is stored in brain and gut tissues,[85] is secreted with G-NH_2 from antral G cells into the circulation, and achieves concentrations in plasma roughly equivalent to those of G-NH_2.[86] Moreover, G-Gly is seen in greater concentrations than G-NH_2 during development and in some malignant tissues that express gastrin, such as Zollinger-Ellison tumors and colon cancers.[87,88] Finally, biosynthetic studies suggested that G-Gly may be a distinct end-product of progastrin processing.[89] Thus the evidence pointed to G-Gly's role as a growth factor but not as a direct acid secretagogue.

To further characterize the potential trophic effects of G-Gly, we examined whether G-Gly might function as a growth factor in a fashion that could be distinguished from its relatively weak effects on the standard gastrin-CCK_B receptor.[84] We compared the abilities of G-NH_2 and G-Gly to stimulate DNA synthesis.[90] Both G-NH_2 and G-Gly stimulated [^{3}H]thymidine incorporation in a dose-dependent fashion. As expected, the stimulation induced by G-NH_2 was completely reversed by selective gastrin-CCK_B receptor antagonists. In further studies, we characterized a distinct receptor and signaling cascade for G-Gly.[91] However, the inability of investigators to isolate a complementary DNA encoding the putative G-Gly receptor has hampered further study in this area. Other data help confirm the role that G-Gly may play in gastrointestinal physiology. G-Gly can stimulate growth in an autocrine fashion.[92] Although acute administration of G-Gly has no effect on gastric acid secretion,[84,93] chronic administration of G-Gly markedly enhances stimulated but not basal acid secretion from isolated parietal cells and in vivo. This action of G-Gly is mediated via an increase in the expression of H^+,K^+-ATPase within gastric parietal cells.[94] G-Gly may play a role in the growth of the colon.[95,96] Indeed, gastrin-deficient mice have a diminished colonic proliferative index, and transgenic mice overexpressing G-Gly have enhanced colonic proliferation.[97] These observations suggest that growth-related receptors for G-Gly work in concert with G-NH_2 to enhance the functional development of the gut (Figure 111-5).

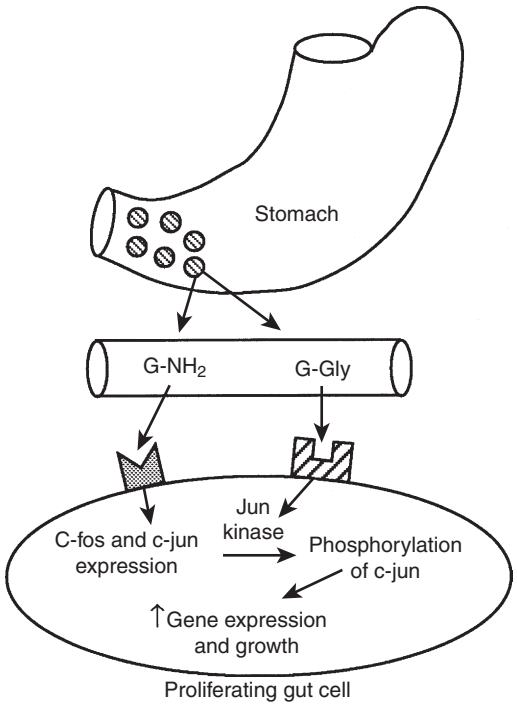

Figure 111-5 Mechanisms of G-NH_2 and G-Gly trophic effects. Amidated gastrin *(G-NH_2)* and its glycine-extended precursor *(G-Gly)* are released from G cells in the gastric antrum into the circulation. G-NH_2 acts through gastrin-CCK_B receptors to enhance the expression of c-fos and c-jun. G-Gly, via another distinct receptor and jun kinase, phosphorylates and thus bioactivates c-jun. Then c-fos and phosphorylated c-jun induce the expression of other genes necessary for the proliferation of gut cells.

D-CELL FUNCTION

In the fetal human, somatostatin has been found as early as 8 weeks gestation.[98,99] However, unlike gastrin, somatostatin exerts its effects in a paracrine manner, and therefore the release of gastric somatostatin may not result in an increase in plasma levels. Thus it has been difficult to describe carefully the development of gastric D-cell function in humans.

Gastric D-cell development, however, has been studied in animal models. In the rat, antral G cells can be detected at day 19 of gestation, but D cells are not clearly identified until day 4 of life.[79,100,101] Gastric somatostatin concentrations increase slowly from birth to weaning at day 21.[79] At day 21, there is a marked increase in gastric acid secretion, which is followed by an abrupt increase in gastric somatostatin content on day 24 that is more marked in the antrum than in the fundus.[79] Others have noted similar changes in somatostatin gene expression,[102] suggesting that peptide content is closely linked to gene expression. As is the case with the development of G-cell function, diet and glucocorticoids play a similar role in the development of D-cell content.[100,103] Rabbits and sheep are similar to humans in that immunoreactive somatostatin can be detected during fetal development although at levels much lower than that seen in mature animals.[104,105] The rabbit stomach also demonstrates a marked reduction in somatostatin and an increase in gastrin content in the third trimester that coincides with the development of acid secretion.[104]

To explore the effect of somatostatin on gastric development, investigators created a mouse deficient in the somatostatin receptor subtype found in the stomach (SSTR-2).[106] SSTR-2 mice developed and gained weight normally but have a marked increase in gastric acid secretion that was abolished by an antigastrin antibody. This is similar to the effect seen in humans overexpressing gastrin and confirms the inhibitory role of somatostatin on gastrin release and gastric acid secretion.

ENTEROCHROMAFFIN-LIKE CELLS

Few data exist concerning histamine-secreting ECL cells during development. Histamine is synthesized from histidine via the action of histidine decarboxylase (HDC). HDC activity is first seen in the developing rat at day 10 of life.[59] Gastrin stimulation of HDC activity is first noted on day 16 of life.[59] However, other investigators can detect the presence of immunoreactive histamine on embryonic day 16 in the rat gastric muscular layer and on embryonic day 18 within the mucosa.[107] From embryonic day 18 the number of histamine-positive cells increases, and at birth many of these have the paracrine-like processes that are characteristic of mature ECL cells. The number of mature ECL cells increases from birth to weaning, when their numbers and distribution are similar to those seen in a mature animal.[107] Because mature ECL cells express gastrin-CCK_B receptors, it is likely that the diminished number of gastrin receptors found in the developing rat reflect a loss of receptors not only on the parietal cell but also on ECL cells.[52,55,65] This has not been tested experimentally, but, because gastrin is an important regulator of histamine release from ECL cells, it suggests that histamine secretion might also be diminished.

Histamine's effects on gastric acid secretion are mediated via histamine2 receptors. As was the case for gastrin- and SSTR-2–deficient mice, histamine2 receptor–deficient mice are viable and grow normally.[106] However, unlike the gastrin-deficient mice, these mice have unexplained normal gastric acid secretion. They do have an elevated serum gastrin level and an increase in gastric mucosal thickness that contains increased numbers of small parietal cells.

SUMMARY OF REGULATION OF GASTRIC ACID SECRETION IN DEVELOPMENT

From the various human and animal studies, it appears that at birth gastric acid secretion from parietal cells is diminished (see Figure 111-3). The reasons for this include a decrease in the number of cell surface receptors and a diminished number of fully functional parietal cells.[52] This lack of acid production results in a decrease in somatostatin release that further increases gastrin secretion. One clinical implication of these observations is that, because gastric acid secretion is requisite to the formation of duodenal ulcers, one would expect to see a low incidence of this condition in neonates. Moreover, the lack of acid production contributes to the relatively low incidence of erosive esophagitis in infants with gastroesophageal reflux.

CHIEF CELL FUNCTION

In humans, the primary function of the chief cell is to secrete the proteolytic enzyme pepsin. Pepsin is packaged and stored in the chief cell within secretory granules in an inactive or zymogen (pepsinogen) form. Immunoreactive pepsinogen can be detected in the human fetus by 8 weeks of gestation,[108] and chief cells can be identified by the end of the 13th week.[3] Peptic activity can be seen in the fetal stomach by 16 weeks of gestation.[4] Peptic activity increases thereafter, and thus premature infants weighing 1 kg have approximately half the gastric peptic activity of term infants.[109] There are several different forms of pepsinogen in humans, but the primary type is pepsinogen IV.[108] Pepsin is the primary enzyme responsible for gastric proteolytic activity in humans; however, other species secrete proteolytic enzymes, such as chymosin, that are not found in humans.[110] Thus it is difficult to use animal models to examine the total gastric proteolytic activity for insight into human development.

Like gastric acid secretion, the secretion of pepsinogen appears to be diminished in the rat pup before weaning.[111] The rat chief cell response to carbachol is present at birth, but the amount of pepsinogen secreted is very low.[111] As is the case with the development of gastric acid secretion, the development of pepsinogen secretion is sensitive to corticosteroids.[112] Although thyroxine has a similar effect, this effect is mediated by an increase in endogenous glucocorticoid levels.[111]

GASTRIC LIPASE

Although not generally thought of as an organ responsible for fat absorption, the neonatal stomach secretes a lipase distinct from that found in the pancreas. It is not surprising that gastric lipase has a lower pH optimum than does pancreatic lipase.[113-115] Moreover, gastric lipase is somewhat more important in the neonate than in the adult because of the relative pancreatic insufficiency seen in newborn infants.[116] Although lingual lipase is the major source of gastric lipolytic activity in the rat,[117] it appears that there is little lingual lipase in humans.[118] Human gastric lipase is synthesized in gastric fundic chief cells and cosecreted with pepsinogen.[119,120] In humans, gastric lipase appears as early as 10 to 13 weeks after conception, consistent with the development of early gastric glands.[121] In preterm infants, gastric lipolytic activity is low at 24 to 26 weeks gestation but increases to reach a peak around 32 weeks gestation.[122] Thereafter, gastric lipase activity slowly declines until term and remains level throughout infancy.[122,123] In adults, lipase secretion is stimulated by agents such as gastrin that promote pepsin secretion from chief cells, but this has not been studied in human neonates.

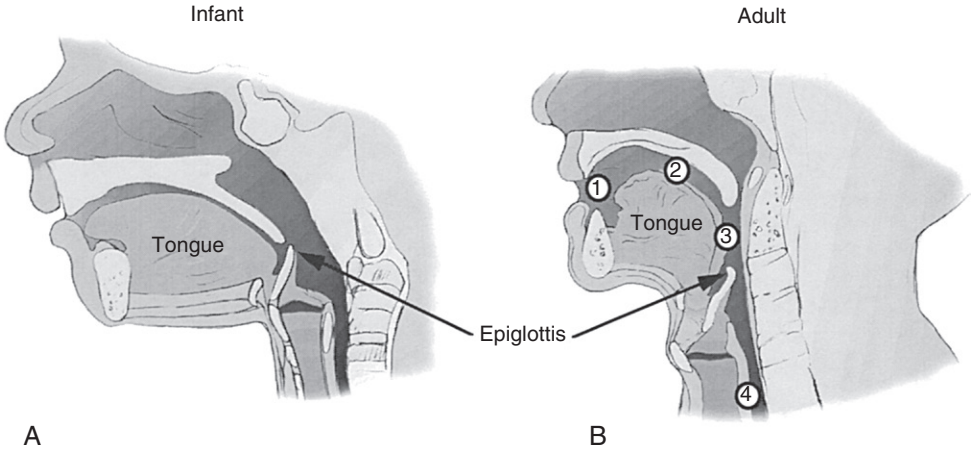

Figure 112-1 Comparative diagrams of the anatomy of the mouth and pharynx of neonates (A) and adults (B). Note the reduction in the relative size of the pharyngeal chamber and overlap between the soft palate and the epiglottis. The numbers on the figure refer to the phases of swallowing in the adult. *1,* Preparatory; *2,* oral; *3,* pharyngeal; *4,* esophageal. *(From Rudolph CD: Diagnosis and management of children with feeding disorders. In Hyman PE, Di Lorenzo C, editors:* Pediatric Gastrointestinal Motility Disorders. *New York, Academy Professional Information Services, 1994, p 37.)*

Figure 112-2 Mechanism of sucking from a nipple. Note that the lips seal the anterior oral cavity and the tongue seals against the palate to close the posterior opening of the oral cavity. The tongue and jaw descend with sucking, creating a negative intraoral pressure. *(From Bu'Lock F, Woolridge MW, Baum JD: Development of coordination of sucking, swallowing and breathing,* Dev Med Clin Neurol *32:669, 1990.)*

tongue movements develop that move a food bolus from the front of the tongue back toward the pharynx. At 6 months, infants will occlude their lips to remove pureed foods from a spoon and will move the food toward the midline with their tongue for chewing. As alveolar ridges and teeth develop over the next year, the infant develops increased tongue mobility that allows lateralization of solid foods for mature mastication.[10,11]

Pharyngeal Swallowing

The exquisite pattern of muscular contractions that produce the swallowing action is centrally integrated by two regionally distinct groups of medullary interneurons, the nucleus tractus solitarius (ventrally located) and the nucleus ambiguus (dorsally located), which form the "swallowing center." The nucleus tractus solitarius receives inputs from cortical fibers and peripheral sensory fibers originating in the pharynx, larynx, and esophagus. The nucleus tractus solitarius acts as a "pattern generator" and precisely regulates the sequence of motor nuclei excitation that leads to pharyngeal and esophageal contraction. The nucleus ambiguus receives some sensory input but predominantly acts as a relay station for the sequential activation of motor neurons responsible for pharyngeal and esophageal contraction and UES and LES relaxation.[12,13]

Swallowing reflexes are triggered when the contents of the oral cavity are propelled posteriorly toward the pharynx. This is achieved via highly complex contractions of the longitudinal and transverse intrinsic lingual musculature of the tongue.[1] Swallowing is initiated by distal elevation of the tongue followed by a posteriorly propagated peristaltic-like wave along the medial portion of the tongue.[3,14] Abnormal tongue movements such as incomplete peristaltic contractions and tremulous contractions are frequent in premature infants and diminish as they approach term.[3] If these poorly coordinated lingual movements fail to clear the oral cavity of its contents, the residue may overflow into the oropharynx when the airway is not protected, leading to aspiration.

As the oral contents enter the pharynx, a pharyngeal swallow is triggered. In term infants the time delay between initial suck and pharyngeal contraction is 500 milliseconds,[15] suck-oral transit time is 900 milliseconds, and pharyngeal transit time is 600 milliseconds.[4] The phasic relationship between sucking and swallowing is not constant; preterm and newborn infants demonstrate one to four sucks per swallow[3,5,15] whereas older term infants demonstrate one to two sucks per swallow.[3,4] During pharyngeal swallowing the velum and laryngeal musculature elevate, closing the nasopharynx and epiglottis and forming a conduit for passage of the milk bolus through the pharyngoesophageal junction. In adults, contraction of pharyngeal musculature does not actively propel the food bolus. Instead, the pressure wave associated with pharyngeal contraction occurs after the bolus has passed and functions predominantly to clear the pharynx of food residues.[16] Uncoordinated or low-amplitude pharyngeal contraction may lead to the retention of feeding bolus residues in the pharynx.

Coordination of Swallowing With Breathing

In utero, the pharynx is a conduit for fluid. The human fetus ingests up to 750 mL of amniotic fluid per day.[17] Swallowing of amniotic fluid contributes to amniotic fluid homeostasis,[18,19] and

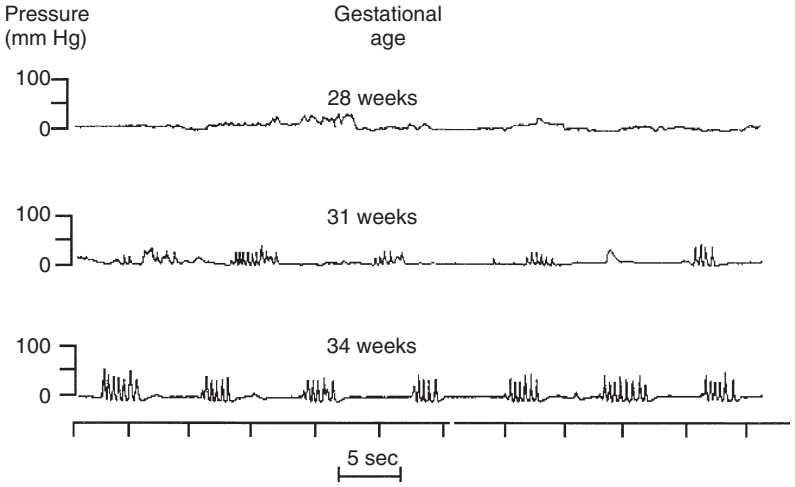

Figure 112-3 Intraoral pressure recordings of sucking patterns in premature infants during active sleep. Between 28 and 34 weeks post-menstrual age sucking develops from poorly coordinated low-amplitude sucks to higher-amplitude burst sucking. *(From Hack M, Estabrook MM, Robertson SS: Development of sucking rhythm in preterm infants,* Early Hum Dev *11:133-40, 1985).*

Stage	Sample Tracing	Suction/Expression Amplitude (mm Hg)	Description
1A	Suction Expression	Absent +0.5 to +1.0	No suction Arrhythmic expression
1B	Suction Expression	–2.5 to –12.5 +0.5 to +1.0	Arrhythmic alternation Suction/expression
2A	Suction Expression	Absent +0.2 to +4.0	No suction Rhythmic expression
2B	Suction Expression	–7.5 to –150 +0.2	Arrhythmic alternation Suction/expression
3A	Suction Expression	Absent +0.8 to +1.0	No suction Rhythmic expression • Suction amplitude increase • Wide amplitude range • Prolonged sucking bursts
3B	Suction Expression	–15 to –75 +0.5 to +0.7	Rhythmic suction/expression
4	Suction Expression	–50 to –75 +0.4 to 1.0	Rhythmic suction/expression • Suction well defined • Decrease amplitude range
5	Suction Expression	–110 to –160 +0.6 to +0.75	Rhythmic/well defined suction/expression • Suction amplitude increase • Sucking pattern similar to that of full term infant

A

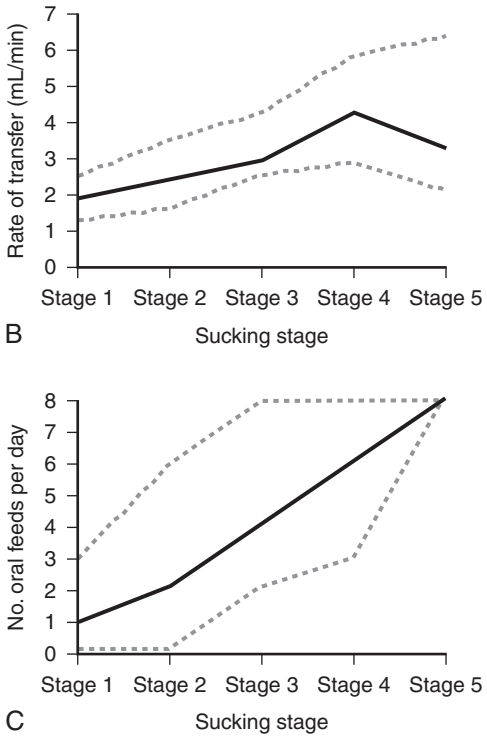

Figure 112-4 A, Stages of sucking characterized in preterm infants. **B,** Rate of milk transfer during feeding in infants at the different stages of sucking. **C,** Number of feedings per day at different stages of sucking. Data shown as median with *dotted lines* indicating the interquartile range. *(Modified from Lau C, Alagugurusamy R, Schanler RJ, et al: Characterization of the developmental stages of sucking in preterm infants during bottle feeding,* Acta Paediatr *89:846-52, 2000.)*

the swallowed fluid appears to be trophic for mucosal development of the GI tract.[20] After birth, however, the pharynx performs a dual function regulating the passage of food (into the esophagus) and air (into the larynx). As discussed above, anatomic differences between the newborn and adult larynx provide some protection of the airway in the neonate.[21] The laryngeal inlet is located high in the pharynx in the newborn at the level of cervical vertebrae C1-3. The tip of the epiglottis often extends into the nasopharynx, separating the respiratory passages and digestive conduit. During the 3rd year of life the larynx descends to the adult C3-5 location, creating a longer common passageway for the airway and digestive tracts in the oropharynx. This anatomic arrangement facilitates phonation but increases the risk of aspiration during swallowing. Although swallowing and respiration must be precisely controlled in the newborn, the prevention of aspiration becomes more difficult with growth.

Neonates possess an airway inhibitory mechanism that is triggered 200 milliseconds before pharyngeal swallowing and lasts approximately 600 milliseconds.[15] In mature term infants the ratio of swallowing to breathing is usually 1:1.[3] In contrast, newborn and preterm infants rarely synchronize breathing and swallowing. In the newborn, unstable breathing, prolonged inhibition, and depressed respiratory rate and minute volume occur frequently during periods of rapid swallowing.[5,15,22] The premature infant exhibits bursts of rapid swallowing interpolated with periods of rapid breathing.[3,23] Episodes of apnea, bradycardia, and oxygen desaturation are therefore common during burst swallowing.[23] The poor coordination of breathing and swallowing seen in premature and some newborn infants indicates that the interneuronal pathways between the medullary swallow and respiratory centers that synchronize respiratory inhibition are not fully functional.

ESOPHAGEAL MOTILITY

The motility of the esophagus, comprising the UES, LES, and the esophageal body, has now been well characterized in premature infants from 26 weeks gestation to term. The major features of esophageal motility are summarized in Figure 112-5.

Upper Esophageal Sphincter

UES pressure is generated predominantly by tonic contraction of the cricopharyngeus muscle. With swallowing, the cricopharyngeus muscle is inhibited, producing relaxation. Approximately 100 milliseconds after relaxation the UES is opened by the intrabolus pressure and the superior excursion of the hyoid and larynx.[24,25] Studies of term infants and children (2 months to 7 years) have demonstrated UES pressures comparable with those of adults (40-50 mm Hg) and UES relaxation in response to swallowing.[26-28] UES function has been investigated in premature infants at gestational ages as young as 33 weeks. In these infants, UES resting tone ranged from 2 to 28 mm Hg, and the UES was found to relax appropriately in response to dry swallow.[29] In addition, the magnitude of UES resting pressure is dependent greatly on the behavioral state with periods of apparent "comfort" associated with significantly lower UES pressures than periods of activity and apparent "discomfort" or abdominal straining.[29] These findings are consistent with effect of behavior and arousal reported in older children and adults.[26,30,31] Premature infants demonstrate a UES contractile reflex in response to esophageal distension with air or liquids.[32-35]

Esophageal Body

Swallowing initiates primary peristaltic esophageal contractions, which can be measured as pressure wave sequences propagated in an aborad direction along the length of the esophageal body. Primary esophageal peristalsis has been recorded in the human premature infant down to 26 weeks gestation[34-36] and term infants.[37] This peristalsis is essentially *normal;* however, the rate of propagation of the peristaltic wave is slower in younger premature infants.[34] Infusion of fluids and air into the esophageal lumen triggers reflex secondary peristalsis and reflex swallowing in the premature infants that is volume dependent.[32-35] Premature infants also exhibit esophageal body contractions that occur spontaneously and that are not triggered by the usual mechanisms (i.e., swallowing or esophageal distension). These spontaneous contractions are usually propagated in a nonperistaltic fashion (i.e., retrograde, synchronous, or incomplete propagation).[36-38] Similar spontaneous esophageal motor activity has been observed in adults, but these events are far less common and are usually associated with occurrence of the migrating motor complex of the small intestine.[39] It would appear that these motor patterns occur as a background to what appears to be normal, mature, primary and secondary peristalsis and therefore do not appear to impair esophageal function at least in the healthy infant. An example tracing illustrating swallow-related peristaltic and spontaneous nonperistaltic contractions is shown in Figure 112-5.

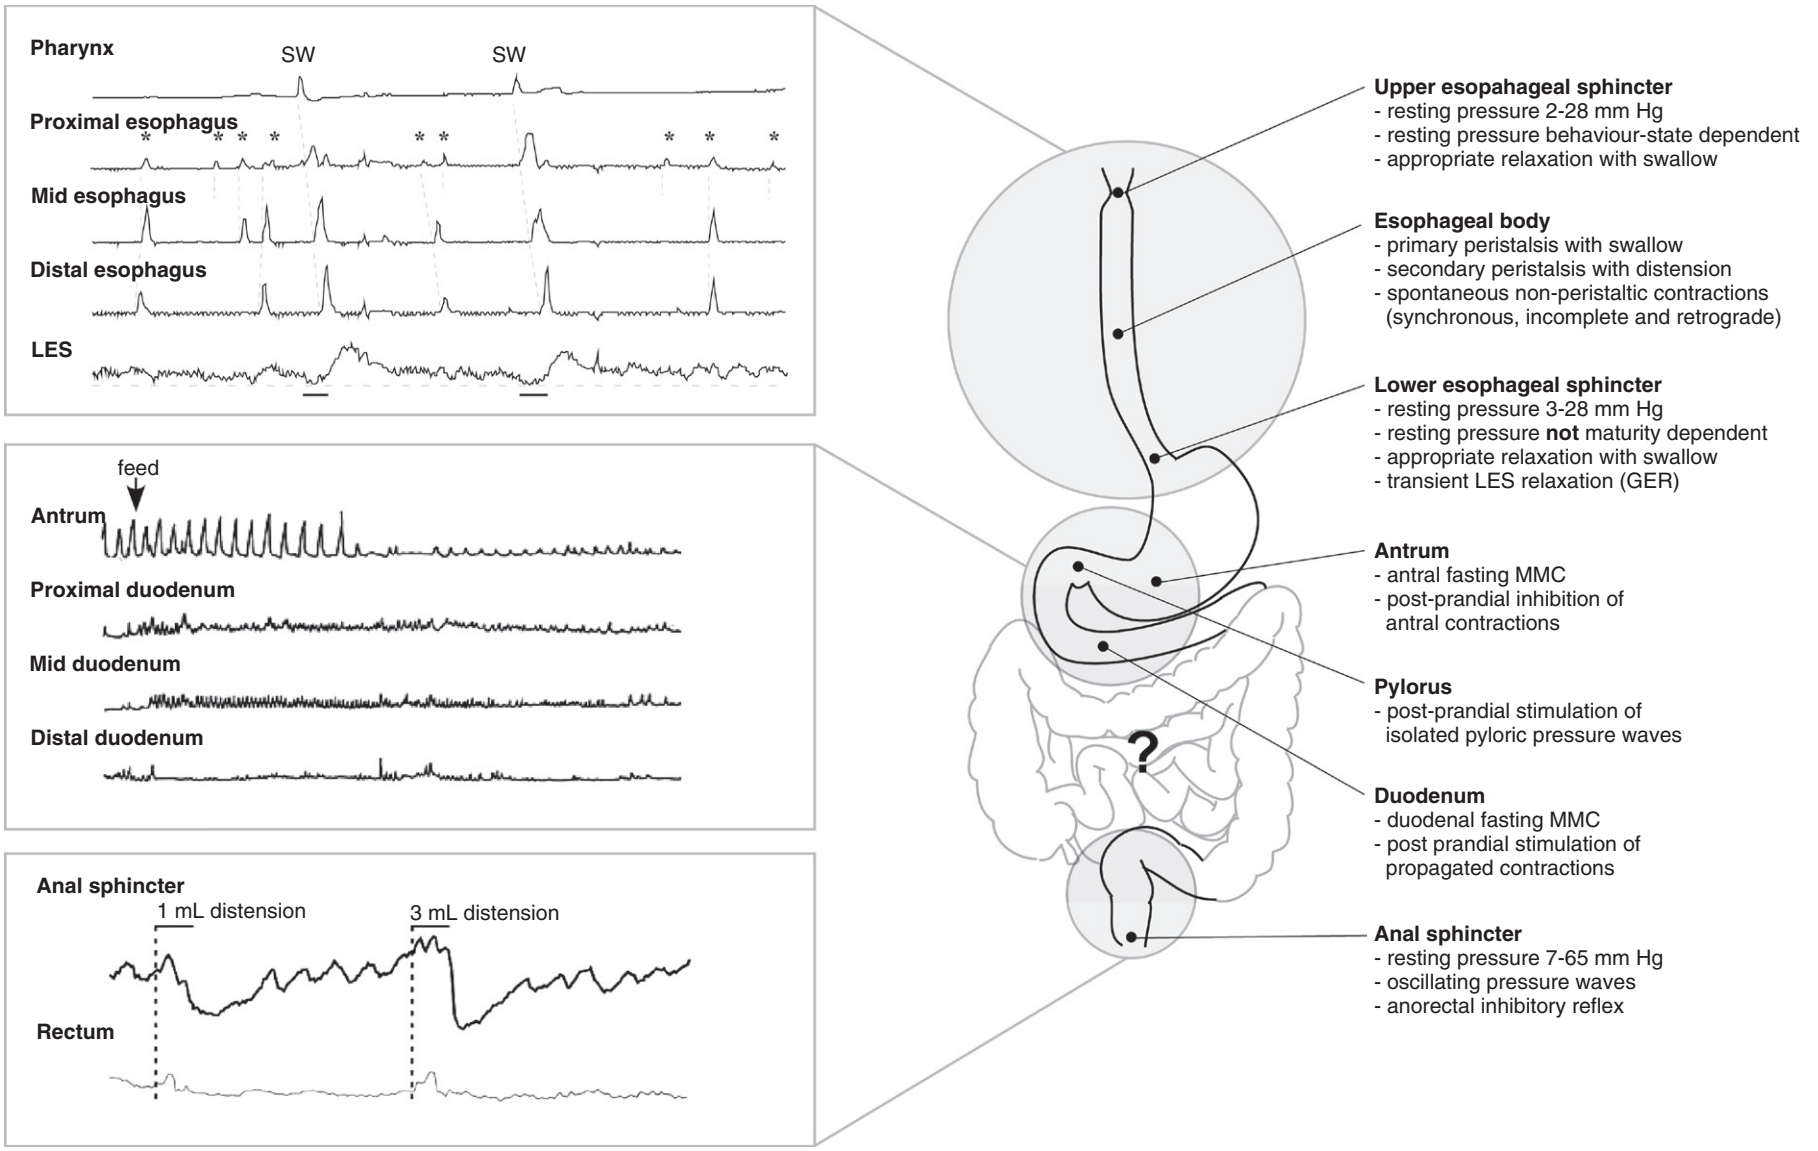
Lower Esophageal Sphincter

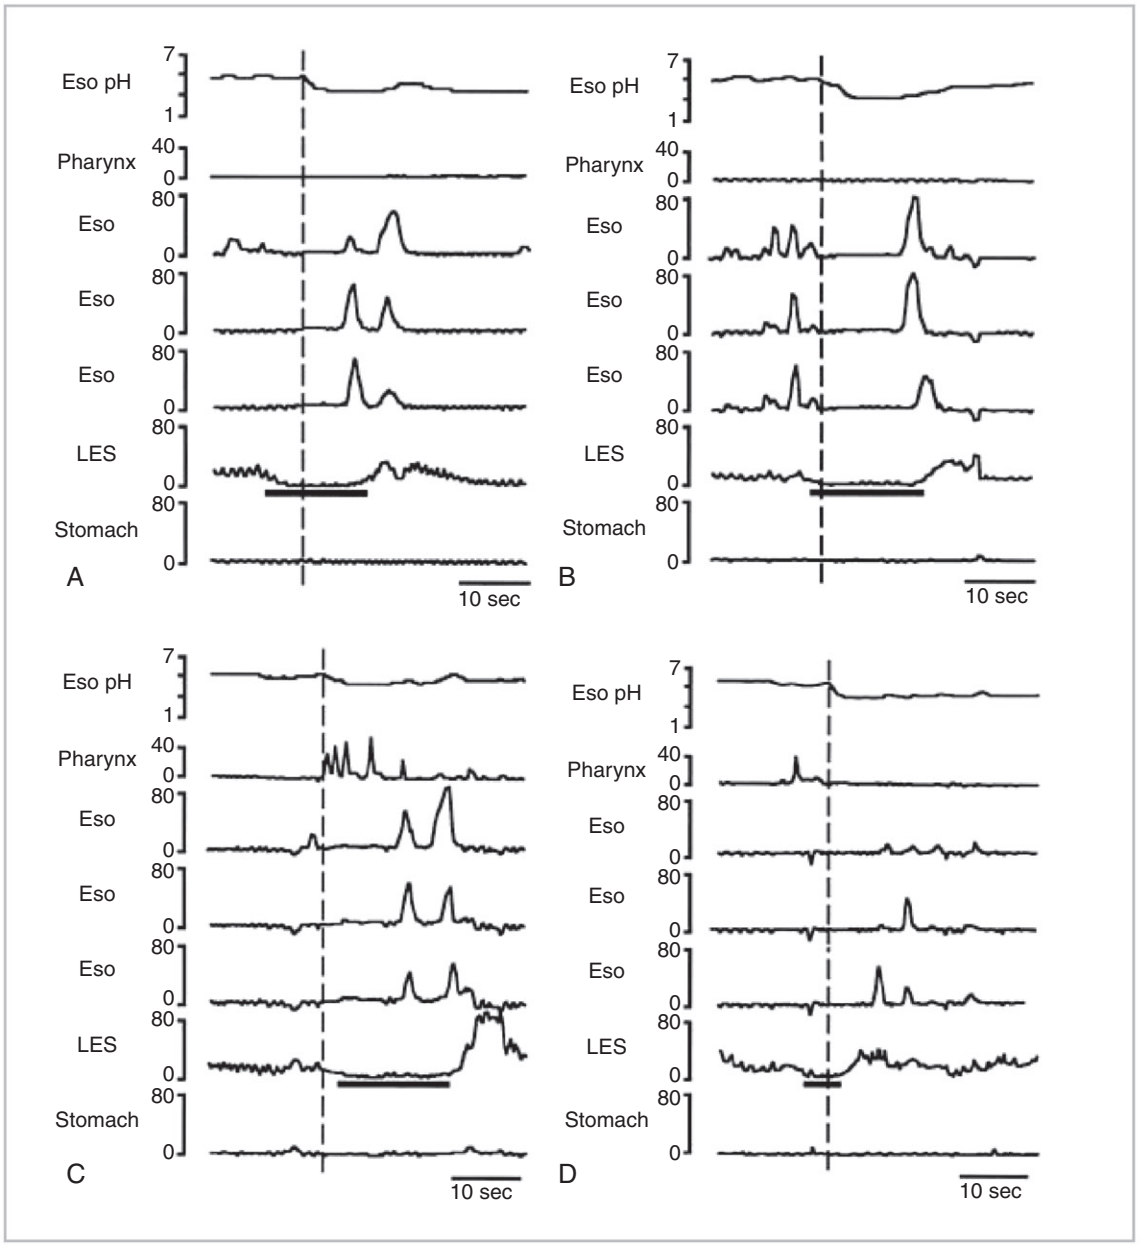
The LES functions as a physical esophagogastric antireflux barrier and comprises two sphincter mechanisms, the intrinsic smooth muscle sphincter and the crural diaphragm, which provides extrinsic support and squeeze. Both sphincter components work together and contribute to LES pressure. Early reports concluded that premature infants have poor LES tone because of immaturity of sphincter control mechanisms.[40-42] However, more recently it has been shown that in premature infants the LES generates tonic pressures that are sufficiently higher than intragastric pressure to maintain effective esophagogastric competence (5-10 mm Hg).[34-36,40,43] Contrary to early reports indicating that LES pressure increases with maturation,[43] more recent evaluations have shown no such pattern of maturation.[44] The LES relaxes with swallowing to allow passage of a food bolus (see Figure 112-5). This "swallow-related" relaxation lasts for 3 to 6 seconds during which the LES pressure drops to within 2 to 4 mm Hg of intragastric pressure. Swallow-related relaxation is well developed in the premature infant.[36-38] In addition to swallow-related relaxation, the LES exhibits transient LES relaxation (TLESR) (see later).

Sphincteric Mechanisms of Gastroesophageal Reflux

Gastroesophageal reflux (GER) results when stomach contents (liquid, gas, or liquid and gas in combination) are expelled into the esophageal lumen; this is a normal physiologic phenomenon that often occurs during or after feeding. Abnormally frequent GER, poor clearance of GER from the esophageal lumen, or exposure of GER to airway structures may lead to the manifestation of GER disease, which has a number of clinical presentations including feeding problems with or without weight loss, irritability, and obstructive apnea. GER is common in premature infants, and it was originally thought that this was related to poor LES competence resulting from immaturity of neural control mechanisms. As described previously, more recent studies in these infants have shown that mechanisms of sphincter competence are well developed and that GER usually occurs in association with complete sphincter relaxation. A number of motor mechanisms of GER triggering have been identified; these include predominantly swallow-related LES relaxation in association with failed peristalsis, prolonged inhibition of LES tone and esophageal contraction by multiple swallowing, and TLESR, which are triggered in the absence of swallowing[33] (Figure 112-6). TLESR is by far the most common mechanism of GER triggering (see Figure 112-6) and has been described in all age-groups from 26-week premature infants[45] through to adults.[46] Compared with normal swallow-related LES relaxations, TLESRs occur independently of pharyngeal swallowing, are prolonged in duration (>10 seconds), relax more completely (lower nadir), and are associated with inhibition of the esophageal body and crural diaphragm. Physiologically, TLESRs serve to vent gases from the stomach during belching to prevent GI bloating.[46,47] TLESRs are also stimulated in response to gastric distension after a meal, being most common in the early postprandial period and reducing in frequency after the first postprandial hour[48]; this is also the case in infants[49] (see Figure 112-6).

Neurophysiologically, TLESRs occur via a vagovagal reflex initiated by stretch-sensitive receptors located in the smooth muscle of the stomach wall, particularly the cardia of the stomach, which





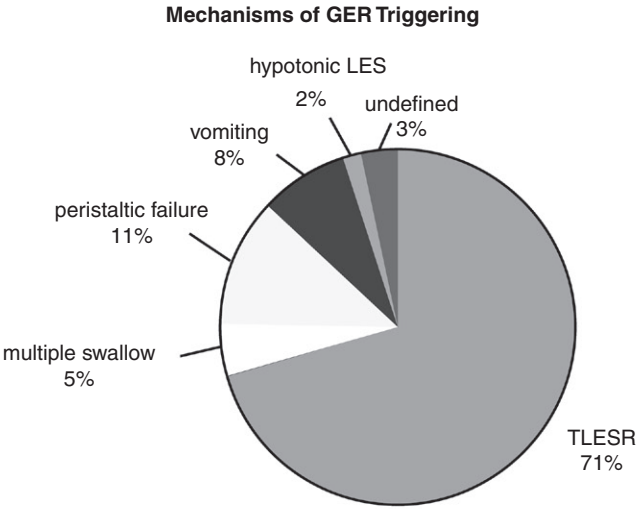


Figure 112-5 Patterns of GI motility described in the premature neonate and example tracings *(left)* of esophageal, antroduodenal, and anorectal motility recorded with perfusion manometry. *Top tracing,* Esophageal motility; two pharyngeal swallows *(sw)* trigger primary peristalsis, which is propagated down the length of the esophagus. The swallows also trigger LES relaxation *(black bars).* Spontaneous nonperistaltic contractions (incomplete and synchronous) are also shown *(asterisks). Middle tracing,* Antroduodenal response to feeding; feeding inhibits antral contraction and stimulates duodenal contraction. *Bottom tracing,* Anorectal motility; rectal balloon distension initiates reflex relaxation of the anal sphincter.

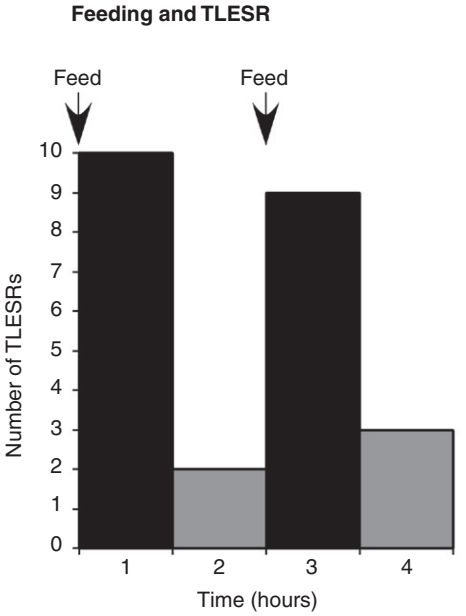

Figure 112-6 Mechanisms of acid GER in premature infants. Manometric tracings,TLESR (**A** and **B**), prolonged LES relaxation during multiple swallowing **(C),** and failed peristalsis during normal swallow-related LES relaxation **(D).** In all cases LES relaxation initiates acid GER, which is indicated by the drop in esophageal pH (onset marked by *dotted line*). *Pie chart,* The proportion of acid GER triggered by different mechanisms;TLESR is the predominant reflux mechanism and LES hypotonicity is the least common mechanism. *Graph,* The relationship between feeding and TLESRs; gastric distension by feeding resulting in an increased rate of TLESR via vagovagal mechanisms. Data from two hourly fed premature infants.

is the region most sensitive to TLESR triggering.[50] The stretch-sensitive sensory nerve fibers of the afferent arm of the reflex pathway terminate in the brain stem (nucleus tractus solitarius) and ultimately synapse with vagal motor neurones (dorsal motor nucleus of the vagus nerve and nucleus ambiguus) projecting to the LES, esophagus, pharynx, and crural diaphragm.[47] In premature infants TLESRs have the same characteristics (duration, nadir pressure) as those described in adults,[38] indicating that the basic integrative mechanisms underlying TLESR are well developed in these infants. Infants with reflux disease may have functional differences that pathologically increase the likelihood of liquid (rather than gas) reflux being triggered during a TLESR.[49] The mechanisms that precisely regulate the rate of triggering of TLESR, as well as the GER "type" triggered during TLESR, are complex and poorly understood.

GASTRIC MOTILITY

The motility of the stomach is less completely characterized in infants than that of the esophagus. Gastric emptying, gastric pacemaker activity (by electrogastrography), and antropyloric motility have been evaluated in infants down to 27 to 30 weeks. The predominating patterns of gastric motility are summarized in Figure 112-5.

The stomach is divided into two myoelectrically distinct regions: the proximal stomach, consisting of the fundus and orad third of the corpus, and the distal stomach, comprising the remaining corpus, antrum, and pylorus. Each of these regions exhibits a distinct pattern of contractile activity that contributes to the storage and mechanical breakdown of ingested foods and facilitates the selective emptying of solids and liquids into the duodenum. The frequency of gastric contractions is regulated by gastric slow-wave activity that can be measured by surface electrogastrography (EGG). The predominant frequency of the gastric slow wave is approximately 3 cycles/minute. EGG activity is absent at the time of birth in both preterm and term infants.[51] In the younger infant, regular 3 cycles/minute gastric slow waves are largely absent, with fewer than 30% of gastric slow waves occurring at the normal frequency of 2 to 4 cycles/minute, but this increases steadily over the first 6 months of life[52] to the range of 70% to 90% observed in older infants, children, and adults. As described later, premature and term infants can empty stomach contents normally in early life, and therefore the functional significance of these EEG-based findings is currently unclear. However, because EGG electrical patterns reflect an electrical activity generated by contractile waves that are responsible for mechanical digestion in the older infant and adult, it is not surprising that their ontogeny coincides with the timing of introduction of pureed or solid feedings in the normal infant.

Control of Gastric Emptying

Ingestion of a meal inhibits the tone of the fundus and contraction of the antrum; this mechanism enables the stomach to function as a food reservoir undergoing substantial changes in volume without significantly altering intragastric pressure. Gastric tone is best measured by a barostat, a device that records the volume of air contained within a bag placed in the proximal stomach and maintained at a constant pressure. In adults gastric volume can increase by more than 400% in response to a meal.[53] In the term neonate the mechanisms responsible for proximal gastric relaxation function poorly, but compliance quickly doubles in the first 3 postnatal days.[54] Gastric inhibition will normally be triggered by swallowing; this is known as receptive relaxation and aids the passage of the food bolus into the stomach.[55,56] Esophageal or gastric distension also triggers gastric inhibition; this is known as adaptive relaxation and is mediated via a vagovagal reflex initiated by excitation of highly sensitive gastric mechanoreceptors. In the cat esophageal and/or gastric distension will produce long-lasting inhibition of gastric tone that is absent in the presence of vagal cooling.[57] Mechanoreceptor excitation occurring with distension of the proximal stomach will also trigger local or vagal reflexes that stimulate motility of the antrum.[58,59]

Intraduodenal infusion of nutrients decreases fundic tone, suppresses antral contraction, and stimulates the pylorus to contract phasically and tonically (isolated pyloric pressure waves).[60,61] These changes in the pattern of motility act to slow gastric emptying and are regulated by neural feedback. Changes in the physical or chemical nature of intraluminal contents are detected by mucosal receptors located in or immediately below the gastric, duodenal, and small-intestinal epithelium. Although mucosal receptors with specificity for carbohydrates, pH, amino acids, short- or long-chain fatty acids, temperature, and touch have been described (mostly in the cat), the majority of mucosal receptors in most species are multimodal and are excited by both mechanical and chemical stimuli. Afferent signals originating at these receptors are transmitted to the brain stem (nucleus tractus solitarius) principally via unmyelinated vagal afferent fibers.The liver also contains receptors to detect osmotic, ionic, nutrient (glucose, amino acids, and sugars), pressure-volume, and temperature changes in the portal circulation and possesses a rich vagal afferent innervation that may alter gastric contraction via vagovagal pathways.[62-65] A variety of hormones also alter gastric emptying. For example, the products of protein or fat digestion stimulate the release of cholecystokinin from the small-intestinal mucosa. Cholecystokinin increases satiety, inhibits gastric motility (possibly via excitation of gastroduodenal vagal mucosal mechanoreceptors), and stimulates duodenal contraction.

Liquid Emptying

Liquids empty from the stomach faster than solids; fluids pass around solids whereas solids must be reduced into smaller-sized particles.[66] During initial filling the greater curvature of the gastric sinus bulges downward, a posture that facilitates the separation of liquids and solids and favors selective liquid emptying across the pylorus.[66] Liquid emptying is regulated by the pressure gradient between the stomach and the duodenum generated by tonic contraction of the proximal stomach[67]; the pylorus also has a profound effect on gastric emptying through the action of isolated pyloric pressure waves leading to pulsatile transpyloric flow.[68-70]

Solid Emptying

Solid food is processed by the distal stomach. After initial liquid emptying the bulge of the greater curvature of the gastric sinus is reduced, and the antrum assumes a tubular posture, bringing solids into line with the pylorus.[66] Movement of gastric contents from the corpus into the antrum is regulated via vagal mechanoreceptors in the antrum that reflexly inhibit corpus tone.[57] Distally propagating antral contractions occur at a frequency of two or three per minute, and these serve to break up digestible solids and sweep particles toward the gastric opening. The passage of solid particles across the pylorus is exquisitely controlled. Particles greater than 1 mm in diameter are usually blocked by pyloric contractions, some of which can be followed by retrograde flow from the duodenum, which returns particles to the antrum to be broken down further.[66,67]

Gastric Emptying in Neonates

Gastric emptying in neonates is generally considered a function of fluid (milk) flow across the pylorus; however, on acidification milk does separate into a semisolid curd and liquid whey fraction. This may account for differences in gastric emptying of formulas containing different ratios of casein and whey. The presence of

milk in the fundus stimulates gastric contraction that empties the milk into the duodenum. Gastric emptying rate of term and preterm infants has been extensively evaluated with use of ultrasonographic, scintigraphic, marker dilution, and breath test techniques. Gastric emptying is biphasic; that is, a rapid linear phase is then followed by a slower exponential phase. Measurements of 50% emptying times in premature infants fed breast milk range from 25 to 72 minutes.[71-74]

Feedback regulation of gastric emptying rate in response to the duodenal nutrient infusion is exhibited by infants as young as 32 weeks gestation.[75] As in adults,[76] increased caloric density of feedings slows gastric emptying,[77,78] and long-chain triglycerides produce greater inhibition than medium-chain triglycerides.[77] In term infants, starch solutions do not inhibit gastric emptying as effectively as isocaloric glucose solutions because of the lack of pancreatic amylase responsible for hydrolyzing starch into glucose.[79] Nonnutritive influences such as feeding temperature, nonnutritive sucking, or phototherapy do not influence gastric emptying rate.[80-82] The effect of gestational age on gastric emptying rate is not clear. Newell and colleagues[71] reported that infants ranging from 25 to 36 weeks gestation exhibit similar rates of emptying whereas Gupta and Brans[83] found that gastric emptying in term infants is faster than in preterm infants in the first 12 hours of life. Studies in premature infants have shown that nasogastric feeding or intraduodenal feeding infusion inhibits antral motility (see Figure 112-5) and stimulates isolated pyloric pressure waves.[84] As previously mentioned isolated pyloric pressure waves serve to regulate fluid flow across through the gastric outlet.

A profound but as yet unexplained difference exists between gastric emptying of expressed breast milk and infant formula. Despite the two being isocaloric, emptying of breast milk can occur at double the rate of infant formula.[71-73] Breast milk contains various regulator peptides such as gastrin, growth factors, and cytokines. In addition, feedings of breast milk alter the postprandial expression of gut peptides in the plasma compared with formula feedings.[85] The effects of these factors on gastric motility have not been evaluated. In contrast to the emptying rate, feeding type does not alter gastric slow-wave activity based on EGG,[52] which further questions the functional significance of EGG recordings as a marker of gastric function.

SMALL-INTESTINAL MOTILITY

Direct measurement of small-intestinal motility in infants has been limited to studies of the duodenum. The major motility patterns characterized in premature infants are shown in Figure 112-5.

The small intestine is a long tubular structure lined with absorptive epithelium, surrounded by layers of smooth muscle. The innermost layer is a thin layer underlying the mucosa, the muscularis mucosae. The middle and thickest layer, the circular muscle layer is arrayed circumferentially so that contraction narrows the lumen, whereas contraction of the thinner, outermost longitudinal layer foreshortens the intestine. Between the mucosa and each layer of muscle lies a meshwork of nerve fibers and ganglia that integrate varied contractile responses depending on the input of sensory signals from the lumen and mechanoreceptors in the muscles, as well as extrinsic input from vagal and sympathetic nerves. During the 5th to 8th week of gestation, circular muscle layers develop in the small intestine, with the longitudinal muscle not being present until 10 weeks gestation. The neurons migrate to the bowel as neural crest cells and differentiate through gestation with mature phenotypes being achieved in the third trimester. During fetal morphogenesis, the small intestine elongates, reaching a length of approximately four times the heel-to-crown length at birth (200-250 cm) and subsequently elongates to approximately 6 m in the adult.[86,87] The small intestine is segmented into a relatively short proximal segment, the retroperitoneal duodenum; a midregion, the jejunum; and distal portion, the ileum. Mucosal functions clearly vary in each region of the small intestine; however, regional differences in the organization of the muscle and nerve in each region are not well characterized. Most studies of small intestinal patterns of contraction have focused on the duodenum and jejunum, but limited studies of the ileum demonstrate somewhat different organization and control of patterns of contraction.[88,89]

Small-Intestinal Contraction

The smooth muscle cells of the small intestine are connected by gap junctions to form a syncytium. Between the muscle layers, specialized cells known as the interstitial cells of Cajal generate "slow-wave" oscillations of membrane potential that are transmitted through the syncytium (Figure 112-7). The slow wave is propagated rapidly around the circumference of a ring of bowel but not longitudinally, creating the conditions for the simultaneous contraction of a localized ring of bowel around the lumen. However, the slow-wave depolarizations do not cause muscle contraction. Further depolarization to a "threshold potential" is stimulated by the release of acetylcholine from nerves, triggering a rapid influx of calcium into the cells, generating a "spike" potential associated with contraction of the muscle cells. Thus the slow wave determines the maximal rate of contraction for each segment of the intestine, but the linkage of slow-wave depolarization with the actual occurrence of contractions depends on neural activity. In humans, the slow-wave frequency decreases from approximately 12 per minute in the duodenum to 8 per minute in the ileum. Slow waves propagate longitudinally down the bowel at a rate of 60 to 100 cm/minute.

As a ring of muscle contracts around the lumen, it generates force that is measured as a change in pressure in the lumen. The intrinsic neural plexus integrates excitatory and inhibitory input from mucosal sensory receptors, mechanoreceptors, and extrinsic vagal and sympathetic nerves to determine whether a segment of the intestine contracts. Sequential, coordinated contraction of rings of bowel along the longitudinal axis of the small intestine results in regions of high lumen pressure and low lumen pressure that mix and move the contents of the small intestine. In humans, most contractions involve only 1 to 4 cm of bowel at a time and last approximately 5 seconds.[90]

Coordination of Small-Intestinal Contraction

During fasting, small-intestinal contractions are grouped into characteristic patterns (Figure 112-8). The migrating motor complex (MMC) consists of a pattern of contractions that migrates

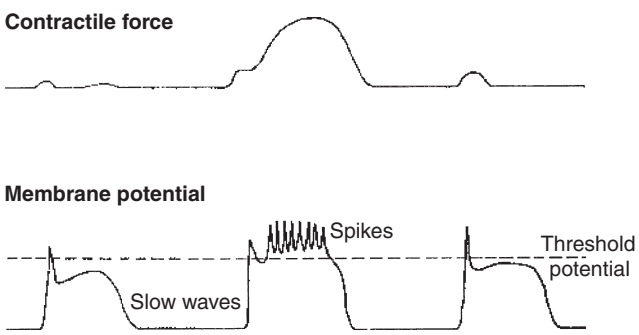

Figure 112-7 Diagram of the electrical and mechanical activity of smooth muscle showing the relationship between fluctuations in membrane potential and contractile force. *(Modified from Read N: Small intestinal motility physiology. In McCallum R, Champion M, editors:* Gastrointestinal Motility Disorders: Diagnosis and Treatment. *Baltimore, 1990, Williams & Wilkins, pp 23-36, with permission.)*

aborally from the antrum to the cecum.[91,92] In each region of the bowel, a period of no contractile activity (phase 1) is followed by irregular activity (phase 2) and then strong, regular contractions at the slow-wave frequency (phase 3).The bowel then again becomes quiescent. In the adult human, this pattern recurs every 45 to 180 minutes. Phase 3 activity lasts from 6 to 10 minutes and occupies 5% to 10% of the total MMC cycle whereas phase 2 activity occupies 20% to 30% of the MMC cycle.The migration velocity of the MMC along the small intestine is 4 to 6 cm/minute in the proximal intestine and decreases to 1 to 2 cm/minute in the ileum. The absence of this MMC pattern is associated with the development of bacterial overgrowth of the small intestine,[93] probably because the entire luminal contents, including bacteria, are swept out of the bowel during the migration of the strong phase 3 contractions down the bowel.

Feeding, bowel distension, and a variety of other stimuli disrupt the fasting MMC pattern with a more irregular pattern of contractions (see Figure 112-8). During this irregular pattern of contractile activity intestinal chyme is mixed and churned, but the net effect is to propel the nonabsorbed contents aborally from the stomach to the cecum within 2 to 12 hours after feeding.[94] The period of disruption by a meal varies with the size and content of a meal. Meals containing fat disrupt the MMC for a longer period of time than meals that contain equivalent amounts of energy in the form of protein or carbohydrate.[94] Vagotomy inhibits the conversion from a fasting to fed pattern suggesting that sensory input from the vagus initiates a reflex alteration of intestinal contractile patterns or suppresses the interdigestive patterns. Local factors are also important because the infusion of glucose into an isolated denervated loop of the small intestine can disrupt the fasting motor pattern.[95] The MMC pattern returns after the meal is conveyed down the small intestine. In most mammals, the MMC pattern is present only during fasting, but in ruminants, after weaning, the MMC persists after the meal.[96] In the pig, the MMC persists after fasting when food is taken without limit, but if pigs are fed only once per day the large meals disrupt the MMC cycle.[96]

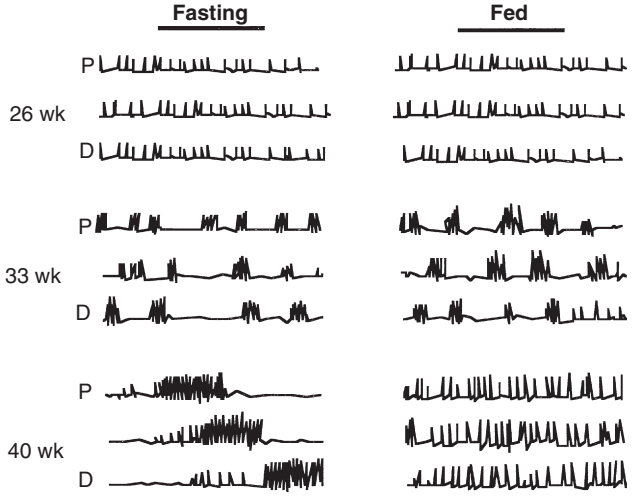

Figure 112-8 Examples of fasted and fed intraluminal pressure recordings from the upper small intestine at increasing gestational age in human infants. At 26 weeks, a random disorganized pattern is present with low-amplitude contractile waves. No change in pattern occurs with feeding. At 33 weeks, clusters of contractions are prolonged with intervening quiescence. Cluster activity persists after feeding, with a decrease in the periods of quiescence. At 40 weeks gestation, an organized MMC exists. Feeding results in an irregular, disorganized contractile pattern. In normal newborn infants, cluster patterns can persist after feeding. *P,* Proximal; *D,* distal.

Several other patterns of small-intestinal contractile activity have been described. Migrating clusters of contractions that last less than 2 minutes and migrate approximately 20 to 30 cm are observed after the ingestion of indigestible substrates such as cellulose, laxatives, or enterotoxins or partial obstruction. In the ileum, high-amplitude contractions lasting up to 15 seconds occur on exposure of mucosa to short-chain fatty acids, bile acids, and laxatives.[88,89] These contractions appear to clear the ileum of refluxed fecal contents and therefore may also be important for the prevention of bacterial overgrowth of the small intestine. Vomiting is often preceded by vagal nerve–mediated, retrograde giant migrating contractions that are two to three times larger in amplitude and four to six times longer in duration than the usual short-duration phasic contraction. These contractions usually begin in mid–small intestine and rapidly propagate to the antrum at a velocity of 10 to 12 cm/second, clearing intestinal contents into the stomach.[97]

Ontogeny of Coordinated Small-Bowel Contraction

The ontogeny of organized patterns of contraction of the small intestine was first studied in fetal and newborn lambs and dogs[98] (see Figures 112-8 and 112-9). Electrodes implanted on the intestine revealed "slow-wave" electrical rhythms at the earliest time recorded, the beginning of the third trimester. Episodic "spike" contractions occurred throughout the bowel, but no organized contractions were observed. As gestation progressed, this pattern of unorganized activity was replaced by a pattern described as the *fetal burst* pattern. Clusters of spike activity progressed for distances along the intestine in a pattern similar to the migrating cluster pattern observed in adult intestine. In the older fetus, the clusters became more organized and tended to migrate aborally for longer distances. In the lamb, an MMC pattern emerged before birth, whereas in the dog this pattern was not observed until 10 days after birth.

Since these early fetal studies, the ontogeny of small-bowel contractile activity in the human premature infant has been well studied with use of intraluminal perfused catheter techniques.[99-103] A similar sequence of development of increasingly coordinated activity begins with disorganized, low-amplitude, irregular contractile activity at 25 to 30 weeks gestation. Between 30 and 33 weeks rhythmic clusters of activity are observed that rarely migrate over large distances. From 33 to 36 weeks, migrating clusters with higher amplitudes of contraction are present. Increasing periods of time are seen with no contractile activity. By 36 weeks gestation, the mature MMC pattern is detected with quiescent periods (phase 1), irregular (phase 2), and regular (phase 3) contractions sequentially occurring in an aborally migrating pattern along the intestine. The length of time between episodes of phase 3 activity increases from 25 to 45 minutes in newborns[100,102,103] to 60 minutes at approximately age 2 years,[104] and approximately 100 to 150 minutes in adolescents and adults.[105] The duration of phase 3 does not change significantly after birth. Migration velocities of 2 to 4 cm/minute and mean amplitudes of contraction of 20 mm Hg in newborns increase to nearly double in adulthood.[93] Cluster activity persists after birth but becomes less common through childhood.

As patterns of coordinated contraction mature, the bowel also appears to undergo maturation in the responses to various factors that alter motility. In the term infant, feeding abruptly interrupts the MMC with the onset of irregular contractions,[106,107] although some cluster activity may persist. In older premature infants, an irregular pattern of activity replaces the fetal burst pattern, but, in infants younger than 30 weeks gestation, feeding has little effect on intestinal motor patterns. As is observed in adults, in preterm infants of approximately 33 weeks gestation, the length and degree of interruption of the fasting patterns vary with the number of calories delivered to the bowel.[108] Alterations in response to pharmacologic agents also mature with

age. Erythromycin initiates an almost immediate MMC pattern in adults and newborn infants[109] but not in premature infants before 31 weeks gestation (Figure 112-10).[109,110]

The factors controlling the ontogeny of small-intestinal motility remain rather unclear. The maturation of the enteric nervous system is likely an important factor. Hormonal changes may also play a role. Morriss and colleagues[111] noted an increase in duodenal contraction in those infants exposed to prenatal maternal corticosteroids. Some evidence exists that early feeding of preterm infants promotes postnatal maturation of intestinal motor activity.[112] The nutrient exposure in the feedings may replace exposure to the nutrients and growth factors in swallowed amniotic fluid. The effects of a lack of swallowed amniotic fluid on fetal development of small-bowel motility have not been studied. Assessment of the maturity of small-bowel motility may be useful to predict feeding readiness of preterm infants. Those infants with less-mature patterns of small-intestinal motility and without conversion to other motility patterns after feeding appear to be less tolerant of feeding challenges.[113] Perhaps monitoring of intestinal motility will provide a rational approach for determining the stage of gut neuromaturation and the relative risk of feeding for each preterm infant. Technical improvements in the methods of monitoring small-intestinal motor activity will be required before this approach can be adopted for routine clinical use.

COLONIC AND ANORECTAL MOTILITY

Colonic motility has not been directly measured in infants because of the technical difficulty of performing such measurements. Understanding of the development of colonic motility is

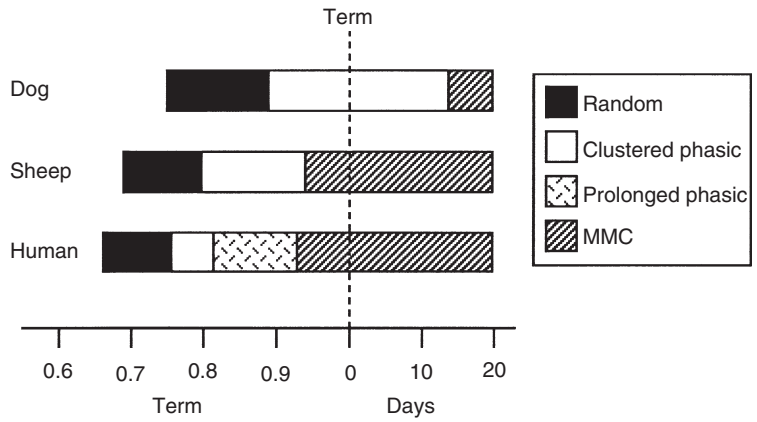

Figure 112-9 Qualitative maturation of motility patterns in the dog, sheep, and human. *(From Bisset W, Watt J, Rivers R, Milla P: Ontogeny of fasting small intestinal motor activity in the human infant,* Gut *29:483-8, 1988.)*

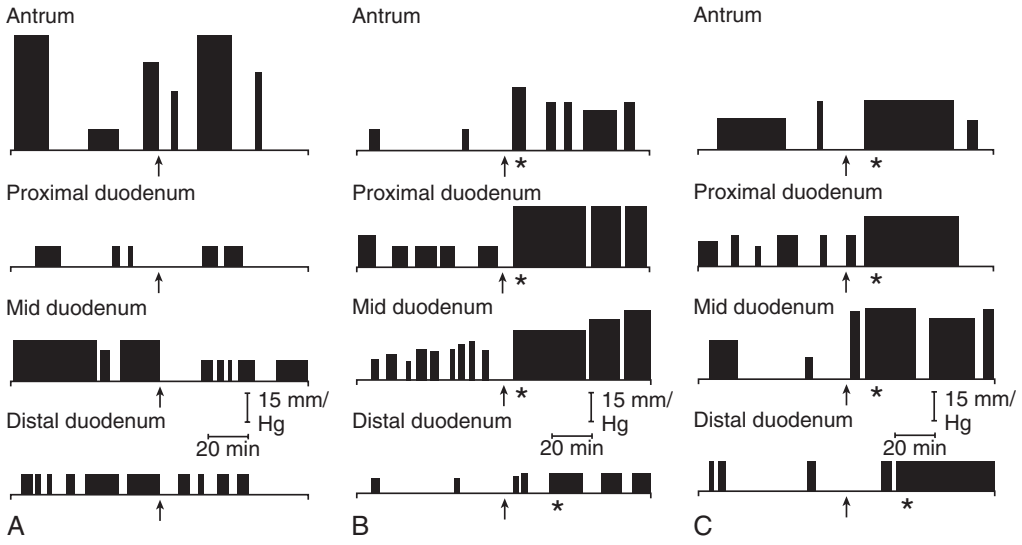

Figure 112-10 Schematic representation of motor activity recorded in a very preterm **(A),** a preterm **(B),** and a term **(C)** infant. In all three illustrations, motor activity recorded from the most proximal port is shown in the *top line;* motor patterns in each *lower line* were recorded from sites 2.5 cm distal to the one above it. Where the line is flat, motor quiescence was present. The *dark bars* show the duration and amplitude of contractions. In the very preterm infant **(A),** motor activity occurs independently in each lead before and after the administration of erythromycin *(arrows).* In the preterm infant **(B),** the administration of erythromycin *(arrows)* results in an increase in the amplitude of contractions in the antrum and the duodenum and in an increased motor activity that migrates distally, as indicated by the *asterisks.* In the term infant **(C),** erythromycin *(arrows)* also causes the appearance of migrating activity identified by the *asterisks;* however, the overall duration of each episode is longer than that which is seen in the preterm infant. *(From Jadcherla SR, Berseth CL: Effect of erythromycin on gastroduodenal contractile activity in developing neonates,* J Pediatr Gastroenterol Nutr *34:16-22, 2002.)*

therefore limited and based on measurements performed in older children and animal models. Anorectal motility has, however, been well characterized, and the major features are described in Figure 112-5.

Colon

The colon is a region of the digestive tract that is largely inaccessible and difficult to investigate. The placement of probes via anal intubation and endoscopic techniques is widely used; however, this requires bowel preparation that cleanses the colon of its normal fecal and bacterial environment, having unpredictable effects on motility. Nevertheless, investigations of colonic transit and contractile activity in children and adults have provided some insight into colonic function in health and disease.[114] Colonic transit is usually very slow, constituting two thirds of total mouth-to-anus transit (34-55 hours in normal adults).[115] This allows the colon sufficient time to carry out its primary function, the facilitation of transmural exchange of water and electrolytes.

Unless extreme circumstances prevail the colon is in a continuous digestive state and does not exhibit interdigestive motility patterns such as the MMC. Instead the colon exhibits specific patterns of motility that result in either mass movement or mixing of ileal effluent. Mass movement is achieved via high-amplitude propagated contractions (HAPCs). HAPCs are seen in the entire colon, exhibit contraction amplitudes of greater than 80 mm Hg, have durations greater than 10 seconds, and are propagated in an aboral direction over at least 30 cm at approximately 1 cm/second (Figure 112-11). Although highly effective in moving colonic intraluminal contents, HAPCs occur infrequently in adults, usually six times a day in the cleansed colon[116,117] and two times a day in the normal unprepared colon.[112] In children, HAPCs occur more often and are more likely to be associated with defecation.[118]

Other types of motility that are more frequently seen include independent contractions of individual or multiple colonic segments (Figure 112-12). These contractions move the colonic contents over short distances both aborally and orally to facilitate mixing. These segmental or nonpropagating contractions are not normally seen in infants but are expressed in older children.[118] The expression of colonic motility follows a circadian rhythm occurring after awakening and then cyclically during the day. Both adults and children demonstrate an immediate postprandial colonic response that manifests as an increase in colonic motility in direct response to nutrient (predominantly fats and carbohydrates) contact with the duodenojejunal mucosa and perhaps gastric distension. The mechanism for this response is unclear but may involve both vagal and endocrine systems. The duration of this response increases with age, lasting 30 minutes in infants[118,119] and 2 hours in adults.[120] In children younger than 4 years of age the postprandial response consists solely of HAPCs whereas children older than 4 years exhibit 60% HAPCs and 40% segmental contractions.[118,119]

Very little information is available regarding the prenatal development of colonic motility. In rhesus primates, the postprandial increase in colonic motility observed in the term infant is similar to the human and adult response. In the preterm rhesus primate a lesser response to meals occurs, suggesting that the colon response to meals matures late in gestation.[121] This finding may explain why the first meconium bowel movement is delayed by up to 3 days in premature infants.[122-124] Fetal hypoxemia frequently provokes passage of meconium by the term infant in utero, with resultant risks of meconium aspiration.[125] In contrast, even severe hypoxia rarely causes in utero meconium passage in the premature infant,[126] which further supports the contention that colonic motility is deficient in the preterm infant.

Anorectum

The anorectum is an anatomically complex region. Fecal continence is dependent on the ability to perceive rectal filling and then to retain its contents until the appropriate moment for defecation arises. Neonates usually defecate immediately on entry of stool into the rectum. The ability to delay defecation until a socially appropriate time requires coordination of the muscles of the sigmoid colon, rectum, levator ani, puborectalis (U-shaped striated muscle passing around the distal rectum), and anal canal. This is usually learned with toilet training. Normal term neonates pass their first meconium stool within 48 hours of birth whereas premature infants may experience a delay of more than a week before their initial defecation.[122-124]

The rectum acts as receptacle for fecal matter that arrives as a consequence of colonic HAPCs. In adults the rectum has a resting

(From Di Lorenzo C, Flores AF, Reddy SN, et al: Colonic manometry in children with chronic intestinal pseudo-obstruction,* Gut *34:803-7, 1993.)*

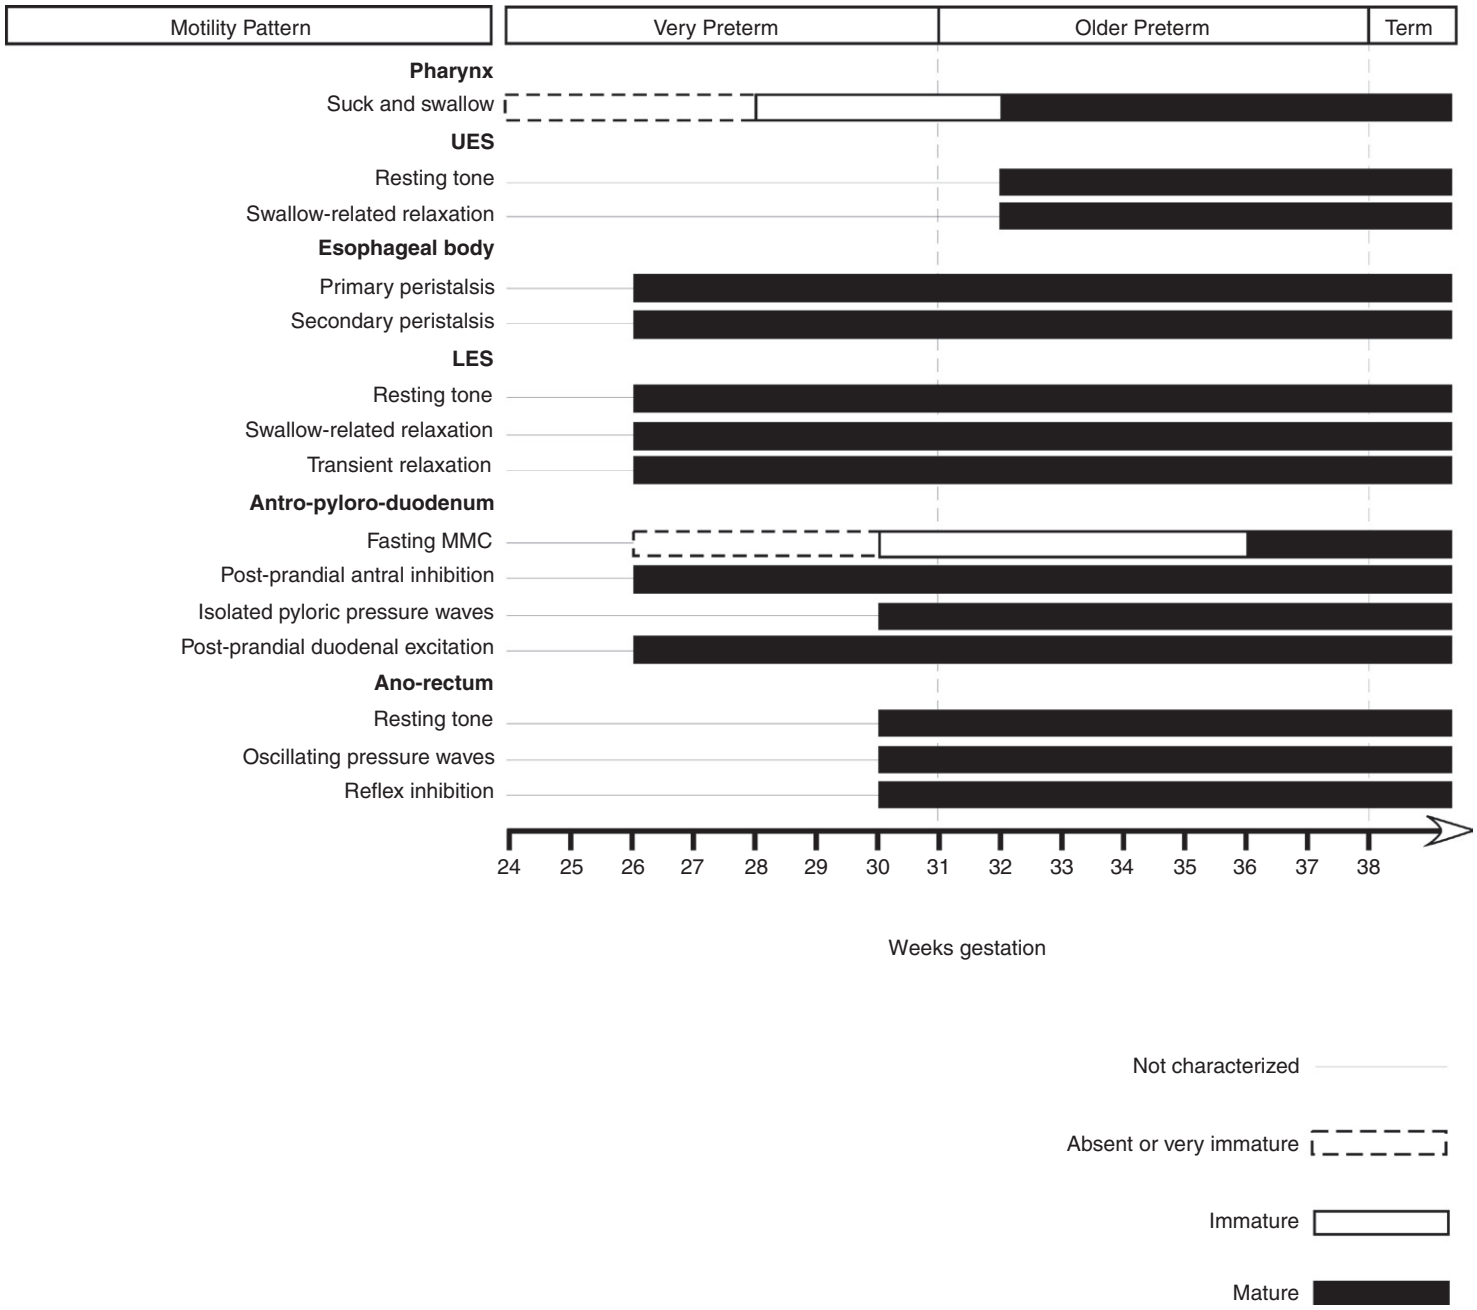

Figure 112-13 Pictorial summary of the understanding of the relative maturity of predominant GI motility patterns in very premature, older premature, and term infants.

pressure of 6 mm Hg and demonstrates three different patterns of phasic contraction: (1) isolated prolonged contractions (10 to 20 seconds' duration), (2) cluster contractions lasting 1 to 2 minutes and occurring every 20 to 30 minutes (10 to 12 seconds' duration), and (3) the rectal motor complex, a series of phasic contractions at the rectosigmoid junction lasting 10 minutes and occurring in a cyclical nature every 50 to 300 minutes dependent on the time of day (see Figure 112-11).[127] During defecation, rectal contraction serves to position fecal material into the proximal anal canal. Extrusion of the feces is achieved via relaxation of the anal canal in combination with straining (contraction of diaphragmatic and abdominal muscles) and propagated colorectal contractions. In addition, the puborectalis muscle relaxes and the levator ani muscles contract, causing the pelvic floor to descend, opening the anorectal angle, and assisting fecal passage.[128-131]

The anal canal measures 3 to 4 cm in adults and 1.25 to 2 cm in neonates. It consists of two sphincteric muscle groups, the external striated sphincter and the thicker internal smooth muscle sphincter. The external sphincter is under voluntary control via the pudendal nerve, and the internal sphincter is under both parasympathetic and sympathetic autonomic control. Resting anal sphincter tone is predominantly (85%) generated by the internal smooth muscle sphincter. The external striated muscle sphincter plays only a partial role in generating resting tone but can generate squeeze pressures that double the pressure in the anal canal. The ability to develop adequate squeeze pressure is essential in the maintenance of fecal continence because it overrides the effect of involuntary internal sphincter relaxation. It is thought that contraction of the external sphincter during internal sphincter relaxation allows the rectal contents to be sampled by receptors at the border of the anal canal that allow discrimination among solid, liquid, and gas.[132]

Anorectal Motility in Neonates

Basal pressure of the anal sphincter is 0 to 74 mm Hg in newborn infants and 15 to 98 mm Hg in older children and adults.[133,134] The internal sphincter contracts rhythmically 8 to 14 times per minute (oscillating pressure waves) and relaxes via a local reflex in response to balloon distension of the rectal wall, the rectoanal reflex (see Figure 112-5).[133] The threshold volume of air required to produce rectoanal reflex relaxation is 2 to 3.5 mL in infants,[133,134] 11 mL in older children,[130] and 20 mL in adults.[126] The anorectal relaxation reflex is present[135-137] and can be elicited in infants as young as 28 to 30 weeks gestation.[137,138] The anorectal reflex is normal in most infants, even those who experience delay in meconium passage,[139] but is absent in infants with Hirschsprung disease because of the lack of intrinsic inhibitory innervation of the rectum.[140]

OVERVIEW OF THE DEVELOPMENT OF MOTILITY IN THE INFANT

Numerous investigations performed over the last 10 to 20 years have characterized patterns of GI motility in preterm and term infants, in older preterm and term infants (>31 weeks gestation), and in some instances in infants as young as 26 weeks gestation. As shown in Figure 112-13 an almost complete picture now exists of the relative maturation of the motor patterns and reflexes of greatest importance to appropriate functioning of the GI tract (with the exception of the colon). The GI tract itself exhibits "mature" motility patterns in most regions with some notable exceptions. These are impairment of lingual function, ability to generate sucking pressures, and patterns and coordination of suck and swallow. This immaturity is the most likely cause of delays and difficulties in establishing full oral feeding; however, this deficiency is easily overcome in most infants with use of nasogastric tube feeding. Once nutrients enter the stomach it would appear that an appropriate fed antroduodenal motility response ensures regulated delivery of nutrients to the duodenum and mixing of luminal contents with GI secretions. Despite these normal fed patterns, however, a delay occurs in development of the fasting MMC that may lead to bacterial overgrowth and/or may contribute to feeding intolerance associated with slow intestinal transit. Well-developed esophageal motility allows for effective esophageal volume clearance in response to GER; however, if materials (feedings, oral secretions, or refluxate) come into contact with airway structures (made more likely by poor coordination of swallowing and breathing) then this may lead to significant complications including apnea and aspiration.

Fetal and Neonatal Intestinal Motility

During fetal development, nutrients are provided by placental circulation; at birth, the intestinal tract is called on to ingest, transport, and assimilate nutrients necessary for survival. In preterm infants these functions are often compromised to varying degrees. This has led to an interest in determining the developmental sequence of events within the gastrointestinal tract involved in the digestive sequence.

Ingestion of food and its presentation into the intestinal tract are the functions of suck and swallow reflexes. Many difficulties that arise in this area are a result of the complex integration required of the skeletal muscle of the oropharynx or its integration with the smooth muscle of the esophagus. The stomach is responsible for receiving and storing ingested nutrients and initiating mechanical trituration. Evidence is increasing that the

changing dietary requirements during the first year of life are accompanied by basic changes in gastric physiology during that same period of time. The primary responsibility of the small intestine is to deliver nutrients close to the intestinal mucosa, which has the regional specialization necessary to absorb various intestinal contents. The colon, particularly in early life, has a limited role in delivering nutrients to the body. It primarily stores the nutrients that are not absorbed in the small intestine and packages them into a form that is suitable for defecation.

ESOPHAGUS

Sucking consists of organized movements of skeletal muscular origin. The primary purpose of sucking is to create a fluid bolus that can be transported into the esophagus where a monophasic peristaltic smooth muscle contraction transports the bolus into the stomach. A coordinated suck and swallow mechanism does not usually begin until the 30th week of gestation or later. Many indications certainly exist from in utero studies that the fetus is able to swallow amniotic fluid as early as 15 to 20 weeks gestation.[1,2] The mouthing and poorly coordinated sucking performed by the midgestational fetus and the early preterm infant reflect the inability of this age group to coordinate the oral, pharyngeal, and esophageal phases of swallowing. As the newborn reaches 34 to 36 weeks gestational age, he or she is able to undertake bursts of at least 30 sucks. At this stage, the infant generates sufficient intraoral pressure to form a bolus and is better able to coordinate the suck and swallow mechanism with breathing. Initiating oral feedings in premature infants before effective sucking and coordinated swallowing are developed places the neonate at risk for aspiration. The degree of sophistication of the neural processes responsible for the skeletal muscle involved in sucking and swallowing often develops later than the integration required for satisfactory performance of the more distal smooth muscle aspects of the intestinal tract. This often results in infants' requiring nasogastric tube feedings to receive adequate nutrition.

After a bolus has passed to the hypopharynx, relaxation of the upper esophageal sphincter is required. Inability to relax the upper esophageal sphincter at the appropriate time can result in reflux of food into the oral or nasal pharynx. As a bolus passes the upper esophageal sphincter, it enters the smooth muscle portion of the esophagus, which in the human infant is the distal one half to two thirds of the esophagus. Here a peristaltic wave transports (or pushes) the ingested nutrient into the stomach.

In the distal esophagus is found a tonic region of muscle called the *lower esophageal sphincter.* This sphincter inhibits the reflux of gastric contents into the esophagus. The lower esophageal sphincter must relax at the appropriate time to allow ingested foodstuffs to enter the stomach. Great interest has been shown in the ability of the lower esophageal sphincter to inhibit gastroesophageal reflux in the neonate. It appears from animal studies that the muscle in this area is able to generate stress similar to muscle from this region in the adult; however, it may be at a mechanical disadvantage in generating lower esophageal sphincter pressures.[3] It is also possible that much of the gastroesophageal reflux seen in the infant may be caused by inappropriate relaxation.[4-6]

GASTRIC MOTOR FUNCTION

The stomach acts as a reservoir for ingested food, begins mechanical trituration of ingested food, and empties the nutrients into the small intestine. Various regions of the stomach are responsible for these different physiologic functions. The proximal region of the stomach, known as the *fundus*, through a process of receptive relaxation or gastric accommodation, is able to receive relatively large volumes of ingested nutrients with only small increases in pressure. This allows the fundus of the stomach to serve as a reservoir for the ingested nutrients. This function is mediated to a large extent by the central nervous system through the action of the vagus nerve, which mediates inhibitory neurotransmitters during gastric distension. Receptive relaxation during the newborn period has received little study, although it is likely that this area may be important in the pathophysiology of certain events such as gastroesophageal reflux during infancy. It has also been proposed that the fundus can facilitate emptying of liquids from the stomach by developing low-grade tonic contractions that enhance gastric emptying effects, which are primarily due to coordinated antral-pyloric peristalsis. One study has shown that the neuroregulatory mechanisms that result in the coordination of antral-pyloric motility and gastric emptying are developed by 30 weeks postgestational age.[7]

The most distal portion of the stomach is known as the *antrum* and is responsible for the mechanical trituration or mixing and grinding of ingested foodstuffs, which occur before gastric emptying. Although newborns rarely ingest solids, curds formed from ingested milk products may require some trituration before they are emptied from the stomach. The antrum participates in a peristaltic sequence with the pylorus and duodenum to promote emptying of food. This implies that the antrum and pylorus do more than simply act as a filter to prohibit large food particles from leaving the stomach. Data from newborn animal models suggest that newborn antral smooth muscle does not have the ability to use the same calcium stores for contraction as in the adult.[8] It is possible that this contributes to the newborn antral smooth muscle's relative inability to contract with short, transient contractions and makes it more likely that contractions will occur in a prolonged tonic fashion.[8]

To attempt to compare the rates of gastric emptying in the preterm infant with those of the term infant and the adult is in many respects similar to comparing apples and oranges because the composition of diet and method of feeding are so different. In adults, the most important factor in determining the rate of gastric emptying of a liquid is the liquid caloric density. In addition, the rate of gastric emptying is controlled by feedback from the small intestine. Stimulation of duodenal receptors by acid, fat, carbohydrate, tryptophan, or increasing osmolarity decreases rates of gastric emptying. Similarly, the stimulation of ileal receptors by acid, fat, and carbohydrate may decrease gastric emptying, apparently by humoral mechanisms.[9,10]

Similar to findings in these adult studies, evidence in studies of term infants suggests that increasing caloric density is associated with slower rates of gastric emptying.[11,12] In that regard, Siegel and colleagues performed a series of careful studies evaluating the effects of caloric density[13] and the nutrient content of formula[14] on gastric emptying in infants ranging in gestational age from 32 to 39 weeks. Incremental increases of caloric density from 0.2 to 0.66 cal/mL decreased the rate of gastric emptying, indicating that feedback control mechanisms were comparable with those in the adult.[15] In term neonates, starch-containing solutions empty at a rate similar to that of water.[11,12] This finding is most likely explained by the slower rates of starch hydrolysis caused by the low amylase concentrations in the proximal intestine of the infant,[16] resulting in glucose's not being released in the duodenum; therefore gastric emptying is not reduced accordingly. A similar lack of effect of complex carbohydrates on gastric emptying is seen in adults with pancreatic insufficiency.[17]

Clinical experience suggests that gastric emptying is delayed in preterm infants. It is oftentimes not clear whether this is caused by a primary problem with gastric motor function or whether it reflects the inability of the duodenum to receive the gastric contents. Studies comparing gastric emptying rates in preterm and term infants are difficult to evaluate, but this suggests that gastric emptying is slower in preterm infants than in term infants.[18,19] One study evaluated gastric electrical activity and gastric emptying in preterm and term infants and showed that

gastric electrical activity and gastric emptying show an intrinsic maturation depending on gestational age.[20]

It is unclear whether formulas of different composition and roughly the same caloric content are emptied at different rates by the newborn. In adults, it has been suggested that triglycerides of various chain lengths exert variable effects on gastric emptying, with medium-chain triglycerides being less inhibitory than long-chain triglycerides. Similar findings have been demonstrated in infants of 30 weeks gestation[13] or longer; however, other studies have not confirmed these differences. One study showed no gastric electrical activity or gastric emptying in preterm infants fed either a standard preterm formula or protein hydrolysate formula.[21]

Nonnutritive sucking does not appear to have much influence on gastric emptying times in the infant.[22] Various other nonnutritive factors, such as formula temperature,[23,24] phototherapy,[23] and position,[18] have been shown to have no effect on gastric emptying times in infants who are examined within reasonable limits of physiologic variation. However, it has been shown that elevated bilirubin levels can decrease rates of gastric emptying.[25] Systemic illness can also decrease rates in newborn infants, as is demonstrated by dilution markers in infants with respiratory distress syndrome.[26]

The use of pharmacologic agents to accelerate gastric emptying in infants should be reserved for those instances when one is certain that no other underlying abnormality exists. Although metoclopramide has been shown to increase the gastric emptying rate in preterm and term infants,[27,28] it has also been shown to cross the blood-brain barrier. Its very high incidence of central nervous system side effects in older children and its relatively low therapeutic efficacy have largely led to its abandonment as a front-line therapeutic agent. Similarly, cisapride[29] and low-dose erythromycin[30] may increase emptying rates in preterm infants, although clinical success attributable to these agents has not been consistently observed.[31] One study showed that low-dose erythromycin accelerated gastric emptying and improved feeding intolerance in preterm infants.[32] Nasojejunal feedings bypass the stomach, allowing enteral feeding even if gastric emptying is delayed; however, because intestinal motility also is immature, the nasojejunal feeding may provide only limited improvement in feeding tolerance.[33,34]

SMALL INTESTINE

In contradistinction to the esophagus and stomach, both of which tend to have more regionalized motor function, the small intestine can be viewed as a hollow tube consisting of supporting tissue, three muscle layers, and mucosa that absorbs nutrients. The three layers of muscle are identified as the muscularis mucosae, the internal circular muscle layer, and the external longitudinal muscle layer. Most evaluations of small-intestinal motility center on the role of the internal circular muscle layer in the generation of intraluminal pressure, which results from contraction of this muscle layer.

These muscle layers are closely regulated and have their motor activity coordinated by the enteric nervous system, which is modulated by the central nervous system and a variety of neurohumoral agents. In the normal adult it has become clear that there are at least two different types of small-intestinal motor activity. One occurs during the fasting state. This type of motor activity consists of clusters of phasic activity that migrate down the intestinal tract at periodic intervals. These migrating clusters of phasic motor activity normally occur every 1 to 2 hours and are known as migratory motor complexes (MMCs). One of the primary functions of these MMCs is to act as an "intestinal housekeeper" to move forward intestinal contents that have been left behind and to stop bacterial counts from increasing to high levels in the proximal small intestine. In the postprandial period after food is ingested, this periodicity of MMCs changes into what appears to be a continuous series of seemingly sporadic contractions that occur throughout the intestine. It is thought that this activity is responsible for the mixing and churning of ingested nutrients as they leave the stomach. It is also likely that the somewhat random-appearing nature of these contractions is actually a rather sophisticated series of peristaltic cascades that results in propulsion of nutrients through the small intestine.

When one examines movement of foodstuffs through the small intestine, it is important to understand what is being described. Techniques exist to measure actual transit time of foodstuffs from the proximal to the distal small intestine, but the measurements of contractile activity in the small intestine do not necessarily equate with transit times. The actual motor activity that is responsible for the movement of foodstuffs in the postprandial period through the small intestine has not been well characterized and is poorly quantitated in most clinical settings. This is because the peristaltic sequences that are responsible for the movement of foodstuffs through the small intestines are not monophasic but consist of a multitude of contractions that coordinate peristalsis, retroperistalsis, and mixing in a manner that ultimately results in movement of food in an aboral direction. Most quantitative analysis of small intestinal motor activity consists of analysis of MMCs, most of which occur in the fasting period.[35]

It has been noted by Amarnath and colleagues[36] and by Berseth[37] that few infants display a pattern consistent with a true MMC. They tend to have episodes of motor inactivity interspersed with nonmigrating phasic motor activity. This nonmigrating motor activity has been demonstrated in up to 60% of the recording time in both term and preterm infants. It has been shown that these episodes of nonmigrating activity change with gestational age in that episodes lengthen in duration and increase in overall frequency.[37]

The sporadic contractions seen in the adult intestine in the postprandial state are not as predictable as in the preterm infant[38] in whom one can see no change, an increase, or a decrease in the intestine in response to feeding. Berseth and Nordyke[39] have noted that, as the infant increases in gestational age, the likelihood of a mature feeding pattern increases. They have suggested that the presence of such a pattern may predict which infants are more likely to tolerate enteral feedings.[38] It has also been suggested that infants who have difficulty tolerating feedings are more likely to show an immature feeding pattern after enteral feedings.[40] A more recent study showed that term infants have increased duodenal motor activity after a feeding like adults, whereas most preterm infants have decreased duodenal motor activity.[41]

In adults, initiation of an MMC is coincident with a rise in serum motilin levels. Intravenous motilin in an adult can cause the premature appearance of an MMC,[42,43] as can erythromycin, which competitively binds to the motilin receptor.[44] Because MMCs are rarely seen in extremely preterm infants, Jadcherla and Berseth studied the correlation of small-intestinal motor activity with serum motilin levels. They found that even when MMCs did occur in infants, no rise was seen in serum motilin levels.[45] However, it was demonstrated that the administration of erythromycin did initiate MMCs in infants of 32 weeks gestation, suggesting that motilin receptors are available at that age. More recently, Jadcherla and Berseth showed that erythromycin, a motilin-receptor agonist, increased antral and duodenal contractions in term and preterm infants whose gestational ages were 32 weeks and older.[46]

Initiation of enteral feedings tends to bring about a more rapid maturation of motor patterns in the preterm infant.[47,48] It is possible that, in preterm infants lacking MMCs during the fasting phase, a defect exists in the "housekeeping" function of small-intestinal motor activity, which may predispose to bacterial

overgrowth. Some clinicians have speculated that this may be a predisposing factor to necrotizing enterocolitis.

COLONIC MOTILITY

Colonic motility has not received as much study as the functions of upper areas of the gastrointestinal tract, although it is known that its embryologic development occurs in concert with that of the small intestine. Peristaltic waves in the colon can be seen early in gestation. Meissner and Auerbach plexuses are present by the 10th to 12th weeks. The distribution of ganglion cells has been studied quite fully in infants because of the pathophysiology associated with colonic aganglionosis. It is now believed that aside from the well-described area of hypoganglionosis present within the first 10 mm of the anal valve, a normal distribution of ganglion cells exists in the premature infant as young as 24 weeks gestation.[49] More than 98% of normal newborns pass meconium within the first 36 to 48 hours. However, preterm infants weighing less than 1 kg oftentimes do not pass stool in the first 3 days.[50] It has been noted that high-amplitude propagating contractions in the colon are a good indicator of normal bowel function and passage of fecal material. These high-amplitude propagating contractions have been noted to decrease in frequency from several an hour after a meal in toddlers to just a few per day in adults.[51,52] Very little is known about high-amplitude propagating contractions during the newborn period. Work done on colonic motility of newborn rhesus primates suggested that the term newborn colon exhibits responses to feeding similar to those seen in the adult colon, whereas the response in the preterm primate is less well defined. This suggests that the colonic response matures late in gestation.[53]

Development of the Exocrine Pancreas

EMBRYOLOGY AND HISTOGENESIS OF THE HUMAN PANCREAS

The dorsal and ventral anlagen of the human pancreas develop as evaginations of the primitive foregut during the 5th week of gestation (Figure 114-1).[1] The larger dorsal anlage, which develops into the tail, body, and part of the head of the pancreas, grows directly from the duodenum. The ventral anlage develops from one or two buds from the primitive liver and eventually forms the major part of the head of the pancreas. At approximately 17 weeks gestation, the dorsal and ventral anlagen fuse as the buds develop and the gut rotates. The ventral duct forms the proximal portion of the major pancreatic duct of Wirsung. The dorsal duct forms the distal portion of the duct of Wirsung and the accessory duct of Santorini. Variations in fusion account for the variety of developmental abnormalities of the pancreas.

Histologic examination of the early pancreas reveals predominantly undifferentiated epithelial cells, which by 9 to 12 weeks development form a lobular-tubular pattern; zymogen granules are absent, but the Golgi apparatus is present.[2,3] Primitive acini containing rough endoplasmic reticulum and recognizable zymogen granules are present by 14 to 16 weeks. Golgi vesicles become prominent at this time. Activity of secretory enzymes is first detectable at this age. By 16 to 20 weeks development, large numbers of zymogen granules are present. As the pancreas matures, the luminal volume decreases and acinar cell volume increases. Connective tissue continues to decrease both throughout gestation and in the postnatal period. By 20 weeks gestation, acinar cells contain mature-appearing zymogen granules, well-developed endoplasmic reticulum, and highly developed basolateral membranes. The pancreas from the 6-day-old rat shows a similar increase in acinar volume and small lumina. Stroma continues to decrease, and acinar cells have a mature appearance. After birth, the volume of the exocrine pancreas continues to grow, nearly tripling in size during the first year of life from 5.5 g to 14.5 g.[4] The adult pancreas weighs 85 g. During the first 4 months, the ratio of acinar cells to connective tissue increases fourfold.

Centroacinar and duct cells (which are responsible for water, electrolyte, and bicarbonate secretion) are also found by 20 weeks. The ductal system contains less than 5% of the volume of the exocrine pancreas and only 0.5% of total pancreatic volume. In the postnatal period, luminal volume increases, along with the increase in acinar cell volume.

Islets are first identifiable at 12 to 16 weeks, at which time immunoreactive insulin is present in beta cells. Mixed cells, those with characteristics of both acinar and islet cells that are only rarely seen in the adult, may be found.[5] Endocrine cells of the fetus, but not the adult, may contain more than one hormone, and more than one hormone may also be found within a single granule. The histologic appearance of the pancreas in an infant born at term is similar to that in the adult.

ONTOGENY OF NONHUMAN PANCREAS

Many of our concepts concerning human pancreatic development are based on studies performed in rodents. Although the time span is different, the histologic, ultrastructural, and biochemical developmental stages of rat and human pancreas are thought to be similar. Several distinct prenatal developmental periods have been defined.[6-8] With use of a mouse model and a retroviral vector, it has now been shown that the endocrine pancreas and exocrine pancreas derive from a common cell origin.[9]

Using the combination of embryo microdissection and reverse transcriptase polymerase chain reaction to measure low-level gene expression, Gittes and Rutter[10] related the onset of cell-specific gene expression to morphogenesis within 2 to 3 hours. They found expression of pancreas-specific transcripts in the foregut before formation of the pancreas. Insulin and glucagon were detected 10 to 12 hours before evagination of the pancreatic bud but only in the area destined to become pancreas. Carboxypeptidase was first detected at 10.5 days and amylase at 12 days, both after the formation of the pancreas. Early expression of endocrine protein suggests a possible role in ontogenesis.

Human mucin gene expression *(Muc 1)* was evaluated in the fetal pancreas by Batra and colleagues,[11] who found that *Muc 1* messenger RNA (mRNA), a marker for differentiation of pancreatic cells, was not detectable until 18 to 19 weeks gestation. In adults, *Muc 1* expression correlates with the differentiation state of pancreatic tumors.

Hisaoka and colleagues[12] related pancreatic morphogenesis and organization of the extracellular matrix. Throughout fetal development, epithelial compartments are separated by the basement membrane components (laminin and type IV collagen) present at the epithelial mesenchyme interface. Spatial distribution of types I and III collagen changes with time. Laminin-1 expression is important in the induction of exocrine cell differentiation.[13] These extracellular matrix components are presumed to play a role in the regulation of differentiation. Organ culture studies have shown that local mesenchymal factors, but not nerves or hormones, are required for morphogenesis and cytodifferentiation, which themselves are separable events.

The proliferating cell nuclear antigen (PCNA), a protein associated with DNA polymerase Δ, is expressed during the S phase of the cell cycle. Activity of PCNA is related to [^{3}H]thymidine uptake.[14] With use of monoclonal antibody immunostaining, the percentage of PCNA-positive cells was high at 16 days gestation in the rat (60%), declined (to below 10%) at birth, increased to 30% at age 5 days, and then fell slowly until the pup weaned, at which time a precipitous fall to the adult level (below 5%) occurred (age 60 days).[14] This was highly correlated with [^{3}H] thymidine uptake.

The acinar cell population is predominantly mononuclear at birth but after weaning becomes progressively binucleate.[15] Before weaning, acinus formation is due to mononuclear acinar cell and duct cell proliferation. In Syrian hamsters primordial pancreatic cells most resemble centroacinar cells, and transitional cells are also found in the fetal pancreas.[16]

The shape of the mature acinar cell is pyramidal with a basal nucleus. The most prominent organelles in the fasted state are large numbers of zymogen granules, located apically. Abundant rough endoplasmic reticulum (the location of protein synthesis) and Golgi apparatus (the nidus of packaging proteins for export) are present. Junctional complexes join adjacent acinar cells.

The apical membrane contains abundant microvilli projecting into the lumen. The final three-dimensional structure of the exocrine pancreas consists of a complex series of branching ducts surrounded by grapelike clusters of acinar cells. The ontogeny of cell surface glycoproteins is critical for normal cell-cell interactions and morphogenesis.[17,18] Stage-specific polylactosamine (carbohydrate) antigens have been described in many organs, including the pancreas. These antigens are thought to be important for cell-to-cell communication and recognition.[19]

In the rat the expression of the mature phenotype is first detected at a gestational age of 15 days, the onset of the differentiated stage. Inhibition of glycoprotein synthesis (with tunicamycin therapy) in pancreatic rudiments between days 15 and 17 delays histogenesis, as well as the normal increase in amylase found at this age.[20] At 17 days, acinar lumina are first seen coincident with differentiation of the apical and basolateral domains of the acinar cell membrane. The adult pattern is fully developed at age 19 days.

Until day 14 of gestation, little or no secretory product, specific mRNA for secretory proteins, or zymogen granules are found. From days 14 to 18, synthesis of embryonic proteins (found in a wide variety of other fetal tissues, but not in zymogen granules) continues. A constant low level of a few pancreas-specific secretory proteins is found. From days 18 to 21, a rapid increase in specific mRNA transcripts occurs, followed by a nonparallel increase in pancreas-specific proteins and zymogen granules.[21,22] RNA synthesis peaks at day 18 followed by a peak in protein synthesis 1 day later. During this period, although total pancreatic protein synthesis increases only 25%, synthesis of some pancreas-specific proteins (e.g., amylase and chymotrypsinogen) increases by more than 100%. Amylase-specific mRNA increases 600-fold at a gestational age between 14 and 20 days, coincident with a 1000-fold increase in amylase-specific activity. During the final days of gestation and during early neonatal life, synthesis of secretory proteins accounts for more than 90% of all pancreatic protein synthesis. Synthesis of secretory proteins is regulated at the level of transcription.

The temporal profiles of secretory proteins in the prenatal pancreas have been defined in the rodent.[23-25] Because the appearance of the various secretory proteins is not parallel, independent regulation of gene expression is suggested.[23,24] The times of first appearance of digestive enzymes in the human fetal pancreas have been variably described. Trypsin, chymotrypsin, phospholipase A, and lipase are present in the 14- to 16-week fetus in low concentrations, and these steadily increase with gestation.[3,26,27] Chymotrypsin activity is low at birth, peaks at age 3 days, then declines slightly. Pancreatic secretory trypsin inhibitor is present in the fetal pancreas at 10 weeks gestation.[28] Pancreatic amylase is present in amniotic fluid at 14 weeks gestation.[29] A wide day-to-day variation of enzyme concentration is found. Thus amylase, lipase, trypsinogen, and chymotrypsinogen are present in the fetal pancreas by 16 weeks gestation, the time of rapid development of zymogen granules.

The postnatal developmental profile of mRNA transcripts coding for chymotrypsinogen, trypsinogen, lipase, and amylase and the expression of these proteins in the calf have been described.[30] Specific mRNA levels of amylase, lipase, and trypsin increased with age; chymotrypsin mRNA decreased from birth until day 28 and then increased at day 119 back to the level found in the newborn. Specific activities of the proteins did not necessarily parallel mRNA levels. At day 119, levels of trypsinogen, lipase, and amylase mRNAs were markedly increased; the level of chymotrypsinogen mRNA remained decreased when compared with the level found in the animal born at term. All four mRNAs were increased in weaned animals but to differing

degrees. Thus, in the cow, these genes are differently expressed during development.

The presence of at least three different lipases, one of which may be identical to the zymogen granule membrane protein GP3, has been described.[31] Each lipase appears to be under different regulatory control, both before and after birth. Yang and co-workers[32] have also shown dis-coordinate expression of pancreatic lipase and two related proteins in the human fetal pancreas.

Thus the timing of initiation of synthesis of individual proteins is different, and the final levels are also different. Although the curves for the appearance of each protein are quite similar, they are time shifted. The final adult level of each enzyme is unrelated to the onset of synthesis or to the peak fetal level. Concentrations of enzyme change considerably after birth.[23] The level of secretory protein in the mature pancreas represents the balance between synthesis and secretion. In addition, the presence of mRNA does not necessarily indicate an abundance of its translational product.

SECRETION FROM THE EXOCRINE PANCREAS

Although a continuous slow basal secretion of pancreatic enzymes occurs, physiologically significant secretion occurs only after stimulation by a secretagogue. A large number of agents have been described that are effective secretagogues in the experimental animal, but only acetylcholine, secretin, and cholecystokinin (CCK) are of significance in humans. Acetylcholine is released locally in the pancreas after vagal stimulation. CCK and secretin are synthesized and stored in the intestinal amine precursor uptake and decarboxylation cells and released after ingestion of a protein or fatty meal.

Each secretagogue then interacts with its specific receptor on the acinar cell membrane. Intracellular second and third messengers include Ca^{2+}, protein kinase C, diacylglycerol, and inositol phosphates.[33,34] This process eventually leads to fusion of zymogen granules and cell membranes and to exocytosis of pancreatic protein into the ductal system. Luminal factors, including the process of assembly and disassembly of a matrix (containing GP2 and proteoglycans), are thought to perform critical functions during storage and secretion of pancreatic secretory proteins.[35] Regulation by CCK and secretin is critical. Secretin acts directly on the pancreatic ducts. Human pancreatic acinar cells lack both CCK-A and CCK-B receptors. The primary target for CCK is now thought to be vagal receptors.[36] A portion of GP2 is cleaved by protein kinase C and released into the pancreatic duct during stimulated secretion.[37] Although nonparallel secretion of pancreatic proteins has also been described, at the present time, most authors consider that nonparallel secretion is probably the exception and not the norm.[38]

Fluid and electrolyte secretion from the centroacinar and ductal cells is controlled by secretin, which was the first hormone identified. Intracellular messengers in this system are cyclic adenosine monophosphate and protein kinase A. The concentrations of bicarbonate and chloride in pancreatic secretion depend on the flow rate. At lower flow rates, the concentration of bicarbonate is low and that of chloride is high.[38] As the rate increases, bicarbonate secretion increases and chloride secretion decreases, whereas sodium and potassium secretions remain constant.

The pancreas synthesizes more than 20 proteins specifically designed for export. After synthesis, it must segregate those proteins designated for export from those synthesized for internal use. Classic studies have demonstrated the synthetic pathway with use of the pulse-chase technique. Newly synthesized proteins travel from the endoplasmic reticulum to the Golgi apparatus, where they are "packaged" to the condensing vacuoles and then converted into mature zymogen granules in the apical portion of the cell. Little or no processing of individual proteins takes place from the time they leave the rough endoplasmic reticulum until the time they leave the cell. In rodents this entire process takes less than 1 hour. Molecular chaperones or chaperonins are involved in the transit process as they are in other cell types.[39]

ONTOGENY OF SECRETORY FUNCTION IN THE HUMAN

Because of both the technical difficulties and the ethical concerns about performing invasive procedures in healthy infants, few studies of pancreatic secretory function in the human infant have been published. Because direct collection of pancreatic juice is not possible in the infant and young child, pancreatic secretions must be collected in the duodenum in the fasted or basal state, after indirect stimulation with a meal, or after direct stimulation with secretagogues such as secretin or cholecystokinin, or both. Pancreatic function may be determined indirectly by the measurement of fecal elastase and by fat balance studies.

Many of the early studies of pancreatic function in infants are fraught with methodological difficulties including the qualitative nature of the collections and the lack of separation between the pancreatic and salivary amylase and lipase isoenzymes.[40-43] In a small group of older children, Zoppi and associates[41] demonstrated that amylase secretion continues to increase with age (the oldest child studied was 13 years old), whereas output of lipase, proteinases, fluid, and bicarbonate was independent of age. A good correlation was found between protein secretion and enzyme activity. Norman and co-workers[44] measured pancreatic secretion in eight healthy term infants aged 3 to 15 days after a test meal of breast milk. Although the trypsin-to-chymotrypsin ratio was relatively constant, the levels of the individual enzymes varied considerably between infants. Salivary but not pancreatic amylase was present in low levels.

Basal and stimulated pancreatic secretion in groups of well premature and term neonates, infants 1 month of age, and toddlers 2 years of age have been reported[45] (Figure 114-2). Results obtained from term and premature infants were similar, and data were pooled in the report. Although total protein content was similar in the pancreatic secretions collected from the duodenum of all three groups, each of the five individual secretory proteins studied had its own developmental profile. Trypsin was low at 1 day, but at 1 month it was similar to the level seen at 2 years. Chymotrypsin remained low at 1 month. Carboxypeptidase was low both at 1 day and at 1 month when compared with the level found at 2 years. Amylase was not detected until age 2 years. Similarly, lipase was undetectable at 1 day and at 1 month. Thus the ontogeny of the various enzymes is not parallel, a finding that has also been documented in rodents. Responses to secretin and CCK were poor in the newborn and infant. Responses at 1 month were similar, whether the infants were fed a cow's milk–based formula or a soy formula.

These data confirm previous reports concerning proteinases but are contradictory with respect to amylase and lipase. It has clearly been shown that pancreatic amylase is present early in gestation. Similarly, salivary amylase is secreted in high concentration in the newborn. Serum pancreatic isoamylase and isolipase are both low at birth and increase with age. These findings suggest that the newborn pancreas can synthesize but not secrete amylase. The failure to find measurable amylase may reflect the fasted state of the infants. A similar argument can be constructed to explain the extremely low levels of lipase.

Compared with secretion in the adult, enzyme secretion is decreased in the infant and young child, and secretion of water and bicarbonate is blunted as well. An increase in ductal cell function also occurs with increasing age. Secretion of water increases 10-fold by age 9 months.[43]

Despite this relative pancreatic insufficiency the human newborn infant and the premature infant absorb both fat and carbohydrate with seemingly little difficulty. Although an adult-type

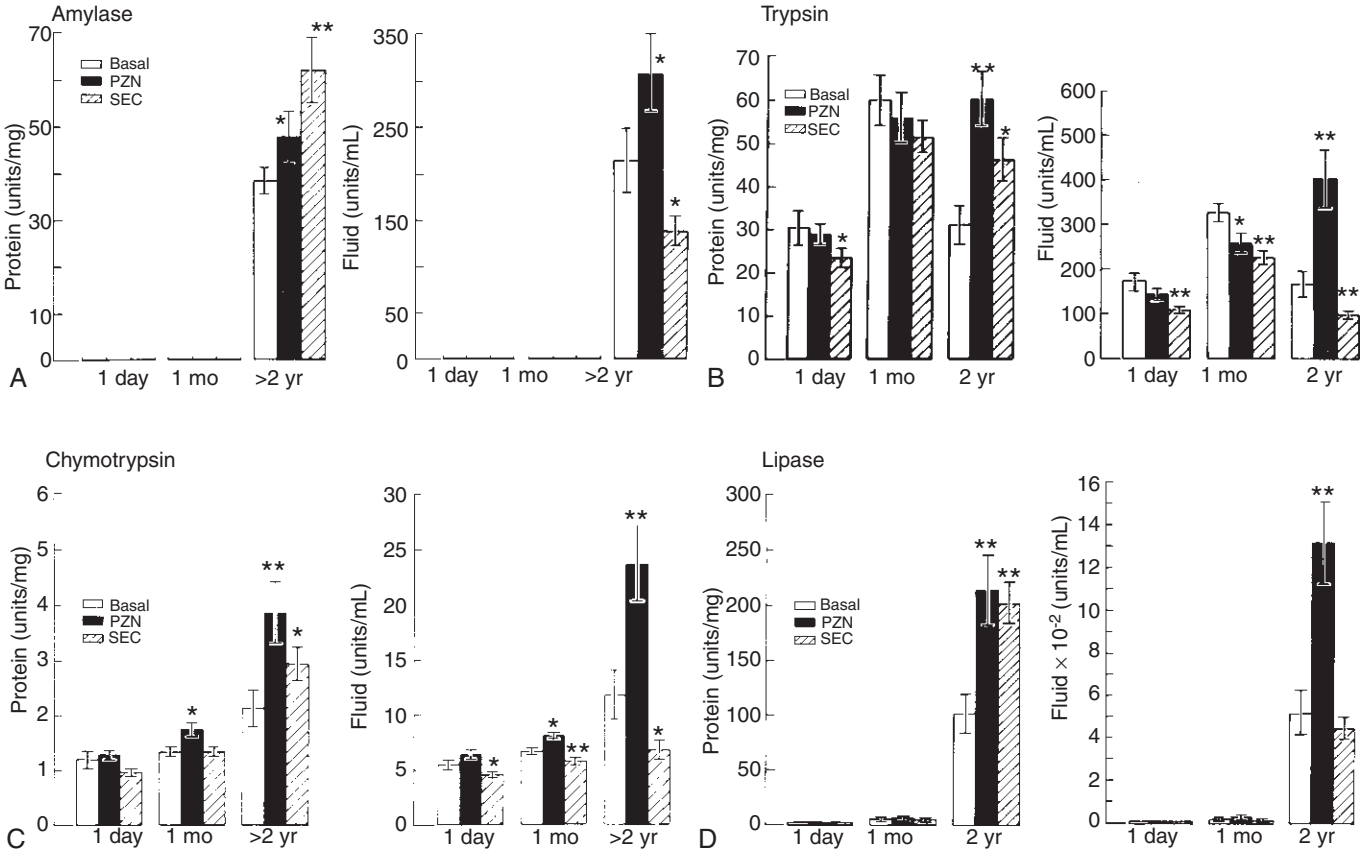

Figure 114-2 Effect of CCK and secretin on specific activities of pancreatic enzymes in duodenal fluid in infants and children. A, Amylase. **B,** Trypsin. **C,** Chymotrypsin. **D,** Lipase.

coefficient of fat absorption is not seen until age 4 to 6 months of life, "clinically" important malabsorption does not occur unless an additional pancreatic insult, such as cystic fibrosis, is present.[46] The lack of significant malabsorption is almost certainly a result of the presence of the nonpancreatic (lingual and gastric) lipases.

Although the ontogeny of complex carbohydrate digestion and absorption has not yet been as carefully examined as that of fat absorption, some information exists regarding the ability of the newborn to digest starches. Blood sugar rises only minimally after the ingestion of cooked starch. Intestinal hydrolysis of starch is rapid in the 1-year-old; at age 6 months, hydrolysis of amylopectin is incomplete and duodenal amylase activity is low. Despite the poor duodenal hydrolysis of starch, only minimal carbohydrate is found in the stool of infants fed formulas containing complex carbohydrates, because of salvage of colonic carbohydrate by bacterial fermentation and absorption of short-chain organic acid products.[47] The digestibility of starches, modified starches, and complex carbohydrates varies considerably. In adults the increase in breath hydrogen after ingestion of meals containing complex carbohydrates varies considerably, suggesting that even in the adult a large amount of fermentable material escapes small-bowel absorption.[48] Neonates also have glucoamylase, brush border enzyme, which aids in the digestion of starch and increases intraluminal glucose by removing glucose units from the nonreducing ends of starch molecules.

Most infants, even those who are premature, thrive on formulas that contain glucose polymers or corn syrup solids as their carbohydrate source. It has been our experience, which is supported by a small number of published case reports, that some infants have watery diarrhea when fed such formulas.[49-51] This diarrhea resolves when the formula is changed to one containing an alternative carbohydrate.

Diet modulates pancreatic enzyme secretion in the human as it does in the animal models discussed later in this chapter. Although these changes may occur at the level of synthesis, some changes reported to occur in animals clearly occur faster than can be explained by changes in synthesis. Premature infants fed a soy-based formula have greater stimulated secretion of lipase and trypsin compared with infants fed a cow's milk–based formula.[52] Total parenteral nutrition induces reversible pancreatic atrophy in animals and pancreatic hyposecretion in humans. Thus, as in the animal models described later in this chapter, some changes in pancreatic enzyme secretion are programmed, and others are inducible by diet.

ONTOGENY OF RODENT EXOCRINE PANCREATIC SECRETION

The pancreas of the newborn rat is both histologically and ultrastructurally fully developed; it is packed with secretory proteins. Although it appears poised to secrete, it is functionally immature. Immaturity has been documented at a number of steps along the stimulus-secretion chain. Responsiveness to cholinergic and peptidergic (e.g., CCK) secretagogues in a manner similar to, but not identical with, that of the adult gland does not occur until age 24 to 48 hours.[53-55] The newborn pancreas, although unresponsive to cholinergic agents and to CCK, responded with increased secretion of amylase to the calcium ionophore A23187 in some studies but not in others.[55-57] Responsiveness would suggest that the secretory mechanism distal to calcium mobilization is intact.

Muscarinic receptor density is low in the fetal and newborn periods and steadily increases with age, reaching maximal levels at age 1 month; it then decreases steadily until age 1 year.[58] A parallel increase occurs in secretory response and receptor density.

Binding of radiolabeled CCK to pancreatic acinar cells rises rapidly (from low levels at birth), reaching levels of the mature pancreas at age 3 weeks.[59,60] Others have found that the postnatal increase in secretory responsiveness was not associated with increased CCK binding.[57] These receptors are of the A or intestinal type that just after birth are already coupled to G proteins.[61] CCK-A glycoforms were different before birth. In the cow the CCK-A receptor predominates at birth, but later the CCK-B receptor predominates.[19] Results of these studies suggest that decreased receptor density cannot explain the lack of secretory responsiveness in the immature pancreas and that the immaturity is distal to calcium mobilization. The absence of the zymogen granule membrane protein GP2 in the fetus may contribute to secretory unresponsiveness.[11]

The ontogeny of the vasoactive intestinal polypeptide (VIP) receptor has been described in rats and calves. In the rat, VIP receptors are present at day 19 of gestation.[22,62] In the cow, a single class of receptors is present at birth; however, at 28 and 119 days after birth, two classes (high affinity and low affinity) of receptors are found.

Because protein phosphorylation appears to play an important role in the pancreatic response to secretagogues, the roles of protein kinases have been examined. Calcium-calmodulin–dependent protein kinase increases in parallel with responsiveness to secretagogues from the late fetal to the newborn period.[63] Similarly, protein kinase C was found to be low in the term fetus. Levels increased in the newborn period, reaching adult values by age 2 days.[64] Newborn rat pancreas was unresponsive to 12-0-tetradecanoylphorbol acetate (TPA), an activator of protein kinase C, but the 2-day-old pancreas responded to TPA with increased amylase secretion. These studies of protein kinases suggest immaturity of the secretory response to regulatory peptides at a number of levels.

Thus immaturity both of receptors to secretagogues and of protein kinases is found in the neonatal rat. At this time, the lack of responsiveness to secretagogues in the neonatal rat cannot be attributed to any one pharmacologic deficiency and may in fact be multifactorial.

EFFECTS OF DIET AND WEANING IN RODENTS

A protein-free, carbohydrate-rich diet has no effect on mRNA coding for elastase isoenzymes; however, trypsinogen isoenzyme mRNA levels increase slightly.[65] Because this same dietary manipulation decreases cationic trypsinogen synthesis, the trypsinogen genes must be under different translational and transcriptional control.

In the rat fed a high-fat diet, lipase synthesis increases within 24 hours, amylase synthesis does not increase, and peptidase synthesis increases by day 5.[66] Lipase-specific mRNA increased fourfold on day 1 followed by a second 6.5-fold increase on day 4. Amylase mRNA levels remained unchanged. Because of the biphasic increase in lipase and lipase-specific mRNA, these authors postulated that the first phase was a result of an increase in mRNA synthesis and the second phase was a result of increased translation, possibly caused by hormonal influences.

The pancreatic content of exportable proteins and zymogen granules falls dramatically after birth.[8,67] This fall is not preprogrammed but rather relates to feeding and stimulation of secretion.[68,69] Alterations in diet, time of weaning, and time of first feeding all affect the levels of secretory proteins in predictable ways.

Studies in which the diets of immature animals are altered have shown that the changes in concentrations of various pancreatic enzymes are not all preprogrammed. The molecular basis for many of these effects has been reviewed.[70] Changing the diet from high fat–low carbohydrate to high carbohydrate–low fat by early weaning increases chymotrypsin and lipase and decreases amylase. Delaying weaning, by prolonged nursing, postpones these changes in enzyme concentration. Animals weaned on a high-fat diet similar to mother's milk demonstrated changes in enzyme patterns similar to those found in animals prematurely weaned. The changes found with early weaning are similar to those induced with glucocorticoids. Premature weaning induces an increase in corticosteroid levels in the infant rat. Changes in diet after 21 days of age induce characteristic changes in pancreatic enzyme composition; thus increasing the dietary intake of starch increases amylase, increasing intake of fat increases lipase, and increasing protein intake increases trypsin. Thus glucocorticoids may modulate some effects of feeding; however, others seem to be preprogrammed.

REGULATORY FACTORS

Plasma CCK (CCK-8 + CCK-33 + CCK-39) levels were measured before and after breast-feeding in 4-day-old infants.[71] A significant increase was seen immediately after a meal, followed by a decrease to basal levels at 10 minutes and a secondary increase at 30 and 60 minutes after feeding. This biphasic rise is not seen in older children or adults. Plasma gastrin-34 levels increased by 50% 5 and 10 minutes after the onset of suckling and immediately after breast-feeding in 3-day-old infants. Postprandial levels of 11 regulatory hormones were measured by Salmenperä and colleagues[72] in 9-month-old infants who had been fed exclusively by either breast or bottle. The basal level and postprandial rise in CCK were lower in breast-fed than in bottle-fed infants.

In the rat colon, CCK mRNA is found in low amounts in the fetus, is absent at birth, and then increases steadily until adulthood.[73] Immediately after birth, the rat small intestine contains CCK-like bioactivity. In the pig, CCK immunoreactivity is found in the small intestine at 6 to 8 weeks gestation.[74] In the guinea pig, plasma CCK levels are low at birth but rise to near adult levels at day 15.[75] Thus CCK is present in the gut and is presumably available to participate in the regulation of pancreatic growth in the fetus.

Progastrin and gastrin are present in many species, including humans.[76] In the human fetal pancreas, the levels of gastrin and progastrin are low when compared with those in other species. In the mouse, the gastrin gene is first expressed at 9.5 to 10 days gestation, whereas immunoreactivity does not develop until day 20. The gastrin gene is unique among those expressed by the pancreas in that it is active in the fetus but inactive in the adult, except when the Zollinger-Ellison syndrome develops. Thus CCK and gastrin, both trophic agents for the pancreas, are present at birth when the rate of pancreatic growth is the greatest.

CCK controls gene expression at the translational level.[77] Long-term stimulation with CCK and cerulean (a CCK analogue) stimulates mRNA synthesis for genes coding for trypsinogen and chymotrypsinogen but not amylase.[78]

Pancreatic growth in the mature animal can be altered by a variety of agents, diets, and experimental procedures.[79] The trophic effects of CCK, gastrin, and CCK-like peptides have been well documented. In the adult rat, the postprandial CCK level regulates ornithine decarboxylase and secretory protein gene expression at the translational level. Treatment of rats with the CCK antagonist L364718 not only prevents the trophic effects of exogenous CCK but also causes pancreatic atrophy, suggesting that CCK is necessary for both growth and maintenance of the gland.[80] When given to the immature rat, this agent does not alter normal growth but does block the trophic effects of exogenous

CCK.[81] CCK-induced growth is mediated by a single-type variety of type A receptors with both high- and low-affinity states.[82-85]

Although published studies exist concerning the roles of many of the previously discussed agents and treatments in the immature pancreas, interpretation and comparison of these studies present numerous difficulties in data analysis, including that (1) the various agents tested were given in different doses, at different ages, and for different lengths of time and (2) the animals were evaluated for effects on growth in different ways. A major fact often overlooked is that the growth rate and the rates of synthesis of both DNA and protein vary considerably with developmental ages.[86]

The concentrations of DNA and protein in immature rat pancreas do not parallel the rates of their synthesis.[86] DNA concentration increases rapidly from a low level on the first day of life, peaks between ages 3 and 14 days, then slowly falls to a lower adult level. In contrast, DNA synthesis decreases in the first 24 hours, peaks at age 3 days at a rate 30 times that observed in the adult, then falls slowly to the adult value. Similarly, protein concentration, nearly as high at birth as in the adult, plummets at day 3 before it slowly begins to rise to adult levels. Protein synthesis, in contrast, is as low at birth (as it is in the adult) but is three to five times higher at all intermediate ages tested.

A great deal has been learned concerning the effects of many agents on the growth of the exocrine pancreas in the developing animal. CCK and CCK-like peptides have a variety of effects that seem to be age dependent. DNA synthesis is not increased by CCK before age 28 days, and variable effects on growth have been described depending on age, dosage, and CCK analogue studied.[87-89] The potent specific CCK antagonist L364718 blocks the effects of exogenous cerulean on the growth of the neonatal rat pancreas, but when given alone it has no effect. This suggests that endogenous CCK is not a controlling factor in the growth of the neonatal rat pancreas.[90]

CCK action is mediated by CCK receptors. Of the two types of CCK receptors (A and B), the adult rat pancreas has only type A, which mediates pancreatic growth in adult rats. Although the Otsuka Long-Evans Tokushima fatty rats lack the CCK-A receptor gene, pancreatic growth in the immediate postnatal life is normal although the pancreas is slightly smaller at 5 to 6 weeks of age.[91] However, in later growth at 24 to 25 weeks, Otsuka Long-Evans Tokushima fatty rats showed a significantly lower protein-DNA content than the wild-type strain, which suggests that the CCK-A receptor plays a small role in the early postnatal growth of the pancreas but is required for later cell growth. Thus CCK might not be important in regulating pancreatic growth in early postnatal life.

The role of gastrin is likewise questioned. Administration of a specific gastrin antagonist, CI-988, to neonates for 5 days reduced stomach growth but not pancreatic growth.[92] Thus although pharmacologic doses of gastrin and CCK are trophic for the neonatal exocrine pancreas, it is unclear whether they play a role in the early development of the exocrine pancreas.

Hydrocortisone decreases protein synthesis in the first week of life but has no effect on DNA synthesis in the immature animal.[87] Other studies have described hypertrophy and hyperplasia or hypertrophy alone,[88,93] depending on age. Cerulean and hydrocortisone potentiate each other's trophic effects. The lack of increase in DNA synthesis in the suckling animal after treatment with either CCK or hydrocortisone may be due to the finding that synthesis is already proceeding at the maximum rate possible.

A temporal relationship exists between corticosterone levels, cytoplasmic corticosteroid receptors, and increases in pancreatic secretory products in the developing rat pancreas.[93,94] Corticosterone levels and dexamethasone binding increase from birth, reach a peak at approximately age 25 days, then decrease to adult levels. Increases in circulating levels of steroids precede increases in receptor density, which increases sharply after age 15 days. These increases parallel those of both amylase and hydrolase activities, which can be induced by exogenous steroids. The pancreatic glucocorticoid receptor is under autologous control by glucocorticoid. Early weaning, which augments corticosterone levels, causes similar changes in the content of exportable proteins in the pancreas. The highest density of steroid receptors occurs at age 21 to 28 days, the period of peak responsiveness of the pancreas to hydrocortisone. Thus glucocorticoids clearly modulate postnatal pancreatic development.[95]

Thyroxine induces precocious increases of amylase, lipase, chymotrypsin, and trypsin in neonatal rats, and chemical thyroidectomy retards pancreatic development.[96] Endogenous thyroxine peaks between days 10 and 16, the time point when amylase levels are also increasing. Thyroxine induces maturation of secretory function by modulating the maximum binding capacity of high-affinity CCK receptors. In the immature animal, thyroid hormone acts both directly on the pancreatic acinar cell and indirectly through the adrenal system.[97]

Pancreatic duct cells have high levels of epidermal growth factor.[98] Parenteral but not oral epidermal growth factor increases pancreatic amylase in suckling rabbits.[99] Inhibition of ornithine decarboxylase (and thus polyamine metabolism) inhibits stimulated pancreatic growth.[100] The role of polyamines in normal pancreatic growth and development is not established. Secretin increases DNA, amylase, and chymotrypsin in 6-day-old rats.[101] The effects of peptide YY (PYY) and somatostatin, which are antitrophic to the pancreas in mature animals, have not been studied in developing animals.

Other regulatory factors have also been implicated in rodent pancreatic exocrine development. Acting directly on the pancreas, bombesin induces hypertrophy and hyperplasia in newborn rats by.[102] In adult animals bombesin regulates pancreatic gene expression at the level of mRNA. This effect is not mediated by CCK.[103,104] Transforming growth factor (TGF) alpha appears after birth and increases progressively with age in the exocrine pancreas.[105] Artificially mutated TGF-β receptor in mice leads to a pancreas with acinar hyperplasia and atypia.[106] Overexpression of TGF-β interferes with acinar differentiation.[107] TGF-β added to rat embryonic pancreatic rudiments resulted in differential gene activation.[108] Fibroblast growth factors (FGFs) and FGF receptors (FGFRs) are important mediators of epithelial-mesenchyme interactions. FGFs are expressed throughout rat pancreatic development. In mesenchyme-free culture of embryonic pancreatic epithelium, addition of FGFs promotes growth, morphogenesis, and cytodifferentiation of exocrine pancreatic cells.[109] In the presence of mesenchyme, growth and development of pancreatic epithelium progresses without the addition of FGFs. Abrogation of FGFR-2IIIb in the system attenuates both growth and development.

FETAL ANTIGENS

Fetoacinar protein (FAP) is a specific acinar cell antigen found only in the exocrine pancreas. In the human fetus, FAP is present at 9 to 10 weeks gestation[110] and peaks at 15 to 25 weeks when acinar cell proliferation is most intense. FAP synthesis then progressively decreases. The levels found in adults are lower than those in the fetus. FAP is found in high concentration in amniotic fluid. FAP can also be considered an oncodevelopmental antigen, because in pancreatic cancer and in some cases of chronic pancreatitis FAP is elevated. FAP has been shown to be a variant of bile salt–dependent lipase, differing only by a decrease in O-glycosylation.[111]

A second fetal antigen, fetal antigen 1 (FA1), is found in both the exocrine and endocrine fetal pancreas and hepatocytes.[112] FA1 is found in high concentration in the fetal venous blood and amniotic fluid during the second and third trimesters. At 7 weeks

gestation, FA1 is found in 94% of the ductal epithelial cells. By week 17, only 64% of the duct cells test positive for FA1 by immunoperoxidase staining, decreasing to only 11% in the 4-month-old infant. The role or roles and controls of FA1 in pancreatic development are not known.

MOLECULAR EMBRYOLOGY

The parenchyma of both endocrine and exocrine glands originate from the endodermal epithelium of the primitive gut tube[113] (Figure 114-3). Even before the pancreatic primordia evaginate from the primitive gut tube, many molecular programs that specify a pancreatic fate have been set in motion by the inductive influences of neighboring tissues. During gastrulation, the endoderm is subdivided into anterior and posterior domains by signals from the adjacent mesectoderm. Retinoic acid,[114] bone morphogenic proteins, and FGFs[115] play an important role during late gastrulation in localizing the prepancreatic domain, which will respond to subsequent instructive signals that induce pancreatic tissue.

The ventral and dorsal aspects of the endoderm that will give rise to the pancreas are exposed to different local contacts and therefore rely on distinct sources for their induction. The endoderm fated to become the ventral pancreas begins to express pancreatic genes first, induced by activin and bone morphogenic protein–family molecules derived from the adjacent lateral plate mesoderm.[116] The dorsal pancreas is induced by transient contact with the notochord, followed by interposition of the dorsal aorta. Contact with the notochord induces a localized exclusion of sonic hedgehog (shh) from the prepancreatic endoderm. This signaling event is necessary for dorsal pancreatic development, because ectopic expression of shh interferes with subsequent events.[117] The dorsal aorta also provides essential signals to promote pancreatic fate,[118] among them vascular endothelial growth factor.[119]

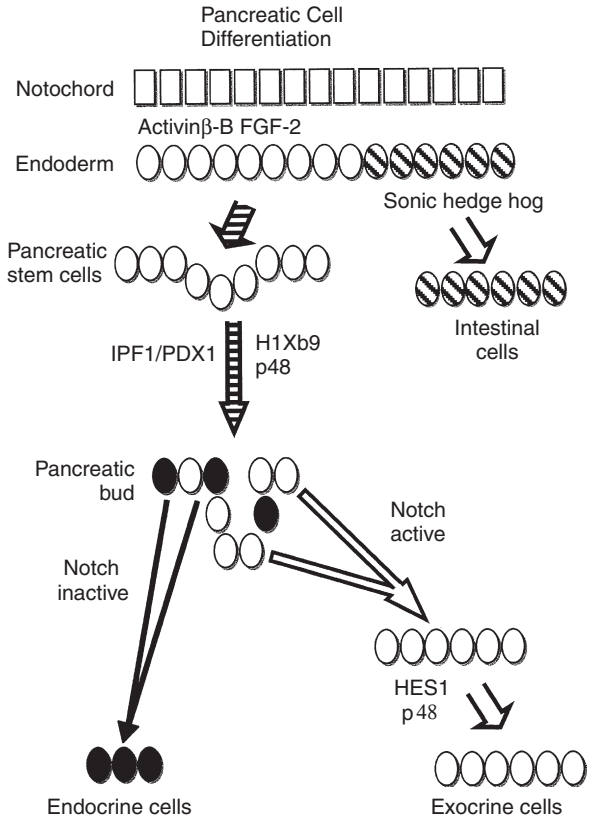

Figure 114-3 Origin of the exocrine and endocrine cell lineages in the developing pancreas. This model is based on descriptions from various reports (e.g., see Kim and Hebrok[143] and Crisera and colleagues[144]). *Arrows* in the diagram indicate the sequential activities based on the appearance of specific cell markers in the developing mouse pancreas. *(Modified from Edlund H: Pancreas: how to get there from the gut?* Curr Opin Cell Biol *11:663-8, 1999.)*

These early events render the prepancreatic endoderm competent to form pancreatic tissue. The next step involves expression of transcription factors in the endoderm and in the surrounding mesenchyme to further specify a pancreatic fate. One of the essential genes is Hlx9, encoding the homeobox protein HB9. Its genetic ablation results in selective absence of the dorsal pancreas.[120] Highlighting the role of the surrounding mesenchyme, the LIM homeodomain protein Isl1 is expressed in the dorsal pancreatic mesenchyme and is required for its elaboration. In the absence of Isl1, the dorsal pancreas does not form, but the ventral pancreas is unaffected.[121]

The pancreatic-duodenal homeobox gene 1(Pdx-1) gene is expressed in the prepancreatic endoderm at e8.5 in the mouse,[122] and its ablation results in arrest of pancreatic development shortly after formation of the pancreatic anlagen.[123] A mutation in the human Pdx-1 gene was found to cause congenital pancreatic agenesis in an infant.[124] The function of Pdx-1 is instructive, as evidenced by the ability to transform liver into pancreas by hepatic expression of the *Xenopus* Pdx-1 homologue fused to the VP16 transactivator.[125] Pdx-1 also has a later role in the maintenance of beta-cell identity and the transcription of the insulin gene.

The transcription factor PTF1a is expressed in the early pancreas around E9.5, after Pdx-1 and in a domain more narrowly approximating the developing pancreas. Genetic ablation of PTF1a has provided important insight into the early events of pancreatic specification. Normally, all the PTF1a-expressing cells will be found in both the endocrine and exocrine pancreas. By genetically tagging the mutant cells that would otherwise express PTF1a, cells lacking the gene were shown to be incorporated into the developing duodenum as full-fledged intestinal epithelial cells.[126] This illustrates the developmental plasticity of early pancreatic development and highlights the principle that multiple successive specification events are needed to guide cells from progenitor to a fully differentiated state.

After specification of pancreatic cell fate and initial budding of the pancreatic primordium, the pancreatic precursor cells become diversified into exocrine and endocrine lines. The molecular effectors that influence these events have been deciphered in recent years, revealing a striking conservation of mechanism for cell fate allocation between different organ systems. Recent data have demonstrated a role for retinoic acid in the exocrine-endocrine cell fate decision, possibly upstream of Notch signaling (see later).[127] Of interest, retinoic acid treatment seems to have divergent effects on the dorsal and ventral pancreas, promoting endocrine fate in the dorsal pancreas but exocrine fate in the ventral pancreas. These data stand as further evidence for distinct developmental programs in the dorsal and ventral primordia.

Taking a cue from earlier work in neuronal cell fate allocation,[128] researchers examined Notch signaling pathway mutant mice and discovered that Notch signaling is a key participant in the exocrine-endocrine cell fate allocation decision. Specifically, it was previously known that the basic helix-loop-helix (bHLH) transcription factor Neurogenin3 (Ngn3) is required for all endocrine cell lineages.[129] Ngn3 activates expression of Notch ligands Delta, Serrate, and Jagged, which then activate Notch signaling on adjacent cells. This signal results in expression of Hes-1, which in turn represses Ngn and other target genes. Thus

an undifferentiated pancreatic cell fated to become an islet cell will signal to its immediate neighbors to adopt an exocrine fate. By this mechanism, known as lateral inhibition, Notch signaling promotes the divergence of the pancreatic lineage into exocrine and endocrine fates.[130] Subsequent cell fate decisions further diversify the endocrine cells into the four lineages known to populate the islets: alpha cells (glucagon secreting), beta cells (insulin secreting), delta cells (somatostatin secreting), and PP cells (pancreatic polypeptide). Each of these is derived from a common Ngn3-expressing precursor by a combinatorial hierarchy of transcription factors that promote a lineage-specific program.

Whereas Notch is required for early commitment to the exocrine lineage, continuous activation of Notch signaling can inhibit exocrine development as well.[131,132] The reason for this seemingly contradictory result is that Notch maintains pancreatic progenitors in an undifferentiated state and prevents their terminal differentiation. Thus Notch signaling reserves a population of cells for subsequent formation of the exocrine gland, beginning around E13.5 in the mouse. Outgrowth of the pancreas is closely linked to exocrine morphogenesis and differentiation, but the essential factors that influence this step remain partially characterized. Factors secreted from the mesenchyme that stimulate exocrine growth include FGF 10 (Fgf10)[133] and epidermal growth factor (Egf).[134] Pbx[135] is a transcription factor the genetic ablation of which can be complemented by exogenous wild-type mesenchyme, thus implicating this factor as a mesenchymal mediator of pancreatic outgrowth. On the basis of the detection of dephospho-β-catenin, the Wnt signaling pathway was shown to be activated in the pancreatic anlage.[136] Using a conditional knockout strategy, Murtaugh and colleagues[136] showed that specification of Ptf1a-positive exocrine pancreatic progenitors was dependent on β-catenin. In contrast, the endocrine lineages were not affected by loss of β-catenin. Consistent with this result, attenuation of Wnt signaling by expressing a dominant-negative Wnt receptor affects pancreatic growth, but endocrine function remains normal.[137]

Compared with the islet cells, considerably less is known about the molecular determinants of exocrine pancreatic differentiation. As such, only two factors are known to be specifically required for exocrine differentiation: Ptf1a and Mist1. Ptf1 consists of a heterodimer comprising the ubiquitous transcriptional regulator E2A and a tissue-specific protein p48.[138] This complex binds to the promoter regions of exocrine-specific genes and activates their transcription. Genetic ablation of p48 in mice results in failure to form an exocrine pancreas, as well as morphologic deformities of the islets.[139] More recent studies using Ptf1a-Cre knock-in mice have broadened our understanding of the role for p48 to include a much earlier function in specifying pancreatic identity from uncommitted endodermal precursors.[126]

Mist1 is also a bHLH transcription factor expressed in the exocrine pancreas but also in salivary gland and stomach.[140] *Mist1*-null mice exhibit lesions in the exocrine pancreas, possibly resulting from defective cell-cell adhesion, but still retain exocrine-specific gene expression.[141] Mist1 has thus been proposed to function in cooperation with PTF1 to maintain a stable exocrine differentiated state. Mist1 is also required for granule organization in acinar and other exocrine cell types.[142]

In summary, the exocrine pancreas is a relatively late–developing organ in the scheme of embryonic development. Its formation is contingent on the successive execution of multiple earlier steps, from specification of pancreatic cell fate in the endoderm, to cell lineage allocation, induction of outgrowth, and then completion of the differentiation program. In the last several years genetic technology has helped to provide molecular annotation of these events, offering novel connections between genes and developmental mechanisms.

Developmental Aspects of Protein Digestion and Absorption

Digestion

Gastric Acidity

The first traces of gastric acidity appear in 4-month-old fetuses.[5] The human fetus has the potential to produce gastric acid and gastrin from the middle of the second trimester. Parietal cell activity is present in the body, antrum, and pyloric regions in the fetus from 13 to 28 weeks.[5-7] When term and premature infants were compared, hydrochloric acid secretion was found to be much lower in premature infants than in term infants.[8] No change was seen in basal and pentagastrin-stimulated output of acid in term neonates between days 1 and 2 of life; furthermore, the basal acid secretion was no different from the stimulated one.[9] Thus gastric acid secretion in the newborn infant is maximal under basal conditions. The other possibility is that newborn parietal cells are unresponsive to pentagastrin.

Gastric acid secretion is limited in very-low-birth-weight infants. However, both basal and pentagastrin-stimulated acid secretion doubles from the first to fourth week of postnatal life in preterm infants.[10] The actual pH of the stomach contents in infants is substantially influenced by food intake. The entry of milk into the infant's stomach causes a sharp increase in the pH of the gastric contents and a slower return to lower pH values than in older children and adults.[11]

Gastric Proteolytic Activity

Proteolytic activity is present in fetuses older than 16 weeks gestation.[12] Pepsinogen and cathepsin do not appear until 17 to 18 weeks gestation.[13] Peptic activity of newborn infants is low and is in proportion to the degree of maturity.[14] It increases in the fundus about four-fold after food intake on the second day of postnatal life.[15]

The output of pepsin is low in the newborn infant and increases until the third postnatal month. The range of values found in the second and third postnatal month is less than the range of adult values.[16] In contrast, pepsin activity in biopsy specimens from the stomachs of infants and children did not change between the ages of 6 months and 15 years.[17] Formula feeding evokes an increase of pepsin activity in the stomach content of 3- to 4-week-old, orogastrically fed, premature infants.[18]

Pancreatic Proteolytic Activity

The protease cascade in the small intestine is catalyzed by food-stimulated secretion of enterokinase from the upper small-intestinal epithelium (see Figure 115-1 and Box 115-1). This enzyme catalyzes the activation of trypsinogen to trypsin that, in turn, activates several other inactive zymogens into proteases, which are active in the intestinal lumen. However, even though enterokinase is detectable at 24 weeks gestation, its concentration is relatively low and reaches only 25% of adult activity at term.[19] This theoretically can be limiting to protein digestion and may be responsible for an increased capability of larger antigens

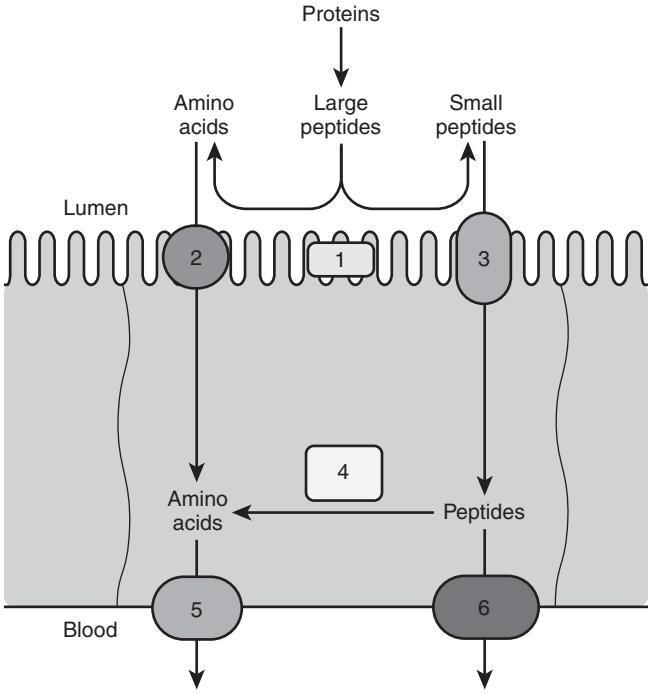

Figure 115-2 Protein absorption in the small intestine. *1,* Brush border membrane peptidases; *2,* brush border membrane amino acid transporters; *3,* brush border membrane dipeptide and tripeptide transporters; *4,* intracellular peptidases; *5,* basolateral membrane amino acid carriers; *6,* basolateral membrane dipeptide and tripeptide carriers. *(Modified from Johnson LR, editor:* Physiology of the Gastrointestinal Tract. *New York, 1994, Raven Press, pp 1751-1772.)*

BOX 115-1

Protein Digestive Processes

Stomach
Proteolytic enzymes contained in gastric juice
Requires acid environment of stomach to hydrolyze protein
Synthesized in the gastric chief cells as inactive pre-proenzymes (pepsinogen)

Pancreas
Enterokinase—an intestinal brush border enzyme that activates pancreatic proteases. Stimulated by trypsinogen contained in pancreatic juice.

Pancreatic endopeptidases
Trypsin: cleaves peptide bonds on the carboxyl side of basic amino acids (lysine and arginine)
Chymotrypsin: cleaves peptide bonds on the carboxyl side of aromatic amino acids (tyrosine, phenylalanine, and tryptophan)
Elastase: cleaves peptide bonds on the carboxyl side of aliphatic amino acids (alanine, leucine, glycine, valine, isoleucine)

Pancreatic exopeptidases
Carboxypeptidases A and B: zinc-containing metalloenzymes that remove single amino acids from the carboxyl-terminal ends of proteins and peptides
Carboxypeptidase A: polypeptides with free carboxyl groups are cleaved to lower peptides and aromatic amino acids
Carboxypeptidase B: polypeptides with free carboxyl groups are cleaved to lower peptides and dibasic amino acids

Modified from Johnson LR, editor: *Physiology of the Gastrointestinal Tract.* New York, 1994, Raven Press, pp 1751-1772.

or microorganisms to pass into the intestine without breakdown by luminal enzymes.

Pancreatic enzymes begin to form at about the third fetal month,[12] and pancreatic secretion starts at the beginning of the fifth month of gestation. Biochemical studies on the activity of trypsinogen and chymotrypsinogen at various gestational ages have been reported.[20] Immunoreactive trypsin 1 and immunoreactive chymotrypsin A are detectable in amniotic fluids at 17 to 18 weeks of pregnancy.[21] Levels of trypsin concentration encountered during the first 2 years of life are reached by the age of 3 months. Chymotryptic activity was low in the newborn infant (3 days of age) and increased gradually, approaching the levels of older children at approximately 6 months.[22] From birth onward, the concentration of chymotrypsin (after pancreozymin-secretin stimulation) increases approximately three-fold and reaches adult levels in 3-year-old children. Serial measurement of fecal chymotrypsin concentrations in preterm infants (23 to 32 weeks gestation) during the first 4 weeks of life demonstrated values generally similar to those found in term infants. Median fecal chymotrypsin concentrations calculated for each infant (with use of data from stools passed between day 2 and day 12 of life) have been shown to be lower in infants who were small for gestational age when compared with those who were appropriate for gestational age.[23] Premature infants fed soy-based formula for 1 month exhibited higher trypsin activity after cholecystokinin-pancreozymin stimulation than did those fed a milk-based formula.[24]

Absorption

For a very few days after birth, neonates have the ability to absorb intact proteins. This ability, which is rapidly lost, is of importance because it allows the newborn animal to acquire passive immunity by absorbing immunoglobulins in colostral milk. The small intestine rapidly loses the capacity to absorb intact proteins—a process called closure—and, consequently, animals that do not receive colostrum within the first few days after birth will likely die of opportunistic infections.

Otherwise, absorption of intact proteins occurs only in a few circumstances.[25] Preterm neonates, particularly those of less than 33 weeks gestation, have higher serum concentrations of β-lactoglobulin than term neonates given equivalent feeding. Thus the ability of the gastrointestinal tract to exclude antigenically intact food proteins increases with gestational age, and gut closure occurs normally before birth in humans.[25] With use of lactulose-to-mannitol ratios, in preterm infants (26-36 weeks gestation) intestinal permeability was not related to gestational age or birth weight but was higher during the first 2 days of life than 3 to 6 days later. It is higher in preterm infants than in healthy term infants only if measured within 2 days of birth. This suggests rapid postnatal adaptation of the small intestine in preterm infants.[26]

Proteolytic and Peptidase Activity

During fetal development, protease and aminopeptidase activity in the jejunum does not change markedly between weeks 8 and 17 of gestation, but in the ileum a pronounced increase occurs.[27] In the embryonal developmental period (to week 8), the activity of proteases was mainly detected on the luminal surface of the primitive pseudostratified columnar epithelium of the intestine anlage. The highest activity was displayed by dipeptyl peptidase IV (DPP IV). Beginning with week 8, villi are formed from the duodenum up to the ileum, and, after week 9, differentiation of crypts of Lieberkühn is observed. The activity of proteases was

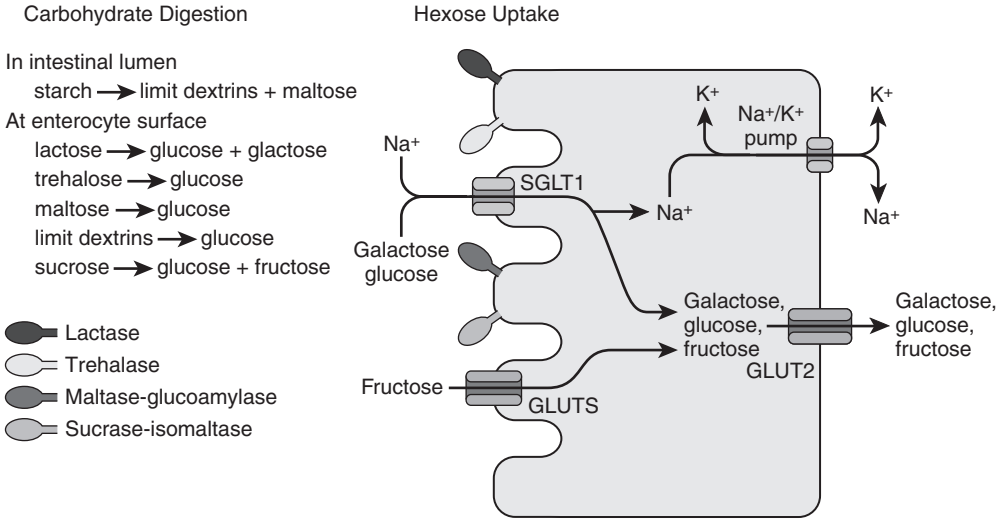

Figure 115-3 Digestion and absorption of carbohydrates.

high (especially DPP IV) in the differentiating microvillus zone of primitive enterocytes.The gradient of apex-base activity of the villus is maximal on the apex of the villi. In one study, brush border and intracellular proteolytic enzyme activities were measured in fetuses (8-22 weeks gestation), children (7 months–14 years), and adults. The peptidase activities in all three of the groups were comparable, suggesting that the small intestine of the term and preterm newborn should be able to efficiently digest peptides.[28]

Proteins are present in the amniotic fluid. Approximately 50% of its volume is swallowed by the fetus daily[29]; thus the protein amount obtainable at or near term from the amniotic fluid is approximately one fifth of the daily protein gain by the fetus.A fairly wide spectrum of protein is transferred to the fetus by this process and includes human serum albumin, immunoglobulin G, immunoglobulin A, chorionic gonadotropin, and growth hormone.[29]

Various studies have indicated increased small intestinal permeability for intact food proteins during the neonatal period,[25] but passage of proteins has also been demonstrated in older children and even in adults.[30] The serum of infants contains a higher percentage of antibodies to food antigens than does the serum of adults,[31] which suggests that food proteins are absorbed intact in sufficient quantities for an immunologic response. On the basis of determination of serum concentration, the absorption of β-lactoglobulin was considered to be higher in preterm infants than in term infants.[25]

Clinical Correlations

Acid secretion limitations in premature infants should be kept in mind when considering the use of histamine-2 (H_2) blockers, which are widely prescribed in many neonatal intensive care units. Studies suggest that critically ill premature infants who receive treatment with H_2 blockers have a higher incidence of nosocomial sepsis and necrotizing enterocolitis.[32,33] Although speculative, it is possible that, with the already limited hydrogen ion production in the stomach of the premature infant, additional blockage further diminishes the acid barrier to microorganisms and allows for a higher load of bacteria in the more distal regions of the intestine.

In terms of protein absorption, the mechanisms for brush border hydrolysis are present early, dipeptides and tripeptides are absorbed faster than amino acids, and protein digestion and absorption rarely appear to be an issue in premature infants.[34]

Despite the potential limitations of digesting and enzymatic capability in premature infants, data showing significant benefits with use of hydrolyzed protein fractions appear to offer only minimal advantage over whole protein formulas.[32,35] Studies have yet to demonstrate a benefit of hydrolyzed protein formulas over human milk.

Hydrolyzed formulas are also extensively prescribed to prevent allergic and atopic disease. However, a recent Cochrane metaanalysis showed no evidence to support feeding with a hydrolyzed formula for the prevention of allergy compared with exclusive breast-feeding. Furthermore, in high-risk infants who are unable to be completely breast-fed, evidence is limited that prolonged feeding with a hydrolyzed formula compared with a cow's milk formula reduces infant and childhood allergy and infant cow's milk allergy.[36]

CARBOHYDRATE DIGESTION AND ABSORPTION

General

The overall digestion and absorption of carbohydrates is illustrated in Figures 115-1 and 115-3 and Box 115-2. Starches and complex carbohydrates must first be hydrolyzed to oligosaccharides by digestive processes in the mouth, stomach, and intestinal lumen. This is accomplished primarily via salivary and pancreatic amylases. Oligosaccharides must then be hydrolyzed at the epithelial brush border to monosaccharides before absorption, and the key catalysts in these processes are the brush border hydrolases, which include maltase, lactase, and sucrase. Dietary lactose, sucrose, and maltose come in contact with the surface of absorptive epithelial cells covering the villi where they engage with brush border hydrolases:

- Maltase cleaves maltose into two molecules of glucose.
- Lactase cleaves lactose into a glucose and a galactose.
- Sucrase cleaves sucrose into a glucose and a fructose.

Glucose and galactose are taken into the enterocyte by cotransport with sodium with use of the same transporter. Fructose enters the cell from the intestinal lumen via facilitated diffusion through another transporter.

Developmental Aspects of Carbohydrate Digestion and Absorption

Carbohydrate Digestion

In addition to the classic enzymes capable of digesting starches and glucose polymers (i.e., salivary and pancreatic α-amylase, intestinal glucoamylase), an enzyme present in breast milk, α-amylase, may participate in digestion. A high amylase activity

BOX 115-2

Monosaccharide Transport

Glucose uptake is Na^+ dependent.
Fructose is absorbed via facilitated diffusion.
Galactose and glucose are actively transported.

1. SGLT1 is the transport protein responsible for Na^+-dependent glucose transport.
2. GLUT2 transports glucose out of the cell and into the portal circulation.

exists in preterm colostrum, which slowly decreases during the first 2 months.[37-39] The individual variation in amylase activity is considerable. No difference is seen in amylase activity in preterm and term human milk. The isoamylase of preterm milk is of the salivary type, just as in term milk. Variation in amylase activity is not great during a feeding or from one feeding to another.[37,40] This can survive the relatively mild acidity and the lower activity of pepsin in the stomach of the newborn infant. Amylase in saliva is present in lower concentrations in children than in adults.[41]

Pancreatic amylase activity has been demonstrated in amniotic fluid and pancreatic tissue from 14- to 16-week-old fetuses.[42,43] Although salivary amylase activity rapidly increases shortly after term birth, pancreatic amylase remains low until 3 months and does not reach adult levels until nearly 2 years of age.[44]

The digestion of starch in the newborn infant has been examined by both carbohydrate tolerance type and balance studies. Gastric administration of a starch solution results in a slow, small increase in blood glucose levels in neonates; an equicaloric amount of glucose solution administered to the same children evokes a greater, earlier increase, with an earlier return to starting values within 120 minutes.[45]

Carbohydrate Absorption

Fetus

Activity of sucrase and lactase is lower in young fetuses than in specimens from the small-intestinal mucosa of adults.[19] Sucrase activity is present in the fetal colon and disappears before birth.[46] The presence of lactase in the fetal colon (13 to 20 weeks of age) has also been described previously.[19]

Sucrase-isomaltase in the human fetal intestine is present in a different form from that in adults, and it differs in degree of glycosylation (different electrophoretic mobility) and in the size of the polypeptide.[47] The difference in polypeptide length in fetuses and adults can be related to low activity of pancreatic proteases in the fetal intestinal lumen. Villa and co-workers[48] confirmed that intestinal lactase is low between 14 and 20 weeks gestation and exhibits a relatively high level of activity at 37 weeks; amounts of lactase messenger RNA (mRNA) correlated with the enzymatic activity. It is interesting that lactase mRNA was not detectable in the colon of normal adult subjects, whereas it was detectable at low levels in fetal colon.[49]

Postnatal

Studies suggest that colonic fermentation activity is adequate for colonic salvage of lactose even during the second week of life. Using a stable isotope method for serial assessment of lactose carbon assimilation, Kien[50] demonstrated efficient absorption of lactose in premature infants (30 to 32 weeks gestation and 11 to 36 days of age). In spite of that finding, in a study in 130 preterm infants fed standard preterm formula with and without lactase, lactase-treated infants were shown to grow faster the first 10 days of life but similarly thereafter, suggesting that limitations in lactose absorption are short-lived in the preterm infant.[51] In fact, infants absorb 98% of lactose from lactose-containing formulas.

Glucoamylase, an intestinal brush border enzyme, removes glucose units from the nonreducing ends of molecules of starch and dextran. This enzyme, which is present in the developing small intestine,[52] exhibits activity in an infant at the age of 1 month[53] that is comparable to the activity in young adults.[54]

Absorption of Monosaccharides

Prenatal

Transport of hexose monosaccharides increases between weeks 10 and 18 of gestation.[55] Developmental and regional expression of mRNAs encoding sodium-dependent and facilitative glucose transporter proteins in human fetal and adult small intestine demonstrated an abundance of mRNAs encoding the sodium glucose cotransporter isoform SGLT1, and the facilitative glucose transporter isoforms GLUT2 and GLUT5 exhibited highest levels in adult small intestine, but the levels of GLUT1 mRNA were found to be higher in fetal than in adult small intestine.[56] Immunohistochemical analysis of the fetal small intestine showed that GLUT5 was localized along the intercellular junctions of the developing villus. Other studies[57] also demonstrated expression of sodium-dependent glucose transporter mRNA in the small intestine of fetuses between 9 and 18 weeks gestational age. The sodium-dependent glucose transporter mRNA is also expressed in the fetal colon but in lower levels than in the adult colon.

Postnatal

Glucose absorption in infants is less efficient than in adults. The kinetics of glucose absorption are related to gestational age and appear to be affected by diet and exposure to glucocorticoids.[58] Other studies demonstrated that carrier-mediated monosaccharide absorption increases the first 2 postnatal weeks in infants born at 28 to 30 weeks gestation.[59]

Clinical Correlations

Because pancreatic secretion is poorly developed in the first several months after birth, this mode of starch hydrolysis could serve as a limiting factor that leaves substantial undigested starch in the intestine. Many infant formulas, including those formulated for preterm infants, contain partially hydrolyzed starches. The more extensively the starch is hydrolyzed, the less reliance is placed on an immature digestive capability, but the greater the osmolality. Whether there is any advantage of these hydrolyzed starch formulas over those containing disaccharides or lactose has not been established. Some data suggest that glucose polymers (18 to 29 glucose units) can be hydrolyzed by salivary amylases, but this digestion still falls substantially short of that accomplished by the usual concentrations of pancreatic amylase.[60,61] Whether limitations in salivary or pancreatic amylase play a significant role in premature infants is questionable because the major carbohydrate in human milk or cow's milk–based formulas is lactose. Furthermore, many premature infants are fed by tube in the neonatal intensive care unit, a practice that, at least partially, bypasses the action of salivary amylase.

If a shortage of lactase activity in premature infants actually is present, the scenario illustrated in Figure 115-4 is likely to occur. Insufficient lactase activity results in unhydrolyzed lactose in the distal intestine, which in turn is then hydrolyzed by luminal microbes into short-chain fatty acids, which can be absorbed. One study in premature infants was designed to ascertain whether the timing of feeding initiation affected the development of intestinal lactase activity and whether clinical ramifications of lower lactase activity exist.[62] Early feeding increased intestinal lactase activity in preterm infants. Lactase activity is a marker of intestinal maturity and may influence clinical outcomes. Whether the effects of milk on lactase activity were due to the greater

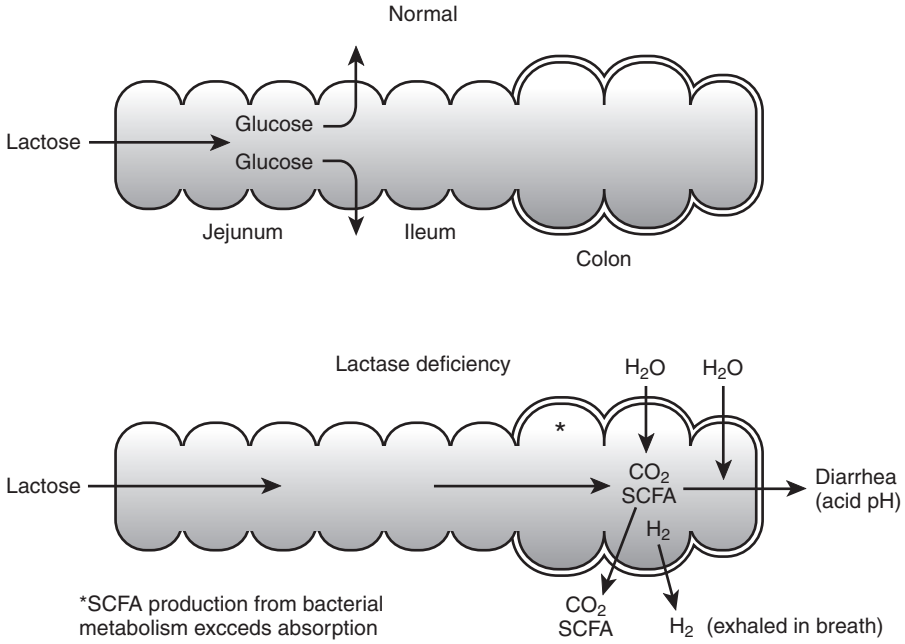

Figure 115-4 Lactose malabsorption. *SFCA,* Short-chain fatty acids.

concentration of lactose in human milk compared with that in formula has not yet been determined.[62]

The finding of low lactase activities in the intestines of fetuses has led to the notion that premature babies cannot tolerate lactose.[19] The presence of a high lactose concentration in human milk should not be a contraindication for its use in the very-low-birth-weight infant. Microbial salvage pathways that convert nonabsorbed lactose to short-chain fatty acids that can be absorbed and used for energy production are functional in these infants.[50] Furthermore, feedings for very-low-birth-weight infants rarely are initiated at levels intended to meet the infants' entire nutritional requirements and usually are advanced slowly. The rationale for using a lactose-free formula instead of human milk or even a commercial lactose-containing formula is weak and theoretically may be harmful. Slow initiation of enteral feedings is unlikely to exceed the lactose hydrolytic and salvage capability of the small and large intestines. This is especially unlikely when the quantity fed is less than 50% of the caloric requirement provided via the gastrointestinal tract (unless the infant has a bowel that has been radically shortened by surgery). Human milk also contains several lactose-derived oligosaccharides and other glycoconjugates that may play important roles in the infant's host defense. When formulas are provided for preterm infants, some evidence exists that, at full feedings, a combination of lactose and glucose polymers is better absorbed than lactose alone.[63] Furthermore, formulas that contain primarily glucose polymers appear to have a better calcium absorption in preterm infants.[64] However, a comparison with human milk, which contains primarily lactose, has not been reported.

Studies examining the crypt-to-villus gradient of intestinal carbohydrase activities demonstrate that most lactase activity is found at the mid to upper villus; sucrase, maltase, and glucoamylase are concentrated at the mid villus region.[65-68] This is likely to be pertinent to intestinal injury and villus damage. Lactase usually is the first enzyme to be lost and the last to be regenerated fully. Whether this necessitates a prolonged period of lactose-free feeding after intestinal injury (until the villus has undergone repair and restitution) remains debatable.

Infants in the neonatal intensive care unit undergo significant stresses. Chronic psychologic stress, such as maternal separation, impacts many functions of the gastrointestinal tract.[69] Studies using water immersion stress in rats have demonstrated that psychological stress induces major changes in glucose transport with a decrease in Na^+-dependent glucose absorption and an increase in GLUT2 expression at the brush border membrane level.[70] Whether similar changes occur in the sick neonate in the intensive care unit is not known, but the potential implications for nutrient absorption could be significant. Whether this contributes to feeding intolerance in these infants is unknown.

LIPID DIGESTION AND ABSORPTION

General

The bulk of dietary lipid is neutral fat or triglyceride, composed of a glycerol backbone with each carbon linked to a fatty acid via an ester moiety. Foodstuffs typically also contain phospholipids, sterols such as cholesterol, and many minor lipids, including fat-soluble vitamins. Finally, small intestinal contents contain lipids from sloughed epithelial cells and considerable cholesterol delivered in bile.

For the triglyceride to be absorbed, two processes must occur:

- Large aggregates of dietary triglyceride, which are virtually insoluble in an aqueous environment, must be broken down physically and held in suspension—a process called micellar emulsification (Figure 115-5).
- Triglyceride molecules must be enzymatically digested via triglyceride hydrolysis to yield monoglyceride and fatty acids, both of which can efficiently diffuse or be transported into the enterocyte (Figure 115-6).

The key mediators in these two transformations are *bile acids* and *lipases.* Bile acids are also necessary to solubilize other lipids, including cholesterol.

Emulsification, Hydrolysis, and Micelle Formation

Bile acids promote lipid emulsification. Bile acids have both hydrophilic and hydrophobic domains (i.e., they are amphipathic). On exposure to a large aggregate of triglyceride, the hydrophobic portions of bile acids intercalate into the lipid, with the hydrophilic domains remaining at the surface. Such coating with

bile acids aids in breakdown of large aggregates or droplets into smaller and smaller droplets. For a given volume of lipid, the smaller the droplet size, the greater the surface area, which provides greater surface area for interaction with lipase. Hydrolysis of triglyceride into monoglyceride and free fatty acids is accomplished predominantly by pancreatic lipase. The activity of this enzyme is to clip the fatty acids at positions 1 and 3 of the triglyceride, leaving two free fatty acids and a 2-monoglyceride. As monoglycerides and fatty acids are liberated through the action of lipase, they retain their association with bile acids and complex with other lipids to form micelles, which are small aggregates (4-8 nm in diameter) of mixed lipids and bile acids suspended within the ingesta. Micelles, providing much greater lipid surface area than the original fat globule, allow for amplified interaction with the brush border of small intestinal enterocytes, where the monoglyceride and fatty acids are taken up into the epithelial cells.

The major products of lipid digestion—fatty acids and 2-monoglycerides—enter the enterocyte by simple diffusion across the plasma membrane. A considerable fraction of the fatty acids also enter the enterocyte via a specific fatty acid transporter protein in the membrane.

Lipids are transported from the enterocyte into blood by a mechanism distinctly different from that of monosaccharides and amino acids. This process is dependent on the chain length of the fatty acids. Once inside the enterocyte, long-chain fatty acids and monoglyceride are transported into the endoplasmic reticulum, where they are used to resynthesize triglyceride. Beginning in the endoplasmic reticulum and continuing in the Golgi, triglyceride is packaged with cholesterol, lipoproteins, and other lipids into particles called chylomicrons. Chylomicrons are extruded from the Golgi into exocytotic vesicles, which are transported to the basolateral aspect of the enterocyte. The vesicles fuse with the plasma membrane and undergo exocytosis. Instead of being absorbed directly into capillary blood, chylomicrons are transported first into the lymphatic vessel that penetrates into each villus. Chylomicron-rich lymph then drains into the lymphatic system, which rapidly flows into blood. Blood-borne chylomicrons are rapidly disassembled and their constituent lipids used throughout the body. After entry into the cell, medium-chain triglycerides, which also require minimal emulsification by bile acids, undergo a relatively simple process of assimilation in which they do not undergo reesterification and chylomicron formation, as the long-chain lipids do. Medium-chain triglycerides are taken directly into the portal venous system; chylomicrons formed from long-chain fats enter the lymphatics. In conditions that involve obstruction of the lymphatics, feeding formulas containing primarily medium-chain triglycerides rather than long-chain triglycerides are recommended.

In the process of fat digestion, several lipases hydrolyze fatty acids from glycerol. Figure 115-7 illustrates some of these, which include the lipase found in human milk (bile salt–stimulated lipase [BSSL]) and lingual, gastric, pancreatic, and epithelial lipases. Bile acid–stimulated lipase is present in milk and becomes active in the small-intestine lumen in the presence of bile acids. Lingual lipase is secreted by glands at the base of the tongue and is involved in gastric lipid hydrolysis. Lipases produced in the stomach, secreted from the pancreas, and present in the mucosa also are involved in lipid hydrolysis.

Developmental Aspects of Lipid Digestion and Absorption

Prenatal Period

The presence of lipase in the stomachs of fetuses in early gestation, along with increased activities proceeding with gestation, has been reported.[71,72] Its activity increased with subsequent development. Ménard and colleagues[71] reported the appearance of lipase at 10 weeks gestation. In the pancreas, lipase immunoreactivity appears at week 21 of pregnancy; 5 weeks later, immunoreactivity for trypsinogens and chymotrypsinogen can be demonstrated.[21] Intensities of lipase increase greatly at birth. The ontogenesis of carboxyl ester hydrolase does not follow that of lipase.[21]

Postnatal Period

Bile Acids

Bile acids are critical to efficient fat digestion and absorption. These processes are limited in both term and preterm infants because the duodenal concentration of bile acids is low as a result of lower synthesis and ileal reabsorption.[73-75] Lower micellar solubilization leads to inefficient cell-mucosal interaction and subsequently lower absorption of the molecules of the mucosal-cell surface interface. Long-chain fatty acids (but not medium-chain fatty acids) depend on bile acids for solubilization and thus are the most susceptible to inefficient absorption.

Bile Salt–stimulated Lipase

Human milk contains esterolytic activity that is not detectable in bovine milk.[76] It has been shown that the digestion of long-chain triglycerides proceeded only in the presence of bile salts by an enzyme, later classified as BSSL, which is present in human colostrum and in preterm and term milk.[77-79] It has been estimated that in milk produced during the first 2 weeks of lactation 40% of triglycerides are hydrolyzed within 2 hours, and during later lactation only 20% of triglycerides are hydrolyzed.[79,80] This apparent decrease is caused by an increase in milk fat content during lactation, rather than a real change in absolute BSSL activity.

Properties of BSSL make it suitable to survive in the stomach with little or no loss of activity and to act in the duodenum when activated by bile acids (cholate, chenodeoxycholate) in concentrations close to those found in the infant duodenum.[78,79] Thus, at a low bile salt concentration, the action of milk BSSL may facilitate fat absorption. BSSL hydrolyzes long-chain triglycerides with no positional specificity and thus hydrolyzes 2-monoacylglycerol.[78] This property, to hydrolyze 2-monoacylglycerol, makes this enzyme complementary to the pancreatic lipase that delivers as its main products fatty acids and 2-monoacylglycerol. The significance of the presence of BSSL for the digestion of milk lipids is supported further by studies in low-birth-weight preterm infants (3 to 6 weeks old) fed raw or heat-treated (pasteurized or boiled) human milk. Fat from the former was absorbed more (74%) than from the latter two (54% and 46%).[81]

Lipoprotein Lipase

Milk also contains a serum-activated lipoprotein lipase (LPL).[78,82,83] Its activity is inhibited by bile salts. Although the concentration of BSSL activity in milk does not change during the duration of lactation, LPL activity increases during lactation, exhibiting a peak around the third week of life.[82] LPL has been implicated in the prolonged neonatal jaundice of breast-fed infants. Fresh milk samples from mothers of infants with jaundice exhibit an increased level of LPL.[84] The relationship between the high activity of LPL in milk and jaundice is not simple, because high levels of LPL in mother's milk are not always associated with jaundice.[85]

Preduodenal Lipases

At the end of the 1800s, von Ebner[86] described the presence of serous glands located on the proximal dorsal site of the tongue. These glands appear to be the source of lingual lipase. The release of these lipases is stimulated by feeding.[87] Preduodenal lipases exhibit partial stereospecificity for *sn*-3 esters over *sn*-1 esters.[88] Lipase activity is present in gastric aspirates as early as 6 months gestation and increases substantially around 8 to 9 fetal months.[89] With use of tributyrin as a substrate, it was shown that lipase activity in gastric aspirates collected from premature infants was lower at birth in infants at 26 weeks and less, peaked at 30 to 32 weeks, and declined to lower levels at term. Continuous feeding, as opposed to intermittent parenteral alimentation, appeared to promote the development of this lipase activity.[90]

Pancreatic Lipases

In adults, pancreatic juice contains two enzymes that are active against neutral lipids. The so-called pancreatic lipase is more active against insoluble, emulsified substrates than against soluble ones. The second lipase, also called pancreatic carboxylase esterase, is more active against micellar or soluble substrates than against insoluble, emulsified substrates. In contrast to the first lipase, it is strongly stimulated by bile salts. Colipase removes the inhibiting effect of bile salts on lipase. Studies usually do not differentiate between these lipases. Generally, lipases show the lowest values after birth.[91] The increase toward adult values occurs within the first 6 months of life, which is earlier than in the case of amylase. Premature and very-low-birth-weight infants have lower values than do term neonates.[92] During the first week of life, lipase activity increases about four-fold in premature infants.[91]

In healthy preterm infants between days 3 and 40 after birth, this activity increased linearly (in infants both at gestational age 29 to 32 weeks and at 33 to 36 weeks).[73] At 1 month of age, values reached 35% in 2- to 6-week-old infants. Premature infants fed soy-based formula at the age of 1 month exhibited higher lipase activity in the duodenal fluid after cholecystokinin-pancreozymin-secretin stimulation than did premature infants fed milk-based formula.[24]

Clinical Correlations

Although we have mentioned that, because of the lack of necessity for bile acid emulsification for medium-chain fats compared with long-chain fats, these should have a greater likelihood of absorptions, this does not appear to be the case. Studies have shown medium-chain triglycerides to be just as readily absorbed as long-chain triglycerides,[93] and the mechanisms of this are speculated to reside in greater gastric lipolytic activity of the longer-chain lipids. This observation is supported by a Cochrane review that showed no differences in growth, necrotizing enterocolitis, or other morbidities in infants fed primarily medium- versus long-chain triglycerides.[94]

Interest is considerable in the capability of neonates to convert the essential fatty acids into longer-chain fatty acids with 20 or more carbons. These long-chain polyunsaturated fatty acids are critical in the formation of eicosanoids and structural components of the central nervous system. They are found in relatively high concentrations in human milk but are not found in total parenteral nutrition or most neonatal formulas. Whether the addition of long-chain polyunsaturated fatty acids to formulas results in improved neurodevelopment is the subject of current intense investigation.

Most essential fatty acids provided to neonates are derived from the omega-6 family (linoleic acid). This is because much of the lipid derived from formulas or intravenous lipid solutions is from vegetable oil, which is rich in the omega-6 but not the omega-3 fraction. The likelihood of health benefits to infants provided greater quantities of the omega-3 lipids than they are currently receiving deserves additional study.

Absorption of fat from breast milk increases slightly during the first month in term infants, achieving values close to 90%. In premature infants, absorption values are close to those found in term infants.[95] Although absorption of long-chain fatty acid triglycerides is lower during the first 6 weeks of life, medium-chain fatty acid triglycerides and short-chain fatty acid triglycerides are already absorbed quite efficiently in premature infants soon after birth.[96]

By comparing the plasma triacylglycerol total and *sn*-2 position fatty acid levels in breast-fed and formula-fed term infants, Innis and associates[97] provided evidence that palmitic acid from

human milk is absorbed as *sn*-2 monoacylglycerol in infants receiving breast milk. Breast-fed infants have a significantly higher proportion of acetic acid in the fecal short-chain fatty acid spectra than the bottle-fed infants. This finding may be related to a different composition of the intestinal microflora and may be associated with protection against diarrhea and respiratory infection in the infant.[98]

Pathophysiology of Gastroesophageal Reflux

COMPONENTS OF THE ANTIREFLUX MECHANISM

A pressure gradient that normally exists between the stomach and the esophagus, in the absence of other factors, would propel gastric contents into the esophagus. To counteract this gradient, a *high-pressure zone* exists at the gastroesophageal junction.[1] This high-pressure zone reflects the combined activities of two sphincters: the lower esophageal sphincter (LES) and the crural diaphragm. The activities of these two sphincters are constantly changing to prevent reflux despite changes in gastric, abdominal, and thoracic pressures. The high-pressure zone must also relax to allow passage of material across the gastroesophageal junction during swallowing, vomiting, eructation, and esophageal distention.

High-Pressure Zone

Manometrically, the high-pressure zone is characterized by the following two components: a tonically elevated basal pressure and a respiratory-induced pressure oscillation, both of which are of greater magnitude than the pressure simultaneously found in the adjacent stomach and esophagus (Figure 116-1).[2-4] The basal pressure in the high-pressure zone can be accounted for by an intrinsic smooth muscle sphincter located at the distal esophagus known as the *lower esophageal sphincter.* Pressure changes in the high-pressure zone associated with respiratory oscillations are primarily the result of active diaphragmatic contractions that occur during inspiration.[4,5] The combined activities of both an internal sphincter (the LES) and an external sphincter (the crural

Pathophysiology of Gastroesophageal Reflux

COMPONENTS OF THE ANTIREFLUX MECHANISM

A pressure gradient that normally exists between the stomach and the esophagus, in the absence of other factors, would propel gastric contents into the esophagus. To counteract this gradient, a *high-pressure zone* exists at the gastroesophageal junction.[1] This high-pressure zone reflects the combined activities of two sphincters: the lower esophageal sphincter (LES) and the crural diaphragm. The activities of these two sphincters are constantly changing to prevent reflux despite changes in gastric, abdominal, and thoracic pressures. The high-pressure zone must also relax to allow passage of material across the gastroesophageal junction during swallowing, vomiting, eructation, and esophageal distention.

High-Pressure Zone

Manometrically, the high-pressure zone is characterized by the following two components: a tonically elevated basal pressure and a respiratory-induced pressure oscillation, both of which are of greater magnitude than the pressure simultaneously found in the adjacent stomach and esophagus (Figure 116-1).[2-4] The basal pressure in the high-pressure zone can be accounted for by an intrinsic smooth muscle sphincter located at the distal esophagus known as the *lower esophageal sphincter.* Pressure changes in the high-pressure zone associated with respiratory oscillations are primarily the result of active diaphragmatic contractions that occur during inspiration.[4,5] The combined activities of both an internal sphincter (the LES) and an external sphincter (the crural

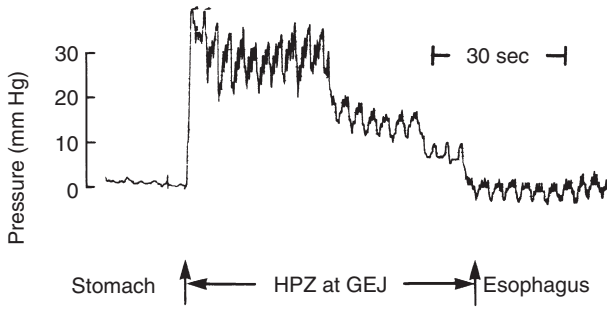

Figure 116-1 High-pressure zone *(HPZ)* at the gastroesophageal junction *(GEJ)* as measured by the station pull-through technique.[2,3] This zone is characterized by an elevated basal pressure and an oscillating pressure wave corresponding to respiratory rate.

diaphragm) allow the high-pressure zone to modify the gastroesophageal pressure gradient during a variety of physiologic processes, such as deglutition, esophageal distention, and abdominal straining.[5-9]

Lower Esophageal Sphincter

The LES is a muscular structure with distinctive mechanical and electrical characteristics, unique responses to drugs and hormones, and specialized neural innervation.[10-24] The muscles of the LES appear thicker than those of the more proximal esophagus when they are examined by ultrasound scan.[25] In contrast to the adjacent esophagus, in which the plexus lies only between the circular and longitudinal muscle layers,[26] the innervation of the LES is unique in that the myenteric plexus occupies multiple muscle planes.

The activity of the LES has been studied in a feline model in which esophageal distention results in changes in sphincter tone. During esophageal distention, the baseline high-pressure zone decreases to gastric baseline pressure; simultaneously, the magnitude of the respiratory-induced oscillations in the high-pressure zone is markedly reduced (Figure 116-2). This observation suggests that the response of the sphincter mechanism to esophageal distention involves a relaxation of the intrinsic LES. These events provide an ideal situation for the transit of a swallowed bolus through the gastroesophageal junction.

The neural pathways controlling such rapid changes in LES tone have been characterized. During swallowing, afferent signals from the pharynx travel to the nucleus solitarius in the medulla. Efferent signals then travel from the adjacent dorsal vagal nucleus and the nucleus ambiguus through the vagus nerve to the esophagus, thereby mediating both esophageal peristalsis and LES relaxation to propel swallowed material into the stomach.[27]

Measurements of lower esophageal pressure have also revealed high-amplitude (≤80 mm Hg) fluctuations in sphincter tone. These fluctuations occur at a frequency of approximately three per minute, and they correspond to the activity of the migrating motor complex of the stomach. Thus the LES allows the high-pressure zone to compensate for wide variations in gastric pressure caused by the motor activity of the stomach.[28]

The region of the stomach just below the LES also contributes to the intrinsic antireflux barrier. The smooth muscle fibers of this region form a sling around the greater curvature of the stomach.[29] Although they are not strictly part of the LES, the sling fibers help to prevent reflux by acting as a flap valve in which fundic distention presses the closed end of the sling against the distal esophagus.[30]

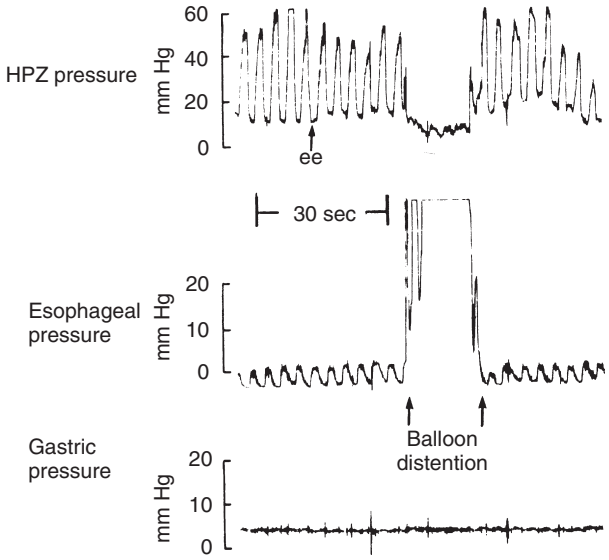

Figure 116-2 Effect of esophageal balloon distention on high-pressure zone *(HPZ)* pressure in a cat. During the period of balloon distention, baseline end-expiratory *(ee)* high-pressure zone pressure decreases to the level of gastric pressure, and a marked reduction is seen in the magnitude of the respiratory-induced oscillations in high-pressure zone pressure.

Crural Diaphragm

The crural diaphragm is distinguished from the costal diaphragm by its attachment to the vertebral column rather than the rib cage. Because the esophagus passes through the crural diaphragm, diaphragmatic contractions create an external sphincter mechanism at the gastroesophageal junction. The activity of the crural diaphragm varies with the respiratory cycle, thereby compensating for variations in thoracic and abdominal pressure that would otherwise favor gastroesophageal reflux during inspiration (see Figure 116-1). The activity of the crural diaphragm is increased or decreased in various other physiologic settings to allow forward passage of swallowed material but to prevent gastroesophageal reflux despite changes in abdominal pressure (see later). Indeed, in the absence of the LES (after resection), the crural diaphragm alone is able to maintain the high-pressure zone.[31]

In mammals, swallowing, distention of the esophagus, eructation, vomiting, regurgitation, and rumination are associated with an inhibition of diaphragmatic electrical activity, thereby facilitating passage of material through the gastroesophageal junction.[5,32-38] A consistent finding associated with transit through the gastroesophageal junction is that inhibition of the crural diaphragm occurs to a much greater degree than that of the costal diaphragm (Figure 116-3). In a feline model, swallowing and esophageal balloon distention resulted in concurrent relaxation of the LES and inhibition of crural inspiratory activity. The respiratory-induced oscillations in high-pressure zone pressure were abolished as a result of inhibition of crural inspiratory activity, whereas relaxation of the LES resulted in a decrease in baseline end-expiratory pressure. Costal diaphragmatic activity remained unchanged and allowed continued ventilation with little change in the respiratory rate or intrapleural pressure (Figure 116-4). During periods of increased intraabdominal pressure, such as the Valsalva maneuver, coughing, straight-leg raising, or abdominal compression, an increase occurs in crural diaphragmatic tone, thereby compensating for the increased pressure gradient favoring gastroesophageal reflux.[39]

In summary, the manometrically defined high-pressure zone at the gastroesophageal junction depends on the tone generated by

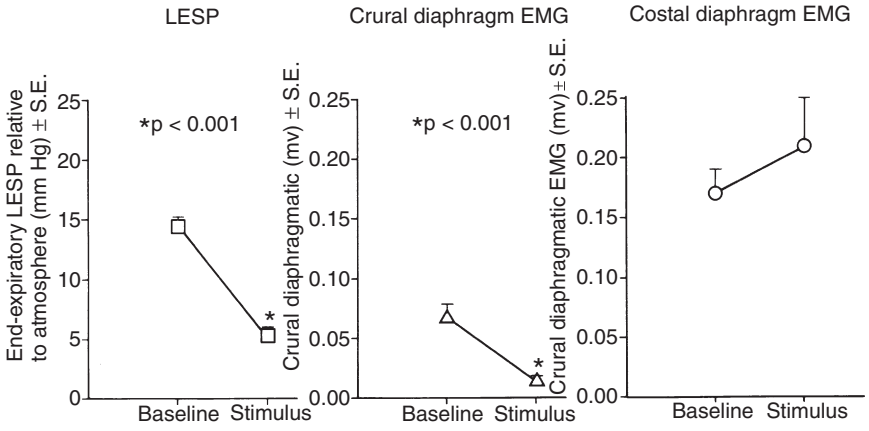

Figure 116-3 Summary of the effect of distention of the lower esophagus on intrinsic LES tone and diaphragmatic electromyographic *(EMG)* activity. It can be seen that distention (stimulus) caused a decrease in the activity of the crural diaphragm, together with a decrease in LES pressure *(LESP)*. In contrast, the activity of the costal diaphragm does not change significantly.

the intrinsic LES and on the magnitude of crural diaphragmatic contraction. Transit of material through the gastroesophageal junction is most likely to occur during simultaneous relaxation of the LES and inhibition of the crural diaphragm.

MECHANISMS OF GASTROESOPHAGEAL REFLUX

In theory, gastroesophageal reflux occurs in either of the following two situations: relaxation of the high-pressure zone (either transiently or for longer periods) or elevation of the gastroesophageal pressure gradient above that of the high-pressure zone (Figure 116-5, *A*). Using techniques that allow for simultaneous and continuous recording of LES pressure (manometry) and both acid and nonacid esophageal reflux (using pH and multichannel intraluminal impedance monitoring), investigators have been able to distinguish these two possibilities.[6-9,38-46] It has become clear that most gastroesophageal reflux is associated with a transient relaxation of the high-pressure zone involving decreased activity in both the LES and the crural diaphragm. However, the converse is not true; most transient relaxations are not associated with reflux events. Transient relaxations of the high-pressure zone occur in normal subjects, but it appears that those with gastroesophageal reflux disease have both a higher frequency of relaxations and an increased rate of reflux per episode of relaxation. Other factors must therefore also play a role in the pathogenesis of reflux disease, such as transient increases in intraabdominal pressure, impaired clearance of refluxed material, or the presence of hiatal hernia.

Transient Relaxation of the High-Pressure Zone

As illustrated in Figure 116-5, most episodes of gastroesophageal reflux occur during transient relaxation of the high-pressure zone (see Figure 116-5, *A*).[8,9,47,48] Transient relaxation is caused by an abrupt collapse of pressure in the high-pressure zone in the absence of a swallow or primary esophageal peristalsis. Pressure in the high-pressure zone before and immediately after these episodes is always greater than gastric pressure. The pressure profile of the high-pressure zone during transient relaxation is similar to that observed during a swallow and is characterized by decreases in both LES activity and crural diaphragm activity (Figure 116-6). The physiologic role of transient relaxations is to allow eructation (belching) to occur, consistent with the finding that gastric distention can trigger transient relaxations.[49-53]

Other triggers for transient relaxation remain unclear. Swallow-induced and transient relaxations of the high-pressure zone are identical manometrically, and, in humans, transient relaxations frequently occur within a few seconds of a previous swallow-induced relaxation or in association with an incomplete peristaltic sequence (Figure 116-7).[1,8,53-55] In an experimental

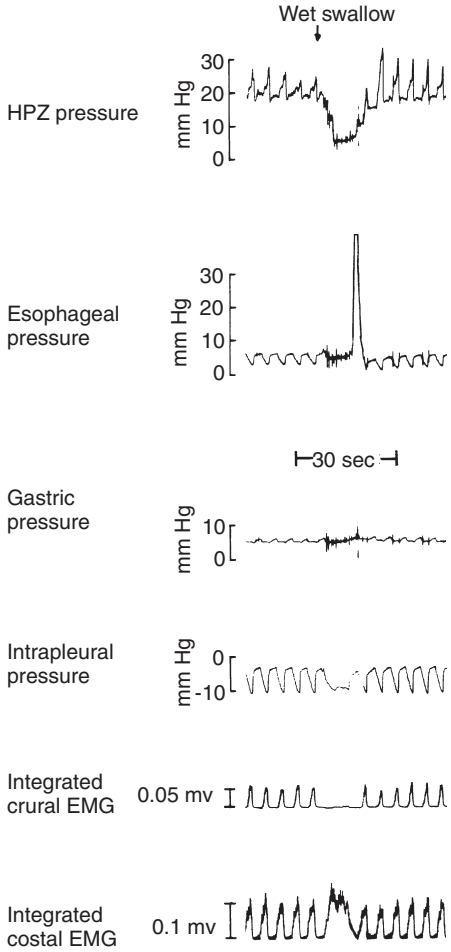

Figure 116-4 Effect of a wet swallow on high-pressure zone *(HPZ)* pressure and diaphragmatic activity. The wet swallow was induced by a bolus injection of water into the posterior pharynx. The swallow results in an esophageal contraction, with a simultaneous relaxation of the intrinsic LES and inhibition of integrated crural electromyographic *(EMG)* activity. The combination of these events results in end-expiratory high-pressure zone pressure decreasing to gastric baseline and an absence of respiratory-induced oscillations in high-pressure zone pressure. The costal diaphragm remains active during the swallow, thus allowing ventilation to continue. *(From Altschuler SM, Boyle JT, Nixon TE, et al: Simultaneous reflex inhibition of lower esophageal sphincter and crural diaphragm in cats,* Am J Physiol *249:G586, 1985.)*

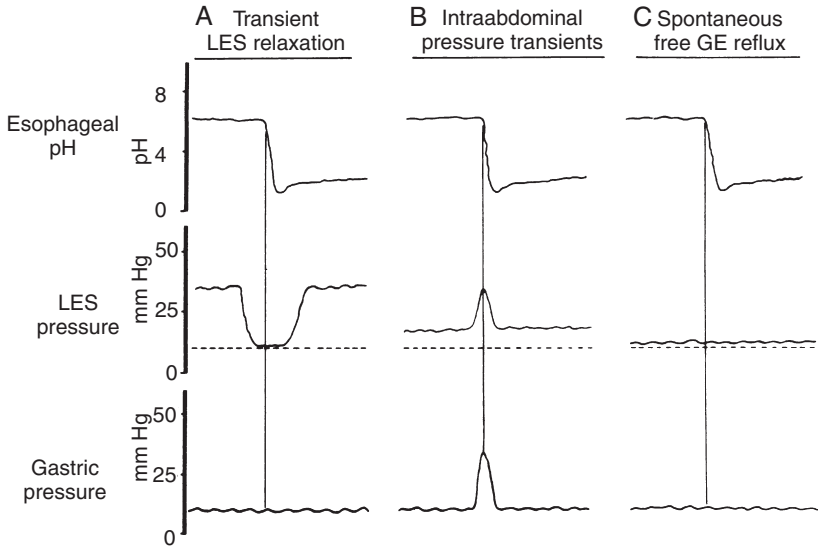

Figure 116-5 Schematic representation of different mechanisms of gastroesophageal *(GE)* reflux with use of the sleeve sensor to monitor high-pressure zone *(HPZ)* LES pressure. Episodes of gastroesophageal reflux occur during transient relaxation of the high-pressure zone **(A),** during increases in intraabdominal pressure that overcomes high-pressure zone pressure **(B),** or as spontaneous reflux across an atonic high-pressure zone **(C).** *(From Dodds WJ, Dent J, Hogan WJ, et al: Mechanism of gastroesophageal reflux in patients with reflux esophagitis,* N Engl J Med *307:1547, 1982.)*

model using the opossum, transient relaxations were produced by stimuli that tended to be less vigorous than the threshold required for inducing a full deglutition sequence or for the induction of secondary esophageal peristalsis.[56] Aggressive pharyngeal stroking tended to cause a full deglutition reflex, whereas a single pharyngeal stroke was most commonly associated with isolated LES relaxation. Electrical stimulation of the central end of the superior laryngeal nerve (vagal afferent stimulation) or the peripheral end of the cervical vagus (vagal efferent stimulation) at high frequencies resulted in a normal deglutition sequence, whereas low-frequency stimulation resulted in isolated LES relaxation. Studies in humans have shown that transient relaxation is frequently associated with mylohyoid and pharyngeal activity of a much lower magnitude than that observed during a swallow or with a nonperistaltic esophageal contraction.[54] As a result of these studies, it has been suggested that transient relaxations occur by the same neural pathways as swallowing-associated relaxation (see earlier) and may be induced by a long train of subthreshold stimuli originating in the pharynx.[56]

Studies in both normal subjects and in patients with gastroesophageal reflux disease have shown that most reflux episodes occur during transient relaxations.[50-52] Although transient relaxations of the high-pressure zone may last from 10 to 45 seconds, the actual episodes of reflux occur only during the period when the baseline high-pressure zone pressure is zero and respiratory-related pressure oscillations are absent (see Figure 116-6). Why are transient relaxations associated with gastroesophageal reflux disease in some subjects and not in others? Studies of transient relaxations in patients with and without reflux symptoms have found only a slight increase in the frequency of relaxations in those with symptoms.[52] Some of these patients, and children in particular, may have delayed gastric emptying resulting in gastric distention, which, in turn, may produce transient relaxations of the LES.[47,49,57,58] A more important difference appears to be an increase in the percentage of transient relaxations that result in reflux from 40% to 50% in physiologically normal persons to 60% to 70% in patients with gastroesophageal reflux disease.[52]

Intraabdominal Pressure Transients

Although transient relaxation of the high-pressure zone is the major criterion for episodes of gastroesophageal reflux in both physiologically normal persons and patients with symptoms, other mechanisms must contribute to reflux in patients with symptoms.[1,9,47,48] Some of these mechanisms are illustrated in Figure 116-5. Active increases in abdominal pressure occur during coughing, straining, and changes in position. In physiologically normal persons, an increase in crural diaphragm activity during active increases in abdominal pressure is thought to prevent episodes of gastroesophageal reflux.[39] In contrast, during passive abdominal compression (which may occur frequently in neonates and infants), crural diaphragmatic activity is inhibited and the activity of the LES is increased, thus leaving the LES as the sole barrier to gastroesophageal reflux (Figure 116-8). This adaptive response involves a vagally mediated increase in LES pressure in excess of the transmitted pressure increase in the stomach.[59] The degree to which failure of these responses to active or passive increases in intraabdominal pressure is responsible for symptomatic gastroesophageal reflux remains to be determined.

Spontaneous Free Gastroesophageal Reflux

Before the development of the sleeve sensor device to measure high-pressure zone transient relaxations and the simultaneous recording of esophageal pH, a depressed basal high-pressure zone pressure was considered the major factor leading to episodes of gastroesophageal reflux. A low resting high-pressure zone pressure was primarily attributed to a hypotonic intrinsic LES,[17] which allows free reflux of gastric contents into the esophagus. Strawczynski and colleagues[60] demonstrated that LES pressure is normally decreased in infants compared with that in adults. In addition, studies in the opossum have illustrated that lower esophageal pressure is depressed at birth and gradually achieves normal levels later in life.[61]

The presence of a hypotonic LES has also been observed in patients with neurologic impairment, connective tissue disorders such as scleroderma, previous surgery of the gastroesophageal

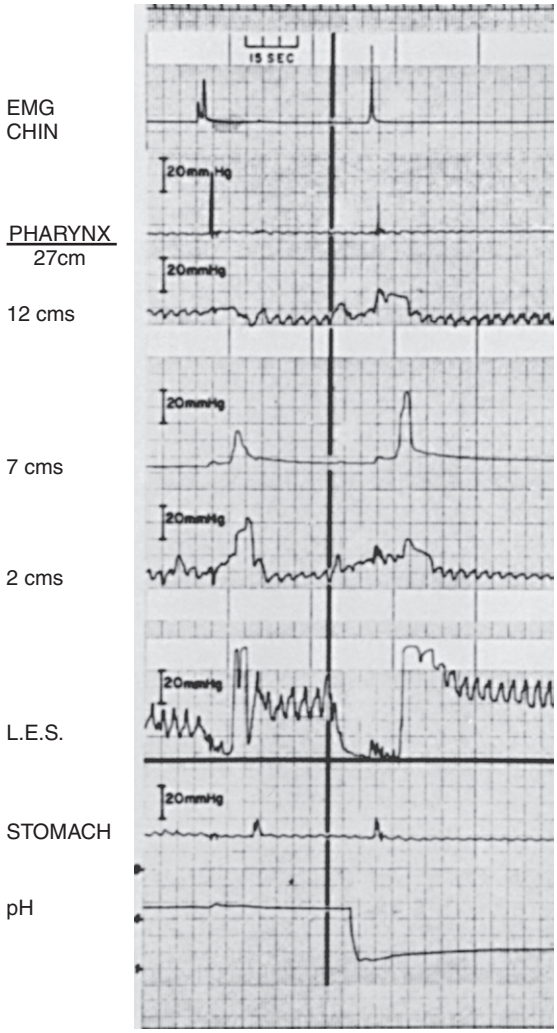

Figure 116-6 Comparison of swallow-induced high-pressure zone LES relaxation with transient relaxation of the high-pressure zone. The swallow-related high-pressure zone relaxation *(left* of the *dark vertical line)* is associated with a submental electromyographic *(EMG)* spike, a pharyngeal contraction, and an esophageal peristaltic contraction. The presence of the esophageal peristaltic contraction prevents the occurrence of gastroesophageal reflux. The *dark vertical line* indicates the start of a transient high-pressure zone relaxation. The relaxation is of longer duration than the swallow-induced high-pressure zone relaxation. An episode of gastroesophageal reflux occurs (esophageal pH falls from 5 to 1) when baseline high-pressure zone pressure approaches 0 and no respiratory-related oscillation occurs in high-pressure zone pressure. *L.E.S.,* Lower esophageal sphincter. *(From Mittal RK, McCallum RW: Characteristics and frequency of transient relaxations of the lower esophageal sphincter in patients with reflux esophagitis,* Gastroenterology *95:543, 1988. Copyright 1988 by the American Gastroenterological Association.)*

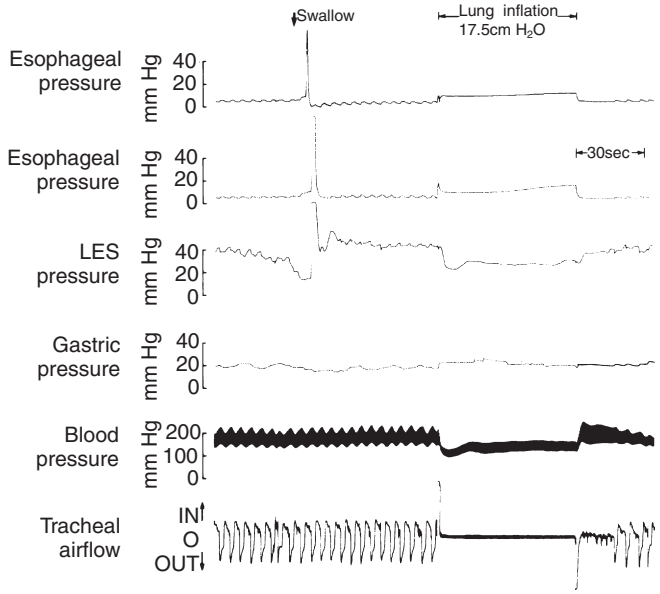

Figure 116-7 Effect of static lung inflation on high-pressure zone LES pressure. Lung inflation induces a reflex relaxation of high-pressure zone pressure that persists for the duration of the stimulus. During the lung inflation, no spontaneous respiration occurs, and thus respiratory oscillation in high-pressure zone pressure is absent. The high-pressure zone relaxation induced by lung inflation is not associated with any esophageal motor events. The swallow-induced high-pressure zone relaxation is terminated by a contraction of the LES. *(Courtesy J.T. Boyle, MD.)*

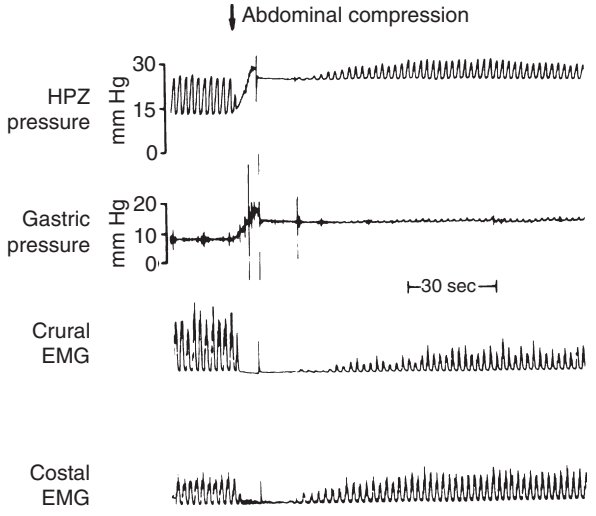

Figure 116-8 Effect of abdominal compression on the high-pressure zone *(HPZ)* pressure profile. With the onset of abdominal compression, end-expiratory high-pressure zone pressure increases and crural and costal diaphragmatic electromyographic *(EMG)* activity decreases. The crural diaphragmatic EMG activity remains inhibited for the duration of the stimulus, whereas costal activity returns to baseline levels. As a result of the inhibition of crural EMG activity, a decrease occurs in the magnitude of the respiratory-induced oscillations in high-pressure zone pressure. The increase in end-expiratory high-pressure zone pressure is greater than the increase in gastric pressure induced by the abdominal compression, a finding indicating that the LES has undergone an adaptive response during the period of abdominal compression. *(From Boyle JT, Altschuler SM, Nixon TE, et al: Responses of feline gastroesophageal junction to changes in abdominal pressure,* Am J Physiol *253:G315, 1987.)*

junction, and esophagitis.[1,48] An alteration in central neural input to the LES or an impairment of the contractile function of the LES muscle is likely present in these patients.[1,49] In many cases, it is difficult to establish the sequence of cause and effect, because reflux esophagitis itself causes esophageal dysmotility. Likewise, although hiatal hernia can exacerbate gastroesophageal reflux, it may be a secondary result of esophageal shortening caused by chronic esophagitis.[1] Although episodes of gastroesophageal reflux are now known to occur infrequently by the mechanism of a hypotonic LES, this mechanism may be important with regard to the previously mentioned disorders.

GASTROESOPHAGEAL REFLUX IN THE NEONATAL PERIOD

The mechanisms of gastroesophageal reflux in the neonate, and in particular in premature infants, have been less well described than in adults. Regurgitation is very common in this age group; up to 40% to 60% of normal 0- to 4-month-old infants regurgitate some amount of their feedings.[62] Basic mechanical considerations provide some explanation for the high frequency of regurgitation in infants. Newborns spend most of their time in the supine position, which has been shown to promote gastroesophageal reflux. The newborn term infant's esophageal length is only 8 to 10 cm, and the intraabdominal esophagus is less than 1 cm, thereby facilitating passage of refluxed material to a relatively higher anatomic level than in adults.

Esophageal pH monitoring, the current standard for the diagnosis of gastroesophageal reflux in adults, is of limited value in infants because gastric acid is buffered by frequent feedings. Nonetheless, it is possible to measure esophageal pressures in neonates and even premature infants and to identify ways in which their antireflux mechanisms differ from those of adults.[63-66] As suggested by prenatal ultrasound images of fetuses swallowing amniotic fluid, the primary esophageal mechanisms are present at an early stage. Manometric studies of both premature and term neonates have confirmed normal primary esophageal peristalsis. Moreover, even premature infants as young as 33 weeks postmenstrual age have been found to have a lower esophageal high-pressure zone although the pressure increases with age.[63-65] However, premature infants at 30- to 34-week gestational ages have lower esophageal peristaltic velocity and amplitude than term infants.[67,68] In response to mid-esophageal liquid infusion, premature infants have a longer delay to LES relaxation, but once the relaxation occurs it is of a longer duration than in term infants.[69] Premature infants have an elevated frequency of synchronous (i.e., nonperistaltic) esophageal contractions in the absence of a swallow, and this lack of coordination may lead to inadequate clearance of refluxed material.[63,64] As in adults, it appears that transient relaxations of the high-pressure zone are the primary mechanism of gastroesophageal reflux in neonates.[63-66] Thus it appears that the high frequency of gastroesophageal reflux in neonates reflects both anatomic factors and immaturity of the esophageal clearance mechanisms.

Manifestations of Gastroesophageal Reflux in the Neonate

Neonatal gastroesophageal reflux is considered pathologic if it is associated with growth failure resulting from poor feeding, excessive regurgitation, pulmonary complications, or neurobehavioral manifestations, such as severe irritability or Sandifer syndrome. In these cases, the diagnosis is made on the basis of a clear temporal association of the symptoms with feeding times or episodes of regurgitation. The relationship between gastroesophageal reflux and apnea of prematurity is less clear. Although it had been assumed that apnea of prematurity is caused at least in part by gastroesophageal reflux, several studies using combined pH monitoring, multichannel intraluminal impedance, and polysomnography have demonstrated that apnea is no more likely to occur after a reflux event (either acid or nonacid) than during a reflux-free period.[46,70-78] Thus it is not clear that measures directed toward reducing gastroesophageal reflux will be effective in reducing the frequency or severity of apnea of prematurity.

117 Pathophysiology and Prevention of Neonatal Necrotizing Enterocolitis

Michael Caplan

Neonatal necrotizing enterocolitis (NEC) is an ischemic and inflammatory necrosis of bowel that primarily afflicts premature neonates after the initiation of enteral feeding.[1,2] Despite the significant morbidity and mortality associated with NEC, the pathophysiology has remained poorly understood. The disease is seen clinically in premature neonates with variable symptoms of intestinal bleeding, emesis, abdominal distention and tenderness, lethargy, apnea and bradycardia, thrombocytopenia, metabolic acidosis, respiratory failure, and, if severe, shock.[3] Clues to the origin are suggested by the pathologic changes observed in surgical specimens and autopsy material, including coagulation necrosis (suggesting some component of ischemic injury), inflammation (acute or chronic), and less commonly ulceration, hemorrhage, reparative change, bacterial overgrowth, edema, and pneumatosis intestinalis.[4]

Although most cases of NEC are diagnosed in premature neonates, term infants with specific underlying risk factors are at risk for this disease.[5-8] Previous studies have identified birth asphyxia, polycythemia, exchange transfusion, intrauterine growth restriction, cyanotic congenital heart disease, myelomeningocele, gastroschisis, and intrauterine cocaine exposure as potential events leading to the development of intestinal injury.[9] Nonetheless, the presentation of NEC in these cases is typically different from that in premature infants, with the onset in the first days after delivery and the course often less dramatic. For these reasons, the pathophysiology in term infants may be quite different from that in the premature neonate and is therefore not considered further in this chapter.

PREMATURITY: THE MAJOR RISK FACTOR FOR NECROTIZING ENTEROCOLITIS

The multifactorial theory has been suggested to explain the pathophysiology of neonatal NEC and purports that several risk factors (prematurity, formula feeding, ischemia or asphyxia, and bacterial colonization) result in the final common pathway of bowel necrosis. More than 90% of cases of NEC occur in premature infants, whereas stratification studies have shown that gestational age and birth weight inversely correlate with a higher incidence of disease.[10-12] Epidemiologic observations suggest an association between intestinal ischemia, infection, and feeding practice on the development of NEC; however, the presence of these factors is less consistent than the presence of prematurity. Although there are many differences between preterm and term neonates, the specific underlying mechanisms responsible for the predilection of NEC in the premature condition remain incompletely elucidated. Studies in humans and animals have identified alterations in multiple components of intestinal host defense,[13-15] motility,[16-19] bacterial colonization,[20-24] blood flow regulation,[25-27] and inflammatory response,[28-30] and these may contribute to the development of intestinal injury in this unique population (Box 117-1).

Host Defense

Intestinal host defense involves a complex combination of factors that function to prevent intraluminal pathogens and toxins from resulting in disease while allowing for normal absorption of nutrients. This intricate system includes the following: (1) physical barriers such as skin, mucous membranes, intestinal epithelia and microvilli, epithelial cell tight junctions, and mucin; (2) immune cells such as polymorphonuclear leukocytes, macrophages, eosinophils, and lymphocytes and secretory immunoglobulin A (IgA); and (3) various biochemical factors.[15,31-39] Although not exhaustively studied, many of these important functions appear to be abnormal in the premature infant and may

BOX 117-1

Premature Infants: Factors That May Increase Their Susceptibility to Necrotizing Enterocolitis

Compromised intestinal host defense
Physical barriers
- Skin
- Mucous membranes
- Epithelia and microvilli
- Tight junctions
- Mucin

Immune factors
- Neutrophils
- Macrophages
- Eosinophils
- Lymphocytes (including intraepithelial lymphocytes)
- Secretory IgA

Biochemical factors
- Antimicrobial proteins (trefoil factor, defensins and cryptidins)
- Oligosaccharides
- Glutamine
- Lactoferrin
- Polyunsaturated fatty acids
- Nucleotides
- Growth factors (EGF, TGF, IGF, erythropoietin)
- Gastric acid
- Cytokines

Intestinal dysmotility
Migratory motor complexes

Bacteria
Patterns of colonization or overgrowth
Pathogenicity of organisms

Altered autoregulation of intestinal circulation
Basal vascular resistance
Response to stress

Disordered inflammatory response
Increased proinflammatory response to stimuli
Suppressed antiinflammatory components

EGF, Epidermal growth factor; *Ig,* immunoglobulin; *IGF,* insulin-like growth factor; *TGF,* transforming growth factor.

therefore put this population at risk for NEC. Intestinal permeability to macromolecules including immunoglobulins, proteins, and carbohydrates is known to be greater in neonates compared with older children and adults, and in premature infants this permeability may be more pronounced.[37,40] Although mucosal permeability is beneficial for developing animals to augment passive immunity and nutrient absorption, the precise mechanisms accounting for these differences are poorly understood. The microvilli and tight junctional barrier may be deficient in the premature infant, but the data are inconclusive.[41] It is known that intestinal mucus (a complex gel consisting of water, electrolytes, mucins, glycoprotein, immunoglobulins, and glycolipids) protects against bacterial and toxin invasion and is abnormal in developing animals.[33,42] In addition, key bacteriostatic proteins are secreted from epithelium that bind to or inactivate the function of invading organisms. Intestinal trefoil factor is one such molecule that appears to be developmentally regulated and therefore deficient in the premature neonate.[43-45] Human defensins (or cryptidins) are bacteriostatic proteins synthesized and secreted from Paneth cells that protect against bacterial translocation and are altered in premature infants and those with NEC.[46,47]

Immunologic host defense is abnormal in developing animals.[48-50] It is known that intestinal lymphocytes are decreased in neonates (B and T cells) and do not approach adult levels until 3 to 4 weeks of life. Newborns have markedly reduced secretory IgA in salivary samples, reflecting the decreased activity presumed in the intestine.[51,52] Breast milk feeding provides multiple immune factors; formula-fed neonates have impaired intestinal humoral immunity, and this deficiency may predispose to the increased incidence of infectious diseases noted in this population.[53,54] A complete review on the importance of breast milk in immunologic host defense can be found in Chapters 149 to 158 of this textbook.

Several biochemical factors that are present in the intestinal milieu play an important role in the maintenance of gut health and integrity. Substances such as lactoferrin[55] and glutamine[56,57]; growth factors such as epidermal growth factor,[28] transforming growth factor-β,[58] insulin-like growth factor,[59] and erythropoeitin[60,61]; gastric acid; oligosaccharides[62]; polyunsaturated fatty acids[63,64]; nucleotides[65]; and many others affect mucosal barrier function, intestinal inflammation, and the viability of intraluminal bacteria. Many of these factors are deficient or absent in the preterm neonate, especially in those patients not receiving breast milk feedings. Intensive research is ongoing to define the specific role of each on gut integrity and the development of intestinal inflammation and necrosis.

Motility

The premature infant has altered gastrointestinal motility; term newborn motility patterns or "migratory motor complexes" do not appear until 34 to 35 weeks gestation.[16,66] Abnormal peristaltic activity may allow for bacterial overgrowth that could increase endotoxin exposure and predispose the infant to NEC. Furthermore, dysmotility causes intestinal dilatation and compromised intestinal blood flow, with further ischemic stress to compromised intestinal circulation.

Bacterial Colonization

Premature infants hospitalized in the neonatal intensive care unit have different patterns of gut bacterial colonization than healthy breast-fed term infants have.[67] Although epidemics of NEC have been described associated with specific bacteria (e.g., *Clostridia* spp., *Escherichia coli*, *Klebsiella* spp., *Staphylococcus epidermidis*), most cases occur endemically and demonstrate a variety of bacterial isolates from stool cultures.[24,68] Blood cultures are positive in only 20% to 30% of affected cases, and this likely represents the degree of mucosal damage at presentation. At birth, the intestine is a sterile environment, and no cases of NEC have been described in utero, a finding supporting the importance of bacterial colonization in the pathophysiology. Colonization develops from several species in breast-fed infants by 1 week of age that include probiotic (facultative anaerobes defined to confer benefit to the host) organisms such as *Bifidobacteria* spp. and *Lactobacillus* spp., whereas the intestine in the hospitalized, extremely premature infant has less species diversity and fewer facultative anaerobes.[54,69-71] This imbalance may allow for pathologic proliferation, binding, and invasiveness of otherwise nonpathogenic intestinal bacteria. Alternatively, probiotic organisms can modulate the inflammatory response and improve mucosal barrier function by multiple mechanisms that can contribute to overall intestinal health. It remains unclear whether bacterial translocation into submucosa is a prerequisite for NEC or, rather, the activation of the toll-like receptors from endotoxin and other pathogen-associated molecular patterns is adequate to initiate the final common pathway of intestinal injury.[22,72-74] Nonetheless, certain bacteria such as adherent *E. coli* produce disease in a rabbit model of NEC, whereas nonpathogenic strains of gram-positive organisms prevent disease.[75] Furthermore, reports have suggested that early enteral supplementation of probiotics (e.g., bifidobacterium and lactobacillis) reduces the risk of NEC in animals and humans.[20,76] Two randomized, placebo-controlled, single-center trials performed in Taiwan and Israel demonstrated a marked reduction of NEC incidence in subjects supplemented with separate probiotic preparations.[77,78] Large multicenter trials will be necessary to confirm the efficacy and safety of this approach, but this strategy might offer the first breakthrough in the prevention of NEC. In summary, bacterial colonization is an important factor in the initiation of intestinal injury, but the specific events in the pathophysiology are not well delineated.

Intestinal Blood Flow Regulation

Early observations on the pathophysiology of NEC suggested that profound intestinal ischemia was a critical predisposing factor.[79,80] Similar to the "diving reflex" observed in aquatic mammals, it was hypothesized that, in periods of stress, blood flow was diverted away from the splanchnic circulation, with resulting intestinal necrosis. Although early epidemiologic observations identified asphyxia as an important risk factor, subsequent studies have shown that most cases of NEC are not associated with profound impairment in intestinal perfusion.[3] In animal models, studies have shown that the reperfusion after intestinal ischemia is required for the initiation of bowel necrosis,[81,82] and therefore investigations of the role of intestinal ischemia in the pathophysiology of NEC are focused on this construct.

Intestinal and somatic growth is dramatic in developing animals, and therefore providing sufficient flow is mandatory. Neonatal animals have been shown to have differences in the intestinal circulation that may predispose them to NEC. The basal intestinal vascular resistance is elevated in the fetus and decreases significantly after birth, thus allowing for rapid increase in intestinal blood flow.[25] It has been shown that this change in the resting vascular resistance is dependent on the balance between the dilator (nitric oxide) and constrictor (endothelin) molecules and the myogenic response.[83,84] In findings perhaps more relevant than basal vascular tone, studies have shown that the newborn has alterations in response to circulatory stress, resulting in compromised intestinal flow and/or vascular resistance. In response to hypotension, newborn animals (3-day-old but not 30-day-old swine) appear to have defective pressure-flow autoregulation, resulting in compromised intestinal oxygen delivery and tissue oxygenation.[26,27,85] In addition, in the presence of arterial hypoxemia, the newborn intestinal circulatory response differs from that in older animals. Although intestinal vasodilation and

increased intestinal perfusion occur after modest hypoxemia, severe hypoxemia causes vasoconstriction, intestinal ischemia, and hypoxia, mediated in part by loss of nitric oxide production. Multiple chemical mediators (nitric oxide, endothelin, substance P, norepinephrine, and angiotensin) affect intestinal vasomotor tone, and, in the stressed newborn, abnormal production of these mediators may result in compromised circulatory autoregulation, leading to perpetuation of intestinal ischemia and tissue necrosis.[86-88]

Enteral Alimentation

Enteral alimentation has long been considered an important risk factor in the initiation of NEC; more than 90% of cases occurred in premature infants after feedings were introduced. Although the onset of disease used to occur several days after the first feeding, in reports of extremely low-birth-weight infants from the 1990s, NEC was often diagnosed several weeks later.[10,89] Whereas the precise relationship between enteral feedings and NEC remains poorly understood, studies have identified the importance of breast milk (versus formula), volume and rate of feeding advancement, osmolality, and substrate fermentation as important factors.[90-93]

Breast milk feeding appears to reduce the incidence of NEC in human studies and in carefully controlled animal models.[12,21] Breast milk contains multiple bioactive factors that influence host immunity, inflammation, and mucosal protection including secretory IgA, leukocytes, lactoferrin, lysozyme, mucin, cytokines, growth factors, enzymes, oligosaccharides, and polyunsaturated fatty acids, which are absent in or recently added to (e.g., polyunsaturated fatty acids) neonatal formula preparations. Specific intestinal host defense factors acquired from breast milk such as epidermal growth factor, polyunsaturated fatty acids, platelet-activating factor (PAF) acetylhydrolase, IgA, and macrophages are effective in reducing the incidence of disease in animals,[28,63,94,95] and some have been effective in human trials.[52,64] Nonetheless, breast milk is not completely protective against NEC in premature infants; the largest prospective trial identified a reduction by 50% in most birth-weight–specific groups.[12,96] Because most premature infants receive breast milk by the nasogastric route after artificial collection by mothers and subsequent freezing, it has been suggested that the methods of collection and feeding interfere with specific milk immunity and thereby reduce the protection against the neonate's microbial flora.

Specific components of milk feedings have been implicated in causing mucosal injury in the high-risk neonate. Studies have shown that hyperosmolar formulas resulted in NEC, and the addition of medication to feedings can markedly increase osmolality.[97,98] Animal studies have shown that short-chain fatty acids such as propionic or butyric acid can damage the developing intestine and that in situations of carbohydrate malabsorption colonic fermentation may lead to production of these acids by the host microflora.[99-101] This pathway may be especially problematic in the premature infant, deficient in lactase activity and other brush border enzymes.

Different approaches to feeding have been associated with the initiation of NEC. Early studies suggested that rapid volume increases with full-strength formula made the incidence of disease more prevalent, and protocols were designed to limit feeding advancement. Several studies have shown that early, hypocaloric, or trophic feedings are safe and improve gastrointestinal function in very-low-birth-weight infants.[102-105] Feeding advancement has been evaluated, and the results suggest that judicious volume increase may be safer. It has been postulated that overdistention of the stomach with aggressive volumes may compromise splanchnic circulation leading to intestinal ischemia.

In summary, the premature neonate has several unique features that may increase susceptibility to NEC, but the precise interrelationship of these factors in the final common pathway of intestinal necrosis remains unclear.

FINAL COMMON PATHWAY: THE INFLAMMATORY CASCADE

On the basis of a growing body of evidence obtained from humans and animal and tissue experimentation, the final common pathway of intestinal injury appears to result from the activation of the inflammatory cascade.[39,106,107] This cascade involves a complex balance of proinflammatory and antiinflammatory endogenous mediators, receptors, signaling pathways, second messengers, and a variety of downstream effects that ultimately results in end-organ damage in certain circumstances (Figure 117-1). Inflammation can be initiated by a variety of factors, most notably the exposure to the bacterial cell wall product, endotoxin. After endotoxin stimulation of the toll receptor family in animals, tissue, or cells, several mediators are rapidly produced including PAF, tumor necrosis factor, and interleukin (IL)-1.[108-112] With use of a neonatal mouse model of NEC that resembles the human condition after exposure to formula feeding and asphyxial stress, it was shown that the interaction of endotoxin with toll receptor TLR4 is a critical determinant in this disease model.[113] In intestine, subsequent events lead to chemotaxis, transmigration, and activation of leukocytes and to synthesis and release of many products from epithelial and inflammatory cells such as IL-6, IL-8, IL-10, IL-18, thromboxanes, leukotrienes, prostaglandins, nitric oxide, endothelin-1, and oxygen free radicals.[114-121] If counterregulatory responses are insufficient, pathologic changes to gut mucosa occur and may include accentuated apoptosis of epithelial cells, perturbation of tight junctional proteins and complexes, increased mucosal permeability, bacterial translocation, alterations of vascular tone and microcirculation, and additional neutrophil infiltration and accumulation. The process may then be perpetuated by the activation of the secondary inflammatory response, and the final common pathway will result in intestinal necrosis. Although these events remain localized in some cases, in others this activation results in the systemic inflammatory response syndrome, in which patients have capillary leak, hypotension, metabolic acidosis, thrombocytopenia, renal failure, respiratory failure, and, often, death.[122]

Although endotoxin is a well-characterized activator of inflammation, additional factors may play a role in stimulating the NEC cascade in premature infants. Asphyxia and ischemia-reperfusion activate the early mediators of inflammation in many tissues including intestine. Neonatal animal studies have shown that the stress of formula feeding accompanied by hypoxia stimulates phospholipase A_2 gene expression, intestinal PAF production, apoptosis, and the inflammatory response with resulting NEC.[107,123] Therefore many of the purported risk factors for NEC may activate the inflammatory response that results in the final common pathway described earlier.

The evidence suggests that the premature neonate may have an abnormal balance between proinflammatory and antiinflammatory mediator production, thereby increasing the neonate's predisposition for diseases such as NEC. PAF is a potent phospholipid inflammatory mediator that is associated with NEC in several experimental models and human analyses.[124-128] PAF infusion causes intestinal necrosis in animals, and PAF receptor antagonists prevent injury after hypoxia, endotoxin challenge, tumor necrosis factor infusion, and ischemia-reperfusion.[129-131] It has been shown that neonates are markedly deficient in their ability to degrade PAF because of decreased activity of the PAF-specific enzyme PAF acetylhydrolase.[29] PAF acetylhydrolase is present in breast milk but absent in commercial formula, and this may in part explain the beneficial effects of breast milk feeding. IL-10 is an antiinflammatory cytokine thought to be important in reducing intestinal inflammation and possibly NEC in animals and

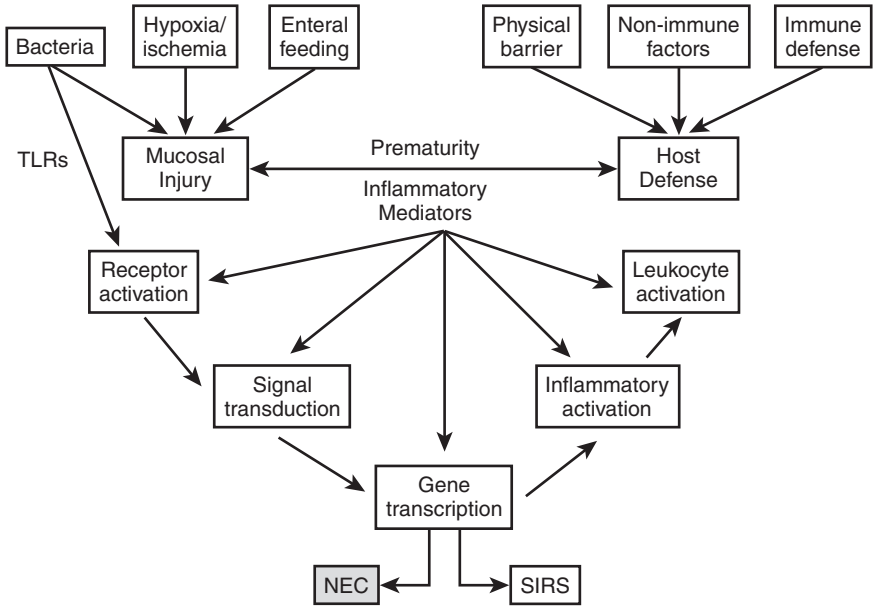

Figure 117-1 Hypothetical events leading to the final common pathway of inflammatory mediator activation and NEC in premature infants. Note the important balance between host defense and mucosal injury in the pathway. *SIRS,* Systemic inflammatory response syndrome.

humans.[132,133] In neonatal rats, maternal milk feedings increased IL-10 and reduced the incidence of NEC, whereas in human milk specimens, significant percentages of NEC patient-pairs were deficient in this important cytokine. Studies have compared proinflammatory response to endotoxin and/or IL-1 in different cell lines and have found that IL-8 response is significantly higher in fetal intestinal epithelium compared with mature, adult intestine.[30] Additional studies have shown persistent activation of a key proinflammatory transcriptional regulator, nuclear factor kappa beta (NF-κB), in premature or neonatal intestine compared with more mature samples.[134] These findings suggest that the balance of the inflammatory response in the neonate may be weighted toward the proinflammatory side and more likely to result in the pathologic outcome of NEC.

In conclusion, NEC is a multifactorial disease without one clear and precise cause. The well-described epidemiologic risk factors including bacterial colonization, intestinal ischemia or hypoxia, and formula feeding stimulate a final common pathway that results in intestinal injury in a subset of premature infants. Premature infants differ from term infants and older patients in multiple ways, including the complex system of intestinal host defense, intestinal motility, bacterial colonization patterns, autoregulation of splanchnic blood flow, and the regulation of the inflammatory cascade. Because each case of NEC is different, and the importance of each of the complex factors may vary between cases, no single approach has been completely successful in preventing this disease, although the prospect for probiotic supplementation in this context is compelling. Although preventing prematurity would be the most successful approach to prevent NEC, several strategies have been tested in humans and animals with intriguing results (Table 117-1). Carefully controlled trials in high-risk premature infants will be needed to significantly reduce this morbidity and mortality that currently plagues neonatal intensive care units worldwide.

SECTION XV

Liver and Bilirubin Metabolism

118 Organogenesis and Histologic Development of the Liver

Steven Lobritto

The liver is the largest internal organ of the body, comprising approximately 6% to 7% of the total weight of an adult. The organ is unique in that it receives both a venous blood supply, predominantly from the intestines, pancreas, and spleen, and an arterial blood supply from the aorta. Together, this blood supply delivers nutrients, hormones, toxins, and oxygen to the liver tissues.[1] The hepatocytes, organized into linear plates, are exposed to these blood elements on their basal surface, which abuts a plexus of sinusoidal capillaries.[2-4] The hepatocytes are the predominant cellular element of the liver but are supported by interactions with other cellular components, including cholangiocytes, stellate cells, Kupffer cells, Ito cells, endothelial cells, and hematopoietic elements. An intercellular matrix that provides both structural integrity and pathways for intracellular communications supports these cellular elements.[5-7]

The hepatocytes perform various secretory and metabolic functions, including but not limited to detoxification of drugs and toxins, synthesis of key serum proteins (e.g., albumin, clotting factors, complement, apolipoproteins), synthesis and metabolism of dietary lipids, glucose homeostasis, and bile production.[8-12] Distortion of the normal architecture of the liver by either chronic disease states or congenital malformations can have a significant impact on the ability of the liver to perform these complex functions. As expected, the developmental steps necessary to ensure proper hepatic organization and function involve multiple and complex communications between the cellular and matrix components of the organ during organogenesis of the liver.[13-16] Investigators continue to discover new intracellular signals (specific growth factors and transcription factors) that appear to combine to initiate and propagate the transformation of fetal endodermal tissue into differentiated hepatic cellular elements and a functioning organ. This chapter summarizes some of the experiments by means of molecular genetics, molecular biology techniques, and tissue explant culture techniques that have shed light on our understanding of early steps in hepatic development.

EARLY EMBRYOGENESIS: AN OVERVIEW

Recent important discoveries have helped clarify some of the steps involved in the early development of the liver and the specific messengers and tissue signals that orchestrate this process, as well as the maturation of the hepatocytes.[13,17] Specific signaling molecules, hormones, growth factors, transcriptional factors, and intracellular matrix interactions have been shown to contribute to the induction of pluripotential primitive tissues into cells committed to a hepatic fate. In addition, these molecules are critical to the maturation of the cells into specialized epithelium, and they contribute to the proper organization of these cells into the correct configuration comprising the fully functioning organ. Much of this work has been derived from observations in genetically altered mice and tissue culture systems.

During the third to fourth week of gestation, a bud of proliferating endodermal tissue is observed originating from the ventral foregut constituting the hepatic diverticulum. The primitive cells of this bud, referred to as hepatoblasts, appear to be bipotential, with the ability to differentiate into either mature hepatocytes or cholangiocytes.[18] These cells are in contact with embryonic cardiac mesoderm, and they abut the septum transversum mesenchyme.[13,17] The hepatoblasts migrate as cords into the septum transversum, closely associated with primitive sinusoidal endothelial cells. As the process progresses, the sinusoidal structure is established, initially lacking the fenestrations observed at later stages of maturity. The undifferentiated hepatoblasts have few organelles at this stage, with a high nuclear-to-cytoplasmic ratio; scant, rough endoplasmic reticulum; and few lysosomes.[11] Intercellular communication appears to be mediated via cell surface adhesions with other hepatoblasts and surrounding mesenchymal cells. The anterior vitelline vessels of the yolk sac are the initial source of sinusoidal blood.[19] Early synthesis and secretion of alpha fetoprotein, transferrin, and α_1-antitrypsin can be observed from these immature prehepatic cells.[20]

LATE EMBRYOGENESIS: AN OVERVIEW

Early in the second month of gestation, the hepatoblasts gradually begin to differentiate into mature hepatocytes, with the necessary intercellular components (rough endoplasmic reticulum and Golgi apparatus) to conduct their multiple synthetic and metabolic functions.[11] These cells also acquire polarity with the increased production of specific membrane-associated proteins and transmembrane transporters.[21] This process creates both a basolateral hepatocyte domain with clusters of these membrane-associated receptors and transporters for protein secretion, in association with sinusoidal vessels, and an apical hepatocyte domain constituting the bile canaliculi, with transporters related to bile secretion.[22] Both these surfaces develop a microvillous architecture, presumably to optimize surface area for extracellular contact. Other hepatoblasts are thought to develop into cholangiocytes that organize into the hepatic biliary system.[23,24] The intrahepatic bile ducts are formed from periportal hepatoblasts constituting the ductal plate. Differentiation and maturation of the intrahepatic ducts occur via interactions with periportal connective tissue, glucocorticoid hormones, and basal laminar components.[18] Intrahepatic hematopoiesis increases at this stage and appears to progress with interactions between maturing hepatocytes and undifferentiated mesenchymal elements.[25-27]

SPECIFIC INTERACTIONS PROMOTING HEPATOGENESIS

The initial induction of the ventral foregut to commit to a hepatic fate has been shown in embryo tissue transplant studies in the chick to be a function of interactions of this endodermal

TABLE 118-1

Liver Cell Derivations

Cell type	Tissue of origin

Endothelial cells	Septum transversum mesenchyme, angioblast
Biliary epithelial cells	Foregut endoderm, bipotential hepatoblast
Hematopoietic cells	Septum transversum mesenchyme
Kupffer cells	Yolk sac and bone marrow
Ito cells	Septum transversum mesenchyme

region with cardiac mesoderm[28] (Table 118-1). The growth factors found to mediate this process produced by cardiac mesoderm are fibroblast growth factors (FGF)–1 and –2. Further studies with purified FGFs and FGF inhibitors confirmed this interaction.[29] The specificity of FGF for this region appears to be related to the fact that FGF migration is limited by high-affinity interactions with extracellular matrix.[30,31] In fact, without this induction stimulus, the fate of the ventral foregut that normally gives rise to the hepatic diverticulum will default to a pancreatic fate.[32] Specifically, FGF stimulation of the ventral foregut endoderm inhibits pancreatic genes and induces liver genes in this bipotential precursor cell population.

The induction stimulus provided by FGF is not sufficient to stimulate hepatocyte differentiation. Hepatocyte differentiation appears to be a function of a second induction stimulus from another mesoderm-derived tissue, the septum transversum mesenchyme. The signal proteins for this interaction appear to be bone morphogenetic proteins (BMP).[33] Specifically, BMP-2, BMP-4, and BMP-7 are produced by the septum transversum mesenchyme cells. Further studies with a BMP signal inhibitor, Noggin, demonstrated that BMP, as well as FGF, was needed to achieve hepatoblast induction from ventral gut endoderm.[33] The stimulatory effects of FGFs are focused on the prehepatic endodermal tissue by a network of transcription factors expressed in embryonic gut tissue. One such molecule is hepatocyte nuclear factor (HNF) 3B.[34] These transcription factors appear to be important mediators of hepatocyte differentiation; they bind to specific hepatic gene enhancer regions, promoting gene expression and cellular differentiation.[35]

The importance of the interaction between the septum transversum mesenchyme and the developing prehepatic endoderm cannot be overemphasized. The septum transversum mesenchyme is the source of BMP signaling, leading to induction of hepatoblast differentiation and propagation of the hepatocyte maturation process.[36] Extracellular matrix components of the septum transversum mesenchyme aid in the regulation of differentiation by binding and concentrating signaling molecules.[37,38] In addition, extracellular matrix components can mediate intracellular communication directly through interactions with integrins, focal adhesion kinase, and other signaling molecules.[7,39] Hepatocyte growth factor (HGF) is a potent hepatocyte proliferation stimulant that affects cell migration, as well as differentiation.[40,41] These are but a few of the recognized components of the septum transversum mesenchyme and its extracellular matrix that are part of an integrated and diverse signaling process ensuring integrity to the hepatocyte maturation process and the overall hepatic structural organization.[42]

HEPATIC VASCULAR ANATOMY

During fetal development, highly oxygenated blood is delivered to the liver through the falciform ligament from the placenta via the umbilical vein.[1,43,44] The blood supply to the right lobe is derived from the right branch of the portal vein. The left branch of the portal vein connects via the portal sinus to the umbilical vein. The blood supply to the left lobe of the liver is derived from direct branches off the umbilical vein. This difference in blood oxygen saturation gives preferential dominance to the left lobe in utero. The umbilical vein continues past these branch points as the ductus venosus, delivering well-oxygenated blood to the inferior vena cava, which is directed across the patent foramen ovale to the left side of the heart.[19,43,45] At birth, the ductus venosus and umbilical veins obliterate, and the normal adult hepatic vascular supply is established.

INTRAHEPATIC VASCULAR DEVELOPMENT

In the adult, the portal vein enters the liver and branches into smaller and smaller vessels that travel within the portal tracts, along with branches of the hepatic artery and the interlobular bile ducts. The portal veins terminate in the sinusoids of the liver that are characterized by fenestrated endothelial epithelium. Sinusoids are separated by single cell–thick sheets of hepatocytes, referred to as the hepatic plates. Therefore the hepatocytes are directly exposed to portal blood, permitting transfer of macromolecules. The sinusoidal blood empties into the central branches of the hepatic veins, which terminate into the left, right, and middle hepatic veins and return blood to the inferior vena cava and back to the heart. This important anatomic arrangement is critical for proper gland function and is under the control of a number of factors during hepatic development.[1,46]

Angioblasts, or primitive precursors to functional endothelial cells, have been found in an intermediate position between the prehepatic endoderm and the surrounding septum transversum mesenchyme[13] (see Table 118-1). These endothelial cell precursors intermingle with hepatoblasts as the endoderm organizes into the hepatic bud. The development of this cell population is under the influence of vascular endothelial growth factor 2.[47,48] Observations in transgenic mice and explant systems of liver bud tissue suggest that angioblasts stimulate development of the hepatic bud in endodermal tissues before the local blood vessels are formed.[49] The origin of the angioblast cells remains unknown. The current thinking is that vessel anatomy does not follow a rigid predetermined pattern, but rather vasculogenesis appears to be guided by local needs and flow dynamics. The vascular endothelium may well be equally important in providing signaling to the surrounding tissue, affecting the differentiation of organ cell precursors and the ultimate structural integrity of the organ.[50,51]

BILIARY DUCT DEVELOPMENT

In the adult liver, mature hepatocytes secrete bile into the canaliculi, which are small channels along the apical surface created by clusters of adjacent hepatocytes. These channels coalesce into a network of intrahepatic bile ducts and eventually into the main hepatic ducts lined by biliary epithelial cells or cholangiocytes. Bile is exported from the liver and stored and concentrated in the gallbladder for excretion during a meal.

The origin of biliary cells appears to be bipotential hepatoblasts originating at the hepatic bud[18] (see Table 118-1). Under the influence of the transcription factor HNF-6 (and its effect on HNF-1B) these cells undergo differentiation and proliferation.[52] These subsets of hepatoblasts strongly express biliary-specific cytokeratins.[24] The biliary precursor cells form the ductal plate that is characterized as a continuous, single-layered ring around the portal mesenchyme, which proliferates into a bilayer. Focal dilatations of the ductal plate along the bilayer give rise to the bile ducts. The newly formed ducts are incorporated into the hepatic mesenchyme. The whole process is moderated by

biliary precursor cell interactions with neighboring cells and with matrix proteins, including laminin, fibronectin, and collagen types I and IV.[37,38,53,54] The process of bile duct formation also appears to be influenced by interactions with the nearby developing blood vessels, as evidenced by abnormalities in bile duct morphology observed with genetic deficiencies in the vascular Notch pathways.[55]

HEPATIC HEMATOPOIESIS

The yolk sac contributes significantly to early fetal hematopoiesis.[25] The yolk sac delivers blood from the anterior vitelline vessels to the developing sinusoids of the liver. Around the 6th week of gestation, the earliest hematopoietic elements appear to differentiate from the undifferentiated mesenchymal cells derived from the septum transversum[56] (see Table 118-1). These cells appear to interact with the developing hepatocytes and may derive trophic signals stimulating growth and development.[26] This stimulatory effect appears to change with time, diminishing as the hepatocyte matures.[57] Hematopoietic elements produced in the liver migrate through regulated temporary migration pores (not between the intact endothelial cell lining of the sinusoids), a process termed diapedesis.[2,3] Interesting new evidence suggests that hepatocytes themselves may be derived from multipotential bone marrow cells, as well as from prehepatic endoderm.[58,59] As the hepatocyte matures and differentiates into the cells responsible for serum protein production, there appears to be a diminished role for intrahepatic hematopoiesis, which is then assumed by the marrow.

SINUSOIDAL CELLS: KUPFFER AND ITO CELLS

Kupffer cells are manifested during the second month of gestation. These specialized cells residing on sinusoidal surfaces of the endothelium have macrophage-like activity.[3] These cells appear to originate from both the embryonic yolk sac and from the bone marrow at later stages of development[60] (see Table 118-1). The position of these cells permits regulation of migration across the endothelium of the sinusoid.

Ito cells are specialized cells that reside in the perisinusoidal space of Disse between the endothelial cells and the developing hepatocytes of the hepatic plate.[61] These cells appear to originate from the undifferentiated mesenchyme of the septum transversum[4] (see Table 118-1). These cells store fat and vitamin A. Along with endothelial cells, these cells are involved with the production and secretion of basement membrane collagen and may therefore contribute to fibrosis in chronic liver injury.[61,62]

ACINAR ORGANIZATION

The functional unit of the liver is known as the acinus. This functional unit is defined by the hepatic blood flow from the portal vein branches within adjacent portal tracts, through the hepatic sinusoids separated by hepatocyte plates, terminating in the central branches of the hepatic veins. These basic units of function are recognized in the second and third months of gestation as the cell elements of the liver differentiate and as the matrix elements proliferate. In the mature liver, the hepatocytes within this functional unit perform different operations depending on their position within the acinus. The hepatocytes within the acinus have been divided into three zones. Zone 1 cells are closest to the portal tracts and therefore receive blood with the highest nutrient and oxygen content. These cells appear to be best suited to extract bile acids, perform gluconeogenesis, produce glycogen, synthesize and secrete protein, and metabolize lipids.[63-67] Zone 3 cells are located adjacent to the branches of the hepatic vein. Zone 3 hepatocytes appear to have a higher capacity to perform glycolysis; have higher cytochrome P-450 expression; and perform various metabolic reactions, including drug detoxification, glycosylation events, and ureagenesis.[10,68-70] Zone 2 cells are intermediate in position, and the hepatocytes in this zone appear to express activities similar to the cells of the other two zones depending on their relative proximity.

Investigations of the differences in the functions of the cells within these defined zones have led to two likely overlapping theories.[71] The first assumption is that differences in the oxygen and macromolecule content of the blood supply to these zones may influence the development and differentiation of hepatocytes. The second theory is that regional differences in cell signaling and matrix element interactions influence hepatocyte differentiation in local populations. Modulators of gene function and expression within the hepatocytes of a particular zone ultimately will define and refine their respective functions.[72] In addition, intercellular communications between adjacent hepatocyte populations will further affect hepatocyte differentiation and regional coordination of function. The likely conclusion is that both of these influences are responsible for the observed differences and similarities in hepatocyte function within the acinus.

REGULATION OF FETAL LIVER GROWTH AND MATURATION

As cell differentiation proceeds, the fetal liver also undergoes growth and structural organization. The molecules stimulating these processes are poorly understood. The process seems to be under the influence of circulating hormones and various growth factors (Box 118-1). Specifically, growth hormone and its gestational homologue placental lactogen are thought to be important stimuli for hepatocellular hyperplasia.[73,74] Furthermore, insulin, cortisol, and thyroid hormone have been shown to alter protein production and growth factor receptor expression in the developing liver and may be important mediators of growth and maturation of the organ both in utero and post partum.[75-77] In part, the effect of these hormones is a function of their effect on the production and binding of secondary messenger molecules, the insulin-like growth factors.[73,75-80] Differential production and binding of these messengers may contribute to cell growth and replication, cell migration, and tissue organization and maturation.

Other molecules contributing to cell hyperplasia, migration, and tissue organization are HGF and epidermal growth factor (see Box 118-1). HGF has emerged as an important tissue-specific signaling molecule between epithelial and mesenchyme tissues. This molecule is a ligand for the c-*met* proto-oncogene product of receptor tyrosine kinase and originates from mesenchymal tissues.[81] As such, this paracrine molecule supports

organogenesis, mature organ regeneration, and neoplastic processes.[81,82] HGF and the expression of its receptor in liver and other tissues have been demonstrated in association with tissue injury, suggesting a focused tissue-specific regeneration response.[82] The diverse biologic functions of this multipotent polypeptide now lead investigators to consider it a key molecule for tissue organization, organogenesis, and organ repair.

Epidermal growth factor has been identified as a key molecule involved with liver regeneration and may play a role in embryogenesis and fetal growth, because receptors have been found in fetal tissues.[83,84] The liver appears to modulate serum levels of this molecule, providing efficient clearance and degradation of the internalized protein.[85] Also, extensive data indicate interactions between epidermal growth factor and other circulating hormones.[84] Growth hormone increases epidermal growth factor binding in the liver.[86] Thyroid and steroid hormones modulate both epidermal growth factor and its receptors in multiple tissues.[87] Epidermal growth factor stimulates hormone release from the pituitary, the placenta, and the adrenal gland but inhibits hormone production by the gonads and thyroid. The effect on fetal growth and development may be mediated by gene activation, or it may be a function of other protein interactions.[88] The significance of this molecule in hepatic growth and maturation has yet to be proved.

CONCLUSION

In summary, the development of the liver from primitive endoderm and mesoderm is a complicated yet orchestrated process that mandates continued intercellular and matrix signaling. Our current knowledge of the multitude of contributing messengers to this process is likely just the tip of the "organogenesis iceberg." The expanding knowledge base of the steps ensuring proper hepatocyte differentiation, growth, and organization will permit the application of learned techniques to promote regeneration and restoration of the damaged mature organ. In addition, by increasing the knowledge of the signaling pathways governing normal growth and development of the liver, we may expand our understanding and ability to manage the uncontrolled growth of hepatic malignancies. The key to the evolution of this process in the short term is our expanding technical expertise with tissue culture systems and transgenic animal models.

Bile Acid Metabolism During Development

Human milk contains a lot of fat (range, 20 to 90 g/L of milk), and infants derive almost 60% of their energy from fats. This energy-dense food fuels dramatic increases in body weight, but the hydrophobic nature of fats conflicts with the hydrophilic properties of digestive enzymes and transporter proteins. To solve this problem, the liver secretes bile acids, which act like detergents to facilitate fat digestion and absorption. Hence, bile acids are critically important for infant nutrition.

In this short chapter, we focus on bile acid metabolism during early development. In general, we will abide by the outline followed by earlier versions of this chapter, and initially and briefly describe bile acid structure and synthesis as well as enterohepatic circulation, which are generally similar between adults and neonates. We then describe bile acid metabolism unique to infants and the regulation of bile acid transport by the placenta, and we end with a brief description of disorders of bile acid metabolism that are initially detected in the young. We refer readers interested in the details of bile acid metabolism to numerous reviews (about 150 between 2002 and 2006) on this topic.

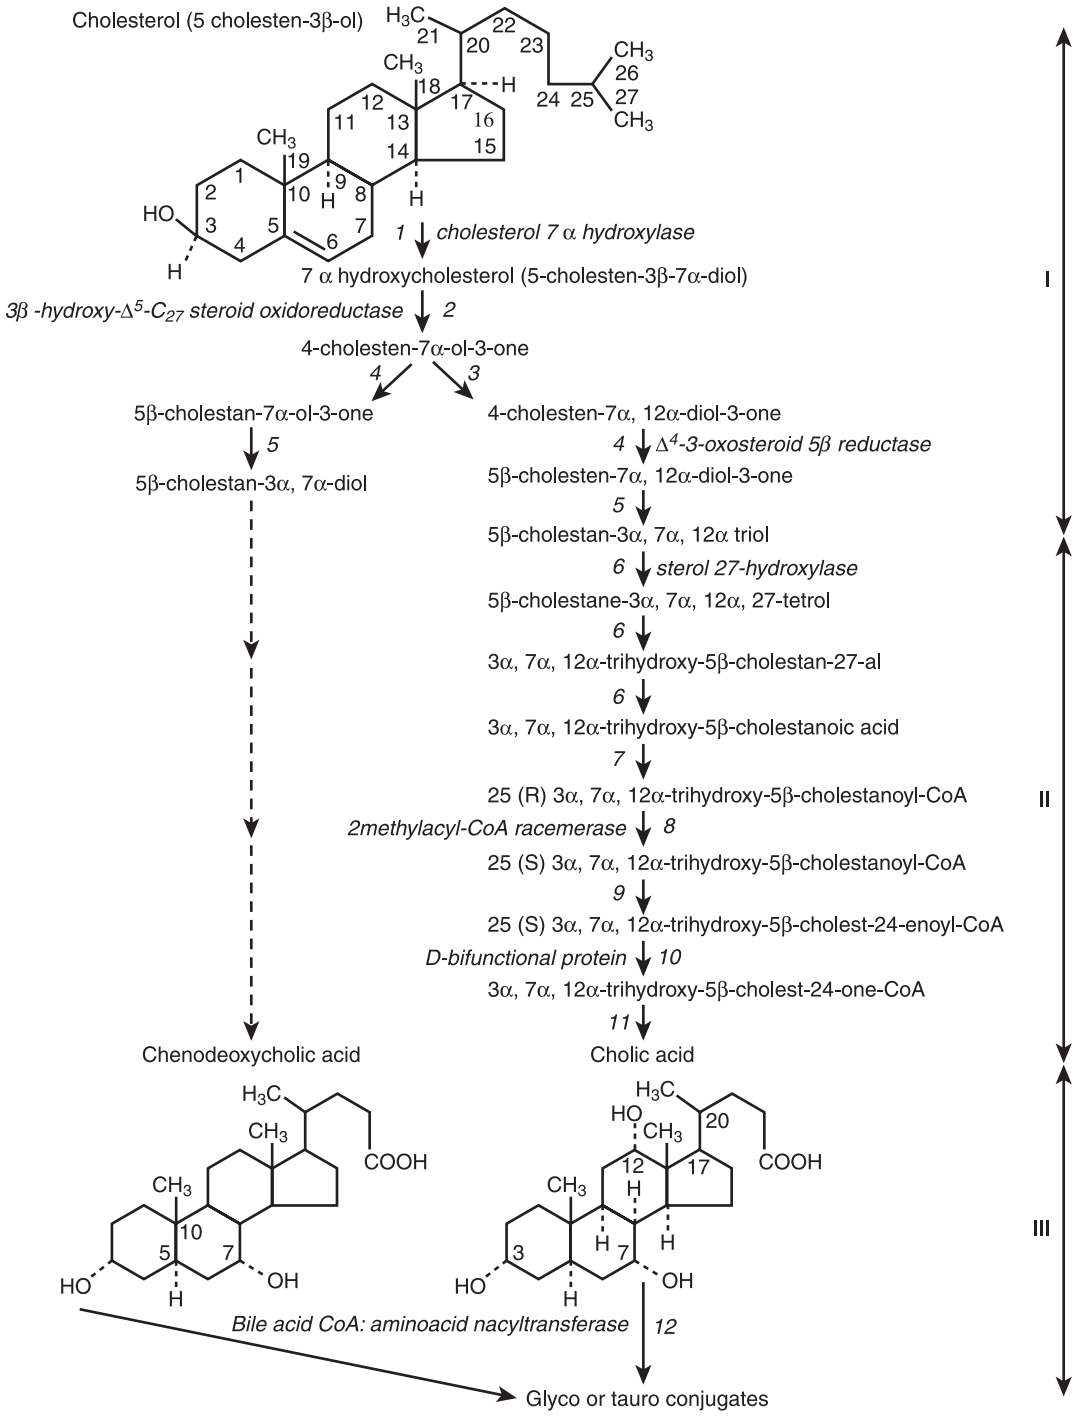

Figure 119-1 The classic pathway of bile acid synthesis. Numbers in italics by the *arrows* indicate different enzymes mediating the reaction. Enzymes for which defects have been identified to cause clinical problems are named and shown in italics. Roman numerals: *series I,* nuclear modification; *series II,* side-chain oxidation and shortening; *series III,* conjugation. In the absence of 12α-hydroxylation, chenodeoxycholic acid is formed by an alternative pathway (see text). *(Adapted from Vogh BP, Maren TH: Sodium, chloride, and bicarbonate movement from plasma to cerebrospinal fluid in cats,* Am J Physiol *228:673, 1975.)*

BILE ACID CHEMICAL STRUCTURE AND PROPERTIES

Bile acids are made up of a steroid nucleus with an aliphatic side chain consisting of 5 carbons and are very similar to the structure of cholesterol (Figure 119-1). However, the properties of bile acids and cholesterol differ markedly. Cholesterol is a flat, water-insoluble molecule, whereas the predominant human bile acids have a β configuration of the hydrogen atom at C5, giving them a kinked appearance and making them relatively more water-soluble. The number and orientation of the hydroxyl groups determine the capability of bile acids to form micelles and solubilize lipids. The α side of the bile acids is hydrophobic, and the β side is hydrophilic. When a micelle is formed, the β side forms a water-soluble exterior, and the α side forms a lipid-soluble interior.

Bile acids with a side chain containing 5 carbons are called cholanoic acids and comprise the primary human bile acids: cholic and chenodeoxycholic acids (see Figure 119-1, section III). Precursors of the primary bile acids are called cholestanoic acids and have 8 carbon side chains.

Cholic and chenodeoxycholic acids form conjugates by the formation of amides between the carboxyl group of the bile acid side chain with the amino group of glycine and taurine, to make glycocholic acid, taurocholic acid, glycochenodeoxycholic acid, and taurochenodeoxycholic acid in the liver. In proportionally smaller amounts, bile acids are also conjugated with glucoronate, sulfate, glucose, or *N*-acetylglucosamine. In humans, bile acids are primarily conjugated with glycine, but in early life, taurine conjugates predominate.[1] Conjugation increases the solubility of bile acids in aqueous solutions at the pH prevailing in the intestinal lumen. This decrease in hydrophobicity also minimizes potentially harmful bile acid interactions with plasma membranes and reduces the rate of passive absorption of bile acids in the more proximal intestinal regions, which have insignificant, if any, numbers of bile acid carriers. Reduced absorption in the proximal regions, in turn, leads to increased concentrations of bile acids in the lumen and contributes to luminal bile acids exceeding the critical micellar concentration, thus facilitating dietary fat digestion.

In the small intestinal lumen, small amounts of primary bile acids are converted into secondary bile acids by the action of the bacterial enzymes which remove hydroxyl groups. Most primary and secondary bile acids are reabsorbed through passive and active transport (see Enterohepatic Circulation) in the small intestine. A modest amount of bile acids enters the large intestine. Here, the remaining primary bile acids are mostly converted to secondary bile acids deoxycholic acid (from cholic acid), ursodeoxycholic acid, and lithocholic acid (from chenodeoxycholic acid) by colonic bacteria and are then reabsorbed passively.[2] Sulfation leads to formation of tertiary bile acids such as sulfolithocholic acid in the colon.

BILE ACID SYNTHESIS

In the liver, bile acids are synthesized from cholesterol through multiple enzymatic reactions (see Figure 119-1).[3,4] There are two basic changes that occur: the initial steps (see Figure 119-1, steps 1 to 5, series I) involve modification of the cyclopentanoperhydrophenanthrene ring or the nucleus, which is made up of the four closed rings; the second set of steps modify the 8 carbon side chain of the sterol linked to C17 (see Figure 119-1, steps 6 to 11, series II). Cholesterol, which is practically insoluble in water (solubility: 0.2 mg/100 mL water), is converted to cholic acid, which is more soluble in water (solubility: 28 mg/100 mL water), which by the process of conjugation (see Figure 119-1, step 12, series III) is converted to highly water-soluble bile salts (i.e., sodium taurocholate) (solubility: 100 mg/100 mL water). The enzymes involved in the conversion of cholesterol to bile acids are localized to different sites in the hepatocytes (i.e., endoplasmic reticulum, cytoplasm, mitochondria, and peroxisomes). The exact mechanism and sequence of the interorganelle movement of bile metabolites during bile acid synthesis have not yet been elucidated.

In the classical pathway, the first step in the modification of the sterol nucleus is the addition of an OH group on the α configuration at position C7 of cholesterol. This step is mediated by a microsomal P-450 enzyme expressed only in the liver, cholesterol 7α–hydroxylase (CYP7A1) (see Figure 119-1, step 1). In the alternate or oxysterol pathway, cholesterol is first hydroxylated either at carbon 24, 25, or 27 by the 24-, 25-, or 27-hydroxylase enzymes, respectively. These hydroxylated products are subsequently hydroxylated at C7 by oxysterol 7α-hydroxylase (CYP7B1). They then undergo side-chain oxidation and shortening similar to the classical pathway. The 24-hydroxylase enzyme is abundant in the brain and contributes little to overall bile acid synthesis but is important in turnover of cholesterol in the brain. 25-Hydroxylase messenger RNA (mRNA) is present in most tissues and is abundant in the retina and may have some role in bile acid synthesis. 27-Hydroxycholesterol is the most abundant oxysterol and is synthesized from cholesterol by sterol 27-hydroxylase. In mice, 25% of the bile acid pool comes from oxysterols, and 27-hydroxycholesterol is the major contributor.[5] In humans, the oxysterol pathway contributes to 5% to 10% of the bile acid pool.[6]

REGULATION OF BILE ACID SYNTHESIS

Classical Pathway

CYP7A1 is the rate-limiting enzyme in the synthesis of bile acids in the hepatocytes. Interruption of the enterohepatic circulation either by administration of bile acid binding resins,[7,8] fasting,[9] or surgical intervention[10] results in induction of this enzyme. Dietary cholesterol also induces CYP7A1 in the liver. Taurine feeding increases the CYP7A1 activity in rats fed cholesterol or bile acids.[8] Hence, reductions in luminal bile acid concentrations, increases in supply of its precursors, and increases in demand for bile acids apparently stimulate their synthesis. This adaptive mechanism is important in compensating for some pathologic conditions described below.

CYP7A1 is suppressed by bile acids and inflammatory cytokines. Inhibition appears to be mediated through hepatocyte nuclear factor (HNF)-3, -4, and -6 transcription factors essential for morphologic or functional expression of liver-specific genes. Interleukin-1β (IL-1β), chenodeoxycholic acid (through the JNK/c-jun pathway), and HNF-4 inhibit bile acid synthesis by inhibiting *CYP7A1* gene transcription in human primary hepatocytes and HepG2 cells.[11] A reduction in HNF-6 mRNA and protein expression in mouse liver after bile duct ligation is correlated with a reduction in hepatic CYP7A1 mRNA expression. Because bile duct ligation prevents bile acids from entering the intestinal lumen, this finding appears to contradict the previous finding that bile acid resins stimulate CYP7A1 synthesis. Bile duct ligation, however, markedly increases hepatic and plasma bile acid concentrations; therefore the signal regulating CYP7A1 may be the extracellular fluids bathing the hepatocytes. In fact, increases in HNF-6 levels in mice with bile duct ligation have been shown to increase CYP7A1 mRNA levels.[12]

Small heterodimer partner (SHP) is a nuclear receptor that modulates the activities of other nuclear receptors. The human SHP promoter is activated by sterol regulatory element binding protein-1 (SREBP-1), which regulates the expression of various genes involved in cholesterol and fatty acid synthesis. Overexpression of SREBP-1 activates the human SHP but not mouse SHP.[13] SHP physically interacts with HNF-3 and decreases CYP7A1 expression.[14]

Some of the nuclear receptors originally termed *orphan receptors* (i.e., farnesoid X receptor [FXR], pregnane X receptor [PXR], and liver X receptor [LXR]) play a major role in cholesterol and bile acid metabolism. These receptors are activated by a large number of physiologic ligands. Ligands for FXR that are relevant to this chapter are primary bile acids,[15-17] for PXR are secondary bile acids,[18,19] and for LXR are oxysterols.[20,21] Through coordinated regulation of transcriptional programs, these nuclear receptors regulate key aspects of cellular and whole-body sterol homeostasis, including cholesterol absorption, lipoprotein synthesis and remodeling, lipoprotein uptake by peripheral tissues, reverse cholesterol transport, and bile acid synthesis and absorption.[22]

FXR, when bound by primary bile acids in hepatocytes, suppresses bile acid synthesis by inhibiting CYP7A1, limits bile salt

uptake by repressing the sodium-taurocholate cotransporting polypeptide (*NTCP*) gene, and stimulates bile acid export from the cells, thus protecting the hepatocytes from bile acid toxicity.[16,23] PXR and vitamin D receptor (VDR) induce catabolism of secondary bile acids by stimulating CYP3A, a cytochrome P-450 enzyme that detoxifies lithocholic acid in the liver and intestine.[19,24,25] Hence, excess bile acids reduce bile acid synthesis and increase bile acid catabolism through FXR-, PXR-, and VDR-mediated pathways.

Conversion of cholesterol to bile acids in the liver is positively regulated by LXR.[26] Excessive dietary cholesterol leads to increased oxysterol formation. Oxysterols bind to LXR and induce transcription and synthesis of CYP7A1, thus increasing the removal of cholesterol by conversion to bile acids.[27] Hence, LXR and FXR have opposite effects on CYP7A1 transcription in the liver.

Hormones have been shown to modulate acute changes in bile acid metabolism. Addition of triidothyronine to human primary hepatocytes resulted in a decrease in bile acid production in parallel with decreases in mRNA expression of CYP7A1 and sterol 12α-hydroxylase (CYP8B1) (see Figure 119-1, step 3).[28] In mice, however, thyroid hormone induces bile acid synthesis in vivo, and in fact two thyroid hormone receptor binding sites on the *CYP7A1* gene have recently been reported.[29] Both sites are required for full induction of the CYP7A1 promoter by thyroid hormone. Addition of physiologic concentrations of insulin to human hepatocytes rapidly leads to stimulation of the *CYP7A1* gene; however, prolonged insulin treatment induces SREBP-1c, which inhibits human *CYP7A1* gene transcription.[11] Glucagon and cyclic adenosine monophosphate (cAMP) inhibit human *CYP7A1* expression by phosphorylation of HNF-4α.[9] Hence, glucagons, cAMP, chenodeoxycholic acid, and interleukins inhibit *CYP7A1* and may share the same HNF-4α–mediated inhibitory mechanism.

Alternative Pathway

The alternative, like the classical, pathway is also regulated by bile acids and bile salt binding resins. Oral administration of cholic acid, chenodeoxycholic acid, and deoxycholic acid in mice significantly down-regulated CYP7B1 (oxysterol 7α-hydroxylase), whereas administration of cholestyramine, which decreases luminal bile acid concentrations, up-regulated CYP7B1.[30] In rat primary hepatocytes, taurocholic acid decreased CYP7B1 activity.[31]

Bile acids repress the transcription of sterol 27-hydroxylase (CYP27 in the alternate pathway) in rat primary hepatocytes by decreasing HNF-1α binding to the CYP27 promoter.[32] Likewise, cytokines also modulate the alternative pathway because IL-1 and tumor necrosis factor decrease sterol 27-hydroxylase mRNA levels in human hepatocyte cell lines (HepG2).[33] Therefore, like in the classical pathway, reductions in luminal bile acid concentrations up-regulate enzymes in the alternative pathway, whereas increases in luminal bile acids down-regulate the alternative pathway.

These two pathways can interact. Humans with mutations of *CYP7A1*, who therefore have their classical pathway compromised, show evidence of up-regulation of the alternative bile acid pathway.[6] However, CYP27 was not regulated by cholesterol or cholestyramine feeding in CYP7A1 knockout mice.[5]

ENTEROHEPATIC CIRCULATION

After synthesis and conjugation with glycine and taurine, bile acids are secreted into bile and then stored in the gallbladder, where they become increasingly concentrated by the active transport of sodium and chloride followed by the passive resorption of water out of the gallbladder lumen. The gallbladder evacuates its contents in response to a meal by means of cholecystokinin, and more than 70% of the stored bile is expelled into the proximal small intestine.[34] In adults, the amount of bile acids entering the intestine is 4 to 6 g per meal (2 g/hour) or 12 to 18 g per day.[35] The average amount of bile acids synthesized by the liver is only 0.2 to 0.5 g per day, and the remainder is obtained from the enterohepatic recycling of bile acids (95% of bile acid pool). In the small intestinal lumen, bile acids reach critical concentrations to form mixed micelles and act as detergents in emulsifying dietary fats, facilitating absorption of dietary fats and of lipid-soluble vitamins.

About 90% of bile acids entering the intestinal lumen are absorbed in the distal third of the ileum. Intestinal absorption is a major step in the enterohepatic circulation of bile acids (Figure 119-2). To accomplish their enterohepatic circulation, bile acids cross four enterohepatic membrane barriers: the sinusoidal (basolateral) and canalicular (apical) membranes in the hepatocytes and the apical (luminal) and basolateral membranes in the enterocytes (Figure 119-3). The large number of membrane transporters involved in this process has been reviewed.[36,37] Bile acids absorbed from the intestines circulate in blood bound to albumin and to high-density lipoproteins. Upon return to the liver through the portal circulation, bile acids are reabsorbed, resecreted into the gallbladder, and then reenter the intestinal lumen. This completes the enterohepatic circulation of bile acids, which cycle 6 to 10 times per day depending mainly on the fat content of the meals.[38] A small fraction of the total bile acids enters the systemic circulation, 5 μmol/L, compared with the adult human portal venous plasma concentration of 20 to 50 μmol/L.[35]

The efficiency of enterohepatic circulation is very high, such that about 95% of circulating bile acids are conserved or recycled, and only 5% of the bile acid pool is lost. This amount is lost through fecal excretion but is replaced by the de novo synthesis of equivalent amounts of bile acids in the liver, keeping the size of the bile acid pool relatively constant.[39]

Hepatic Bile Acid Transport:

Basolateral

Along the sinusoidal (basolateral) membrane of the periportal hepatocytes, bile acids are extracted from the portal venous blood either by a sodium-dependent or a sodium-independent mechanism (see Figure 119-3). Sodium-dependent uptake of taurine- and glycine-conjugated bile acids is mediated by the sodium taurocholate cotransporting polypeptide NTCP (*SLC10A1*).[40] Up to 90% of conjugated bile acids are extracted at first pass by NTCP, irrespective of systemic bile acid concentrations.[41,42] NTCPs mediate the electrogenic, unidirectional, sodium-coupled uptake of taurocholate and other bile acids with the same stoichiometry (i.e., sodium–bile acid ratio of 2:1) and similar K_m values (taurocholate K_m ~ 6 μM, taurochenodeoxycholic acid K_m ~ 2 μM).[40,43] NTCP belongs to the same family as the apical sodium-dependent bile acid transporter in the ileum, ASBT (*SLC10A2*). However, NTCP transcription regulation or control, which is different from that of ASBT, is through a farnesoid X receptor and bile acid receptor (FXR/BAR)-dependent manner.[44] The *NTCP* gene is located on chromosome 14 in humans.[40]

Several members of the organic anion transporting polypeptide (OATP) family of anion exchangers, mainly OATP-A (*SLC21A3*), OATP-B (*SLC21A9*), and OATP-C (*SLC21A6*), and, to a lesser extent, OATP8 (*SLC21A8*), mediate the sodium-independent hepatic uptake of bile acids by facilitated exchange with intracellular anions.[38,45-47] The large OATP family has been reclassified, and the new names and symbols of these transporters are, respectively, OATP1A2 (*SLCO1A2*), OATP2B1

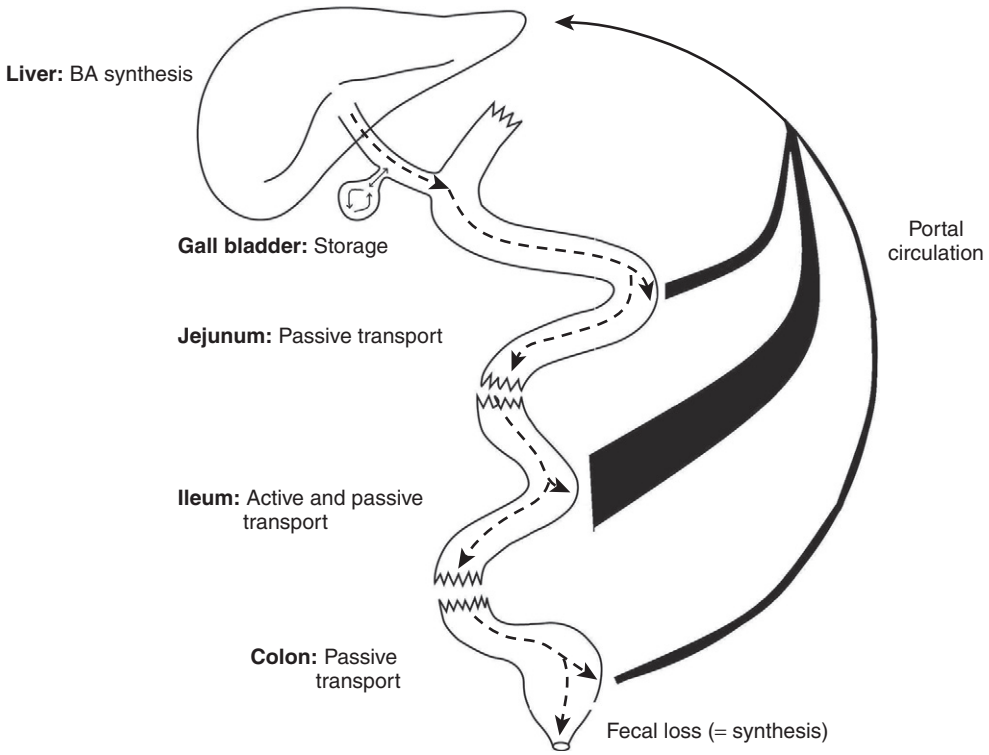

Figure 119-2 Enterohepatic circulation of bile acids. *Arrows* indicate the direction of bile acid movement, whereas *thickness of solid arrows* indicates relative amounts emanating from each intestinal region. Bile acids synthesized in the liver are stored in the gallbladder and then expelled into the gastrointestinal tract *(dashed arrows),* where they emulsify dietary fats; they are then reabsorbed into the portal circulation.

(*SLCO2B1*), OATP1B1 (*SLCO1B1*), and OATP1B3 (*SLCO1B3*).[48] Rat liver OATPs transport conjugated and unconjugated bile acids with K_m between 7 and 54 μM.[38] In general, the OATP transporters mediate anion exchange, coupling the cellular uptake of bile acids with the efflux mainly of bicarbonate[49] and of glutathione metabolites.[48] Cholestasis[50] and cholate feeding[51] down-regulate OATPs in mice.

Although the amount is modest, some bile acids also efflux out of the hepatocytes along the sinusoidal membrane into the portal blood through MRP3 (multidrug resistance protein 3) (*ABCC3*) and MRP4 (*ABCC4*),[37] especially during periods of cholestasis when these transporters are up-regulated[52,53] (see Figure 119-3). Patients with deficient canalicular MRP2 (*ABCC2*) expression have high levels of sinusoidal MRP3.[54] This efflux machinery therefore helps keep intracellular bile acid concentrations low when canalicular transport is compromised.

Cytosol

After entering the hepatocytes, unconjugated bile acids get reconjugated. The cytosolic hepatic bile acid binding proteins (HBABPs; see Figure 119-3) that have been identified in rats include 3α-hydroxysteroid dehydrogenase (3α-HSD), glutathione S-transferases, and liver–fatty acid binding protein (L-FABP).[55] These proteins act as cytosolic carriers for bile acids, moving them from the sinusoidal compartment to the canalicular side, to facilitate export by transporters.

Apical

Under physiologic conditions, conjugated bile acids are excreted into the bile across the canalicular (apical) membrane by the bile salt export pump, BSEP (*ABCB11*), also known as sister-to-P-glycoprotein, SPGP, a member of the *MDR* (multidrug resistance) gene family of adenosine triphosphate (ATP) binding cassette transporters (ABC).[56] BSEP plays a key role; the canalicular secretion of bile acids represents the rate-limiting step in the overall transport of bile acids from the portal blood into bile. While BSEP transports monovalent bile acids, which represent 98% of total bile acids, another transporter, the canalicular MRP2 (*ABCC2*) handles divalent, glucuronidated, and sulfated bile acids.[57] Meanwhile, the canalicular bile acid efflux pump breast cancer resistance protein BCRP (*ABCG2*), which functions as a xenobiotic transporter, transports sulfated bile acid conjugates into bile.[58] MRP2 is down-regulated in cholestasis.[59,60] MDR3 (*ABCB4*) mediates biliary excretion of phospholipids, which are second only to bile acids as the predominant solutes in bile. Bile then drains through bile ductules from the biliary canaliculi to the terminal branches of the biliary tree and bile ducts through the canals of Herring.

Role of Cholangiocytes

Cholangiocytes are epithelial cells lining the bile ducts, and they can modulate bile composition. Within the bile ducts, conjugated bile acids are reabsorbed at the cholangiocyte apical or luminal membrane by the apical sodium-dependent bile acid transporter ASBT (*SLC10A2*) and possibly by OATP-A (*SLC21A3,* now OATP1AC [*SLC01A2*]).[61-63] Unconjugated, relatively hydrophobic bile acids may be passively transported. The cholangiocytes secrete bile acids across the basolateral plasma membrane through MRP3 (*ABCC3*) along with a truncated form of ASBT, t-ASBT, that may mediate taurocholate efflux. This completes

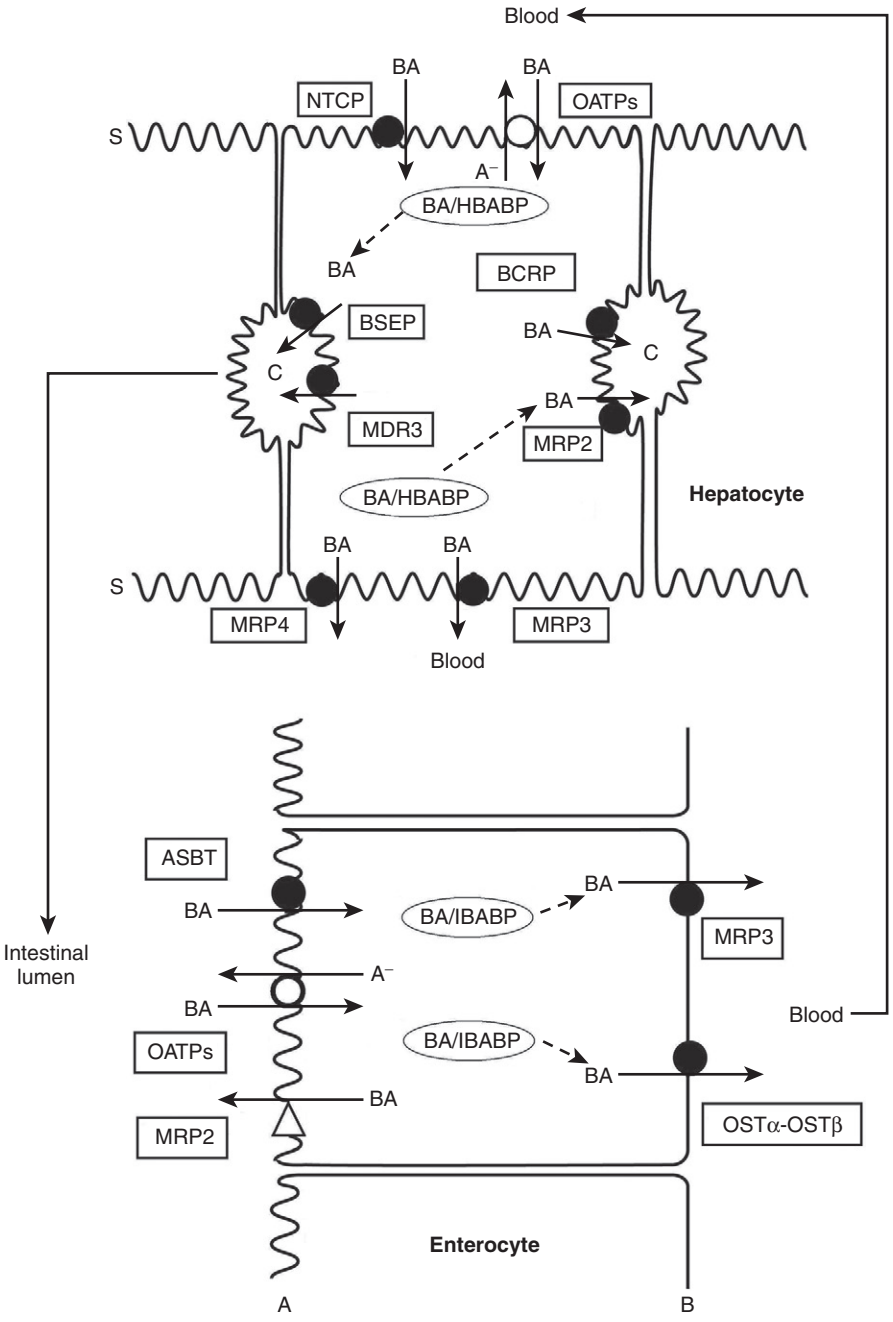

Figure 119-3 Bile acid (BA) transport across hepatic and intestinal membranes. *Arrows* denote direction of bile acid movement. *Hepatocyte:* At the basolateral or sinusoidal (*S*) membrane, the sodium-dependent bile acid transporter NTCP is the major uptake system for conjugated bile acids. OATPs (*SLC21*) mediate the sodium-independent bile acid uptake by facilitated exchange with intracellular anions A^-. A hepatic bile acid binding protein HBABP shuttles bile acids (BA/HBABP) across the cytosol of hepatocytes. At the canalicular membrane (*C*), the bile salt export pump BSEP (*ABCB11*) mediates excretion of monovalent bile acids, while the multidrug resistance–associated protein MRP2 (*ABCC2*) mediates divalent sulfated or glucuronidated bile acids. Other mediators of bile acid transport are the MDR3 (*ABCB4*) and BCRP (*ABCG2*). MRP3 (*ABCC3*) and MRP4 (*ABCC4*) mediate basolateral efflux for anionic conjugates and monovalent bile acids. *Enterocyte:* At the luminal or apical (*A*) membrane, the apical sodium-dependent bile salt transporter ASBT (*SLC10A2)* mediates bile acid uptake, while the anion exchanger OATPs mediate the sodium-independent bile acid transport. An ileal bile acid binding protein IBABP shuttles bile acids (BA/IBABP) from the apical to the basolateral membranes. Bile acid efflux across the apical membrane is carried out by MRP2. Other potential efflux transporters along the apical membrane include MDR1 and ABCG5/ABCG8 cholesterol transporter. At the basolateral (*B*) membrane, MRP3 and the heteromeric organic solute transporter α-β, OSTα-OSTβ, mediate bile acid transport into the portal circulation. (See text for references.)

the so-called cholehepatic shunt pathway[64,65] that allows the cycling of bile acids through the periductular capillary plexus back to the liver.

Intestinal Bile Acid Transport

Under physiologic conditions, more than 90% of bile acids secreted into bile are conjugated. While passing through the intestinal lumen, bile acids are absorbed along the entire gut, passively in the jejunum and colon, and both actively and passively in the distal ileum (see Figure 119-2).

Jejunal bile acid absorption is carried out through a sodium-independent, nonsaturable process, indicating uptake by passive diffusion or by low-affinity, passive transport systems.[66] Oatp3 (*Slc21a7* [now Oatp1as, *Slc01a5*]), the sodium-independent bile acid transporter cloned from rat ileum, is expressed in the brush border membrane of jejunocytes[67,68] and may mediate passive facilitated transport in this region. Ileal bile acid absorption is a combination of an active sodium-dependent, carrier-mediated process that predominates, and a sodium-independent transport. Active transport in the ileum results in a total transport rate that may be 5× faster in this region compared with that in the jejunum.[69]

Apical Absorption

The apical, sodium-dependent bile acid transporter, ASBT (*SLC10A2*), also known as ileal bile acid transporter, IBAT, is expressed in the distal ileum[70] and transports both conjugated and unconjugated bile acids with a higher affinity for chenodeoxycholic and deoxycholic acids than for taurocholate[71] (see Figure 119-3). This sodium-coupled transporter is critical for enterohepatic circulation and handles up to 90% of bile acids crossing the apical membrane of ileal enterocytes.[70-72] Like its close relative NTCP in the liver, it is electrogenic with a sodium–bile acid stoichiometry of 2:1.[73] In contrast to NTCP, the transcriptional regulation of *ASBT* gene expression is under control of HNF-1α and not regulated in an FXR/BAR-dependent manner.[44] ASBT expression has been shown to be up-regulated by glucocorticoids.[74-77] Thyroid hormone, although essential in regulating ASBT appearance during early rat development,[69] did not up-regulate its expression in weaning rats.[78] Bile acid feeding down-regulates total ileal bile acid transport.[79]

The sodium-independent transporters OATPs (particularly Oatp3, *Slc21a7* [now Oatp1as, *Slc01a5*]) have been found to be expressed also in the ileocyte brush border membrane[47,67] and may mediate passive transport of bile acids. Unconjugated bile acids, which are relatively hydrophobic, can also readily diffuse through the intestinal mucosal membrane after their passage through the intestinal mucosal "unstirred" water layer overlying the enterocytes.[80]

MRP2, which in the liver mediates the canalicular excretion of divalent, sulfated, or glucuronidated bile acids as well as non–bile acid organic anions such as bilirubin glucuronides, is also localized in the apical membrane of ileocytes. Here, MRP2 may mediate the efflux of bile acids back into the intestinal lumen. MDR1 (*ABCB1*), a PXR-inducible xenobiotic efflux pump, and the cholesterol transporter ABCG5/ABCG8 are also expressed along the enterocyte apical membrane.[37]

Cytosolic Transport

Bile acids absorbed at the apical membrane are moved intracellularly across the enterocyte cytosol by an ileal bile acid binding protein, IBABP, also known as ileal lipid binding protein (see Figure 119-3). Specific bile acids increase their own IBABP through the transcription factor FXR/BAR, up-regulating their expression.[16,81-83] FXR binds to a bile acid response element in the IBABP promoter. Reducing bile acid concentrations by cholestyramine decreases IBABP expression. The magnitude of changes in expression of IBABP and ASBT during development, including their biphasic regulation, parallel one another and like ASBT, IBABP is also up-regulated by dexamethasone, suggesting that both IBABP and ASBT might be under similar transcriptional control.[74,84-87]

Basolateral Transport

The anion exchange transport protein MRP3 (*ABCC3*) is localized in the basolateral membrane and may mediate bile acid efflux out of the enterocyte into the portal circulation (see Figure 119-3). However, human MRP3 has a lower affinity for conjugated bile acids than the rat MRP3, making it less likely to be the principal basolateral bile acid transporter in the ileocytes.[88-92] There is also an alternatively spliced form of ASBT, called t-ASBT, which is targeted to the basolateral membrane. t-ASBT expressed in the *Xenopus* oocytes mediates sodium-independent taurocholate efflux[65]; hence, in ileocytes, it may also mediate the exit of bile acids into the portal circulation. The recently described heteromeric organic solute transporter α-β, OSTα-OSTβ has been localized to the mouse ileal basolateral membrane and mediates sodium-independent basolateral bile acid transport.[93] α-β, OSTα-OSTβ may be responsible for bile acid efflux in ileum and other ASBT-expressing tissues. It remains to be resolved whether t-ASBT, MRP3, or α-β, OSTα-OSTβ is the principal basolateral bile acid efflux transporter.

Bile Acid Transport in the Colon

Absorption of bile acids (predominantly the secondary bile acids deoxycholic acid and lithocholic acids) in the colon is passive. The sodium-independent transporter OATP8 or OATP1B3 (*Slc21a7 or SLC01B3*) is expressed not only in the brush border membranes of jejunal and ileal enterocytes but also in the colonocytes.[94] Hence, they may mediate transport of bile acids in the colon. Here, the direction of net transport is likely dependent on concentration gradients across the membrane.

Alteration of Bile Acid Enterohepatic Circulation

Disruptions of the enterohepatic circulation lead to derangements in bile acid metabolism. Among the conditions that affect bile acid metabolism include conditions or disorders that involve cholestasis, intestinal bacterial overgrowth, and increased fecal loss of bile acids. Cholestasis and cholestatic disorders are discussed in another chapter. Disorders of bile acid synthesis, conjugation, and transport are discussed in a later section of this chapter.

Intestinal Bacterial Overgrowth Leads to Increased Bile Acid Deconjugation

Colonic bacteria entering through the ileocecal valve back into the small intestine deconjugate bile acids in the distal small intestine. Within the small intestine, bacterial overgrowth leads to bacterial modification of primary bile acids to form secondary bile acids (deoxycholic and lithocholic acid). Anaerobic bacteria deconjugate bile acids in the ileum, thereby reducing water solubility and compromising the ability of the bile acid to aid fat absorption because of decreased micelle formation. Secondary bile acids tend to be passively absorbed, and the efficiency of enterohepatic circulation may be reduced because of decreased ileal active transport. Increased levels of secondary bile acids in the small intestine thus lead to more bile acids in the colon and greater fecal excretion.

Luminal deconjugated bile acids like lithocholic acid may directly inhibit small intestinal absorption of carbohydrates and proteins because of their toxic effects on the intestinal

epithelium.[95] These unabsorbed sugars in turn ferment into organic acids, which reduce intraluminal pH in the colon, subsequently inducing osmotic diarrhea. Collectively, this bacterial backwash causing a combination of malabsorption and diarrhea symptoms is referred to as *bacterial overgrowth syndrome* (BOS). This syndrome also commonly occurs in patients with short bowel syndrome. High levels of deconjugated bile acids also can damage enterocytes and induce water secretion by the colonic mucosa, hence worsening the diarrhea. Lithocholate, which is hepatotoxic, has been detected in recirculated bile.[96]

Increased Fecal Bile Acid Loss in Short Gut Syndrome

Increased fecal loss of bile acids is secondary to decreased distal intestinal reabsorption of bile acids. Because the ileum absorbs more than 80% of intestinal bile acids, any pathology in this region leads to significant losses of bile acids in the feces and to decreases in total circulating bile acid pool. In an experimental rat model of necrotizing enterocolitis, unabsorbed bile acids induce ileal damage, causing further alteration in bile acid transport and increased intestinal-to-fecal loss.[97] Surgical removal of the terminal ileum secondary to neonatal necrotizing enterocolitis, among other neonatal pathologies that lead to short bowel syndrome, causes bile acid malabsorption and disrupts the enterohepatic circulation. The degree or severity and the location of ileal resection determine the adaptive behavior of the remaining segment. Minimal resection causes minimal perturbations in bile acid metabolism because rates of bile acid biosynthesis in the liver increase to compensate for potential losses (see earlier section on regulation of CYP7A1). Proximal ileal resection leads to diminished total bile acid pool and supraphysiologic ASBT expression in the remaining ileal segment with paradoxical reduction of cholesterol 7α-hydroxylase (see Figure 119-1, step 1), sterol 27-hydroxylase (see Figure 119-1, step 6), and hydroxymethylglutaryl coenzyme A reductase enzyme activities.[98] This finding seems contradictory to concepts of feedback regulation of bile acids on their synthetic enzymes. One possible explanation is the frequent cycling of bile acids secondary to the diminished bile acid pool, exposing the hepatocytes to a greater flux of bile acids.

Resection of the entire terminal ileum does not induce ASBT expression in the more proximal segments of the small intestine.[99] With no active and passive bile acid transport in the distal intestines, less bile acids will return to the liver for re-secretion, a situation that eventually leads to a diminished bile acid pool. The liver overcompensates by increasing rates of bile acid synthesis, up to 5 to 20 times more than normal, in an effort to maintain the bile acid pool size.[100] Hepatic compensation in ileal resection is usually insufficient to maintain adequate bile acid output.[35] This creates a vicious cycle of diminished bile acid concentration in the jejunum, which further leads to fat malabsorption and steatorrhea. The additional loss of water and electrolytes and other nutrients leads to a "short bowel syndrome" condition. Oral treatment with a conjugated bile acid preparation leads to improved fat absorption.[101] Resection may also induce bacterial overgrowth in the small intestine. Small intestinal bacterial overgrowth from the colonic flora (especially if the ileocecal valve is also removed) augments the loss of bile acids in the feces, as is observed in inflammatory bowel disorders,[102] the manifestations of which include diarrhea and steatorrhea.

BILE ACID METABOLISM DURING DEVELOPMENT

Composition

As early as in the 10th week of pregnancy, bile acids are synthesized from cholesterol and then conjugated with amino acids by the fetal liver (Figure 119-4).[103-105] The fetal gallbladder is functional and capable of storing bile. Bile secretion from hepatocytes into the gallbladder begins by the 12th week of gestation.[3] The bile acid composition in the fetus has unusual characteristics and differs from that in adults, as follows.

First, there is a high proportion of atypical C1-, C2-, C4-, and C6-hydroxylated bile acids (see cholesterol structure in Figure 119-1) in human fetal gallbladder bile, reflecting either synthesis of new bile from fetal liver[106] or an alternative pathway for converting maternally derived toxic bile acids, such as lithocholic acid, by hydroxylations at C1, C2, C4, and C6 positions, which render bile acids less toxic.[107] The presence of high proportions of hypocholic acid and several 1β-hydroxycholanoic acid isomers provides evidence for C1 and C6 hydroxylations by the fetal liver. Moreover, gas chromatographic and mass spectrometric analyses of bile by the 16th week of gestation show C4-hydroxylated bile acids (e.g. 3α,4β,7α-trihydroxy-5β-cholanoic and 3α,4β-dihydroxy-5β-cholanoic acids) accounting for 5% to 15% of total bile acids, suggesting that C4-hydroxylation is also an important pathway in bile acid metabolism during early fetal life.[1] These C1- and C6-hydroxylated bile acids have been detected in infants' meconium and in infants and adults with cholestasis. Bile acid patterns in human meconium show that in addition to cholic, chenodeoxycholic, deoxycholic, and lithocholic acids, several other atypical bile acids are also found, providing additional evidence for an alternative fetal bile acid synthesis pathway.[1,108]

Second, unlike human adult bile (which has a chenodeoxycholic acid–cholic acid ratio of 1:1.6), chenodeoxycholic acid concentration predominates over that of cholic acid in the fetal bile (chenodeoxycholic acid–cholic acid ratio of 1:0.85).[1] This is due in part to the preferential clearance by placental passive diffusion of bile acids formed from cholic acid by the rapid hydroxylation at the C1, C2, C4, and C6 positions[109] (see also later discussion of passive diffusion in the section Placental Bile Acid Transport). Amniotic fluid studies during preterm and full-term gestations not only confirm the predominance of chenodeoxycholic acid in the fetal bile but also show a reversal of the ratio in full-term newborns (chenodeoxycholic acid–cholic acid ratio of 1:2.5).[1,109] In fact, the adult ratio of 1:1.6 is achieved during the first year of life.[1]

Third, more than 80% of bile acids secreted in human fetal liver are conjugated to taurine, whereas glycine-conjugated and unconjugated bile acids account for only 5% to 10% of the total bile acid. In adults, glycine conjugation predominates (glycine-taurine ratio of 3.1:1),[110] whereas the level of unconjugated bile acids increases by approximately 50%. Based on duodenal bile acids measurements in infants, this adult pattern of predominantly glycine-conjugated bile acid is achieved by 2 to 7 months of life.[111]

The taurine conjugation of toxic bile acids (such as lithocholic acid conjugated to taurine, or taurolithocholic acid) in the fetus offers added fetal protection. Only trace amounts of bile acid sulfates are present in the fetal circulation, indicating that quantitatively, sulfation is not an important pathway in bile acid metabolism during development. The presence in the fetal circulation of bacteria-derived secondary bile acids, lithocholic acid in particular, implies maternal source and not synthesis by the fetus through the 3β-hydroxy-5-cholenoic acid pathway[1] because the fetal intestine is sterile and devoid of bacteria.

Pool Size

Figure 119-4 illustrates the timeline in the development of the bile acid pool. Serum bile acid levels progressively increase postnatally, peak by the second month, and then gradually decline to adult levels by 1 year of life.[112] The total bile acid pool increases progressively from the fetal to neonatal to older infants. It reaches

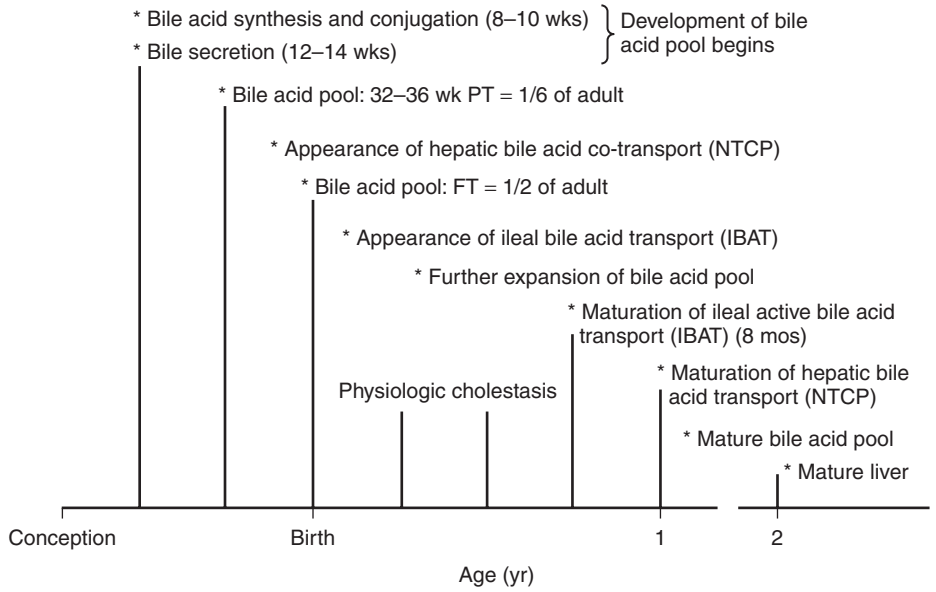

Figure 119-4 Timeline (not to scale) of developmental changes in the size of the human bile acid pool, compared with the adult (adult total bile acid pool size = 3 to 4 g). *FT,* Full-term; *PT,* preterm. See text for details.

adult levels of 3 to 4 g by 2 years of life, but when corrected for body surface area, pool size in grams per centimeter squared (g/cm^2) is similar between adults and infants 2 months of age.[113] The small size of the fetal bile acid pool is due to low synthesis rates and to placental clearance.[114] Between 32 and 36 weeks gestation, cholic acid levels in preterm infants and cholic acid synthesis rates are one third those of full-term infants.[115] In turn, the cholic acid levels in full-term infants are half those of adult levels[116] when normalized to body surface area. The clinical relevance of these phenomena is linked to the diminished intestinal luminal bile acid amount in the fetus, which is less than the critical micellar concentration (2 to 20 mM) that is effective in fat digestion.[1]

Development and Regulation

There are few studies on the regulation of bile acid synthesis and absorption in development. ^{14}C-labeled taurocholate tracer studies show during early development significant passive reabsorption of bile acids in the human jejunum and a poorly developed active taurocholate reabsorption in the ileum,[117] thereby affecting enterohepatic circulation. This immature nature of bile acid metabolism during early development affects the nutritional management of the preterm infant as it relates to malabsorption of fat and other nutrients. In rats, ASBT undergoes biphasic regulation; that is, it is expressed during the late fetal stage, down-regulated during the neonatal period, and up-regulated at weaning.[87] Lowered ASBT expression during certain developmental stages may be the mechanism underlying poor bile acid reabsorption.

Hormones also modulate bile acid metabolism in the neonate. Administration of glucocorticoids and phenobarbital allowed preterm cholic acid levels to approximate those of full-term infants.[115,118] Triiodothyronine (T_3) accelerated the maturation of bile acid metabolism in baboons,[119] primarily by altering the cholic acid–chenodeoxycholic acid ratio at the end of the preweaning period to near adult values. The combination of immaturity of ileal and hepatic bile acid transport systems, reduction in bile acid pool size, and increases in bile acid synthesis rates have been referred to as *physiologic cholestasis* or *hypercholanemia*[120] (see Figure 119-4).

FETAL LIVER-PLACENTA-MATERNAL LIVER PATHWAY

Although the fetal liver is capable of bile acid synthesis, it is incapable of bile acid elimination through the fetal hepatobiliary excretory pathway,[121] owing in part to underdeveloped intestinal function and the lack of necessity for digestion and absorption. Fetal bile acids have been detected in fetal gallbladder, but how they are secreted by the fetal hepatocytes is not fully known. If there is no significant excretion or loss, bile acids in the plasma should increase, and in fact, fetal bile acid concentrations in the plasma of rats and humans are higher than those of the mother.[122-124] If bile acids accumulate to high concentrations, these are potentially toxic to the fetus. Therefore the placenta and the maternal liver play key roles in bile acid elimination from the fetus.[125]

To be excreted, fetal bile acids have to cross five membranes through the fetal liver-placenta-maternal liver pathway (Figure 119-5): the basolateral membrane of the fetal hepatocytes, the fetal-facing (basolateral or basal) and maternal-facing (apical) trophoblastic membranes of the placenta, and the sinusoidal (basolateral) and canalicular (apical) membranes of the maternal hepatocytes. Efflux of bile acids across the basolateral membrane of fetal hepatocytes is handled by several members of the OATP family of transporters.[126]

Placental Bile Acid Transport

Simple diffusion across both trophoblastic membranes of the placenta has previously been widely accepted as the major route of transfer of bile acids based on their lipid nature and the concentration gradient. Transplacental bile acid diffusive transport is bidirectional, between the maternal and the fetal circulations, with a net balance favoring a fetal-to-maternal bile acid transfer.[127] However, the presence of secondary bile acids in the fetal bile acid pool (fetus should not have secondary bile acids because the fetal intestine is devoid of bacterial flora) is evidence of a maternal-to-fetal transplacental transfer of relatively hydrophobic secondary bile acids.[124]

Because of the conjugated, protein-bound, and ionized nature of fetal bile acids, passive diffusion is less likely to

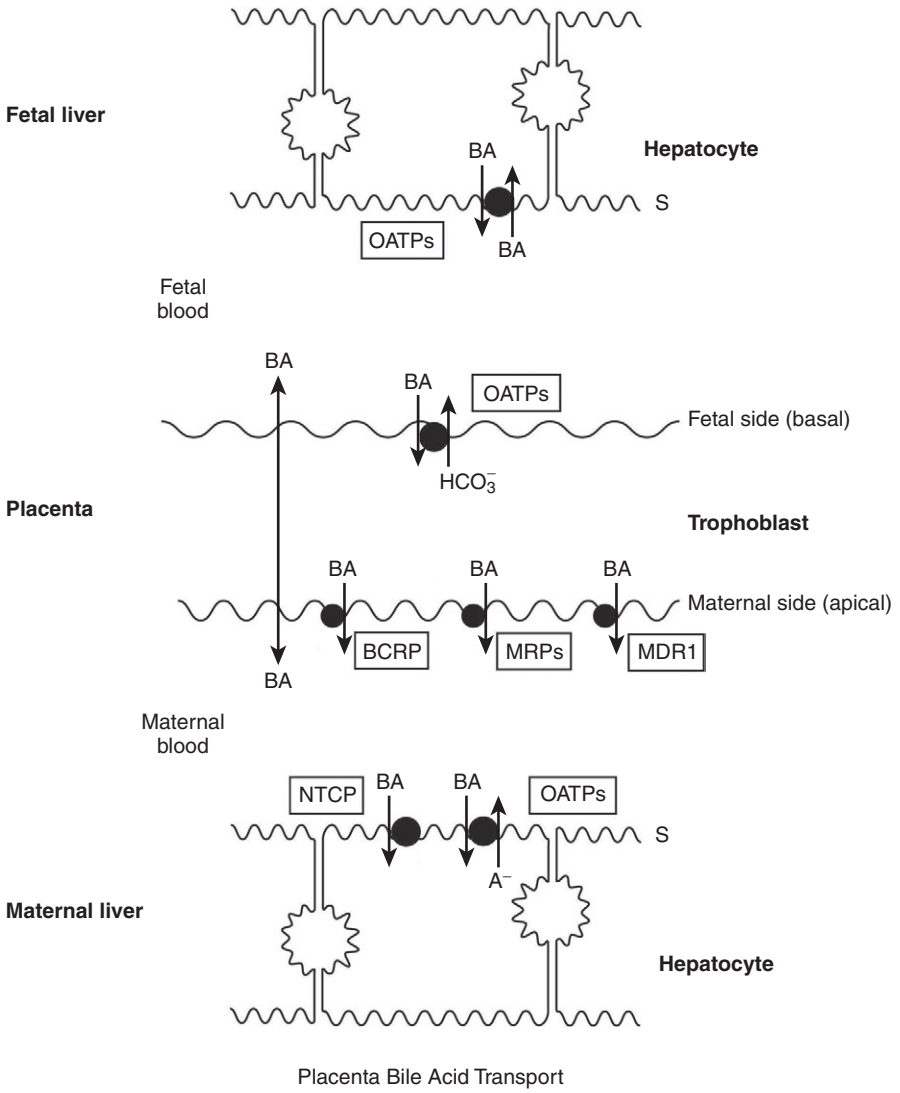

Figure 119-5 Bile acid exchange between fetal and maternal livers. Bile acids *(BA)* synthesized in the fetal liver are transported out of the fetal hepatocytes into the blood along the sinusoidal membrane *(S)* through members of the anion exchanger OATP family of transporters. Transport is bidirectional, and net transport is dependent on the gradient of bile acids across the basolateral membrane. There is no significant transport into the fetal canaliculus. Fetal blood through the umbilical arteries returns to the placenta. Along the basal trophoblastic (fetal-facing) membranes, the OATP anion exchangers transport BA into the cytosol mainly through HCO^-_3 exchange. Transport across the apical trophoblastic (maternal-facing) membranes is mediated by multidrug resistance–associated proteins (MRP1, MRP2, and MRP3), BCRP, and MDR1. Bile acids in the maternal blood from the placenta return to the maternal liver and are processed as in Figure 119-3.

be the major route of placental bile acid transfer.[128] Bile acid transport proteins in the basal and apical membranes of the trophoblasts account for unidirectional transport of bile acids from fetal to maternal circulation. The OATP family of transporters mediates bile acid transport across the placenta, where they are highly expressed.[129-131] Fetal bile acids cross the basal (fetal-facing) plasma membrane of the trophoblast by a sodium-independent bicarbonate anion exchange mediated by OATPs.[132] Several OATP transporters that are expressed in human placenta include OATP1B1 (formerly OATP3), OATP1B3 (OATP8), and OATP4A1.[129,133] In rats, the expression levels of these placental basolateral bile acid carriers OATP1a1, OATP1a4, and OATP1b2 are up-regulated during maternal cholestasis.[134] OATPs have also been shown to mediate the pregnenolone-sensitive placental uptake of fetal-derived sulfated steroids.[135]

Present in the apical (maternal-facing) plasma membrane of the trophoblasts are several ABC protein bile acid transporters, MRP1 (*ABCC1*), MRP2 (*ABCC2*), and MRP3 (*ABCC3*), whose expression have been confirmed in human placenta.[136] These transporters mediate the transfer of bile acids from the trophoblast cytosol to maternal circulation (see Figure 119-5). All MRPs are markedly up-regulated in pregnant rats with cholestasis.[134] BCRP (*ABCG2*) and MDR1 (*ABCB1*) also participate in the bile acid efflux across the apical trophoblastic membrane.[137] Carrier proteins in both the fetal and maternal blood (i.e., albumin and lipoproteins) ferry bile acids from the fetal liver to the basolateral membrane of trophoblasts and from the apical membrane of trophoblasts to the maternal liver.[137] Within the trophoblast, the identity of the cytosolic bile acid carrier or transporter that shuttles bile acids from the fetal (basal) to maternal (apical) trophoblastic membranes is not known. In the maternal liver, bile

acids are excreted following the pathways described in Figure 119-3.

DISORDERS OF BILE ACID METABOLISM

These can be subdivided into disorders of bile acid synthesis, of the tight junctions in the liver, and of membrane transport. We will only briefly touch on the transport defects because these are described further in the following chapter.

Disorders of Bile Acid Biosynthesis

CYP7A1 Deficiency

CYP7A1 converts cholesterol to 7α-hydroxycholesterol (see Figure 119-1, step 1). The gene is located on chromosome 8q11-12.[138] Patients with a homozygous deletion mutation of the *CYP7A1* gene have hyperlipidemia, increased hepatic cholesterol leading to formation of gallstones, and premature cardiovascular disease.[6] Oral cholic acid proved to be an effective treatment.

CYP7B1 Deficiency

Oxysterol 7α-hydroxylase is the major enzyme involved in the acidic or alternate pathway for bile acid synthesis. It is located on chromosome 8q21.3. One case has been described of an infant born of consanguineous parents, with severe neonatal cholestasis and cirrhosis. This infant had elevated 27α -hydroxycholesterol,[139] and cholic acid therapy proved ineffective. Identification of oxysterol 7α-hydroxylase deficiency in this infant with liver disease indicates the importance of the acidic pathway in early human life.

3β-Hydroxy-Δ⁵-C27 Steroid Oxidoreductase Deficiency

The gene for this enzyme is mapped to chromosome 16p11.2-12 (see Figure 119-1, step 2).[140] Accumulation of C24 and C27 steroids leads to hepatotoxicity. Patients present with neonatal jaundice, hepatomegaly, fat malabsorption, and fat-soluble vitamin deficiencies. Bile acid therapy with chenodeoxycholic acid, alone or in combination with cholic acid, leads to a decrease in pruritus and normalization of urinary steroids.[141]

Δ⁴-3-Oxosteroid 5β-Reductase Deficiency (AKR1D1 or SRD5B1)

Located on chromosome 7q32-33,[142] AKR1D1 deficiency leads to an increase in Δ4-3 oxo and allo bile acids (see Figure 119-1, step 3) and to severe cholestasis.[143] Mutations in the SRD5B1 gene have been recently demonstrated.[144,145] Oral bile acid therapy with a combination of cholic and chenodeoxycholic acid is effective; however, ursodeoxycholic acid therapy is not effective.[146]

Sterol 27-Hydroxylase (CYP27A1) Deficiency

This deficiency was one of the initially described defects in bile acid synthesis (see Figure 119-1, step 6). The gene has been localized to chromosome 2q33-qter.[147] This is an autosomal recessive condition that causes cerebrotendinous xanthomatosis. Decreased bile acid synthesis results in elevated plasma concentrations of cholesterol and cholestanol, which eventually cause neurologic symptoms, including dementia, psychiatric disturbances, pyramidal or cerebellar signs, and seizures. Other clinical manifestations are diarrhea, tendon xanthomas, and cataracts.[148] Treatment with chenodeoxycholic acid decreases plasma cholesterol and cholestanol concentration by about three-fold and results in normalization of electroencephalogram and biochemical abnormalities but not of the clinical symptoms. Cholic acid therapy is equally effective and has much less side effects.[149] Fatal neonatal cholestasis has been reported secondary to this deficiency.[150]

2-Methyl Coenzyme A Racemerase Deficiency

This enzyme is located in the peroxisomes and not only acts on bile acid synthesis but also participates in the degradation of methyl branched chain fatty acids (see Figure 119-1, step 8). The *AMACR* gene has been mapped to chromosome 5p11-13.[151] 2-Methyl coenzyme A racemerase (AMACR) deficiency leads to accumulation of pristanic acid and di- and tri-hydroxycholestanoic acids. Pristanic acid causes neurotoxicity. Adults present with neuropathy,[152] but an infant is described with coagulopathy, vitamin D and E deficiency, and mild liver impairment with no neurologic disease. AMACR-deficient mouse models consuming a diet supplemented with phytol, a source of branched-chain fatty acids, had impaired livers.[153]

D-Bifunctional Protein Deficiency (HSD-17B4)

The defect is in the 17β–hydroxysteroid dehydrogenase type IV enzyme (see Fig. 119-1, step 10). The gene is located on chromosome 5q2.[154,155] Loss of this enzyme is associated with accumulation of C27 bile acid intermediates and pristanic acid. Suzuki and colleagues[156] reinvestigated two Japanese patients thought to have L-bifunctional protein deficiency. Before D-bifunctional protein was described as an entity, these patients were thought to have L-bifunctional protein deficiency, but when the patients were retested, they actually had D-bifunctional protein deficiency. Many other patients previously diagnosed with L-bifunctional protein were subsequently established to have D-bifunctional protein deficiency. The infants present with neonatal seizures, hypotonia, hepatomegaly, and other defects. D-bifunctional protein deficiency is usually fatal before 2 years of age, although a few children have survived beyond this age.[157,158]

Disorders of the Tight Junction

Familial Hypercholanemia

This disorder has been described in 12 families of Amish descent.[159] The candidate gene is *TJP2* (tight junction protein 2) and is located on chromosome 9q12-9q13. Tight junctions separate bile in the lumen from plasma and the canalicular membranes from sinusoidal membrane domains. A proposed mechanism for this disorder is that the bile salts are transported into the lumen but then leak through the paracellular pathway represented by the tight junction back into the plasma. A second locus is on 9q22-9q23, which is a candidate gene for bile acid coenzyme A amino acid N-acyltransferase (BAAT) (see Figure 119-1, step 12). This enzyme conjugates bile acids with glycine and taurine. Unconjugated bile acids cannot be excreted by the BSEP into the canalicular lumen (see Figure 119-3), thereby leading to the accumulation of bile salts and their precursors in the hepatocyte cytosol and eventually in the plasma. Decreased levels of bile salts in the bile lead to fat malabsorption, vitamin K deficiency, and rickets. The increased bile salts in the plasma occasionally lead to pruritus, cholestasis, and chronic hepatitis. Ursodeoxycholic acid and rifampicin have been shown to improve the pruritus and normalize bile acid levels.[160]

Disorders of Transport of Bile Acids

These disorders are discussed in the next chapter and are mentioned here only briefly.

Progressive Familial Intrahepatic Cholestasis Type 1 (PFIC1)

This disease was first described in an Amish family, descendants of Jacob Byler, and was formerly called *Byler disease*. The underlying cause is a genetic defect in *ATP8B1* located on

18q21-q22.[161] The gene encodes a member (class V, type 10A) of the family of aminophospholipid-transporting ATPases or translocases. These aminophospholipid translocases transfer phosphatidylserine and phosphatidylethanolamine phospholipids from one side of a bilayer of the plasma to another. The PFIC1 protein is found on the apical membrane of the gastric pits, small intestine, pancreatic acinar cells, cholangiocytes, and hepatocytes in mice.[162] This is a well-characterized clinical syndrome in which patients have low bile salt concentrations in the intestinal lumen and increased bile acid concentrations in the plasma. These patients also have extrahepatic manifestations like steatorrhea, diarrhea, and failure to thrive. The patient response to ursodeoxycholic acid treatment varies. Partial external biliary diversion, a procedure that diverts some bile away from the intestine, may ameliorate cholestasis and pruritus.[163] Eventually, liver transplantation is required for liver failure.

Progressive Familial Intrahepatic Cholestasis Type 2 (PFIC2)

This defect is in the *ABCB11* gene, formerly called SPGP and BSEP, and is located on chromosome 2q24.[164] This gene encodes for BSEP, which is an ABC transporter found on the canalicular membrane of the hepatocytes (see Figure 119-3). About 13 different mutations have been found in this gene.[165] Infants with this disorder present with cholestasis. An increased risk for hepatocellular carcinoma has been reported.[165] Similar to those with PFIC1, some patients respond to ursodeoxycholic acid therapy or to partial external biliary diversion. Liver transplantation is required for end-stage liver disease.

Progressive Familial Intrahepatic Cholestasis Type 3 (PFIC3)

The defect is in the *MDR3* (*ABCB4*) gene (see Figure 119-3), a member of the multidrug resistance gene family, located on chromosome 7q21.[166,167] The MDR3 p-glycoprotein is a transmembrane protein that translocates phosphatidylcholine and may be involved in the transport of bile acids from the hepatocyte to the canaliculus as well as in transport of drugs. Bile salt secretion into the canaliculus is normal, but the bile is devoid of phosphatidylcholine. Phospholipids in the bile lumen normally form micelles with the bile acids and protect the canalicular membrane from damage by bile acids. Patients present with hepatosplenomegaly, portal hypertension, and jaundice and later in life develop liver failure. Some patients respond to ursodeoxycholic acid. Liver transplantation is required for end-stage liver disease.

Benign Recurrent Intrahepatic Cholestasis

The defect in this disorder is in the aminophospholipid translocase (*ATP8B1*) and *BSEP* (*ABCB11)* genes (see above for description). This appears to have the same genetic defect as those described previously, but phenotypically, it is a benign disorder with recurrent bouts unlike the ones discussed previously that typically progress to liver failure. Patients present with recurrent episodes of cholestasis. No effective medical therapy is available. Complete and long-lasting disappearance of pruritus and normalization of serum bile salt concentrations in cholestatic patients within 24 hours after endoscopic nasobiliary drainage have recently been reported.[168]

Intrahepatic Cholestasis of Pregnancy

This disease, which occurs in the third trimester of pregnancy, is prevalent in certain ethnic groups[169] and is due to a heterozygous non-sense mutation of the *MDR3* gene that has been demonstrated in familial intrahepatic cholestasis of pregnancy.[170] Recurrent prolonged intrahepatic cholestasis of pregnancy followed by periportal fibrosis or cirrhosis has been reported in four sisters.[171] The disease is reversible in the mother after delivery with excellent prognosis. However, the effects on the fetus include prematurity, stillbirth, and fetal distress. Estrogen and progesterone may play a role in the etiopathogenesis.[172] The severity of fetal complications is directly proportional to the magnitude of maternal hypercholanemia.[173] Ursodeoxycholic acid has been found to be effective in improving pruritus in the mother and also in improving fetal outcome.[174]

Lymphedema Cholestasis Syndrome (Aagenaes Syndrome)

Patients have severe neonatal intrahepatic cholestasis, which improves during childhood and becomes episodic as in benign recurrent intrahepatic cholestasis. Later, these children develop lymphedema. Bull and associates[175] mapped a locus for lymphedema cholestasis syndrome to chromosome 15q in Norwegian patients; however, no linkage was detected at chromosome 15q in a Serbian family.[176] Fifty percent of the patients can expect a normal life span.[177]

North American Indian Childhood Cirrhosis

This familial cholestasis with autosomal recessive inheritance in Ojibway-Cree children from Northwest Quebec presents with transient neonatal cholestasis progressing to biliary cirrhosis.[178] A missense mutation has been detected in the Cirhin (*CIRH1A*, cirrhosis autosomal recessive 1A) gene at chromosome 16q22.[179] No specific therapy is available, and patients with advanced cirrhosis require liver transplantation.

Bile Formation and Cholestasis

The functions of the liver can be generally divided into three main areas: (1) synthesis and secretion of serum proteins including clotting factors; (2) energy metabolism, detoxification of endobiotics and xenobiotics; and (3) bile secretion. Perturbations in any of these functions, whether by genetically inherited or acquired conditions (e.g., sepsis and the acute phase response), can lead to liver disease, act as a cofactor in other conditions, and ultimately may lead to death. To date, no bioartificial device can satisfactorily replace a liver.

ANATOMY OF THE LIVER

The liver is the largest abdominal organ, receiving 20% to 25% of the cardiac output from two separate sources—the portal vein and the hepatic artery.[1] The portal vein delivers deoxygenated blood efflux from the intestines, spleen, and pancreas, contributing approximately 70% of total blood flow to the liver. Oxygenated blood is provided by the hepatic artery, which usually derives from the celiac axis. The blood from these two

circulations merges at the tissue level in the sinusoidal spaces that separate one- to two-cell-thick hepatocyte cords (Figure 120-1). The sinusoidal membranes are lined with receptors and transporters that efficiently accomplish numerous tasks. These include the uptake of nutrients, toxins, endobiotics, and xenobiotics; a robust response to circulating signals (e.g., cytokines); and delivery of secreted substances to the circulation. After filtering through the sinusoids, blood flows into central veins that coalesce into one of the three hepatic veins; these empty into the systemic circulation via the inferior vena cava, immediately inferior to the right atrium.

Blood flow through the liver changes around the time of birth. Before birth, the ductus venosus shunts blood from the left umbilical vein to the inferior vena cava. After birth, it collapses and begins to atrophy, eventually forming the ligamentum venosum, which is continuous with the ligamentum teres, the remnant of the left umbical vein (Figure 120-2).

On a cellular level, the liver is organized as functional units called hepatic lobules (see Figure 120-1). Each hexagonally shaped lobule comprises a central vein and contains a portal triad, usually at three or more of the corners. Blood flows in from the portal triad via the emptying of hepatic arterial and portal venous blood at the start of the sinusoids, then coursing toward the central vein. This arrangement of blood flow into the portal triad allows for the mixture of well-saturated arterial blood with the relatively desaturated portal blood. It also creates a zonal gradient within the lobular architecture whereby the periportal region is exposed the highest concentration of oxygen, nutrients, and toxins, which confers regional advantages and disadvantages for certain hepatic insults. Lobular heterogeneity in the expression of genes in the periportal and perivenous regions relate to the exposure and needs of these hepatocytes.

The polarized architecture of the hepatocyte allows for the majority (>90%) of the cell surface to contact blood (the sinusoidal surface), separated from the apical (canalicular) surface that is in contact with bile. Bile flows countercurrent to blood from the intercellular canaliculi at the apical regions, toward the bile ducts in the portal triad[2,3] (see Figure 120-1). The flow of bile is dependent on the active secretion of biliary solutes into the canalicular space, and impairment of this process leads to intrahepatic cholestasis[4,5] (see later discussion).

MICROARCHITECTURE

The hepatic parenchyma is comprised mainly of hepatocytes (>70%), but several other cell types are critical for coordinated function of this organ, including cholangiocytes, Kupffer cells, stellate cells, sinusoidal endothelial cells, and Pit cells.[6] Cholangiocytes (bile duct cells) are also polarized, with their apical surfaces in continuity of the flow derived from hepatocyte canaliculi.[7] These cholangiocytes line the bile ducts and gallbladder and originate in the ducts of Hering adjacent to portal triads. Kupffer cells are the resident macrophages within the liver and are the largest collection of macrophages in the body.[8] They can migrate from the sinusoids

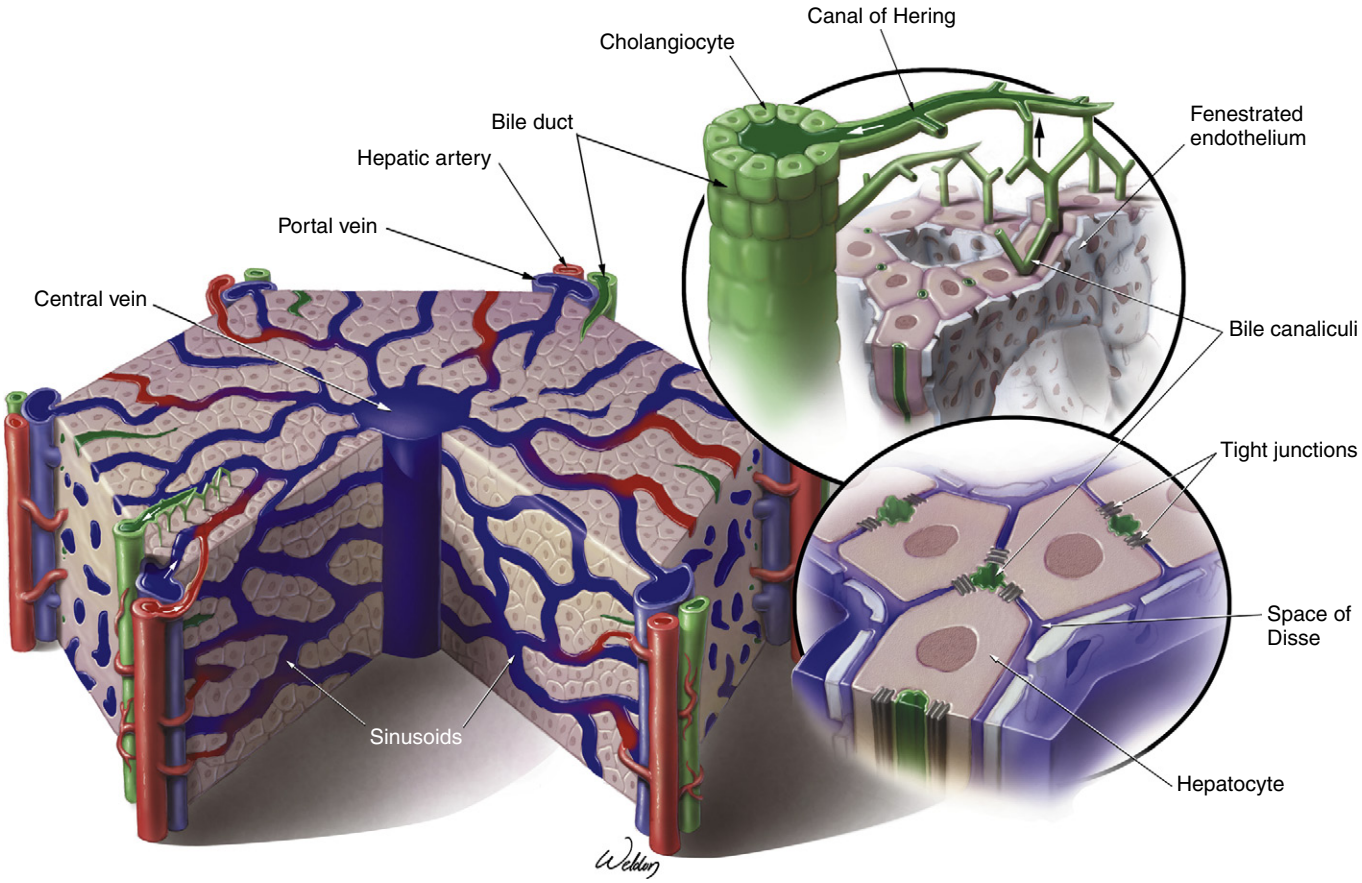

Figure 120-1 Schematic view of the liver lobule. The central vein is shown in the center of the lobule, separated by cords of hepatocytes forming sinusoids from six portal areas at the periphery. The portal areas contain a portal vein, hepatic artery, and bile duct. Blood flow is toward the center of the lobule, while bile flows toward the portal triads at the margins. Note the hepatic artery providing oxygenated blood to the hepatic sinusoids as well as the peribiliary plexus. The *top inset* provides a more detailed view of the fenestrated endothelium and the connections between intercellular canaliculi and the canals of Hering. The *lower inset* emphasizes the separate basolateral and canalicular membranes, as well as the junctional complexes.

to regions of insult or infections and are major components in the genesis of the inflammatory response within the liver. Pit cells may contribute to the immune defenses in the liver because they appear to have natural killer cell activity. Stellate cells are arguably the most complex and least well-characterized cell type within the liver. They express neuroendocrine markers, consistent with their neural crest origin, but express storage and fibroblastic-like activities.[9] Stellate cells occupy the perisinusoidal space with cytoplasmic extensions that encompass the sinusoidal endothelial lining, making them particularly well situated for their role in maintenance of the microvascular tone. In addition, they are the primary producers of collagen and extracellular matrix in response to inflammation and injury.[10,11] The combined effects of activated stellate cells, along with myofibroblasts that migrate to an injured liver, lead to fibrosis and, if prolonged, to cirrhosis.[12] Even sinusoidal endothelial cells have adapted to their unique environment and role in the liver, with fenestrated membranes to allow passage of relatively large molecules.[13]

Hepatocyte Polarity and Membrane Features

The distinct membrane domains found on the hepatocyte (basolateral, intercellular, and apical) not only contribute to their architecture as polarized cells but also are critical for their functions. The basolateral (sinusoidal) membrane is contiguous with the intercellular domain, both of which are in contact with the sinusoidal blood via the space of Disse (see Figure 120-1). The sinusoidal membrane contains numerous transporters, which import substances into the hepatocyte for metabolism and detoxification, as well as receptors for microbial products (e.g., Toll-like receptors) and cytokines.[14,15]

The intercellular (lateral) domain comprises almost 50% of the hepatocyte membrane and extends the sinusoidal surface up to the canalicular space, separated by tight junctions (zonula occludens). These tight junctions serve to define the polarity of the hepatocyte and create a semipermeable membrane between the blood and bile. They also serve as means of cell-cell communication and their permeability can be altered in response to certain conditions, mainly due to injury, inflammation, and toxins.[16]

Biliary Tree

The biliary tree begins as small (0.75 μM) tubules formed at the apical surface of two adjoining hepatocytes that define the canaliculus. Bile flows from the canalicular spaces into a network of canaliculi (see Figure 120-1), then to the canal of Hering, ultimately to drain into terminal bile ducts.[17] These terminal branches first become grossly visible as area ducts, which coalesce into segmental ducts, then into right and left hepatic ducts. In the biliary tree of the rat, at least seven orders of bifurcation define this arrangement that serves the entire liver.[7] Bile is then carried by the common hepatic duct to the gallbladder, where it is stored until hormonal action (primarily cholecystokinin) initiates a muscular contraction that delivers this stored gallbladder bile into the common bile duct via the cystic duct and then to the intestine to participate in digestion.

The cholangiocytes that line the biliary tree comprise only approximately 5% of the cells of the liver. These polarized epithelial cells modify the contents of bile via active transport of fluid and electrolytes in response to hormonal signals from the intestine.[18] Stimulation of the duodenum by fatty acids, acidic pH, and bile acids leads to the release of several hormones including secretin, which is carried by the portal circulation to the liver, altering the content and volume of bile secretion in a feedback mechanism. These alterations in bile composition are accomplished by the action of several transporters found on the apical membrane of the cholangiocyte, including the cystic fibrosis transmembrane conductance regulator and a chloride and bicarbonate exchanger.[19] The chloride and bicarbonate exchanger serves to alkalinize bile and increase fluid secretion and bile flow. The cystic fibrosis transmembrane conductance regulator transports chloride and mutation of the gene for the transporter results can lead to neonatal jaundice and liver disease in approximately 10% of patients with cystic fibrosis.[20]

Bile Composition

Bile is formed mainly of solutes and water secreted by both hepatocytes and cholangiocytes. The role of bile is mainly twofold: to aid in the digestion and absorption of long-chain fats and fat-soluble vitamins from the intestine and to provide a means of excretion for drugs, toxic substances, endobiotics, and xenobiotics that have been modified and/or detoxified by the hepatocyte.[5,21,22] To that end, the composition of bile reflects both of these roles. Although exact measurements of bile production in infants are not available, the average adult liver secretes approximately 600 to 800 mL of bile per day.[23]

Bile acids are the main organic solute contained in bile and are present in concentrations of 20 to 30 mmol/L. Secretion and recirculation of bile acids are the main forces driving bile flow[5,14] (see Figures 120-3 and 120-4). Four main bile acids comprise

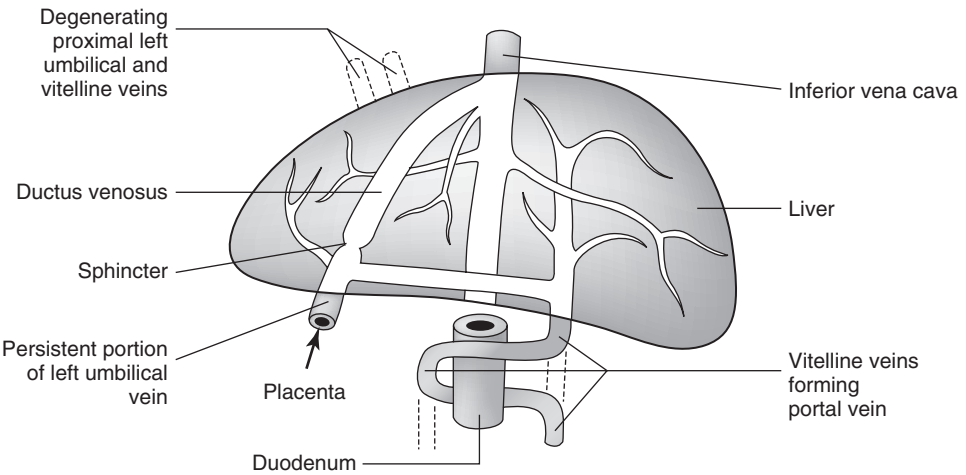

Figure 120-2 Dorsal view of the liver demonstrating the venous circulation at 7 weeks gestation. Note the path from the umbilical vein through the ductus venosus to the inferior vena cava and the vitelline veins forming the portal vein. *(From Moore KL:* The Developing Human: Clinically Oriented Embryology, *3rd ed, Philadelphia, 1982, WB Saunders, p 301.)*

more than 95% of the bile acid pool and are categorized as primary or secondary bile acids.[24,25] The two primary bile acids, cholic acid (CA) and chenodeoxycholic acid, are synthesized via a multienzyme series of reactions from cholesterol precursors solely within hepatocytes.[26-28] The more hydrophobic secondary bile acids, deoxycholic acid and lithocholic acid (LCA), are formed by the action of intestinal bacteria that 7α-dehydroxylate the primary bile acids. The vast majority of the bile acid pool is conjugated to either taurine or glycine in a 3:1 ratio, depending on the availability of dietary taurine. At high concentrations, bile acids function as detergents that can solubilize phospholipid membranes, if retained intracellularly. The more hydrophobic monohydroxy bile acids, such as LCA, are poorly soluble even when conjugated and are more damaging to membranes and hepatocytes when they accumulate.

In addition to bile acids, several other key components of bile include cholesterol, phospholipids, electrolytes, proteins, and conjugated bilirubin (Figure 120-3). Phosphatidylcholine is the most prevalent phospholipid in bile (approximately 95%) and is present in concentrations of 7 mmol/L. Cholesterol, which makes up approximately 3% of biliary solute, is secreted almost exclusively in the free or unesterified form. Phytosterols, plant-based sterols with similar structure to cholesterol, are secreted in small amounts.[29] Phospholipids, cholesterol, and bile acids form mixed micelles in bile and generally exist in a phospholipid:bile acid ratio of 2:1. Although normative ratios of cholesterol, bile acids, and phospholipids in neonatal bile are not known, it is thought that the formation of sludge and gallstones is a function of imbalances in the ratio of bile acid and cholesterol:phospholipids.[30] When bile is supersaturated by cholesterol, it can exist in several forms (micelles, lamellar phases, and crystals).

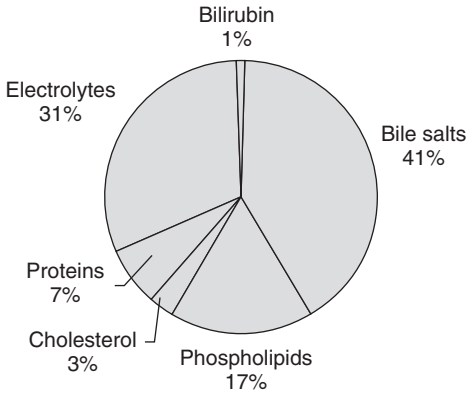

Figure 120-3 Solute composition of human bile. Note that bile acids are the most prevalent solute, followed by phospholipids and cholesterol. Conjugated bilirubin makes up a small fraction of biliary solute loads. *(From Vlahcevic et al: [chapter title. In Zakim D, Boyer TD, editors:* Hepatology: A Textbook of Liver Disease, *Philadelphia, 1996, Saunders, 381.)*

Bile flow is also driven by bile acid independent mechanisms, mainly via the secretion of glutathione, and conjugates of endobiotics or xenobiotics (glucuronides, glutathione, and sulfated forms primarily[31]; see Figure 120-4). Glutathione is used within the hepatocyte for many reducing reactions and is present in the cytosol at concentrations of 5 to 10 mmol/L. The characteristic yellow color of bile is due to the presence of bilirubin, which is secreted mainly in its diglucuronide form. Bilirubin concentrations in bile are typically approximately 0.2 mmol/L but can vary with certain disease states. Because bile is a primary mechanism for excretion of many toxic substances, small concentrations of drugs, vitamins, steroids, xenobiotics, and products of lipid metabolism are also present. In addition, bile is the main route for excretion of metals such as iron, copper, manganese, and zinc. It is readily apparent that retention of these substances during periods of cholestasis, from any mechanism, serves to promulgate ongoing liver damage. Moreover, impairments in the handling of potentially toxic substances due to inherited mutations in genes involved in these pathways can contribute to liver disease. Examples of clinical situations in which mutations or polymorphisms in select genes lead to retention of metals and liver disease include adult-onset hemochromatosis (iron) and Wilson disease (copper).[32,33] Recent research indicates that polymorphisms are likely in essential genes whose proteins encode products involved in the metabolism and transport that lead to "idiosyncratic" or idiopathic liver disease or drug toxicities.[34-37]

Enterohepatic Circulation of Bile Acids and Bile Flow

Bile flow is driven primarily by two factors: bile acid dependent mechanisms and bile acid independent mechanisms (Figures 120-3 and 120-4). The main determinants of bile acid dependent

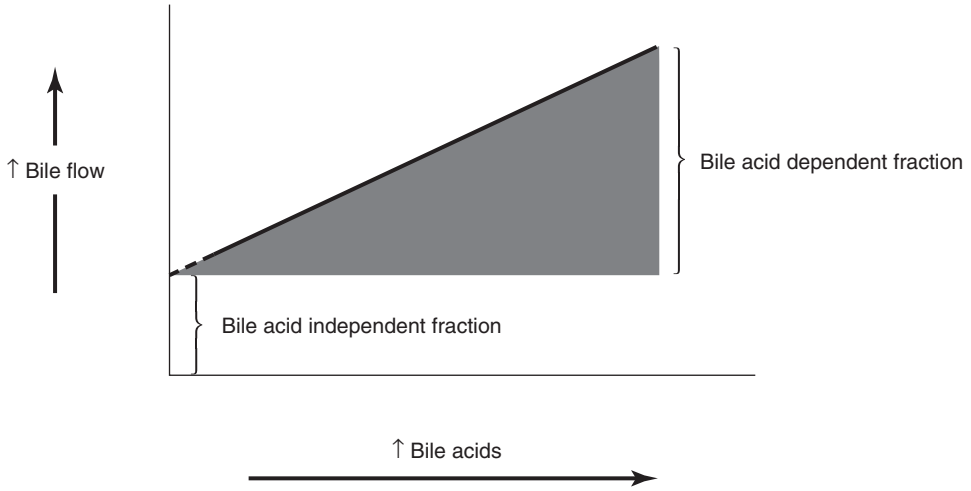

Figure 120-4 Bile acid dependent bile flow (BADF) and bile acid independent flow (BAIF). Note the linear relationship between bile acid secretion and BADF. The majority of bile flow is BADF that is reduced with smaller bile acid pool sizes, such as those of infants. The contribution made by BAIF to total bile flow is approximately 25% and estimated by the extrapolation of the relation between biliary flow and bile acid excretion to the *y*-axis, the imaginary point at which no bile acid secretes.

flow are the enterohepatic circulation of bile acids and the secretion of bile acids from the hepatocyte into the canalicular lumen, the rate-limiting step.[4,5,14] Bile acids are secreted by an active transport mechanism on the canalicular membrane, where the gradient from within the hepatocyte across the apical surface to the canalicular lumen can reach up to 1000-fold. After secretion into the duodenum from the extrahepatic biliary tree, bile acids are modestly absorbed in the jejunum but primarily reabsorbed in the terminal ileum, then returned to the liver via the portal circulation. Distinct but related transporters on the apical membrane of the ileal enterocytes and the sinusoidal membrane of the hepatocyte efficiently accomplish this process, leading to retention of nearly 95% of excreted bile acids. Despite being recirculated six to ten times per day, only a small fraction of the total pool (approximately 0.5 g of the 4- to 5-g pool in adults) is lost daily in the stool.

This process is well balanced, with the amount of de novo bile acid synthesis being relatively equal to fecal loss.[26,38] This feedback loop is effected by two mechanisms: bile acid sensing nuclear receptors in hepatocytes and factors released from the terminal ileum that travel through the portal vein to the hepatocyte.[14] Overall, this process allows for upregulation of bile acid synthesis in times of intestinal loss (e.g., diarrhea or short gut) or repression of synthesis in cholestasis.[39-41]

The relationship between bile acid secretion and bile flow is linear[42-45] (see Figure 120-4). Bile acids increase flow mainly by creating an osmotic gradient that draws in water, electrolytes, and other solutes. In addition to bile acid pool size and efficiency of enterohepatic circulation, the choleretic potency of different bile acids modulates this process. The bile acid pool size can be manipulated pharmacologically to produce increased bile flow via administration of certain bile acids (e.g., ursodeoxycholic acid) in patients with cholestasis.[46]

The bile acid independent pathway and cholangiocyte secretions drive the remainder of bile flow. Secretion of glutathione, glutathione conjugates, and organic anions by specific transporters on the canalicular membrane is the main determinant of bile acid independent flow and is influenced by hormones, certain drugs, and signaling properties of bile acids.[47,48] Cholangiocyte (ductular) cell secretion is mainly controlled by the hormone secretin, which promotes the alkalinization and dilution of bile via transport of ions into the canalicular space.[49,50] This process is species specific; secretin is a potent choleretic in humans and dogs, but has little influence in rodents.[24,51]

Water flows from the sinusoids to the bile canaliculi via several pathways: transcellular, paracellular, and transcytotic. The majority of water movement occurs through the paracellular pathway via tight junctions, with limited contribution from the other pathways.

BILE FORMATION IN THE NEONATE

Before birth, the placenta is responsible for bile acid metabolism and the detoxification and elimination of lipophilic organic anions in the fetus.[52] Abrupt disconnection from the placenta at birth unmasks the functional immaturity of the fetal/neonatal liver. During fetal life, the liver functions both as a metabolic and hematopoietic organ. The transition to an organ primarily responsible for metabolism and detoxification begins at birth and slowly reaches adult levels by 1 to 2 years of age.[53] Thus hepatic immaturity negatively affects the expected functionality of a premature newborn in multiple ways. In particular the immaturity of neonatal bile acid metabolism is clinically significant because adequate bile acid synthesis and secretion are essential for hepatic bile formation and for intestinal fat and fat-soluble vitamin absorption.

Bile acids have been detected in the fetal liver and gallbladder as early as 14 to 16 weeks gestation.[54] By the beginning of the third trimester (22 to 26 weeks), the primary bile acids found in the fetal gallbladder are taurine-conjugated dihydroxy bile acids, mainly tauro-chenodeoxycholic acid. As the third trimester progresses, tauro-CA, a trihydroxy bile acid, and glycocholate appear at approximately 28 weeks gestation.[55] These taurine conjugates are the predominant ones during fetal life, with a switch to tauro-CA as the principal bile acid at birth. The progression to the adult pattern of glycine conjugates is not accomplished until 2 to 7 months of life.[56-58]

The fetus does not generate the secondary bile acids because this process requires enzymatic cleavage by colonic bacteria, which are not present in the fetal intestine. A small amount of secondary bile acids is present in the fetal circulation, however, from the maternal pool. Specific transporters found on the brush-border and basolateral membranes of the placental syncytiotrophoblast provide bidirectional transport of bile acids between the fetal and maternal circulations.

Some degree of enterohepatic recirculation seems to be present; animal studies using radiolabeled taurocholate in utero showed passive reabsorption of conjugated bile acids in the proximal jejunum, but poorly developed active reabsorption of taurine-conjugated bile acids in the terminal ileum.[59,60] Poor reabsorptive capacity of the fetus coupled with efficient clearance through the maternal placenta lead to a small bile acid pool size in the fetus and neonate, with the term neonate bile acid pool approximately half that of the adult. The preterm neonate is at an even greater disadvantage because the CA synthesis rate and pool size is approximately one third that of a term infant. It is assumed that extremely preterm infants, less than 32 weeks gestation, are likely to have an even smaller bile acid pool size, although exact figures are not currently available.[61,62]

As with many other developmental processes, the adrenal axis appears to have a role in maturation of the synthesis and enterohepatic recirculation of bile acids in the fetus, likely through developmental increase in transporter expression and function.[62] Prenatal dexamethasone treatment has been shown to increase bile acid pool size in significantly preterm neonates to levels comparable with term infants. This is corroborated with animal studies that showed acceleration of CA conjugation levels after a 1-day treatment with cortisone.

The immaturity of the fetal liver and the small bile acid pool size are clinically relevant because bile acid synthesis and secretion are essential for bile flow and absorption of intestinal fat and fat-soluble vitamins.[63-65] Effects of this are manifest as fat malabsorption, poor growth, and deficiencies in fat-soluble vitamins, such as vitamin D.

MOLECULAR DETERMINANTS OF BILE TRANSPORTERS AND THEIR REGULATION

At physiologic pH, taurine and glycine conjugated bile acids exist in the anionic form and are unable to cross membranes by diffusion and thus are completely dependent on membrane transport proteins to enter or exit the hepatocyte. Thus the creation, maintenance, and regulation of bile formation rests mainly on the functional competency of membrane transporters, with central reliance on the transport of bile acids.[14] Recent research from a variety of laboratories have led to the discovery of transporters responsible for the import and export of specific substrates into and out of the hepatocyte[14,22] (Figure 120-5).

Basolateral Transporters

NTCP

The Na^+-taurocholate cotransporting polypeptide (NTCP, SLC10A1) is a high-affinity Na^+-dependent transporter expressed exclusively on the basolateral membrane of hepatocytes.[66,67] Approximately 75% of the conjugated bile acids and

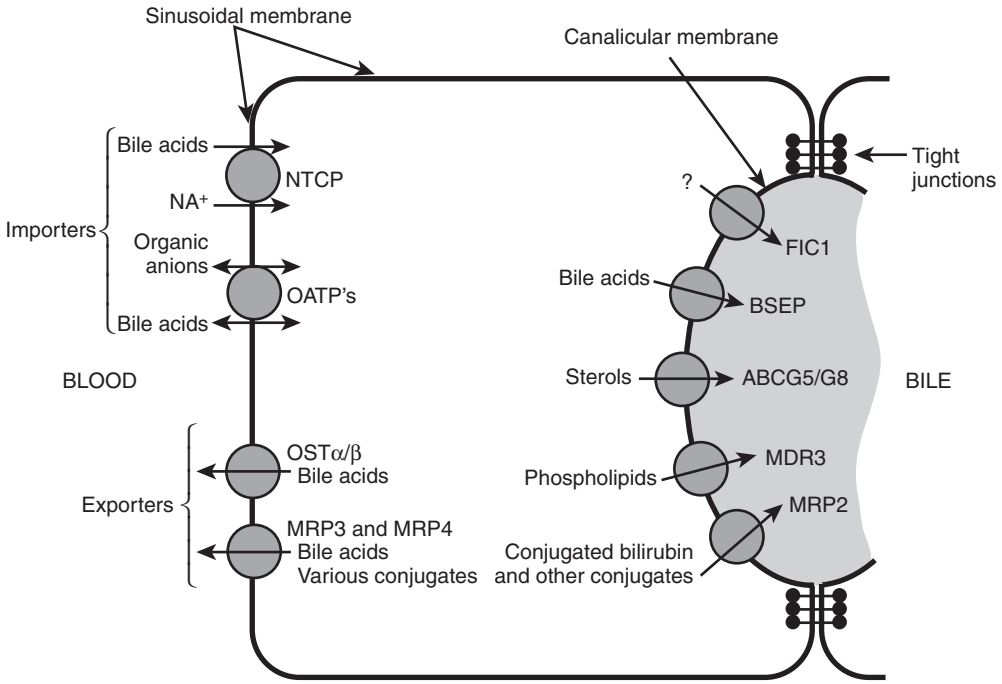

Figure 120-5 Composite schematic of select hepatobiliary transporters involved in bile formation. The hepatocyte is oriented with sinusoidal *(BLOOD)* transporters on the left, canalicular *(BILE)* on the right. *Arrows* connote general directions that the listed solutes may be transported. *Arrows* denote distinct membranes, and the tight junctions that help define these membrane domains. Note that the resident canalicular transporters are responsible for active secretion of nearly all components of bile. *BA,* Bile acids; *BSEP,* bile salt export pump; *MDR,* multidrug resistance protein; *MRP,* multidrug resistance-associated protein; *NTCP,* Na^+/taurocholate co-transporting polypeptide; *OA,* organic anion; *OC,* organic cation; *OATP,* organic anion transporting polypeptide; *PL,* phospholipid; *XOL,* cholesterol.

less than 50% of unconjugated bile acids are imported via this transporter in both rodents and humans. The inward Na^+ gradient necessary for this process is maintained by a Na^+/K^+ adenosinetriphosphatase and facilitates the uptake of conjugated bile acids such as taurocholate. This process is extremely efficient, with 75% to 90% first-pass clearance of bile acids from the sinusoidal blood.[68,69]

Because of its integral role in removal of bile acids from the portal circulation, the NTCP gene product is under substantial transcriptional regulation, which is particularly evident in times of cholestasis and inflammation.[14] Nearly all animal models of inflammation (cecal ligature or puncture, injection of endotoxin or proinflammatory cytokines: tumor necrosis factor-α (TNF-α), interleukin-1β and cholestasis (bile acid feeding, bile duct ligation) produce a rapid and profound decrease in NTCP RNA levels.[14,70-78] By suppressing NTCP expression, the hepatocyte attempts to insulate itself against the toxic effects of accumulating bile acid levels by decreasing import.[40,73,79] This transcriptional negative feedback loop helps protect the hepatocyte against increasing intracellular bile acid levels, which will eventually lead to cell damage and apoptosis.

NTCP was the first hepatobiliary transporter cloned, initially from the rat genome, and with its identification began the field of transporter biology.[80] In addition to the role in metabolism, bile acids also act as transcriptional regulators via certain nuclear receptors.[81] Bile acids are strong activators (ligands), for several NR family members including the farnesoid X receptor (FXR, NR1H4), the vitamin D receptor (NR1I1), the pregnane X receptor (NR1I2) and the liver X receptor (NR1H3).[82,83] Experiments in FXR+/+ mice fed a CA-enriched diet showed a marked reduction in NTCP RNA levels, whereas FXR−/− mice showed no change in NTCP levels in response to increasing bile acid concentrations.[78] The failure to initiate these hepatoprotective mechanisms in the FXR−/− mice led to continued import of bile acids with increased intracellular accumulation, ultimately resulting in bile acid–induced hepatocellular damage and apoptosis. These studies highlight the coordinated response designed to help shield the hepatocyte from bile acid damage. There are contributions from both the intestine and the hepatocyte that lead to the reduction in NTCP expression in cholestasis.[40]

Decreasing bile acid import also leads to decreased bile flux across the hepatocyte and an obligate decrease in bile flow, which contributes to the nutritional consequences of cholestasis. Given the high bile acid levels in infants and the low NTCP expression (inferred from studies in developing rats), it is likely that NTCP plays a key role in cholestasis seen in the sick or premature infant.[58,84]

Organic Anion Transporting Peptide Family

Although the majority of bile acid uptake is accomplished via the Na^+-dependent processes outlined above, approximately 25% of bile acids enter the hepatocyte through Na^+-independent mechanisms.[85,86]

The *organic anion transporting polypeptides* (humans OATP; other species Oatp) are 12 transmembrane domain glycoproteins that belong to the *SLC* gene superfamily of transporters.[31] Members of this group mediate sodium independent transport of a variety of structurally independent, mainly amphipathic organic compounds across the basolateral membrane of the hepatocyte, including bile salts, hormones, both conjugated and unconjugated bilirubin, toxins, and various drugs. OATP/Oatp are expressed in various epithelial cells, some in a single organ and others expressed ubiquitously. They participate in the bidirectional transport of solutes across membranes as diverse as the liver, kidney, intestine, choroid plexus, and retina.

The expression of the OATP transporters is critical for the coordinated import and metabolism of these compounds, so it not surprising that crossover in the transcriptional regulators between NTCP and the OATP genes is substantial, although regulation during development, inflammation, and cholestasis are not well characterized at this time. In animal models of sepsis and cholestasis, rapid, profound suppression of OATP-C (SLCO1B1) occurs, which primarily imports taurocholate, unconjugated bilirubin, and a variety of other organ anions into the hepatocyte.[87-89] The exact molecular mechanisms driving this suppression are still under investigation but, like NTCP, may involve intestinal products or altered function of nuclear receptors that regulate these genes. Developmental studies in rats show that adult levels of OATP expression were not achieved until postnatal day 29. Together, these studies suggest coordinated suppression of both NTCP and OATP transporters likely occurs in the sick, premature infant leading to reduced bile flow and hyperbilirubinemia.

Multidrug Resistance-Associated Protein 3

Multidrug resistance-associated protein 3 (MRP3, ABCC3) is a member of the adenosine triphosphate (ATP)-binding cassette protein superfamily of transporters.[40] It serves a unique role in the hepatic response to cholestasis by exporting retained bile acids and conjugated organic anions, including conjugated bilirubin, out of the hepatocyte. MRP3 is usually expressed in low levels on the basolateral membranes of cholangiocytes and perivenous hepatocytes, but its expression is induced under cholestatic conditions in both animal models and humans. Studies in rats have shown a coordinated increase in MRP3 expression when the canalicular transporter, MRP2 (ABCC2, see later discussion), is mutated.[31]

Organic Solute Transporters α and β

When partnered together, half-transporters organic solute transporters α and β (Octα and Ostβ) are strong exporters of intracellular bile acids.[14,41] They are transcriptionally inducible transporters that act as a sinusoidal "pop-off valves" when intracellular bile acid concentrations increase and exporting across the canalicular surface is not possible (e.g., bile duct obstruction). Both Ostα and Ostβ genes are activated by FXR.[90]

Canalicular Transporters

Bile Salt Export Pump

Bile acid export across the canalicular membrane is the rate-limiting step in the enterohepatic recirculation of bile acids and the primary determinant of bile flow.[86,91] Both newly synthesized and recirculated conjugated bile acids are transported into the bile canalicular space against a steep concentration gradient. This process requires ATP-dependent transport and is accomplished exclusively by the bile salt export pump (BSEP, ABCB11), which is expressed on the apical membrane of hepatocytes. Although BSEP has a high affinity for conjugated bile acids, it has a poor affinity for unconjugated bile acids and accomplishes little transport of these molecules.

In contrast to basolateral transporters, such as NTCP, expression of BSEP is maintained during periods of cholestasis as a coordinated mechanism designed to protect the hepatocyte against the toxic effects of accumulating intracellular bile acid levels. The importance of this process is underscored in patients with the disease *progressive familial intrahepatic cholestasis type 2* (PFIC2; see later), which presents in infancy with severe cholestasis, hepatomegaly, elevated serum bile acids, and aminotransferases, but low serum γ-glutamyltranspeptidase (GGT) levels.[37,91] In patients with PFIC2, mutations in the *BSEP* gene nearly eliminate canalicular *BSEP* expression, dropping biliary bile acid concentrations to nearly 1% of normal but allowing for marked accumulation of bile acids within hepatocytes. Because efflux of bile acids is the driving force for bile flow, this quickly leads to the consequences of cholestasis and liver injury.

As the sole bile acid transporter on the canalicular membrane, it is not surprising that *BSEP* expression is under extensive transcriptional regulation. Bile acids act in a feed-forward manner to increase the expression of BSEP via interactions with the nuclear receptor FXR, leading to enhanced bile acid secretion.[91] This mechanism explains the observation that bile acid feeding in mice results in induction of BSEP RNA and protein. In contrast, FXR−/− mice have low basal BSEP expression levels that fail to respond to a bile acid enriched diet.[78]

Multidrug Resistance-Associated Protein 2

Multidrug resistance-associated protein 2 (MRP2, ABCC2) is another ATP-binding cassette transporter that is found on the canalicular membrane of hepatocytes, as well as on the apical membrane of enterocytes of the duodenum and jejunum and renal proximal tubule epithelial cells. MRP2 mediates the export of glutathione, sulfated and glucuronidated conjugates of drugs, toxins, and bilirubin and is the main mechanism for bile acid–independent bile flow across the canaliculus.[92-96] MRP2 can also transport some unconjugated drugs such as ampicillin, ceftriaxone, methotrexate, irinotecan, and some statins.

As with other transporters, MRP2 RNA expression is severely reduced in animal models of sepsis and inflammation.[79,87] Mice fed diets of CA or ursodeoxycholic acid show enhanced expression of MRP2 RNA, but this is markedly reduced in response to inflammatory cytokines. Inflammation-mediated suppression of MRP2 gene expression is the likely cause of sepsis-associated increases in serum levels of conjugated bilirubin. Mutations in MRP2 lead to reduced bile acid independent flow and cholestasis seen in Dubin-Johnson syndrome (see later).

Multidrug Resistance Protein 3

Multidrug resistance protein 3 (MDR3, ABCB4) is an ATP-cassette transporter that belongs to a group of "flippases" responsible for translocating phospholipids from the outer leaflet of the canalicular membrane into the bile.[97] These phospholipids are critical for the formation of micelles, which protect the biliary tract cells from the detergent actions of bile. Mice deficient for the *MDR3* gene lack phospholipids in their bile, leading to ductular damage and cholestasis.[98] Mutations in the *MDR3* gene in humans result in *PFIC type 3* (see later), which is characterized by high serum bile acid and GGT levels, indicative of biliary tract damage. *MDR3* polymorphisms are associated with some forms of drug-induced liver injury and may be relevant in determining the length of cholestasis in some infants.[37]

ABCG5/G8

The ABCG5/ABCG8 transporters are a functional heterodimers that are coexpressed in the canalicular membrane of the hepatocyte and the apical membrane of the enterocytes. They serve to export cholesterol and phytosterols across both these membranes, thereby excluding them from the circulation. Mutations in either of these half-transporters results in defective biliary sterol transport, leading to the human disease sitosterolemia.[99,100]

CHOLESTATIC DISORDERS

Cholestasis is the clinical manifestation of impaired bile flow, yet practically, it is unlikely that one will ever directly measure this parameter in patients. Levels of serum conjugated bilirubin and bile acids serve as surrogate markers and are thus the most practical measures of cholestasis currently available. Clinically, patients with cholestasis appear jaundiced and often have dark urine and pale stools. With severe liver disease or long-standing

cholestasis, the results of hepatocyte damage are seen as impairments in hepatocellular synthetic dysfunction reflected in hypoalbuminemia, hypoglycemia, coagulopathy, hyperammonemia, impaired drug metabolism, and elevated levels of conjugated bilirubin and serum bile acids. Elevations in alanine aminotransferase and aspartate aminotransferase suggest hepatocellular damage, whereas elevated GGT and alkaline phosphatase levels suggest damage to cholangiocytes.[84]

Patients with cholestasis have defects in bile acid metabolism and the enterohepatic circulation of bile acids. Conversion of primary bile acids to secondary bile acids in the gut is enhanced, as are concentrations of alternatively modified bile acids (glucuronidation and sulfation). The intracellular accumulation of retained biliary constituents, especially hydrophobic bile acids, can be toxic to the liver and other tissues even at submicellar concentrations. Experimental studies have shown that infusions of LCA or feeding of LCA diets to rodents directly causes cholestasis. Exposure to micromolar concentrations of bile acids causes disruption of the lipid bilayer of cell membranes in a detergent-like manner, leading to dissociation of many membrane proteins. These accumulated bile acids can also increase calcium fluxes across membranes, leading to altered mitochondrial function, cell toxicity, and apoptosis. In addition, bile acids are potent modulators of cell signaling processes in the liver, including those linked to growth and the development of hepatocellular carcinoma. In fact subjects with PFIC2 who retain bile acids early in life are at high risk of developing hepatocellular carcinoma before 2 years of age.[101]

Separating cholestatic disorders anatomically into extrahepatic causes (e.g., biliary atresia, choledochal cyst) versus intrahepatic (e.g., Alagille syndrome, genetic or metabolic causes) is a useful first step in identifying the cause of cholestasis.[102,103] Imaging is helpful (ultrasonography) but usually is not definitive, except in choledochal cyst. Determining whether the process is acquired or congenital is the next issue, and here is where much of the difficulty lies in evaluating the infant with persistent elevation of conjugated bilirubin levels. In general, all forms of cholestasis lead to elevated conjugated (direct) bilirubin levels greater than 2 mg/dL and thus warrant consideration for evaluation for underlying liver disease. However, it is well known that sepsis, parenteral nutrition, and certain drugs and infections can lead to liver injury and elevated conjugated bilirubin levels, yet can improve with time. A high level of suspicion (e.g., elevated conjugated bilirubin levels within the first week of life or persistence after the administration of parenteral nutrition ceases) should lead to consideration of a prompt and detailed evaluation for a cholestatic disorder in an infant.[102]

GENETIC DISORDERS

A wide variety of genetic disorders involving intermediary metabolism, storage, bile acid synthesis, and lipid metabolism can lead to liver disease in infancy that can manifest as cholestasis. These include tyrosinemia, glycogen storage diseases, hereditary fructose intolerance, Niemann-Pick disease, amino acidopathies, and mitochondrial hepatopathies. It should come as no surprise that, given the central and essential role that liver metabolic processes play in the health of infants, any mutations in principal genes involved in metabolic pathways can lead to liver impairments and cholestasis.

Progressive Familial Intrahepatic Cholestasis Syndromes

FIC1 Deficiency and PFIC1

Homozygous loss of the *FIC1* gene (ATP8B1), which maps to chromosome 18, results in the disorder termed progressive familial intrahepatic cholestasis type 1 (PFIC1).[104,105] This gene is homologous to P-type ATP-ases, but the ultimate role, or transported substrate, of it remains unknown. The FIC1 protein is expressed mainly in the pancreas and intestine, with small amounts present on the canalicular membrane of the hepatocyte. It is interesting to note that *FIC1* deficiency (Byler disease) leads to reduced bile acid efflux into the canaliculus, yet it is not a bile acid transporter. The FIC1 protein seems to enhance the function of BSEP. One link could be the main transcriptional regulator of the BSEP gene, *FXR*, which is phosphorylated, and activated by mechanisms that include *FIC1* activity.[106]

BSEP Deficiency and PFIC2

Mutations in the primary canalicular bile acid transporter, BSEP (ABCB11), result in progressive familial intrahepatic cholestasis type 2 (PFIC2).[107] Patients typically present in infancy with progressive cholestasis, hepatomegaly, pruritus, elevated serum bile acids and aminotransferases, with normal serum GGT levels.[104] This disease progresses to end-stage liver disease in early childhood (2 to 10 years of age), and currently liver transplantation is the only available curative therapy.[108]

MDR3 Deficiency and PFIC3

The *MDR3* gene product (ABCB4) is responsible for maintaining an appropriate phospholipid concentration in bile, enhancing the formation of micelles that protect the biliary tract from the damaging effects of bile. Mutations in this canalicular transporter gene result in high bile acid:phospholipid ratios, leading to portal inflammation and bile duct proliferation (PFIC3). The high GGT levels seen in this disorder are a marker for the damaged caused by the highly detergent actions of hydrophobic bile acids on the biliary lining.[109,110]

Dubin Johnson Syndrome

Dubin-Johnson syndrome is a rare condition characterized by a benign elevation in serum and conjugated bilirubin levels. In addition to conjugated bilirubin, mutations in the *MRP2* (ABCC2) gene result in decreased transport of other organic anions and conjugated or glutathione-reduced products of drug metabolism.[111,112]

Disorders of Bile Acid Synthesis

The conversion of cholesterol to bile acids involves a 14-step enzymatic cascade.[28] At least seven of these genes have been noted to be mutated in cholestatic disorders that lead to the accumulation of bile acid synthetic intermediate species, liver damage, and low primary bile acid concentrations.[113,114] Many of these diseases are responsive to primary bile acid therapy, thus should be considered in liver disease with low GGT levels.

Acquired Cholestatic Disorders

Sepsis-Associated Cholestasis

As early as 1901, the functional impairment in bile flow associated with sepsis was described. Sir William Osler was among the first to make the connection between nonhepatitic infections with cholestasis and coined the phrase "toxaemic jaundice."[115] With greater recognition of this association, Dunham reported the concept of jaundice as the first presenting sign of sepsis in the neonate in 1933.[116] It has become apparent that sepsis-associated cholestasis does not require direct infection of the liver but is likely mediated by circulating bacterial products (i.e., endotoxin) and cytokines, such as TNF-α and interleukin-1β.[70,87]

In nearly all animal models, administration of endotoxin (bacterial lipopolysaccharides from gram-negative bacteria) results in a profound decrease in bile flow. The mechanism appears to involve the release of inflammatory cytokines from Kupffer cells in response to endotoxin, which in turn act on

receptors on the sinusoidal membranes of hepatocyte. In this manner, endotoxin causes direct effects on hepatocyte transporter trafficking and expression via nuclear receptor-mediated gene regulation.

During sepsis, the liver also plays an important role in the acute phase response, which functions to prioritize the functions of the liver and restore homeostasis to the body.[117,118] This coordinated transcriptional reprogramming in response to cytokines changes gene expression to increase the secretion of many factors that benefit the body as a whole (e.g., protease inhibitors), complement C-reactive peptide (to fight infection), and redirect nutrients to the periphery where they are needed. These cytokines, however, also serve to suppress the function and expression of critical hepatobiliary transporters.

Exposure to endotoxin results in a rapid (15 to 60 minutes) and significant decrease in membrane localization of both MRP2 and BSEP.[79,87] This rapid response appears to be a combination of enhanced degradation and trafficking of receptors to submembranous vesicles. Longer-term exposure to endotoxin and inflammatory cytokines results in activation of the mitogen-activated protein kinase (MAPK) family, which leads to marked alteration in the expression of a wide array of hepatic transporters, prolonging cholestasis.

It is likely that the enhanced susceptibility to inflammation-associated cholestasis in infants is related to hepatic immaturity, which is even more apparent in more premature infants. A common scenario involves the premature infant who has necrotizing enterocolitis, which therefore directly delivers bacteria and bacterial contents from a damaged gut wall to the immature liver. Treatment for this form of cholestasis involves proper attention to sepsis and gut integrity.

Drug-Induced Cholestasis

Because of the innate immaturity of the neonatal liver, infants display a reduced ability to handle drugs and toxic substances compared with older children and adults. They have reduced detoxification capacity and deficient antioxidant mechanisms with which to handle toxic substances. The enhanced susceptibility of infants to the cholestatic effects of certain drugs is not well understood but may be related to immature protective measures against apoptosis and necrosis, an enhanced inflammatory response to damaged tissues and decreased developmental expression of detoxification and transport genes.[37]

Some drugs lead to direct hepatocyte damage (e.g., acetaminophen); others interfere with the formation and flow of bile. Cholestasis is the result of many toxin-related injuries but may have involved a variety of mechanisms, including direct toxicity and necrosis of hepatocytes and cholangiocytes, impaired bile acid transport, and alterations in the viscosity of bile. Cephalosporins are an example of the latter; their high concentrations within bile can lead to the formation of sludge or stones and result in obstructive cholestasis. Interestingly, polymorphisms in ATP8B1 have recently been linked to prolonged cholestasis of the newborn.[119]

Parenteral Nutrition–Associated Liver Disease

The advent of intravenous nutrition in the early 1970s revolutionized the care of critically ill neonates, allowing survival of the most fragile infants in whom enteral feeding was not possible. Research demonstrated that administration of an intravenous solution composed of concentrated glucose solutions containing amino acids, micronutrients, vitamins, and minerals could support both growth and weight gain in children and adults.[120,121] The high glucose load in these early parenteral nutrition preparations caused hyperglycemia and poor immune function, leading researchers to experiment with ways to alter the composition of these solutions to supply a source of non–glucose-based energy and essential fatty acids. Since that time, the addition of a lipid emulsion, comprised of mainly soybean-derived oils rich in omega-6 polyunsaturated fatty acids (PUFA), has become standard practice.

Long-term parenteral nutrition has been associated, however, with the development of acquired cholestasis and progressive parenteral nutrition–associated liver disease (PNALD) in those infants unable to achieve significant enteral nutrition.[120,122-124] The infants most at risk for this disease process are extremely-low-birth-weight infants (<1000 g), infants with congenital abdominal wall and intestinal defects, necrotizing enterocolitis and hypomotility syndromes. The exact etiology of PNALD is not known, but it likely represents a multifactorial process with contributions from immaturity, repeated bouts of sepsis, inadequate bowel function, hydrophobic bile acids, and soy-derived lipid emulsions.[125] Clinically PNALD initially presents with jaundice, conjugated hyperbilirubinemia, and hepatomegaly. As this intrahepatic cholestasis progresses, babies develop hepatocellular dysfunction with elevated transaminases, portal hypertension eventually leading to hepatic failure as evidenced by hypoalbuminemia, elevated clotting times, hypoglycemia, and hyperammonemia. PNALD is a reversible condition in infants capable of achieving enteral nutrition, but the rapid progression from cholestasis to end-stage liver disease in nearly 65% of the most severely affected infants in approximately 4 to 6 months underscores the unique risk to the neonate.

Until the last few years, the only options for parenteral nutrition-dependent infants with end-stage liver disease were liver and/or small bowel transplantation. Recent studies have shown that parenteral fish oil (Omegaven, Fresenius, Bad Homburg, Germany) has been shown to reverse most of the biochemical derangements seen in PNALD.[126,127] This effect is likely due in part to the removal of the offending soy lipid component, likely stigmasterol, and partly as a result of the antiinflammatory effects of omega-3 fatty acids contained in fish oil emulsions.[128] Concern remains, however, that although the conjugated bilirubin is corrected, progressive fibrosis and cirrhosis continues to occur, which is unchanged by parenteral fish oil administration.[129] Further prospective studies, both clinical and laboratory, need to be undertaken to better elucidate the effects of omega-3 fatty acids on hepatic transporter regulation, bile flow, and fibrogenesis.

Work is ongoing into the development of newer lipid emulsions, which may contain a mixture of various fat sources to better balance the risks and benefits of these lipid cocktails. Soy-based oil products are high in omega-6 PUFAs but contain essential fatty acids.[130,131] In vitro work has shown that omega-6 PUFAs can initiate or worsen the inflammatory cascade by increasing TNF-α and interleukin-6 via activation of NF-κB and may also have immunosuppressive features. Fish oil emulsions are high in omega-3 PUFAs, eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) (reviewed in references 132 and 133). Studies in animal models and humans characterized the antiinflammatory properties of omega-3 PUFAs, although others have shown an increase in collagen deposition and fibrosis. Medium chain triglyceride oil originates mainly from palm kernel or coconut oils and contains less omega-6 PUFAs than soybean derived product. The metabolism of MCT is partially independent of the carnitine pathway, allowing for more rapid plasma clearance, metabolism, and energy utilization without accumulating in the liver. Olive oil is high in omega-9 PUFAs and α-tocopherol, a major antioxidant, and may be beneficial in patients at risk for oxidant damage or stress.

The future of intravenous lipid emulsion therapy may rest on a basic composition, which can then be customized with the addition of different oil components to benefit a particular patient population.

SUMMARY

The anatomy of the liver and the microanatomy of the hepatic lobule direct the abilities of the liver to act as a bioactive filter and modifier as well as a bile secretory organ. The formation of bile is mainly determined by active transport of bile acids and other biliary solutes across the canalicular membrane of the hepatocyte. Alterations in the expression of both sinusoidal and canalicular transporters directly affect bile flow and composition, with clinical consequences manifesting as cholestasis and hyperbilirubinemia in the infant. Neonates are particularly prone to develop cholestasis, likely because of an inherent developmental immaturity of the multiple components necessary to form bile (mainly the enterohepatic circulation of bile acids, hepatobiliary transport, and intermediary metabolism), combined with relatively poor hepatoprotective responses. Recently recognized patient-specific polymorphisms in genes integral to bile formation—transporters, synthetic enzymes, and nuclear receptors—may also contribute to neonatal liver disease. Recognition that infants with seemingly "innocent" cholestasis may rapidly develop cirrhosis and even end-stage liver disease can only help clinicians in determining the timing of potentially life-saving therapies.

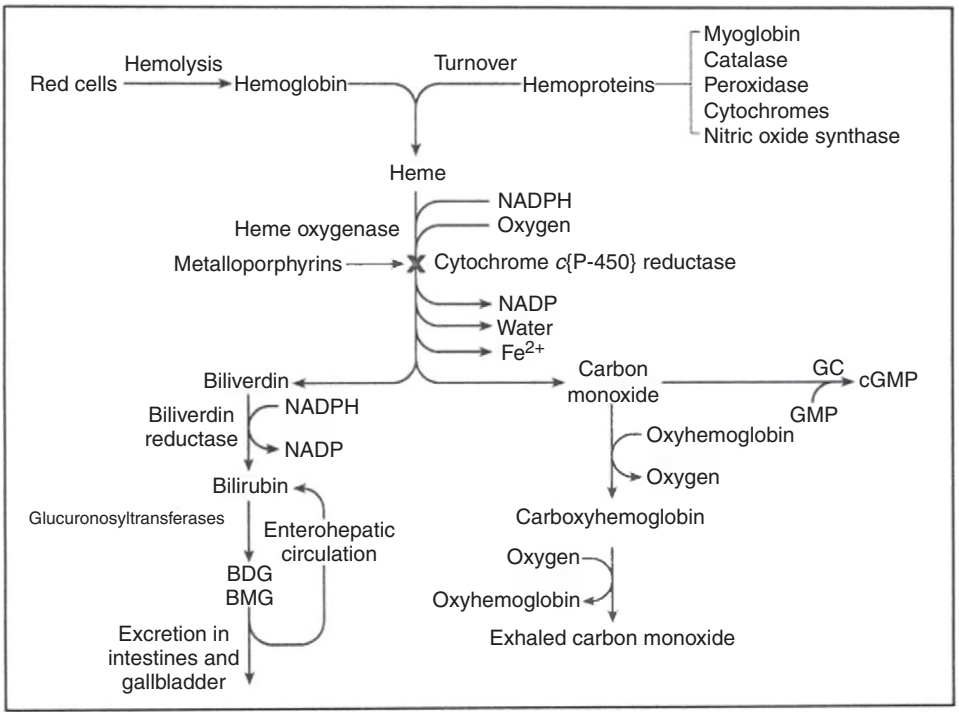

Figure 121-1 Metabolic pathway for the degradation of heme and the formation of bilirubin. *(From Dennery PA, Seidman DS, Stevenson DK: Neonatal hyperbilirubinemia,* N Engl J Med *344:581-590, 2001.)*

to albumin in the extracellular fluid and the plasma.[18] The albumin-bilirubin complex is in equilibrium with a very low concentration of unbound or free bilirubin, generally found in nanomolar concentrations at or below the limits of water solubility for unconjugated bilirubin.[18,19]

Albumin delivers bilirubin to fenestrated sites in the hepatic sinusoids within the space of Disse,[19] probably by passage of the albumin-bilirubin complex through the fenestrae and dissociation of bilirubin from albumin at the hepatic cell surface. Intracellular transport of bilirubin is facilitated by a cytosolic form of glutathione *S*-transferase, probably GSTA-2 (*g*lutathione *S*-*t*ransferase *a*lpha-2),[20,21] which was assigned the generic designation *ligandin* when first identified.[22] The ligandin-mediated function of intracellular transport appears to be shared between bilirubin and other hepatically metabolized molecules of low water solubility or similar structure and molecular weight.[21-23] It is not clear whether the initial passage of bilirubin across the basolateral portion of the hepatocyte membrane is carrier-mediated, contact-mediated, or caused by diffusion of free bilirubin.[19] Recent investigations have implicated still other hepatocellular membrane–associated polypeptides, notably OATP1B1 or SLC21A6, as specific or collaborative organic anion transporters in the sinusoidal or basolateral membrane uptake of bilirubin.[24,25] Although several investigators have identified a potentially important role for these transport polypeptides in bilirubin uptake and for their mutations in the risk for unconjugated hyperbilirubinemia,[24-27] a transfection study of SLC21A6 in HeLa and HEK293 cells did not support a role for it as an exclusive transporter of bilirubin.[28] Instead, transporters of the OATP (*o*rganic *a*nion–*t*ransporting *p*olypeptide) or SLCO (*sol*ute *c*arrier, *o*rganic) family may be collaborators with other transporters in a relay of extracellular to intracellular transport functions. Lin and ssociates[27] have recently estimated the frequency of coexpression for glucose 6-phosphate dehydrogenase (G6PD), OATP, and glucuronyl transferase polymorphisms in a reference population sample. To date, specific syndromic deficiencies of hepatic bilirubin uptake transporters have not been clearly delineated or genetically categorized.

CONJUGATION OF BILIRUBIN

Bilirubin is transported within the hepatocyte to the smooth endoplasmic reticulum, where its carboxyl groups are conjugated with glucuronic acid. Conjugation of bilirubin is catalyzed by bilirubin UDP-glucuronyl transferase (UDPGT-1),[29] one of a family of enzymes that catalyze the hepatic glucuronidation of a number of endogenously produced or exogenously introduced small molecules, such as bilirubin, barbiturates, and phenols.[30] Conjugation of bilirubin and similar small molecules increases their aqueous solubility in preparation for their canalicular transport to the bile.

The first step in the conjugation of bilirubin is formation of bilirubin monoglucuronide, which is sufficiently soluble for canalicular transport and in some instances may be the predominant form of conjugated bilirubin in fetal and early neonatal life.Addition of another molecule of glucuronic acid to bilirubin's second carboxyl group forms bilirubin diglucuronide, the fully conjugated form of bilirubin and the main component of "direct-reacting" bilirubin.

GENETIC VARIATIONS IN BILIRUBIN CONJUGATION

The gene that governs bilirubin conjugation, *UDPGT1,* is located on the long arm of chromosome 2 (at 2.q37)[31] and is part of a gene complex at that locus[29] with a common promoter region and a number of shared and individualized exons that catalyze glucuronidation of a variety of types of small molecules.[32] *UDPGT1* is the member of this gene family responsible for the conjugation of bilirubin.

More than 50 mutations and polymorphisms in the gene for UDPGT-1 have been identified, many of them in association with clinical manifestations of severe, prolonged, or recurrent unconjugated hyperbilirubinemia.[33] In general, the identified mutations have an autosomal recessive inheritance pattern, but the combined effects of heterozygosity for different mutations may produce clinical disease. Several genetic lesions of UDPGT-1 have distinctive clinical phenotypes, whereas others show variable patterns of unconjugated hyperbilirubinemia. The age at onset, severity, and duration of clinical jaundice may be related to (1) the rate of bilirubin production, (2) nutritional status, (3) developmental regulation of liver functions, and (4) intercurrent illness, as well as to specific mutations in the conjugating enzyme. All mutations and polymorphisms of clinical importance can cause severe or prolonged neonatal jaundice, especially if the rate of bilirubin production is increased by hemolysis.

Several *clinical syndromes* (or phenotypes) are associated with specific types of UDPGT-1 mutations. Other phenotypes of prolonged or severe hyperbilirubinemia associated with compound heterozygosity for various polymorphisms, or with the mixed effects of subtle hemolysis and inefficient conjugation, are not so easily classifiable according to the traditional terminology of recognized hyperbilirubinemia syndromes.

Examples of recognized syndromes are Crigler Najjar syndrome, types I and II, and Gilbert disease. Type I Crigler-Najjar syndrome is an autosomal recessive disorder in which no functioning UDPGT-1 is produced. Several nonsense mutations that terminate synthesis or delete key amino acid sequences of the enzyme have been described.[33] The most common variant (also found in the congenitally jaundiced Gunn rat) appears to be a single guanosine deletion at nucleotide 1206, resulting in a frame shift and deletion of 115 to 150 amino acids from the carboxyl-terminal (C-terminal) end of the protein. This defect prevents the binding of glucuronide for conjugation with bilirubin and related compounds. Severe, prolonged unconjugated hyperbilirubinemia begins in infancy and persists throughout life, usually with bilirubin levels of 20 to 45 mg/dL or higher, with eventual signs of central nervous system injury in nearly all cases. The nonsense or "stop" codons causing type I Crigler-Najjar syndrome preclude pharmacologic induction of the enzyme, so gene replacement and liver transplantation are the only effective long-term therapies.

Gilbert syndrome is a milder form of prolonged or recurrent unconjugated hyperbilirubinemia with occasional severe neonatal hyperbilirubinemia, usually followed by peak bilirubin levels of approximately 1 to 6 mg/dL, but with persistence or recurrences of more severe hyperbilirubinemia in older children and adults with the syndrome.[33] The most common genotype associated with the classic form of Gilbert syndrome is that involving an insertion of two extra bases (TA) in the 5′ promoter region of the gene for UDPGT-1, resulting in a sequence of A(TA)7TAA instead of the normal A(TA)6TAA.[29,30] A high carrier rate for this polymorphism has been documented in some families and ethnic groups, and polymorphisms incorporating other "abnormal" sequences of between 5 and 8 TA repeats in the TATAA portion of the promoter have been reported in affected patients with Gilbert syndrome and their family members.[34]

A variant form of the syndrome is caused by a substitution of adenine for guanine at nucleotide 211 in exon 1, with a glycine-to-arginine substitution in the amino terminus (N-terminus—the bilirubin-binding region—of the enzyme molecule. This and several less common substitution mutations are associated with prolonged breast-feeding jaundice and are responsible for a variant of Gilbert syndrome in Japanese kindreds, most members of which show no mutations in the TATAA sequence.[36] Newborns with Gilbert syndrome mutations may have severe hyperbilirubinemia and even kernicterus, especially with a concurrent disorder such as ABO incompatibility or G6PD deficiency.[35] Adults with this syndrome have mild recurrent jaundice, often exacerbated by intercurrent illness such as viral infections. Enzyme synthesis and activity can sometimes be increased and bilirubin levels decreased by administration of phenobarbital, for which a drug-responsive site is located in the promoter region of the gene.

A diagnosis of Crigler-Najjar syndrome, type II, is sometimes assigned to patients with a heterogeneous group of conjugating defects resulting from a number of single-site missense or insertion mutations that may retard synthesis of the enzyme or impair the glucuronide binding of its carboxyl terminus (C terminus).[33,37,38] Although small amounts of bilirubin conjugates may be found in the hepatocytes and bile of these patients, unconjugated hyperbilirubinemia may be severe in the newborn period and persist or recur in adulthood. Peak or intermittent bilirubin levels usually are 6 to 20 mg/dL but may be higher in newborn infants. Insertion or substitution mutations in exons 1, 2, 4, and 5 have been associated with the clinical diagnosis of type II Crigler-Najjar syndrome. Some persons with this phenotype have compound heterozygosity for two or more recessive mutations at different exons. In some patients, enzyme synthesis or activity may be induced or enhanced by phenobarbital, with an increase in bilirubin conjugates and a decrease in plasma levels of total and unconjugated bilirubin.

Persons heterozygous for two or more of the mutations associated with Crigler-Najjar or Gilbert syndrome may have neonatal or subsequent jaundice of intermediate severity, sometimes responsive to enzyme induction with phenobarbital. Exact classification of these mixed, heterozygous cases of unconjugated hyperbilirubinemia as manifestations of Gilbert or Crigler-Najjar syndrome may be difficult using clinical criteria, or even by determination of genotype in some patients. One possible approach would be to classify mutations that impair the promoter region, N-terminal binding of bilirubin, or initiation of enzyme synthesis as "Gilbert type" defects, and those that impair glucuronide binding or completion of C-terminal synthesis as Crigler-Najjar type defects. As an alternative to the classification of hereditary hyperbilirubinemia into two or three eponymous "syndromes," more detailed description and categorization of the specific types of gene defects and their physiologic consequences may ultimately be more useful.

HEPATIC AND ENTERIC EXCRETION OF BILIRUBIN

Conjugated bilirubin is excreted into canalicular bile by way of the multispecific organic anion transport (C-MOAT) system located in the canalicular membrane within the apical region of the hepatocyte.[39] The C-MOAT system shows genetic and structural homology with the multidrug resistance (MDR) family of proteins,[40] and with glutathione *S*-transferase,[41] but incorporates a different glutathione *S*-transferase isozyme from that involved in basolateral intracellular ligandin transport of unconjugated bilirubin.

In the small bowel, bilirubin may be transiently deconjugated by bacterial and brush border enzymes before further metabolism to other heme-derived compounds. Such metabolism occurs mainly in the large bowel and requires bulk transport of bile products by peristalsis and additional changes in the molecule by bacterial enzymes. Because bilirubin β-glucuronidase is indigenous to the small bowel brush border in the newborn, some bilirubin in the small bowel is deconjugated (by β-glucuronidase), reabsorbed at the brush border, and recirculated to the blood in a loop of excretion and reabsorption known as the enterohepatic recirculation of bilirubin.[42,43] Premature infants, surgical patients not being fed, and some infants poorly responsive to

phototherapy may have protracted unconjugated hyperbilirubinemia associated at least in part with a large enterohepatic recirculation of bilirubin before they are fully fed or fully colonized by normal intestinal flora.

Maturation of the hepatic conjugating system, development of adequate canalicular transport, elimination of bile products in the stool, and an eventual developmental close matching of the rates of bilirubin production and excretion allow plasma unconjugated bilirubin to decrease to normal adult levels in most newborns within 2 to 4 weeks or less. Persistent hyperbilirubinemia results if the rate of bilirubin excretion fails to match its rate of formation and production.

122 Mechanisms of Bilirubin-Induced Brain Injury

Thor Willy Ruud-Hansen

Jaundice is a common transitional phenomenon in newborn infants and was purportedly first described in the Chinese textbook *On the Origins and Symptoms of Diseases* written in 610 AD.[1] In Western medical literature one of the earliest references to this phenomenon may have been in Bartholomaeus Metlinger's book from 1473 on the raising of children.[2] It is not clear when the association between neonatal jaundice and yellow staining of the brain was first noticed, but in work he did for his dissertation in 1847 the French medical student Jacques François Édouard Hervieux described jaundice of the brain during autopsy in 31 of 44 infants who had been noted to be jaundiced at the time of death.[3] Hervieux described some brains as being uniformly yellow, whereas in others some regions were more heavily stained. However, the staining phenomenon later known as *kernicterus* was first described in 1875 by Johannes Orth, who had performed an autopsy on an infant who died at 2 days of age with very intense jaundice.[4] The actual term *kernicterus*, the German word for jaundice of the nuclei (or basal ganglia), was coined by another German pathologist, Christian Georg Schmorl, in a landmark paper in 1904.[5] It is noteworthy that among the 120 jaundiced infants he had autopsied he found 114 jaundiced brains, but of these only six exhibited a pattern of more intense yellow color of the basal ganglia and medulla oblongata, which gave rise to the term. As will be discussed later, during the more than 100 years that have passed since then, the explanation for this localization phenomenon has eluded medical researchers.

The clinical picture in the infants who died included, in addition to severe jaundice, opisthotonos, seizures, spasticity, severe hypotonia, fever, high-pitched cry, and poor sucking. Arkwright[6] may have been the first to describe the acute picture of kernicterus. During the first half of the 20th century it became clear that the pathoanatomic finding of jaundiced brain nuclei had a clinical correlate in infants who survived extreme jaundice. These manifestations, as summarized by Byers and colleagues in 1955,[7] appeared to evolve over time. Thus during the first weeks to 2 to 3 months of life, hypertonicity, opisthotonos, absent Moro reflex, high-pitched cry, and poor feeding dominated the clinical picture. From then on until approximately 2 years of age marked delay of motor development became obvious, with decreased muscle tone, hyperreflexia, and persistence of immature postural patterns. Athetosis could begin toward the end of the second year of life but might not become apparent until 8 to 9 years of age. The degree of athetosis was quite variable, from hardly detectable except to the trained observer, to completely disabling athetosis. Some degree of hearing loss was present in most patients. Paresis of upward gaze appears to be fairly obligate in kernicterus but rare in other types of cerebral palsy. Intellectual deficits were not an obligate feature, and only a minority of the patients had developmental delay. This description is surprisingly compatible with the most recent discussions of kernicterus.[8] Recently, with the recognition that the long-term sequelae of bilirubin encephalopathy may present a many-faceted picture, a set of diagnostic criteria was proposed, which takes into consideration both the clinical findings (classified as isolated, mixed, and classic), the evolution over time (classified as acute, subacute, and chronic), and the severity (mild, moderate, and severe).[9] Time will show whether this tool will be helpful as far as increasing understanding of the processes and mechanisms involved in kernicterus.

Although it has been discussed whether the yellow staining seen in the brain of the infants described in the preceding paragraphs might be a phenomenon caused by other events, and where bilirubin just happens to be the coloring substance, there appears to be general agreement among present-day bilirubin researchers that bilirubin and its toxic influence on brain cells are the primary and causative factor. However, as yet no agreement exists on which mechanism (or mechanisms) might mediate brain bilirubin toxicity. The purpose of this chapter, therefore, is to give an overview of the research that has been carried out on bilirubin effects in and interactions with the brain and to discuss the relative merits and weaknesses of the various theories on the "basic mechanism of bilirubin neurotoxicity."

KERNICTERUS: WHAT IT IS AND WHAT IT IS NOT

Kernicterus strictly speaking refers to the pathoanatomic finding of intense yellow coloring of the basal ganglia superimposed on a paler yellow background as first described by Orth and Schmorl.[4,5] Areas that are found to have this staining include, in descending order of frequency, the hippocampus, thalamus, hypothalamus, corpus striatum, medulla, olives, pons, and dentate nucleus.[10] In these areas ultrastructural findings include membrane alterations, dense cytoplasmatic bodies thought to represent degenerated mitochondria, and calcium granules.[11] Changes of this nature are likely to be irreversible and to represent the pathoanatomic correlate of chronic bilirubin encephalopathy, also known as kernicterus. Thus a discussion of the mechanisms of bilirubin-induced brain injury must necessarily include events that cause or are associated with cell death.

However, evidence is ample that bilirubin has effects on the brain that are likely to be transitory. It is well described in the literature that neonates with significant jaundice exhibit lethargy or drowsiness, hypotonia, and feeding problems.[12] Evoked response studies, both in human infants and in experimental animals, have given more objective evidence of such apparently reversible toxicity,[13-19] although permanent changes have been found in some.[20] An increased incidence of apneas in jaundiced premature infants as compared with less jaundiced controls appears to abate after the first week of life and to be associated with the progression of changes in the auditory brain stem response.[21] This type of reversible toxicity cannot be called kernicterus, yet there is little doubt that it reflects bilirubin effects on the brain. At present no agreement exists on the terminology that should be used to describe this phenomenon.

It is not clear whether acute, and subsequently chronic, kernicterus represents the extreme end of a continuum, where the other end is represented by the slightly somnolent, moderately jaundiced term newborn whose somnolence improves in a couple of days, or whether separate and distinct mechanisms are involved in cell death versus apparently milder perturbation of neuronal signaling.[22] Recent data suggest that even

moderate degrees of hyperbilirubinemia may have discernible long-term effects on behavior,[23] and questions relating to the sensitivity and specificity of the tools used to study the long-term effects of neonatal jaundice will have to be resolved before we can be certain as to what is reversible. This chapter therefore discusses bilirubin-induced brain injury in a wide sense, including bilirubin effects on processes that may not result in cell death and residual damage. Whether such effects may permanently alter cell functions without causing cell death is at present not known.

BILIRUBIN CHEMISTRY AND SOLUBILITY

Certain phenomena relative to bilirubin chemistry and solubility appear inextricably linked to the questions of bilirubin neurotoxicity and therefore are briefly discussed here. The main bilirubin isomer in humans is bilirubin-IXα (Z,Z), which exists either as a charged dianion or as bilirubin acid. In dianion the presence of eight hydrophilic groups imparts some water solubility at neutral pH, whereas in the acid form the presence of intramolecular hydrogen bonds results in near insolubility in water.[24,25] The hydrophobic bilirubin-IXα isomer appears to be responsible for the toxic effects, whereas the water-soluble isomers are thought to be nontoxic.[26-29] Bilirubin becomes water soluble when it is conjugated in the hepatocytes and when bound to albumin for transport in serum. The isomerization of the bilirubin molecule that occurs during phototherapy also results in molecules that are more polar.[30]

Bilirubin is transported in plasma bound to albumin[31] and as such probably does not cross the blood-brain barrier, assuming the latter is intact.[32] However, a minute amount of bilirubin (in the nanomolar range) is always present in plasma as "free" or unbound bilirubin. According to the "free bilirubin theory," it is the unbound bilirubin molecule that enters the brain to produce neuronal injury.[33] Increased concentrations of unbound bilirubin in the blood will, by the laws of equilibrium, shift more bilirubin into the tissues, including the brain. Factors that are associated with increased concentrations of unbound bilirubin, and thus with risk for increased bilirubin entry into brain, include altered albumin characteristics[34,35] or the presence of exogenous or endogenous binding competitors.[36-38] Of these, bilirubin-displacing drugs (e.g., sulfisoxazole) previously used to treat sick infants have had a significant impact. Bilirubin IXα (Z,Z) is an amphipathic molecule but, with respect to membranes, behaves as lipophilic; thus it binds to and crosses phospholipid membranes.[39-41] It is presumably this characteristic that enables bilirubin to cross the intact blood-brain barrier and enter the brain.[42] However, the blood-brain gradient is high; in control animals with an unperturbed blood-brain barrier, the brain bilirubin concentration is only 1% to 2% of the serum bilirubin concentrations.[43-45] Bilirubin experts disagree on the issue of bilirubin solubility, leading to claims that many experiments on bilirubin toxicity have been carried out at concentrations that are unphysiologic and that the results are thus irrelevant.[46,47] This argument appears to rely exclusively on solubility figures from a single publication.[48] At this point the discussion about relevant concentrations of bilirubin for in vitro studies should probably still take into account the actual concentrations of bilirubin found in the brains of infants with kernicterus,[49] as well as those found in experimental animals with clinically relevant levels of serum bilirubin.[50-53]

THE BLOOD-BRAIN BARRIER AND BILIRUBIN-BRAIN KINETICS

Entry of bilirubin into brain is a sine qua non for neurotoxicity. Although the relative lipophilicity of bilirubin allows some passage through an intact blood-brain barrier, this occurs to a lesser degree than would be expected of a truly lipophilic molecule.[54] A recent review lists the characteristics of molecules that are able to cross the blood-brain barrier in significant amounts.[55] They must have a molecular weight (MW) <400 daltons, be lipid soluble, and not be a substrate for an active efflux transporter at the blood-brain barrier such as phosphoglycoprotein (P-gp). Bilirubin has an MW of 585, its lipophilicity depends on the isomeric form, and, as will be discussed later, it is a substrate for P-gp. These characteristics may help to explain the limited entry of bilirubin into brain in most circumstances. The blood-brain barrier may be more permeable to bilirubin in neonates than in more mature subjects, whereas albumin permeability is equally restricted in both young and old subjects.[56-58] Recent work with P-gp seems to support the concept of an "immature" blood-brain barrier as far as its role in keeping bilirubin out of the brain.[59]

An unstable state of equilibrium appears to exist between bilirubin in the blood and bilirubin in the brain, and this equilibrium is influenced by a number of factors (**Figure 122-1**). Bilirubin is bound to albumin, apparently at a primary and a secondary binding site with a high affinity, such that the concentrations of unbound bilirubin in serum are very low.[24,31,38] An epidemic of kernicterus occurred in the 1950s and was shown to be related to the use of sulfisoxazole.[60] In subsequent years it was shown that many drugs compete with bilirubin for binding to serum albumin.[61] Bilirubin displacers are now well recognized to increase the risk for bilirubin neurotoxicity in jaundiced infants, and this has significantly influenced the use and choice of drugs in neonatal medicine. Numerous animal studies show that the blood-brain equilibrium for bilirubin is shifted toward the brain when bilirubin-displacing substances are administered.[32,37,43-45,53]

Bilirubin may interact with biologic membranes in a way that affects their function[62-64]; thus it seems reasonable to ask whether bilirubin could also affect the blood-brain barrier. Bilirubin toxicity to glial cells might also conceivably translate into effects on blood-brain barrier function.[65,66] Some studies have addressed the question of bilirubin effects on the blood-brain barrier directly and found that preexposure to bilirubin increased the permeability of the blood-brain barrier both to a dye[67] and to bilirubin itself.[68]

P-gp is a member of the adenosine triphosphate (ATP)–binding cassette superfamily of membrane transporters. These transporters are expressed both in normal and in diseased tissues and appear to limit the entry of xenobiotics into cells.[69] Bilirubin is a substrate for P-gp and may also inhibit P-gp function.[70,71] This has several interesting implications for the interaction between bilirubin and brain. Thus brain bilirubin content in P-gp knockout mice after an IV bilirubin bolus was almost two-fold higher than in wild-type mice.[72] Drugs known to inhibit P-gp significantly enhanced bilirubin entry into rat brain after an IV bilirubin bolus.[73] P-gp function appears to be phosphorylation regulated, and phosphorylation has been linked to enhanced activity of P-gp.[74,75] This provides a possible link to understanding how bilirubin may increase blood-brain barrier permeability,[67,68] as bilirubin has been shown to inhibit phosphorylation of a wide range of protein-peptide substrates.[76,77]

Other organic anion transporters, such as multidrug resistance–associated proteins (MRPs), have also been hypothesized to play a role in limiting bilirubin accumulation in the cerebrospinal fluid.[78] Preliminary data appear compatible with a role for MRP1 (ABCC1) in keeping bilirubin out of brain cells.[79] In astrocytes bilirubin appears to mediate up-regulation of MRP1, resulting in decreased sensitivity to bilirubin toxicity.[80] In mouse embryo fibroblasts, intracellular accumulation of [^{3}H]bilirubin, as well as cytotoxicity, were significantly greater in cells from MRP1 knockout mice than from wild-type

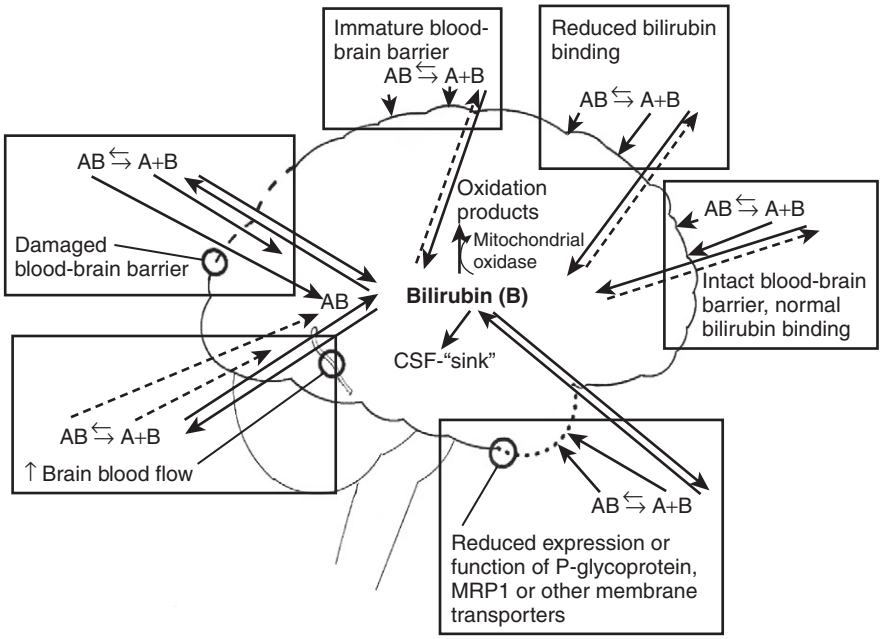

Figure 122-1 Factors that modulate the bilirubin-brain equilibrium. A number of factors can modulate bilirubin uptake into and clearance from brain. These include the avidity of bilirubin binding to serum albumin, the presence of competitors for the albumin binding site, immaturity or other factors that may affect blood-brain permeability, the presence and activity or expression of membrane pumps in the blood-brain barrier, and brain blood flow. *A,* Albumin; *AB,* albumin-bound bilirubin; *B,* (unbound) bilirubin.

controls.[81] The implications of these findings for blood-brain bilirubin transfer remain to be elucidated.

Opening of the blood-brain barrier produced by radiation, asphyxia, hyperosmolality, and hypercarbia has been shown to increase bilirubin entry into brain in a number of studies.[32,44,45,82,83] The latter three conditions may occur quite frequently in sick neonates and thus appear to be relevant for the clinical management of jaundice in infants in the neonatal intensive care unit. In hypercarbia most, but not all, of the bilirubin enters brain as the unbound molecule; in hyperosmolality significant entry of albumin into brain also occurs; and in the jaundiced individual a large proportion of this albumin will carry bilirubin.[32] In hypercarbia the acute entry of bilirubin into brain is increased relative to control conditions, but clearance is also rapid.[45] In hyperosmolality it appears that bilirubin remains in the brain significantly longer than under control conditions.[45] Whether such prolonged exposure is associated with increased risk for toxicity is speculation, but some clinical data suggest that not only the level of serum bilirubin but also the duration of hyperbilirubinemia are associated with risk for neurologic sequelae.[84]

Opening of the blood-brain barrier may contribute to or exacerbate bilirubin neurotoxicity.[82,83,85] In vitro studies suggest that albumin blocks the toxic effects of bilirubin when present in equimolar concentrations.[63,86,87] Opening of the blood-brain barrier permits the entry of albumin-bound, as well as unbound, bilirubin, and, because the equilibrium balance in serum is heavily tilted toward albumin-bound bilirubin, the observation of increased toxicity in vivo is perhaps somewhat surprising. Signs of toxicity may, however, best be predicted by total brain bilirubin content, and enhanced binding to albumin appears to be protective.[83]

The role of brain blood flow may best be illustrated by the studies of hypercarbia, which results in increased brain blood flow.[32,45,52,58,88] These studies show that increased brain blood flow in experimental animals is associated with increased entry of bilirubin into brain. One may speculate that with increased brain blood flow each circulating bilirubin molecule passes the blood-brain barrier more often and thus has more opportunity to equilibrate with bilirubin in the brain in a situation where a blood-to-brain concentration gradient exists.

The question of how bilirubin localizes to the basal ganglia will be addressed here, although whether the localization phenomenon is related to bilirubin entry into or clearance from brain is not at all clear. The predilection of bilirubin for certain brain regions has been described earlier and was primarily based on visual inspection of brain slices. However, more objective, albeit limited, data are available from human subjects. Thus Claireaux and colleagues[49] extracted bilirubin from the brains of four infants who died with severe jaundice. They found approximately 35 nmol/g in the nuclear regions and 8 nmol/g in the remainder of the brains, speculating that bilirubin concentrations may have been several-fold higher in the most intensely stained areas of the nuclei.

Attempts to recreate this staining pattern in animal models have met with variable success. Burgess and colleagues found regional differences in bilirubin concentration in piglets that had received a [^{3}H]bilirubin infusion plus either hypercarbia or hyperosmolality.[52,89] The question remains, however, whether these differences were due to variations in bilirubin entry into or disappearance from brain, or whether they might be related to redistribution or binding to specific tissue or cell elements. Cannon and colleagues[90] examined regional bilirubin concentrations in 15- to 19-day-old Gunn rat pups pretreated with sulfadimethoxine and found significant differences. Thus the cerebellar bilirubin concentration was 32 nmol/L, whereas the brain stem and cortex contained 18 nmol/L and 8 nmol/L, respectively. These numbers are surprisingly similar to those previously found in human brains.[49] The brain bilirubin concentrations were higher in the male pups, suggesting that sex may modulate brain bilirubin uptake or clearance. However, no clear explanation was given for how these regional differences arose, nor could they be said to mimic a typical kernicteric pattern. Attempts to recreate a kernicteric staining pattern in

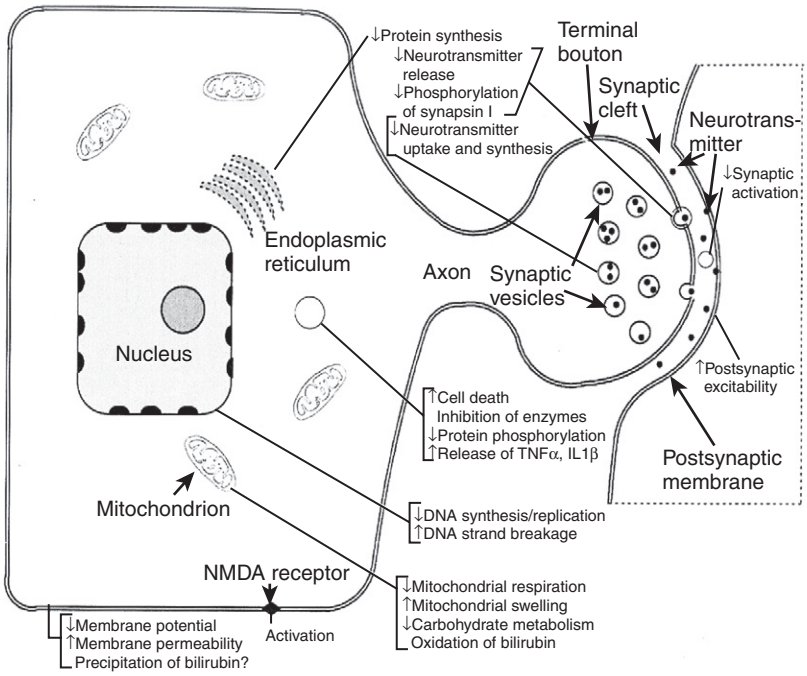

Figure 122-2 Interactions of bilirubin with cells and cellular processes. Bilirubin has been shown to interact with many different cellular processes and reactions. Although several of the studies have been performed in nonneuronal cells, in this figure these processes and reactions are depicted in a schematic and simplified neuron.

Sprague-Dawley rats through infusion of bilirubin and manipulations of bilirubin binding, blood-brain barrier opening, and brain blood flow have not been succesful.[32,43-45] These studies also failed to show interregional differences between bilirubin uptake into or clearance from brain. Other studies have examined bilirubin metabolism in brain, and, although differences were found, they did not conform to or explain the staining pattern of kernicterus.[91]

Hemolysis is believed to be implicated in the mechanisms underlying bilirubin neurotoxicity, and this is reflected in most therapeutic guidelines, which call for more aggressive management in the presence of hemolysis.[92,93] However, the mechanisms underlying this putative increased toxicity are not known. In rats with a chemically induced hemolytic anemia, neither entry into nor clearance of bilirubin from the brain was different from that in control animals after an IV bolus of bilirubin.[94] This obviously does not model the immunologic aspects of anemia in infants with blood group incompatibility and thus cannot discount the possibility that blood-brain barrier permeability may be affected by such mechanisms. However, immunology is not involved in the hemolysis of glucose-6–phosphate dehydrogenase deficiency, where increased risk for kernicterus is well described.[95] The question of whether the products of hemolysis, aside from bilirubin, could exacerbate the neurotoxic effects of bilirubin, appears not to have been the subject of study.

INHIBITION-UNCOUPLING OF OXIDATIVE PHOSPHORYLATION: "THE CLASSIC STORY"

The first experimental studies of bilirubin toxicity were performed in 1954[96] and showed that bilirubin inhibited respiration in a rat brain homogenate. In rat liver mitochondria in vitro, 300 μmol/L bilirubin partially inhibited respiration, and phosphorylation was nearly completely inhibited.[97] The interpretation was that bilirubin uncoupled oxidative phosphorylation. This, for many years, was the prevailing theory as far as the basic mechanism of bilirubin toxicity. A number of in vitro studies from recent years also lend some credence to the role of mitochondria in bilirubin toxicity. Thus bilirubin can affect the mitochondrial membrane, resulting in increased membrane permeability, decreased membrane potential, release of cytochrome *c*, and triggering of apoptosis.[98-102] A cartoon depicting some of the many different effects and interactions of bilirubin with cells and cellular processes is shown in Figure 122-2.

However, these data do not unequivocally confirm a role for the mitochondria as primary targets of bilirubin toxicity in vivo. Thus early electron microscopic observations in Gunn rats suggested that the mitochondrial changes might result from earlier effects in the cytoplasm.[103] A comparison of the effects of bilirubin with known uncouplers of oxidative phosphorylation and inhibitors of reduced nicotinamide adenine dinucleotide oxidase on L-929 cells in culture was more indicative of membrane perturbation than of toxic effects on the respiratory chain.[63] Studies in newborn pigs failed to show changes in cerebral oxygen, glucose, and lactate metabolism that would be compatible with perturbation of mitochondrial function.[104] Furthermore, bilirubin has been found to perturb neurotransmitter metabolism in permeabilized synaptosomes in vitro in the presence of high ATP, so that depletion of endogenous ATP could not have contributed to the observed effects.[105] However, some in vivo support exists for the role of mitochondria. Thus ultrastructural changes are found in the mitochondria of Gunn rats with bilirubin encephalopathy.[103,106] Rats with infusion-induced hyperbilirubinemia exhibited significantly decreased phosphocreatine and ATP in the brain, but only after opening of the blood-brain barrier with hyperosmolality.[107] In a recent study of magnetic resonance spectroscopy in infants with severe neonatal jaundice, one of five infants had an abnormally high lactate–*N*-acetyl aspartate ratio.[108] This was the only infant who also exhibited abnormalities in the basal ganglia on magnetic resonance imaging and one of two who demonstrated neurologic abnormalities during follow-up. The elevated lactate–*N*-acetyl aspartate ratio may have been the result of changes in mitochondrial function.

However, in another study in six infants with extreme jaundice, of whom four were neurologically abnormal at 1 year of age, none demonstrated elevated brain lactate levels.[109] In fact, the findings in this study were more compatible with changes in *N*-methyl-D-aspartate (NMDA) receptor sensitivity. For bilirubin to perturb mitochondrial function, it needs to get there in concentrations sufficient to cause toxicity. Whether this be the case has only been addressed by one study, in which [^{3}H]bilirubin was given as an IV bolus to rats. The animals were killed after 10 and 30 minutes, respectively, and their brains subjected to subcellular fractionation.[110] Although absolute values for bilirubin could not be computed, the bilirubin content relative to protein in mitochondria was much less than in the cytoplasm and membrane fractions. In conclusion, whether the mitochondria are the primary targets for bilirubin neurotoxicity remains a theory for which some experimental support exists, but a number of studies point in other directions.

INTERACTION WITH MEMBRANES

Evidence is ample that bilirubin may interact with biologic membranes.[62-64] Bilirubin content in rat brains subjected to subcellular fractionation was higher in the myelin (membrane) compartment than in any of the others.[110] In brain slices exposed to [^{3}H]bilirubin, bilirubin appeared to bind more avidly to neurons, suggesting a particular affinity for neuronal cell membranes.[111] An important question regarding the interaction of bilirubin with membranes is whether such interaction is primarily a phenomenon of physicochemical binding with perturbation of membrane integrity and potentials or is associated with effects on membrane-located enzymes, pumps, or transporters. Furthermore, it is unknown whether the putative effects of bilirubin on membranes are reversible or nonreversible.

It has been suggested that interaction of bilirubin with polar lipids may play an important role in the toxic mechanism.[112] The addition of bilirubin to cell cultures was associated with leakage of cytosolic enzymes into the medium.[63] Erythrocytes from jaundiced neonates examined by scanning electron microscopy demonstrated a crenated surface structure, compatible with an interaction of bilirubin with the outer half of the erythrocyte plasma membrane bilayer complex.[26] Phototherapy reversed the membrane changes. Others have also found evidence for crenation of the red cell outer surface in nonaggregating conditions in the presence of clinically relevant bilirubin concentrations.[113] Depression of the membrane potential of synaptosomes by bilirubin suggested a mechanism involving alterations in ion permeability.[114] However, it is not clear that perturbation of the membrane potential is an essential element in bilirubin toxicity. Thus in a model involving synaptosomes permeabilized with streptolysin O (excluding the importance of plasma membrane polarity) bilirubin was shown to inhibit Ca^{2+}-dependent neurotransmitter exocytosis and, at higher concentrations, to disrupt vesicular norepinephrine storage.[105] Bilirubin appears to have a high affinity for the phospholipids in cell membranes, and some evidence exists that it may form complexes with these phospholipids.[24,115,116] Partitioning into membranes was increased if they contained proteins, but the effect of proteins could not be attributed to specific binding sites.[116]

Bilirubin in its acid conformation may possibly precipitate, particularly in the presence of acidosis, resulting in irreversible aggregation.[40,117] Precipitation of bilirubin aggregates remains a theory that is supported by some investigators.[78] Others have proposed that bilirubin in the form of the monovalent anion of the acid might bind reversibly to membranes.[118] This is consistent with the finding that bilirubin binding to liposomes and red blood cells is reversible,[118] as well as with clinical and experimental observations regarding the reversibility of the milder signs of bilirubin influence on the brain.[119] However, reversibility of membrane changes caused by bilirubin appears to be dependent on model and experimental conditions. Thus in an erythrocyte model, washing with albumin could not fully reverse the membrane changes associated with bilirubin toxicity.[120] Of note, inherent in the proposed model of reversible bilirubin binding to membranes is also the possibility that decreasing pH could result in irreversible aggregation of bilirubin in tissues.[118]

Some effects of bilirubin on cell membranes may also be understood in terms of bilirubin interaction with membrane-localized enzymes, pumps, or transporters. Thus the break temperature for sodium, potassium–adenosine triphosphatase (Na^+,K^+-ATPase) activity was shifted to lower levels if tested with enzyme from young rats in the presence of bilirubin, whereas the enzyme from adult rats was unaffected.[121,122] This suggests an interaction between the enzyme, bilirubin, and the surrounding membrane lipid environment. Similar changes in the transition temperature under the influence of bilirubin have been found for NO synthase (NOS).[123] Bilirubin-induced changes in NOS activity may be attenuated by 7-nitroindazole, a specific inhibitor of neuronal NOS.[124] Na^+,K^+-ATPase and acetylcholinesterase activities in rat brain exhibited an age-dependent decrease (enzymes from young rat brains were more strongly inhibited)[125] after administration of bolus doses of bilirubin.

Bilirubin has been shown to inhibit the enzymes involved in the transfer of reducing equivalents across the inner mitochondrial membrane,[126] and also to inhibit vasopressin-stimulated water and Na^+ transport across the toad bladder membrane,[127] showing that bilirubin may exert a tissue-specific effect on membrane transport mechanisms. Inhibition of membrane ion transport, accompanied by increased water retention, is another bilirubin-associated perturbation of membrane function.[128]

NEUROTRANSMITTER METABOLISM

Both the inhibitory effects of bilirubin on evoked potentials and the reversible inhibition of synaptic activation in rat transverse hippocampal slices[129] suggested that neurotransmitter metabolism might be affected by bilirubin. Phosphorylation of synapsin I is an important step in neurotransmitter release at the synapse, and the ability of bilirubin to inhibit synapsin I phosphorylation[76] might therefore also predict bilirubin effects on neurotransmitter cycling.

Studies in synaptosomes (synaptic nerve endings that retain their function in vitro) showed that bilirubin was both able to inhibit the uptake of tyrosine, a precursor to dopamine, and to inhibit the formation of dopamine in these nerve endings.[130] Other studies showed that bilirubin inhibited direct uptake of dopamine into synaptosomes, but not its release.[131]

However, the release of endogenous acetylcholine was inhibited, and depolarization of the synaptosomal membrane was also observed. Of note, in preliminary studies other investigators observed inhibition of dopamine release by bilirubin using a different stimulus for release.[132]

Another contribution to decreased synaptic function in the jaundiced brain might be the inhibitory interaction between bilirubin and transport proteins in synaptic vesicle membranes, leading to inhibition of neurotransmitter uptake into these vesicles.[133] It is noteworthy in the studies cited above that uptake of dopamine and glutamate into synaptic vesicles was equally inhibited, though these are presumed to be driven by two different mechanisms (proton gradient and membrane potential, respectively). In a further attempt to delineate the relative importance of membrane potential versus energy metabolism, the same group used permeabilized synaptosomes to study the release of norepinephrine and found that bilirubin inhibits both exocytotic release and synaptic vesicular storage of brain catecholamines independently of ATP and in the absence of a membrane potential.[105]

The NMDA receptor ion–channel complex is localized at the surface of synaptic membranes, is activated by glutamate, and appears to be important during development.[134,135] In vivo administration of bilirubin in piglets resulted in increased affinity of the NMDA receptor for the blocking agent MK-801, suggesting that bilirubin modifies the function of the NMDA receptor–ion channel complex.[136] Acute bilirubin encephalopathy induced in homozygous Gunn rats by injection of a "displacer" was reduced by concurrent treatment with MK-801,[137] suggesting that NMDA-mediated excitotoxicity may be involved in bilirubin encephalopathy (see Figure 122-2). However, such interaction between bilirubin and the NMDA receptor was not observed in a different experimental model.[138] The effect of bilirubin on in vitro cell cultures has been studied by several groups. Glutamate uptake in rat cortical astrocytes was inhibited by bilirubin.[139] Apoptosis in developing rat brain neurons was reduced by the NMDA blocker MK-801,[140-142] and these observations have been confirmed by others working with human neurons.[143,144]

Exposure of astrocytes, microglia, and neurons in culture to bilirubin was followed by release of glutamate and cell death.[145-148] Immature cells were more vulnerable to loss of glutamate. L-carnitine, which protects neurons in culture from glutamate toxicity, has been shown to significantly reduce bilirubin toxicity in cerebellar granule cells in culture,[149] further pointing to the role of glutamate and excitotoxicity in bilirubin cell toxicity.

BILIRUBIN METABOLISM IN BRAIN

Bilirubin that has entered the brain is also cleared from the brain. In early studies the half-life of bilirubin in brain was estimated at 1.7 hours, and the clearance rate from blood was 1.6 hours.[58] However, this study was carried out in hyperosmolar conditions. Subsequent work has resulted in the much lower estimated half-life of 16 to 18 minutes during baseline conditions[43] and approximately 38 minutes during hyperosmolality.[45] A meta-analysis of these data indicated that clearance from brain could be more rapid than from blood, suggesting that additional mechanisms might be operating to metabolize bilirubin in brain.[91] Data from a study by Brodersen and Bartels could throw light on this phenomenon.[150] They described an enzyme capable of oxidizing bilirubin that was found on the inner mitochondrial membrane of brain cells, as well as in other tissues. Subsequent studies by others have verified the existence of a bilirubin-oxidizing activity in brain.[91,151-156] In brief, this enzyme appears to have some of the characteristics of the cytochrome oxidases, although it has not been unequivocally identified. Recent data suggest that cytochrome P-450 2A5 may play an important role in hepatic oxidation of bilirubin,[157] but it is not known whether hepatic and brain metabolic pathways are the same. As far as the brain enzyme, the activity is lower in the immature organism and in neurons versus glia.[152] These data appear compatible with clinical impressions suggesting greater vulnerability to bilirubin toxicity in infants compared with older children and adults, and in brain neurons compared with glia. The activity is also subject to genetic variability,[153] and one may speculate as to whether apparent interindividual differences in vulnerability to bilirubin neurotoxicity may, perhaps in part, have a genetic basis. However, the clinical implications of bilirubin metabolism in brain are as yet unknown, and further studies are needed to understand this phenomenon.

APOPTOSIS AND NECROSIS

Cell death is clearly involved in the devastating effect of bilirubin neurotoxicity seen in victims of kernicterus[158] and is observed in the brains of Gunn rats where Purkinje cells appear particularly vulnerable.[159] After the development of methods to study cell death processes in detail, a large number of studies have addressed the question of how cells die when exposed to bilirubin toxicity.

In vitro cell cultures have been especially useful, and several different cell lines have been used. In rat cerebellar granule cells bilirubin causes apoptosis, which can be blocked by inhibitors of RNA and protein synthesis inhibitors. This suggests that execution of the death process required de novo synthesis of RNA and protein.[160] In embryonic rat forebrain neurons in culture, apoptosis caused by toxicity was bilirubin dose dependent and was blocked by an NMDA receptor antagonist, suggesting a role for NMDA receptors.[140,141] In a comparison of bilirubin effects on rat brain astrocytes and neurons, toxicity was evident in both cell types but required higher bilirubin concentrations for the astrocytes.[161] In addition, glutamate uptake and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) reduction (a measure of cell function) were inhibited, whereas neurons exhibited a greater tendency to necrosis and apoptosis. Apoptosis was preceded by signs of impaired mitochondrial metabolism and membrane perturbation in the form of altered lipid polarity and fluidity, protein order, and redox status.[98] However, when neurons and astrocytes were compared from young versus old rats, immature cells were more susceptible to the toxic effects of bilirubin, although mitochondria from the younger animals were more resistant.[162] This suggests that, although mitochondrial injury may play a role in mediating bilirubin toxicity, it is not likely to be the sole, nor probably the primary, mechanism.

In murine hepatoma cells, bilirubin also appeared to have an effect on cell membranes, possibly involving the aryl hydrocarbon receptor.[163] In rat oligodendrocytes bilirubin-induced apoptotic cell death was associated with induction of NOS.[164] Additional studies in rat neurons suggested that apoptosis triggered by mitochondrial depolarization and Bax translocation could be prevented by ursodeoxycholate.[99] It is interesting that hyperphosphorylation of enzyme activity (p38MAP kinase) (as a trigger for bilirubin-induced neuronal death) was observed in rat cerebellar granule cells.[165] This finding is intriguing in light of other evidence that bilirubin appears to have inhibitory effects on the protein–peptide phosphorylation interactions.[76,77,166-167] Minocycline, which acts partly by inhibiting glial caspase 1 and inducible NOS (iNOS) activity, appears to block bilirubin toxicity in rat cerebellar granule cells in vitro and to largely prevent loss of Purkinje cells and cerebellar hypoplasia in homozygous Gunn rat pups.[168] Somewhat surprisingly, phototherapy, which might also have been posited to be neuroprotective because of the formation of presumably nontoxic water-soluble photoisomers, appears to accentuate bilirubin toxicity in cultured cells.[169]

Although the studies just mentioned have been carried out in cells of animal origin, a human neuron-like cell line (NT2-N neurons) has been investigated with respect to bilirubin's ability to cause apoptosis or necrosis. These studies have shown that the induction of apoptosis as opposed to necrosis may depend on bilirubin concentration, such that high bilirubin concentrations induce early necrosis, whereas low-to-moderate concentrations predominantly induce delayed apoptosis.[170] Further studies with a specific caspase-3 inhibitor, a general caspase inhibitor, and an NMDA receptor antagonist indicated that both NMDA receptor–mediated and caspase–mediated pathways may be involved in bilirubin-induced cell death.[143] Concomitant inhibition of both pathways resulted in synergistic protection. However, in follow-up studies looking at recovery after short-term bilirubin exposure in NT2-N cells, caspase inhibition did not have a positive impact on cell survival, whereas NMDA blockade significantly increased the number of undamaged nuclei, without impacting MTT reduction, another measure of cell viability.[144]

INFLAMMATION AND INFECTION

Neonatal jaundice in the presence of infection has been believed to increase the risk for kernicterus, and this is supported by some clinical studies,[171] whereas others do not find this association.[172] In animal studies endotoxemia was found to increase the net accumulation of bilirubin in brain, which appeared to be caused by an increase in total and unbound bilirubin in the endotoxemic rats.[173] This is compatible with data from infected human infants, who had a lower reserve albumin binding capacity for bilirubin.[174] However, bilirubin metabolism in rat brain was not affected by endotoxemia or sepsis.[151]

In mouse fibroblasts in vitro the cytotoxicity of bilirubin was increased by endotoxin and tumor necrosis factor α (TNF-α).[175] In astrocytes exposed to bilirubin in conditions that induced <10% cell death, the release of TNF-α and interleukin (IL)-1β was significantly enhanced, whereas the production of IL-6 was inhibited.[148] Young astrocytes in culture were more prone to bilirubin-induced cell death and exhibited a greater inflammatory response than older cells, and bilirubin cytotoxicity was increased by endotoxin,[147] a finding also confirmed by other studies.[146] Microglia exposed to bilirubin in vitro were activated and released high levels of TNF-α, IL-1β, and IL-6,[145] suggesting that bilirubin-induced cytokine production can exacerbate neurotoxicity. The interaction of bilirubin with the immunologic cascade may be very complex. Thus in astroglia bilirubin induced a rapid rise in the levels of TNF-α receptor 1, which was followed by activation of mitogen-activated protein kinase p38 and nuclear factor κB (NF-κB), among others.[176] This suggests that NF-κB may play a role in astroglial response to bilirubin.

In apparent contradiction to these findings, others working with in vivo animal models have failed to find an effect of bilirubin on NF-κB or p38 mitogen-activated protein kinase. In fact, bilirubin may exert a cytoprotective effect through inhibition of iNOS expression, stimulation of local prostaglandin E_2 production.[177] In another study jaundiced rats were more resistant to endotoxin-induced hypotension or death compared with nonjaundiced controls, and iNOS expression was reduced.[178] Thus the questions concerning infection or inflammation and bilirubin neurotoxicity are unresolved at the present time.

EFFECTS OF BILIRUBIN IN OTHER SYSTEMS

Some investigators have studied the effect of bilirubin on enzyme activity. A 1979 review listed 25 separate enzymes and four pathways that bilirubin appeared to inhibit.[179] A number of other enzymes and pathways have subsequently been studied, and with few exceptions the effects of bilirubin are inhibitory.[121,126,166,180-182] The inhibitory effects of bilirubin on protein kinases are discussed elsewhere in this chapter.[76,77,183]

Several studies have found that bilirubin inhibits protein synthesis,[62,184-186] although at least one recent study came to the opposite conclusion.[142] Inhibition of DNA synthesis[62,187,188] and increased strand breakage in DNA in combination with phototherapy[189,190] have also been described. Finally, several older studies documented bilirubin inhibitory effects on carbohydrate metabolism.[180,191,192]

PROTEIN PHOSPHORYLATION

As will be evident from the topics discussed in this chapter, bilirubin toxicity has been found across a wide range of biologic reactions and systems. It is, of course, not clear that all of these reactions or systems are actually implicated in the effects of bilirubin observed in jaundiced infants. Similarly, no agreement exists as to which of these systems might be the principal or basic mechanism for bilirubin neurotoxicity.

Energy failure caused by inhibition of oxidative phosphorylation was first proposed as the basic mechanism,[96] and this theory continues to have support.[78] Perturbation of membrane function has been proposed as the triggering event in a cascade leading to excitotoxicity and mitochondrial energy failure.[193] However, studies in permeabilized synaptosomes (a model system in which the impact of both membrane polarity and endogenous energy metabolism is excluded) continue to show toxic effects of bilirubin on neurotransmitter metabolism.[105] Furthermore, studies with purified kinases and peptides in experimental systems devoid of membranes and with excess ATP present show widespread inhibitory effects of bilirubin on peptide-kinase interactions.[77]

Thus it seems reasonable to consider whether the many apparently divergent toxic and inhibitory effects of bilirubin may have something in common and whether bilirubin inhibition of such a putative basic reaction might explain the wide range of bilirubin toxicity. Protein-peptide phosphorylation has been shown to be an important regulatory mechanism for many cell processes.[194] A review of current knowledge regarding the many bilirubin-affected processes suggests that regulation by protein-peptide phosphorylation might indeed constitute a common theme. A detailed discussion would vastly exceed the limits for this chapter, but some aspects will be mentioned.

Early studies showed that bilirubin inhibited the binding of cyclic adenosine monophosphate (cAMP) to protein kinase, as well as the phosphorylation of histone,[166] and that protein phosphorylation in cell-free preparations from newborn rabbit brains was inhibited by bilirubin administered IV before the animals were killed.[167] Bilirubin inhibits phosphorylation of synapsin I, a protein that is preferentially localized to presynaptic vesicles.[76] Dephosphorylated synapsin I inhibits neurotransmitter release; thus this observation might explain why bilirubin inhibits synaptic activation in transverse rat hippocampal slices.[129] These observations are compatible with the clinical observation of drowsiness in jaundiced infants, as well as the documented changes in brain stem auditory evoked responses in such infants. Further, bilirubin has been shown to inhibit phosphorylation of endogenous proteins in fibroblasts.[195] Indeed, the inhibitory effect of bilirubin on synapsin I phosphorylation is not unique: a number of protein-kinase interactions are similarly inhibited by bilirubin, suggesting that inhibition of protein-peptide phosphorylation might explain the effects of bilirubin in many biologic systems.[77]

An intriguing new perspective may link the role of P-gp as a membrane-localized pump that may limit the intracellular and intracerebral accumulation of bilirubin (see earlier),[70,72,73] regulating by phosphorylation.[74,196-199] Although no studies that directly address the impact of bilirubin on P-gp phosphorylation have been published, the fact that both protein kinases A and C are involved in P-gp phosphorylation, and that bilirubin has been shown to inhibit the interaction between these two kinases and other peptide-protein substrates,[77] suggests that P-gp phosphorylation may have an integral role in bilirubin toxicity. The apparent ability of bilirubin to increase the permeability of the blood-brain barrier for bilirubin itself[68] could potentially be understood in terms of modulation of P-gp function. However, this has yet to be studied specifically.

Bilirubin binds to albumin in serum, as well as to ligandin in hepatocytes. Lysine seems to be common to both binding sites.[200,201] A review of the literature showed that lysine appears to be a constituent of the active sites of many of the reactions perturbed by bilirubin, including the ATP-binding subdomain II of the protein kinase family.[202] Lysine-containing peptides were shown to modulate the toxic effects of bilirubin in a model peptide-kinase system.[203] Thus binding of bilirubin to lysine may play a role in the mediation and/or modulation of bilirubin neurotoxicity.

Bilirubin has been shown to inhibit a wide range of phosphorylation reactions. Indirect evidence suggests that binding to lysine may play a role in these reactions. Given the key role of protein-peptide phosphorylation in the regulation of cell processes, widespread inhibition of such processes by bilirubin deserves consideration as a possible basic mechanism of bilirubin toxicity.

BILIRUBIN CELL TOXICITY: SELECTIVITY VERSUS GLOBAL EFFECTS

Bilirubin appears to be toxic in all in vitro cell systems that have been studied. However, evidence exists to suggest that some cell types are more vulnerable than others and that the age of the cells may also modulate toxicity. This is in accordance with clinical data. Thus, although clinical signs of cerebellar affection are quite rare when kernicterus is the result of severe neonatal jaundice,[8,204,205] cerebellar symptoms have been reported in persons with Crigler-Najjar syndrome type 1 who were neurologically normal in infancy and early childhood but who had signs of bilirubin encephalopathy later in life.[206]

Bilirubin effects in in vitro cell culture systems were studied in cells derived from a mouse neuroblastoma line, as well as in rat astrocytoma cells.[185] Bilirubin toxicity was evident in the neuroblastoma cells, but not in the glial cells. This is interesting in light of data suggesting that mitochondria from glial cells oxidize bilirubin at a greater rate than mitochondria from a pure neuronal source and thus may have a greater ability to protect themselves against bilirubin toxicity.[152] Bilirubin may also have a greater affinity for neurons, as suggested by binding of [^{3}H] bilirubin to hippocampal pyramidal and granular cells, as well as to Purkinje cells in rat brain slices,[111] though the mechanism for this phenomenon has not been explained.

The difference in reactions to bilirubin exposure between neurons and glia may not be simply one of tolerance versus sensitivity. Thus, in rat brain astrocytes and neurons exposed to 85.5 μmol/L bilirubin, apoptosis, cytoskeleton disassembly, and membrane leakage were greater in the neurons than the glial cells, whereas inhibition of MTT metabolism and glutamate uptake were more pronounced in astrocytes.[161] Differences may also exist between classes of glia. For example, microglia appear to be more sensitive to bilirubin toxicity than astrocytes.[145] Though regulation of MRP1 was curtailed, and the cells exhibited a significant increase in apoptosis. Cells exposed to the lower bilirubin concentration, however, became increasingly apoptotic if treated with a MRP1-blocking agent (MK571). Thus one potential explanation for differential sensitivity to bilirubin toxicity might be variable expression of membrane "flippases" such as MRP1.

Neuroblastoma cells that had differentiated under exposure to prostaglandin E_1 and cAMP lost their sensitivity to the toxic effects of bilirubin.[185] A similar observation was made in rat astrocytes exposed to dibutyryl cAMP.[207] It is noteworthy that both cAMP and prostaglandin E_1 increase phosphorylation of a membrane phosphoglycoprotein in human platelets.[208,209] Both MRP1 and P-gp are expressed in cultured rat astrocytes,[210,211] and data from human studies show that drug treatment may lead to overexpression of P-gp[212] and may even be associated with therapy resistance in epilepsy.[213] Evidence exists that MRP1 and P-gp are expressed in several different brain cells and with a different pattern of distribution.[214] Thus it is conceivable that a closer study of the importance of regulation of membrane transporter expression may shed light on aspects of differences in vulnerability to bilirubin toxicity.

Rat glial cells in culture became more resistant to bilirubin effects from day 2 to day 12 in culture, suggesting that immature cells are more vulnerable,[66] a finding recently confirmed with use of different cells and techniques.[146] It is noteworthy in this context that the expression of P-gp in both rat and mouse brain increases with maturation,[59,215] and, given the evidence that increased expression of MRPs may protect cells against bilirubin cytotoxicity,[81] it is possible that decreasing sensitivity to bilirubin with increasing age may be, at least in part, tied to increasing membrane transporter expression. In addition, increased bilirubin oxidation by more mature brain cells might also confer protection.[152]

Ngai and colleagues[216] compared cells with some relation to the central nervous system (neuroblastoma and glioblastoma cells) with fibroblasts and liver cells. With increasing bilirubin-albumin ratio, cells of central nervous system origin were clearly more vulnerable. When two neuronal cell lines, NBR10A and N115, were compared, the latter were more resistant to bilirubin toxicity.[188] Pathoanatomic data from kernicterus cases, as well as from Gunn rats, clearly show that not all neurons are damaged by bilirubin. The reasons for such differences in sensitivity are not clear. Although both P-gp and MRP1 may be expressed in neurons in experimental or refractory epilepsy,[217,218] they do not appear to be generally expressed in neurons.[219] Other MRPs appear to be found in neurons[220,221]; however, the implications for bilirubin neurotoxicity are unknown.

INTERINDIVIDUAL DIFFERENCES IN SENSITIVITY TO BILIRUBIN TOXICITY

Clinical data suggest a wide interindividual disparity regarding sensitivity to bilirubin neurotoxicity.[95,222-226] Thus, whereas some infants may tolerate serum bilirubin levels in excess of 500 to 600 μmol/L, the literature has reported cases of kernicterus in term infants with serum bilirubin levels barely in excess of 350 μmol/L,[227,228] and at even lower levels in preterm infants.[229]

Considerable discussion has occurred among bilirubin experts regarding this phenomenon. Although immaturity and diseases may explain vulnerability in some cases, apparently healthy, term infants remain in whom kernicterus develops at serum bilirubin levels that many others tolerate without residual damage. The explanation for this remains speculative. Future research should probably investigate genetic differences in the expression of membrane transporters, as well as how their expression may be modulated by such factors as disease, drugs, and even bilirubin itself. Bilirubin oxidation in brain may be hypothesized to be protective, but this remains to be proved. Whether genetic differences in such oxidation might play a role is also awaiting further studies.

IMPLICATIONS OF BILIRUBIN NEUROSCIENCE FOR CLINICAL MANAGEMENT

It will be obvious from this chapter that our understanding of the mechanism(s) of kernicterus and bilirubin encephalopathy is far from complete. It is not surprising, then, that the challenge of translating these data into clinical guidelines has been daunting. The resulting guidelines indicate great variability between practitioners: infants may receive an exchange transfusion in one neonatal intensive care unit for serum bilirubin levels that would not even trigger phototherapy elsewhere.[92] Nevertheless, our current state of knowledge regarding the mechanism(s) of bilirubin neurotoxicity does provide some input into the practical management of a newborn with jaundice.

SECTION XVI

The Kidney

123

William E. Sweeney, Jr., and Ellis D. Avner

Embryogenesis and Anatomic Development of the Kidney

EMBRYOLOGIC FEATURES OF THE MAMMALIAN RENAL EXCRETORY SYSTEM

Embryonic development is regulated by sequential activation and inactivation of developmental gene programs. Such genes encode proteins that determine cell interaction and developmental function. As a result of sequential and reciprocal cell and tissue interactions progenitor cells develop into complex organs. The possibility of creating gene-targeted mouse models has led to new insights into the complex hierarchy of genes that control organogenesis from the earliest developmental stages. Gene targeting approaches have revealed that relatively small gene families encoding transcription factors, proto-oncogenes, and secreted signaling molecules regulate organogenesis in a variety of systems. However, how signaling by such relatively similar signals leads to establishment of a panoply of unique organ structures with highly specialized cells is a challenge for future research.

The mammalian kidney is an excellent model system for investigating developmental mechanisms. The process can be modeled in vitro in organ culture, which provides a means to carry out gain- and loss-of-function and knock-down experiments. The combination of classic and modern experimental embryologic methods has the power to reveal developmental control mechanisms relevant to multiple organ systems. The genes that regulate development are often reactivated in various pathologic conditions, and changes in such genes may predispose organisms to diseases and to become targets of epigenetic changes. Hence, research in the field of developmental biology can be expected not only to influence knowledge and understanding of normal mechanisms of ontogeny, evolution, and development of diseases but also to lead to new therapeutics.

A detailed compilation of the regulatory pathways of renal development is beyond the scope of this chapter, and the following will highlight only those studies that are supported by multiple models, provide novel insights, or raise interesting new questions regarding renal organogenesis. Exhaustive, regularly updated reviews of (1) the developing mammalian urogenital tract, at http://www.gudmap.org,[1] and (2) the Kidney Developmental Database,[2] the molecular basis of kidney development, at http://golgi.ana.ed.ac.uk/kidhome.html, are excellent sources of current findings.

EXCRETORY SYSTEM

During embryonic development, three sets of kidneys form within the mammalian intermediate mesoderm.[3,4] The three kidneys form in a significant temporal and anterior-to-posterior sequence such that the differentiation of the definitive mammalian kidney, or metanephros, will not take place unless it has been preceded by the successive formation and involution of two embryonic kidneys, the pronephros and the mesonephros.[5,6]

The mesoderm forms during gastrulation, and rudimentary or embryonic kidneys subsequently develop from intermediate mesoderm (nephrogenic cords), between the dorsal somites and the lateral plate mesoderm. The pronephros and mesonephros develop segmentally as tubules are induced to differentiate from the intermediate mesoderm by the adjacent pronephric and mesonephric ducts.

Early in development (day 22 in humans), the pronephric duct arises just ventral to the anterior somites.[6] The cells of this duct migrate caudally, and the anterior region of the duct induces the adjacent mesenchyme to form the tubules of the initial kidney, the pronephros. In humans, the pronephros is a rudimentary, nonfunctional kidney that develops during the third embryonic week (eight- to nine-somite stage); it contains rudimentary tubules opening into the pronephric duct and regresses by the fifth week.[6] The human pronephric duct persists as a remnant after pronephric tubular regression. It becomes the mesonephric or wolffian duct, which, in turn, evolves into the ureteric bud (UB), an epithelial structure required for the formation of the metanephros. The mesonephros appears in the third to fourth week of gestation immediately caudal to the last pronephric tubules.[5,6] The mesonephros is the second transient kidney of higher vertebrates but is the definitive functioning kidney of fish and amphibians. Mesonephric nephrons develop a vascularized, glomerulus-like filtering component connected to proximal and distal tubules draining into the mesonephric duct that constitutes the first definitive functional renal unit in the human embryo.[4,5] As with the pronephros, the mesonephros degenerates in a cephalocaudal direction from the fifth to the 12th week of gestation and ceases to function as an excretory organ.[4,5] The distal end of the mesonephric duct gives rise to the UB, and other mesonephric structures participate in genitourinary development. In the male, mesonephric tubules in the area of the gonad form the efferent ductules, whereas the mesonephric duct gives rise to the epididymis and the ductus deferens. In the female, the mesonephric duct completely disappears during the third month, whereas some mesonephric tubules persist as the epoöphoron and paroöphoron, which have no known function in humans.

FORMATION OF THE METANEPHROS

The formation of the metanephros gives rise to the permanent kidney in humans, as well as in other mammals, reptiles, and birds. Unlike other organs that develop through simple epithelial branching morphogenesis, the metanephros develops from reciprocal, sequential inductive interaction of the epithelial UB with the mesenchymal nephrogenic blastema or metanephric mesenchyme (MM).[7,8] Whereas the mesenchyme induces the UB to extend and branch (branching morphogenesis), the UB

induces the formation of epithelial nephrons from MM cells (mesenchyme-to-epithelial [MET] transformation).[9]

The UB in the human embryo arises as an outgrowth from the dorsal aspect of the caudal end of the mesonephric or wolffian duct in the fourth to fifth week of gestation. It extends dorsally into the caudal-most portion of the nephrogenic cord and then draws the MM in a cranial direction. The upward movement of the MM from a pelvic position to its final lumbar position is complete by the eighth embryonic week. On emerging from the pelvis, the metanephros undergoes a 90-degree rotation so that the original ventral hilum takes its final medial position.

The UB undergoes a complex development program of growth, branching, and remodeling in response to inductive signals from the MM, to eventually give rise to the entire urinary collecting system during kidney development. UB branches form the epithelium of the collecting ducts, calyces, pelvis, ureter, and bladder trigone.[4,5] The MM differentiates into glomeruli, proximal tubules, loop of Henle, distal tubular segments, and interstitial stroma.[10]

Normal development and embryogenesis of the UB are fundamental to renal organogenesis. The patterned migration and division of the UB (branching morphogenesis) determine the elaborate three-dimensional branching pattern of the mammalian kidney and are responsible for formation of the urinary collecting system. Further, the specific induction of MM by the ampullary portion of the UB is responsible for individual nephron formation (nephrogenesis). The two basic organogenetic processes of pattern formation (architectonics) and nephrogenesis occur simultaneously during the period of UB ampullary activity, which in the human embryo extends from week 6 through week 36 of gestation. The kidney has thus become the prototype organ for studying the developmental processes of branching morphogenesis, inductive signaling, MET transformation, and epithelial cell polarization.

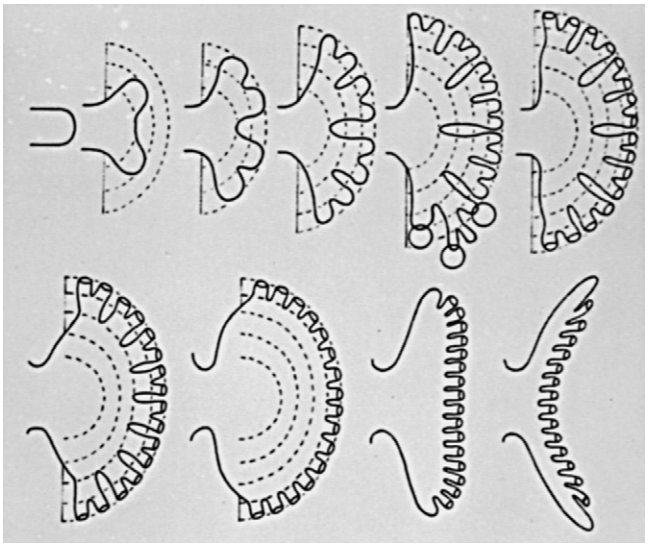

Figure 123-1 Development of a minor calyx and papilla. After the dilation of the first three to five generations of the UB that forms the renal pelvis and major calyces, a second series of three to five generations of UB divisions occurs in rapid succession. This second series of rapidly formed short tubules expands to produce the cavity of the minor calyx, whereas the tubules of the next generations expand to become the cribriform plate that covers the papillary surface. It is thought that the definitive cup shape of the calyx and the conical form of the papilla are formed by the combination of intratubular pressure generated by urine formation and the extratubular pressure generated by enlargement and differentiation of nephrons distally. *(From Potter EL:* Normal and abnormal development of the kidney, *Chicago, 1972, Year Book Medical Publishers.)*

RENAL ARCHITECTONICS

Mammalian kidney function requires the coordinated development of specialized cell types within a precise architectural framework so that body fluid composition can be monitored and optimally regulated. The morphogenesis of the collecting system and the distinct zonal arborization of the developing kidney are controlled by the patterned divisions of the nephron-inducing UB. The renal pelvis, calyces, and intrarenal collecting ducts arise from phases of rapid dichotomic branching of the UB, which alternate with phases of enlargement and structural reorganization (Figure 123-1). Dilation of the early generations of UB branches and final structural modification of the pelvis, calyces, and papillae occur concomitantly with the formation of functional nephron units and probably result from accumulation of urine.

During renal embryogenesis, the pattern of UB branching determines the topographic distribution of nephrons and the elaborate patterns of arborization by which they attach to successive branches of the cortical collecting ducts. The branching of the UB is highly structured, and dissection of early embryonic kidneys revealed several types of repeating patterns of divisions.[11-13] Lateral branches originate from a main stem at equally spaced or at random intervals. The budding of the UB from the wolffian duct is the first lateral branch that then divides into two, producing the first bifid branch point. In bifid branches, the main stem divides into two daughter branches similar in size. Each daughter branch can divide again in a bifid manner until a terminal set of branches is reached. The angle of bifurcation is variable, but in the first bifurcation of the UB it is as large as 180 degrees. Formation of the characteristic collecting duct system of the kidney requires both lateral and bifid branches, which then form three different patterns of branching (lateral, bifid, and trifid) that unfold sequentially. The formation of lateral branches is followed by terminal bifid branching (bifurcation of one stem into two daughter branches). As each ureteric tip connects to a nephron, it is effectively removed from further branching events. This type of branching appears to induce the majority of initially formed nephrons.[14] The remaining fraction develops through the poorly understood process of late-phase branching.[13,15]

The early patterns of renal branching morphogenesis had been previously inferred from static observations derived from microdissection, and serial reconstruction of sectioned kidneys.[6,11,12] Dynamic observations of murine renal organ cultures[13,16] and in vivo time-lapse analysis of UB branching in a transgenic mouse strain expressing enhanced green fluorescent protein specifically in the UB epithelium[17] confirmed many of the hypothesized branching events and also provided new insights into this complex, highly regulated process. Readers interested in more detailed analysis of branching morphogenesis are referred to recent reviews.[18-20]

Differences in embryonic behavior of the ampullae of UB branches make it possible to artificially divide the structural development of the human kidney into four periods[5]: period 1 (embryonic weeks 5 through 14), in which ampullae actively divide and induce formation of nephrons only when not carrying an attached nephron (Figure 123-2); period 2 (embryonic weeks 14 to 15 through 20 to 22), when ampullae rarely divide but induce new nephrons while carrying an attached nephron, resulting in arcade formation (Figure 123-3); period 3 (embryonic weeks 20 to 22 through 32 to 36), in which ampullae do not divide but induce new nephron formation when not carrying an attached nephron (Figure 123-4); and period 4 (embryonic weeks 32 to 36 through adult life), when ampullae are inactive and do not divide or induce formation of new nephrons. All renal growth from period 4 through adulthood is a result of enlargement of existing structures and expansion of interstitial tissue.

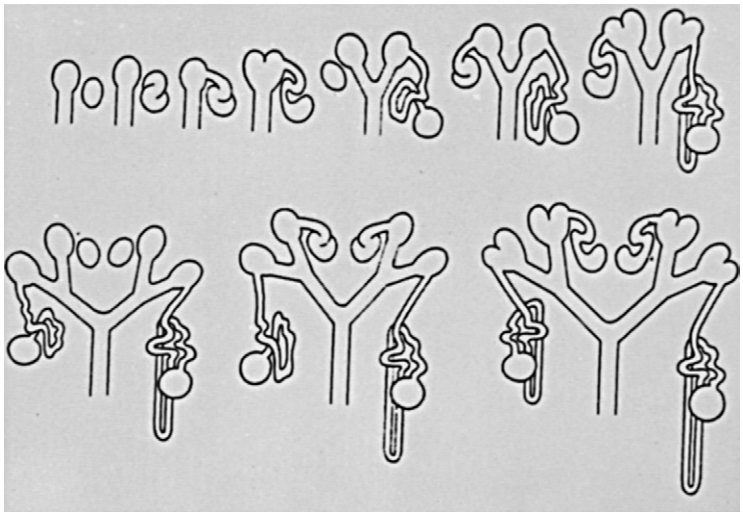

Figure 123-2 Period 1 of nephron formation (embryonic weeks 5 to 14). Ampullae actively divide and induce formation of nephrons only when not carrying an attached nephron. *(From Potter EL:* Normal and abnormal development of the kidney, *Chicago, 1972, Year Book Medical Publishers.)*

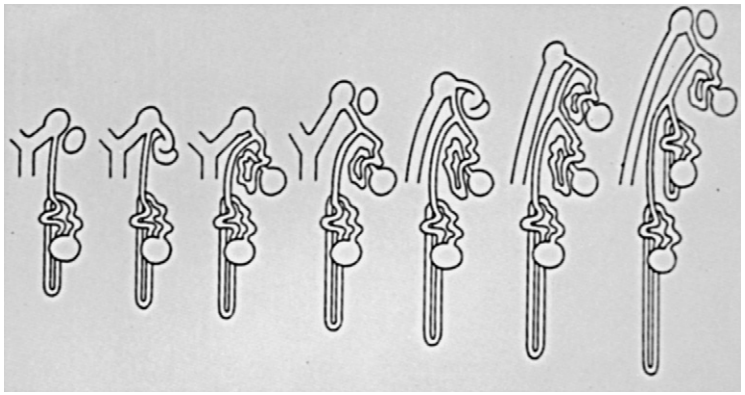

Figure 123-3 Period 2 of nephron formation (embryonic weeks 14 to 15 through 20 to 22). Ampullae no longer actively divide and become capable of inducing new nephrons, even though they already carry an attached nephron. Although two nephrons may be attached to each terminal ampulla temporarily, the connecting piece of the more mature nephron shifts to communicate only with the connecting piece of the younger nephron. In this fashion, arcades of four to six nephrons become attached to each tubule. *(From Potter EL:* Normal and abnormal development of the kidney, *Chicago, 1972, Year Book Medical Publishers.)*

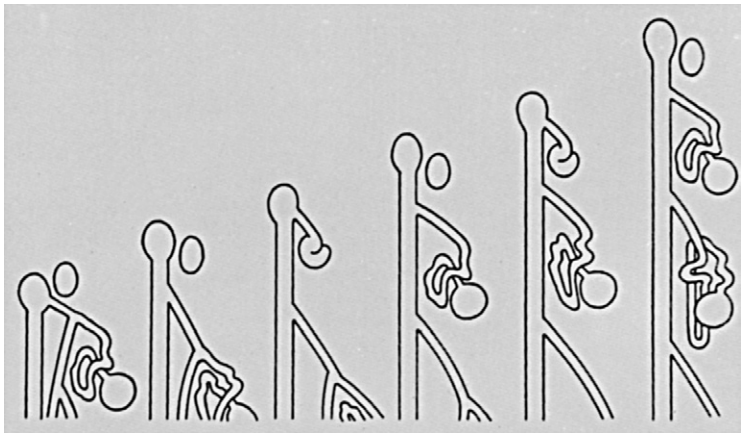

Figure 123-4 Period 3 of nephron formation (embryonic weeks 20 to 22 through 32 to 36). During this period, ampullae branch rarely, induce formation of new nephrons when not already carrying nephrons, and permit attachment of new nephrons only behind the active growth zone at the junction of ampulla and collecting tubule. This results in direct attachment of nephrons to the terminal portion of each collecting tubule. *(From Potter EL:* Normal and abnormal development of the kidney, *Chicago, 1972, Year Book Medical Publishers.)*

The actual differentiation of individual nephrons occurs continuously and without variation in pattern during the different periods of ampullary activity.

The programmed stages of UB division and induction result in a predictable pattern of nephron arborization in the newborn kidney (Figure 123-5). The connecting tubules of all nephrons in the mature kidney are connected to the last two to three generations of collecting ducts produced by UB divisions (13th to 15th generation of UB branches). Because nephrons are successively attached to the UB within a zone of accelerated interstitial growth, they advance with the ampullae. As the ampullae divide, nephrons of different ages and at different stages of development are carried along one ramification of an extending UB branch. The nephron attachments are thus carried along in a centrifugal fashion from generation to generation of UB branches.

The development of the renal vascular system parallels the branching pattern of UB division and nephron induction.[5,6,21,22] Branches of the aorta and vena cava invade the MM soon after initial UB division. Such branches proliferate, arborize, and extend to the periphery of the developing kidney, at which point they merge into a subcapsular network. At approximately 14 embryonic weeks, arterial branches at the future corticomedullary junction elongate at right angles to the basic centrifugal branching to form the arcuate arteries. Branches of the interlobar arteries directly supply the medulla as the vasa recta and return to the corticomedullary area as venules, which drain into the interlobar

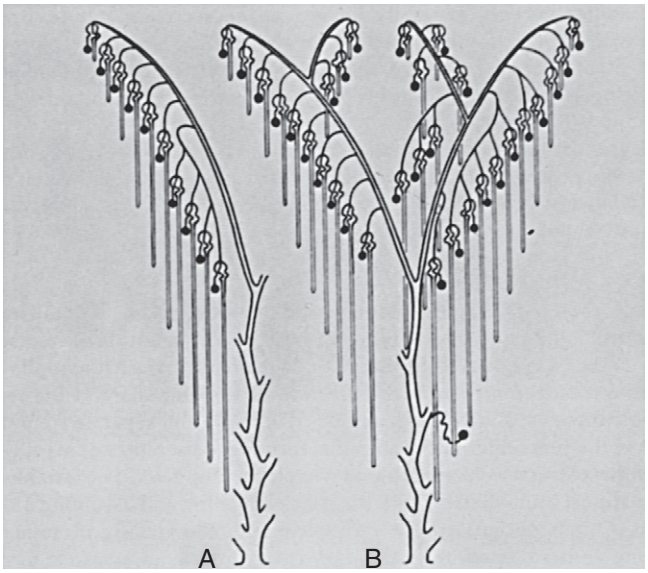

Figure 123-5 Nephron arborization in the newborn kidney. The programmed periods of UB division and induction result in a predictable pattern of nephron arborization in the newborn kidney. **A**, The most common arrangement, whereas **B** shows possible variations. *(From Potter EL:* Normal and abnormal development of the kidney, *Chicago, 1972, Year Book Medical Publishers.)*

veins. The vascular supply of the human fetal kidney is similar to that of the newborn kidney by 15 embryonic weeks.

NEPHROGENESIS

Nephrogenesis is a complex process involving the coordinated growth and differentiation of endothelial, mesangial, neuronal, and epithelial cells that occur throughout the previously noted periods of renal architectonic development. Cytodifferentiation and spatial assembly of different cells during nephron formation are governed by complex interactive events and changing gene expression patterns among transcription factors and protooncogenes, polypeptide growth factors and their receptors, cell adhesion molecules and extracellular matrix (ECM) glycoproteins, ECM receptor molecules, and ECM degrading proteases. These reciprocal signals coordinate developmental processes such as cell proliferation, apoptosis, migration, adhesion, differentiation, vascularization, and neurogenesis that occur concurrently during nephrogenesis. Experimental studies have provided considerable insight into the molecular basis of mammalian nephron formation and thereby provide a basis for exploration of the pathoembryologic characteristics of renal developmental abnormalities.

NORMAL DIFFERENTIATION OF THE INTERMEDIATE MESODERM

The intermediate mesoderm, from which the pronephric, mesonephric, and metanephric kidneys originate, is specified along the mediolateral axis by the temporal expression of specific proteins, and the anterior-posterior axis can be represented by the pronephric, mesonephric, and metanephric kidneys themselves. Therefore a unique combination of mediolateral and anterior-posterior markers can be used to specify any position within the developing mesoderm. The proper differentiation and specification of the intermediate mesoderm along both axes are critical for the eventual development of the metanephros or adult kidney. Disruption in any of the sequential steps of pronephros development and involution, mesonephros development, and metanephric induction leads to abnormal or even complete absence of kidney development.

Developmental profiling of murine embryos reveals a number of proteins initially expressed in the lateral plate mesoderm that become restricted to the intermediate mesoderm before any morphologic indication of urogenital development. The expression pattern of these proteins is the first indication that intermediate mesoderm is differentiating from surrounding cells. Normal differentiation of the intermediate mesoderm has been shown in targeted gene deletion experiments to be dependent on expression of several transcription factors including *Lim1*[23] and *Odd1* (odd-skipped related 1).[24] *Odd1* (*Osr1,* Mouse Genome Informatics) expression is confined to undifferentiated renal progenitor tissue, and its expression precedes all known renal regulatory genes. Murine loss-of-function studies revealed an absolute requirement for *Odd1* in the establishment of the MM and in the activation of the earliest known genes expressed during metanephric kidney formation, *Lim1* and *Pax2.*[25] The paired-domain genes *Pax2* and *Pax8* are expressed subsequent to *Odd1* and *Lim1* activation and further restrict the area fated to become MM and eventually renal epithelia.[25] Targeted deletion experiments demonstrate that *Odd1, Lim1,* and *Pax2/8* are all required to delineate the mediolateral margin of the intermediate mesoderm destined to become MM.[25-31] A complex temporal and spatial relationship exists among these marker proteins suggesting that other positional signaling cues remain to be identified. Recent evidence suggests that bone morphogenetic proteins (BMPs) and other members of the transforming growth factor β (TGF-β) superfamily of growth factors are involved.[24,32]

At the posterior end of the nephric duct, the evagination of the UB is a critical event that is tightly regulated along the anterior-posterior axis. Failure to correctly position the UB along the axis can have severe consequences, resulting in clinical phenotypes ranging from complete renal agenesis to congenital abnormalities of the urinary tract including reflux and hydroureter, to hypertension and progressive renal failure as a result of reduced nephron number.[14]

During embryonic development, anterior-posterior body axis is specified in part by activities of *Hox* genes. The *Hox* genes are conserved among all metazoans and specify positional information along the body axes. Targeted gene deletion experiments revealed that the *Hox11* paralogous genes are essential for early patterning of the MM. The loss of *Hoxa11* and *Hoxd11* resulted in misrouted ureters and hypoplastic kidneys, and the deletion of all three *Hox11* paralogs (*Hoxa11, Hoxc11,* and *Hoxd11*) resulted in complete failure of the MM to induce UB evagination.[33,34]

Before UB induction, the condensing MM expresses a unique combination of markers, including the *Hox11* paralogs (*Hoxa11, Hoxc11,* and *Hoxd11*), *Odd1, Pax2, Eya1, Wt1, Six1, Six2,* and *Gdnf.*[35]

In *Hox11* triple mutants, the expression of both *Six2* and *Gdnf* is absent whereas the remaining early kidney patterning markers in the uninduced MM are unperturbed.[34] Gong and coinvestigators[36] recently demonstrated that the Hox11 paralogous proteins formed a complex with Pax2 and Eya1 that directly activated the expression of both *Six2* and *GDNF* in the MM. These data reveal a novel Hox11-Eya1-Pax2 cassette that activates critical target genes (*Six2* and *Gdnf*) during early renal development, thereby translating anterior-posterior positional information within the developing mammalian kidney.

URETERIC BUD OUTGROWTH

Directed by inductive signals emanating from the MM, and as previously described earlier, the wolffian duct forms the UB as an epithelial outpouching, which invades the adjacent MM. In vitro studies have shown that glial cell–derived neurotrophic factor

(GDNF), produced in the MM, is a primary inducer of ureteric budding.[37] GDNF, a member of the TGF-β family, signals through a receptor tyrosine kinase, RET (*RE*arranged during *T*ransfection proto-oncogene), and the glycosylphosphatidylinositol (GPI)-linked cell surface coreceptor Gfrα1.[38,39]

The initial outgrowth of the UB is a critical step in the development of the urogenital system. The formation of a single, properly positioned UB is critically dependent on appropriately regulated expression of GDNF. Therefore mechanisms to ensure the restricted expression of GDNF involve a complex network of positive and negative regulatory elements that are required for normal development. Common birth defects such as failure to form a ureter and/or the kidney, as well as incorrect positioning of the ureter, result from faulty UB development, and more subtle defects in UB branching can trigger reduced nephron numbers, which may lead to hypertension and renal disease later in life.[6,13,14]

The regulation of GDNF-RET signaling occurs at the level of both gene expression and signal transduction regulation.[35] Positive regulators include the *Hox11* paralogs,[34] *Odd1*,[25] *Pax2/8*,[27,28,40] *Eya1*,[41] *Wt1*,[42] *Six1*,[43] *Six2*,[44] and *Sall1*.[45] In addition to positive regulatory genes that specify the metanephric mesenchyme, negative regulatory mechanisms exist that restrain GDNF expression and therefore limit the area along the wolffian duct from which the UB can evaginate.[35]

GDNF functions as a chemoattractant for RET-expressing cells providing guidance that ensures proper alignment of the UB with the MM. The transcription factors FOXC1 and FOXC2 are normally expressed in the MM and help to define the anterior edge of GDNF expression. Deletion of either gene results in anterior expansion of GDNF expression resulting in evagination of multiple UBs anterior to the normal site of UB outgrowth.[35,46] Similarly, deletion of the secreted protein Slit2 or its receptor Robo2 also results in expanded GDNF expression resulting in multiple, ectopic UBs anterior to the normal position.[47]

Deletion of Sprouty1, an inhibitor of the Ras/Erk/MAPK pathway, results in multiple, ectopic ureters, without altering GDNF expression.[48] Instead, Sprouty1 appears to regulate the response to GDNF by an unknown mechanism. Bmp4, which is expressed in the MM along the wolffian duct before the onset of kidney development, in the mesenchyme surrounding the nascent UB before invasion, and in mesenchyme cells adjacent to the ureter trunk once induction is complete, appears to play a critical role in limiting the site and number of UBs elaborated from the wolffian duct.[32]

The transcription factor Gata-3 is required for proper expression of RET in the wolffian duct.[40] *Gata-3* mutations exhibit increased duct cell proliferation and misdirected UBs.[40]

REGULATION OF GROWTH AND BRANCHING OF THE URETERIC BUD BY THE METANEPHRIC MESENCHYME

The initiating step in renal development is the sprouting of the UB off of the wolffian duct into the genetically preprogrammed MM. Reciprocal inductive signaling between the UB and MM leads to multiple iterations of branching and elongation of the UB while the mesenchyme is induced to condense and epithelialize around the branched ampullary tips of the UB (MET transformation or MET).[9] It has long been hypothesized that the MM controls many aspects of UB growth and branching through inductive interactions, and more recently it has been learned that the renal stroma, which is derived from a distinct cell population in the metanephric blastema, is also important for continued UB development.[6,14,49,50] A number of growth factors expressed by the MM and/or stromal cells or the UB itself, including members of the fibroblast growth factor (FGF), TGF-β, and Wnt families, have been implicated in the initiation of the MET process. Cell surface and ECM proteins such as integrins, heparan sulfate proteoglycans (HSPs), and matrix metalloproteinases (MMPs) are also likely to play roles in MET.

It is likely that inductive signaling from the UB constitutes a complex set of secreted factors, and several UB-derived signals may be required in a temporal and spatial sequence for the proper execution of the induction program.

The balance of data to date suggests that members of the Wnt family of proteins, specifically *wnt9b,* are critical renal MET-inducing factors. These data include the observations that (1) LiCl, a specific inhibitor of glycogen synthase kinase 3 (GSK3) in the canonical Wnt signaling pathway, mimics the early response to induction[51]; (2) cells expressing the Wnt proteins can effectively replace the potent inductive effects of spinal cord[52,53]; (3) Wnt9b is expressed in the UB, and *wnt9b* mouse mutants fail to induce the mesenchyme, despite undergoing early branching morphogenesis[54]; (4) cells that form a "pretubular aggregate," the precursor to the renal vesicle, express Wnt-4[55]; (5) HSP synthesis is required for early kidney development,[56] and Wnt proteins require HSP for activity; (6) a cocktail of factors used to promote epithelial differentiation in isolated rat mesenchyme depended on Wnt ligand activity[57]; (7) Wnt1 can substitute for the UB as an inducer of tubulogenesis (although it is not expressed in the developing kidney)[52]; and (8) six Wnts are expressed in developing kidneys (Wnt2b, Wnt4, Wnt6, Wnt7b, Wnt9b, and Wnt11[54,58,59]). These data strongly suggest that a Wnt signal is essential and permissive for epithelialization and induction, which is a multistep process requiring an initiation signal, factors that suppress apoptosis, and factors that promote proliferation of induced mesenchyme.[35]

EXPANSION AND SURVIVAL OF RENAL STEM CELLS

Only the MM has the competence to respond to the UB to form kidney tubules, and, if induced by other tissues (such as embryonic salivary gland or neural tube tissue), the MM will respond by forming kidney tubules and no other structures.[60] Thus the MM is preprogrammed to produce the diverse epithelial cell types of the nephron.[61,62] However, not all cells of the MM become epithelia. A portion of the MM cells must maintain their mesenchymal character and remain as interstitial stromal cells between the developing tubules. Signaling between induced mesenchyme fated to become epithelia and stroma is essential for proliferation of both cell types as the kidney grows. Failure to expand and renew the epithelial precursor cells leads to developmental arrest and rudimentary kidneys, without inhibiting the differentiation of already induced cells.[35] Reciprocal, inductive interactions are essential for survival and differentiation of both the mesenchymal and epithelial components within the early kidney.[7,63]

The competence of the MM to respond to UB inducers is regulated by the transcription factor called WT1. MM that lacks expression of WT-1 undergoes apoptosis resulting in renal agenesis.[42] GDNF is synthesized in the MM and, as previously described, acts as a chemoattractant to induce the outgrowth of the UB, which expresses c-RET, the receptor for GDNF.[64] The UB also expresses the receptor c-Met, which responds to a MM-produced growth factor HGF.[65] The absence of either GDNF or HGF expression in the MM leads to apoptosis of the MM and renal agenesis. The synthesis of both GDNF and HGF is thought to be regulated in part by WT-1.

Proteoglycan production by the MM has also been shown to provide a critical survival cue to the UB once it has entered the MM. Mesenchymal proteoglycans are necessary to stimulate the continued growth of the UB by maintaining the expression and secretion of Wnt11 from the tips of the UB.[51]

The UB also secretes antiapoptotic factors such as BMP7 and FGF2, which are necessary for the survival of the MM.[66,67,68] In vitro, BMP7 inhibits apoptosis of the uninduced MM and,

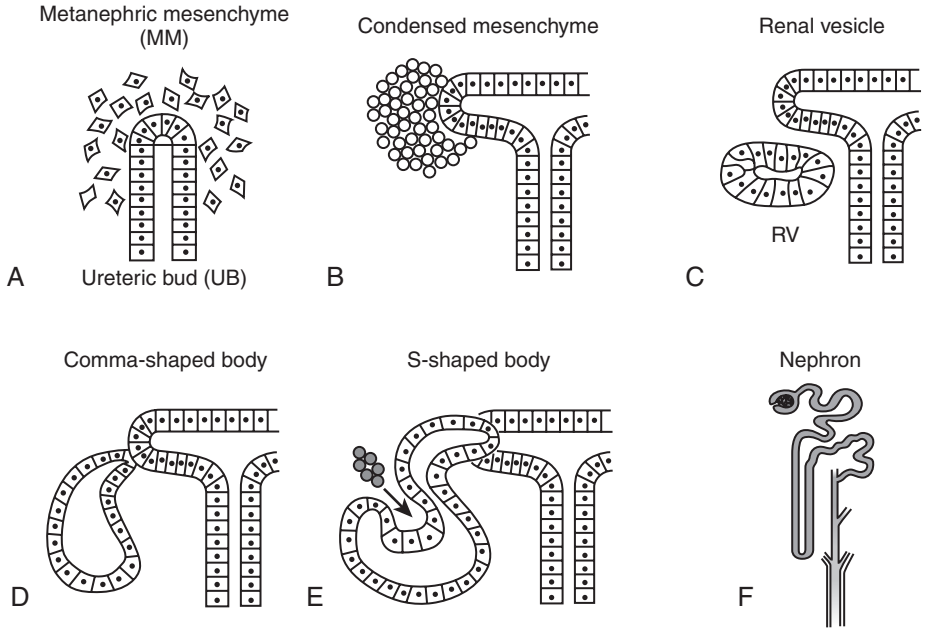

Figure 123-6 The stages of normal nephron formation. Development of the nephron begins when the UB invades a population of prespecified MM **(A).** Shortly thereafter, a group of mesenchymal cells within the MM condense and form a cap around an ampullary tip of a UB branch **(B).** A subset of cells within the condensate will aggregate and undergo a MET transition, forming a renal vesicle *(RV)* **(C).** The majority of the nephron, from the glomerulus through the distal tubule, will differentiate from the RV. The RV will undergo morphogenesis, forming a comma **(D)** followed by an S-shaped body **(E).** Vascular endothelial progenitor cells invade the cleft of the proximal part of the S-shaped body and begin to form the endothelial network of the glomerulus. The distal portion of the S-shaped body will fuse to the UB, forming one continuous lumen. Elongation and subsequent maturation of distinct segments lead to one of approximately 1 million nephrons of the human kidney **(F).**

together with FGF2, maintains the competence of the MM to respond to inductive signals and increase the population of stromal cells.[69] BMP7 and FGF2 work concurrently to inhibit tubulogenesis, suggesting that expansion of the available stem cell pool requires a finely tuned balance between differentiation, survival, and renewal. If cells differentiate too quickly, they can outpace their ability to self-renew, leading to a small, rudimentary kidney.[35]

A recent study by Marose and colleagues[70] demonstrated the necessity of maintaining a similar balance between differentiated and undifferentiated UB-derived epithelia. β-Catenin activity was shown to be necessary for maintaining wolffian duct cells and the duct-derived UB–collecting duct system in an undifferentiated or a precursor state. Decreased expression of β-catenin leads to the premature expression of differentiation markers leading to an imbalance between differentiated and undifferentiated epithelia.[70] Such an imbalance could lead to aberrant branching and a decrease in the number of nephrons.

DEVELOPMENT OF THE NEPHRON

Normal nephron development encompasses four progressive stages that follow embryonic inductive interaction of the metanephric blastema and UB (Figure 123-6, *A*). Ultrastructural glomerular, proximal tubular, and distal nephron development can be seen in the larger context of this framework of overall nephrogenesis. Concomitantly with branching of the UB, the tips of the UB branches induce epithelialization of the MM and subsequent development of the nephron from the glomerulus through the distal tubule.

Nephron development proceeds through a series of intermediate forms, beginning with the condensation or aggregation of induced mesenchyme around the UB tips (see Figure 123-6, *B*). The perpendicular cells form a corona adjacent to the tip of the UB and express Pax2, Wnt4, cadherin-11, and α8 integrin.[58] These cells comprise a subpopulation of what is traditionally called "condensing mesenchyme." These aggregates begin to proliferate and express epithelial properties as a "pretubular aggregate" or the renal vesicle begins to takes shape just beneath the tips of the UB at the juncture of the ampulla and stalk (see Figure 123-6, *C*).

Nephron development continues to proceed through morphologically defined stages known as the comma (see Figure 123-6, *D*) and S-shaped bodies (see Figure 123-6, *E*) before elongation and eventual fusion with the duct. The S-shaped body is generally regarded as the precursor of two distinct processes, that is, glomerulogenesis and tubulogenesis, which are related to the spatial segmentation of the S-shaped body. Glomerular development proceeds from the differentiation of two distinct visceral and parietal epithelial layers during the S-shaped vesicle stage when mesenchymal invagination and development of capillary loops occur (through vasculogenesis and angiogenesis).[71] This is followed by the progressive development of specialized epithelial intercellular connections and basal lamina formation with consequent endothelial fenestration and basilar modification of visceral epithelium into foot processes and slit pores.[72-74]

Nephronegenesis begins as condensations of induced MM cells surrounding the ampullary tip of the UB that are phenotypically and structurally converted to an epithelial vesicle. The proximal tubule and loop of Henle arise from the lower limb and midlimb of the S-shaped body and the distal tubule arises from the upper limb, which ultimately fuses with the collecting duct (see Figure 123-6, *F*). Continued branching of the UB and inductions of new nephrons continue in a radial fashion, such that the first nephrons that develop lie near the corticomedullary junction and the final nephrons form in the outer cortex.

Basic questions about the critical molecular and cellular events that control normal and abnormal nephrogenesis have largely been addressed with in vitro model systems and manipulation of

targeted "developmental" genes in vivo.[1] Model systems that have proved particularly valuable in this regard include both transfilter and whole organ murine metanephric organ culture, isolated mature renal cell lines, isolated embryonic UB and MM cell lines, and in vivo models including zebrafish, *Xenopus,* and the generation of transgenic and genetically engineered mice.[1,10,60,75-81] These approaches have provided important insight into the regulation and modulation of renal organogenesis by characterizing (1) the normal differentiation of the intermediate mesoderm that gives rise to the wolffian duct, UB, MM, and gonadal tissue; (2) induction of the UB outgrowth from the wolffian duct; (3) regulation of growth and branching of the UB by the MM; (4) early nephron morphogenesis and epithelialization; (5) ECM remodeling and cell adhesion changes that pattern early nephron morphogenesis and epithelialization; and (6) the process of nephron vascularization. Studies, to date, have identified more than 400 genes (e.g., secreted growth factors, tyrosine kinase receptors, transcription factors, extracellular components, proteases) involved in renal developmental pathways.

EARLY NEPHRON MORPHOGENESIS AND EPITHELIALIZATION

The differentiation of each nephron starts with mesenchymal cell aggregation around a UB branch tip (ampullae). Each condensate subsequently forms a lumen (the vesicle shape) and elongates to form a tubule (the comma-shape body), which then undergoes regional specialization into primitive glomerular and proximal tubular epithelia (the S-shaped body). The proximal end of each S-shaped body becomes the glomerular epithelia, and the distal end fuses with the adjacent branch of the UB. Soon afterward, the cells of this epithelial structure begin to differentiate into regionally specific cell types, including the capsule cells, the podocytes, and the distal and proximal tubule cells.

To date, the use of mice with targeted mutations has conclusively identified a few important molecules involved in the early events of nephron formation and epithelialization, but these data provide little information regarding the orchestration of nephrogenesis beyond the S-stage. These results demonstrate that nephrogenesis becomes "frozen" at the condensation stage in mice with homozygous mutations in *Wnt-4*[58] or *Foxd1* (originally BF-2)[82] and *Emx2.*[83] The epithelialization of MM is delayed or reduced in mice lacking expression of cadherin-6, and a significant number of tubules that form do not fuse to the UB.[84] Genetic deletion of *Wnt-9b* leads to an arrest of epithelialization in the MM before occurrence of Wnt-4–positive pretubular aggregates. In addition, epithelialization can be rescued in *Wnt-9b−/−* animals by overexpressing Wnt-1 from the UB, indicating that a Wnt signal is essential and permissive for epithelialization.[54]

Few data are available regarding the specification or polarization along the proximodistal or glomerulo-collecting duct axis during nephrogenesis. Asymmetric expression of Brn-1,[85] E-cadherin, and cadherin-6[86] provides the first known evidence of polarization of the proximodistal axis. However it is not readily distinguishable until the S-shaped body stage when Pax2 is highly expressed within the distal portion of the S-shaped body, including the region that fuses to the UB.[87] Podocyte precursors reside in the proximal limb of the S-shaped body and express high levels of Wilms tumor-1 (Wt1).[42] Adjacent to the podocyte in the cleft of the proximal limb, the vascular endothelial network of the future glomerular filtration apparatus starts to assemble.

Previous studies had indicated the likelihood of the importance of Notch activity in establishing the proximodistal axis, as podocytes and proximal tubules were lost when γ-secretase activity was abolished.[88,89] Cheng and colleagues[87] recently demonstrated that Notch2 activity is essential for patterning of the proximal regions of the nephron and a central determinant of segmented pattern in the mammalian nephron.

This induction process of MM must be initiated by secreted signals at the tip or ampullae of the UB because contact is not required. In vivo and in vitro UB cells have been shown to secrete FGF2 and 9, TGF-α, tissue inhibitor of metalloproteinases (TIMP) 1, TIMP2, and MMP2.[90] Conditioned medium from an isolated UB cell line was found to trigger MET conversion of isolated MM grown in three-dimensional gel cultures.[91] The MM generated several differentiated epithelial cell types, cysts, tubules, and segmented nephrons. Isolation and purification of the UB conditioned medium demonstrated that it contained FGF2, which was required for MM survival, and leukemia inhibitory factor (LIF), a member of the interleukin (IL)-6 cytokine family, which initiated an epithelialization program through activation of STAT3.[92] In vitro, at least three IL-6 family members can substitute for LIF, and all can bind to their own receptor or heterodimerize with gp130 receptors and activate STAT3, demonstrating a remarkable degree of redundancy.[92]

The development of chemically defined serum-free medium to promote nephrogenesis in organ culture models provided the opportunity to explore the role of soluble growth factors in nephron growth and differentiation.[75,93-96] During experimental nephrogenesis, transferrin and prostaglandin E_1 have major roles in organotypic metanephric growth and differentiation.[94,96] Additional organ culture studies have suggested important roles for certain polypeptide growth factors in segmental nephron differentiation.[93,97-99] Thus epidermal growth factor (EGF) and TGF-α increase overall renal growth and specific differentiation of distal nephron elements (thick ascending limb to early distal tubule, collecting tubule) but retard epithelial differentiation of glomeruli and proximal tubules. These effects are mediated by the tyrosine kinase activity of the EGF receptor.[99] Insulin-like growth factors I and II stimulate overall renal growth and promote segmental differentiation of tubular, but not glomerular, epithelia. TGF-β globally retards growth and differentiation of all nephron segments.[97,98] These findings indicate that inductive signaling from the UB probably constitutes a complex set of secreted factors, and several UB-derived signals may be required in a temporal and spatial sequence for the proper execution of the induction program.[55] Postinductive nephrogenesis thus appears to be regulated by the overall balance of a number of local autocrine and/or paracrine growth factor systems. Alterations in the critical balance of positive or negative regulatory factors might produce a variety of hypoplastic or dysplastic nephropathies.[100]

THE STROMA IN KIDNEY DEVELOPMENT

As previously mentioned, the MM also gives rise to cell types other than those that contribute to the nephron. One such cell type is the stromal cell, which does not differentiate into nephrons or into the collecting-duct system. Gene-targeting studies in mice have demonstrated that, in addition to the UB and the MM, the stroma is an important source of signaling in renal organogenesis. Ablation of the forkhead box D1 *(Foxd1)* gene (formerly called the *Bf2* gene), expressed in the stromal-cell compartment, led to defects in the collecting-duct system and the nephrons[82] despite its lack of expression in these cell types. This suggests that *Foxd1* might contribute to kidney development by regulating the expression of a stromal cell–derived signal that promotes tubulogenesis and UB development.

Evidence also suggests that stromal cell–derived signaling through retinoic acid maintains *RET* expression in the UB, which then reciprocally regulates the differentiation of mesenchymal cells.[49,101] Stromal cells have been found to secrete FGF7, a growth factor the receptor of which is found on the UB. FGF7 is seen to be critical for maintaining UB epithelia growth and ultimately ensuring an appropriate number of nephrons in the kidney.[102] These data indicate that a signaling loop might exist

between the stroma, UB, and kidney mesenchyme that coordinates kidney development.

The recent progress in identifying crucial regulatory molecules involved in renal organogenesis has been remarkable. The use of genetically engineered animals and the development of new models have provided new insights into the complexities of renal development. Future progress will require the continued development of cell lines and transgenic models with inducible gene expression[103] so that the temporal expression, relative prioritization, and interaction of specific signaling pathways can be elucidated. These ongoing studies of the molecular and cellular biology of renal development form the basis for future investigations into the molecular mechanisms of gene activation and signal transduction in renal embryogenesis and will provide insight into the complex processes that underlie normal and abnormal renal organogenesis.

Functional Development of the Kidney in Utero

In early embryogenesis, a primitive kidney, the pronephros, appears at 3 weeks gestation, to disappear after another 2 weeks.[1] An intermediate kidney, the mesonephros, then appears from 5 to 12 weeks gestation and also undergoes involution through apoptosis (programmed cell death). Development of the permanent kidney or metanephros overlaps that of the mesonephros, appearing at 5 weeks gestation and first producing urine at 10 weeks (Figure 124-1).[1] Nephrogenesis progresses most rapidly in midtrimester and is complete by 34 weeks gestation as described in the preceding chapter. During this time, renal mass increases exponentially, reflecting the rapid development of renal tubules in the third trimester (see Figure 124-1).

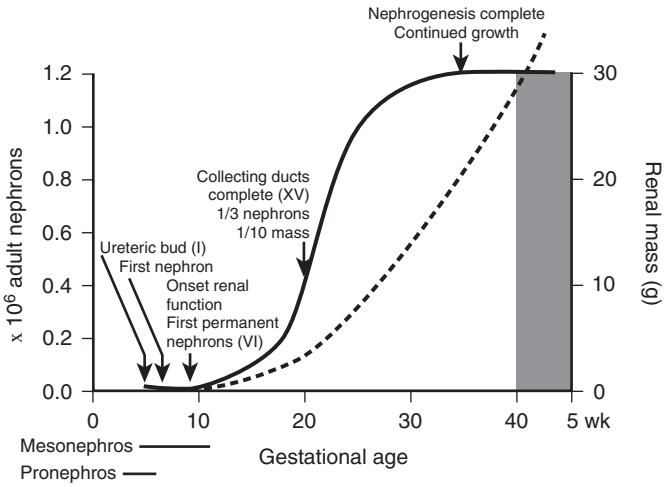

Figure 124-1 Human fetal renal development. The most rapid period of nephrogenesis occurs between 20 and 30 weeks gestation *(solid line).* This is also the period of exponential increase in renal mass *(dashed line). (Modified from Harrison MR, Golbus MS, Filly RA, et al: Management of the fetus with congenital hydronephrosis,* J Pediatr Surg *17:728, 1982.)*

DEVELOPMENT OF RENAL FUNCTION IN THE FETUS

Function of the developing fetal kidney is closely linked to the rapid changes resulting from ongoing morphogenesis. Although fetal homeostasis is primarily dependent on placental function, the contribution of fetal renal function in the third trimester has a significant impact on fetal health. Bilateral nephrectomy of fetal sheep does not cause fetal death after 2 weeks, but animals become hypoxic without increase in fetal plasma erythropoietin. In addition, fetal plasma renin becomes undetectable, chloride falls 20%, and phosphate doubles.[2] Management of the condition of the preterm infant, particularly the very-low-birth-weight infant, requires knowledge of the adaptive potential of the immature kidney and the process of transition from the intrauterine to extrauterine environment.

Urine Flow Rate

Fetal urine flow rates increase rapidly in the second half of gestation, averaging 40 mL/hour at 40 weeks (Figure 124-2).[3] These data were generated from serial ultrasound measurements of fetal bladder volume at 2- to 5-minute intervals. The increasing fetal urine production is paralleled by amniotic fluid volumes that also increase dramatically after 20 weeks (Figure 124-3).[4] Fetal oliguria or anuria resulting from renal or urinary tract anomalies impairs pulmonary development, which can result in neonatal morbidity and mortality from respiratory failure.[5] The determinants of urine flow are complex and involve the dynamics of renal blood flow, glomerular filtration rate, tubular function, and hormonal regulation. These are individually addressed in the following sections.

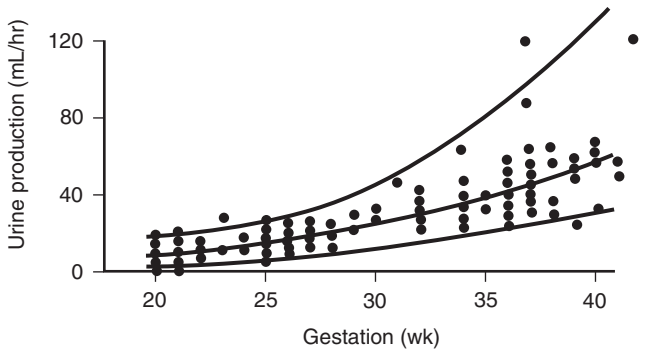

Figure 124-2 Hourly fetal urine production rate measured by maternal real-time ultrasonography, showing individual measurements *(circles),* mean, and 95% confidence intervals. *(Modified from Rabinowitz R, Peters MT, Vyas S, et al: Measurement of fetal urine production in normal pregnancy by real-time ultrasonography,* Am J Obstet Gynecol *161:1264, 1989.)*

Renal Blood Flow

Color-pulsed Doppler measurements of fetal renal blood flow in human fetuses reveal a nearly 10-fold increase from 20 to 40 weeks gestation (Figure 124-4).[6] In contrast to the fetal kidneys, which receive less than 5% of the cardiac output, neonatal kidneys receive 15% of cardiac output.[7] After birth, renal blood flow increases linearly in concert with increasing systemic blood pressure and decreasing renal vascular resistance.[8] Renal blood flow is tightly regulated by a process termed autoregulation, by which blood flow to the kidneys is maintained within a narrow range independent of blood pressure fluctuations above a critical minimum pressure. Autoregulation of renal blood flow has been demonstrated in fetal sheep in response to a modest increase in blood pressure,[9] as well as in immature rats subjected to decrease in blood pressure.[10] Of importance, the range of blood pressure within which renal blood pressure is maintained in the immature rat is the normal range for this age: the "autoregulatory range" increases as blood pressure increases into adulthood.[10]

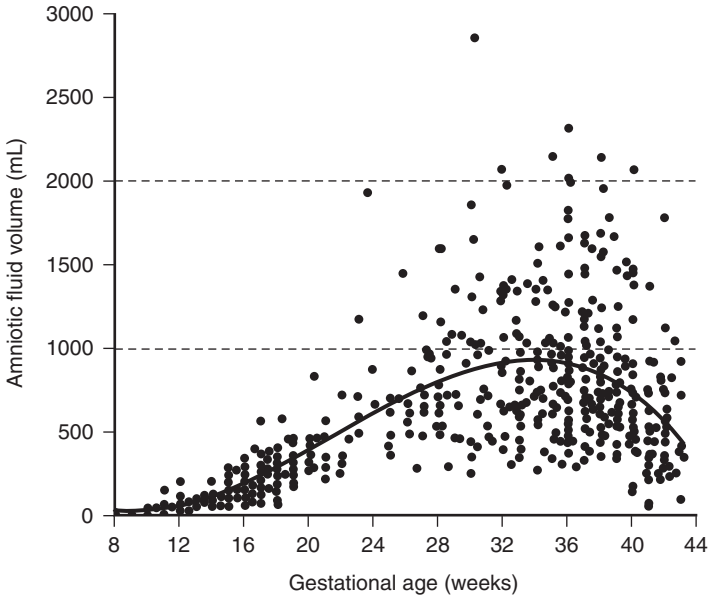

Figure 124-3 Amniotic fluid volume in human pregnancies in the second and third trimesters (*individual data points* [n = 705 pregnancies]). *Solid line* is polynomial regression. *(Modified from Brace RA, Wolf EJ: Normal amniotic fluid volume changes throughout pregnancy,* Am J Obstet Gynecol *161:382, 1989.)*

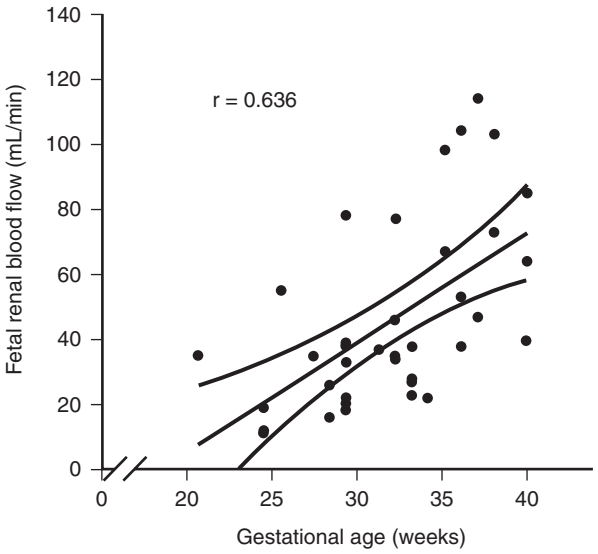

Figure 124-4 Renal blood flow in human fetuses in the second half of gestation measured by color-pulsed Doppler evaluation of the renal artery (*individual data points* [n = 22 fetuses each studied three times], with lines showing mean and 95% confidence intervals). *(Modified from Veille JC, Hanson RA, Tatum K, et al: Quantitative assessment of human fetal renal blood flow,* Am J Obstet Gynecol *169:1399, 1993.)*

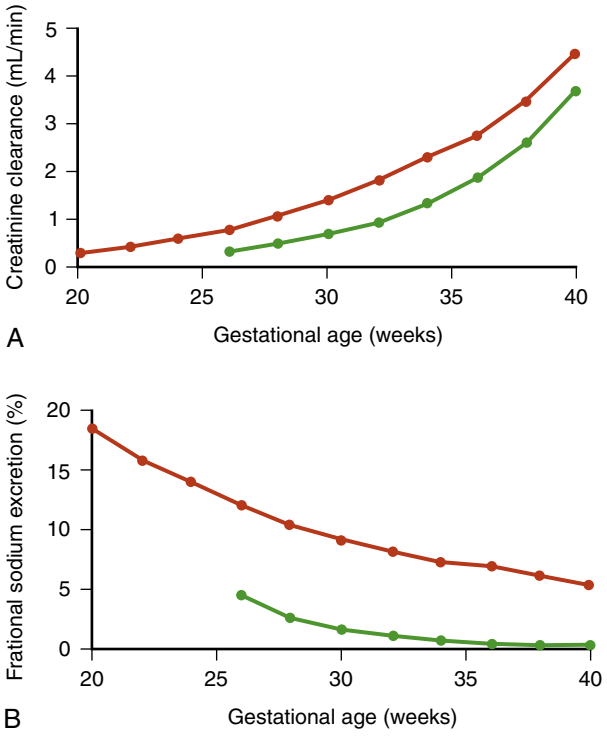

Figure 124-5 Renal function in the human fetus *(red circles)* and neonate *(green circles)* in the second half of gestation. **A,** Estimated creatinine clearance. **B,** Calculated fractional sodium excretion. Fetal values were calculated from several groups of data from a single human fetal research center,[3,12,13] and postnatal values were previously reported.[20] *(Modified from Haycock GB: Development of glomerular filtration and tubular sodium reabsorption in the human fetus and newborn,* Br J Urol *81[suppl 2]:33, 1998.)*

Glomerular Filtration Rate

Concurrently with renal blood flow, glomerular filtration rate increases progressively during the second half of gestation: values for neonates at corresponding gestational ages are similar (Figure 124-5, *A*).[11-13] Compared with that in older infants and children, fetal glomerular filtration rate is very low, ranging from <1 mL/minute at 20 weeks to 5 mL/minute at term (see Figure 124-5, *A*). After birth, glomerular filtration rate increases rapidly. Although glomerular filtration rate at birth is proportional to gestational age, the rate doubles within 2 weeks regardless of gestational age (Figure 124-6).[14] Catch-up in glomerular filtration rate for very-low-birth-weight infants may not be achieved for many months.[15] Determinants of glomerular filtration rate in the fetus and neonate include the number of functioning nephrons, arterial blood pressure, blood volume, glomerular filtration surface area, and glomerular permeability. Glomerular filtration surface area is the most important factor, which is determined by the number of glomeruli, as well as the state of glomerular

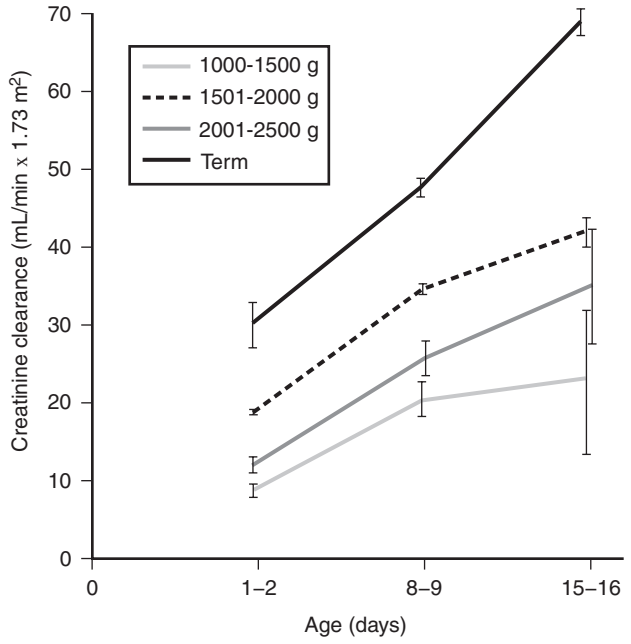

Figure 124-6 Creatinine clearance (corrected for 1.73 m^2 surface area) during the first 2 weeks of life for preterm and term neonates. *(Modified from Bueva A, Guignard JP: Renal function in preterm neonates,* Pediatr Res *36:572, 1994.)*

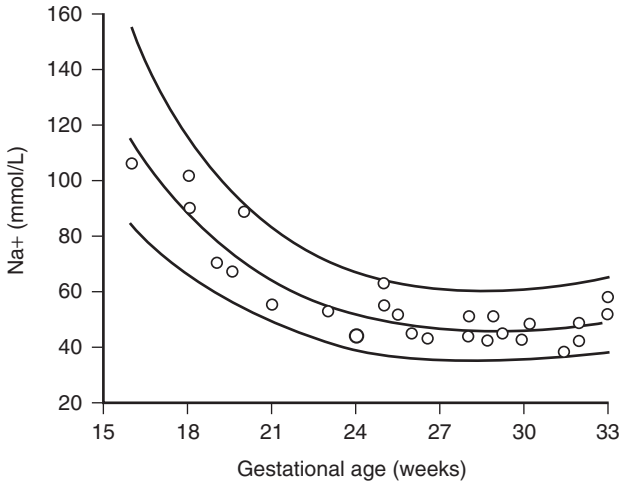

Figure 124-7 Fetal urinary sodium concentration based on data from 26 human fetuses 16 to 36 weeks gestation with normal urinary tracts (mean and 95% confidence intervals). *(Modified from Nicolini U, Fisk NM, Rodeck CH, et al: Fetal urine biochemistry: an index of renal maturation and dysfunction,* Br J Obstet Gynaecol *99:46, 1992.)*

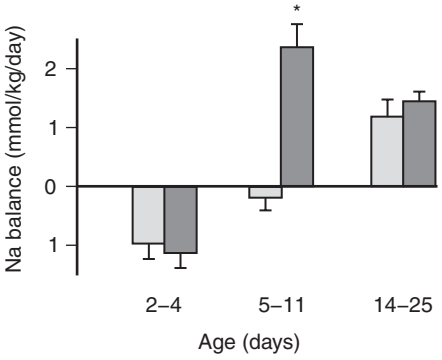

Figure 124-8 Net external sodium balance for preterm infants in the first 3 weeks of life (*gray bars,* control infants; *black bars,* infants receiving sodium supplementation 4-5 mEq/kg/day, $p < .0005$ vs. controls). In the first 2 to 4 days after birth, infants undergo natriuresis regardless of sodium intake, whereas, by 1 week, infants receiving supplementation achieve positive sodium balance sooner than controls. *(Modified from Al-Dahhan J, Haycock GB, Nichol B, et al: Sodium homeostasis in term and preterm neonates: III. Effect of salt supplementation,* Arch Dis Child *59:945, 1984.)*

maturation.[16] In addition to genetic factors, a number of factors in the intrauterine environment can modulate the number of nephrons, which can vary by almost 10-fold among normal individuals.[17] Of particular importance in preterm infants, a number of drugs and therapies (including angiotensin and prostaglandin inhibitors) administered to critically ill infants can reduce glomerular filtration rate (see later).[18]

Tubular Function

As with renal hemodynamics and glomerular filtration rate, renal tubular function is dependent on the stage of renal maturation, as well as the intrauterine or extrauterine environment.

Sodium

Fetal urinary fractional sodium excretion decreases throughout the second half of gestation (see Figure 124-5, *B*), and urinary sodium concentration progressively decreases from 16 to 32 weeks gestation (Figure 124-7).[19] Contributing factors to this state of relative natriuresis in the fetus include a greater proportional extracellular space and immaturity of tubular transporters. Most important, dramatic changes in sodium homeostasis take place at the time of birth, such that fractional excretion of sodium decreases markedly in the first 2 weeks of life.[14,20] Thus transition from the intrauterine to extrauterine environment significantly decreases urinary fractional sodium excretion for corresponding gestational ages in the third trimester (see Figure 124-5, *B*).[11] For a given intratubular pressure, proximal tubular reabsorptive rate is 10-fold greater in the immature compared with the adult kidney.[21,22] Activity of the sodium-hydrogen exchanger increases immediately after birth,[23] and the basolateral sodium-potassium adenosine triphosphatase (ATPase) activity increases steadily after birth.[24] The increase in sodium-potassium ATPase appears to be regulated by increasing sodium-hydrogen exchanger activity.[25] In the neonatal rabbit, intrarenal distribution of the sodium-potassium ATPase α-subunit parallels nephron maturation, with greatest concentration in the medullary region.[26] Sodium enters tubular epithelial cells through the amiloride-sensitive sodium channel: subunits mature in concert with maturation of the transporters to enhance sodium conservation. Infants with mutations of this channel are unable to conserve sodium, and pseudohypoaldosteronism type 1 and life-threatening volume depletion develop.[27]

These changes are reflected by an initial negative sodium balance in the first days after birth, reflecting renal excretion of expanded extracellular fluid and loss of up to 15% body weight, followed by a transition to positive sodium balance by the second week of life (Figure 124-8).[28] The transition can be accelerated by sodium supplementation, but this does not prevent the initial postnatal natriuresis (see Figure 124-8). Transition to positive sodium balance is soonest in infants of gestational age greater than 32 weeks and is delayed in very-low-birth-weight babies.[29] In these infants, fractional distal sodium reabsorption approaches that of term infants by 2 weeks of age.[30] Throughout the animal kingdom, positive sodium balance is essential for

normal somatic growth during early development, a response mediated by numerous overlapping regulatory mechanisms.[31]

Potassium

Urinary potassium excretion is regulated by tubular secretion rather than by reabsorption, and fetal tubular potassium transport mechanisms are mature in the third trimester.[32] Bilateral nephrectomy in the lamb fetus does not alter fetal plasma potassium concentration after 2 weeks, indicating that nonrenal mechanisms are responsible for regulating potassium homeostasis before birth.[2] However, transition from fetal to extrauterine life depends on intact renal function: neonatal plasma potassium concentration ranges from 4.5 to 6.5 mmol/L, and hyperkalemia is a common electrolyte abnormality in the preterm neonate.[33]

Calcium and Phosphorus

Compared with that in the older child and adult, neonatal urinary calcium concentration is increased, with even higher levels in the preterm infant.[34] This becomes important in the critically ill neonate receiving calciuric drugs such as furosemide or glucocorticoids, which can lead to nephrocalcinosis or nephrolithiasis.[35]

Phosphorus is actively transported across the placenta from mother to fetus,[36] and fetal renal phosphorus reabsorption is similar to that in the adult.[37] Tubular reabsorption of phosphorus normally exceeds 95% in term infants and 75% in preterm infants after the first week of life.[34] Lower values point to a proximal renal tubular abnormality or hyperparathyroidism.

Glucose and Amino Acids

Tubular reabsorption of glucose is very efficient in the fetus, exceeding that of the adult.[38] Both the maximal tubular excretory capacity and plasma threshold for glucose reabsorption are increased in the fetus, the latter increasing with gestational age.[38] In very-low-birth-weight infants, fractional excretion of glucose is increased,[39] but neonatal glucosuria is generally a consequence of excessive IV dextrose administration. Tubular amino acid reabsorption is lower in the neonate than in the older child, such that the normal neonate has relative generalized amino aciduria.[40]

Organic Acids and Bases

Renal excretion of organic acids and bases is of importance with respect to elimination of toxins and drugs from the circulation. Compared with that in the adult, fetal excretion of organic acids (such as penicillin) is very low, whereas excretion of organic bases (meperidine) is more similar.[41] Fortunately, efficient maternal renal excretion of organic acids generally protects the fetus from toxic exposure.

Acid-Base Balance

Fetal urine pH is consistently less than plasma pH, a consequence of efficient proximal tubular bicarbonate reabsorption and titratable acid excretion.[42] Increasing bicarbonate reabsorption with increasing gestational age may depend on maturation of carbonic anhydrase activity.[43] Although reduced in magnitude compared with that in the adult, the fetal renal response to metabolic acidosis is similar to that of the adult.[44] The tubular threshold for bicarbonate reabsorption is lower in the preterm neonate compared with the adult, ranging from 14.5 to 24.5 mmol/L.[45] Excretion of an acid load is also lower in the neonate, reaching adult levels within 6 weeks of birth.[46]

Renal Concentrating Capacity

Fetal urine concentration normally ranges from 100 to 250 mOsm/kg H_2O but can be regulated beyond this range in response to changes in maternal hydration or fetal infusion of arginine vasopressin.[47,48] A number of factors contribute to the reduced renal concentrating capacity of the fetus compared with the adult. The loops of Henle are markedly shorter in the fetus compared with the adult,[49] and redistribution of renal blood flow to the inner cortex increases relative blood flow to the vasa recta, washing out the medullary concentration gradient. Because urea contributes significantly to generation of the renal concentrating gradient, the relatively low protein intake of the fetus also limits maximal urinary concentration. The fetal collecting duct is relatively insensitive to the action of arginine vasopressin, which is produced by the fetus.[9,50,51] This may result from decreased coupling between receptor binding and cyclic adenosine monophosphate generation or a decreased number of receptors.[52,53] Increased water movement across the collecting duct in response to arginine vasopressin is dependent on the expression and activation of water channels (aquaporins). Aquaporin-1 is expressed in the kidney of the first-trimester fetal sheep, increasing throughout gestation.[54] In very-low-birth-weight neonates, maximal urinary concentration is below 500 mOsm/kg H_2O.[55] In term infants, maximal concentrating capacity can exceed 1000 mOsm/kg by 2 months of age.[56] The clinical importance of maximal urinary concentration relates to calculation of fluid requirements for the preterm neonate, who has greater obligatory urinary losses compared with the term infant.

Regulation of Renal Function in the Fetus

Renal function is controlled by a variety of endocrine, paracrine, and autocrine factors with coordinated actions on renal hemodynamics, glomerular filtration, and tubular function. Maintenance of homeostasis in the fetus and neonate therefore depends on the relative maturation of these factors, as well as on renal morphogenesis itself.

Renin-Angiotensin Aldosterone System

The renin-angiotensin system is a highly conserved vital regulatory system necessary for normal growth, renal organogenesis, and maintenance of homeostasis. All components of the renin-angiotensin system are present in fetal kidney and are even expressed in the mesonephros.[57,58] Plasma renin concentration in the fetus exceeds that of the mother.[59] Fetal angiotensin II regulates blood pressure and renal blood flow, but vasoconstrictor responses are attenuated compared with those in the adult.[60] However, fetal renin and angiotensin are released in response to hemorrhage, preserving perfusion to vital organs.[61,62] Because angiotensin II preferentially constricts the efferent compared with the afferent glomerular arteriole, administration of an angiotensin receptor blocker or angiotensin-converting enzyme inhibitor to the fetal sheep decreases glomerular filtration rate and urine flow while increasing renal blood flow.[63]

As in the adult, increased activity of the renin-angiotensin system enhances fetal tubular sodium reabsorption.[64] Avid renal sodium reabsorption in the neonate is mediated by endogenous angiotensin II acting through the angiotensin II type 1 receptors,[65] an effect that can be suppressed by chronic sodium loading.[66] Although aldosterone moves from the maternal to fetal circulation across the placenta, the majority of fetal aldosterone is fetal in origin, is regulated by fetal angiotensin production, and contributes to tubular sodium reabsorption.[67-69] However, the kaliuretic effect of aldosterone is decreased in the fetus and neonate compared with the adult,[70] which may contribute to relative hyperkalemia in the preterm infant.

In addition to the physiologic role of the renin-angiotensin system in fetal hemodynamics and renal function, this system plays a major role in renal morphogenesis, with angiotensin behaving as a growth factor.[71] In contrast to the systemic renin-angiotensin system, a number of tissue-specific systems have been identified, including the brain, vasculature, gonads, and kidneys. The study of mutant mice lacking functional components of the renin-angiotensin system has revealed a variety of abnormalities in renal morphogenesis, including abnormal glomeruli, thickened truncated renal vessels, and primitive renal tubules.[72] Experimental

placental insufficiency in the sheep results in suppression of renal renin and angiotensinogen gene expression, which may impair renal development.[73] Of clinical importance, exposure of the fetus to maternal administration of angiotensin-converting enzyme inhibitors or angiotensin receptor blockers during the second and third trimesters results in fetal hypotension, growth retardation, hypocalvaria, and neonatal renal insufficiency with increased mortality.[74-76] Even fetal exposure to angiotensin-converting enzyme inhibitors in the first trimester increases cardiovascular and central nervous system malformations.[77]

Prostaglandins

Fetal prostaglandins counterbalance endogenous vasoconstrictors by promoting systemic and renal vasodilation and diuresis. Thus inhibition of fetal prostaglandins by maternal administration of prostaglandin synthase inhibitors to stop preterm labor is associated with oligohydramnios and neonatal oliguria,[78] and renal insufficiency develops in preterm neonates receiving indomethacin to close patent ductus arteriosus.[79]

Maternal exposure to prostaglandin synthesis inhibitors can also result in abnormal fetal renal morphogenesis, including cystic dilatation of developing nephrons.[80] Mice lacking functional cyclooxygenase 2 have abnormal nephron maturation, developing hypoplastic glomeruli and glomerulosclerosis.[81] As for angiotensin, prostaglandins therefore not only are necessary for maintenance of hemodynamics but also play a critical role in renal development.

Endothelin

Endothelin is a 21–amino acid peptide that is a potent vasoconstrictor acting on receptors on vascular smooth muscle cells and is active in the fetal circulation.[82] Fetal blood concentration of endothelin is elevated compared with that in adults, and it is present in amniotic fluid.[83,84] In direct contrast to its effects on the adult kidney, endothelin promotes diuresis in the ovine fetus, which suggests a relatively lower vasoconstrictor effect on the fetal afferent glomerular arteriole.[85]

Kallikrein-Kinin System

Kinins are peptides produced by the kidney in late gestation and in the adult are expressed by the connecting tubule.[86] Bradykinin has been localized to the distal tubules of the embryonic kidney and presumably plays a role in renal morphogenesis.[87,88] The physiologic role of kinins in the fetus has not been clarified, and their synthesis increases rapidly after birth.[89,90] In contrast to the case in the adult, in which bradykinin is associated with vasodilation and diuresis, the reverse is the case in the fetal and neonatal sheep.[89] The underlying mechanisms for these differences remain unclear.

Nitric Oxide

Nitric oxide is produced in the kidney by nitric oxide synthase (NOS) and has multiple actions as a regulator of cell survival, inflammation, vasodilation, and renal function. Inhibition of nitric oxide synthesis in the fetal sheep increases renal vasoconstriction and reduces glomerular filtration and urinary sodium excretion.[91] Just as angiotensin plays an exaggerated role in maintenance of renal vascular tone in the developing kidney, nitric oxide has a greater role in modulating these effects in the developing kidney than in the adult.[92] Three isoforms of NOS exist: neuronal (nNOS), inducible (iNOS), and endothelial (eNOS). In the adult kidney, nNOS is expressed by cells of the macula densa and inner medullary collecting duct, iNOS is found in proximal tubule and collecting duct, and eNOS is distributed throughout renal endothelial cells.[93,94] In the fetal rat, nNOS appears first in the inner cortex, intensifying in the macula densa during the immediate postnatal period.[95] In contrast, eNOS is produced by endothelial cells of capillaries surrounding fetal medullary collecting ducts and is also expressed by proximal tubular cells at birth.[96] Mice lacking functional eNOS develop vascular dysfunction and progressive tubular injury in adulthood.[97,98] Thus, as for angiotensin and prostaglandins, impaired fetal renal production of NOS can lead to alterations in renal structure and function with long-term consequences.

Atrial Natriuretic Peptide

Atrial natriuretic peptide (ANP) is produced by cardiac myocytes and binds biologically active receptors increasing intracellular cyclic 3′,5′-guanosine monophosphate.[99] Generated cyclic 3′,5′-guanosine monophosphate inhibits sodium reabsorption by blocking sodium channels in tubular epithelial cells. In addition to binding to its biologically active receptors coupled to guanylate cyclase, ANP binds to an even greater population of so-called clearance receptors that regulate plasma levels by removing ANP from the circulation.[100] ANP has potent vasodilatory effects, increases glomerular filtration rate, and promotes natriuresis. Fetal plasma ANP levels exceed maternal concentrations and are further increased by acute volume expansion.[101] In both the fetus and adult, ANP decreases blood pressure and blood volume, with an increase in urine flow and natriuresis.[102-104] Of interest, the midtrimester fetus responds to ANP infusion with a greater increase in glomerular filtration rate and natriuresis than does the late-gestation fetus,[105] an effect that may be mediated by greater numbers of clearance receptors in early gestation.[106]

After birth, plasma ANP concentration decreases with postnatal diuresis in preterm infants, which is paralleled by decreasing right atrial size.[107] The production of cyclic 3′,5′-guanosine monophosphate per ANP glomerular binding site decreases in the postnatal period, and extrusion of cyclic 3′,5′-guanosine monophosphate from glomeruli exposed to ANP is reduced in the neonatal period.[108,109] These adaptations contribute to the transition from fetal natriuresis to postnatal sodium conservation necessary for rapid growth.[31]

Renal Sympathetic Nerves

Renal nerves develop in the fetal kidney,[110] and fetal renal vasoconstriction is more sensitive to α_1-adrenoceptor low-level renal nerve stimulation than in neonatal or adult sheep.[111,112] Counterbalancing these effects, norepinephrine activates β_2-adrenoceptors to induce fetal renal vasodilation.[113] Renal sympathetic nerves play an important role in stimulation of renal renin production during the transition to extrauterine life and in attenuating diuresis and natriuresis during this transition: another mechanism to promote sodium conservation necessary for postnatal growth.[114]

Cortisol

Glucocorticoid receptors are expressed in the rat embryonic liver, lung, heart, and kidney.[115] Administration of cortisol to third-trimester fetal sheep increases glomerular filtration rate and urinary phosphate excretion but does not affect fractional sodium excretion.[116] Although exogenous cortisol reduces proximal sodium reabsorption, distal reabsorption is increased by accelerated maturation of Na-H exchanger and Na^+, K^+-ATPase.[117,118] Maternal administration of glucocorticoids also has an impact on fetal nephrogenesis, however, and dexamethasone results in a decrease in the number of nephrons when the fetus is exposed during a critical period (15-18 days gestation in the rat).[119] Dexamethasone-induced reduction in nephron number appears to be due to inhibition of ureteric branching morphogenesis in the fetus.[120] Administration of dexamethasone to pregnant ewes also reduces the number of nephrons in the fetus and leads to adult hypertension.[121] Of greater physiologic relevance, administration of corticosterone (the natural glucocorticoid) to pregnant rats also reduces fetal nephron number and induces postnatal hypertension.[122]

LONG-TERM CONSEQUENCES OF FETAL RENAL FUNCTION

Fetal renal function is closely linked to both the developmental stage of the kidney and the intrauterine or extrauterine environment of the fetus. Adaptation of the kidney after birth of the very-low-birth-weight infant is remarkable, but clinical management of the condition of these patients requires knowledge of normal fetal renal function. Whereas function of the immature kidney had previously been regarded as "limited," advances in developmental renal physiology have revealed that renal function is finely adapted to the needs of the infant.[31,123] As discussed in this chapter, maternal exposure to a variety of drugs not only may alter function of the fetal kidney but also may cause permanent impairment of renal development and function. Recent studies now suggest that although very-low-birth-weight infants have favorable short-term outcomes, nephrogenesis may not progress in the extrauterine environment.[124,125] Reduced nephron number, in turn, may predispose these patients to renal and cardiovascular disease in adulthood.[126] These considerations underscore the lifetime importance of optimal prenatal and neonatal care.

Postnatal Maturation of Renal Blood Flow

Newborn mammals, including humans, exhibit lower renal blood flow compared with their adult counterparts.[1,2] The low neonatal renal blood flow is maintained by a high renal vascular resistance and establishes the newborn's unique renal functional state characterized by a low glomerular filtration rate. The unique renal hemodynamic state at birth affects the clinical management of the newborn. The low renal blood flow and resultant low glomerular filtration rate contribute to the newborn's altered pharmacokinetics of renally excreted medications,[3] as well as avid tubular sodium reabsorption in the distal nephron. This blunts the ability to excrete an acute saline load in the term infant.[4] The newborn's renal hemodynamic state modifies the development and severity of pathophysiologic conditions, such as acute renal failure resulting from adverse perinatal events and the complications of respiratory distress syndrome.[5] Having an understanding of the regulation of renal blood flow in the newborn may provide insights into creating therapies directed at the prevention and treatment of pathologic conditions in the neonate.

The postnatal maturation of renal hemodynamics involves a progressive increase in renal blood flow to reach adult capability.[1,6-8] The major factor influencing the maturational increase in renal blood flow is the synchronous drop in renal vascular resistance, which occurs most notably in the immediate postnatal period.[7,9] Renal blood flow in the postnatal developing kidney is influenced by structural factors, such as the number of existing vascular channels, as well as functional factors, offered by the glomerular resistance vessels.[10] Several studies confirmed that in the developing kidney the functional maintenance of vascular tone (principally through a balance of vasoactive factors) is the paramount mechanism affecting renal hemodynamics.[11-13] The maturational changes in renal blood flow and renal vascular resistance must proceed normally to achieve adult capability for fully integrated renal-cardiovascular homeostasis. Disruption of the maturation of renal hemodynamics may lead to inadequate renal-cardiovascular function in the adult and may produce pathologic conditions such as hypertension.

CHARACTERISTICS OF RENAL BLOOD FLOW IN THE IMMATURE KIDNEY

Total Renal Blood Flow

In most mammalian species, renal blood flow in the neonate is lower than in the adult compared on the basis of body weight, kidney weight, or surface area.[1] In human newborns and infants, total renal blood flow has been determined by the clearance of *p*-aminohippurate (PAH), which measures effective renal plasma flow (ERPF)[6] and by Doppler ultrasonography.[14,15] Renal blood flow measured by Doppler and ERPF by clearance of PAH is lowest in newborns, and it correlates with gestational age. The increase in renal blood flow after birth in preterm infants is influenced by postconceptional rather than postnatal age. ERPF increases from 20 mL/min/1.73 m^2 at 30 weeks gestation to 45 mL/min/1.73 m^2 by 35 weeks gestation and 83 mL/min/1.73 m^2 at term gestation.[16] During the first 3 months of postnatal life, ERPF increases rapidly to 300 mL/min/1.73 m^2. Thereafter ERPF increases gradually, reaching values of 650 mL/min/1.73 m^2 by 12 to 24 months of age[6,17] (Figure 125-1). However, the clearance of PAH underestimates ERPF in the neonatal period because the renal extraction of PAH is only 60% during the first 3 months of age compared with 95% by 5 months of age.[18] The low renal extraction of PAH in the neonate[9,19,20] has been attributed to shunting of blood to non-PAH-extracting tissues (e.g., relatively greater medullary blood flow, intracortical efferent arteriovenous shunting).

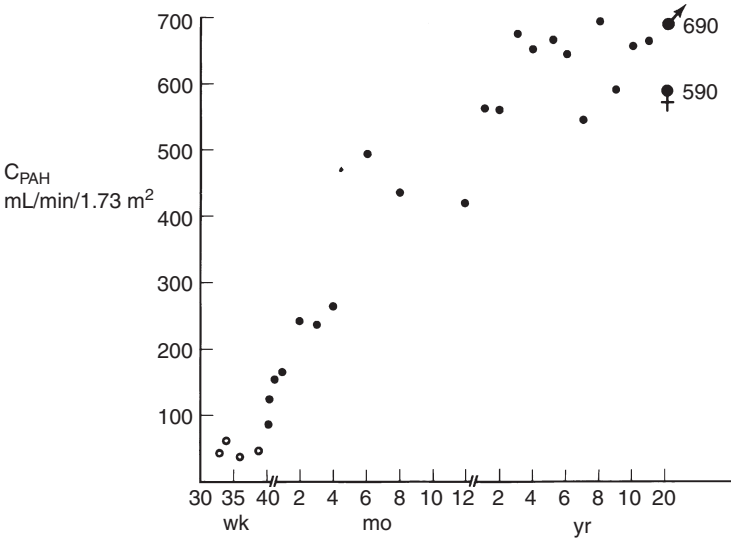

Figure 125-1 The clearance of *p*-aminohippurate (C_{PAH}) with age. *(From Rubin MI, Bruck E, Rapoport M, et al: Maturation of renal function in childhood: Clearance studies,* J Clin Invest *28:1144, 1949, by copyright permission of the American Society for Clinical Investigation.)*

Intrarenal Blood Flow

The renal vasculature is characterized by two capillary networks—the glomerular and peritubular capillary systems—linked in series with each other. The major sites of renal vascular resistance are the glomerular arterioles. Blood enters the glomerulus via the afferent arteriole that arises from the interlobular artery, and it exits via the efferent arteriole. Vasoconstriction or vasodilation at these sites regulates blood flow to the glomerulus (hence, glomerular filtration rate) as well as the intrarenal distribution between the cortex, which contains all the glomeruli, and the medulla, which contains vasa recta and tubules but not glomeruli. In the mature kidney, the afferent arteriole of inner cortical nephrons accounts for the entire preglomerular resistance to blood flow, whereas in superficial cortical nephrons, the interlobular arteries offer the largest resistance to blood flow.[21,22] Blood flow to each region of the kidney (cortical, medullary, and papillary) increases with maturation.[9,20,23-27] The distribution of intrarenal blood flow in the young, however, is different from that reported in adults. The neonatal kidney has a greater percentage of blood flow to the inner cortical and medullary areas than does the adult kidney. The low extraction ratio of PAH in infants younger than 3 months of age may be related to a relatively greater perfusion of juxtamedullary nephrons. As total renal blood flow reaches adult levels with maturation, a greater fraction of renal blood flow is received by the outer cortical nephrons. The duration of this maturational period varies from species to species.

Autoregulation of Renal Blood Flow in the Young

The mature kidney exhibits autoregulation; that is, renal blood flow remains constant even though renal perfusion pressure (determined by mean arterial pressure) varies throughout a range from low to high. Autoregulation depends on intrarenal mechanisms and is modulated by intrarenal factors. In the newborn, the range of autoregulation is set at lower perfusion pressures than seen in the adult, and the renal pressure-flow relationship changes with renal growth.[28-31] Autoregulation of renal blood flow is less efficient in the young than in the adult. Furthermore, uninephrectomy impairs the autoregulatory response in young rats but does not affect this response in adult rats. This reduced autoregulatory efficiency in the neonate is apparently the result of prostaglandin-dependent renin release, which causes vasoconstriction at lower levels of perfusion pressure.[29]

Maturational relationships between tubular flow and glomerular filtration rate (tubuloglomerular feedback) also occur with growth. The tubuloglomerular feedback mechanism is maximally sensitive at a tubular flow range that corresponds to the normal operating range. As the glomerular filtration rate increases with maturation, the maximal response and flow range also increase so the relative sensitivity of the tubuloglomerular feedback mechanism is unaltered during growth.[32] The relative roles of endothelial cell, smooth muscle, and tubuloglomerular feedback have not been defined in the developing animal.

REGULATION OF POSTNATAL RENAL HEMODYNAMICS

The low renal blood flow of the neonate and the increase that occurs with maturation are the result of a combination of effects, including alterations in cardiac output, perfusion pressure, and renal vascular resistance. Lower cardiac output and perfusion pressure may partially account for the decreased renal blood flow noted in the newborn infant. In the dog, however, cardiac output corrected for body weight is highest in the youngest puppies, which also have the lowest renal blood flow per body weight.[20,33] The proportion of cardiac output distributed to the kidneys is 4% to 6% in the first 12 hours of life and increases to 8% to 10% in the first week of life. In comparison, 25% of cardiac output is distributed to the kidneys in the normal adult. Systemic vascular resistance decreases markedly after birth. This may cause a redistribution of blood flow to organs other than the kidney and may immediately contribute to the low neonatal renal blood flow. Systemic vascular resistance gradually increases with maturation and therefore is not a factor in the increase in renal blood flow with age. Renal vascular resistance, however, is the most important regulating component contributing to postnatal renal hemodynamics. Gruskin and colleagues[7] demonstrated that, in the developing piglet, the major factor influencing the maturational increase in renal blood flow was an 86% decrease in renal vascular resistance. Renal vascular resistance in the developing kidney is influenced by *structural* factors, the number and size of vascular channels, as well as by *functional* vasoactive factors, the modulators of the resistance offered by the glomerular arterioles[10,34,35] (Figure 125-2).

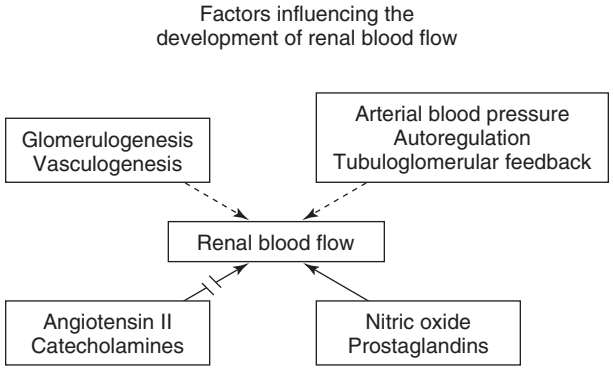

Figure 125-2 Factors that influence the development of renal blood flow include anatomic factors (glomerulogenesis and vasculogenesis), physical factors (arterial blood pressure, myogenic autoregulatory response), and vasoactive factors (autoregulation, tubuloglomerular feedback, angiotensin II, catecholamines, renal nerves, nitric oxide, and prostaglandins). Other vasoactive agents can regulate renal blood flow; however, renal vascular resistance in the newborn regulated by vasoactive agents is probably the result of a balance between the vasoconstrictor influences of angiotensin II and catecholamines or renal nerves and the vasodilatory influences of nitric oxide and prostaglandins.

Role of Anatomic Development

The contribution of structural changes to the maturational changes of renal vascular resistance in the developing kidney is an important consideration. Renal vascular resistance in the developing kidney is a function of the number of existing vascular channels, as well as the arteriolar resistance offered by each channel.[10,34,35] The main structural development that could influence renal hemodynamics postnatally is the addition of vascular channels by nephrogenesis, resulting in a decrease in renal vascular resistance. The increase in renal blood flow after birth is caused by development and formation of new glomeruli and vascular remodeling. This increase may play a role in the postnatal renal hemodynamic development of several of the mammalian species in which nephrogenesis continues after birth, such as canines, swine, and rodents. Renal blood flow, however, continues to increase in these species long after glomerulogenesis has completed.[6,19,20,36] In addition, the increase in the diameter of resistance vessels during maturation is greater in the kidneys than in other organs.[37] In studies in canine puppies, Evan and colleagues[34] found substantial differences, both quantitative and qualitative, between neonatal and adult renal vasculature.[10] However, morphologic changes in renal resistance vessels cannot account for the rapid decreases in renal vascular resistance that occur in the period of renal hemodynamic maturation.

Specifically, in humans, nephrogenesis is completed at 34 weeks gestation, yet renal blood flow continues to rise and renal vascular resistance continues to decrease with postnatal age, a finding indicating that the functional vasoactive characteristics of the immature renal vessels determine this alteration. Several studies confirmed the major contribution of the functional vasoactive attributes of the developing renal vasculature in altering renal blood flow.[9,12,13,38,39] Thus, although structural development may contribute to the changes in developing kidney by decreasing renal vascular resistance during nephrogenesis, the functional vasoactive changes of the resistance vessels are the main factors producing the maturational changes in renal hemodynamics.

Role of Vasoactive Factors

High renal vascular resistance accounts for the low renal blood flow at birth, and the increase in renal blood flow with maturation mainly results from the progressive reduction in renal vascular resistance.[7,9,11,13,19,20] Vasoactive factors modulate renal blood flow through the alteration of renal vascular resistance by (1) the extent of participation of resistance vessels (interlobular artery and afferent and efferent arterioles), (2) the intrinsic properties of immature resistance renal vasculature, and (3) neurohormonal factors unique to the immature kidney. The site of high renal vascular resistance in the newborn animal has been localized mainly to the preglomerular resistance vasculature, the interlobular artery, and the afferent arteriole.[40] In older animals, increases in renal blood flow are associated with a decrease in resistance in all the glomerular vessels: the interlobular, afferent, and efferent arterioles.[8] The decrease in renal vascular resistance with age may be modulated by developmental changes in the intrinsic properties of the renal resistance vasculature. However, little is known about the myogenic internal vasoactive capabilities of these vessels or about any developmental differences in resistance vessel responsiveness to vasoactive factors. Ultimately, the characteristics of postnatal renal hemodynamics are considered to be a balance of neurohormonal vasoactive factors. Both the vasoconstrictors and the vasodilators producing this immature renal condition have differing effects, intrarenal levels, and sites of action compared with the mature adult. Several vasoactive agents participate in the regulation of renal blood flow in the postnatal maturing kidney, including adenosine, arginine vasopressin (AVP), angiotensin II, atrial and other natriuretic peptides, bradykinin, endothelin, nitric oxide (NO), prostaglandins, renal nerves, and the adrenergic nervous system.

Adenosine

The intrarenal vasodilator action of adenosine has been implicated as an important mediator of tubuloglomerular feedback in the adult, and it may play a role in protection of the outer medulla from hypoxia. Tubuloglomerular feedback is important in the renal autoregulation of glomerular filtration rate and blood flow. Adenosine, formed by the breakdown of adenosine triphosphate, can be a renal vasodilator. Several adenosine receptor subtypes have been cloned: A_1, A_{2A}, A_{2B}, and A_3.[41] In the adult, adenosine decreases the glomerular filtration rate and increases renal blood flow apparently by reducing efferent vascular resistance.[42-44] In one study, intrarenal adenosine reduced cortical blood flow via adenosine A_1 receptors and increased medullary blood flow via adenosine A_2 receptors.[45] The stimulation of renal adenosine A_1 receptors is associated with inhibition of renin release and constriction of afferent arterioles, whereas adenosine A_2 receptors promote renin release and dilate afferent and efferent arterioles. Xanthines block all the adenosine receptor subtypes. In the adult, methylxanthines produce no consistent change in renal blood flow. Theophylline, however, via its adenosine receptor blocking property (independent of phosphodiesterase inhibition), increases renal vascular resistance in newborn rabbits.[46] The role of adenosine receptors in the control of renal blood flow during development remains to be determined. It is possible that adenosine A_2 receptors may act to modulate the high neonatal renal vascular resistance.[47]

Arginine Vasopressin

AVP functions as an intrarenal vasoconstrictor. There are three major AVP receptor subtypes: V_{1a}, V_{1b}, and V_2.[41] The V_2 receptors found in collecting ducts of the kidney increase hydraulic conductivity. V_{1a} receptors in arterioles mediate vasoconstriction, whereas V_{1b} receptors in pituitary corticotrophs and the limbic system may mediate corticotroph responsiveness and control of emotional processes. In conscious dogs, AVP has been shown to vasodilate the kidney via V_2 receptors.[48] AVP has the potential to contribute to the increased renal vascular resistance present in the neonate through its action on vascular and glomerular V_1 receptors. The role it plays in regulating basal renal hemodynamics remains to be defined. Infusion of synthetic AVP does not alter renal blood flow and renal vascular resistance in fetal sheep. AVP may still play a role, however, in certain stress-induced reductions in renal hemodynamics. For example, the marked decrease in renal blood flow and renal vascular resistance has been closely correlated with the rise in plasma AVP during hemorrhage but not with hypoxemia.[49]

Angiotensin II

The highly activated renin-angiotensin system, through the vasoconstriction properties of angiotensin II, contributes to the high renal vascular resistance in the immature kidney.[26,50-55] Circulating renin and angiotensin II levels are high in most neonatal mammals, including humans, and they decrease with age.[51,53,54] Angiotensin II is the predominant vasoconstrictor in the developing renal vasculature. There are four angiotensin II receptors: AT1, AT2, AT3, and AT4.[41] In rodents, there are two AT1 receptors: AT1a and AT1b. AT1a and AT2 receptors are differentially expressed during development. AT2 but not AT1 receptors are expressed in the very immature fetal structures, a finding implicating a role in nephrogenesis.[54,56-58] Angiotensin II, AII, perhaps via AT1 but more probably via the AT2 receptor, may be involved in fetal renal development including angiogenesis. The AT2 receptor gene is expressed to the greatest extent in fetal kidneys; its expression decreases rapidly after birth in the rat. In contrast, AT1 receptor expression increases progressively after birth.[59-61] AT1 receptors, which mediate vasoconstriction, are expressed at later stages in the glomerulus, resistance arterioles, and medulla,[56,62] including the period of hemodynamic development. Studies show that AII via the AT receptors has a significant role in renal formation and postnatal function. Abnormalities in renal development are noted in human infants and neonatal rats treated with angiotensin-converting enzyme inhibitors. In neonatal rats, AT1, but not AT2, receptor antagonists produce renal defects similar to those noted with angiotensin-converting enzyme inhibitors, a finding further attesting to the importance of this receptor subtype in kidney development.[58,59,63,64] However, disruption of both AT1 and AT2 receptors can lead to malformations of the kidney and urinary tract.[58] Specific blockade of the AT1 receptor in neonatal rats results in significant functional changes later in life that may show sex differences. AT1 inhibition for 2 weeks after birth in rats produces increased blood pressure and decreased nephron number in both males and females. However, only males exhibit decreased papillary volume, significant proteinuria and reduced GFR at 3 months of age.[64] Although nonspecific inhibition of AII has not revealed developmental differences in renal hemodynamics, the regulatory role of the renin-angiotensin system has been clarified with the use of nonpeptide antagonists of AII receptors. Systemic infusion of an angiotensin-converting enzyme inhibitor in conscious newborn sheep—although decreasing renal vascular

resistance—did not change renal blood flow.[65] Administration of the nonselective angiotensin receptor antagonist saralasin by Osborn and colleagues[66] in piglets and Jose and colleagues[30] in puppies, did not significantly alter renal hemodynamics. However, the intrarenal infusion of a nonpeptide-specific AT1 receptor antagonist produces greater increases in renal blood flow in newborn piglets compared to the adult, suggesting that AII, via the AT1 receptor, is a more important renal vasoconstrictor in the immature kidney than the adult.[55] Chappallez and Smith[67] determined the individual roles of the AT1 and AT2 receptors in renal hemodynamics of conscious lambs. AT1 receptor inhibition significantly decreased RVR and increased RBF, while altering mean arterial pressure only at high doses. Further, the pressor responses to aII infusion were abolished by AT1 inhibition. In contrast, AT2 blockade did not change any of these parameters.[67] AT2 receptors, in fact, may be vasodilatory.[68] This may explain the inability of angiotensin-converting enzyme inhibition to affect renal blood flow in newborn piglets.[69] Thus angiotensin II, via the AT1 receptor, plays an important role in the regulation of renal blood flow in the newborn and during the postnatal period. In contrast to the apparently increased vasoconstrictor effect of angiotensin I via AT1 receptors affecting RBF in the immediate neonatal period, angiotensin II may actually be needed to maintain glomerular filtration rate in the neonatal rabbit. Interruption of the renin-angiotensin system in neonatal rabbits decreases glomerular filtration rate without affecting renal blood flow.[70]

Atrial and Other Natriuretic Peptides

There are several natriuretic peptides: atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), and C-type natriuretic peptide (CNP).[71] ANP and BNP (originally described in brain) are produced in the atria and ventricles, whereas CNP is found mainly in the brain, pituitary gland, vascular endothelium, kidney, and female genitourinary tract. ANP is present in both atria and ventricles of the fetus in several species, and circulating levels of this peptide in plasma are significantly elevated compared with those of the adult.[72-74] Within the first few weeks of life, however, the plasma concentrations of ANP fall to adult levels. During the early developmental period, the release of ANP appears to respond to various stimuli that are associated with volume overload. The most important vascular and renal effects of ANP in mature animals are as follows: (1) vasodilation and decrease in mean blood pressure; (2) increase in renal blood flow, glomerular filtration rate, and filtration fraction; (3) inhibition of sodium and water reabsorption in both proximal and distal tubules; and (4) decreased concentrating ability. Although ANP may play a role in sodium and volume homeostasis during the perinatal period, its role in the regulation of renal hemodynamics is uncertain. In rabbits, clear age differences in the renal response to intravenous infusions of α-human ANP have been noted. In response to ANP, newborn rabbits demonstrate a decrease in diuresis and kaliuresis and no change in natriuresis, whereas an immediate increase in diuresis, natriuresis, and kaliuresis occurs in adult rabbits.[75] The infusion of recombinant ANP into fetal sheep results in minimal declines in mean arterial blood pressure. In contrast, significant decreases in blood pressure and increments in heart rate have been observed in newborn and adult sheep during continuous infusion of pharmacologic doses of ANP. ANP reduces renal blood flow in fetal and newborn sheep. This effect, however, decreases with maturation,[76] and its significance is not clear. Several natriuretic peptide receptors (NPR) have been cloned: NPR-A, NPR-B, NPR-C, and NPR-D.[77] ANP and BNP bind to NPR-A, whereas CNP binds to NPR-B receptors. Both receptors generate cyclic guanosine monophosphate; NPR-C, which has an equal affinity to all the natriuretic peptides, is not linked to cyclic guanosine monophosphate. NPR-C acts as a clearance receptor to regulate circulating levels of natriuretic peptides but may also generate NO. NPR-D has been identified only in eels. Systemic clearance of ANP is increased in the newborn and decreases with development.[78] The decreased effects of ANP in the newborn period cannot be explained by increased clearance of ANP or by decreased production of cyclic guanosine monophosphate.[79]

Bradykinin

Bradykinin is the major functional vasodilator produced by the kallikrein-kinin system. Bradykinin exerts its effects via B_1 and B_2 receptors.[41] Under physiologic conditions, most of the effects of bradykinin are mediated by the B_2 receptor. NO may, in part, mediate the vasodilation of bradykinin.[80,81] Kallikreins are proteinases that liberate vasoactive kinins from the protein precursor kininogen. The bradykinin-synthesizing enzyme, kininase II, is identical to angiotensin-converting enzyme, which produces angiotensin II. Although bradykinin may play a role in renal morphogenesis,[82-84] the role of this vasodilator in the renal hemodynamics is less certain. Several studies indirectly suggest that bradykinin may participate in the maturational increase in renal blood flow. Urinary kallikrein excretion corrected for either renal mass or glomerular filtration rate increases with maturation.[85,86] Kininase II mRNA and enzymatic activity are low in newborn rat kidney and peak at 2 to 3 weeks of age.[87] However, studies have failed to demonstrate a significant role for bradykinin in immature renal hemodynamics. Newborn and 6-week-old lambs failed to show any renal hemodynamic response to acute intrarenal injection of a selective kinin B_2 antagonist.[88] Long-term administration of the same B_2 antagonist to neonatal rats from birth to 3 weeks did not alter the maturational increase in renal blood flow.[89] The possibility remains, however, that bradykinin opposes the basal vasoconstriction of angiotensin II in the immature rat kidney.[89]

Endothelin

Endothelin, one of the vasoconstricting factors produced by the endothelium, is one of the most potent endogenous vasoconstrictor, second only to urotensin II. There are three different endothelin peptides encoded by three distinct genes: endothelin-1 (ET-1), endothelin-2 (ET-2), and endothelin-3 (ET-3). ET-1 produces renal vasoconstriction in both the afferent and efferent arterioles. Two ET receptors, ETA and ETB, mediate endothelin action in the kidney. However, it is most likely that ETA receptors facilitate the ET-1 vasoconstrictor action; endothelins can also mediate vasodilation.[90,91] On the basis of pharmacologic evidence, two types of ETB receptors have been postulated: ETB1, which is a relaxant; and ETB2, which is a constrictor. In ETB knockout mice, both vasodilatory and vasoconstrictor effects of ETB receptors were eliminated, a finding suggesting that the ETB1 and ETB2 receptors are the same receptor.[90] The differences in ETB1 and ETB2 actions are related to the sites where these receptors are expressed. Thus ETB (ETB1) receptors expressed in endothelial cells (tunica intima) cause vasodilation because of their linkage to NO and prostaglandins, whereas ETB receptors expressed in vascular smooth muscle cells (tunica media) cause vasoconstriction.[92,93] In full-term infants, the urinary excretion of ET-1 remains constant in the first month of life; in premature infants, ET-1 excretion increases with maturation such that, after the first week, postnatal values exceed those found in older children.[94] In newborn rabbits, ET-1 failed to change renal hemodynamics at doses that decreased renal blood flow in adults; however, at higher doses, exogenous endothelin induced a marked reduction in renal blood flow and glomerular filtration rate in the newborn as well.[95] Blockade of endogenous ET-1 activity in newborn rabbits by ET-1 antiserum increased renal vascular resistance and decreased renal blood flow.[96] These studies suggest that ET-1 may not be responsible for the increased renal vascular resistance in the newborn period. Rather, ET-1, via endothelial ETB, may function as a renal vasodilator to counteract the vasoconstrictor effects of other systems (e.g., angiotensin II and catecholamines).

The finding that ETA and ETB blockade in the newborn increases renal blood flow but does not affect glomerular filtration indicates that endothelin is probably not an important factor in the increase of renal blood flow with age.[97]

Nitric Oxide

Nitric oxide (NO) synthesized by nitric oxid synthase (NOS) is an important endogenous regulator of renal hemodynamics in the immature kidney, functioning as a critical vasodilator to counterbalance highly activated vasoconstrictors, such as angiotensin II.[55] Three NOS isoforms exist: endothelial (eNOS), inducible (iNOS), and neuronal (nNOS). However, only eNOS and nNOS participate in regulating basal renal hemodynamics. The immature renal vasculature is highly responsive to alterations of the NO synthesizing enzyme, NOS. Figure 125-3 shows the renal blood flow responses of the 3-week-old piglet to sequential intrarenal infusions of acetylcholine, a NOS stimulator, and L-NAME, an arginine analogue that nonselectively competitively inhibits all NOS isoforms.[12] Several reports identify NO as a vital participant in postnatal developing renal hemodynamics under physiologic and pathophysiologic conditions.[12,36,98,99] The intrarenal infusion of the NOS inhibitor, L-NAME, in both whole animals (piglets and newborn lambs)[36,100] and isolated perfused kidneys (newborn rabbits),[101] produces greater renal hemodynamic responses than the adult. These data suggest that renal NO production by NOS is greater in the immature kidney compared with the adult. This increased NO production is supported by the distinct developmental patterns in the postnatal maturing porcine kidney of two NOS isoforms: nNOS and eNOS.[102,103] Whole kidney and corticomedullary nNOS protein abundance is greatest in the newborn (and at all immature ages) but decreases with age to reach the lowest values in the adult.[102] This distinct pattern suggests that nNOS may be the more important NOS isoform participating in immature renal hemodynamics. The ability of NO to counteract the effects of vasoconstrictor agents under physiologic conditions suggests that NO may be even more important in pathologic conditions (e.g., perinatal hypoxemia).[99] In newborn rabbits, the renal blood flow responses to L-NAME are significantly greater during hypoxemia. These conditions induce an intense renal vasoconstriction, mediated by angiotensin II, often resulting in vasomotor acute renal failure.[5] Thus NO may serve to protect the immature kidney from the deleterious effects of adverse perinatal events that lead to vasomotor acute renal failure.

Prostaglandins

Arachidonic acid is an essential fatty acid that is metabolized through different pathways: 5-lipoxygenase leads to formation of leukotrienes, 15-lipoxygenase leads to formation of lipoxins, cytochrome P450 leads to formation of epoxy-20:3, and cyclooxygenase (COX) leads to formation of prostaglandins and thromboxanes. In rats, arachidonic acid metabolism in the kidney shifts from a lipoxygenase-dependent to a cytochrome P450-dependent pathway during development.[102] Two COX isoforms are present in the kidney: COX-1 and COX-2. COX-1 is found in the renal vasculature, glomeruli, and collecting ducts across species lines.[103] However, COX-2 intrarenal localization is species dependent. In rats and dogs, COX-2 localizes to tubules, macula densa, and thick ascending limb of the loop of Henle, whereas in humans, COX-2 co-localizes with COX-1.[104,105] Several therapeutic agents such as nonsteroidal antiinflammatory drugs, including aspirin and indomethacin, nonselectively inhibit both COX-1 and COX-2. Celecoxib and rofecoxib are selective COX-2 inhibitors. Although COX-1 may not undergo postnatal regulation, COX-2 is highest after birth (between 1 and 2 weeks in rats) and declines with age.[103,106-108] COX-2 involvement in nephrogenesis may contribute to renal dysgenesis syndromes associated with COX inhibition. In fetal kidneys, COX-2 strongly localizes to tubular

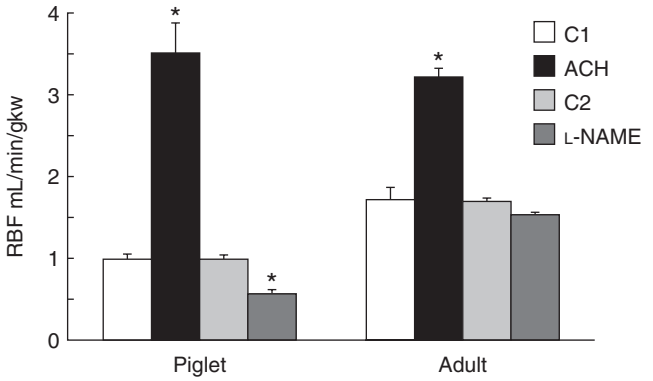

Figure 125-3 Comparison of the renal blood flow (RBF) responses in immature and adult renal vasculature to vasoactive agents that act on the nitric oxide (NO) synthesizing enzyme, nitric oxide synthase (NOS). RBF responses were directly measured by electromagnetic flow probe in anesthetized 3-week-old piglets and adults (n = 4) during the sequential intrarenal infusions of NOS stimulation with acetylcholine, 0.05 μg/kg/min (ACH), and NOS inhibition with L-NAME, 3 μg/kg/min (L-NAME) with interval control periods (C1 and C2). The immature kidney demonstrates lower baseline RBF in both control periods. RBF responses were greater in the immature kidney to NOS stimulation, ACH, and inhibition with L-NAME. *gkw,* Gram kidney weight. *$p < .05$ versus others within each group. *(Modified from Solhaug MJ, Ballèvre LD, Guignard JP, et al: Nitric oxide in the developing kidney,* Pediatr Nephrol *10:529, 1996.)*

structures, which differ from the adult.[98,99] Selective COX-2 inhibition leads to disruption of nephrogenesis in both mice and rats.[109] Genetic ablation of COX-2 results in severe morphologic abnormalities, including impaired glomerulogenesis, cortical dysplasia, and diffuse tubular cyst formation.[110] These studies confirm the teratogenic potential of prenatal use of nonsteroidal antiinflammatory drugs and selective COX-2 inhibitors leading to acute renal failure and renal dysgenesis.[111-113]

Despite the increasing information about the role of COX isoforms in nephrogenesis, the functional vasoactive role of the COX products (prostaglandins) in the immature kidney is uncertain. In fact, the relation of specific COX isoforms to renal function is not well understood. In general, thromboxanes and leukotrienes vasoconstrict the kidney, whereas prostaglandins and lipoxins vasodilate it. Cytochrome P450 metabolites of arachidonic acid can act as vasoconstrictors or vasodilators. Renal prostaglandin production is increased during the perinatal period. In preterm infants, the urinary excretion of prostaglandin E and a prostacyclin metabolite is five times that noted at term and is 20 times greater than that observed in physiologically normal children.[113] Glomerular prostaglandin synthesis and adenylate cyclase response to prostaglandin E_2 also decrease with maturation.[114,115] Moreover, when prostaglandin synthesis is inhibited by indomethacin in the unstressed adult or neonate, blood flow is either unchanged or redistributed to the outer cortex. Therefore, if prostaglandin synthesis was deficient in the newborn infant, one could expect a pattern of blood flow converse to that normally found in the neonatal kidney.[57] Likewise, the increased renal blood flow found in the uninephrectomized young rat is not maintained by increased prostaglandin or decreased thromboxane effects.[29] Although neonatal rabbits may be more sensitive to the vasoconstrictor effects of acetylsalicylic acid,[116] prostaglandin inhibition does not alter basal renal blood flow in the immature piglet kidney.[12] Moreover, the COX inhibitor ibuprofen does not affect renal blood flow in preterm neonates.[117] Thus, in the newborn, as in adults, prostaglandins play little or no role in the

control of renal blood flow in the normal animal at rest. Prostaglandins may, however, attenuate renal vasoconstriction in pathologic conditions. In contrast, prostaglandins may be important in the fetus in the regulation of renal blood flow under both basal and stress conditions.[118] In young and adult rats, the major pathway of arachidonic acid metabolism in glomeruli occurs via the lipoxygenase pathway[114]; however, the effects of this pathway on basal renal blood flow during development remain to be determined. Moreover, the renal development of the eight prostanoid receptors has not been determined.[41,119]

Renal Nerves and the Adrenergic System

The influence of renal innervation and the adrenergic nervous system is both maturation and species dependent. The renal circulation of the pig is under tonic neural vasoconstrictor influence, whereas that of the sheep is not. As such, renal denervation does not alter basal renal blood flow in fetal lambs but does result in an increase in renal blood flow in piglets. Overall, the renal vascular bed of the newborn seems to be more sensitive, but less reactive, than that of the adult in response to renal nerve stimulation.[120,121] Low-level stimulation of the renal nerve of fetal sheep and 1- to 2-week-old piglets results in a greater increase in renal vascular resistance than in their adult counterparts. During higher levels of renal nerve stimulation, however, renal vascular resistance increases to a greater extent in older animals than in younger animals. In the presence of α-adrenergic blockade, renal nerve stimulation induces an increase in renal blood flow in fetal and newborn lambs but not in adults. This effect is apparently the result of a greater density of α- (versus β-) adrenergic receptors in neonatal sheep. After the immediate newborn period, the neonatal renal circulation is more sensitive to α-adrenergic stimulation in several species (dogs, pigs, guinea pigs, sheep) compared with adults.[14,122,123] An age-dependent increase in renal blood flow and a concomitant decrease in renal vascular resistance with α-adrenergic blockade have been shown in piglets[122] and in canine puppies.[13,123] Isolated renal vessels of fetal lambs, studied in vitro, are also more sensitive and reactive to α-adrenergic agonists than are their newborn or adult counterparts. The rabbit seems to be an exception in that the renal vasculature in the adult is more sensitive to catecholamines compared with newborns. β-Adrenergic agonists increase renal blood flow to a greater extent in neonatal than in adult sheep. An opposite effect has been noted in piglets. The renal vasodilator effect of dopamine increases with maturation in several species (pigs, dogs, sheep).[123,124] The earlier reports of apparent absence of ontogenic differences in the renal catecholamine response in sheep can now be attributed to bolus versus constant intrarenal infusions. Fetal and newborn sheep are more responsive to the vasoconstrictor effects of α-adrenergic ligands and less responsive to the vasodilator effects of dopaminergic ligands.[26,122,125-128]

CONCLUSION

The low renal blood flow in the young is the result of several factors, including smaller size, decreased number of glomeruli, lower systemic pressure, and higher renal vascular resistance. The increased renal vascular resistance in the newborn is probably caused by increased activity of the renin-angiotensin system as well as increased sensitivity to vasoconstrictor catecholamines. The latter is the result of receptor and postadrenergic receptor mechanisms. Critical vasodilators, such as NO, may act to counterbalance these vasoconstrictor forces. The increase in renal blood flow with age presumably occurs as the vasoconstrictor influences decline. New ligands and receptors continue to be discovered, but their roles, if any, in the development of renal blood flow remain to be determined.

Development of the Renin-Angiotensin System

The *renin-angiotensin system* (RAS) regulates arterial blood pressure, renal hemodynamics, and fluid and electrolyte balance.[1,2] The RAS cascade comprises a series of enzymatic reactions that culminate in the generation of angiotensin peptides, the main effectors of the system (Figure 126-1). Renin, the key regulatory enzyme of the system, is produced mainly by the juxtaglomerular (JG) cells of the kidney and released into the circulation, where it catalyzes the hydrolysis of angiotensinogen to generate angiotensin I. Angiotensin I is subsequently hydrolyzed by angiotensin-converting enzyme (ACE) to form the octapeptide angiotensin II. Most of the known actions of the RAS are exerted through the binding of angiotensin II to cell membrane–bound receptors, AT_1 and AT_2. Additional receptors and alternative pathways for the generation of other angiotensin peptides with potential biologic actions have been identified (see Figure 126-1).[3]

In addition to the endocrine effects of the circulating RAS, a locally acting intrarenal RAS regulates renal function by paracrine and/or autocrine effects.[4,5] The extrarenal tissue RASs remain controversial, but components of the system and local generation of angiotensins have been described in tissues outside the kidney including brain, heart, blood vessels, adrenal gland, testis, and eye.[6-8] In addition to the well-known hemodynamic effects of the RAS, angiotensin II is also involved in normal and abnormal growth processes.[9,10] These actions seem to be well conserved across the phylogenetic scale and are important in the development and maintenance of normal nephrovascular architecture.[11]

MATURATION OF THE RENIN-ANGIOTENSIN SYSTEM

The major components of the RAS are present from early gestation, but their anatomic distributions and activities are in many cases different from those seen in the adult mammal.These differences are likely to result in distinct functions of the RAS within different tissues in the growing, differentiating, and maturing fetus. Although little information exists regarding the components of the RAS in human fetal or infant tissues, several animal models have been thoroughly studied and are mentioned here.

Angiotensinogen

Angiotensinogen is a 55- to 60-kDa glycoprotein precursor of the angiotensin peptides and is the only known substrate for renin.[12] Angiotensinogen is encoded by a single gene on human chromosome 1, and its messenger RNA (mRNA) product encodes a prohormone. Removal of the leader peptide results in a mature protein of which the angiotensin I decapeptide is the amino terminus.[12]

In adult animals, the primary source of circulating angiotensinogen is the liver, but angiotensinogen mRNA levels have also been detected in other organs and tissues including kidney, brain, heart, vasculature, adrenal gland, ovary, placenta, and adipose tissue.[13] However, in the fetal rat liver, angiotensinogen mRNA levels are almost undetectable.[14] In contrast, angiotensinogen is expressed at relatively high levels in the yolk sac and fetal placenta, as well as fetal brain, fat, and kidney,[14] and circulating

Development of the Renin-Angiotensin System

The *renin-angiotensin system* (RAS) regulates arterial blood pressure, renal hemodynamics, and fluid and electrolyte balance.[1,2] The RAS cascade comprises a series of enzymatic reactions that culminate in the generation of angiotensin peptides, the main effectors of the system (Figure 126-1). Renin, the key regulatory enzyme of the system, is produced mainly by the juxtaglomerular (JG) cells of the kidney and released into the circulation, where it catalyzes the hydrolysis of angiotensinogen to generate angiotensin I. Angiotensin I is subsequently hydrolyzed by angiotensin-converting enzyme (ACE) to form the octapeptide angiotensin II. Most of the known actions of the RAS are exerted through the binding of angiotensin II to cell membrane–bound receptors, AT_1 and AT_2. Additional receptors and alternative pathways for the generation of other angiotensin peptides with potential biologic actions have been identified (see Figure 126-1).[3]

In addition to the endocrine effects of the circulating RAS, a locally acting intrarenal RAS regulates renal function by paracrine and/or autocrine effects.[4,5] The extrarenal tissue RASs remain controversial, but components of the system and local generation of angiotensins have been described in tissues outside the kidney including brain, heart, blood vessels, adrenal gland, testis, and eye.[6-8] In addition to the well-known hemodynamic effects of the RAS, angiotensin II is also involved in normal and abnormal growth processes.[9,10] These actions seem to be well conserved across the phylogenetic scale and are important in the development and maintenance of normal nephrovascular architecture.[11]

MATURATION OF THE RENIN-ANGIOTENSIN SYSTEM

The major components of the RAS are present from early gestation, but their anatomic distributions and activities are in many cases different from those seen in the adult mammal.These differences are likely to result in distinct functions of the RAS within different tissues in the growing, differentiating, and maturing fetus. Although little information exists regarding the components of the RAS in human fetal or infant tissues, several animal models have been thoroughly studied and are mentioned here.

Angiotensinogen

Angiotensinogen is a 55- to 60-kDa glycoprotein precursor of the angiotensin peptides and is the only known substrate for renin.[12] Angiotensinogen is encoded by a single gene on human chromosome 1, and its messenger RNA (mRNA) product encodes a prohormone. Removal of the leader peptide results in a mature protein of which the angiotensin I decapeptide is the amino terminus.[12]

In adult animals, the primary source of circulating angiotensinogen is the liver, but angiotensinogen mRNA levels have also been detected in other organs and tissues including kidney, brain, heart, vasculature, adrenal gland, ovary, placenta, and adipose tissue.[13] However, in the fetal rat liver, angiotensinogen mRNA levels are almost undetectable.[14] In contrast, angiotensinogen is expressed at relatively high levels in the yolk sac and fetal placenta, as well as fetal brain, fat, and kidney,[14] and circulating

levels of angiotensinogen are similar to or higher than those seen in adult animals.[15] In sheep, angiotensinogen mRNA levels increased steadily throughout the last third of gestation.[16] In the human fetus, however, angiotensinogen mRNA is expressed in the fetal liver from early stages of development.[17]

In the umbilical cord of the human fetus angiotensinogen levels are low.[18] Levels rise in the neonatal period and are higher in the infant than the adult.[18] In newborn rats, a 20-fold increase in the expression of angiotensinogen in the liver occurs within 24 hours of birth, and this expression remains elevated until the pups are weaned.[14] Concomitantly, circulating angiotensinogen levels rise quickly after birth.[19]

The production of angiotensinogen by the adult liver is regulated by various physiologic stimuli. Salt depletion, sex steroids, thyroxine, and angiotensin II stimulate angiotensinogen expression, whereas it is suppressed by insulin.[20-23] The fetal liver is also clearly responsive to hormonal stimuli. In the rat, dexamethasone or thyroxine administration stimulates fetal liver angiotensinogen expression.[24]

The functional importance of angiotensinogen in the fetus remains unclear, and the secretion of the protein from its various sources has not been determined. However, its presence in the yolk sac and placenta implies potential actions in the control of fetal perfusion and fluid and electrolyte transport. Its presence in numerous developing organs may also suggest a role in tissue morphogenesis and blood flow regulation.[25]

Overall, these studies indicate that, as the animal matures, angiotensinogen synthesis and regulation mature in preparation for the transition from fetal to extrauterine life. These changes in angiotensinogen availability are accompanied by adjustments in the control of blood flow patterns, blood pressure, and salt and water homeostasis.

Renin

Renin is an aspartyl protease with a unique substrate, angiotensinogen. Renin substrate specificity is so stringent that only homologous angiotensinogen is cleaved efficiently.[26] Human renin is encoded by a single gene in chromosome 1 and is synthesized as pre-prorenin, an inactive single polypeptide precursor molecule. Removal of the signal peptide results in prorenin, which is subsequently glycosylated and is stored in immature granules before further processing into mature active renin. Renin is thought to be secreted by two pathways: a regulated pathway for mature renin and a constitutive pathway for prorenin, which accounts for approximately 70% to 90% of the renin in the human circulation.[27] Therefore prorenin may be a reservoir for local generation of active renin and angiotensin II, but the biologic significance of this finding is still poorly understood. Renin is mainly synthesized in the kidney vasculature. However, extrarenal production of renin has been demonstrated in adrenal, liver, gonads, and brain, although in much lower abundance.[28] The characterization, regulation, and roles of extrarenal renin are areas of active investigation.

In the normal adult, renin is synthesized and released to the circulation by JG cells, a small group of myoepithelioid granulated cells located in the wall of the afferent arteriole at the entrance to the glomerulus. However, during early development, renin-expressing cells are broadly distributed along large intrarenal arteries, inside the glomeruli, and in the renal interstitium.[29-33] As maturation continues, the number of renin cells is reduced as they become progressively restricted to a few cells in the JG area found in the adult kidney. Because adult JG cells contain myofilaments, it has been postulated that they derive from smooth muscle cells.[34] However, it is now clear that renin cells are in fact progenitors for arteriolar smooth muscle cells, mesangial cells, and a subset of proximal and distal tubular cells.[35] Renin cells are also progenitors for specific cell types in extrarenal sites.[35]

The developmental pattern of renin cell distribution and the importance of renin cells in generating other cell types are relevant to understand the phenomenon of recruitment. Recruitment is a survival mechanism whereby a threat to homeostasis (such as dehydration or hypotension) results in an increase in the number of renin-expressing cells along the preglomerular arteries, inside the glomeruli, and in the kidney interstitium resembling the embryonic and fetal pattern (Figure 126-2). The increase in the number of renin-expressing cells, with the attendant increase in circulating renin, is due to dedifferentiation of preexisting adult cells and does not involve migration or replication of cells. It was recently demonstrated that the cells that retain the plasticity to develop phenotypic characteristics of renin cells are the same ones that expressed *renin* earlier in development.[35] Recruitment of renin cells extends to other organs beyond the kidney including the adrenal gland[36,37] and extrarenal arteries,[38] which also express *renin* early in development, again, pointing to the relationship between cell lineage and recruitment.

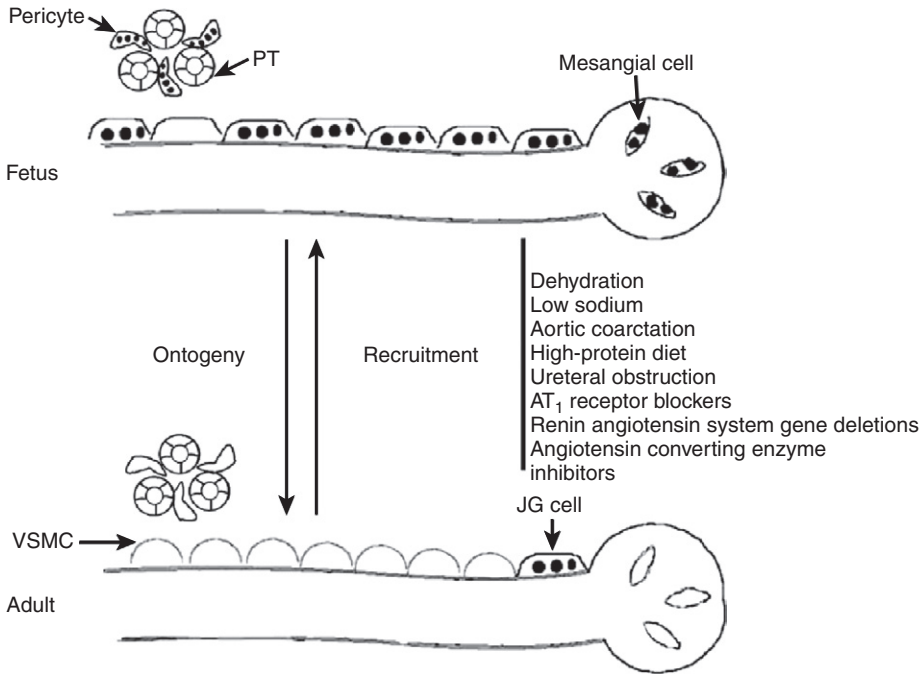

Figure 126-2 Ontogeny and recruitment of renin-expressing cells. Renin-expressing cells are represented with *black dots. JG,* Juxtaglomerular; *PT,* proximal tubule; *VSMC,* vascular smooth muscle cell.

In humans, *renin* expression and activity are markedly different during fetal and neonatal life compared with the mature animal. Renin is observed early in human development, first localized to the mesonephros at 5 to 6 weeks gestation.[29] By 8 weeks gestation, renin is found within the metanephros, several weeks before the onset of fetal urine production.[29] Although renin production is strictly localized to the juxtaglomerular apparatus in the normal adult, its localization (in other mammals) is more widely distributed within the developing renal microvasculature. After birth, renin expression decreases in the larger vessels until it remains only in the classic juxtaglomerular location.[32,33] This developmental pattern of renin expression has been found in every species examined.[29]

The major source of circulating renin during fetal life is the kidney,[39] and fetal plasma renin concentration and activity are elevated compared with levels in newborns who likewise have higher levels than adults.[40-42] In preterm infants, plasma renin activity is high and inversely correlates with gestational age.[43] At birth, plasma renin activity increases further for several weeks and then begins a slow decline through infancy and childhood until adult levels are reached by 6 to 9 years of age.[40]

Renin release is modulated by many different positive and negative stimuli, and control of this process is well established in the late-gestation fetus and in the newborn.[44,45] The principal mechanisms controlling renin release are the macula densa mechanism, the baroreceptor, the sympathetic nervous system, and various hormonal mechanisms. The macula densa mechanism stimulates renin release when macula densa cells (that are in close proximity to JG cells) sense a decrease in sodium chloride concentration in the distal tubule.[46,47] The renal baroreceptor responds to decreases in renal perfusion pressure in the afferent arteriole with increases in renin secretion.[48] The sympathetic nervous system, acting through the renal nerves and cell-surface β-adrenergic receptors, also stimulates renin production and release.[49,50] All of the above mechanisms are active during development, and both humoral and intracellular signals including cyclic adenosine monophosphate, Ca^{2+}, and prostaglandins mediate the release of renin from its storage pools and are active during development.[51,52] Angiotensin II generated by the RAS cascade in turn exerts a negative feedback on renin synthesis and release, thereby preventing uncontrolled hypertension or fluid overload once the homeostatic challenge that triggered renin release has been controlled. These stimuli result in changes in renin release that are qualitatively similar to those seen in adults. The physiologic, pharmacologic, and pathophysiologic factors that affect the RAS during development are shown in Box 126-1.[44] The end result of these integrated regulatory mechanisms is a precise and physiologically responsive control system that accurately governs renin secretion in the immature animal.

Angiotensin-converting Enzyme

Angiotensin-converting enzyme (ACE) is a zinc-containing protease that cleaves carboxy-terminus dipeptides from small peptides, most notably angiotensin I and bradykinin. Human ACE is the product of a single gene that ultimately produces two extensively glycosylated polypeptides: a larger form found in endothelial cells and most somatic tissues and a smaller form found in testis.[53] ACE has hydrophobic amino acids at the N terminus that provide an anchor to the cell membrane. The soluble form of ACE present in plasma and seminal fluid is derived by posttranslational cleavage of the C-terminal region and may reflect turnover of membrane-bound ACE.[54]

A novel enzyme similar to ACE, named ACE 2, has recently been identified, which hydrolyzes only one amino acid from angiotensin I and generates angiotensin (1-9) and from angiotensin II to generate angiotensin (1-7).[55] In turn, the "classic" ACE can convert angiotensin (1-9) to angiotensin (1-7) (see Figure 126-1). ACE 2 is expressed mainly in the airway epithelium and vascular endothelial cells of the lung[56] and in epithelial cells of the kidney.[57] ACE 2 may balance the activity of the RAS counterregulating the actions of ACE on angiotensin II generation and at the same time enhancing angiotensin (1-7) formation.[58]

In contrast to renin expression, ACE activity is relatively low during fetal life and increases slowly as term approaches.[59] After delivery, renal ACE activity in the rat increases to a maximum within the first 2 weeks, followed by a decline to adult values by 1 to 2 months.[60,61] In human infants, plasma ACE levels are similar to those seen in adults.[18] At every age studied, ACE has the same substrate affinity.[59] However, the maximum velocity (V_{max}) of the enzyme is four-fold lower in fetal than in adult tissues, a finding suggesting that increasing ACE activity during development is the

BOX 126-1

Factors that Increase and Decrease the Activity of the Renin-Angiotensin System in the Fetus and Newborn Mammal

Increase
- Prematurity
- Vaginal delivery
- Furosemide
- Hemorrhage
- Hypotension
- Hypoxemia
- Aortic constriction
- Exchange transfusion (withdrawal)
- Upright position

Decrease
- Volume expansion
- Indomethacin
- Phenylephrine
- Cortisol
- Arginine vasopressin
- Recumbent position
- Exchange transfusion (replacement)

Modified from Gomez RA, Pupilli C, Everett AD: Molecular and cellular aspects of renin during kidney ontogeny, *Pediatr Nephrol* 5:80, 1991.

result of the production of more enzyme rather than further activation of preexisting enzyme.[59] During renal organogenesis, ACE is first detected in proximal tubules, endothelial cells invading the S-shaped glomerulus, and the afferent and efferent arteriolar endothelium of more mature glomeruli.[62] With maturation, ACE is predominantly expressed by proximal tubules and peritubular capillaries.[62] The presence of vascular and intraglomerular ACE during nephrogenesis suggests that local angiotensin production may be necessary for normal development of the glomerulus and renal microvasculature.

Angiotensin II

Angiotensin II regulates blood pressure and fluid and electrolyte homeostasis through various actions. Angiotensin II is an extremely potent vasoconstrictor; intravenous infusion results in a pressor response within 15 seconds that lasts for 3 to 5 minutes.[63]

Angiotensin II concentration in the fetus is twice that of maternal plasma, accordingly with the high levels of active renin during development.[18] Circulating angiotensin II levels remain high during the newborn period and decrease with age, paralleling the changes in active renin. In addition, the enzymes responsible for degradation of angiotensin II, the angiotensinases, are relatively inactive in the developing animal, and therefore high circulating levels of angiotensin II are maintained during early life.[64]

Although angiotensin II is the main active product of the RAS, other metabolites of angiotensin I and II (see Figure 126-1) may have significant biologic activity, mostly in tissues. For example, angiotensin (1-7) has a vasodilatory effect, inhibits cell growth, and causes natriuresis, in contrast to the vasoconstrictor and growth-promoting actions of angiotensin II.[65,66] Angiotensin III (2-8) and IV (3-8) are generated by the removal of amino acids from the N terminus of angiotensin II by the action of aminopeptidases (see Figure 126-1). Angiotensin III may play an important role in regulating blood pressure at the central nervous system, and angiotensin IV seems to cooperate with angiotensin II in the brain.[67]

Angiotensin II Receptors

Angiotensin II receptors have been located by radioligand binding in every angiotensin II–responsive tissue or cell type and mediate the physiologic and pathologic effects of angiotensin II. At least four receptor subtypes have been described.[68] The major receptor subtypes, AT_1 and AT_2, have widely divergent patterns of tissue distribution and second-messenger signaling mechanisms.

Both AT_1 and AT_2 receptors contain seven transmembrane domains, but the glycosylated proteins share only 32% homology.[69] AT_1 receptors are coupled to G proteins.[70] Stimulation of AT_1 by angiotensin II induces hydrolysis of inositol phosphates, increases intracellular calcium (Ca^{2+}) and diacylglycerol, inhibits adenylate cyclase, and releases arachidonic acid metabolites.[71] Most of the established actions of angiotensin II are mediated by AT_1 receptors that are widely distributed on many cell types. These physiologic and pathologic effects include (1) cardiovascular effects: vasoconstriction, increased blood pressure, increased cardiac contractility, cardiac and vascular hypertrophy; (2) renal effects: tubular sodium reabsorption, inhibition of renin release; (3) nervous system effects: sympathetic system and adrenal cortex (aldosterone release); and (4) miscellaneous effects: proinflammatory and profibrogenic effects, growth stimulation, and oxidative stress.[70,72-74]

AT_2 receptors are not coupled to G proteins; they activate an intracellular phosphotyrosine phosphatase, thereby inactivating mitogen-activated protein (MAP) kinase and decreasing cyclic guanosine monophosphate levels.[75-78] In addition, a growth-inhibitory function has been described for AT_2.[75,79] The role for AT_2 and other putative receptor subtypes during development remains elusive. AT_2 mRNA is abundant in brain, kidney, and other tissues during fetal life but decreases rapidly after birth.[69] Stimulation of AT_2 receptors decreases blood pressure by the release of nitric oxide, induces differentiation, inhibits growth, and mediates apoptosis.[78]

AT_4 receptors have been identified as insulin-regulated aminopeptidases[80] and may mediate the release of plasminogen activator inhibitor I by angiotensin II, III, and IV.[68] The function of the AT_3 receptors is still unknown.

Some evidence exists that angiotensin (1-7) acts through a Mas receptor (product of the Mas proto-oncogene).[68]

Both AT_1 and AT_2 subtypes are developmentally regulated and are found in fetal membranes as early as 10 days of gestation in the rat.[81] During embryonic life, the AT_2 subtype predominates and is expressed in most mesenchymal tissues.[82] AT_1 receptors are also present, although in fewer numbers.[82] In the fetal rat kidney at 14 days of gestation (the beginning of metanephric development), 80% of angiotensin receptors are the AT_2 subtype and are localized to the undifferentiated renal mesenchymal cells.[83] By 17 days of gestation, AT_1 expression has increased and is found primarily in deep, more mature glomeruli but also diffusely throughout the nephrogenic cortex.[83,84] At birth, AT_1 and AT_2 are equally prevalent. AT_2 continues to be expressed in undifferentiated cells or differentiating structures, whereas AT_1 predominates in glomeruli, arteries, and vasa recta.[83-85] After birth, AT_2 is rapidly down-regulated, but it remains detectable at low levels in the adult adrenal gland, renal glomeruli, and nephrons.[86] AT_1 persists in the renal microvasculature, mesangial cells, and proximal tubules, where it is maintained throughout adulthood.[83-85]

In addition to maintaining fluid and blood pressure homeostasis, during development angiotensin II receptors regulate morphogenetic events in various tissues including the kidney. The AT_1 receptor is linked to certain G protein–associated second-messenger systems (phospholipase C in vascular smooth muscle, phospholipase A_2 in proximal tubules, and adenylcyclase in adrenal cortex) through which smooth muscle contraction, Na^+ reabsorption, and aldosterone secretion, respectively, are mediated.[70] Few of these effects have been studied in the developing human.

The classic representation of the RAS is that of circulating renin acting on constitutively secreted angiotensinogen to produce circulating angiotensin II. This endocrine system is highly functional and is up-regulated during development. As shown in Figure 126-3, circulating levels of angiotensinogen, renin, angiotensin II, and aldosterone are all higher in developing animals than in adults.[87] Evidence supports the additional existence of local, or tissue, RASs that may generate angiotensin II for paracrine or autocrine functions.[4,88] Because all components of the RAS are present early in the developing embryo and are found in the kidney before the onset of fetal urine production, it is possible that the local system may regulate growth and differentiation of developing nephrons and other tissues. Once kidney structures are formed, the RAS then begins to regulate renal hemodynamics and Na^+ transport.

Renin Receptors

Renin and prorenin receptors have recently been described in several tissues, including heart, kidney, brain, and placenta.[89] Two renin-prorenin receptors have been cloned and sequenced, and the existence of a third receptor has been suggested.[89-92] The putative (pro)renin receptor consists of a 350–amino acid protein with a single transmembrane domain, and it is highly homologous in human, mouse, rat, chicken, fish, *Xenopus*, and *Caenorhabditis elegans*.[89,93] Cell culture experiments on cells expressing the (pro)renin receptor in the presence of angiotensin receptor blockers, ACE inhibitors, and/or renin inhibitors showed that both renin and prorenin signal in an angiotensin-independent manner by activation of mitogen-activated protein kinases (MAPK p42/44 and p38) and subsequent heat shock protein (HSP) 27 phosphorylation.[89,94-96] Prorenin stimulation of the MAPK p38/HSP27 pathway in cardiomyocytes showed an alteration in actin filaments and may be the cause of cardiac hypertrophy in transgenic animals overexpressing *prorenin*.[96,97] In the kidney, by up-regulation of transforming growth factor-β1, renin has been linked to the development of renal fibrotic disease.[94,98,99]

FUNCTIONAL EFFECTS OF ANGIOTENSIN II DURING DEVELOPMENT

The production of angiotensin II by the active renin-angiotensin cascade in the fetus and newborn results in systemic and local effects that control systemic blood pressure, renal hemodynamics, and fluid and electrolyte homeostasis by interaction of angiotensin II with its receptors. In addition, angiotensin II regulates various growth and developmental processes that are important to the care of the maturing infant. Although the role of angiotensin II in the maintenance of physiologic processes has been more thoroughly studied in adults,[70] appropriate functional responses to stimuli of the RAS have been well established during development. Hypotension, aortic constriction, hemorrhage, furosemide, ACE inhibition, sympathetic nervous system activity, prostaglandins, vasopressin, and atrial natriuretic peptide can all influence renin secretion and thereby the production of angiotensin II in the fetus (see Box 126-1).

Blood Pressure Control

The role of angiotensin II in the control of systemic blood pressure is exerted through effects on several systems (Figure 126-4). Blood pressure is increased by elevations in both peripheral vascular resistance and cardiac output, which, in turn, are increased by both heart rate and stroke volume. The direct vasoconstrictor effects of angiotensin II, mediated by AT_1 receptor–initiated increases in vascular intracellular Ca^{2+}, provide an exceedingly powerful mechanism for raising systemic pressure rapidly by increasing small-vessel resistance. Additional mechanisms by which angiotensin II can increase blood pressure include alterations in cardiac output through AT_1-mediated increases in myocardial contractility and centrally mediated increases in sympathetic nervous system activity to increase heart rate. Angiotensin II directly stimulates proximal tubular Na^+ reabsorption and also leads to intrarenal vasoconstriction that ultimately results in further Na^+ and water reabsorption and extracellular volume expansion. An additional long feedback loop allows angiotensin II to stimulate aldosterone secretion and thereby increase distal renal Na^+ reabsorption. Meanwhile, angiotensin II in the central nervous system stimulates thirst and salt appetite and further increases extracellular volume. These aggregate effects of angiotensin II provide a closely balanced and integrated endocrine and paracrine system capable of tight regulation of arterial blood pressure and body fluid homeostasis. Studies in genetically engineered animals have confirmed the primary role of the RAS in blood pressure regulation. Disruptions of the genes for *angiotensinogen*,[100] *renin*,[101,102] *ACE*,[103,104] or the AT_{1A} receptor[105] in mice result in marked decreases in blood pressure. These findings confirm the importance of the RAS in the normal regulation of blood pressure and illustrate that no other mechanism completely compensates for the lack of angiotensin II activity.

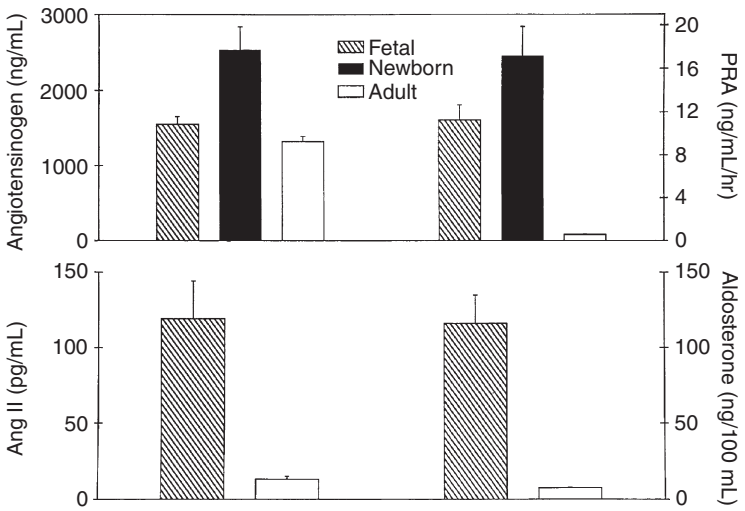

Figure 126-3 Circulating levels of angiotensinogen, plasma renin activity *(PRA)*, angiotensin II *(Ang II)*, and plasma aldosterone in fetal cord blood, newborn infants, and physiologically normal adults. *(From Tufro-McReddie A, Gomez RA: Ontogeny of the renin-angiotensin system,* Semin Nephrol *13:519, 1993; data from Godard C, Gaillard R, Vallotton MB: The renin-angiotensin-aldosterone system in mother and fetus at term,* Nephron *17:353, 1976.)*

The potency of angiotensin II changes with development. The pressor response to exogenous angiotensin II is lower in fetal and newborn lambs than in adults,[106] and it may be caused by occupancy of the receptors by high concentrations of endogenous angiotensin II, as well as maturational differences in receptor density or function. The hypotensive response to fetal hemorrhage is mediated in part by angiotensin II, but it also increases as maturation proceeds. A 20% reduction in fetal placental blood volume results in hypotension in young fetuses but has no effect near term, a finding suggesting that the control of fetal blood pressure by the RAS increases with maturation.[107]

As in the adult, alterations in the activity of the RAS during early life may lead to pathologic situations. In the human infant, hypertension usually results from activation of the RAS. Renal artery thromboembolism caused by umbilical artery catheter use, coarctation of the aorta, renal artery stenosis, obstructive uropathy (especially ureteropelvic junction obstruction), glucocorticoid administration, and bronchopulmonary dysplasia all stimulate angiotensin II production. These infants are usually given treatment with ACE inhibitors such as captopril or enalapril. However, the potency of these drugs is enhanced in the first 6 months of life, and care must be taken to avoid hypotension and oliguria.[108] Effective reductions in blood pressure have been obtained with doses much lower than those required by older infants. Current recommendations suggest a starting captopril dose of 0.05 mg/kg with careful increases until the appropriate effect is obtained. Adverse effects of these drugs include neutropenia, rash, hyperkalemia, and decreased glomerular filtration rate (GFR) necessitating careful follow-up for infants requiring these medications. Although of benefit in the treatment of hypertension, the angiotensin-receptor blockers have not yet been as thoroughly evaluated in infants or young children.

Renal Hemodynamics

The intrarenal actions of angiotensin II include control of renal blood flow, GFR, and tubular Na^+ excretion. The effects on renal blood flow and GFR are primarily mediated through AT_1 receptors in the afferent and efferent arterioles, with the dominant vasoconstriction occurring in the efferent arteriole.[4] As in adult animals, administration of angiotensin II to fetal lambs decreases renal blood flow and maintains GFR by increasing efferent arteriolar tone.[106] Within the adult glomerulus, angiotensin II binding to mesangial cell AT_1 receptors results in contraction and decreased filtration by decreasing the surface area available for filtration.[109] This response may serve as a counterbalance to the increase in GFR caused by efferent arteriolar constriction. AT_1 receptors are also present in fetal mesangial cells,[110] but their role in intraglomerular hemodynamic control is unknown. Treatment of the fetus with ACE inhibitors decreases renal vascular resistance and GFR by decreasing efferent arteriolar tone.[111] When given on a long-term basis to fetuses, ACE inhibitors can dramatically decrease fetal GFR and urine flow,[111] and this may explain the neonatal anuria and renal compromise seen in human

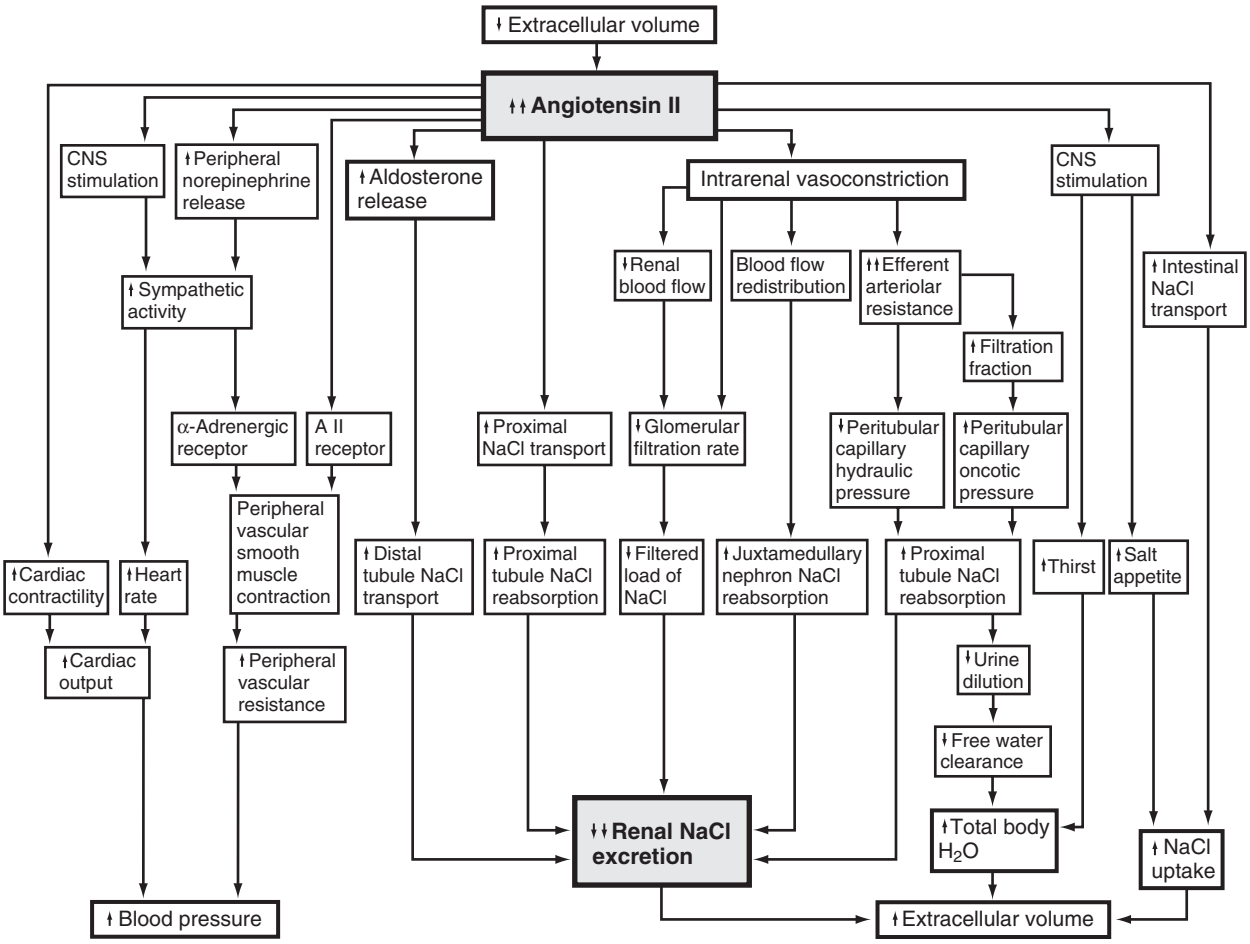

Figure 126-4 The integration of angiotensin II *(A II)* effects to maintain arterial pressure and extracellular fluid volume. *CNS,* Central nervous system. *(From Ballermann BJ, Zeidel ML, Gunning ME, et al: Vasoctive peptides and the kidney. infants exposed to these drugs in utero. The use of these drugs during the second and third trimesters of pregnancy is associated with renal dysplasia, oligohydramnios, pulmonary hypoplasia, and renal failure in the fetus, features that make these drugs contraindicated during pregnancy.[112] These effects are most likely the result of loss of angiotensin II–dependent blood flow to the fetal kidney, as well as inhibition of the angiotensin II–dependent growth effects.

Fluid and Electrolyte Balance

Angiotensin II mediates the control of systemic fluid and electrolyte balance through various mechanisms, some directly affecting renal hemodynamics or tubular transport and others indirectly altering intake or output of water and solutes. In the brain, angiotensin II, through AT_1 receptors, stimulates thirst, salt appetite, and vasopressin release, all of which increase extracellular fluid volume.[113] AT_1 receptors in the adrenal cortex respond to angiotensin II stimulation by production and secretion of aldosterone that subsequently enhances basolateral Na^+, potassium–adenosine triphosphatase (Na^+,K^+-ATPase) and Na^+ channel activity in the distal nephron, resulting in increased Na^+ reabsorption. Although the fetal adrenal gland responds to angiotensin II stimulation by secretion of aldosterone, the rise in plasma aldosterone is less than that seen in adult animals, a finding suggesting relative insensitivity of the fetal adrenal gland to angiotensin II stimulation.[106] In the proximal tubule, AT_1 receptors activate both luminal and basolateral Na^+ transport mechanisms including the Na^+/H^+ antiporter,[114] the Na^+/bicarbonate cotransporter,[115] and Na^+,K^+-ATPase,[116] all of which result in net Na^+ reabsorption. In the cortical collecting duct, angiotensin II, acting through AT_1 receptors, stimulates H^+-ATPase activity, a finding suggesting additional roles for angiotensin II in the control of acid-base balance.[117] An additional mechanism by which angiotensin II controls fluid and electrolyte balance is via control of peritubular blood flow. The capillaries that compose the peritubular network are downstream from the glomerulus, having branched from the efferent arteriole. As a result, factors that affect afferent and efferent blood flow and GFR directly affect peritubular flow. Efferent vasoconstriction decreases postglomerular flow and hydrostatic pressure and increases peritubular oncotic pressure, resulting in enhanced Na^+ and water reabsorption. Therefore the net effect of angiotensin II stimulation in the renal tubule is to encourage Na^+ and water reabsorption.

Although direct evidence of the function of the various components of the tubular RAS in the fetus and newborn is not available, it is likely that the relative immaturity of all or some of these control mechanisms may account for the negative Na^+ and water balance seen in premature infants. The relatively poor capacity for Na^+ reabsorption seen in the immature newborn explains the tendency for development of hyponatremia in these infants when they are given diets with Na^+ contents appropriate for older infants. As maturation proceeds, renal reabsorptive capacity for Na^+ increases, and the term infant maintains a positive Na^+ balance on various diets. In fact, acquisition of adequate Na^+ stores is required for cellular growth and bone mineralization.[118] It has been hypothesized that the ongoing deposition of Na^+ into growing bone may be the mechanism driving the higher set point for the RAS in the developing animal.[118]

Angiotensin II as a Growth Factor

The role of angiotensin II as a modulator of growth is now well established in various cardiovascular, renal, and other cell types and tissues. These effects have important implications for organogenesis, tissue maturation, glomerulosclerosis, and aging. In vascular smooth muscle cells, angiotensin II stimulation of AT_1 receptors elicits hypertrophic,[119,120] hyperplastic,[121] or dual effects.[122] In contrast, the AT_2 receptor inhibits proliferation in coronary endothelial cells.[123] Angiotensin II has also been shown to induce angiogenesis in the chick embryo chorioallantoic membrane.[124] Angiotensin II may also play a role in the architectural development and growth of the renal vasculature.

Within the various cell types of the nephron, angiotensin II has both hypertrophic and proliferative effects. The type of growth response to angiotensin II appears to be both species specific and cell specific, as well as developmentally regulated. Human and murine fetal mesangial cells respond to angiotensin II with proliferation,[110] whereas adult mesangial cells respond primarily with hypertrophy.[125,126] Proximal tubular cells from rabbits, mice, and pigs all respond to angiotensin II by increasing cell size and protein content,[119,127] whereas medullary thick ascending limb cells proliferate in response to the peptide.[128] The mechanisms by which angiotensin II exerts these effects remain incompletely understood, but to date all have been ascribed to the AT_1 receptor.[125,126] These responses may be mediated directly by angiotensin II, or they may involve various growth factors, protooncogenes, kinases, and phosphatases.[10]

The growth effects of angiotensin II have also been explored in whole animal models. Blockade of the neonatal rat AT_1 receptor with losartan results in decreased ratios of kidney to body weight and suppressed renal cell proliferation.[52] Similar results have been shown with use of ACE inhibitors.[129] The kidneys from treated animals exhibited fewer, smaller glomeruli and tubular dilation, as well as vascular malformations.[130,131] Kidneys from animals receiving an AT_2-specific inhibitor showed no abnormalities,[130] a finding indicating that the nephrogenic effects of angiotensin II are mediated through AT_1. The lack of AT_2 effect in this model is most likely the result of the rapid down-regulation of this receptor after birth.

Transgenic animals carrying targeted disruptions of components of the RAS raise new questions regarding the importance of angiotensin II in renal developmental processes. Animals lacking renin,[101,102] angiotensinogen,[100] ACE,[104] or both AT_{1A} and AT_{1B} receptors[132,133] demonstrate an increased neonatal mortality and progressive development of renal arterial and cortical disease after birth. Abnormalities include delayed glomerular maturation, tubular atrophy, decreased renal vascular branching, arterial and arteriolar wall thickening, and interstitial fibrosis. *AT_2*[134,135] homozygous null mice have no renal abnormalities on some genetic backgrounds but various genitourinary abnormalities on other backgrounds, suggesting that AT_2 control of renal development may be modified by other factors.[136] These results imply a central role for angiotensin II and its receptors in the appropriate development of the kidney and in the maintenance of structural integrity of the adult kidney.

Unfortunately, the growth effects of angiotensin II have also been demonstrated in human infants, in whom ACE inhibition during pregnancy has been associated with intrauterine growth restriction, renal dysplasia and anuria, pulmonary hypoplasia, bone malformations, and neonatal death.[112] These drugs are consequently contraindicated during pregnancy. Although nephrogenesis is complete in the human fetus by 32 to 36 weeks gestation, further growth and maturation of glomeruli and tubules occur until approximately 2 years of age. This brings into question the safety of ACE or other angiotensin II inhibitors during infancy. Premature and term newborns are very responsive to ACE inhibition, and they require lower doses and have more significant problems with decreased GFR, hyponatremia, and hyperkalemia than do older children.[108] These effects are explained by the highly activated state of the RAS during development and the known effects of RAS blockade. The potential effects of ACE inhibitors on renal growth and differentiation in premature and newborn infants have not been defined. Therefore the risks of these agents must be carefully weighed against the benefits of managing renin-mediated hypertension.

BOX 126-2

Primary Renal Tubular Dysgenesis

- Oligohydramnios
- Potter facies
- Anuria
- Hypotension
- Skull ossification defects
- Respiratory distress
- Perinatal death

BOX 126-3

Secondary Causes of Renal Tubular Dysgenesis

- Renal ischemia
- Twin-twin transfusion
- Major cardiac malformations
- Severe liver disease
- Infantile renal artery stenosis
- In utero exposure to renin-angiotensin system inhibitors

Recently, mutations in genes of the RAS (*renin, angiotensinogen, ACE*, or AT_1 receptor) in humans have been associated with autosomal recessive renal tubular dysgenesis, a severe disorder of tubular development characterized by persistent fetal anuria with oligohydramnios, Potter facies, hypotension, respiratory distress, and perinatal death, probably because of pulmonary hypoplasia (Box 126-2).[137,138] In the kidney this disease is characterized by an absence of proximal tubules. It has been proposed that renal lesions and early anuria result from chronic low perfusion pressure of the fetal kidney.[137] This syndrome should be differentiated from secondary causes of renal tubular dysgenesis resulting from renal ischemia as encountered in twin-twin transfusion, major cardiac malformations, severe liver disease, infantile renal artery stenosis, and in utero exposure to RAS inhibitors (Box 126-3). Altogether, those findings further support the crucial role of the RAS in human kidney development.

SUMMARY

The RAS is present and active at the earliest phases of development and appears to acquire different functions as maturation proceeds. Initially, the complex interplay between the mitogenic and trophic effects of angiotensin II and other growth mediators suggests an important role for angiotensin II in the tightly regulated processes of organogenesis and remodeling in the fetus. Along with other organ systems, these coordinated effects direct the kidney to become a properly differentiated and architecturally organized organ. At a slightly later time during development, coincident with differentiation and maturation of the kidney, the RAS gains the capability to control water and solute balance and renal hemodynamics. After birth, these mechanisms become more tightly regulated and efficient and allow the maintenance of homeostasis in the extrauterine environment.

Postnatal Development of Glomerular Filtration Rate in Neonates

The production of urine begins with the formation of an ultrafiltrate of plasma by the glomerulus. The function of the tubule is to modify this ultrafiltrate to allow an efficient excretion of waste products and the retention of those substances required to maintain body fluid volume and homeostasis. Glomerular filtration is also essential for the elimination of drugs. Alterations in glomerular filtration rate (GFR) have severe consequences on the body fluid homeostasis. An estimate of GFR may be required to prescribe fluids, electrolytes, or drugs excreted by the kidney. This chapter reviews the factors that regulate GFR and the methods available to assess GFR in the newborn infant.

PHYSIOLOGY OF GLOMERULAR FILTRATION

Each kidney contains approximately 1 million nephrons (227,327 to 1,825,380) consisting of a glomerulus and a tubule. The number of nephrons correlates with birth weight[1,2] (Figure 127-1), the count increasing by 25,743 for each 100 g of birth weight.[1] The glomerulus is a unique structure made out of a capillary network, the glomerular capillaries, supplied and drained by two resistance vessels, the afferent and the efferent arterioles. Urine formation starts by the production of an ultrafiltrate of plasma across the permselective glomerular capillary wall.[3,4] This wall consists of three layers: (1) the endothelial cell lining of the

glomerular capillaries; (2) the glomerular basement membrane, composed of connective, noncellular tissues; and (3) the visceral epithelial cells of the Bowman capsule. The endothelial cells have numerous fenestrae with a diameter of 70 to 100 nm. The capillary endothelium acts as a screen to prevent blood cells and platelets from entering into contact with the basement membrane. The endothelial cells contain on their surface negatively charged sialoproteins and proteoglycans. The endothelial glycocalyx could contribute to a primary glomerular anionic barrier that diminishes the load of macromolecules being passed into the glomerular basement membrane (GBM) and up to the slit diaphragms.[5] Under the endothelium, the GBM forms a continuous layer that probably behaves as the filtration barrier of large molecules. It is an amorphous, 300- to 350-nm–thick extracellular structure formed of negatively charged glycoproteins, mainly triple-helical type IV collagen, proteoglycans, laminin, and nidogen. The GBM-specific proteoglycans perlecan and agrin probably contribute to its charged selectivity because they contain negatively charged heparan sulfate side chains. The basement membrane is the main filtration barrier. The epithelium is formed by highly specialized cells called podocytes, which are attached to the basement membrane by foot processes known as *pedicels*.[6] Membrane proteins such as nephrin and prodocin are found in the foot processes and slit membranes. Mutations in these proteins result in massive proteinuria.[7] Adjacent pedicels are separated by filtration slits measuring approximately 25 by 60 nm in width, and each gap is bridged by a thin diaphragm. The diaphragms, in turn, contain rectangular "pores" with a dimension of 4 by 14 nm. Thus the filtration slits with their diaphragms could also constitute a size-selective filtration barrier. The podocytes may help in the phagocytosis of macromolecules. The size of the apertures in the glomerular filtration "barrier" is not the only factor that limits the passage of compounds through the glomerular capillary wall. The shape of the molecule, its flexibility and deformability, and its electrical charge also play important roles. The molecular weight (MW) cutoff for the glomerular filter is approximately 70,000 Da. Thus 69,000 Da MW albumin passes through the filter in minute quantities. Smaller molecules pass the filter more easily. Molecules with MW less than 7000 Da pass freely. The glomerular ultrafiltration thus initially contains small solutes and ions in the same concentration as present in the plasma.

The central part of the glomerular tuft is composed of irregularly shaped cells, the mesangial cells, that hold the delicate glomerular structures. By contracting, the mesangial cells can modify the filtering surface area of the glomerular capillaries. The mesangial cells also act as phagocytes to prevent the accumulation in the basement membrane of macromolecules that have escaped from the capillaries.

The rate of ultrafiltration is governed by several factors: the balance of Starling forces across the capillary wall, the rate at which plasma flows into the glomerular capillaries, the permeability of the glomerular capillary wall to water and small solutes, and the total surface area of the capillaries.[3] The ultrafiltration coefficient (K_f) is defined as the product of the glomerular capillary permeability and the area of the capillary available for filtration. The permeability of the glomerular capillaries is approximately 100 times greater than the permeability of other capillaries elsewhere in the body. The mean hydrostatic pressure within the glomerulus favors filtration. It is opposed by the oncotic pressure in the glomerular capillary. ΔP and $\Delta\pi$ represent the glomerular transcapillary hydrostatic and oncotic pressure, respectively. The net ultrafiltration pressure (P_{UF}) is defined as $\Delta P - \Delta\pi$. GFR is proportional to the sum of the Starling forces across the glomerular capillaries ($\Delta P - \Delta\pi$) times the K_f:

$$GFR = K_f\,(\Delta P - \Delta\,\pi)$$

In normal conditions, P_{UF} and GFR are highly dependent on the arterial pressure within the glomerular capillaries, on renal blood flow (RBF), and on the glomerular plasma flow rate. The transcapillary hydrostatic pressure is also regulated by the balance between the afferent and efferent arteriolar resistance (Figure 127-2). Pathologic conditions and drugs can affect GFR by

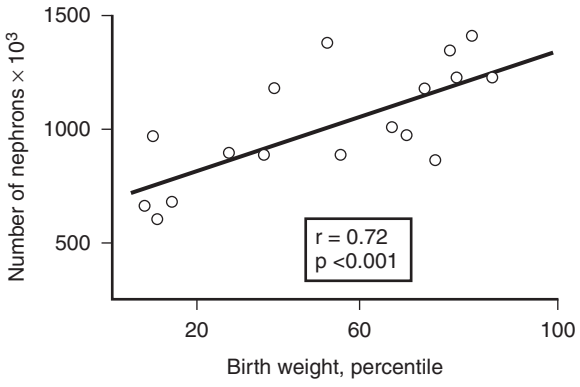

Figure 127-1 In humans the number of nephrons correlates positively with birth weight, here expressed in percentiles. *(Modified from Merlet-Bénichou C, Gilbert T, Vilar J, et al: Nephron number: variability is the rule—causes and consequences,* Lab Invest *79:515, 1999.)*

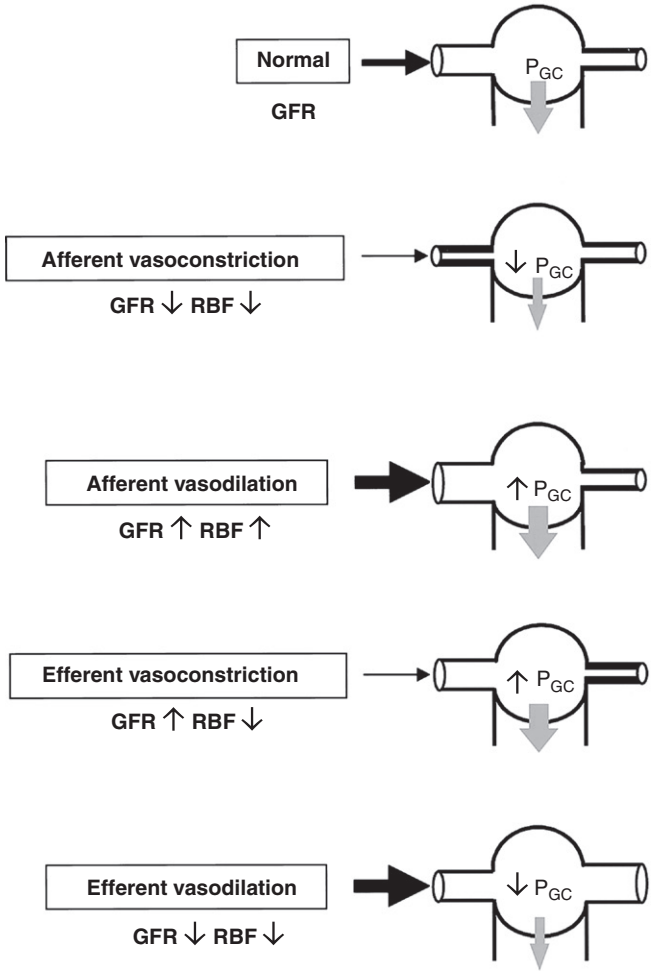

Figure 127-2 Effects of changes in the afferent or efferent arteriolar tone on renal blood flow *(RBF)* and glomerular filtration rate *(GFR)*. P_{GC}, Glomerular capillary hydraulic pressure.

modifying the pressure within the glomerular capillary (severe hypotension), the K_f (drugs, diseases), or the oncotic pressure within the glomerular capillary (changes in plasma proteins).

Vasoactive Agents

Several vasoactive agents modulate GFR and RBF during fetal and postnatal life.[8] Such agents include angiotensin II, the prostaglandins, atrial natriuretic peptide, endothelin, nitric oxide (NO), bradykinin, and adenosine. Sympathetic nerves can also affect vascular tone. All these factors modulate GFR by affecting afferent or efferent vascular tone (see Figure 127-2), as well as mesangial contractility. The main actions of the vasoactive agents are as follows.

Angiotensin II: This peptide is a very potent constrictor of the efferent arterioles and, to a lesser extent, of the afferent arterioles, acting on two types of receptors, the AT_1 and the AT_2 receptor subtypes. The AT_1 receptors are widely distributed and appear to mediate most of the biologic effects of angiotensin II. The exact role of the AT_2 receptors remains uncertain. Angiotensin II predominantly vasoconstricts the efferent arteriole, thereby increasing the intraglomerular pressure.[9] This mechanism serves to maintain GFR when the renal perfusion pressure decreases to low levels.

Prostaglandins: The prostaglandins are potent vasoactive metabolites of arachidonic acid.[10] They are of major importance for maintaining the GFR of the newborn kidney perfused at low arterial pressures. They further protect the kidney when vasoconstrictor forces are activated, as for instance during hypotensive, hypovolemic, and sodium depletion state or during congestive heart failure.[10]

Atrial natriuretic peptide: This 28–amino acid polypeptide increases GFR by producing afferent vasodilation and relative efferent vasoconstriction, thus increasing GFR without significantly affecting renal blood flow.[11] The kidney also produces a 32–amino acid natriuretic peptide, urodilatin, with the same local actions as atrial natriuretic peptide.

Nitric oxide: NO is a very potent vasodilator synthesized from L-arginine in endothelial cells throughout the body. In superficial nephrons, NO appears to decrease the preglomerular resistance with much less effect on the postglomerular resistance.[12] In juxtamedullary nephrons, NO decreases both the afferent and the efferent resistance. NO appears essential to fine-tune the vasoconstrictor action of angiotensin II.[13]

Bradykinin: This vasodilator and diuretic peptide is produced in the kidney by the effect of the enzyme kallikrein on kininogen. Bradykinin exerts its renal effects via β_2-receptors. The expression of this receptor is higher in neonatal than in adult kidneys, a finding suggesting a role for this peptide during renal development. Bradykinin vasodilates the newborn kidney, as evidenced by the renal vasoconstriction that results from β_2-receptor blockade.[14] It decreases the ultrafiltration coefficient.

Adenosine: Adenosine is an end product of adenosine triphosphate metabolism. Adenosine decreases GFR by vasodilating the efferent arteriole via A_2 receptor stimulation and by vasoconstricting the afferent arteriole via A_1 receptor stimulation.[15] By constricting the mesangial cells, adenosine further decreases the ultrafiltration coefficient.

Endothelin: This peptide released from endothelial cells constricts the afferent and the efferent arterioles, thereby decreasing both GFR and RBF. However, circumstantial evidence exists that, at low endogenous concentrations, endothelin may actually vasodilate the glomerular vessels in fetuses and neonates.[16,17] Endothelin stimulates whole kidney production of vasodilating prostaglandins that can partially balance its vasoconstrictive effects.

Sympathetic nervous system: The sympathetic nerve endings are primarily of the α_1- and β-adrenergic subtypes and secrete norepinephrine. Modest increases in renal nerve activity produce equivalent constrictions of both the afferent and efferent arterioles, reducing RBF without significantly affecting GFR.[18] At elevated concentrations, as occurring in severe acute hemorrhage fetal distress and asphyxia, norepinephrine vasoconstricts the mesangial cells, thus decreasing GFR.

Autoregulation of Glomerular Filtration Rate and Renal Blood Flow

Autoregulation is necessary to prevent abrupt changes in GFR and RBF when blood pressure varies acutely. Two systems are responsible for renal autoregulation: (1) a myogenic mechanism and (2) a tubuloglomerular feedback mechanism.

The myogenic mechanism refers to the intrinsic ability of arteries to constrict when blood pressure rises and to vasodilate when it decreases. This phenomenon prevents excessive changes in RBF and GFR when blood pressure varies.

The tubuloglomerular feedback mechanism involves the macula densa and the juxtaglomerular cells. The macula densa cells sense the changes in sodium chloride delivery to the distal tubule that follow changes in blood pressure. A drop in blood pressure and the consequent decrease in sodium chloride delivery stimulate angiotensin II formation by the juxtaglomerular cells. By constricting the efferent arteriole, angiotensin II increases the intraglomerular hydrostatic pressure and thus returns GFR toward normal levels.

CONCEPT OF CLEARANCE

The most common measurement of GFR is based on the concept of *clearance,* which relates the quantitative urinary excretion of a substance per unit time to the volume of plasma that, if "cleared" completely of the same contained substance, would yield a quantity equivalent to that excreted in the urine. The clearance *(C)* of a substance *(x)* is expressed by the following formula:

$$C = U_x \cdot V / P_x$$

where U_x represents the urinary concentration of the substance, V the urine flow rate, and P_x the plasma concentration. For its clearance to be equal to the rate of glomerular filtration, a substance must have the following properties: (1) it must be freely filterable through the glomerular capillary membranes, that is, not be bound to plasma proteins or sieved in the process of ultrafiltration; (2) it must be biologically inert and neither reabsorbed nor secreted by the renal tubules; and (3) it must be nontoxic and not alter renal function when infused in quantities that permit adequate quantification in plasma and urine.

Several substances, endogenous or exogenous, have been claimed to have the foregoing properties: inulin, creatinine, iohexol, ethylenediaminetetraacetic acid, diethylenetriaminepentaacetic acid, and sodium iothalamate. The experimental evidence that this is true has been produced only for inulin. The most commonly used markers in neonates are creatinine and inulin.

GLOMERULAR MARKERS

Inulin

Inulin, a fructose polysaccharide derived from dahlia roots and Jerusalem artichokes, has an Einstein-Stokes radius of 1.5 nm and a MW of approximately 5200. It diffuses as would a spherical body of such radius. Inulin is inert, is not metabolized, and can be recovered quantitatively in the urine after parenteral administration.

The rate of excretion of inulin is directly proportional to, and a linear function of, the plasma concentration of inulin over a wide

range. The clearance of inulin *(U • V/P)* is consequently independent of its plasma concentration. Evidence that inulin is neither reabsorbed nor secreted by the renal tubules has been obtained in experimental micropuncture studies showing that (1) the concentration of inulin was identical in the Bowman space fluid and plasma, (2) 99.3% of inulin injected in the proximal tubule could be collected in the distal tubule, and (3) the rate of recovery was the same when the peritubular plasma was loaded with inulin.[19]

Because the renal excretion of inulin thus occurs exclusively by glomerular filtration, its clearance is the most accurate index of GFR. Estimates of inulin clearance provide the basis for a standard reference against which the route or mechanisms of excretion of other substances can be ascertained.

Inulin as a Marker of Glomerular Filtration Rate in Neonates

The hypothesis that inulin may not be freely filtered across the immature glomerulus has not been confirmed by studies of inulin handling in several species. The same conclusion was reached from studies in preterm infants that showed that higher-MW inulin did not accumulate in the plasma of very immature babies infused with inulin for several days, thus excluding any retention of the larger molecules.[20,21]

In clinical practice, sinistrin, a readily soluble preparation of polyfructosan with side branching (extracted from bulbs of *Urginea maritima*), is more widely used. The clearance of sinistrin is identical to that of inulin. Because complicated analytic methods are required for its measurement, inulin and sinistrin cannot be used for routine clinical purposes. In neonates, only creatinine has been used broadly to assess GFR.

Creatinine

Creatinine is the anhydride of creatine, a compound that exists in skeletal muscle as creatine phosphate. It has a MW of 113 Da. Conversion of creatine to creatinine is nonenzymatic and irreversible. The serum creatinine level reflects total body supplies of creatine and correlates with muscle mass. Creatinine is excreted through the kidneys in quantities proportional to the serum content. The renal excretion of endogenous creatinine is very similar to that of inulin in humans and several animal species. However, in addition to being filtered through the glomerulus, creatinine is secreted in part by the renal tubular cells. In spite of this, creatinine clearance correlates well with inulin clearance when the GFR is normal. This agreement results from the balance of two factors: (1) excretion rate of creatinine is higher than the filtered rate because of the occurrence of tubular secretion of creatinine, and (2) the measured plasma creatinine is higher than the true creatinine because of the presence of noncreatinine chromogens that interfere with the colorimetric analysis of creatinine *(Jaffe reaction).*

Overestimation of GFR by creatinine clearance is usually more evident at low GFR. As GFR falls progressively during the course of renal disease, the renal tubular secretion of creatinine contributes an increasing fraction to urinary excretion, so that creatinine clearance may substantially exceed the actual GFR.

The use of creatinine clearance to estimate GFR may be unreliable when one studies uremia in patients. Creatinine is uniformly distributed in the body water, and it diffuses into the gut. At a normal plasma concentration, the amount of creatinine entering the gut is negligible; it may become significant during renal failure when the plasma creatinine increases.[22] This phenomenon may also explain why creatinine clearance overestimates true GFR in patients with renal failure.

Although in use for decades, the methods available for the chemical determination of creatinine still present important drawbacks. The traditional assay for measuring creatinine is based on the alkaline picrate Jaffe reaction. Because of the presence of interfering pseudochromogenic constituents in the blood, this method substantially overestimates true serum creatinine levels. The major drawback for routine use in neonates is interference by bilirubin. Adaptations of the alkaline picrate assay have reduced the overestimation without totally eliminating the interference.[23] Although more specific than the Jaffe method, the enzymatic techniques are still biased by various interfering substances.[23] A new method coupling high-performance liquid chromatography and isotope dilution mass spectrometry appears to have an excellent specificity and low relative standard deviation.[24]

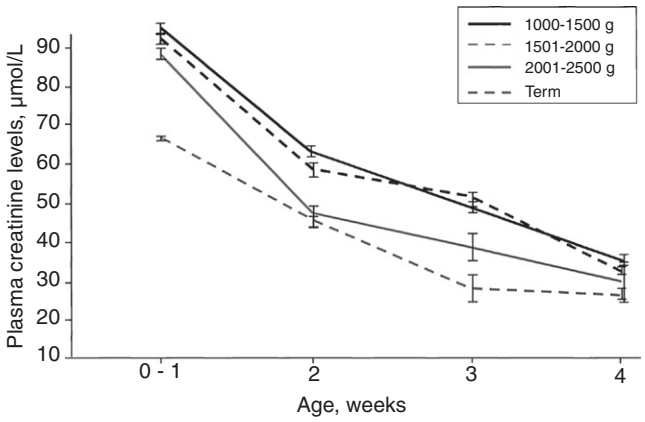

Figure 127-3 Plasma creatinine concentrations (micromoles per liter) during the first weeks of life. *(From Bueva A, Guignard JP: Renal function in preterm neonates,* Pediatr Res *36:572, 1994.)*

Creatinine as a Marker of Glomerular Filtration Rate in Neonates

The plasma creatinine concentration varies during the first postnatal weeks.[25,26] It is elevated at birth and decreases rapidly during the first week of life (Figure 127-3); values stabilize at approximately 0.40 mg/dL (35 µmol/L; range, 0.14 to 0.70 mg/dL [12 to 61 µmol/L]) on the fifth postnatal day in term infants and somewhat later in very-low-birth-weight infants.[26,27] The elevated plasma creatinine concentration at the time of birth reflects maternal creatinine levels. Indeed, a perfect equilibrium between fetal and maternal plasma creatinine concentrations has been observed throughout gestation.[28,29] In very premature neonates, the elevated plasma creatinine at birth increases transiently; the highest levels are reached by the third day of life (Figure 127-4 and Table 127-1).[30,31] The plasma urea level also rises significantly over time, but it does so in a more variable manner. This postnatal transient increase in plasma creatinine values is probably the consequence of creatinine reabsorption (back diffusion) across leaky tubules,[32] as suggested by studies in piglets and newborn rabbits.[32,33] Plasma creatinine levels may take a month to reach *neonatal* levels in very-low-birth-weight infants.[27,28]

Iohexol

Iohexol is a nonionic contrast agent with a MW of 821 Da that appears to be eliminated exclusively by glomerular filtration. In spite of reports showing a significant correlation between the plasma disappearance curve of iohexol and the standard clearance of inulin, its usefulness in clinical pediatric practice remains to be demonstrated. It should not be used in the neonatal period.

Iothalamate Sodium

Iothalamate sodium has a MW of 637 Da. It is only minimally bound to plasma proteins,[34] and its clearance is independent of variations in plasma activity. The clearance of iothalamate was

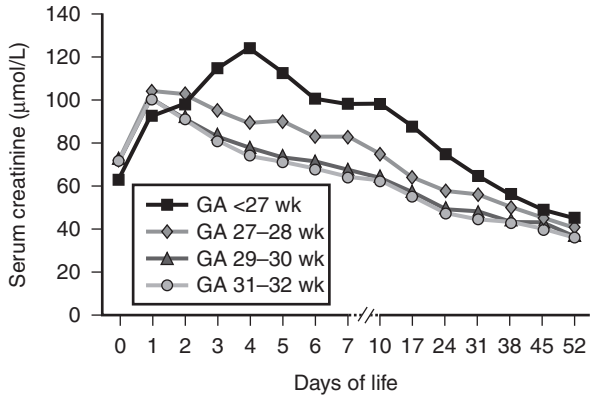

Figure 127-4 Changes in serum creatinine in preterm neonates during the first 52 hours of postnatal life. Peak increases were noted on day 4 in the most premature infants. *(Modified from Gallini F, Maggio L, Romagnoli C, et al: Progression of renal function in preterm neonates with gestational age ≤32 weeks,* Pediatr Nephrol *15:119, 2000.)*

initially shown to correlate well with that of inulin. However, later studies unequivocally demonstrated that iothalamate is actively secreted by the renal tubules and perhaps also undergoes tubular reabsorption in humans and animal species.[35] The agreement of iothalamate clearance with inulin clearance appears to be a fortuitous cancellation of errors between tubular excretion and protein binding. Iothalamate sodium has rarely been used in human neonates and in neonatal animal studies. Its use during the first month of life should be avoided.

Radioisotopic Clearance Studies

Radioisotopic substances should not be used in the neonatal period and will not be discussed here.

CLINICAL ASSESSMENT OF GLOMERULAR FILTRATION RATE IN NEONATES

Standard Clearances

Inulin Clearance

Classic inulin clearance studies have been performed in premature and term neonates to provide data on (1) the reliability of inulin as a marker of GFR in human neonates, (2) the development of GFR in early postnatal life, and (3) the effect of disease states on GFR.

In the classic method, inulin is administered as a priming dose to achieve plasma concentrations close to 300 to 400 mg/L and is constantly infused to maintain such levels. Accurate urine collection is performed by using bladder catheterization, spontaneous voiding into plastic bags, or a collection tray. The clearance study is performed over a period of 3 to 4 hours.

Several studies clearly demonstrated that inulin is freely filtered in even the most immature of human patients.[20,21] The standard inulin clearance must thus be considered the reference test in human neonates with which all other methods of estimating GFR should be compared.

Creatinine Clearance

Creatinine is the most commonly used marker of GFR. Its clearance has been claimed to approximate true GFR in both term and preterm neonates. The validity of creatinine clearance has been assessed in low-birth-weight infants (mean birth weight, 1600 g; range, 1040 to 2275 g; postnatal age, 10 hours to 10 days). A significant correlation was found ($r = 0.738$) between inulin and creatinine clearance, but the scatter of values was substantial.[36] In infants with the lowest GFR (C_{in} <12.5 mL/minute per 1.73 m^2), creatinine clearance overestimated true GFR, whereas it underestimated it in infants with higher filtration rates. A substantial underestimation of GFR by creatinine clearance has usually been reported in preterm and mature neonates.[37] Measurement of creatinine by a manual resin adsorption method, rather than by the automated method, improved the correlation.[37] Several factors can account for the variability of creatinine clearance determinations in very premature infants. These factors fall into two major categories: (1) those related to the transport of creatinine by the premature kidney and (2) those affecting the accuracy of plasma creatinine assays. Because of the low-normal levels of creatinine in the blood of neonates, small variations in laboratory measurement may spuriously alter the estimated concentration. Most clinical laboratories determine creatinine with the Jaffe reaction, which may be affected by many interfering substances, such as bilirubin. Values obtained by this method greatly overestimate the true creatinine concentration at values lower than 1.0 mg/dL.[38]

Inaccuracies in determining the true creatinine concentration in neonates, as well as uncertainties in renal tubular handling, point to a possible drawback in the use of creatinine as a glomerular marker, at least in very-low-birth-weight infants. With these limitations in mind, the true creatinine clearance probably remains the best index of GFR for routine use.[39,40]

Estimation of Glomerular Filtration Rate Without Urine Collection

Constant Infusion of Inulin Without Urine Collection

The constant infusion technique[41] assumes that the rate of intravenous infusion needed to maintain the plasma concentration of inulin at a constant level is equal to the rate of its excretion. At constant plasma levels, after inulin has equilibrated in its diffusion space, the $U \cdot V/P$ clearance must be equal to the rate of infusion (I) divided by the plasma concentration: $C = U \cdot V/P = I/P$. To accelerate the achievement of a steady plasma concentration of inulin, a loading dose of inulin precedes the constant intravenous infusion. An estimate of the extracellular fluid volume (where inulin distributes) and of GFR is required to select the correct loading dose and infusion rate.

In studies in which inulin was constantly infused for only a few hours, significant overestimation of true GFR has been observed.[42] As demonstrated by Coulthard and Ruddock,[20] reliable estimates of GFR can be obtained, provided inulin is constantly infused for 24 hours, with or without bolus injection at the start of the test. This method has the obvious advantage of eliminating the need for urine collection. Its main disadvantage is that it requires a constant infusion of long duration, as well

as careful supervision of the test. Should the infusion stop for a moment, a long extra period of infusion would be necessary because the plasma inulin falls exponentially but only rises again asymptomatically. The constant infusion method also has the disadvantage of not reflecting acute changes in GFR.[41,43]

Single-Injection (Plasma Disappearance Curve) Technique

The mathematical model for this technique is an open two-compartment system. The glomerular marker is injected in the first compartment, equilibrates with the second compartment, and is excreted from the first compartment by glomerular filtration. To obtain a well-defined plasma disappearance curve, and therefore an accurate calculation of the plasma clearance, numerous blood samples are required. Extension of the sampling period to 4 to 5 hours improves the precision of the results.

The single-injection method has been used in neonates, most often by using inulin as a glomerular marker. Inulin is injected intravenously at a dose of 100 mg/kg, and the plasma concentration is measured at regular intervals over a few hours. Simplified techniques have been proposed that are based on a single-compartment model. They obviate the need for frequent blood sampling, but they are less accurate.

Results comparing data obtained by the single-injection technique with those obtained by the standard inulin clearance method are conflicting. Early studies using the plasma disappearance curve of inulin or polyfructosan claimed it to be a reliable index of GFR.[44] Later studies, however, questioned the validity of the single-injection technique in neonates. The overestimation in the younger neonates was ascribed to incomplete equilibration of inulin in its diffusion space during the 130 minutes of the test.[45]

Simple Creatinine Clearance Method in Neonates Without Urine Collection

A formula often used to estimate GFR in children is

$$\text{GFR (mL/min)} \times 1.73\ \text{m}^2 = k \cdot L / P_{Cr}$$

where k is a constant, L (centimeters) represents body length, and P_{Cr} (milligrams per deciliter) is the plasma creatinine concentration. This formula is based on the assumption that creatinine excretion is proportional to body height and is inversely proportional to plasma creatinine.[46] The value of factor k can be obtained from the formula k = GFR • L/P_{Cr}. Under steady-state conditions, k should be directly proportional to the muscle component of body weight, which correlates reasonably well with the daily urinary creatinine excretion rate. The value of k has been determined in term and low-birth-weight neonates, with use of the 8- to 12-hour creatinine clearance as an estimate of GFR in the formula $k = C_{Cr} \cdot L/P_{Cr}$.[47] The mean value of k, calculated in 118 low-birth-weight infants with a corrected age of 25 to 105 weeks, was 0.33 ± 0.01. It rose to 0.45 in term infants up to 18 months.[46] When the plasma creatinine was expressed in micromoles per liter, the corresponding values were 29 and 40, respectively. In both groups, a large scatter of values for k was observed, which the authors ascribed to the variability in body composition, differences in diet and creatinine excretion, errors in collection of urine, and inaccuracies in the measurement of creatinine. In spite of these limitations, the formula was claimed to be useful, because it correlated well with the inulin single-injection technique.[47] It is unfortunate that the $k \cdot L/P_{Cr}$ formula has not been validated in neonates by comparing its results with those given by the standard $U \cdot V/P$ inulin clearance.

The accuracy of the $k = L/P_{Cr}$ formula as an estimate of GFR has been questioned.[42,48] In a study in infants younger than 1 year of age, the value of k varied from 0.17 to 0.82 (15 to 72 when P_{Cr} was given in micromoles per liter), even though it was derived from the standard inulin clearance. Factor k was found to vary markedly with the state of hydration. Moreover, the regression line relating the clearance estimated from the formula with the results obtained from the standard inulin clearance differed significantly from the identity line.[41]

It is true that the $k \cdot L/P_{Cr}$ formula may be more informative clinically than the plasma creatinine alone because the creatinine value, in addition to renal function, is critically dependent on the percentage of muscle mass. Caution should be exercised, however, when using the formula as an estimate of GFR in studies aimed at defining pathophysiologic mechanisms in neonates.

Detection of an Abnormal Glomerular Filtration Rate by Cystatin C

Cystatin C, a nonglycosated 13-kDa basic protein, is a proteinase inhibitor involved in the intracellular catabolism of proteins.[49] It is produced by all nucleated cells, freely filtered across the glomerular capillaries, almost completely reabsorbed, and catabolized in the renal proximal tubular cells. Its production rate is apparently constant and was initially claimed to be independent of inflammatory conditions, muscle mass, and sex. This claim has been questioned by a large recent study in 8058 adult inhabitants of Groeningen.[50] In this study, male sex, older age, greater weight, higher serum C-reactive levels, and cigarette smoking were independently associated with higher cystatin C levels after adjusting for creatinine clearance. It thus appears that, in adults at least, cystatin C levels are influenced by factors other than renal function alone. Cystatin C does not appear to cross the placental barrier, and no correlation exists between maternal and neonatal serum cystatin C levels.[51] Cystatin C concentrations are highest at birth and then decrease, to stabilize after 12 months of age (Figure 127-5). It is uncertain whether cystatin C is significantly higher in premature infants as compared with term infants.[52,53] Mean values of 1.63 ± 0.26 mg/L (mean ± SD) were recorded during the first month of life, 0.95 ± 0.22 mg/L during months 1 to 12, and 0.72 ± 0.12 mg/L after the first year of life.[54] The concentration of cystatin C has been claimed to offer a greater sensitivity than creatinine in detecting an abnormal GFR in newborn infants, as well as in children or adults. Whether this advantage is clinically significant is doubtful, however. The use of cystatin C to predict GFR has important drawbacks. Because cystatin C is not excreted in the urine, the GFR predicted from its plasma concentration cannot be verified by its clearance. Cystatin C only predicts the presence of renal failure and not the precise level of GFR. In children, cystatin C has also been shown to be less reliable than the Schwartz formula in distinguishing impaired from normal GFR.[55] In addition, the assessment of GFR by the Schwartz formula has the obvious advantage of providing rational semiquantitative values of GFR related to the body surface area.

DEVELOPMENT OF GLOMERULAR FILTRATION RATE

Glomerular Filtration Rate at Birth

GFR is low at birth. Standard inulin clearance studies performed by Guignard and co-workers[56-58] on the first 2 days of life indicated that GFR related to the body surface area increases rapidly from the 28th to the 35th week of gestation (Figure 127-6). At the 35th week of gestation, GFR reaches a plateau that is maintained up to the time of birth, a finding reflecting the parallel increase in kidney size and function. In these studies, GFR approximated 20 mL/minute × 1.73 m^2 at birth in term infants and 12 to 13 mL/minute × 1.73 m^2 in preterm infants of 28 to 30 weeks of gestation. Low values of GFR of 0.85 mL/kg/minute, as assessed by the inulin constant infusion technique, were also recorded by van der Heijden and colleagues[59] on the second day of life of neonates. Using standard creatinine clearance techniques to assess GFR, Siegel and Oh[40] and Gallini and associates[31] reported somewhat lower values of GFR in 2-day-old premature infants with gestational age of less than 30 weeks. This underestimation

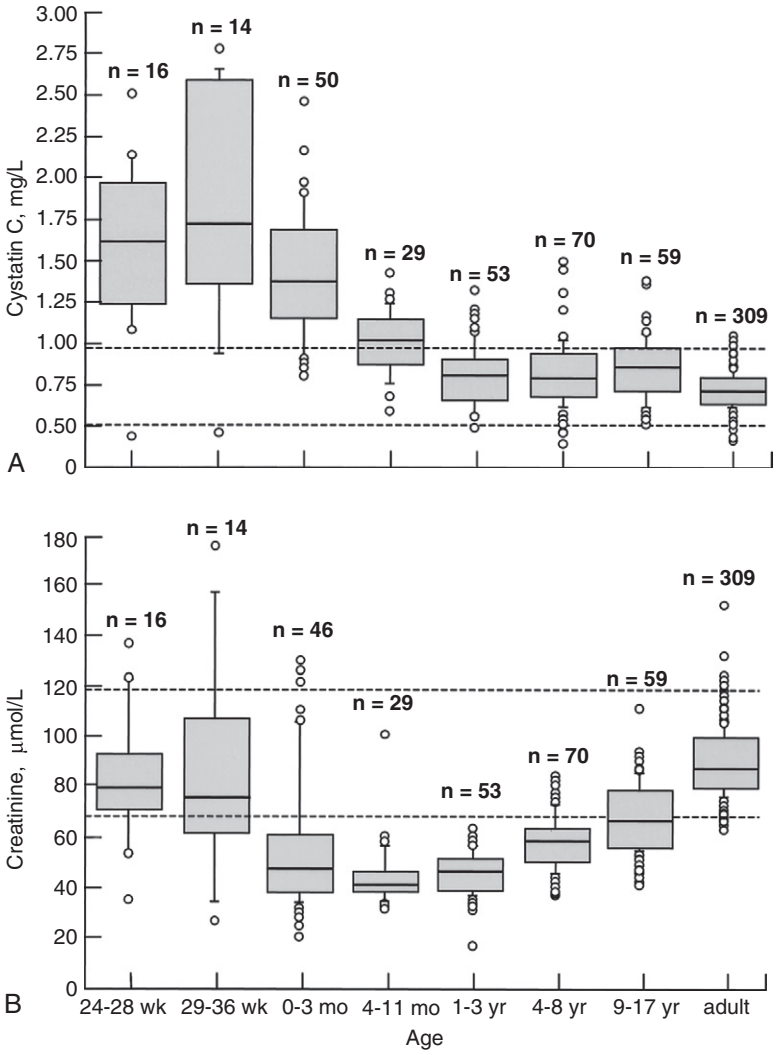

Figure 127-5 Box plot distributions showing **(A)** cystatin C and **(B)** creatinine values (10th, 25th, 50th, and 90th centiles) across the age-groups. The categories of 24 to 28 weeks and 29 to 36 weeks refer to gestational ages of preterm infants. *Dotted lines* indicate the 95% confidence interval of the adult range. Preterm infants born between 24 and 36 weeks gestation were 1 day old. *(Modified from Finney H, Newman DJ, Thakkar H, et al: Reference ranges for plasma cystatin C and creatinine measurements in premature infants, neonates, and older children,* Arch Dis Child *82:71, 2000.)*

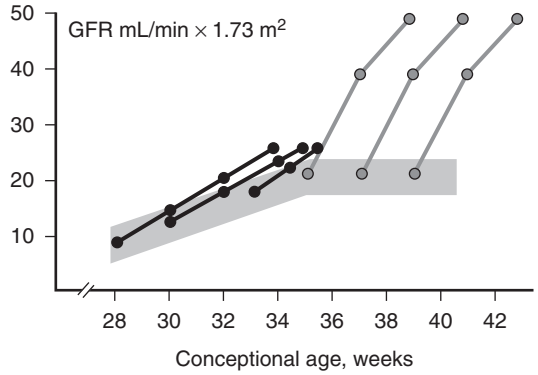

Figure 127-6 Development of GFR in relation to conceptional age during the last 3 months of gestation and the first month of life. The *shaded area* represents the range of normal values. The postnatal increase in GFR observed in neonates born before (•) or after (◦) 35 weeks gestation is schematically represented. *(Modified from Guignard JP: Renal function in the tiny, premature infant,* Clin Perinatol *13:377, 1986.)*

of GFR by the clearance of creatinine was also observed by Coulthard and co-workers.[60] Such an underestimation can be accounted for by the reabsorption of creatinine across leaky immature tubules.[28,32] In all these studies performed on the first days of life, GFR correlated with gestational age.

Maturation of Glomerular Filtration Rate in the First Month of Life

A rapid increase in GFR takes place in the first month of life. As shown in Figure 127-7, inulin clearance doubles in the first 15 days of life.[56-59] The rate of increase in GFR is somewhat lower in the most premature infants. In spite of this impressive increase in GFR, as expressed in milliliters per minute per 1.73 m^2, the values achieved at 1 month of life are still only 50% of the adult values that are reached during the second year of life (Figure 127-8). This can be considered a state of "physiologic" renal insufficiency. Using the 24-hour constant infusion method in preterm infants, van der Heijden and colleagues[59] confirmed that GFR increases rapidly after birth; the postnatal increase is independent of body weight.

A similar pattern of maturation was observed in 66 physiologically stable term and premature infants undergoing creatinine clearance studies.[27] The lowest values of creatinine clearance were observed in the infants with the lowest birth weight (mean birth weight, 1332 ± 40 g; mean gestational age, 31.3 ± 0.5 weeks). This was true both for absolute values of creatinine clearance and for values expressed in relation to the body surface area. The progressive increase in creatinine clearance observed in the first 15 days of life also correlated significantly with postnatal age.[27,59-62] The study by Gallini and associates[31] confirmed the occurrence of a steady increase in creatinine clearance over the first 52 days of life, at which time values close to 42 mL/minute × 1.73 m^2 and 27 mL/minute × 1.73 m^2 were recorded in term

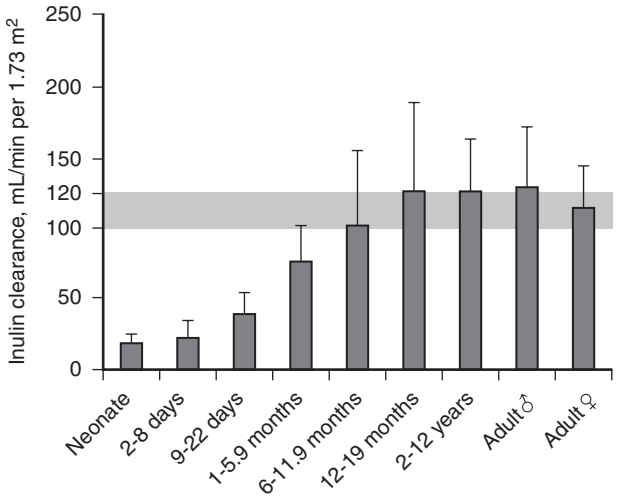

Figure 127-7 Changes in GFR (inulin clearance) as a function of age.

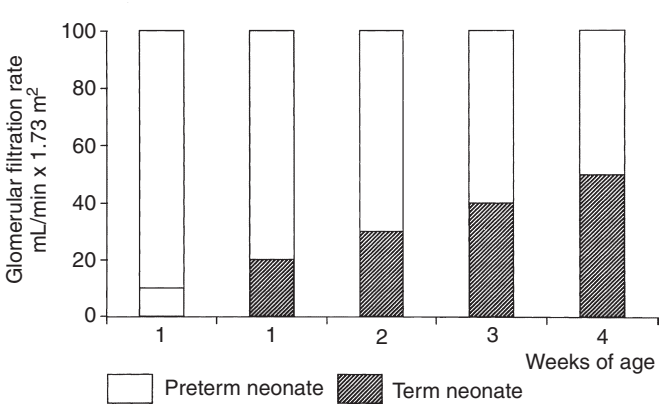

Figure 127-8 Maturation of GFR during the first month of life of newborn infants. The *open columns* represent normal adult values. *(From Guignard JP, Drukker A: Clinical nephrology. neonates and neonates born at less than 27 weeks gestational age, respectively.

Determinants of the Postnatal Increase in Glomerular Filtration Rate

Several factors account for the striking postnatal maturation of GFR: (1) a decrease in renal vascular resistance and consequent increase in RBF, (2) an increase in systemic blood pressure and in glomerular plasma flow rate, (3) an increase in the effective filtration pressure, and (4) an increase in the K_f.

1. Renal vascular resistance is elevated at birth. It decreases rapidly in the first postnatal weeks. In rats, both afferent and efferent arteriolar resistances decrease by a factor of 3 during maturation.[63] The elevated renal vascular resistance is mainly the result of the high activity of vasoactive agents and hormones and the relative responsiveness of the newborn infant to these vasoconstrictor and vasodilator substances. The decrease is associated with a rise in RBF and an improvement in glomerular plasma flow rate. In human neonates, the maturational increase in GFR parallels the increase in RBF.[56] Improved RBF and glomerular plasma flow rate also probably explain the 30% immediate increase in inulin clearance associated with delayed clamping of the umbilical cord.[64]
2. The striking increase in systemic blood pressure occurring during the first weeks of life (Table 127-2) is associated with an increase in the glomerular capillary hydrostatic pressure. This favors filtration. Creatinine clearances measured on the first 2 days of life in neonates of 28 to 43 gestational weeks have been shown to correlate significantly with blood pressure.[27,56]
3. The low oncotic pressure present in newborn infants resulting from low plasma protein concentrations favors the ultrafiltration pressure. Furthermore, because the glomerular hydrostatic pressure increases more rapidly than the oncotic pressure during development, the effective filtration pressure rises. Because of the low systemic blood pressure, the glomerular capillary hydraulic pressure is extremely low in early life and increases in parallel with blood pressure. The glomerular transcapillary hydraulic pressure difference increases by 10 mm Hg from the third week of life to adulthood in rats.[65] In guinea pigs, the effective filtration pressure increases 2.5 times in the first 50 days of life.[66] Increases in glomerular capillary hydraulic pressure and glomerular transcapillary hydraulic pressure difference could contribute to changes in GFR during early maturation.

TABLE 127-2

Normal Mean Arterial Blood Pressure in the Newborn Infant

Age	<1.0 kg	1.0-1.5 kg	>2.5 kg
Birth	33 ± 15	39 ± 18	49 ± 19
1 week	41 ± 15	47 ± 18	60 ± 19
2 weeks	45 ± 15	50 ± 18	64 ± 19
4 weeks	48 ± 15	53 ± 18	68 ± 19

Values expressed in mm Hg as mean ± 95% confidence limits for single measurements; measurement via umbilical artery catheterization or by Dynamap, GE Health Care, Missouri City, TX.

From Ong WH, Guignard JP, Sharma A, Arandaet JV: Pharmacological approach to the management of neonatal hypertension, *Semin Neonatol* 3:149, 1998.

4. The K_f reflects both the surface and the permeability of the filtration barrier. Maturational changes in K_f also account for the postnatal rise in GFR. The K_f is low in the newborn. It is significantly lower in 40- to 64-day-old rats than in adult animals.[67,68] The glomerular basement membrane surface area has been shown to increase 3.5-fold from birth to adulthood in rats,[69] whereas the glomerular capillary cross-sectional area increased 10-fold from 3 weeks to adulthood in dogs.[70] A 40% increase in glomerular corpuscular diameter has been observed in humans from birth to adulthood.[71] If they correspond to increases in the glomerular filtering area, these changes should improve GFR. The increases in the area of the endothelial fenestrae observed in growing rats can also explain the postnatal rise in GFR. From studies in 1- and 6-week-old dogs, Goldsmith and colleagues[72] concluded that an increase in both the glomerular filtering area and pore density accounted for the postnatal increase in GFR.

The increase in the number of negatively charged sites in the GBM[73] and the 2.5-fold increase in GBM thickness[68] observed in growing rats could account for the decreased permeability to large molecules (proteins) in the first postnatal weeks of human neonates. Clearance studies in human infants infused with inulin or polyfructosides with variable MWs have clearly shown that the high-MW inulin did not accumulate in preterm infants (birth weight of 850 to 1250 g) infused with inulin for 2 to 10 days.[20] The filterability of inulin (MW 5200) appears similar in neonates and older children. This does not, however, exclude subtle changes in glomerular capillary permeability during growth. Experimental studies on isolated rat glomeruli also failed to demonstrate an increase in glomerular hydraulic permeability during growth.[74]

FACTORS THAT CAN IMPAIR GLOMERULAR FILTRATION RATE IN THE PERINATAL PERIOD

The low GFR of the very-low-birth-weight infant is maintained by a delicate balance of intrarenal vasoconstrictor and vasodilator forces. In immature animals, various conditions such as hypoxemia, hypercapnia, metabolic acidosis and alkalosis, hypothermia, and hyperthermia can dramatically increase renal vascular resistance. Similarly human neonates are prone to the development of vasomotor nephropathy and acute renal failure, the main causes including hypotension, hypovolemia, hypoxemia, and perinatal asphyxia.[75] Other causes include the administration of angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory drugs, and tolazoline. Positive-pressure artificial ventilation also impairs GFR. In all these situations, the interaction between the vasoconstrictive and vasodilation forces that are stimulated are rather complex. Several of the vasoconstrictor or vasodilatory forces indeed differ in their effects on the systemic and the intrarenal circulations.

Perinatal hypoxemia and asphyxia are common causes of impaired GFR in neonates. The renal vasoconstriction is the consequence of the overactivation of the renin-angiotensin system, intrarenal adenosine, vasopressin, the catecholamines, and other vasoconstrictor substances.[75] Contraction of blood volume (hypovolemia) with or without failure of the cardiac pump is often presented in the neonates.[76] Experimental neonatal studies on the hypoxemia-induced decrease in GFR suggest a key role for intrarenal adenosine[77] in mediating the vasomotor nephropathy. By decreasing the postglomerular resistance, this agent induces a fall in the intraglomerular pressure and consequently GFR (Figure 127-9). The hypothesis that adenosine plays a key role in the pathogenesis of the hypoxemic vasomotor nephropathy is supported by the fact that theophylline, an antagonist of adenosine cell surface receptors, protects the immature kidney from the deleterious hypoxemic stress. Recent clinical studies using theophylline in high-risk asphyxiated neonates with respiratory distress syndrome[78-80] or in neonates with severe respiratory distress syndrome[81] suggest a beneficial effect of theophylline in protecting GFR. Interestingly enough, in the neonatal rabbit model, the specific adenosine A_1 receptor antagonist 8-cyclopentyl-1,3-dipropylxanthine does not offer the same protection as theophylline.[82] Other conditions that impair GFR by stimulating vasoconstrictive forces are hypothermia, hyperthermia, and severe respiratory or metabolic acidosis.[75]

Ventilation of human neonates and newborn animals with high airway pressures has deleterious effects on renal function resulting from decreased venous return and low cardiac output, increased renal sympathetic nervous activity, and high serum vasopressin levels.[83]

ACE inhibitors can lead to a dramatic fall in mean arterial pressure accompanied by persistent oliguria.[75] The oliguric renal insufficiency is similar to that observed in fetuses and neonates of women who are administered angiotensin-converting enzyme inhibitors shortly before birth. It is explained by the interference with the renin-angiotensin system, which is physiologically overactive during fetal and neonatal life.[75]

High prostaglandin activity is physiologically necessary to maintain sufficient perfusion of the newborn kidney. Serum prostaglandin levels are also high in infants with chronic cardiac failure, patent ductus arteriosus, and all instances of hypotension and hypovolemia. Prostaglandin synthesis inhibitors, used before birth to prevent the premature onset of labor or after birth to promote the closure of a hemodynamically active patent ductus arteriosus, reduce GFR and RBF.[84,85] They do so by blunting the effect of vasodilator prostaglandins on the afferent arteriole. Decreases in GFR have been described in neonates exposed to indomethacin before birth, as well as in neonates administered indomethacin for the closure of patent ductus arteriosus. The deleterious effect is usually transient and results in water retention and hyponatemia.[84,85] Other nonselective (ibuprofen) or selective (nimesulide) cyclooxygenase inhibitors likely share the same adverse effects.[87,88] In experimental immature animals, cyclooxygenase–nonselective and cyclooxygenase-2–selective inhibitors similarly impair GFR and RBF.[89]

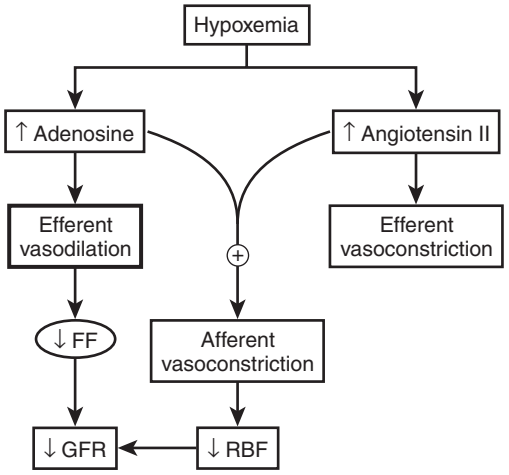

Figure 127-9 Hypoxemia activates the release of intrarenal adenosine and angiotensin II. Whereas angiotensin II preferentially vasoconstricts the efferent arteriole, adenosine effectively vasodilates it. The decrease in the filtration fraction induced by hypoxemia reflects net efferent vasodilation. The combined net effect of angiotensin II and adenosine is thus afferent vasoconstriction and efferent vasodilatation. This results in a decrease in the intraglomerular pressure and consequently in GFR.

CONCLUSION

Glomerular filtration is the first essential step in urine formation. Its maintenance within narrow limits is mandatory and requires subtle autoregulatory mechanisms that involve the action of autacoids, vasoactive substances, and intrinsic myogenic mechanisms. Because not only pathologic changes but also physiologic changes in GFR during maturation may affect body fluid homeostasis and the excretion of drugs by the neonate, an estimation of GFR will help the neonatologist to rationally prescribe fluids, electrolytes, and drugs.

Renal Transport of Sodium During Early Development

The regulation of intracellular and extracellular sodium is a prerequisite to life in a nonaqueous environment. Whereas mature animals maintain sodium homeostasis, immature animals must maintain a positive balance of sodium. This positive sodium balance is achieved by at least two complementary mechanisms.

First, newborn animals universally prefer to ingest a salt solution rather than sodium-free water.[1] In the term rat, this "sodium preference" can be demonstrated by day 5 of life.[2] Second, developing nephrons tend to retain sodium. In the term infant, approximately 65% of ingested sodium is retained rather than excreted by the kidneys.[3,4] Together, "salt preference" and "renal immaturity" promote a positive sodium balance.

Several investigations have associated sodium transport with somatic growth.[5-8] Bickel and associates[9] evaluated the relative abundances of renal sodium transporters in young lean and obese Zucker rats by semiquantitative immunoblotting. The abundances of the α_1-subunit of sodium, potassium–adenosine triphosphatase (Na^+,K^+-ATPase), the thiazide-sensitive Na-Cl cotransporter (NCC or TSC), and the β-subunit of the epithelial sodium channel (ENaC) were all significantly higher in the kidneys of obese rats. No differences were found for the sodium-hydrogen exchanger (NHE3), the bumetanide-sensitive Na-K-2Cl cotransporter (NKCC2 or BSC1), the type II sodium-phosphate cotransporter (NaP_i-2), or the α-subunit of ENaC.

Leptin, an adipose-induced hormone, up-regulates the expression of the erythrocyte sodium-hydrogen exchanger (NHE1).[10] In normal individuals, insulin also induces the expression of erythrocyte NHE1. In contrast, insulin has no effect on NHE1 activity of erythrocytes from obese individuals.[11] These findings suggest a link between obesity, insulin resistance, and hypertension on the one hand and the active renal transport of sodium on the other.

To better understand sodium handling by the kidney during development, investigators have traditionally used clearance methods to measure the fractional excretion of sodium (FE_{Na}) and the free water clearance (C_{H2O}). These studies point to the distal tubule as the site of the most avid sodium conservation. Using modern techniques of molecular biology and targeted proteomics, more recent investigations have now established the cellular basis of these earlier observations.

FRACTIONAL EXCRETION OF SODIUM DURING DEVELOPMENT

Sodium handling by the kidney may be expressed as the clearance of sodium divided by the clearance of creatinine (FE_{Na}).

[Urinary concentration of sodium (U_{Na}, mEq/L) × Urine volume (mL) / Unit time / [Creatinine or inulin clearance × Plasma sodium concentration (P_{Na}, mEq/L)] becomes

$$(U_{Na} \times P_{cr}) / (U_{cr} \times P_{Na}) \times 100\,\%$$

FE_{Na} measures renal tubular sodium transport "normalized" for the glomerular filtration rate (GFR). As GFR rises dramatically after birth, FE_{Na} is a useful measurement, particularly in the newborn infant.

Several studies have indicated that FE_{Na} varies inversely with the gestational and postconceptional age.[12,13] The entire spectrum of FE_{Na} related to gestational age is shown in Figure 128-1 and summarized in Table 128-1.

In the human, the fetus produces large amounts of sodium-rich urine with a mean FE_{Na} of 12.8%.[3-7] Healthy premature infants, particularly those less than 30 weeks gestational age, continue to excrete large amounts of sodium (average FE_{Na} 5%) (Figure 128-2)[14] and are at risk for negative sodium balance.[15] All preterm infants of less than 30 weeks have a negative sodium balance (Figure 128-3).[14] The incidence decreases to 45% to 70% by 32 weeks gestation and to 0% to 29% after 36 weeks.[15,16]

Vanpeé and colleagues[17] compared the FE_{Na} in infants with a gestational age of 25 to 30 weeks with values found in a cohort of older infants with a gestational age of 31 to 34 weeks. During the first 2 weeks, FE_{Na} fell rapidly in both groups, eventually reaching the low levels found in term infants 4 to 6 weeks after birth (Figure 128-4).[17] In very sick preterm infants of less than 30 weeks gestation, negative sodium balance persisted through the first week of life. In infants of greater than 33 weeks gestation, a positive sodium balance was achieved by days 2 to 4 of life.

In the term infant, the FE_{Na} decreases from 3.4% to 1.5% in the first few hours of life and to even lower values in the subsequent

TABLE 128-1

Fractional Excretion of Sodium at Different Postconceptual Ages for Infants of Different Birth Weights

Weight (g)	1-2 d (%)	8-9 d (%)	15-16 d (%)
1000-1500	2	1.4	0.7
1501-2000	2.2	0.8	0.4
2001-2500	0.4	0.6	0.2
>2500	1.0	0.6	0.3

From Bueva A, Guignard JP: Renal function in preterm neonates, *Pediatr Res* 36:572, 1994.

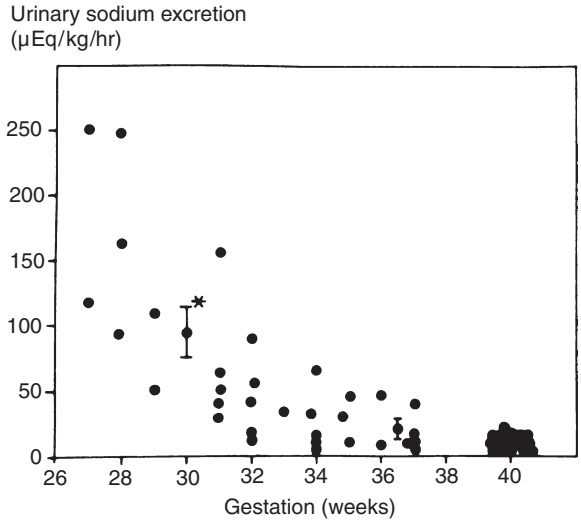

Figure 128-2 Urinary sodium excretion in newborns from 27 to 40 weeks gestational age. Circles with bars at 30 and 37 weeks are mean values for 27- to 32- and 33- to 40-week-gestation infants. *Significant difference between groups. *(From Siegel SR, Oh W: Renal function as a marker of human fetal maturation,* Acta Paediatr Scand *65:481, 1976.)*

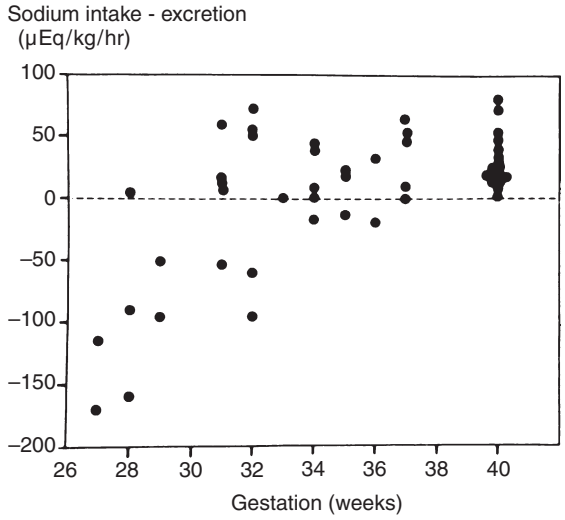

Figure 128-3 Sodium balance is represented by the difference in sodium intake and excretion of infants at 27 to 40 weeks gestational age. *(From Siegel SR, Oh W: Renal function as a marker of human fetal maturation,* Acta Paediatr Scand *65:481, 1976.)*

24 to 48 hours. In most cases, urine sodium excretion over the first few days of life still exceeds the dietary sodium intake (breast milk or low-salt formula) by the infant.[18]

These observations suggest that maturation of the renal tubules is crucial for the newborn infant to conserve sodium. Additional studies (see later) indicate that the major site for sodium conservation by the kidney is the distal portion of the nephron.

Sodium supplementation may prevent a negative sodium balance in the neonate (Figure 128-5).[19] In very-low-birth-weight infants (<1.3 kg at birth) between 2 and 6 weeks of age with a low sodium intake (≤2 mEq/kg/day), the incidence of hyponatremia (≤130 mEq/L) is nearly 40%.[20] A sodium supplementation of approximately 3 mEq/kg/day (provided until a postnatal age of 6 to 7 weeks) will reduce the occurrence of hyponatremia to less than 2%.

However, it is unclear that sodium supplementation is beneficial for the neonate. First, sodium supplementation may interfere with the capacity of the kidney to conserve sodium. In the neonatal rat, GFR does not increase after 1% volume expansion. In nonsupplemented animals, urine sodium excretion increases minimally. In rats that chronically receive sodium supplementation, urine sodium excretion increases markedly, similar to that of the adult.[21] The investigators suggested that the limited sodium in maternal milk may condition the tubules toward antinatriuresis.

Second, excessive administration of sodium to term newborn infants can result in extracellular volume expansion, edema, and in some cases life-threatening hypernatremia.[22] Fortunately, hypernatremia in preterm infants is rare and usually is related to excessive insensible water loss, not to sodium administration.[13] Hypernatremia typically occurs in the first postnatal week when transcutaneous water losses are high.

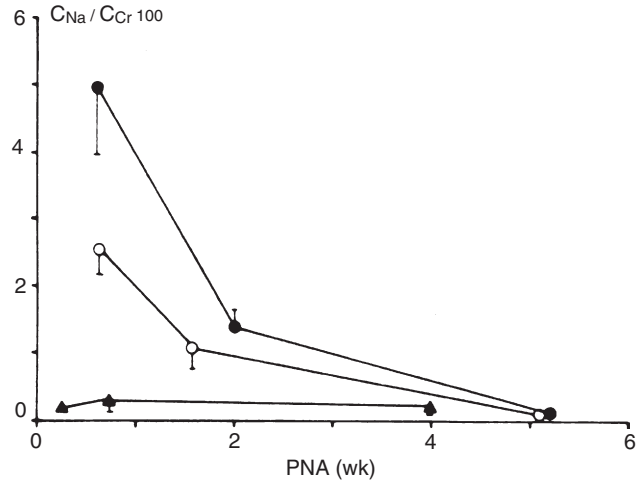

Figure 128-4 Fractional sodium excretion ($FE_{Na} = C_{Na}/_{cr} \times 100\%$) in infants with a gestational age of 28 weeks *(closed circles)* and 32-week *(open circles)* and term *(triangles)* infants. A significant difference was found between the 28- and 32-week groups at 1 week of age. *(From Vanpeé M, Herin P, Zetterström R, Aperia A: Postnatal development of renal function in very low birthweight infants,* Acta Paediatr Scand *77:191, 1988.)*

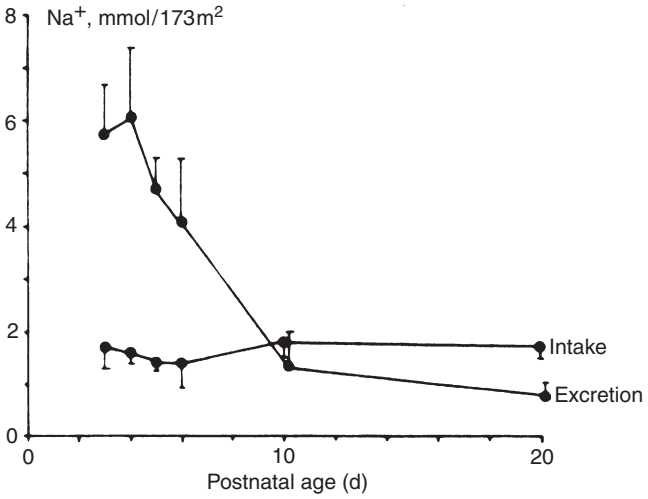

Figure 128-5 Average hourly sodium intake and excretion in preterm infants 3 to 21 days postnatal age. Each circle represents the average of four to nine observations. *(From Aperia AS, Broberger O, Herin P, Zetterström R: Sodium excretion in relation to sodium intake and aldosterone excretion in newborn pre-term and term infants,* Acta Paediatr Scand *68:813, 1979.)*

CLEARANCE STUDIES IN ANIMALS

Newborn animals have a blunted response to saline loading.[23] Banks[24] compared the effects of saline volume expansion on renal tubular reabsorption between newborn and adult animals. Proximal and distal tubule function was estimated by the distal nephron blockade technique with use of ethacrynic acid and amiloride. During saline infusion, which increased extracellular volume by approximately 30% for both age groups, total nephron fractional Na reabsorption was 0.91 for the adult and 0.98 for the puppy ($p < .01$). However, proximal tubule fractional Na reabsorption was greater in the adult (0.64) than in the puppy (0.48, $p < .01$), whereas distal nephron fractional Na reabsorption was much greater in the newborn (0.51) than in the adult (0.26, $p < .01$).

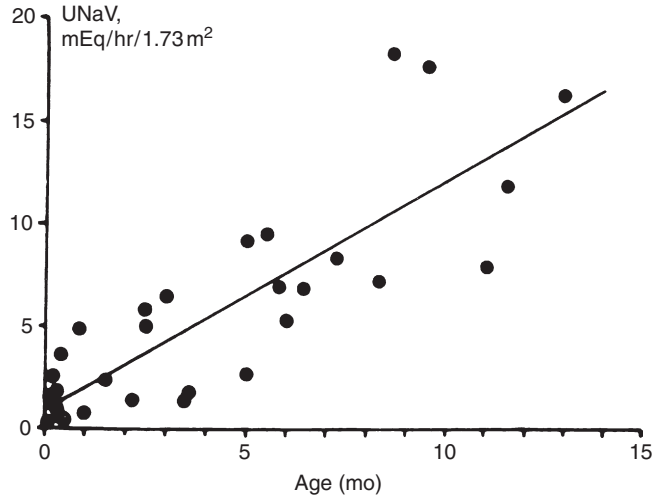

Figure 128-6 Average hourly urinary sodium excretion during the first 13 months of life. Correlation coefficient = 0.764. *(From Aperia A, Broberger O, Thodenius K, Zetterström R: Development of renal control of salt and fluid homeostasis during the first year of life,* Acta Paediatr Scand *64:393, 1975.)*

Using renal micropuncture re-collection techniques in proximal tubules of guinea pigs, Schoeneman and Spitzer[25] found a low proximal fractional reabsorption at all ages; however, a higher whole kidney fractional reabsorption was observed in newborn when compared with adult animals. On the basis of these studies, the tendency to retain an IV sodium load was primarily due to enhanced sodium reabsorption in segments beyond the proximal convoluted tubule.

These observations suggest that factors affecting the function of the distal tubule are mainly responsible for developmental changes in sodium conservation by the nephron. These factors may include the distal delivery of sodium, the activity of natriuretic factors, the secretion of or renal response to aldosterone, and the expression of sodium transport proteins.

CLEARANCE STUDIES IN THE NEONATE

Aperia and collaborators[26] studied preterm (<35 weeks gestation) and term infants under maximal water diuresis after an oral load of sodium chloride. Both groups were unable to excrete the sodium load as efficiently as older children (8 to 14 years).[27] In term infants, the renal response to an oral sodium load of 2.2 mEq/kg body weight is poor in the immediate postnatal period. The urinary sodium excretion rate per hour corrected for body surface area (0.1 to 3 mEq/hour/1.73 m^2) is only approximately 10% of that found in older children (16 mEq/hour/1.73 m^2). However, the renal response to an oral sodium load reaches the latter value by 10 to 13 months of age and remains constant thereafter (Figure 128-6).[28]

Sulyok and co-workers[29] also studied preterm and term neonates, although the conditions of maximal water diuresis were not met. Sodium delivery to the distal tubule was significantly greater and distal sodium reabsorption was significantly less in premature than in term infants, suggesting the inability of the distal tubule to handle the increased sodium load caused by defective proximal tubule sodium reabsorption. However, the fractional distal tubule reabsorption in preterm infants rose to term values of approximately 85% by 2 weeks after birth.[30]

Rodriguez-Soriano and associates[31] studied premature (<34 weeks gestation) and term infants during maximal water diuresis. Distal tubule sodium reabsorption was significantly higher, and sodium delivery was significantly greater, in the more immature infants (Figure 128-7).[31] Fractional distal sodium reabsorption, however, was significantly lower (82%) than in term infants (92%) (Figure 128-8).[31] Therefore a lower percentage of the sodium load presented to the distal tubule was reabsorbed in preterm than in term infants.

These findings suggest that both proximal and distal tubule reabsorption of sodium are inversely related to gestational age and that the major site of adaptation to extrauterine life is the distal tubule. In the premature newborn infant, sodium reabsorptive capacity lags behind the increase of GFR ("glomerular-tubular imbalance"). The high excretion of β_2-microglobulin (a small peptide reabsorbed entirely in the proximal tubule) found in the preterm infant supports this proposition. In infants with gestational ages greater than 33 weeks, sodium reabsorption is more efficient, suggesting glomerular-tubular balance. In healthy term neonates, an enhanced ability of the distal tubule to reabsorb sodium exists, which explains the blunted sodium excretory response to a sodium load.[32]

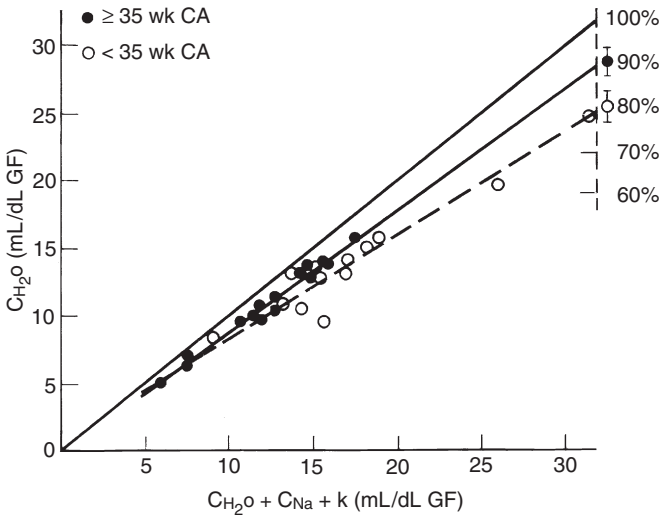

Figure 128-7 Free water clearance (C_{H2O}) and fractional distal sodium delivery ($C_{H2O} + C_{Na} + k$). *(From Rodríguez-Soriano J, Vallo A, Oliveros R, Castillo G: Renal handling of sodium in premature and term neonates: a study using clearance methods during water diuresis,* Pediatr Res *17:1013, 1983.)*

TRANSPORT STUDIES

Plasma sodium is freely filtered by the glomerulus ("filtered load") and is then reabsorbed along the renal tubule, by means of transport systems that are unique to the individual nephron segments (proximal tubule, loop of Henle, distal tubule). The bulk of the filtered load is reabsorbed by the proximal tubule. The proximal tubule is a relatively permeable epithelium with both low-resistance paracellular and transcellular pathways. In the rat proximal tubule, approximately one third of sodium is reabsorbed by active transport, one third is reabsorbed by electrical transference, and one third is reabsorbed by solvent drag.[33] Both active and passive transport forces change with maturation.

Passive Transport During Development

Studies in newborn puppies, guinea pigs, rabbits, and rats have revealed developmental changes in proximal sodium reabsorption.[34-37] In the guinea pig, the single-nephron GFR and the rate of proximal fluid reabsorption increase 20-fold between 1 and 40 days of age.[38] During the same period of time, the length of the proximal tubule increases six-fold. Therefore the rate of sodium and fluid reabsorption per millimeter of tubule length increases approximately fourfold during development. However, the fractional sodium reabsorption along the proximal convoluted tubule remains constant at approximately 60%.[38,39] Without a change in fractional sodium reabsorption in this segment, fractional reabsorption in segments distal to this site must also remain unchanged.[38]

A significant portion of the reabsorption of sodium in young animals is due to passive transport. The leakage of the proximal tubule epithelium to various molecular species is referred to as the reflection coefficient (lower values equal increased permeability). During development, the proximal tubule has a lower reflection coefficient for microperoxidase and mannitol[40] than that in adult animals. This finding may be due in part to changes in membrane permeability with development.

In renal proximal tubule brush-border membrane vesicles (BBMVs), early uptake of ^{22}Na is more rapid in BBMVs from kidneys of 7-day-old than of adult rats. Furthermore, fluorescence

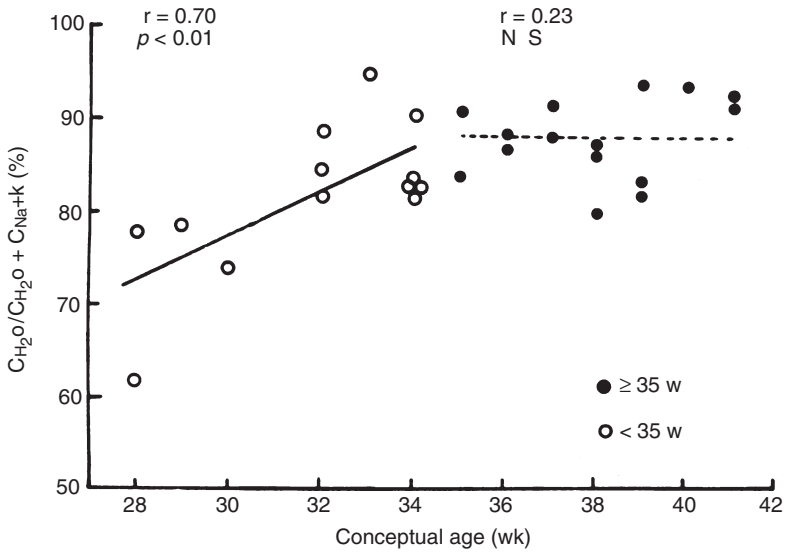

Figure 128-8 Percentage of distal sodium reabsorption versus conceptual age (gestation + postnatal age). *(From Rodríguez-Soriano J, Vallo A, Oliveros R, Castillo G: Renal handling of sodium in premature and full-term neonates: a study using clearance methods during water diuresis,* Pediatr Res *17:1013, 1983.)*

polarization studies reveal that lipids from BBMVs of 7-day-old rats are more fluid than lipids from BBMVs of adult rats.[41] These differences are likely due to age-related changes in the lipid composition of the membranes. These differences in turn could influence the transport and permeability characteristics of the developing tubular membrane. These findings would explain, in part, the alterations of renal BBMV solute transport with growth.

Spitzer and colleagues[37,38] have estimated Starling's hydraulic fluxes ("passive forces") across the proximal convoluted tubule of young and adult rabbits (Table 128-2). By subtracting the passive flux from the total reabsorptive volume flux, one may estimate the relative contribution of active and passive forces to the reabsorption of solute during development.

The reabsorptive flow rate per unit of hydrostatic pressure ($J_{\Delta P}$) is greater in young than in mature animals, possibly because of a higher tubular membrane permeability in the young animal.[38,40,41] Spitzer and associates[37,38] estimated that the hydrostatic pressure–driven flow in the young animal accounts for 7% of the total proximal convoluted tubule reabsorptive flow (J_v) (0.33 nL/min × mm), compared with only 0.6% in the mature animal (J_v = 1.2 nL/min • mm) (Figure 128-9 and see Table 128-2).

The peritubular capillary oncotic pressure is low in the immature animal because of a low plasma oncotic pressure. This results in a two- to three-fold lower reabsorptive flow per unit of applied oncotic pressure ($J_{\Delta\Pi}$) in immature animals compared with adults (0.14 vs. 0.38 nL/min • mm) (see Figure 128-9 and Table 128-2).[38] Therefore, in newborn animals, oncotic pressure–driven flow accounts for 42% of total absorptive flow compared with 32% in adult animals.[38,42] The total reabsorptive flow (J_v) of the young animal is nearly four times lower, and the sum of the hydrostatic ($J_{\Delta P}$)- and oncotic ($J_{\Delta\pi}$)-driven flow is approximately 2.5 times lower than that in the adult.

In summary, active and passive forces may contribute equally to the reabsorption of solute across the immature proximal tubule. With development, protein transport carriers mature and play an increasingly important role in solute reabsorption (see Figure 128-9).[38,42] For example, if total flow is 50 pEq/min • mm in the young animal, 25 pEq/min • mm would occur by active transport. Conversely, if total flow is 180 pEq/min • mm in the mature animal, 60 pEq/min • mm would be accounted for by active processes.[38]

TABLE 128-2

Estimates of Hydraulic Fluxes Across the Proximal Convoluted Tubules of Young and Adult Rabbits

Rabbit	$J_{\Delta P}$	$J_{\Delta\Pi}$	$J_{\Delta P} + J_{\Delta\Pi}$	J_v	Non-Starling
Young (%)	0.023 (7)	0.14 (42)	0.163 (49)	0.33	0.167 (51)
Adult (%)	0.007 (0.6)	0.38 (32)	0.387 (32)	1.2	0.813 (68)

$J_{\Delta P}$, Hydrostatic pressure–driven flow, nL/min • mm; $J_{\Delta\Pi}$, oncotic pressure–driven flow, nL/min • mm; $J_{\Delta P} + J_{\Delta\Pi}$, total pressure-driven flow, nL/min • mm; J_v, reabsorptive volume flux, mL/min • mm; *Non-Starling,* active transport + passive transport caused by transepithelial effective osmotic and ionic gradient. Because the latter term is negligible,[24] "non-Starling" forces are mainly due to active transport.

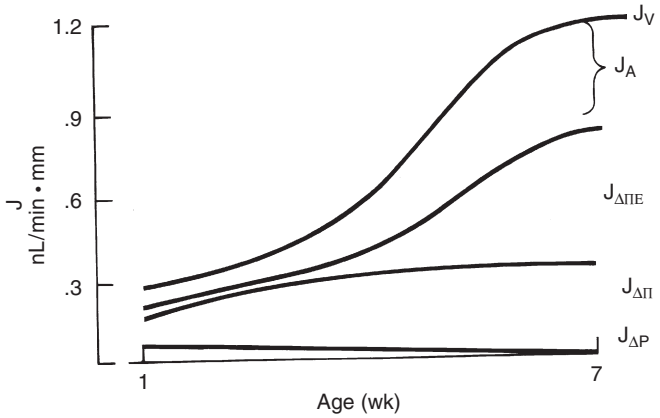

Figure 128-9 Developmental time course of net reabsorptive flow (J_v), oncotic ($J_{\Delta\pi}$), and hydrostatic ($J_{\Delta P}$) pressure-driven flows, and possible course of development of active transcellular flux (J_A) and of fluxes driven by cell-generated effective osmotic and ionic gradients ($J_{\Delta\pi E}$). *(From Barac-Nieto M, Spitzer A: The relationship between renal metabolism and proximal transport during ontogeny,* Pediatr Nephrol *2:356, 1988.)*

Active Transport During Development

Different sets of transport proteins are distributed to the apical and basolateral surfaces of the plasma membranes of renal epithelium.[42] The asymmetric distribution of membrane proteins is generated by an intracellular machinery that addresses the moieties to the appropriate domain. The extracellular environment regulates the protein sorting by conveying the positional information that creates the plasma membrane domains. These interactions are mediated by macromolecular assemblies of cell adhesion molecules, cytoskeleton, and signaling molecules.

To determine the ontogeny of sodium transport proteins in embryonic rat tissue, Schmitt and associates[43] used in situ hybridization and immunohistochemistry to localize the Na-P_i cotransporter type 2 (NaP_i-2), the bumetanide-sensitive Na-K-2Cl cotransporter (NKCC2), the thiazide-sensitive Na-Cl cotransporter (NCC), the Na-Ca exchanger (NaCa), the epithelial sodium channel (rENaC), and 11β-hydroxysteroid dehydrogenase. These proteins were first observed in the post–S-shape stages. NKCC2 was initially expressed at the macula densa region and was observed later extending along the nascent ascending limb of the loop of Henle. In comparison, NaP_i-2 expression along the proximal tubular part of the loop of Henle was observed later in development. The NCC was initially found at the distal end of the nascent distal convoluted tubule and later extended toward the junction with the ascending limb of the loop of Henle. Strong coexpression of rENaC and 11β-hydroxysteroid dehydrogenase was observed in early nascent connecting tubule and collecting ducts and later also in the distal portion of the distal convoluted tubule.

The sodium transporters do not contribute equally to the maintenance of sodium balance. In knockout mice, severe salt wasting results from loss of function of the NKCC2 in the thick ascending limb, or of the ENaC in the collecting duct. However, knockout mice with loss of function of the proximal absorptive NHE do not exhibit severe salt wasting.[44] Apparently, the severity of Na dysregulation is unrelated to the basal rate of absorption of NaCl in a given nephron segment. At least for some nephron segments, a tubuloglomerular feedback mechanism may lower the rate of sodium delivery to compensate for a lower rate of sodium reabsorption.[44]

SODIUM, POTASSIUM–ADENOSINE TRIPHOSPHATASE

Bistritzer and co-workers[45] measured Na^+,K^+-ATPase activity in cord red blood cells of newborn infants at different gestational ages. Red blood cell Na^+,K^+-ATPase activity was significantly lower ($p < .01$) in preterm babies with a gestational age below 35 weeks, compared with those aged 35 weeks and above: 2.3 ± 0.8 and 6.7 ± 1.3 nmol reduced nicotinamide adenine dinucleotide/minute/mg protein, respectively. Two weeks after birth, regardless of gestational age, the enzyme activity of the

preterm babies increased to values similar to those observed in the term neonates at birth. These findings suggest that the Na^+,K^+-ATPase enzyme system undergoes important developmental changes.

Basolateral Na^+,K^+-ATPase provides the electrochemical driving force for solute reabsorption along the proximal tubule and the remainder of the nephron. In animals, the increase in active transport with maturation of the kidney parallels the threefold increase in Na^+,K^+-ATPase activity per millimeter tubule length during maturation.[46-49] The activity of Na^+,K^+-ATPase has been shown to increase in rats during development and to increase after aldosterone treatment.[50] Glucocorticoids can increase the rate of Na^+,K^+-ATPase production and may account for some of the increase in postnatal sodium handling in premature infants when compared with unborn fetuses at the same developmental age.[51] However, the activity of this enzyme system is not rate limiting for sodium transport, because the increase in the tubular membrane area precedes the increase in Na^+,K^+-ATPase activity.[52,53]

In addition to enzyme activity, the distribution of the Na^+,K^+-ATPase to the basolateral tubular membrane also appears to be developmentally regulated. In the distal nephron, messenger RNA (mRNA) expression for the β_2-subunit is expressed apically and is down-regulated after birth, whereas mRNA expression for the β_1-subunit is expressed basolaterally and is up-regulated after birth.[54,55]

Symporters

In primordial prokaryotic cells, families of transport proteins arose to serve a variety of cellular functions, including the regulation of cell pH and the provision of carbohydrate for cellular energy. The protein sequences have been conserved and through evolution modified proteins that now perform additional tasks, including the bulk transport of solutes.

In the proximal tubule, the filtered solutes glucose, phosphate, and amino acids are transported from the lumen into the tubular cells by proteins (symporters or antiporters) located in the brush-border luminal membrane.[56-59] Sodium travels down an electrochemical gradient, and the solutes are coupled to the movement of sodium. Bicarbonate is reabsorbed via the apical NHE3 and the basolateral Na-bicarbonate cotransporter (NBC).

PROXIMAL TUBULE

Sodium-Hydrogen Exchanger (NHE)

Neonates have a lower serum bicarbonate level than do adults because of a lower renal threshold for bicarbonate. Eighty percent of bicarbonate reabsorption occurs in the proximal tubule, in which proton secretion is predominantly mediated by an electroneutral luminal NHE.

The NHEs are plasma membrane proteins that are either sensitive (NHE1, NHE2, and NHE4) or insensitive (NHE3) to inhibition by amiloride. Their pattern of expression differs. NHE1 is transcribed in all tissues tested and functions in the regulation of intracellular pH and cell volume. NHE2 is highly expressed in the kidney and gastrointestinal tract and may play a role in sodium reabsorption. NHE3 is expressed in the kidney and contributes to sodium and bicarbonate reabsorption, and NHE4 is expressed mainly in the stomach. The renal NHEs are sorted either to the apical (NHE3) or to the basolateral (NHE1, NHE 4) membranes.[60,61]

Housekeeping Role

NHE3 plays a "housekeeping role" in maintaining the cell actin cytoskeleton. Members of the ezrin (VIL2)-radixin (RDX)-moesin (MSN) (ERM) protein family are highly concentrated in the apical aspect of polarized epithelial cells. These cells are studded with microvilli containing bundles of actin filaments, which must attach to the membrane to assemble and maintain the microvilli. The ERM proteins, together with merlin, the NF2 gene product, join integral membrane and cytoskeletal proteins and bind directly to actin. Actin cytoskeleton reorganization requires the activation of NHE3 (SLC9A3).[62]

Sodium Reabsorption

Schultheis and co-workers[63] created knockout mice lacking NHE3 function. Homozygous mutant mice survived but had slight diarrhea and mild acidosis. As expected, bicarbonate and fluid absorption were low in proximal convoluted tubules, the blood pressure was low, and a severe absorptive defect was observed in the intestine. These findings indicate that NHE3 is the major absorptive NHE in kidney and intestine and that lack of the exchanger impairs acid-base balance and Na^+-fluid volume homeostasis.

It is important to note that the mutant mice were not severely hyponatremic. Two mechanisms may account for their ability to maintain sodium balance. First, sodium transporters other than NHE were induced. Plasma aldosterone was increased in NHE3-deficient mice, and expression of both renin and the AE1 (Slc4a1) chloride-bicarbonate exchanger mRNAs were induced in kidney. In the colon, epithelial Na^+ channel activity was increased, and colonic H^+,K^+-ATPase mRNA was induced. Presumably, the high activity of these induced transporters compensated for the loss of function of NHE.

Second, the reduction in proximal fluid absorption was accompanied by a proportional decrease in the GFR. Compensation of the transport defect by a reduction in filtered load was so efficient that clinically symptomatic Na losses were not observed.[44,63]

Developmental Changes

The V_{max} of embryonic apical membrane NHE3 is three-fold lower than that in the adult, suggesting a lower abundance or turnover rate.[64] Na-H activity increases during the transition from fetus to newborn sheep.[65] The administration of glucocorticoid to the mother increases V_{max} to the adult level.

To examine the maturation of apical NHE3 antiporter activity in rat proximal convoluted tubules, Shah and associates[66] perfused rat proximal convoluted tubules in vitro. Na^+-H^+ antiporter activity was assayed as the proton secretory rate on luminal sodium removal. Na^+-H^+ antiporter activity was 121.2 ± 18.4 pmol/mm × minute in neonatal and 451.8 ± 40.6 pmol/mm × minute in adult proximal convoluted tubules ($p < .001$). Adult renal cortical NHE3 mRNA abundance was 10-fold greater than that in 1-day-old neonates ($p < .001$). A comparable developmental increase occurred in renal BBMV NHE3 protein abundance ($p < .001$). These observations indicate an age-related increase in rat apical membrane Na^+-H^+ antiporter activity, renal cortical NHE3 mRNA, and BBMV NHE3 protein abundance.

The abundance of mRNA for the basolateral NHE1 and NHE4 and the pH-dependent renal sodium uptake is higher in 2- to 4-week-old rats than in the adult.[67] The functional significance of this observation is unclear, because the major mechanism for the transport of HCO_3^- across the basolateral membrane is via the electrogenic Na^+-HCO_3^- cotransporter (NBC).

Sodium Bicarbonate Cotransporter (NBC)

Molecular cloning experiments have so far identified three NBC isoforms (NBC-1, NBC-2, and NBC-3) in the kidney.[68] Under normal conditions, all appear to mediate the cotransport of Na^+ and HCO_3^-. In addition, they may be functionally altered in certain pathophysiologic states. For example, NBC-1 may be up-regulated in metabolic acidosis and potassium depletion, and also in response to glucocorticoid excess, and may be down-regulated in response

to HCO_3^- loading, or alkalosis.[69] Mutations in the *SLC4A4* gene for NBC cause proximal renal tubular acidosis, with bilateral glaucoma, cataracts, and band keratopathy. Such mutations may increase the bicarbonate concentration in the corneal stroma, which would facilitate calcium deposition, leading to band keratopathy.[70]

Sodium-Phosphate Type IIa

In the intestine and the kidney, the apical sodium Na-P_i cotransport is the rate-limiting step for the reabsorption of phosphate.[71] Three different Na-P_i cotransporters have been identified:

1. Type I cotransporters, such as NPT1 (SLC17A1), are found mainly in proximal tubule and do not appear to be regulated by dietary phosphate levels. These proteins also show anion channel function and may play a role in secretion of organic anions.
2. Type II cotransporters, such as NaP_i-3 (SLC34A1), determine Na^+-dependent transcellular P_i movements in the renal proximal tubule (type IIa) and in the small intestine (type IIb).
3. Type III cotransporters are expressed in many different tissues, where they serve housekeeping functions. Type III transporters also can function as membrane receptors for primate retroviruses.

The Na-P_i symporters derive from ancient lineage. A NaP_i-2 homologue cloned from *Vibrio cholerae* is a functional P_i transporter when expressed in *Xenopus* oocytes.[72]

In the small intestine, expression of IIb protein varies in response to altered P_i intake and levels of 1,25-dihydroxyvitamin D_3. In the proximal tubule, P_i intake, vitamin D levels, and parathyroid hormone all regulate the expression of the IIa cotransporter.

Contribution of Sodium-Phosphate Type 2 to Sodium Reabsorption

The NHE is the major apical sodium transporter in the proximal convoluted tubule. The relative contribution of other transport systems to the reabsorption of sodium can be estimated by using "targeted proteomics." In this method, the kidneys of genetically deficient mice with loss of NHE3 function are probed for renal sodium transporters. Brooks and associates[73] used semiquantitative immunoblotting to estimate the percentage change in abundance of each transporter in knockout compared with wild-type mice. In NHE3 knockout mice, three changes were identified that could compensate for the loss of NHE3-mediated sodium absorption: (1) in the proximal tubule, the sodium-phosphate cotransporter NaP_i-2 was markedly up-regulated; (2) in the collecting duct, the 70-kDa form (aldosterone stimulated) of the γ-subunit of the epithelial sodium channel ENaC was up-regulated; and (3) glomerular filtration was significantly reduced. These findings suggest that the NaP_i-2 transport system plays an important role in sodium, as well as phosphate, handling by the kidney.

Sodium-Phosphate During Development

The renal tubules of the neonate have a high rate of phosphate reabsorption. To determine the mechanism, Woda and colleagues[74] performed renal micropuncture experiments in acutely thyroparathyroidectomized adult (>14-week-old) and juvenile (4-week-old) male Wistar rats in the presence and absence of parathyroid hormone. P_i reabsorption was greater in proximal convoluted and straight tubules of the juvenile compared with adult rats, whether or not parathyroid hormone was present. These findings were consistent with a greater P_i uptake in BBMVs from both superficial and outer juxtamedullary cortices of juvenile animals. This high rate of P_i uptake is due to a high V_{max} of the NaP_i-2 symporter.

In kidneys of newborn rats, the appearance of NaP_i-2 protein and mRNA coincides with the development of the brush border (assessed by actin staining) on proximal tubular cells. Traebert and colleagues[75] found that NaP_i-2 was not detectable in the nephrogenic zone or in the outgrowing straight sections of proximal tubules, which lack a brush border. In 13-day-old suckling rats, strong NaP_i-2 staining was seen in the brush border membrane (BBM) of convoluted proximal tubules of all nephron generations. In contrast, in 22-day-old weaned rats, NaP_i-2 staining in the BBM of superficial nephrons was weaker than that in the BBM of juxtamedullary nephrons. Western blotting demonstrated that the overall abundance of NaP_i-2 protein in the BBM of 22-day-old rats was decreased to approximately 70% of that in 13-day-old rats. These observations suggest a greater abundance of NaP_i-2 in newborn compared with mature animals.

Woda and colleagues[74] found that dietary phosphate restriction in juvenile rats resulted in a significant increase in phosphate reabsorption in the PCT and PST segments. NaP_i-2 expression in the proximal tubule BBM was also increased, as was the expression of intracellular NaP_i-2 protein. In addition, dietary phosphate restriction in the juvenile rat was associated with up-regulation of BBM NaP_i-2 expression, which was associated with a further increase in proximal tubular phosphate reabsorption.

The ancient molecular lineage and the high plasticity of NaP_i-2 suggest an important role in maintaining sodium, as well as phosphate, homeostasis.

DISTAL TUBULE

The thick ascending limb of the loop of Henle in neonates has only 20% of the capacity to transport sodium compared with adults.[76,77] As in the proximal tubule, Na^+,K^+-ATPase activity is significantly lower in the differentiating basolateral membrane of the thick ascending limb. This accounts for an isotonic fluid delivered to the early distal tubule in the immature kidney, in contrast to a hypoosmotic fluid delivered in the adult kidney.

Aperia and Elinder[78] studied distal tubular sodium reabsorptive capacity in immature (24-day-old) and mature (40-day-old) rats during hydropenia and after volume expansion. Under hydropenic conditions, the fraction of filtered sodium entering the early distal tubule was higher, although it was similar in the late distal tubule in the young compared with mature rats (Figure 128-10).[78] This indicates that immature nephrons deliver a greater fraction of sodium from the ascending loop of Henle but

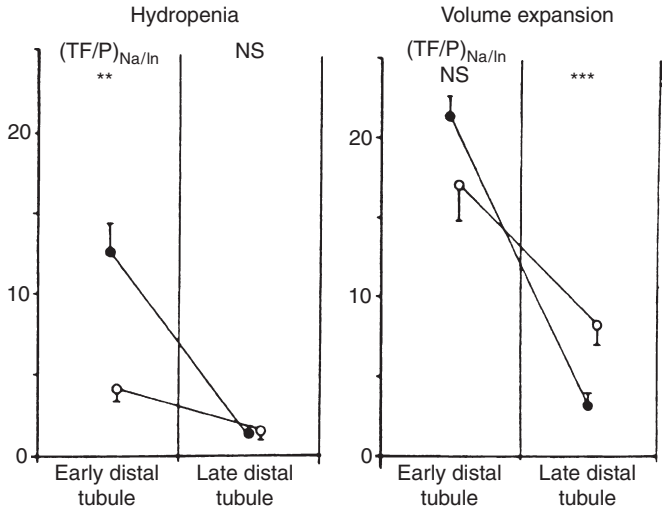

Figure 128-10 Changes in $(TF/P)_{Na/inulin}$ from early distal to late distal tubule in hydropenic and volume-expanded 24-day-old *(closed circles)* and 40-day-old *(open circles)* rats. *NS,* No significant difference. $^{**}p < .01$. $^{***}p < .001$. *(From Aperia A, Elinder G: Distal tubular sodium reabsorption in the developing rat kidney,* Am J Physiol *240:F487, 1981.)*

also have a higher fractional reabsorption of sodium along the distal tubule.

Epithelial Sodium Channel

Canessa and colleagues[79,80] cloned and characterized subunits of a rat ENaC that had the functional properties of the distal renal sodium channel—high sodium selectivity, low conductance, and amiloride sensitivity. The functional channel is composed of at least three subunits, alpha (SCNN1A), beta (SCNN1B), and gamma (SCNN1G). The three subunits show sequence similarities to one another, indicating descent from a common ancestral gene. Each encodes a protein containing two transmembrane domains, with intracellular amino and carboxyl termini.

In the distal nephron, ENaC mediates electrogenic Na transport and is the rate-limiting step of sodium reabsorption. In the adult, ENaC is expressed all along the connecting tubule (70% of the distal convolution) and the cortical collecting duct.[81]

Regulation of the Epithelial Sodium Channel by Aldosterone and Angiotensin II

The level of sodium reabsorption is primarily determined by the action of aldosterone on ENaC in the distal nephron. To conserve sodium, aldosterone must first bind to the mineralocorticoid receptor (MR). MR-deficient knockout mice develop symptoms of pseudohypoaldosteronism, such as weight loss, dehydration, and renal sodium wasting. By day 8, MR-deficient knockout mice develop hyperkalemia, hyponatremia, and high circulating levels of renin, angiotensin II, and aldosterone. GFR is similar to that of controls, but the FE_{Na} is more than eight-fold higher.[82]

In an aldosterone-sensitive renal cell line (A6), aldosterone regulates sodium reabsorption by short- and long-term processes. In the short term, aldosterone regulates sodium transport by inducing expression of the small G-protein K-Ras2A, by stimulating the activity of methyltransferase and *S*-adenosylhomocysteine hydrolase to activate Ras by methylation, and, possibly, by subsequent activation by K-Ras2A of phosphatidylinositol phosphate-5-kinase (PIP-5-K) and phosphatidylinositol-3-kinase (PI-3-K), which ultimately activate ENaC. In the long term, aldosterone regulates sodium transport by altering trafficking, assembly, and degradation of EnaC.[83,84]

Brooks and co-workers[85] examined renal homogenates from mice in which the gene for the angiotensin II type 1a (AT[1a]) receptor had been deleted to determine which sodium transporters and channels are regulated by the AT(1a) receptor. In mutant compared with wild-type mice maintained on a low-NaCl diet, the abundance of the thiazide-sensitive cotransporter and the three subunits of the amiloride-sensitive ENaC was markedly increased. No significant changes were found in the abundances of the proximal tubule NHE or the Na^+-K^+-$2Cl^-$ cotransporter of the thick ascending limb. These observations suggest that angiotensin II directly alters renal sodium transport independently of aldosterone secretion.

Ontogeny of Epithelial Sodium Channel

The total expression of ENaC subunits is very low in the embryonic rat kidney but rises rapidly to adult levels by the first postnatal day.[86] ENaC is expressed in a variety of tissues, including lung and kidney. In knockout mice that do not express ENaC subunits, severe hyponatremia and/or failure to clear pulmonary fluid may occur (Table 128-3).[86-91] These findings indicate that EnaC is critically important to sodium balance.

TABLE 128-3

Epithelial Sodium Channel Subunit Loss of Function Mutations

Type	Lung	Kidney
a-ENaC	Failure of pulmonary fluid clearance	Salt wasting, metabolic acidosis, and high aldosterone
b-ENaC	Cleared fluid	Compensated on normal sodium intake but PHA-1 on low sodium
g-ENaC	Fluid problems	Severe hyperkalemia

ENaC, Epithelial sodium channel.

Cation-Chloride Cotransporters

The cation-Cl cotransporters (CCC) mediate the coupled movement of Na and/or K to that of Cl across membranes of epithelial cells. Eight CCC have been identified to date: two Na-K-Cl cotransporters (NKCC), four K-Cl cotransporters (KCC), one Na-Cl cotransporter (NCC), and one CCC interacting protein (CIP). All the NKCC and KCC are inhibited by loop diuretics.[92]

Sodium-Potassium-Chloride Cotransporter

The Na-K-Cl cotransporters are a family of integral membrane proteins that mediate the coupled transport of Na^+,K^+, and Cl^- across the plasma membrane. Quaggin and colleagues[93] observed that the kidney-specific Na-K-Cl cotransporter (previously called NKCC2) mediates active reabsorption of sodium chloride in the thick ascending limb of the loop of Henle and is the site of action of the clinically important diuretics furosemide and bumetanide. The protein of the transporter gene, symbolized as SLC12A1 in human and mouse, is structurally related (64% amino acid identity in the mouse) to another Na-K-Cl cotransporter (SLC12A2, previously called NKCC1), which is expressed in many tissues, including the basolateral membrane of secretory epithelia, where it mediates active chloride secretion.

Sodium-Chloride Cotransporter

The thiazide-sensitive NCC of the distal convoluted tubule is the principal mediator of sodium and chloride reabsorption in this nephron segment, accounting for a significant fraction of net renal sodium reabsorption. Simon and colleagues[94] and others[95] have associated Gitelman's syndrome of inherited hypokalemic alkalosis with mutations in the electroneutral Na-Cl transporter. Gamba and associates[96] have cloned this transporter from rat kidney. Simon and co-workers[94] have cloned the human homologue, which they designated TSC for thiazide-sensitive Na-Cl cotransporter, and showed that the protein is encoded by 26 exons. The human protein showed 89% identity with the rat homologue and 63% identity with the flounder homologue.

Mastroianni and co-workers[97] also cloned the *SLC12A3* gene. The predicted protein sequence of 1021 amino acids (112 kDa) showed a structure common to other members of the Na-K-Cl cotransporter family: a central region harboring 12 transmembrane domains and the two intracellular hydrophilic amino and carboxyl termini. The expression pattern of the gene confirmed the kidney specificity. By fluorescence in situ hybridization, these investigators mapped the gene to 16q13.

In the NCC knockout mice, the abundance of the 70-kDa form of the γ-subunit of ENaC was higher than in controls. However, the abundance of other sodium transport proteins was similar to that of wild-type mice. Compared with the renal Na transporters of the NCC knockout mouse, the renal Na transporters of NH3 knockout mice undergo extensive adaptation. This observation suggests that NHE3 is more important for bulk sodium transport than is NCC.[73]

REGULATORY SYSTEMS

Development changes in a variety of endocrine and paracrine systems (e.g., the renin-angiotensin-aldosterone system, prostaglandins, catecholamines, atrial natriuretic peptide, glucocorticoids, the kallikrein-kinin system, nitric oxide, and endothelin)

may influence the renal handling of sodium. Detailed reviews have been published.[98,99]

Renin-Angiotensin-Aldosterone System

Studies in the Fetus

In the fetus, the expression of renin in the kidney is different from that in the adult. Reddi and associates[100] observed a shift in renin distribution from interlobar and arcuate arteries in the fetus to the afferent arterioles in the adult. In addition, these investigators identified seven types of renin distribution along the afferent arterioles. In type I, renin was distributed continuously along the whole length of the afferent vessel. This pattern was most frequently observed in the fetus. In type II, renin extended upstream from the glomerulus but did not occupy the whole length of the arteriole. This type was relatively constant throughout postnatal life. In type III, renin was present as bands along the afferent vessel; it was most frequently observed in the fetal and early perinatal periods. In type IV, renin was restricted to the "classic" juxtaglomerular localization. It was the most frequent type observed in the adult rat. In type V, no renin was found in the arteriole. It was the second most frequent type observed in the adult rat. The distribution of renin-expressing cells was spatially and temporally associated with the development of blood vessels. During this process, renin-expressing cells were distributed along the whole of the newly formed vessel. As the vessel matured, renin-expressing cells became restricted to the juxtaglomerular portion of the afferent arteriole.

In chronically catheterized fetal sheep, the renin-angiotensin system is active during intrauterine life.[101] Levels of angiotensin II in fetal sheep are similar to those in maternal sheep. The fetal kidney, like other vascular beds, has high levels of the AT2 angiotensin receptor subtype. With maturation, the proportion of the AT1 receptor subtype increases.

Blockade of the fetal renin-angiotensin system with angiotensin-converting enzyme inhibitors or with the nonpeptide angiotensin II antagonist losartan causes a fall in fetal GFR and a rise in renal blood flow. Angiotensin II reverses the fall in GFR even though renal blood flow decreases. Lumbers[101] observed that the fraction of the filtered sodium load reabsorbed by the proximal tubule was not affected when the fetal renin-angiotensin system was blocked by captopril or losartan. High doses of infused angiotensin II had no effect on renal reabsorption of sodium in the short term, but in the long term had an effect on depressed fractional proximal reabsorption. These studies suggest that the renin-angiotensin system is active in the fetus but that the proximal renal tubule is resistant to the sodium-retaining effects of angiotensin II.

Studies in the Neonate

After birth, the kidneys of newborn animals become sensitive to the salt-retaining effects of angiotensin II. FE_{Na} in rat pups given daily injections of the ATI receptor inhibitor losartan is higher than in control animals administered vehicle.[102]

Plasma renin activity (PRA)[103,104] and plasma aldosterone (PA) concentrations[105,106] are higher in newborn animals and humans. Sulyok and co-workers[107] studied the relationship of PRA, PA, and urinary aldosterone excretion (UAE) in infants given sodium supplements and no supplements with a mean gestational age of 31 weeks. Among infants not given supplements, PRA, PA, and UAE increased dramatically from week 1 to week 3 after birth and then gradually decreased over the subsequent 2 weeks of the study (Figure 128-11).[107] In contrast, no consistent change was seen in the supplemented group, with values similar to those of term neonates. In fact, PRA, PA, and UAE were significantly higher in infants who did not receive supplements versus those who did receive supplements at a postnatal age of 2 to 4 weeks. Godard and co-workers[108] also found PRA to be inversely correlated with urinary sodium excretion in term infants. Highest values were noted in the first 2 days of life and decreased over the subsequent week.[108]

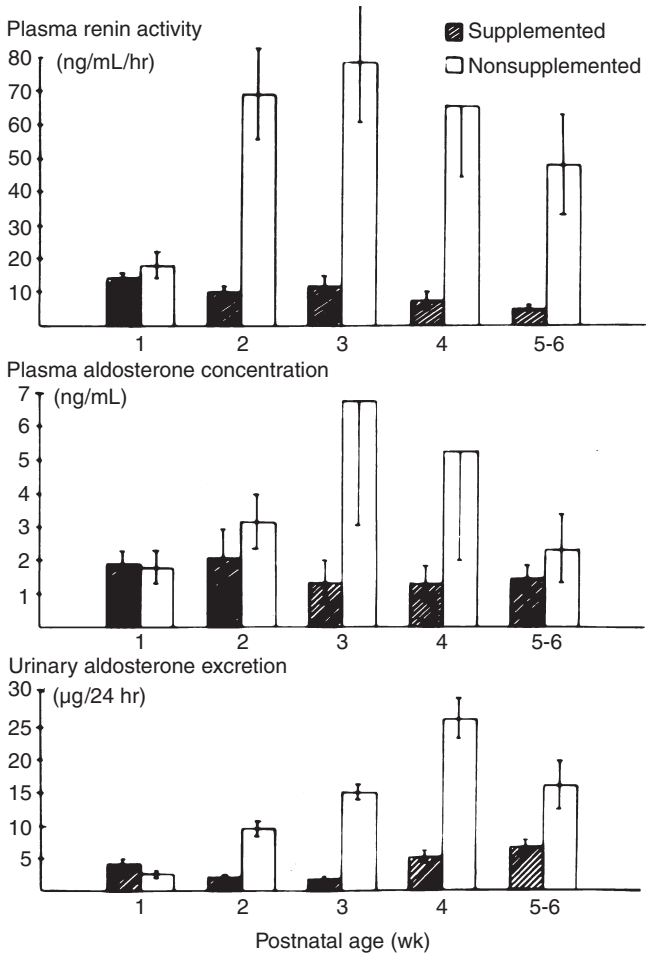

Figure 128-11 Plasma renin activity, plasma aldosterone concentration, and urinary aldosterone excretion in preterm infants with and without sodium supplementation in the first 5 to 6 weeks of life. *(From Sulyok E, Németh M, Tényi I, et al: Relationship between the postnatal development of the renin-angiotensin-aldosterone system and electrolyte and acid-base status of the NaCl-supplemented premature infants. In Spitzer A, editor:* The Kidney During Development, *New York, 1982, Masson, pp 273-281.)*

Aperia and associates[109] have shown that the pattern of UAE was similar in preterm (less than or equal to 34 weeks gestation) and term infants. During the first 3 postnatal weeks, UAE was higher in both groups compared with normal adult values (Figure 128-12).[109] Because aldosterone affects tubular sodium and potassium transport in opposite directions, the urinary sodium–urinary potassium ratio (U_{Na}/U_K or U_K/U_{Na}) has been used to assess the effect of this hormone on distal tubular transport. It is interesting that the urinary potassium–sodium ratio showed a linear relationship to UAE with time only in term infants, whereas the ratio in the preterm group showed a correlation to UAE only after 10 days of age. The hyponatremia found at 2 weeks of age in the premature infants corresponded to the highest UAE and a low urinary potassium–sodium ratio.

An impaired end-organ response to aldosterone seemed to exist, with improvement with increasing postnatal age. Because the absolute urinary sodium excretion was similar in both

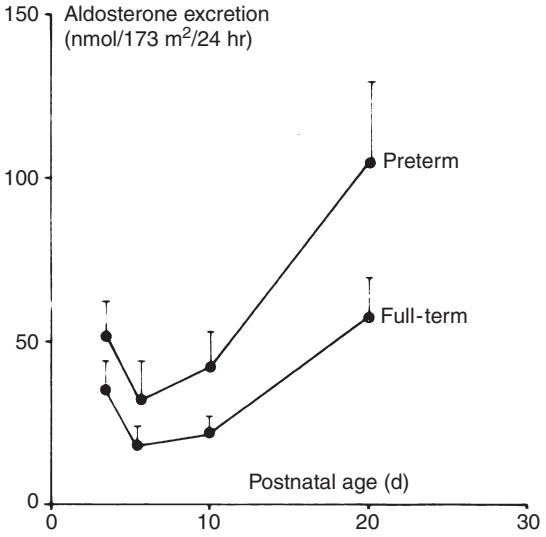

Figure 128-12 Changes in urinary aldosterone excretion in the first 30 days after birth in preterm and term infants. *(From Aperia A, Broberger O, Herin P, Zetterström R: Sodium excretion in relation to sodium intake and aldosterone excretion in newborn pre-term and full-term infants,* Acta Paediatr Scand *68:813, 1979.)*

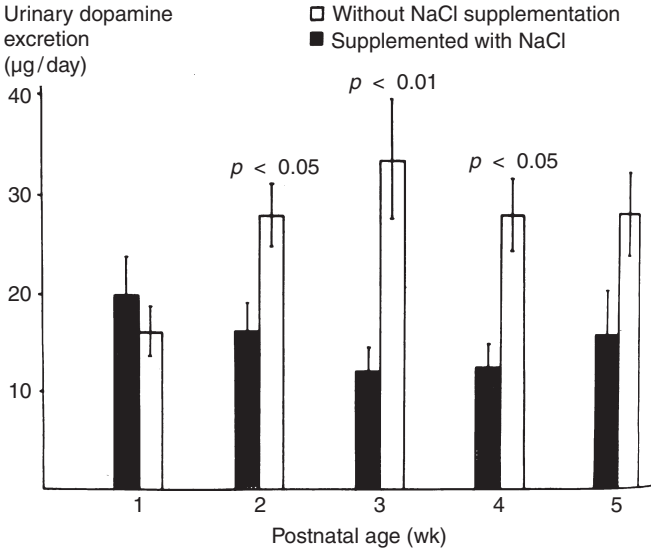

Figure 128-13 Urinary dopamine excretion in preterm infants with and without sodium supplementation in the first 5 weeks of life. *(From Sulyok E, Gyódi G, Ertl T, et al: The influence of NaCl supplementation on the postnatal development of urinary excretion of noradrenaline, dopamine, and serotonin in premature infants,* Pediatr Res *19:5, 1985.)*

groups, factors other than sodium balance contributed to the hyponatremia found in very premature infants. The lack of renal tubular sensitivity to aldosterone may be related to lack of receptors or lack of Na^+,K^+-ATPase activity in the premature infant. However, Stephenson and co-workers[110] found that immature rats (in contrast to older animals) were essentially insensitive to subcutaneously injected aldosterone. In addition, equivalent high-affinity aldosterone-binding sites existed in both groups of rats. They concluded that the resistance of immature rat kidneys to aldosterone was not a defect in signal presentation or receptors but rather was a postreceptor phenomenon.

Prostaglandins

Renal prostaglandin (PGE) production, as measured by urinary PGE_2 and prostacyclin, is highest in preterm neonates and decreases with increasing gestational and postnatal age.[111] PGE concentrations decrease progressively with postnatal age in premature infants receiving sodium supplementation but show no significant change with advancing age in a nonsupplemented group.[112] The steady decline in PGE concentrations in the sodium-supplemented group corresponds to decreased activity in the renin-angiotensin-aldosterone system under similar conditions. From the studies, Ertl[112] suggested that increased PGE synthesis would be needed to offset the vasoconstrictor effect resulting from activation of the renin-angiotensin system to maintain normal blood pressure and reduce renal vascular resistance. In premature neonates, inhibition of PGE synthesis with indomethacin can significantly reduce glomerular blood flow and glomerular filtration, but the role of PGE synthesis inhibition in renal tubular sodium handling is minimal.[113]

Catecholamines

Both neuronally derived and locally produced (renal tubular cells) catecholamines exert control over renal sodium handling. Tubule cells possess receptors for dopamine, norepinephrine, and epinephrine. An association exists between increased sodium excretion and increased dopamine excretion in preterm infants who do not receive supplementation (Figure 128-13).[114,115] Conversely, infants who receive supplementation show no increase in dopamine excretion. These studies demonstrate that the renal sympathetic nervous system enhances sodium reabsorption. However, its relationship to the renin-angiotensin-aldosterone system still requires additional investigations.

The IV administration of dopamine to sick premature infants increases sodium excretion and PRA without a significant change in PA.[116] This could be interpreted as an unresponsiveness of the adrenal gland to additional stimulation. Even though age-related differences exist in the effect of dopamine administration, the results are similar to those reported in adults.

To sort out the differences in the renal response to endogenous versus exogenous dopamine, metoclopramide was given to premature infants to block dopamine production.[117] Urinary sodium excretion was increased in the low–salt intake group, whereas no change was seen in the high–dietary sodium group. No effect also was seen on PRA in either group. Conversely, PA concentration and UAE decreased. These data suggested that increased urinary sodium excretion was due to metoclopramide suppression of aldosterone secretion in these young infants. Therefore endogenous dopamine stimulated renal tubular sodium reabsorption, and increased aldosterone production possibly played a role in restoration of positive sodium balance in premature infants with late hyponatremia.

Studies in fetal sheep have examined the role of renal innervation in the development of sodium homeostasis. The relative distribution of α_1-adrenoceptors (which modulate tubular sodium and water reabsorption) and α_2-adrenoceptors (which modulate sodium, water, and potassium excretion) changes during development.[118] Stimulation of α_1-adrenoceptors in fetal, newborn, and adult sheep showed a maximal ability to decrease urine flow and sodium excretion in newborn sheep, with significantly less conservation of sodium in fetal sheep.[119] The ability to reabsorb sodium and water in the immediate postnatal period is, in part, mediated by development of the renal response to catecholamines. Incomplete development of this system in premature neonates may play a role in the hyponatremia of prematurity.

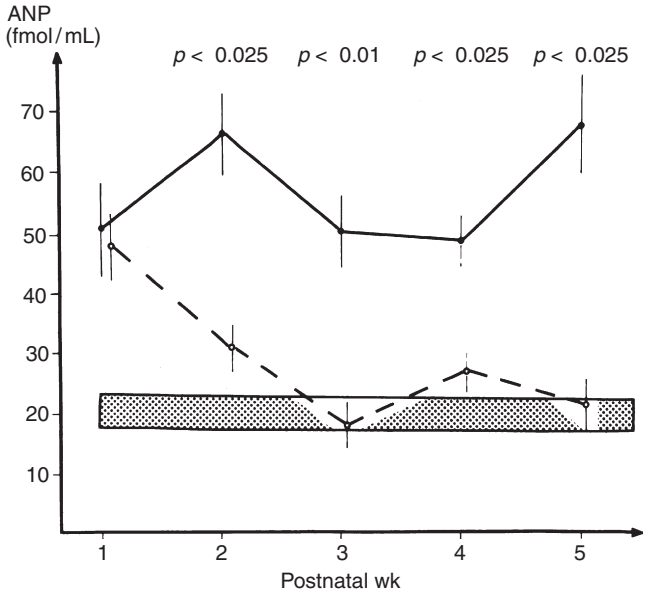

Figure 128-14 Plasma atrial natriuretic peptide (ANP) concentrations in preterm infants on a low-sodium *(dashed line)* and a high-sodium *(solid line)* intake. The stippled area is ANP values for 7- to 10-day-old term infants. *(From Tulassay T, Rascher W, Seyberth HW, et al: Role of atrial natriuretic peptide in sodium homeostasis in premature infants,* J Pediatr *109:1023, 1986.)*

Atrial Natriuretic Peptides

Atrial natriuretic peptide (ANP) is detectable early in fetal development.[120] The distribution of ANP is relatively widespread in both atria and ventricles during early development and localizes to the right atrium near the time of birth.[121] Circulating levels of ANP increase throughout gestation, continue to increase after birth for 7 to 10 days, and are higher in premature infants than in term neonates.[122] The highest ANP levels are seen in the most premature neonates, particularly those with respiratory disease.[123] ANP concentrations are elevated in the plasma of infants who receive sodium supplementation (Figure 128-14).[124] Although the exact mechanism modulating this increase is unknown, it may be a result of an expanded extracellular fluid volume because of the augmented sodium diet. The lower value in infants given a low-sodium diet may be a response of the premature kidney to conserve sodium for tissue growth.

Although circulating levels of ANP are high during development and in the newborn period, the renal natriuretic and diuretic response to ANP is blunted. Possible reasons for this blunted response include the following: (1) lower renal perfusion pressure seen in fetal and newborn kidneys,[125] (2) incompletely developed system of ANP receptors in the kidney,[126] and/or (3) inhibition of ANP effect by high circulating levels of angiotensin II and aldosterone.

The importance of ANP in sodium handling in the young animal is unclear. Deloof and colleagues[127] placed pregnant rats on either a high-sodium or a normal-sodium diet. The high-sodium diet was not associated with a change in the plasma ANP concentrations but significantly decreased the PA concentrations in both the maternal and fetal rats. In response to the high-salt diet, the density and affinity of total ANP, ANPb, and ANPc receptors were not altered in the maternal isolated renal glomeruli or the adrenal zona glomerulosa membranes, or the fetal adrenal gland and kidney membrane preparations. These results suggest that ANP is not involved in the regulation of water and electrolyte balance in maternal and fetal rats during salt-loaded intake.

Digoxin-like immunoreactive substances in both the urine and plasma have been suggested to be natriuretic by virtue of their known inhibition of Na^+,K^+-ATPase activity in vitro.[128] Ebara and colleagues found a correlation between these substances and FE_{Na} in preterm infants.[128] The urine and plasma concentrations of digoxin-like immunoreactive substances remained elevated for 4 weeks in infants of 24 to 29 weeks gestation and decreased in those infants with a gestational age greater than 30 weeks. Additional studies will be required to assess the significance of this study.[129]

SUMMARY

Primordial cells have developed specialized proteins to aid in the maintenance of cellular integrity, pH, and metabolism. More evolved cell types have co-opted and modified these ancient proteins to serve a variety of functions useful to the organism as a whole, including the bulk transport of solutes across epithelial cell membranes. In immature animals, the transport proteins not only maintain homeostasis but also promote growth.

Newborn animals maintain a positive balance for sodium. Clearance studies have indicated that the distal tubule is mostly responsible for the adaptation to extrauterine life. Because of advances in molecular biology, a variety of specialized sodium transporters are now recognized. Studies performed with use of targeted proteomics have revealed the special importance of ENaC and the NCC proteins in maintaining sodium balance.

Some investigators have postulated the existence of growth-specific transporters that are not expressed in the adult. Future studies will determine exactly how these proteins are sorted, distributed, and regulated. The contribution of regulatory paracrine systems such as the renin-angiotensin system can then be rigorously investigated.

129 Potassium Homeostasis in the Fetus and Neonate

Corinne Benchimol and Lisa M. Satlin

Potassium is the most abundant intracellular cation. Maintenance of a high intracellular potassium concentration (100 to 140 mEq/L) is essential for many basic cellular processes, including cell growth and division, DNA and protein synthesis, conservation of cell volume and pH, and optimal enzyme function. The steep gradient between potassium concentration in the cell and that in the extracellular fluid, maintained by the ubiquitous sodium-potassium adenosine triphosphatase (Na^+,K^+-ATPase), is the major determinant of the resting membrane potential across the cell membrane, and thus it affects neuromuscular excitability and contractility. Approximately 98% of the total body potassium content in the adult resides within cells, primarily muscle (Figure 129-1), whereas the remaining 2% is located within the extracellular fluid. The extracellular potassium concentration (generally ranging from 3.5-5.0 mEq/L) is tightly regulated by mechanisms that govern the *internal* distribution between the intracellular and extracellular compartments and the *external* balance between intake and output.

POTASSIUM HOMEOSTASIS

The homeostatic goal of the adult is to remain in zero potassium balance. Thus, of the typical daily potassium intake of 1 mEq/kg body weight, approximately 90% to 95% is ultimately eliminated from the body in the urine; the residual 5% to 10% of the daily potassium load is lost through the stool (see Figure 129-1). Normally, the amount of potassium lost through sweat is negligible.

In contrast to the situation in the adult, infants greater than approximately 30 weeks gestational age (GA) must conserve potassium for growth.[1,2] Postnatal growth is associated with an increase in total body potassium from approximately 8 mEq/cm body height at birth to more than 14 mEq/cm body height by 18 years of age.[3,4] The rate of accretion of body potassium per kilogram body weight in the neonate is greater than in later childhood (Figure 129-2), a finding reflecting an increase in both cell number and potassium concentration (at least in skeletal muscle) with advancing age.[4-6] Given the requirement of the growing organism for potassium conservation, it is not unexpected

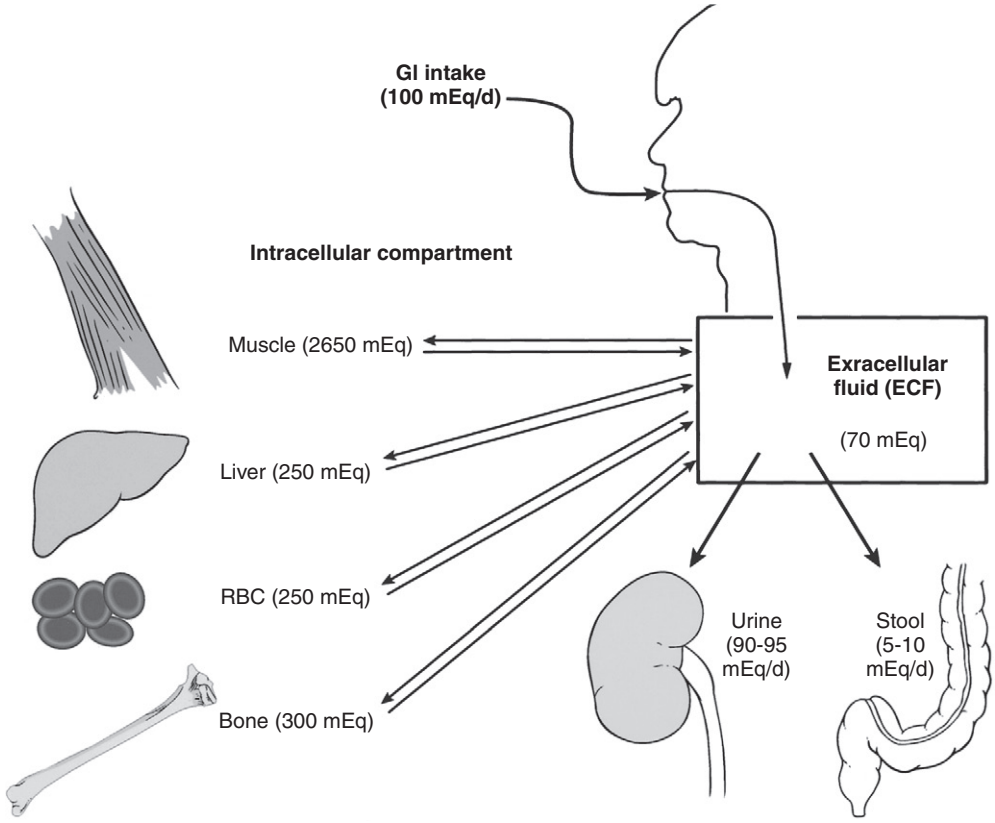

Figure 129-1 Potassium homeostasis in the adult: *internal* and *external* balance. *External* potassium balance is maintained by the urinary (90% to 95%) and fecal (5% to 10%) excretion of the daily potassium intake of approximately 1 mEq/kg/day in the typical adult. *Internal* potassium balance depends on the distribution of potassium between the extracellular fluid (ECF) compartment and the vast intracellular storage reservoirs provided by muscle, liver, erythrocytes (RBC), and bone. *GI,* Gastrointestinal.

that infants maintain a state of positive potassium balance.[2,7] This tendency to retain potassium early in postnatal life is reflected, in part, in the higher plasma potassium values in infants, and particularly in preterm neonates.[2,7]

In fetal life, potassium is transported across the placenta from mother to fetus. Indeed, the fetal serum potassium concentration is maintained at levels exceeding 5 mEq/L even in the presence of maternal potassium deficiency.[8,9]

Urinary potassium excretion varies considerably, depending in large part on dietary intake. Children and adults ingesting an average American diet that contains sodium in excess of potassium excrete urine with a sodium-to-potassium ratio greater than 1.[2,10] Although breast milk and commercially available infant formulas generally provide a sodium-to-potassium ratio of approximately 0.5 to 0.6, the urinary sodium-to-potassium ratio in the newborn up to 4 months of age generally exceeds 1. This high ratio may reflect the greater requirement of potassium over sodium for growth. In fact, some premature (<34 weeks GA) newborns may excrete urine with a sodium-to-potassium ratio greater than 2, a finding suggesting significant salt wasting and a relative hyporesponsiveness of the neonatal kidney to mineralocorticoid activity.[2] Because of the many vital processes dependent on potassium homeostasis, multiple complex and efficient mechanisms have developed to regulate total potassium balance and distribution.

REGULATION OF INTERNAL POTASSIUM BALANCE

The task of maintaining potassium homeostasis is complex, in large part because the daily dietary intake of potassium (approximately 100 mEq in the adult) typically approaches or exceeds the total potassium normally present within the extracellular fluid space (approximately 70 mEq in 17 L of extracellular fluid with a potassium concentration averaging approximately 4 mEq/L) (see Figure 129-1). To maintain zero balance in the adult, all the dietary intake of potassium must be ultimately eliminated, a task performed primarily by the kidney. However, renal excretion of potassium is rather sluggish, requiring several hours to be accomplished. Approximately 50% of an oral load of potassium is excreted during the first 4 to 6 hours after it is ingested, yet life-threatening hyperkalemia is not generally observed during this period because of the rapid (within minutes) hormonally mediated translocation of extracellular potassium into cells, particularly those of muscle and liver. The buffering capacity of the combined cellular storage reservoirs, capable of sequestering up to approximately 3500 mEq of potassium, is vast compared with the extracellular pool (see Figure 129-1).

Cells must expend a significant amount of energy to maintain the steep potassium and sodium concentration gradients across their cell membranes. This is accomplished by the Na^+,K^+-ATPase cation pump, which catalyzes the hydrolysis of cytosolic adenosine triphosphate, thereby providing energy for the active extrusion of sodium from cells in exchange for the uptake of potassium in a ratio of 3:2, respectively. A cell interior negative potential is created by the unequal cation exchange ratio and the subsequent leak of potassium out of the cells through potassium-selective channels in the plasma membrane. Na^+,K^+-ATPase consists of a catalytic (α) and a regulatory (β) subunit.

Thirty percent to 50% of very-low-birth-weight and premature infants <28 weeks GA exhibit nonoliguric hyperkalemia (defined as a serum potassium concentration of >6.5 mEq/L) during the

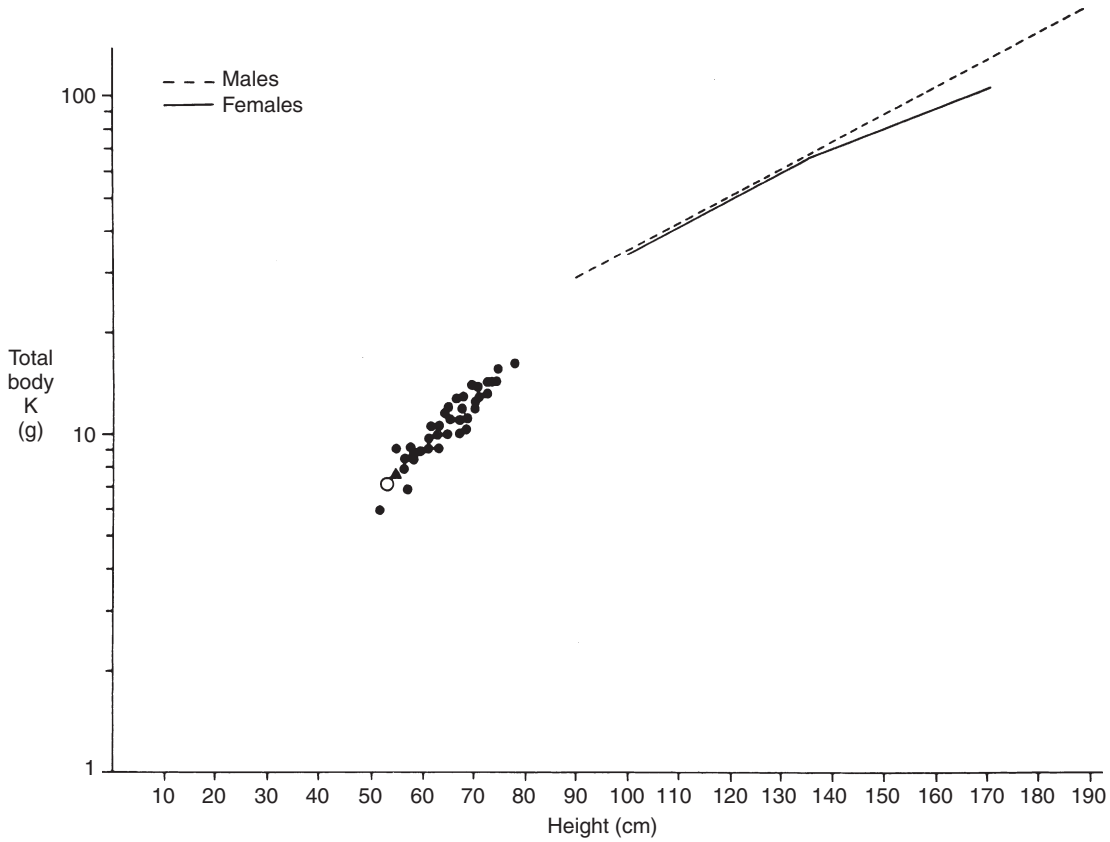

Figure 129-2 Relationship between total body potassium (in grams) and height (in centimeters) for infants and children. The rate of accretion of body potassium in the neonate is faster than in later childhood, likely reflecting an increase in both cell number and potassium concentration, at least in skeletal muscle, with advancing age. *(From Flynn MA, Woodruff C, Clark J, et al: Total body potassium in normal children,* Pediatr Res *6:239, 1972.)*

first 48 hours after birth, despite the intake of negligible amounts of potassium.[11-15] This phenomenon is not observed in mature infants or very-low-birth-weight infants after 72 hours.[13,14] This biochemical observation has been proposed to reflect a shift of potassium from the intracellular to the extracellular fluid space, because of low Na^+-K^+ pump activity, as well as a limited renal potassium secretory capacity.[13,14,16] Prenatal steroid treatment may prevent this nonoliguric hyperkalemia via induction of pump activity in the fetus.[17,18]

Na^+,K^+-ATPase activity is regulated by numerous circulating hormones that exert short-term and long-term control over it.[19] Whereas long-term stimulation of pump activity is generally mediated by changes in gene and protein expression, short-term regulation generally results from alterations in the phosphorylation status of the pump, changes in the subcellular or cell surface distribution of pumps (i.e., membrane trafficking), and/or interaction with regulatory proteins.[19] Regulation of internal potassium balance in the neonate may be influenced by developmental stage–specific expression of potassium transporters (such as the cation pump) and channels, receptors, and signal transduction pathways.

The chemical, physical, and hormonal factors that acutely influence the *internal* balance of potassium are listed in Table 129-1. Potassium uptake into cells is acutely stimulated by insulin, β_2-adrenergic agonists, and alkalosis and is impaired by α-adrenergic agonists, acidosis, and hyperosmolality. Generally, deviations in extracellular potassium concentration arising from fluctuations in internal distribution are self-limited as long as the endocrine regulation of *internal* balance and mechanisms responsible for regulation of *external* balance are intact.

Plasma Potassium Concentration

Active basolateral cellular potassium uptake in large part determines the intracellular pool of potassium. An increase in plasma potassium, either because of a dietary or parenteral potassium load or resulting from a chronic progressive loss of functional renal mass, decreases the concentration gradient (dependent on the ratio of intracellular to extracellular potassium concentration) against which the Na^+,K^+-ATPase pump must function and thus favors an increase in cellular potassium uptake. In those cells of the kidney and colon specifically responsible for potassium secretion, the resulting increase in intracellular potassium maximizes the concentration gradient between cell and lumen, thereby promoting potassium diffusion into the tubular lumen and thus potassium excretion.

TABLE 129-1

Factors, Relevant to the Infant, That Acutely Regulate the Internal Balance of Potassium

Factor	Effect on Cell Uptake of Potassium
Physiologic factors	
Plasma K concentration	
Increase	Increase
Decrease	Decrease
Insulin	Increase
Catecholamines	
α-Agonists	Decrease
β-Agonists	Increase
Pathologic factors	
Acid-base balance	
Acidosis	Decrease
Alkalosis	Increase
Hyperosmolality	Enhances cell efflux
Cell breakdown	Enhances cell efflux

Hormones

Insulin, the most important hormonal regulator of *internal* potassium balance, stimulates Na^+,K^+-ATPase-mediated potassium uptake and sodium efflux in the kidney, skeletal muscle, adipocytes, and brain, a response that is independent of the hormonal effects on glucose metabolism.[20] The mechanism of insulin action in these tissues differs, in part, because of differences in the isoform complement of the catalytic α-subunit of the pump. Insulin stimulates Na^+,K^+-ATPase activity by promoting the translocation of preformed pumps from intracellular stores to the cell surface (as in skeletal muscle)[21-24] and/or increasing cytoplasmic sodium content (as in adipocytes)[25-27] or by increasing the apparent affinity of the enzyme for sodium (as in kidney).[28] Basal insulin secretion is necessary to maintain fasting plasma potassium concentration within the normal range. An increase in plasma potassium in excess of 1.0 mEq/L in the adult induces a significant increase in peripheral insulin levels to aid in the rapid disposal of the potassium load, yet a more modest elevation of approximately 0.5 mEq/L is without effect.[29]

The effect of epinephrine on potassium balance in the adult is biphasic and is characterized by an initial increase, followed by a prolonged fall in plasma potassium concentration to a final value lower than baseline. The initial transient rise in plasma potassium results from α-adrenergic receptor stimulation causing release of potassium from hepatocytes.[30,31] β_2-Receptor stimulation, via stimulation of adenylate cyclase leading to generation of the second messenger cyclic adenosine monophosphate, activates Na^+,K^+-ATPase and thus promotes enhanced uptake of potassium by skeletal and cardiac muscle, effects that are inhibited by the β_2-blocker propranolol.[30-35] The observation that the potassium-lowering effects of insulin and epinephrine are additive suggests that their responses are mediated by different signaling pathways.

The effects of these hormones on the distribution of potassium between the intracellular and extracellular compartments have been exploited to effectively treat disorders of homeostasis. For example, the β_2-adrenoreceptor agonist albuterol has been used to treat life-threatening hyperkalemia in premature and term neonates, children, and adults.[36-38] Administration of this drug to treat hyperkalemia is associated with fewer side effects (mild, reversible tachycardia and tremors)[39] than are observed with many conventional protocols. Administration of glucose, insulin, and furosemide may be associated with significant fluid, electrolyte, and glucose derangements in premature infants.[40-42] Administration of sodium bicarbonate has been associated with an increased incidence of intraventricular hemorrhage.[43] Oral or rectal administration of ion exchange resins can increase total body sodium, can cause cecal perforation,[44] and is often ineffective in small infants.[40,45]

Aldosterone is best known for its effect on transporting tissue, increasing potassium secretion in distal segments of the nephron and colon (see later). Thyroid hormone may also promote the cellular uptake of potassium as a result of its long-term stimulation of Na^+-K^+ pump activity.[19]

Acid-Base Balance

It is well known that the transcellular distribution of potassium and acid-base balance are interrelated.[46] Whereas acidemia (increase in extracellular hydrogen ion concentration) is associated with an increase in plasma potassium resulting from potassium release from the intracellular compartment, alkalemia (decrease in extracellular hydrogen ion concentration) results in a shift of potassium into cells and a consequent decrease in plasma potassium. However, the reciprocal changes in plasma potassium that accompany acute changes in blood pH differ widely among the four major acid-base disorders; metabolic disorders cause greater disturbances in plasma potassium than do those of respiratory origin, and acute changes in pH result in larger changes in plasma potassium than do chronic conditions.[46]

Acute metabolic acidosis after administration of a mineral acid that includes an anion that does not readily penetrate the cell membrane, such as the chloride of hydrochloric acid or ammonium chloride, consistently results in an increase in plasma potassium. As excess extracellular protons, unaccompanied by their nonpermeant anions, enter the cell where neutralization by intracellular buffers occurs, potassium (or sodium) is displaced from the cells, thus maintaining electroneutrality. However, comparable acidemia induced by acute organic anion acidosis (lactic acid in lactic acidosis, acetoacetic, and β-hydroxybutyric acids in uncontrolled diabetes mellitus) may not elicit a detectable change in plasma potassium.[46-48] In organic acidemia, the associated anion diffuses more freely into the cell and thus does not require a shift of potassium from the intracellular to the extracellular fluid.

In respiratory acid-base disturbances, in which carbon dioxide and carbonic acid readily permeate cell membranes, little transcellular shift of potassium occurs because protons are not transported in or out in association with potassium moving in the opposite direction.[46]

Changes in plasma bicarbonate concentration, independent of the effect on extracellular pH, can reciprocally affect plasma potassium concentration. Movement of bicarbonate (outward at a low extracellular bicarbonate concentration and inward at a high extracellular bicarbonate concentration) between the intracellular and extracellular compartments may be causally related to a concomitant transfer of potassium. This may account for the less marked increase in plasma potassium observed during acute respiratory acidosis, a condition characterized by an acid plasma pH with an elevated serum bicarbonate (hence inward net bicarbonate and potassium movement), as compared with acute metabolic acidosis with a low serum bicarbonate concentration (hence outward net bicarbonate and potassium movement).

Other Factors

Many other pathologic perturbations alter the *internal* potassium balance. An increase in plasma osmolality resulting from severe dehydration causes water to shift out of cells. The consequent increase in intracellular potassium concentration exaggerates the transcellular concentration gradient and favors movement of this cation out of cells. The effect of hyperosmolality on potassium balance becomes especially troublesome in patients with hyperglycemia, as observed in patients with diabetes in whom the absence of insulin exacerbates the hyperkalemia.

REGULATION OF EXTERNAL POTASSIUM BALANCE

Renal Contribution

The kidney is the major excretory organ for potassium. In adults, urinary potassium excretion parallels dietary intake (see Figure 129-1), and the speed of renal adaptation depends on the baseline potassium intake and the magnitude of the change in dietary potassium intake. Extreme adjustments in the rate of renal potassium conservation cannot be achieved as rapidly as for sodium, nor are the adjustments as complete; whereas urinary sodium can be virtually eliminated within 3 to 4 days of sodium restriction, a minimum urinary potassium loss of approximately 5 mEq/day occurs in the adult, even after several weeks of severe potassium restriction. An increase in dietary potassium intake is matched by a parallel increase in renal potassium excretion within hours, yet maximal rates of potassium excretion are not attained for several days after increasing potassium intake. In adults, renal potassium excretion follows a circadian rhythm, presumably determined by hypothalamic oscillators, and it is characterized by maximum output during times of peak activity.[49] It is unknown whether a circadian cycle of urinary potassium excretion prevails in infancy.

The processes involved in renal potassium handling in the fully differentiated kidney include filtration, reabsorption, and secretion (Figure 129-3).[50] Filtered potassium is reabsorbed almost entirely in proximal segments of the nephron, and urinary potassium is derived predominantly from distal secretion. Therefore potassium balance, at least in the adult, is maintained by renal secretion rather than reabsorption.

The renal potassium clearance is low in newborns, even when it is corrected for their low glomerular filtration rate.[2,7] Infants, like adults, can excrete potassium at a rate that exceeds its glomerular filtration when given a potassium load, a finding indicating the capacity for net tubular secretion.[51] However, the rate of potassium excretion per unit body weight or kidney weight in response to exogenous loading is less in newborn than older animals.[52,53] Clearance studies in saline-expanded dogs also provide indirect evidence of a diminished secretory and enhanced reabsorptive

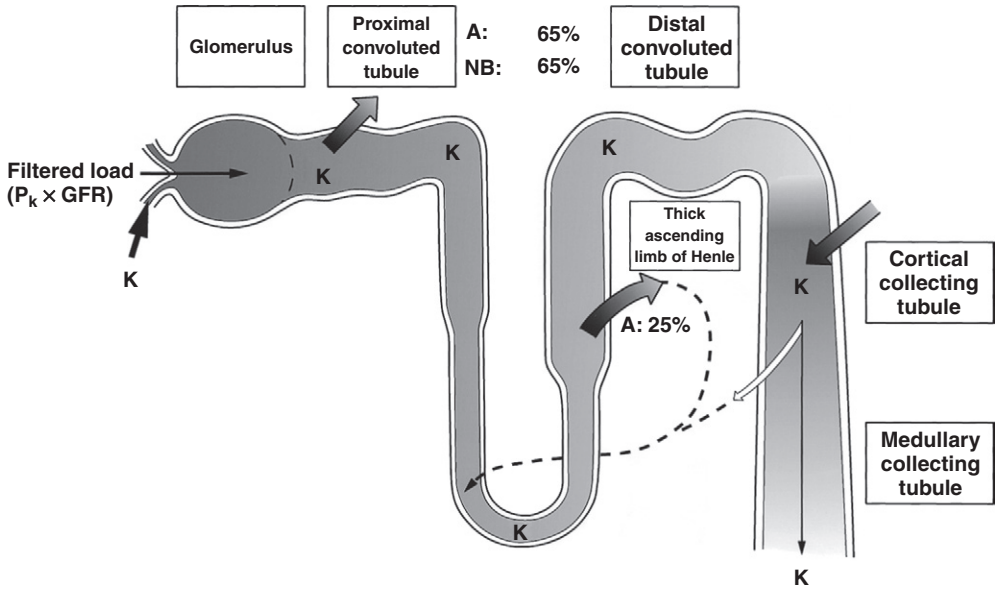

Figure 129-3 Tubular sites of potassium (K) transport along the nephron. The percentages of filtered potassium reabsorbed along the proximal tubule and TALH are indicated for the adult *(A)* and, when known, the newborn *(NB)*. *Arrows* identify the direction of net potassium transport as either out of (reabsorption) or into (secretion) the urinary fluid. *GFR,* Glomerular filtration rate.

capacity of the immature distal nephron to potassium.[54] A similar conclusion can be drawn from a longitudinal prospective study in premature neonates demonstrating a 50% reduction in the fractional excretion of potassium between 26 and 30 weeks GA, in the absence of significant change in absolute urinary potassium excretion.[1] To the extent that the filtered load of potassium increased almost three-fold during this same time interval, the constancy of renal potassium excretion could be best explained by a developmental increase in the capacity of the kidney for potassium reabsorption.[1] In general, the limited potassium secretory capacity of the immature kidney becomes clinically relevant only under conditions of potassium excess. As stated earlier, under normal circumstances, potassium retention by the newborn kidney is appropriate and is required for somatic growth.

Sites of Potassium Transport Along the Nephron

Potassium is freely filtered at the glomerulus. Approximately 65% of the filtered load of potassium is reabsorbed along the proximal tubule of the suckling rat, a fraction similar to that measured in the adult (see Figure 129-3).[55-58] Reabsorption is passive in this segment, closely following water reabsorption, and is driven, in part, by the positive transepithelial voltage that prevails along part of the proximal tubule.

Approximately 10% of the filtered load of potassium reaches the early distal tubule of the adult, a finding reflecting significant further net reabsorption of this cation in the thick ascending limb of the loop of Henle (TALH) (see Figure 129-3).[56] In contrast, up to 35% of the filtered load of potassium reaches the distal tubule of the very young (2-week-old) rat.[55] The observations in the maturing rodent that the fractional reabsorption of potassium along the TALH, expressed as a percentage of delivered load, increases by 20% between the second and sixth weeks of postnatal life, and that both the diluting capacity and TALH Na^+,K^+-ATPase activity increase after birth are consistent with a developmental maturation of potassium absorptive pathways in this segment.[55,59,60] However, direct functional analysis of the potassium transport capacity of the TALH in the developing nephron has not been performed.

The avid potassium reabsorption characteristic of the fully differentiated TALH is mediated by a Na^+,K^+-$2Cl^-$ cotransporter that translocates a single potassium ion into the cell accompanied by a sodium and two chloride (Cl^-) ions (Figure 129-4, *A*). This secondary active transport is ultimately driven by the basolateral Na^+,K^+-ATPase that generates an electrochemical gradient favoring sodium entry at the apical membrane. Diuretics such as furosemide and bumetanide that inhibit the Na^+,K^+-$2Cl^-$ cotransporter block potassium reabsorption at this site and uncover potassium secretion, leading to profound urinary potassium losses.

Activity of the Na^+,K^+-$2Cl^-$ transporter requires the presence of a parallel potassium conductance in the urinary membrane. This luminal secretory potassium channel is encoded by the *ROMK* (rat outer medullary K^+ channel) gene.[61,62] Loss-of-function mutations in *ROMK* lead to antenatal Bartter syndrome, also known as the hyperprostaglandin E syndrome, which is characterized by severe renal salt and water losses, consistent with a pattern of impaired TALH function[63] and similar to the clinical picture observed with the chronic administration of loop diuretics. The typical presentation of antenatal Bartter syndrome includes polyhydramnios, premature delivery, and life-threatening episodes of dehydration during the first week of life. This group of patients also has severe growth failure, hypercalciuria with early-onset nephrocalcinosis, hyperreninism, and hyperaldosteronism but normal blood pressure.[64]

In the healthy adult, regulated potassium secretion by the distal tubule and the collecting duct contributes prominently to urinary potassium excretion, which can approach 20% of the filtered load (see Figure 129-3).[50] Two major populations of cells comprise the distal nephron. Principal cells reabsorb sodium and secrete potassium, whereas intercalated cells primarily function in acid-base homeostasis but can reabsorb potassium in response to dietary potassium restriction or metabolic acidosis. Potassium secretion by the collecting duct requires potassium to be actively transported into principal cells in exchange for sodium at the basolateral membrane by the action of Na^+,K^+-ATPase (see Figure 129-4, *B*). Potassium accumulates within the cell and then passively diffuses across the apical membrane through secretory potassium channels. The magnitude of potassium secretion is determined by its electrochemical gradient and the apical permeability to this cation. The electrochemical gradient is established by the potassium concentration gradient between the cell and lumen, and lumen negative voltage, generated by apical sodium entry through epithelial sodium channels (ENaCs) and its basolateral electrogenic extrusion.

Two apical potassium-selective channels have been functionally identified in the distal nephron. The small conductance secretory potassium (SK) channel, encoded by the *ROMK* gene, is considered to mediate baseline potassium secretion, whereas the high-conductance, stretch- and calcium-activated maxi-K channel has been proposed to regulate flow-stimulated potassium secretion.[65] Any factor that enhances the electrochemical driving force or increases the apical membrane permeability to potassium will favor potassium secretion.

The direction and magnitude of net potassium transport in the distal nephron vary according to physiologic need. Thus, in response to dietary potassium restriction or potassium depletion, the distal nephron may reabsorb potassium. Potassium reabsorption is mediated by a H^+,K^+-ATPase, an enzyme that exchanges a single potassium ion for a proton (see Figure 129-4, *C*), localized to the apical membrane of acid-base–transporting intercalated cells.

Potassium secretion in the distal nephron, and specifically in the cortical collecting duct (CCD), is low early in life and cannot be stimulated by high urinary flow rates.[66] The limited capacity of the neonatal CCD for baseline potassium secretion appears not to be due to an unfavorable electrochemical gradient. Although Na^+,K^+-ATPase activity in neonatal collecting duct segments is only 50% of that measured in the mature nephron, cell potassium content of this segment is similar at both ages, presumably reflecting a relative paucity of membrane potassium channels early in life.[59,67,68] The rate of sodium absorption in the CCD at 2 weeks of age is approximately 60% of that measured in the adult and is not considered to be limiting for potassium secretion.[66] Electrophysiologic analysis has confirmed the absence of functional potassium secretory channels in the luminal membrane of the neonatal CCD.[69] Cumulative evidence now suggests that the postnatal increase in the potassium secretory capacity of the distal nephron is due to a developmental increase in number of SK and maxi-K channels, reflecting an increase in transcription and translation of functional channel proteins.[69-71] Molecular analyses demonstrate that *ROMK* messenger RNA and protein are first detectable in the second week of postnatal life in the rodent, immediately preceding the appearance of functional channels and potassium secretion in this segment.[66,69-71] Messenger RNA encoding the maxi-K channel first becomes detectable after weaning in the rodent, as does functional maxi-K channel activity.[78]

Indirect evidence suggests that the neonatal distal nephron absorbs potassium. As indicated earlier, saline-expanded newborn dogs absorb 25% more of the distal potassium load than adult animals.[52] Functional analysis of the rabbit collecting duct has shown that the activity of apical H^+,K^+-ATPase in neonatal intercalated cells is equivalent to that in mature cells.[72] The latter data alone do not predict transepithelial potassium absorption under physiologic conditions. However, high distal tubular fluid potassium concentrations, as measured in vivo in the young rat, may facilitate lumen-to-cell potassium absorption mediated by the H^+,K^+-ATPase.[55]

The major factors that influence the *external* balance of potassium are listed in Box 129-1 and are discussed in the following sections.

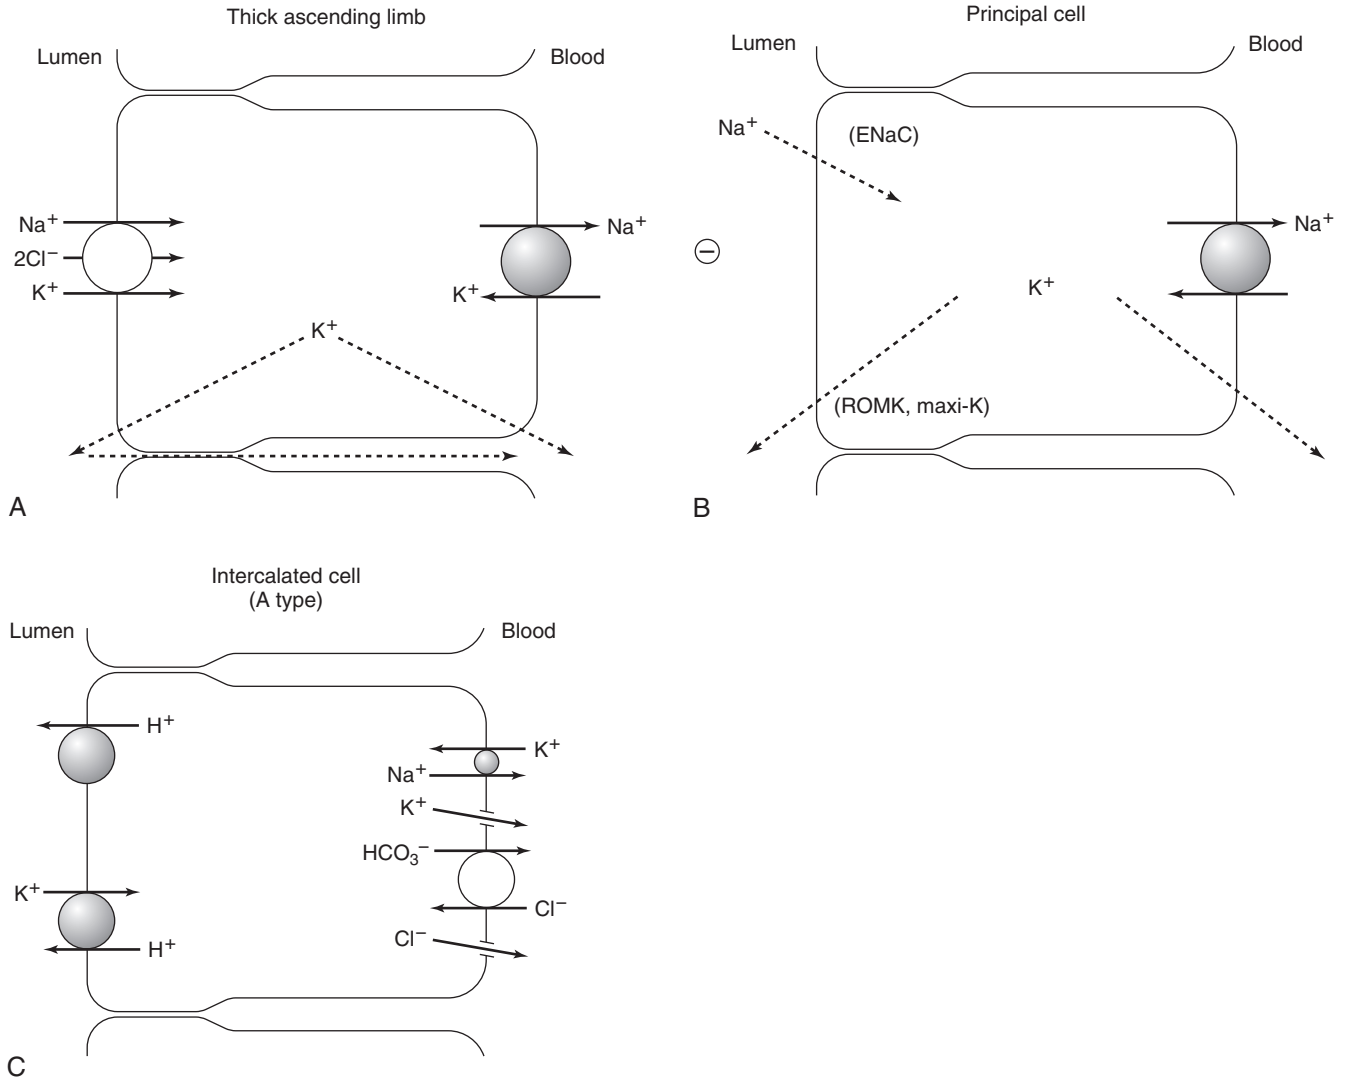

Figure 129-4 Potassium (K^+) transport pathways in specific renal tubular cells. A, In the TALH, potassium is avidly absorbed by specialized luminal Na^+-K^+-$2Cl^-$ cotransport. A luminal secretory potassium channel, encoded by the *ROMK* gene, in this cell, allows potassium to recycle back into the tubular fluid, thereby ensuring a continuous and abundant supply of potassium for the cotransporter. **B,** In the CCD, potassium is pumped into the cell in exchange for sodium by the basolateral Na^+,K^+-ATPase. After entry into and accumulation in the cell, potassium is secreted preferentially across the apical membrane through the *ROMK* or maxi-K channel, a process driven by a favorable electrochemical gradient. The electrochemical gradient is composed of two components: the cell-to-lumen concentration, or chemical gradient, and the cell-to-lumen electrical gradient. The latter is generated by apical sodium entry through amiloride-sensitive ENaCs and its electrogenic basolateral extrusion. **C,** Intercalated cells in the collecting duct mediate potassium absorption via apical H^+,K^+-ATPase, a pump that catalyzes the exchange of a single proton for potassium. *HCO_3^-,* Bicarbonate.

Distal Sodium Delivery and Transepithelial Voltage

As predicted from the principal cell model (see Figure 129-4, *B*), an increase in sodium absorption enhances the electrochemical driving force for potassium diffusion into the lumen. The magnitude of passive apical sodium entry and its electrogenic basolateral extrusion determine the apical membrane electrical potential and rate of basolateral Na^+-K^+ exchange. The dependence of potassium secretion on distal sodium delivery becomes evident at tubular fluid sodium concentrations less than 30 mEq/L, a value below which potassium secretion falls sharply.[73,74] In vivo measurements of the sodium concentration in distal tubular fluid generally exceed 35 mEq/L in both adult and suckling rats and thus should not restrict distal sodium secretion.[55,60,73,75]

Extracellular volume expansion or administration of many diuretics (osmotic diuretics, carbonic anhydrase inhibitors, loop and thiazide diuretics) is accompanied by an increase in excretion of both sodium and potassium. The kaliuresis is mediated not only by the increased delivery of sodium to the distal nephron but also by the increased tubular fluid flow rate, which maximizes the chemical driving forces, as described later, favoring potassium secretion. Other potassium-sparing diuretics, such as amiloride and triamterene, block distal sodium reabsorption, which reduces the electrical potential gradient favoring potassium secretion.

Sodium delivered to the distal nephron is generally accompanied by chloride. Chloride reabsorption, which occurs predominantly via the paracellular pathway, tends to reduce the lumen-negative potential that would otherwise drive potassium secretion. When sodium is accompanied by an anion less reabsorbable than chloride, such as bicarbonate (in proximal renal tubular acidosis), β-hydroxybutyrate (in diabetic ketoacidosis), or carbenicillin (during antibiotic therapy), luminal electronegativity is maintained, thereby eliciting more potassium secretion than occurs with a comparable sodium load delivered with chloride.

BOX 129-1

Factors Regulating the *External* Balance of Potassium

Renal factors
Distal sodium delivery and transepithelial voltage
Tubular (urinary) flow rate
Potassium intake–plasma potassium concentration
Hormones (mineralocorticoids, vasopressin)
Acid-base balance

Gastrointestinal tract factors
Stool volume
Hormones

Tubular Flow Rate

High rates of urinary flow in the mature, but not the neonatal or weanling, distal nephron stimulate potassium secretion.[66] Thus volume expansion and diuretics, both of which increase distal tubular fluid flow rate, enhance potassium secretion in the fully differentiated kidney. A number of factors are responsible for the flow stimulation of potassium secretion. First, flow stimulates sodium reabsorption, which enhances the electrochemical gradient favoring potassium secretion.[76,77] Second, the higher the urinary flow rate in the distal nephron the slower the rate of rise of tubular fluid potassium concentration because secreted potassium is rapidly diluted in urine of low potassium concentration. Maintenance of a low tubular fluid potassium concentration maximizes the potassium concentration gradient (and thus the chemical driving force) favoring net potassium secretion. Finally, increases in tubular fluid flow rate increase the intracellular calcium concentration, which activates the maxi-K channel in the collecting duct to secrete potassium, thereby enhancing urinary potassium excretion.[65,78]

The capacity for flow-stimulated potassium secretion appears to be developmentally regulated. Flow-stimulated potassium secretion, studied in single rabbit CCDs, does not appear until the 5th week of postnatal life, approximately 2 weeks after baseline potassium secretion is first detected.[66,78] Maxi-K channel messenger RNA and protein are not consistently detected in the CCD until the 4th and 5th weeks of life, respectively,[78] suggesting that the postnatal appearance of flow-dependent potassium secretion is determined by the transcriptional and/or translational regulation of expression of maxi-K channels in the distal nephron.

Potassium Intake and Cellular Potassium Content

Ingestion of a potassium-rich meal is rapidly followed by enhanced urinary excretion of potassium. The increase in potassium entry into principal cells from the basolateral (blood) side maximizes the concentration gradient favoring apical potassium secretion into the urinary fluid. Simultaneously, the increase in circulating levels of plasma aldosterone that accompanies potassium loading enhances the electrochemical driving force favoring potassium secretion in the distal nephron. It has also been suggested that a reflex increase in potassium excretion via vagal afferents follows activation of potassium-specific sensors in the gut or hepatic portal circulation, a control system that may be regulated in the absence of change in the plasma potassium concentration.[49]

Chronic potassium loading leads to *potassium adaptation,* an acquired tolerance to an otherwise lethal acute potassium load.[50] This adaptation occurs in the distal nephron and colon; the rate of potassium secretion in these segments varies directly with body stores of potassium. A similar adaptive response is seen in renal insufficiency such that potassium balance is maintained during the course of many forms of progressive renal disease. The mechanisms underlying this adaptation in the principal cell include not only an increase in the density of apical membrane potassium channels but also an increase in the number of conducting sodium channels and activity of the basolateral Na^+-K^+ pump. The latter two processes result in increases in transepithelial voltage and the intracellular potassium concentration, events that enhance the driving force favoring potassium diffusion from the cell into the urinary fluid.

When potassium intake is chronically reduced, potassium secretion by principal cells falls as reabsorption by intercalated cells increases. Stimulation of luminal H^+,K^+-ATPase activity in intercalated cells results not only in potassium retention but also in urinary acidification and metabolic alkalosis.

Hormones

Mineralocorticoids stimulate sodium reabsorption and potassium secretion in principal cells of the distal nephron.[79,80] In the adult, the mineralocorticoid-induced stimulation of renal potassium secretion is considered to be due primarily to an increase in the electrochemical driving force favoring potassium exit across the apical membrane, generated by stimulation of apical sodium entry and reabsorption. Aldosterone action requires its initial binding to the mineralocorticoid receptor, followed by translocation of the hormone-receptor complex to the nucleus in which specific genes are stimulated to code for physiologically active proteins (e.g., Na^+,K^+-ATPase). Cellular effects within the fully differentiated CCD include increases in the density of active ENaC channels, caused by recruitment of intracellular channels to the apical membrane, de novo synthesis of ENaC subunits, and activation of preexisting channels.[81,82] Aldosterone also stimulates Na^+,K^+-ATPase activity through both recruitment of preexisting pumps to the plasma membrane and increased total amounts of sodium pump subunits.[83] The sum effect of these actions is the stimulation of net sodium absorption, leading to an increase in lumen negative transepithelial voltage, thereby facilitating net potassium secretion. The effects of aldosterone on ENaC and, to some extent, the Na^+-K^+ pump appear to be indirect, mediated by aldosterone-induced proteins, including serum- and glucocorticoid-inducible kinase (sgk).[84]

Plasma aldosterone concentrations in the newborn are high compared with those in the adult.[2,85] Yet clearance studies in fetal and newborn animals demonstrate a relative insensitivity of the immature kidney to the hormone.[2,86-88] The density of aldosterone-binding sites, receptor affinity, and degree of nuclear binding of hormone receptor are thought to be similar in mature and immature rats.[88] Thus the early hyposensitivity to aldosterone is considered to represent a postreceptor phenomenon.[2,88]

The transtubular potassium gradient (TTKG) provides an indirect, semiquantitative measure of the renal response to mineralocorticoid activity in the aldosterone-sensitive cortical distal nephron and is calculated by using the equation: $TTKG = \{[K^+]_{urine} / (U/P)_{osmolality}\} / [K^+]_{plasma}$, where $[K^+]$ equals the potassium concentration in either urine (U) or plasma (P), as indicated.[89-91] Measurements of TTKG have been reported to be lower in 27- than 30-week–GA preterm infants followed over the first 5 weeks of postnatal life.[92] The low TTKG has been attributed to a state of relative hypoaldosteronism[92] but may also reflect the absence of potassium secretory transport pathways (i.e., channel proteins).

Acid-Base Balance

Disorders of acid-base homeostasis can induce changes in tubular potassium secretion. Acute metabolic acidosis causes the urine pH and potassium excretion to decrease, whereas both acute respiratory alkalosis and metabolic alkalosis result in increases in urine pH and potassium excretion. Chronic metabolic acidosis has variable effects on urinary potassium excretion.

The alkalosis-induced stimulation of potassium secretion reflects two direct effects on principal cells: (1) the stimulation of Na^+,K^+-ATPase activity and basolateral potassium uptake, and (2) an increase in the permeability of the apical membrane to potassium resulting from an increase in duration of time the potassium-selective channels remain open.[50] Alkalosis also decreases acid secretion in intercalated cells, thereby reducing H^+,K^+-ATPase–mediated countertransport.

Acute metabolic acidosis reduces cell potassium concentration and leads to a reduction in urine pH, which in turns inhibits apical potassium channel (SK/ROMK) activity.[50] The net effect is a fall in urinary potassium secretion. The effect of chronic metabolic acidosis on potassium secretion is more complex and may be influenced by modifications of the glomerular filtrate (e.g., chloride and bicarbonate concentrations), tubular fluid flow rate, and circulating aldosterone levels.[50] The latter two factors may lead to an increase rather than a decrease in potassium secretion and excretion.

Contribution of the Gastrointestinal Tract

Under normal conditions in the adult, 5% to 10% of daily potassium intake is excreted in the stool (see Figure 129-1).The colon is considered to be the main target for regulation of intestinal potassium excretion.[93] Potassium transport in the colon represents the balance of secretion and absorption.[94] Under baseline conditions, net potassium secretion predominates over absorption in the adult, whereas the neonatal gut is poised for net potassium absorption.[93]

Potassium secretion requires potassium uptake by the Na^+,K^+-ATPase and Na^+,K^+-$2Cl^-$ cotransporter located in the basolateral membrane of colonocytes; potassium is then secreted across the apical membrane through potassium channels, including a calcium-activated maxi-K channel similar to that found in the distal nephron.[95-98] Stool potassium content can be enhanced by any factor that increases colonic secretion, including aldosterone, epinephrine, and prostaglandins.[99-101] Indomethacin and dietary potassium restriction reduce potassium secretion by inhibiting the basolateral transporters and apical potassium channels. Diarrheal illnesses are typically associated with hypokalemia, presumably because of the presence of nonreabsorbed anions (which obligate K^+), an enhanced electrochemical gradient established by active chloride secretion, and secondary hyperaldosteronism resulting from volume contraction.

Potassium adaptation in the colon is demonstrated by increased fecal potassium secretion after potassium loading and in the face of renal insufficiency. Fecal potassium excretion may triple in patients with severe chronic renal insufficiency.[99,102-104] The enhanced colonic potassium secretion characteristic of chronic renal insufficiency requires induction and/or activation of apical maxi-K channels in surface colonic epithelial cells.[105]

Net colonic potassium absorption is significantly higher in young compared with adult rats.[93] The higher rate of potassium absorption during infancy is due to robust activity of potassium absorptive pumps located in apical membrane and limited activity of the basolateral transporters that mediate secretion.[106,107]

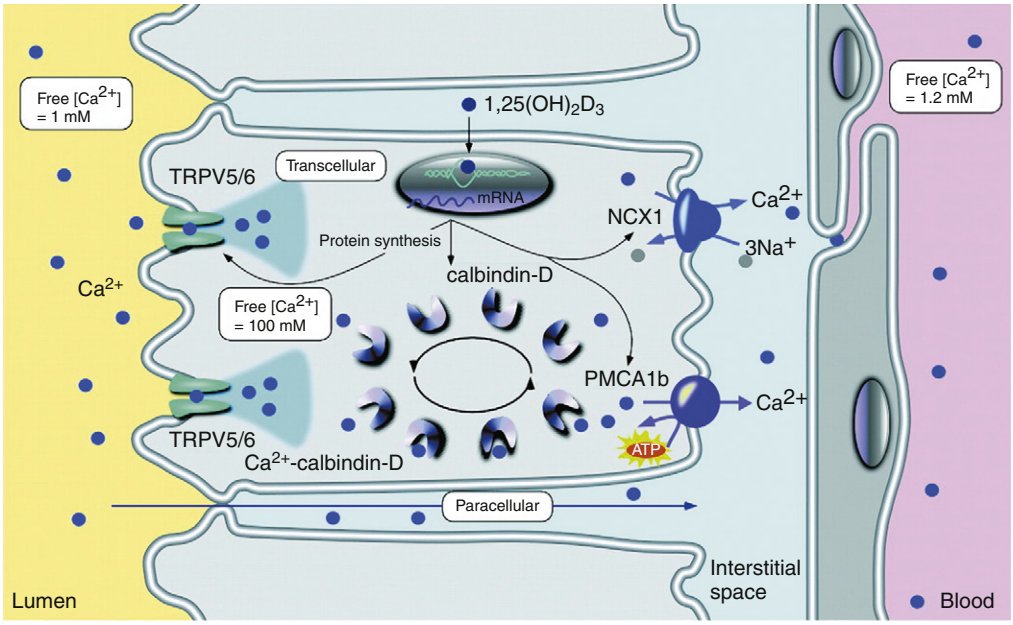

Figure 130-1 Mechanism of epithelial Ca^{2+} transport. Entry of Ca^{2+} is facilitated by the apical Ca^{2+} channel (TRPV5/6). In the cell, Ca^{2+} binds to calbindin-D and diffuses through the cytosol to the basolateral membrane. There, Ca^{2+} is extruded via a Na^{+}-Ca^{2+} exchanger (NCX1) and a Ca^{2+}-ATPase (PMCA1b). *(Modified from Hoenderop JG, Nilius B, Bindels RJ: Calcium absorption across epithelia,* Physiol Rev *85:373-422, 2005. Used with permission.)*

compartment via a sodium calcium exchanger and a calcium adenosine triphosphatase (ATPase).[13,16-18]

Epithelial Calcium Channels

Transient receptor potential (TRP) channel proteins constitute a large and diverse family of proteins that are expressed in many tissues and cell types.[19,20] Within the TRP superfamily is the TRPV subfamily consisting of six members. This group of channels includes TRPV1 through 4, which respond to heat, osmolality, odorants, and mechanical stimuli.[21,22] TRPV5, a highly Ca^{2+}-selective channel in the TRP family, was the first TRP channel identified in the kidney. TRPV5 is abundantly expressed in the distal convoluted tubule (DCT) and the connecting tubule (CNT) and has been recognized as the gatekeeper of active Ca^{2+} reabsorption in the kidney. Its function is further characterized by TRPV5 knockout (TRPV5−/−) mice, which exhibit profound hypercalciuria, intestinal Ca^{2+} hyperabsorption, and reduced bone thickness. TRPV6, a homologous highly Ca^{2+}-selective channel, was originally identified from rat duodenum but is also expressed in DCT, CNT, and cortical and medullary collecting ducts. TRPV6 is involved in intestinal Ca^{2+} absorption, but its role in the kidney remains largely unknown.[21,22]

Genomic cloning has demonstrated that these Ca^{2+} channels are transcribed from distinct genes rather than being splice variants. TRPV5 and TRPV6 are juxtaposed on the human chromosome 7q35 with a distance of only 22 kilobases, which suggests an evolutionary gene duplication event. TRPV5 and TRPV6 have been cloned from many species including rabbit, rat, mouse, and human. The identified sequences have an overall homology of 75%. Several domains in TRPV5 and 6 are completely conserved within these species including the core structure of the protein consisting of six transmembrane (TM) segments and the pore region, ankyrin repeats, PDZ motifs, and putative protein kinase C (PKC) phosphorylation sites, of which three are conserved among all identified TRPV5 and TRPV6 channels.[23,24]

The epithelial Ca^{2+} channels are responsible for the active transcellular entry of calcium at the apical membrane and are the initial, rate-limiting step in the process of transcellular Ca^{2+} transport. They are expressed in tissues such as intestine, kidney, pancreas, brain, prostate, and testis. Immunohistochemistry has shown TRPV5 to be present in the apical membrane of DCT, in CNT in the kidney, and in the brush border membrane of duodenal and jejunal villi. It is colocalized with other proteins of transcellular calcium transport such as sodium-calcium exchanger (NCX1), plasma membrane Ca^{2+}-ATPase (PMCA), and calbindin-D.[25-27]

Ca^{2+} movement across TRPV5 is controlled in multiple ways. TRPV5 gene expression is regulated by calciotropic hormones such as vitamin D_3 and PTH.[28,29] Channel activity is modulated by intracellular Ca^{2+} by feedback inhibition. TRPV5 is also controlled by mobilization of the channel toward the plasma membrane. The recently discovered antiaging hormone Klotho has been shown to enhance TRPV5 activity via a novel mechanism modifying its glycosylation status and entrapping the channel at the cell surface resulting in a prolonged expression of TRPV5 at the plasma membrane.[30] The immunosuppressant tacrolimus has also been shown to decrease activity of TRPV5 and calbindin-28K, causing hypercalciuria.[31] Ca^{2+} uptake in TRPV5 expressing *Xenopus laevis* oocytes is inhibited by acidification of the incubation medium. Extracellular pH determines the cell surface expression of TRPV5 via a unique mechanism. Extracellular alkalinization causes a pool of TRPV5-containing vesicles to be rapidly recruited to the cell surface without collapsing into the plasma membrane, resulting in increased TRPV5 activity. Extracellular acidification on the other hand causes the vesicles to be retrieved from the plasma membrane, resulting in decreased TRPV5 activity. This effect could explain the molecular basis of acidosis-induced calciuresis.[32]

In the distal tubules intracellular calcium concentration is increased by osmosensitive, nonselective ion channels such as TRPV4 (previously described as OTRPC4, VR-OAC, TRP 12, and VRL-2) especially under hypotonic stimulus.[33]

Calcium Buffering Within the Cell

The vitamin D–dependent Ca^{2+}-binding proteins, named calbindins (CaBPs), are expressed in cells that are challenged by a high Ca^{2+} influx such as in brain, bone, teeth, inner ear, placenta,

mammary gland, kidney, and intestine. In these tissues, CaBPs (i.e., $CaBP_{9K}$ and $CaBP_{28K}$) are a key component in cellular Ca^{2+} handling. In the kidney, calbindin-D ($CaBP_{28K}$) facilitates Ca^{2+} diffusion from the luminal Ca^{2+} entry side of the cell to the basolateral side, where Ca^{2+} is extruded into the extracellular compartment. CaBP (28K) provides protection against toxic high intracellular Ca^{2+} levels by buffering the cytosolic Ca^{2+} concentration during high Ca^{2+} influx.[34] Studies using protein-binding analysis, subcellular fractionation, and evanescent-field microscopy have shown that $CaBP_{28K}$ translocates toward the plasma membrane and directly associates with TRPV5 at a low Ca^{2+} concentration. Uptake measurements, electrophysiologic recordings, and transcellular Ca^{2+} transport assays of lentivirus-infected primary rabbit CNT-DCT cells have shown that associated $CaBP_{28K}$ tightly buffers the flux of Ca^{2+} entering the cell via TRPV5, facilitating high Ca^{2+} transport rates by preventing channel inactivation. Therefore $CaBP_{28K}$ acts in calcium-transporting epithelia as a dynamic Ca^{2+} buffer, regulating Ca^{2+} in close vicinity to the TRPV5 pore by direct association with the channel. Calbindins are regulated by calciotropic hormones including vitamin D, estrogens, PTH, and dietary Ca^{2+}.[35]

Previously $CaBP_{28K}$ was identified as a high-capacity Ca^{2+} buffer with Ca^{2+} affinities fitting the classical properties of a Ca^{2+} buffer. However, sequential Ca^{2+} binding and conformational changes suggested that $CaBP_{28K}$ can act as a Ca^{2+} sensor controlling downstream cellular processes.[36-39] It was shown in cerebellar Purkinje neurons that $CaBP_{28K}$ directly interacts with membrane-targeted inositol-1,4,5-trisphosphate and acts as a Ca^{2+} sensor to regulate the degradation of inositol messengers in an activity-dependent manner.[40]

Inside the cell, calbindin directly interacts with a calmodulin-binding isoleucine-glutamine motif present in the C-tail of TRPV5 and TRPV6 channels. Deletion of the first eight amino acids of the isoleucine-glutamine motif in the carboxyl terminus tail of the Ca^{2+}-channel subunit a1C eliminates Ca^{2+}-dependent inactivation of voltage-gated, L-type Ca^{2+} channels.[41] Ca^{2+}-dependent interaction also occurs between calbindin and a novel site in the C-terminal domain of the 1A subunit of P/Q-type Ca^{2+} channels (calbindin-binding domain). In the presence of low concentrations of intracellular Ca^{2+} chelators, Ca^{2+} influx through P/Q-type channels enhances channel inactivation, increases recovery from inactivation, and produces a long-lasting facilitation of the Ca^{2+} current.[26] Ca^{2+} "shuttling" across the intracellular organelles such as mitochondria or endoplasmic reticulum depends on a Ca^{2+} electrochemical gradient, driven by internally negative membrane potential across the inner mitochondrial or endoplasmic reticular membrane.

Calcium Transport Across the Basolateral Membrane

The extrusion of Ca^{2+} across the basolateral membrane into the interstitium occurs against an electrochemical gradient and, as such, is an energy-dependent process. The transport is primarily mediated by two calcium transporters located at the basolateral membrane: Na^+-Ca^{2+} exchanger (NCX)[42] and the Ca^{2+}-ATPase (plasma membrane Ca^{2+}-ATPase [PMCA]).[43]

Na^+-Ca^{2+} Exchanger

Three genes for NCX known as NCX1, NCX2, and NCX3 have been identified in mammals. In the kidney the expression of this transporter is restricted to the distal part of the nephron where it predominantly localizes along the basolateral membrane.[44,45]

NCX1 is widely distributed in many different mammalian tissues, whereas NCX2 and NCX3 are expressed only in brain and skeletal muscle.[46,47] It has been demonstrated that NCX1 is the primary extrusion mechanism, whereas only a minor amount of Ca^{2+} in the distal tubular cells is extruded by the plasma Ca^{2+} pump.[48] It has also been shown that targeted deletion of NCX1 results in NCX1-null embryos that do not have a spontaneously beating heart and die in utero.[49,50] Studies in oocytes and mammalian cell systems show that NCX is regulated by several factors including the membrane potential, PKC activation, protons, nucleotides, and calciotropic hormones.[51] PTH markedly stimulates Ca^{2+} reabsorption in the distal part of the nephron primarily by augmenting NCX1 activity via a cyclic adenosine monophosphate (cAMP)–mediated mechanism.

Plasma Membrane Ca^{2+}–Adenosine Triphosphatase

PMCA belongs to a class of P-type, ion-motive ATPase proteins with molecular weights ranging from 120,000 to 140,000 daltons. PMCAs are high-affinity Ca^{2+} efflux pumps present in almost all cells and are responsible for the maintenance and resetting of the resting intracellular Ca^{2+} levels.[51]

Four different isoforms—PMCA1 to A4—are encoded by separate genes. PMCAs are a universal system for the extrusion of Ca^{2+} in cells. In the kidney PMCAs are present in all nephron segments with highest expression in the basolateral membrane of cells lining the distal part of the nephron. The DCT possesses the highest Ca^{2+}-ATPase activity and exhibits the strongest immunocytochemical reactivity for PMCA protein expression.[52-54]

In humans PMCAs are found along the DCT and, in contrast to other species, along the cortical collecting duct.[44] Studies suggest that PMCA1 and PMCA4 are the major isoforms expressed in the kidney, whereas PMCA2 and PMCA3 are more tissue specific. PMCA1 and PMCA4 are involved in the maintenance of cellular Ca^{2+} homeostasis.[55] PMCA4b plays a significant role in basolateral Ca^{2+} extrusion. PMCA1b is the predominant isoform and abundantly expressed in the small intestine, where NCX1 is expressed at a low level. It is the major Ca^{2+} extrusion mechanism in intestinal Ca^{2+} absorption. PMCA also plays a role in cytosolic acidification, which, in turn, is a signal for activation of the sarcoplasmic reticulum Ca^{2+}-ATPase and other cellular functions in muscle.

Limited data are available regarding the regulation of PMCA by hormones or signaling mechanisms. Several studies indicate that PMCA are positively regulated by 1,25-dihydroxyvitamin D_3 ($1,25\text{-}[OH]_2D_3$) in the intestine to increase Ca^{2+} absorption. In addition, several potassium (K^+)-dependent Na^+-Ca^{2+} exchangers (NCKX) have been described.[51,56] Northern blot analysis demonstrated that some isoforms (i.e., NCKX4 and NCKX6) of this family are expressed in epithelia including small intestine and kidney.[57,58]

These exchangers are found in various tissues suggesting a key role in regulating intracellular Ca^{2+} homeostasis in mammalian cells. Ca^{2+} extrusion from the cell is a Na^+-Ca^{2+} countertransport driven by the Na^+ concentration gradient across the basolateral membrane maintained by Na^+,K^+-ATPase. Ca^{2+} removal by this exchanger is slowed when extracellular Na^+ concentration is diminished or when Na^+,K^+-ATPase is inhibited with ouabain.[59]

Regulation of Calcium Transport

Parathyroid Hormone

The parathyroid glands play an important role in maintaining the extracellular Ca^{2+} concentration. They have the capacity to sense changes in the level of blood Ca^{2+} from its normal level via the Ca^{2+}-sensing receptor (CaR). In response to low blood Ca^{2+} levels, PTH is secreted into the circulation and then acts primarily on kidney and bone, where it activates the PTH-PTHrP receptor. In the kidney, PTH stimulates transcellular Ca^{2+} reabsorption via a slow genomic pathway and a rapid nongenomic pathway.

The rapid pathway is via activation of adenylyl cyclase, accumulation of cAMP, and stimulation of protein kinase A (PKA), resulting in an increase in the cytosolic concentration and transcellular Ca^{2+} transport. PKA inhibitors reduce the PTH-mediated rise of cytosolic Ca^{2+}, which suggests that cAMP–dependent phosphorylation is an essential step in short-term PTH stimulation.

In addition to cAMP, PKC is also involved in the short-term PTH response. The slow pathway results in an elevated expression of the Ca^{2+} transport proteins TRPV5, calbindin-D28K, NCX1, and PMCA1b.

The PTH receptor directly enhances the tubular Ca^{2+} reabsorption, and it stimulates the activity of 1α-OHase and, thereby, increases the $1,25\text{-}(OH)_2D_3$–dependent absorption of Ca^{2+} from the intestine. PTH binds to two types of receptors: PTHR1, which also binds the PTH-related peptide (PTHrP),[60] and PTHR2, which binds only PTH.[61] The PTHR1 receptor is the predominant receptor found in the kidney, and it is expressed in glomeruli and all tubule segments, except the TAL and collecting duct. The PTHR2 receptor is distributed primarily in brain, lung, pancreas, and vasculature (including the vascular pole of the glomerulus). Signal transduction for both PTH and PTHrP is via adenylate cyclase and phospholipase C.[62,63] PTH stimulates active Ca^{2+} reabsorption in the distal part of the nephron. PTH increases transepithelial Ca^{2+} transport via a dual signaling mechanism involving PKA- and PKC-dependent processes.[64,65] PTH has various actions such as membrane insertion of apical Ca^{2+} channels, opening of basolateral chloride channels resulting in cellular hyperpolarization, and modulation of PMCA activity.[66-68] PTH activates dihydropyridine-sensitive channels responsible for Ca^{2+} entry. Once inserted or activated, these dihydropyridine-sensitive channels could mediate Ca^{2+} entry into Ca^{2+}-transporting epithelial cells. It is thought that dihydropyridine-sensitive Ca^{2+} channels play a role in signal transduction processes to maintain the cellular Ca^{2+} homeostasis. Studies of parathyroidectomy in rats showed a decrease in serum PTH levels and hypocalcemia, which was accompanied by decreased levels of TRPV5, calbindin-D_{28K}, and NCX1.[69] Supplementation with PTH restored serum Ca^{2+} concentrations and abundance of these Ca^{2+} transporters in kidney. This suggests that PTH affects renal Ca^{2+} handling through the regulation of the expression of the active renal Ca^{2+} transport proteins, including the epithelial Ca^{2+} channel TRPV5. PTH also stimulates the PMCA activity by increasing the affinity for Ca^{2+} in the distal tubule, unlike $1,25\text{-}(OH)_2D_3$ that does not directly affect the basolateral membrane PMCA activity.

In bone, PTH can induce a rapid release of Ca^{2+} from the bone matrix and can also mediate long-term changes in Ca^{2+} metabolism by acting directly on the bone-forming osteoblasts and indirectly on bone-resorbing osteoclasts by increasing their number and activity.

Calcium-Sensing Receptor

The CaR was discovered in 1993. It is a plasma membrane–bound G-protein–coupled receptor, found in many tissues including the parathyroid gland, thyroid, kidney, intestine, bone, bone marrow, brain, skin, pancreas, lung, and heart. CaR plays a critical role in Ca^{2+} homeostasis by inducing changes in PTH secretion and renal Ca^{2+} reabsorption in response to variations in the extracellular concentration of Ca^{2+}. CaR is not specific for calcium alone as it responds to other cations such as magnesium, aluminum, and gadolinium, but it has the highest affinity for calcium. The human CaR is encoded by six exons of the CaR gene located on chromosome 3q13.3–21.[70] The receptor is expressed abundantly in the parathyroid glands and, to a lesser extent, along the length of the kidney tubule.[45]

Activation of the CaR on the parathyroid gland cells by elevated serum Ca^{2+} leads to activation of many secondary messengers resulting in inhibition of PTH synthesis and secretion. Activation of the CaR in response to hypercalcemia produces several different effects in the renal tubules. In the TAL, decrease occurs in Na^+, K^+, and Cl^- reabsorption and decrease in K^+ transfer across a specific potassium channel at the apical membrane causing a decrease in the lumen positive voltage in the tubular lumen leading to decreased calcium and magnesium reabsorption and increased distal delivery. In the distal tubule, CaR stimulation on the basolateral membrane causes inhibition of calcium transport. In the medullary collecting duct epithelium, CaRs are found on the apical side. Here they reduce the insertion of aquaporin-2 water channels when the luminal calcium concentration is high, decreasing water reabsorption, and thereby decreasing calcium concentration and calcium crystal formation in the urine.[71-73]

Mutations in the CaR gene are associated with familial hypocalciuric hypercalcemia, neonatal severe hyperparathyroidism, and autosomal dominant hypocalcemia.[74-78]

Vitamin D

The physiologic actions of vitamin D are mediated by its metabolite $1,25(OH)_2D_3$, which is formed by 1-hydroxylation of 25(OH) D in proximal tubules. The classic action of vitamin D is to stimulate transcription by binding to nuclear receptors (VDR). It binds with VDR in a ligand-dependent manner. VDR is expressed in epithelia that play a role in Ca^{2+} reabsorption. Microarray analysis of $1,25(OH)_2D_3$-stimulated carcinoma cells has shown TRPV6 as one of the most highly vitamin D–responsive genes.[79]

Rats fed a vitamin D–deficient diet showed diminished Ca^{2+} reabsorption in the kidney, because of the down-regulation of the Ca^{2+} transport proteins TRPV5, calbindin-D28K, and NCX1. Supplementation of $1,25(OH)_2D_3$ restored the expression of the renal Ca^{2+} transport proteins and normalized the hypocalcemia. TRPV5 knockout mice showed renal Ca^{2+} wasting because of impaired reabsorption in the DCT and CNT. However, elevated $1,25(OH)_2D_3$ plasma levels, intestinal Ca^{2+} hyperabsorption, and reduced bone thickness prevented hypocalcemia in these knockout mice. The underlying mechanism of this compensatory hyperabsorption is hypovitaminosis D, which increases the expression of the intestinal Ca^{2+} transport proteins TRPV6, calbindin-D9K, and PMCA1b. The recently developed 1α-OHase and TRPV5 double-knockout (1α-OHase−/−/TRPV5−/−) mice have hypocalcemia and absence of hypervitaminosis D, again reinforcing the role of vitamin D in maintaining calcium levels in TRPV5 knockout mice.[80,81]

Calcitonin

Calcitonin is a 32–amino acid peptide and is secreted by the parafollicular cells of the thyroid gland. It is released in response to hypercalcemia and lowers serum calcium by various mechanisms. Its main action for lowering calcium is by inhibiting bone resorption. Calcitonin receptors are found on osteoclasts. The signal transduction pathways for calcitonin receptors are adenylate cyclase–PKA and phospholipase C–PKC via linking with G-proteins. In the kidney, calcitonin increases the urinary excretion of calcium and phosphorus, independent of PTH.[82-85] Calcitonin has not been shown to affect intestinal calcium absorption but may decrease phosphorus absorption. Calcitonin is a major regulator of renal 1,25-hydroxylase gene expression.[86]

Plasma Calcium Concentration

Hypercalcemia

Hypercalcemia results in an increase in Ca^{2+} excretion caused by a net increase in the filtered load and a decrease in tubular reabsorption. Hypercalcemia, in the presence of intact parathyroid glands, decreases the glomerular ultrafiltration coefficient (K_f) and thus causes a decline in glomerular filtration rate (GFR). Yet, the filtered load of Ca^{2+} may increase as a result of the elevation in serum Ca^{2+} concentration.[87,88] Hypercalcemia also causes a decline in the tubule reabsorption of Ca^{2+} by PTH-independent mechanisms.[89] This effect is mediated by stimulation of the CaR, which inhibits the apical K^+ channel and K^+ recycling, necessary for the activity of the Na^+-K^+-$2Cl^-$ transporter.[90] Decreased activity of the transporter decreases the lumen-positive potential difference and thus Na^+, Ca^{2+}, and Mg^{2+} reabsorption. In addition,

a decrease in intestinal Ca^{2+} absorption is brought about by diminished synthesis of $1,25(OH)_2D_3$.

Hypocalcemia

In hypocalcemic conditions, an increase occurs in PTH secretion that results in the mobilization of Ca^{2+} from the bone and soft tissues. This produces a fall in PTH that, in turn, promotes a decrease in fractional excretion of Ca^{2+} and a decline in net Ca^{2+} excretion. The CaR is thought to play a significant role in the enhancement of Ca^{2+} reabsorption in the TAL.[91] Decreased Ca^{2+} concentration in the vasa recta contributes to enhanced extrusion of Ca^{2+} at the basolateral membrane. Hypocalcemia also stimulates the production of $1,25(OH)_2D_3$, which increases the intestinal absorption of Ca^{2+}.

Phosphate and Magnesium

Hypophosphatemia produces a decrease in PTH resulting from an increase in plasma Ca^{2+} concentration. The ensuing hypercalciuria is, however, only partially corrected by the administration of PTH, a finding suggesting a direct effect of phosphate (PO_4^{3-}) deprivation on renal Ca^{2+} transport.[92] Phosphate infusion enhances Ca^{2+} reabsorption in the distal nephron and reduces Ca^{2+} excretion, even in the setting of volume expansion. Mg^{2+} infusion produces an increase in Ca^{2+} excretion that is not corrected by PTH infusion.[93]

Volume Status

Expansion of intravascular space produces natriuresis and increases Ca^{2+} excretion by inhibiting Na^+ (and therefore Ca^{2+}) reabsorption in the proximal tubule and Ca^{2+} reabsorption in the distal tubule. This effect, which is independent of circulating PTH levels,[94] is used in treating patients with hypercalcemia. Contraction of the extracellular volume increases proximal tubular reabsorption of Na^+ (and Ca^{2+}) and results in decreased Ca^{2+} excretion.

Acid-Base Status

Both acute and chronic metabolic acidosis have been shown to induce the release of Ca^{2+} from bone and to inhibit distal reabsorption of Ca^{2+}, resulting in hypercalciuria.[95] The effect of acidosis on tubular transport is mediated by a reduction in TRPV5 activity.[96] Metabolic alkalosis increases Ca^{2+} reabsorption in proximal tubule and decreases Ca^{2+} excretion.[97]

Insulin, Glucagon, and Glucose

Ca^{2+} excretion is enhanced by glucose infusion. Insulin infusion and hyperinsulinemia are associated with reduced proximal reabsorption of Na^+, water, and Ca^{2+}, but only Ca^{2+} excretion is increased. Insulin induces a rise in near-membrane Ca^{2+} but not in free intracellular Ca^{2+} in muscle cells. The rise in near-membrane Ca^{2+} is the result of an increase in influx through L-type Ca^{2+} channels.[98,99] Glucagon has a natriuretic and calciuretic effect caused by increases in renal blood flow and GFR.[100]

Mineralocorticoids

Acute mineralocorticoid excess is associated with the retention of Na^+ but not Ca^{2+}. Chronic mineralocorticoid excess, conversely, results in an escape from Na^+ retention (after 3 to 5 days) and a concomitant rise in Ca^{2+} excretion.[101] This is the case in the Bartter syndrome, which is characterized by high aldosterone levels, salt wasting, hypokalemic alkalosis, hypercalciuria, and normal plasma Mg^{2+} levels. These manifestations are consequent to genetic defects in the Na^+-K^+-$2Cl^-$ transporter or the adenosine triphosphate–sensitive K^+ channel (renal outer medullary potassium [ROMK]) in the TAL and are similar to those consequent to the administration of loop diuretics.[102] The Gitelman syndrome is also associated with salt wasting and hypokalemia, but, unlike in the Bartter syndrome, the excretion of Ca^{2+} is reduced and plasma levels of Mg^{2+}s are low. The genetic defect resides in the thiazide-sensitive Na^+-Cl^- cotransporter of the distal convoluted tubule encoded by the human thiazide-sensitive Na^+-Cl^- cotransporter (SLC12A3) gene. Reduced function of this cotransporter results in an increase in Ca^{2+} reabsorption because of stimulation of the basolateral extrusion of Ca^{2+} through the NCX transporter and a decrease in Mg^{2+} reabsorption because of inhibition of an apical Na^+-Mg^{2+} exchanger.[103]

Diuretics

Loop diuretics (furosemide, ethacrynic acid, and bumetanide) inhibit the Na^+-K^+-$2Cl^-$ (NKCC2) transporter present in the apical membrane of the TAL resulting in a reduction in NaCl reabsorption and K^+ recycling across the apical membrane. This action diminishes the lumen-positive potential, which is the driving force for paracellular Ca^{2+} reabsorption in this particular nephron segment and explains the hypercalciuric effect of furosemide. The calciuric effect of furosemide enhances the delivery of Ca^{2+} to DCT and CNT, which are the primary sites of active Ca^{2+} reabsorption. It is at present unknown whether these latter nephron segments partly compensate the hypercalciuric effect of the loop diuretics.[104]

Thiazide diuretics cause a fall in urinary Ca^{2+} excretion. They increase renal Na^+ excretion by inhibiting the Na^+-Cl^- cotransporter present in the apical membrane of DCT cells. This inhibition of Na^+ reabsorption results in increased renal salt and water loss and thereby decreases extracellular volume.[105] The underlying mechanism is an enhancement of proximal Na^+ reabsorption observed in volume contraction by diuretics and Na^+ restriction, which leads to an increase in the electrochemical driving force for passive Ca^{2+} reabsorption.[106-109] Thiazide diuretics can reduce Ca^{2+} excretion in the absence of PTH or volume contraction. They increase Ca^{2+} reabsorption and inhibit Na^+ reabsorption, thus revealing the dissociation in the transport of these ions in distal nephron.[110]

Autocrine and Paracrine Calcitropic Hormones

Arginine Vasopressin

Arginine vasopressin is the key regulator of water reabsorption in the distal nephron. In addition, it has a Ca^{2+}-sparing effect, mediated by an increase in the paracellular transport.[111]

Prostaglandin E_2

In the cortical collecting duct, prostaglandin E_2 has a dual effect on Ca^{2+} transport. By interacting with apical and basolateral prostaglandin EP2 or EP4 receptors, prostaglandin E_2 stimulates Ca^{2+} transport, whereas via interaction with basolateral EP3 receptors it inhibits the stimulatory action of other calciotropic hormones.[112] The G-protein–coupled EP3 receptor modulates cAMP: via G_i activation, it inhibits adenylyl cyclase, and, via G_s activation, it stimulates adenylyl cyclase activity.[113] The molecular mechanism by which EP2 or EP4 stimulates and EP3 inhibits the action of calcitropic hormones is unknown.

Adenosine

Acting via apical A1 receptors, adenosine increases transcellular Ca^{2+} transport to the same extent as PTH, arginine vasopressin, and prostaglandin E_2.[114]

Adenosine Triphosphate

Adenosine triphosphate inhibits the action of stimulatory calciotropic hormones. The effect is mediated via both apical and basolateral P2y receptors.[115]

Nitric Oxide

Nitric oxide activates Ca^{2+} reabsorption via cyclic guanosine monophosphate.[116]

Thyroid Hormone

Ca^{2+} uptake is increased in renal brush-border membrane vesicles from hyperthyroid rats and is decreased in those from hypothyroid rats.[117]

Fetal and Neonatal Aspects of Renal Transport of Calcium

Ca^{2+} is vital for the adequate mineralization, growth, and development of the fetal skeleton. Approximately 30 g of Ca^{2+} is transferred via the human placenta from the mother to the fetus, mainly during the third trimester. The syncytiotrophoblasts actively transport 80% of Ca^{2+} from maternal to fetal circulation where it is needed for fetal skeleton growth, especially during the third trimester of pregnancy.[118,119] Syncytiotrophoblasts of the placenta have mechanisms of calcium transport that are similar to those found in the distal renal tubules.[120] TRPV6 expression in human placenta was shown to be much higher compared with its level in the kidney and small intestine. This higher TRPV6 placental expression is in line with the fact that transplacental Ca^{2+} transport is critical for normal fetal growth and development. This is also an indication that the transcellular, rather the paracellular, pathway of the transepithelial Ca^{2+} transport, in which the TRP proteins do not participate, may be dominant in the placenta.[121]

Toward the end of gestation, the Ca^{2+} levels in fetal plasma (total and ionized) are higher than they are in the mother.[122] Hormones such as calcitonin, PTH, and PTHrP have been found in maternal and fetal circulations, and they originate from mother, fetus, and placenta.[123] PTHrP has been found in the parathyroid glands of fetal sheep, in a 7-week-old human fetus, and in human placenta.[124] This protein is reported to stimulate placental Ca^{2+} transfer from mother to fetus in animals and in humans.[125] However, fetal PTH is not required for transplacental Ca^{2+} transfer.[126] The placenta has most of the G-protein–coupled receptors that bind the calcitropic hormones. CaR is expressed in both villous and extravillous regions of the human placenta and contributes to the local control of transplacental Ca^{2+} transport and to the regulation of placental development.[127] Polycystin-2, a ubiquitous transmembrane glycoprotein, mutated in autosomal dominant polycystic kidney disease, is present in term human syncytiotrophoblast, in which it behaves as a nonselective cation channel. Fetal renal cortex adenylate cyclase activity increases in response to PTH, as evidenced by an increase in urinary cAMP excretion after PTH administration in fetal sheep preparations[128] and by adenylate cyclase responsiveness in fetal rabbit[129] and fetal rat kidney preparations.[130] PTH infusion into fetal lambs results in a rise in plasma Ca^{2+}, a decline in plasma phosphate, and increases in urinary flow rate and urinary Ca^{2+} excretion.[131] Several studies in young animals, as well as in premature and term human neonates, revealed an increase in PTH levels during hypocalcemia and a calcemic response to PTH.[124,132] Yet, premature infants given exogenous PTH had minimal increases in urinary cAMP until day 6 of life, a finding suggesting a maturational delay in response to PTH by the nephron. Perfusion of isolated newborn guinea pig kidneys with a PTH-containing solution increased Ca^{2+} reabsorption and cAMP excretion, but it did not affect the reabsorption of phosphate.[133] Similar effects have been observed in full-term human newborns.[134] Vitamin D–dependent Ca^{2+}-binding proteins, thought to be involved in transepithelial Ca^{2+} transfer, have been found in human kidneys as early as 14 weeks gestation.[135] Yet, the major function of the kidneys in fetal Ca^{2+} homeostasis appears to be the production of $1,25(OH)_2D_3$, rather than renal regulation of Ca^{2+} excretion.[136] The urinary Ca^{2+}-creatinine ratio (millimoles to millimoles) was reported to increase from 0.05 to 1.2 in term neonates and from 0.3 to 2.3 in preterm neonates during the first week of life. Children older than 1 year of age have a mean urinary Ca^{2+}-creatinine ratio (millimoles to millimoles) of 0.40, and school-aged children have a ratio of less than 0.21.[137] These findings suggest that the fractional excretion of Ca^{2+} is high in newborns, especially in those born prematurely.[138] However, the high excretion rates observed in these infants may have been caused, at least in part, by a low phosphate intake because these children were largely breast-fed.[139] Urinary Ca^{2+} excretion in preterm neonates has been also found to vary directly with urinary flow rate and with urinary Na^+ excretion. Yet, young animals given a saline load had an attenuated natriuretic response but a similar calciuretic response when compared with adult animals.[140] This finding suggests linked proximal tubular Ca^{2+} and Na^+ reabsorptive mechanism and an unlinked distal mechanism in newborn animals.[141]

PHOSPHORUS

The importance of maintaining proper phosphate balance is illustrated by the wide variety of biologic processes that use phosphate, including adenosine triphosphate production, coenzymes, and signaling proteins, in addition to its role as a major constituent of bone, muscle, and even the cellular bilipid membrane. Although an acute decrease in circulating plasma phosphate produces symptoms consisting of myopathy (weakness and myalgia), sinus bradycardia, and hematologic disturbances, chronic hypophosphatemia can contribute to development of congestive heart failure, as well as bone demineralization (leading to osteomalacia in adults and rickets in children).[142] Thus a positive phosphate balance in neonates and children is critical for proper growth and development.

During the perinatal period, phosphate homeostasis, like that of calcium, involves the integrated action of several hormonal systems and certain key factors. The high metabolic demand of the neonate for phosphate is met through a relatively high intake of dietary phosphate, efficient intestinal phosphate absorption, and reduced urinary phosphate loss. The kidney plays a critical role in this process by limiting the urinary excretion of phosphate through enhanced tubular phosphate reabsorption.[143-149] The rate of renal phosphate uptake largely determines the level of extracellular phosphate and, ultimately, regulates phosphate homeostasis.

Of the total body phosphorus, approximately 80% is present in the skeleton, with the remainder being in muscle, soft tissues, and finally extracellular fluids. Approximately two thirds of the circulating pool of phosphorus is in the form of organic phosphates (such as esters and phospholipids) and one third is as inorganic phosphate, essentially all in the form of orthophosphate. It is estimated that the latter fraction, which represents the plasma phosphate concentration, exists as free phosphate, complexed with calcium or magnesium, or protein bound. The plasma phosphate concentration is highest in infants (4.5-9.3 mg/dL) and higher in children (4.5-6.5 mg/dL) than in adults (3.0-4.5 mg/dL).[150] This section focuses on the adaptations in renal phosphate handling and response to regulators of phosphate transport that facilitate the increased renal retention of phosphate during development. Furthermore, this discussion concentrates on new advances in renal phosphate handling since the publication of excellent reviews.[151-153]

Phosphate Reabsorption and the Transport Maximum

Ninety percent of plasma phosphate is freely filterable across the glomerular capillary as 10% is protein bound. However, because of the Donnan effect (the inability of charged molecules to evenly distribute across a semipermeable membrane) and correction for plasma water, the filtered load of phosphate is still calculated as the product of the total plasma phosphate concentration (not 90%) and the GFR.

Under normal conditions, the kidney reabsorbs 75% to 85% of the filtered phosphate load with the remainder delivered to the collecting duct acting as a titratable acid and excreted in the urine. The tubular reabsorption of phosphate is a saturable process characterized by a transport maximum (TmPi), although the TmPi is not a fixed value but rather influenced by the actions of hormones, dietary phosphate, and growth.[151,153] To facilitate comparison of TmPi values from individuals or animals of different sizes, values are normalized by kidney, body mass, or more commonly the GFR. On this basis, the TmPi-GFR in infants[154,155] and neonatal animals[134,154,156] is greater than in corresponding adults. Furthermore, in contrast to the adult, the developing animal has a renal threshold that is far greater than the normal plasma phosphate concentration, suggesting that the newborn can maintain avid phosphate uptake in the face of high plasma phosphate levels.

For many years, the limited ability of the newborn to excrete phosphate was thought to be a consequence of the reduced GFR. Although this may be a limiting factor in the very early postnatal period, studies performed in weaned rats,[143-153,156] newborn guinea pigs,[157] and older infants[155] indicate that the reduced urinary excretion of phosphate occurs because of a high rate of tubular phosphate reabsorption and does not result from the low GFR.

The bulk of filtered phosphate is reabsorbed in the proximal convoluted tubule. In adult animals under normal conditions, approximately 70% of the phosphate present within the glomerular ultrafiltrate is reabsorbed within this segment, and the rate of renal reabsorption could increase to 85% to 90% in states of phosphate retention such as hypoparathyroidism,[151-153] dietary phosphate deprivation,[158-161] and respiratory alkalosis.[158,161] This increase in phosphate retention is facilitated by reabsorption in segments beyond the proximal convoluted tubule, such as the proximal straight tubule (pars recta),[161-163] DCT,[159,164] and cortical collecting tubule,[165] particularly in states of phosphate conservation.[158,160,163,166] The postnatal period of rapid growth and development may represent a state of phosphate conservation that involves avid renal phosphate retention. Results of micropuncture experiments indicate that a proportionally greater fraction of the filtered phosphate load is reabsorbed in the early part of the proximal convoluted tubule of newborn guinea pigs compared with adults.[157] Kinetic studies in newborn guinea pigs suggest that the elevated phosphate uptake in the proximal tubule is a result of a higher maximum velocity (V_{max}) of phosphate transport, equating to an increased number of Na-dependent P_i cotransporters,[167] whereas studies in newborn rats demonstrated that a rise in the affinity (K_m) of the sodium-phosphate transporter may also play a role.[168] Of interest, fractional phosphate reabsorption along the proximal convoluted tubule in neonatal rats is reduced until 3 weeks of age and then equals or even exceeds the rate seen in older rats.[168]

Studies using nuclear magnetic resonance techniques on isolated kidney cells have reported lower intracellular phosphate concentrations in kidneys of neonates compared with adults,[169,170] despite the known higher rate of phosphate entry into these tubular cells. This suggests that the rate of basolateral phosphate efflux must also be elevated in the newborns and may contribute to their high reabsorptive capacity for phosphate. The concentration of intracellular phosphate has been directly correlated with postnatal age and dietary phosphate supply and inversely correlated with the TmPi. However, it is not significantly altered when TmPi is increased or decreased because of changes in the demand for phosphate that result from reductions in the rate of body growth or bone mineralization.[170] This suggests that variations in intracellular phosphate concentration do not contribute to those renal adaptations.

Estimates based on the differences between proximal tubular phosphate reabsorption and urinary phosphate excretion indicate that phosphate uptake in nephron sites beyond the superficial proximal tubule is enhanced in the newborn compared with the adult.[157] Micropuncture studies in immature rats demonstrated a significant decrease in the delivery of phosphate from the end of the proximal convoluted tubule to the early DCT, compared with older animals, implying a significant amount of phosphate reabsorption within the pars recta of superficial nephron.[149] The descending and ascending limb of Henle probably do not contribute to the reabsorption of phosphate because the permeability of these segments to phosphate is extremely low.[151-153] Heterogeneity of phosphate reabsorption between superficial and juxtamedullary nephrons is another important element to consider in the tubular handling of phosphate by the newborn. The intrinsic capacity to transport phosphate in single nephron proximal tubules, in vivo, is greater in deep than superficial nephrons.[171] This observation could have significant implications for the developmental period, in view of the centrifugal pattern of nephron maturation. Because nephrogenesis begins in the juxtamedullary region and continues with the development of outer cortical nephrons,[172] the relative preponderance of deep nephrons (with a higher capacity for phosphate transport) in the immature kidney may contribute to the high capacity for phosphate reabsorption during development.[144]

Sodium-Phosphate Transporters

The rate-limiting step in the transcellular transport of phosphate (P_i) within the nephron is the movement of phosphate across the luminal brush border membrane and into the tubular cell. Once inside the cell, inorganic phosphate can be incorporated into many organic compounds through a multitude of biosynthetic pathways or simply can pass through the cell to enter the circulatory system. Phosphate entry into the renal proximal tubule cell is mediated by an electrogenic sodium (Na)-coupled, secondary active, transport process that is dependent on an electrochemical gradient for sodium generated by a basolateral sodium-potassium ATPase pump.[151-153]

Three Na-dependent P_i (NaPi) cotransporter families have been described to date. Type I NaPi cotransporters are expressed on the proximal tubular brush border[173] but appear to influence intrinsic cellular phosphate transport.[174] Type II NaPi cotransporters have three known isoforms (NaPi IIa, NaPi IIb, and NaPi IIc), with IIa and IIc almost entirely present within the proximal tubular apical membrane,[175-177] and IIb, primarily found in the small intestine, involved in intestinal phosphate absorption.[178] NaPi IIa is localized throughout the proximal tubule, whereas NaPi IIc is restricted to the first portion (S1) of the proximal tubular cells.[179] Finally, type III NaPi cotransporters are expressed on the basolateral surface of proximal tubular cells and serve a housekeeping function.[180] The movement of P_i across the basolateral membrane is thought to be a passive process.[151-153] Of interest, NaPi IIa transports three Na cations for each divalent P_i anion whereas NaPi IIc remains electroneutral by moving two Na ions across the apical membrane along with each P_i molecule.[181] The isolation and cloning of these specific renal NaPi symporters in a variety of species[182-185] including humans[182,184] has opened opportunities to further elucidate the regulation of these transporters. For instance, NaPi II transporter messenger RNA and protein expression are up-regulated in adult rat brush border membranes of proximal tubular cells exposed to a low-phosphorus diet,[186] a process now known to be microtubule dependent involving the up-regulation of both NaPi IIa and IIc.[187-189] However, although placing mice on a low P_i diet (for 5 days) caused an increase in the proximal tubular expression of apical NaPi IIa and IIc transporters, only NaPi IIc messenger RNA levels were up-regulated under these conditions,[177] suggesting that mechanism underlying the increase in NaPi IIa is via posttranscriptional means. As expected, administration of a high-phosphate diet

leads to a drop in the expression of renal NaPi IIa[188,190] and NaPi IIc[179,188] protein, without affecting the intestinal expression of NaPi IIb.[190] Although thyroparathyroidectomized rats display an up-regulation of NaPi II messenger RNA and protein,[191] infusion of PTH, a factor strongly linked to increasing urinary P_i excretion, has been shown to affect NaPi IIa and IIc expression via the endocytic removal of the proteins from the brush border membrane and subsequent lyosomal degradation.[177,187,189,192] Of note, addition of the microtubule inhibitor colchicine prevented the down-regulation of apical NaPi IIc, but not NaPi IIa transporter, after PTH administration in thyroparathyroidectomized rats.[179] Additional studies are needed to fully elucidate the complex mechanisms involved in the insertion and removal of the NaPi IIa and IIc cotransporters from the renal tubular brush border membrane.

Genetic manipulation over the past decade has confirmed the importance of the NaPi transporters in regulating renal phosphate homeostasis. NaPi IIa gene ablation in mice produces a phenotype that is hypophosphatemic and hypercalciuric and eventually develops skeletal abnormalities, as a result of decreased renal phosphate reabsorption.[193,194] This occurs despite the significantly enhanced expression of brush border membrane NaPi IIc protein in these animals. In addition, NaPi IIa knockout mice have a poor response to PTH or changes in dietary intake,[195] indicating that NaPi IIa is the major cotransporter involved in phosphate homeostasis in the mouse model. Ablation of NaPi IIc produces animals with mild phenotypes compared with the NaPi IIa knockout mice described earlier.[196] Of interest, in 2006, a single nucleotide deletion of the NaPi IIc gene in humans was associated with hereditary hypophosphatemic rickets with hypercalciuria,[197,198] an autosomal recessive disorder characterized by elevated urinary phosphate losses, hypercalciuria (resulting from significant intestinal calcium absorption), and skeletal abnormalities such as rickets and osteomalacia.[199] Thus NaPi IIc appears to play a greater role in renal phosphate handling in humans as compared with the rodent.

Recent findings have determined that renal NaPi II transporter expression is significantly greater in juvenile animals, and a developmental decrease in the transporter protein occurs into young adulthood. These changes in NaPi II expression directly coincide with the increased tubular phosphate uptake seen in these juvenile animals.[148] It is now known that the expression of NaPi IIc is also elevated in weaning animals, suggesting a possible role for this transporter as well during the growth process.[176,200] Thus, although these findings clearly indicate that up-regulation of NaPi II transporters is a key adaptation facilitating avid phosphate uptake in the developing animal, it is not clear the extent that NaPi IIa or NaPi IIc plays during growth, as well as whether other unique, yet undiscovered, transporters are also involved. Further studies are needed to help shed light on this issue.

Age-Dependent Effects of Parathyroid Hormone on Renal Phosphate Reabsorption

PTH, the principal hormonal regulator of renal phosphate transport, is released from the parathyroid glands in response to hypocalcemia (or hyperphosphatemia) and acts on the kidney to increase calcium reabsorption while decreasing phosphate uptake. Of interest, recent evidence shows that exposure of the gut to a high P_i diet rapidly (within 10 minutes) can affect PTH secretion, independent of changes in serum calcium or phosphate.[201,202] In the adult animal, the phosphaturic effect of PTH occurs through a direct action of the hormone on both proximal[162,166] and distal nephron segments.[164,166] In most cases, the action of PTH is mediated by an increase in intracellular cAMP,[151-153] although evidence indicates that both PKA and PKC second-messenger systems are also affected by PTH binding to its receptor.[203,204] Finally, it is interesting to note that juxtamedullary (deep) nephrons elicit a greater phosphaturic response to PTH than do superficial nephrons[205]; whether this effect is due to an increase in PTH receptors or increased maturation of the deep nephrons is not known.

The response of the juvenile animal to the phosphaturic effect of PTH is attenuated compared with that of the adult.[143,146,148,163,206] This reduced sensitivity to PTH occurs despite normal circulating levels of PTH during the postnatal period.[207] Of interest, the blunted phosphaturic response to PTH in the juvenile animal is restored to adult levels when growth hormone (GH) is suppressed, an effect that is mediated through NaPi II transporters.[146,149] Furthermore, immunofluorescence studies demonstrated that, although PTH causes the internalization of the NaPi II cotransporter from the brush border membrane of juvenile rats, it appears to remain within the subapical compartment[148] rather than degraded in the lysosomal system, as noted in adults.[187,188] Although the reason for this is unknown, it may be related to the fact that with the high demand of the growing animal to reabsorb filtered P_i, this allows for the transporters to be available for rapid reinsertion into the apical surface. This potential age-related difference appears to be GH dependent, because the endocytic removal and degradation of the PTH-induced NaPi II transporter can occur in the juvenile kidneys after GH suppression.[149] This indicates that the PTH mechanism is intact in the juvenile kidney, but the ability of PTH to decrease NaPi II transporters is overridden by the ability of circulating GH to prevent the lysosomal degradation on these transporters. Further studies are required to help elucidate this pathway.

Age-Dependent Effects of Dietary Phosphate on Renal Phosphate Reabsorption

Dietary phosphate restriction elevates phosphate reabsorption in the adult animal,[147,148,151,153] through increases in phosphate transport in the proximal tubule.[148,159,162,166] In the adult, phosphate deprivation is associated with increased membrane fluidity and reduced membrane cholesterol content, which may facilitate the observed increase in V_{max}.[167] Conversely, aging is associated with loss of membrane fluidity, increased cholesterol,[208] and a reduction in phosphate reabsorption.[209] The adaptation to enhance tubular phosphate reabsorption during dietary phosphate deprivation is also present in immature dogs[154] and rats.[145,148] Indeed, studies in the juvenile rat have shown that the adaptive increase in phosphate reabsorption is far greater than that observed in the phosphate-deprived adult and is PTH independent.[145,148] Moreover, this increase occurs despite the already high rate of phosphate transport in the immature animal. The elevated TmPi in the phosphate-deprived newborn serves to maintain avid reabsorption of phosphate and facilitate the accelerated rate of growth that occurs on the restoration of phosphate to the diet.[145,148] Micropuncture and NaPi II transporter studies in the juvenile rat demonstrate that sites beyond the proximal convoluted tubule significantly contribute to the high renal P_i uptake seen in P_i-deprived growing animals[148] (Figure 130-2).

Thyroid Hormone

Thyroid hormone may also be integral to proper phosphate homeostasis in the young animal. Thyroid hormone receptors are present in the fetus, with the hormone peaking at birth in humans and by 4 or 5 weeks after birth falling to levels maintained through adulthood. The kidney is a target organ for thyroid hormone and contains the iodothyronine deiodinase enzyme that converts the main circulating hormone T_4 to the more potent T_3. Increases in thyroid hormone stimulate sodium-dependent phosphate transport in adult rats[210] and mice.[211] This effect is probably related to the hormone's ability to up-regulate the V_{max} of the transporter.[212,213] Thyroid hormone may also be involved

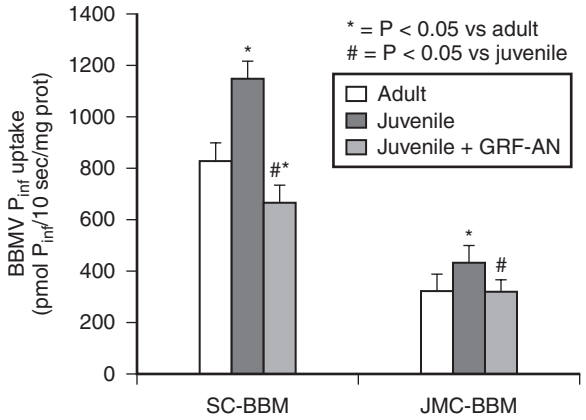

Figure 130-2 Brush border membrane vesicle (BBMV) NaPi uptake in superficial cortex (SC-BBM) and outer medullary cortex (JMC-BBM) in parathyroid gland intact adult, juvenile, and GH-suppressed juvenile rats. BBMVs from control juvenile rats *(dark gray bar)* have significantly greater P_i uptake in both SC-BBM and JMC-BBM compared with adult rats. Suppression of GH (with use of a GH–releasing hormone antagonist, GRF-AN) significantly reduced NaPi uptake to levels at or below that in adults. *(From Woda CB, Halaihel N, Wilson PV, et al: Regulation of renal NaPi-2 expression and tubular phosphate reabsorption by growth hormone in the juvenile rat,* Am J Physiol Renal Physiol *287:F117-F123, 2004, with permission.)*

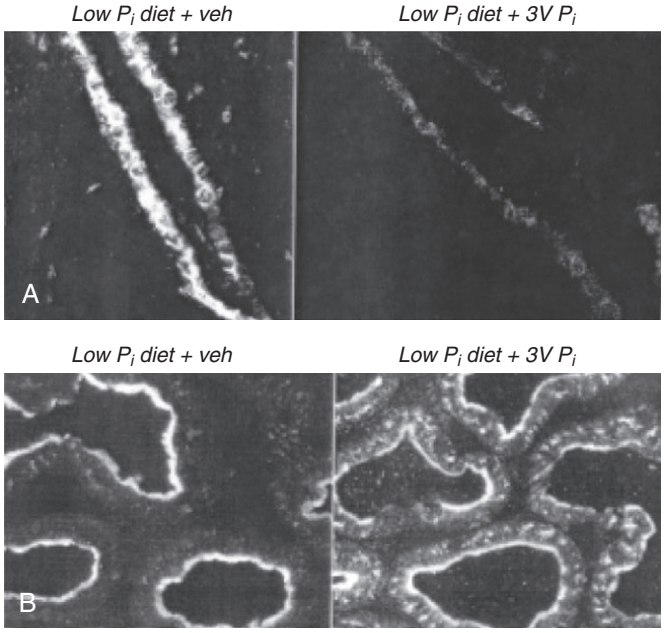

Figure 130-3 Effect of third-ventricle injection of vehicle or P_i in young rats fed a low-phosphate diet. Within 15 minutes, P_i injection into the third ventricle of the brain results in the rapid reduction of NaPi transporters from ependymal cells surrounding the third ventricle and translocation of transporters from the renal brush border to cytosol. *(From Mulroney SE, Woda CB, Halaihel N, et al: Central control of renal sodium-phosphate [NaPi-2] transporters,* Am J Physiol Renal Physiol *286:F647-F652, 2003, with permission.)*

in the maturational increase in the K_m of the proximal tubule brush border phosphate uptake that occurs with weaning, because prolonged weaning in rats is associated with a decrease in both thyroid hormone levels and the K_m for tubular phosphate transport.[214]

Growth Hormone

GH is a key factor regulating renal phosphate reabsorption, particularly in the postnatal period. GH hypersecretion is associated with hyperphosphatemia and a reduction in urinary phosphate excretion.[215,216] Conversely, GH deficiency (dwarfism) is associated with an attenuated growth rate and increased excretion of phosphate.[216] When GH-deficient individuals are given GH injections, growth rate acutely increases and phosphate excretion diminishes.[216] Studies in adult dogs[215-217] and rats[218] have reported that administration of GH increases the tubular reabsorption of phosphate, independent of PTH. Conversely, when adult animals are hypophysectomized to prevent pituitary GH release, an increase in urinary phosphate excretion occurs with a correlated decrease in the TmPi.[218] It is not known whether the increase in phosphate retention results directly from binding to renal GH receptors or indirectly from GH activation of renal insulin-like growth factor (IGF)-I, because IGF-I is also capable of directly increasing phosphate reabsorption in vitro and in vivo.[218,219]

Results from animal studies have established an important link between the growth-promoting effects of GH and renal phosphate reabsorption. Suppressing GH release significantly attenuates the growth rate and reduces the positive phosphate balance in juvenile rats.[144,220] These effects are associated with a decrease in the TmPi to levels observed in the adult animal. Reductions in NaPi II transporters account for the reduced proximal and distal tubular phosphate reabsorption.[148] GH or IGF-I replacement prevents the reduction in TmPi in GH-suppressed juvenile rats. Of importance, suppression of GH has no effect on phosphate handling in adult rats. In addition, suppression of GH release in weaning and juvenile rats produces a phosphaturic response to PTH comparable with that observed in adult rats and drives the increase in tubular phosphate reabsorption in response to dietary phosphate deprivation.[146,148,149] These findings indicate that many of the adaptations to conserve phosphate in the developing animal are facilitated directly, or indirectly, by GH.

Central Regulation of Renal Phosphate Reabsorption

One of the most intriguing findings is that central control of renal NaPi II transporters exists in juvenile animals. Addition of phosphate directly into the third ventricle of the brain in phosphate-deprived juvenile rats rapidly (within 15 minutes) down-regulates renal NaPi IIa transporters, despite the low plasma phosphate milieu (Figure 130-3).[148] The reduction in NaPi II transporters correlates with a significant reduction in the TmPi of these animals. These findings open new approaches for investigating the regulation of phosphate homeostasis in development and aging.

NEW PERSPECTIVES IN THE CLINICAL RELEVANCE OF RENAL P_I REGULATION

Phosphatonins

Phosphatonins, a term coined in 1994, are a collective set of circulating and/or autocrine-paracrine factors shown to inhibit renal tubular phosphate uptake and play a crucial role in a variety of phosphaturic disorders such as autosomal dominant hypophosphatemic rickets (ADHR), tumor-induced osteomalacia (TIO), and X-linked hypophosphatemic rickets (XLH).[221,222] The initial report on the existence of phosphatonins, by Cai and colleagues,[223] demonstrated that opossum kidney cells exposed to media housing cells from patients with TIO, a disease

characterized by renal phosphate wasting, had a reduction in Na-dependent P_i transport. Several recently studied phosphatonins include secreted frizzled-related protein-4 (sFRP-4), matrix extracellular phosphoglycoprotein (MEPE), and fibroblast growth factor 23 (FGF23); with FGF23 being the only factor currently linked to human phosphate wasting diseases.[224-229]

FGF23

FGF23, considered the most potent phosphatonin, was isolated from patients with ADHR, XLH, and TIO, three diseases characterized by hypophosphatemia (subsequent to renal phosphate wasting), as well as skeletal abnormalities.[230-234] These studies implicate FGF23 in the pathogenesis of phosphate wasting disorders and also contribute to our general understanding of renal phosphate homeostasis regulation, particularly during growth and development.

Opossum kidney cells exposed to FGF23 have decreased Na-dependent P_i transport[235] through down-regulation of NaPi IIa expression.[236] Furthermore, FGF23 infusion or overexpression of FGF23 in mice caused a decline in renal P_i uptake, resulting from the decreased NaPi IIa expression.[229,231,233] In vivo studies have demonstrated that NaPi IIc messenger RNA and protein also decrease in response to FGF23.[237,238] As expected, FGF23 ablation studies resulted in hyperphosphatemia and renal P_i retention, as well as elevated levels of circulating $1,25\text{-}(OH)_2D_3$.[232,234] Of note, FGF23 may also be involved in the pathogenesis of McCune-Albright syndrome because circulating levels appear to correlate with the severity of hypophosphatemia and bone dysplasia in these individuals.[239] Because binding of FGF23 to the FGF receptor elicits mitogen-activated protein kinase activation and tyrosine kinase signaling,[240] FGF23 inhibitors or blockers of the FGF receptor signaling cascade may have the potential of preventing the significant P_i losses, and bone abnormalities, seen in these patients.

Of clinical importance is the fact that patients with chronic kidney disease have exceptionally high levels of circulating FGF23,[241-243] and the levels inversely correlate with the maximum tubular capacity of phosphate reabsorption.[241] Furthermore, hemodialysis plays no role in lowering the elevated FGF23 levels in these patients.[244] Although the significance is not currently known of the high circulating FGF23 levels in patients with chronic kidney disease, it is thought that they may contribute to the suppression of $1,25\text{-}(OH)_2D_3$ levels, which is involved in maintaining efficient intestinal calcium absorption, as well as leading to secondary hyperparathyroidism, which has implications in producing bone mineralization abnormalities in these patients.Thus FGF23 suppression may be a novel therapeutic target in the near future for individuals with end-stage renal disease who are receiving dialysis.

Transport of Amino Acids During Early Development

GENERAL FEATURES

The reclamation of filtered amino acids by the proximal tubule of the kidney undergoes a process of maturation coincident with other maturational changes in renal function.[1] To understand the ontogeny of renal amino acid transport, it is useful to review general features of renal amino acid transport.

Glomerular filtrate contains amino acids in concentrations essentially identical to those in plasma. It is from this filtered load that amino acids are reabsorbed exclusively by the proximal tubule. Glycine and taurine are reabsorbed in later segments of the proximal tubule, but for most amino acids, more than 80% of reabsorption occurs in the early proximal tubule.[2,3] This reclamation of amino acids back into the extracellular space is not merely movement across a single plasma membrane but is passage through a cell layer–transepithelial transport.

Figure 131-1 depicts a proximal tubule cell with its major reabsorptive surface, the brush-border membrane, oriented into the lumen of the tubule and the remainder of the cell membrane that any reabsorbed solute must transverse: the basolateral membrane. The directional flux for amino acids is from the tubule lumen to the peritubular capillary. Thus the heavier arrows in the figure are pointed in that direction. The net flux is composed of movement into the cell from the lumen and the interstitial space surrounding the basolateral membrane, as well as movement back into the tubule lumen and out of the cell into the surrounding interstitium. This view is somewhat simplistic in that it does not take into account any contribution made by intracellular metabolic processes or the possibility of amino acid movement by paracellular processes across the tight junction. However, Figure 131-1 does define the general components of transepithelial amino acid transport.

The net movement across the renal proximal tubule cell is primarily an active transport process requiring energy.[4] Passive diffusion plays a small role. For every amino acid studied thus far, the movement across the brush-border membrane is inextricably tied to sodium (Na^+) transport. The present model states that energy is expended by the cell to pump Na^+ from the cell into the extracellular space. The pump at the basolateral membrane is sodium-potassium-adenosine triphosphatase (Na^+-K^+-ATPase). The extrusion of Na^+ from the cell creates an inward (into the cell) driving force for Na^+ (down a concentration gradient) at the brush-border membrane. Thus amino acids and Na^+ are cotransported. In studies with brush-border membrane vesicles, in

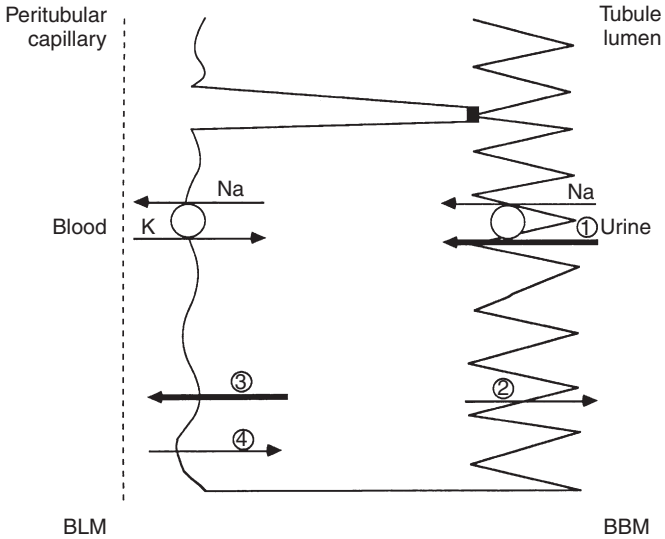

Figure 131-1 Representation of process involved in transepithelial transport of amino acids by the renal proximal tubule: (1) sodium amino acid co-transport; (2) efflux back into tubule lumen (backleak); (3) efflux from tubule to peritubular space (extracellular space) and return to plasma; (4) transport from peritubular space into tubule cell. *BBM,* Brush border; *BLM,* basolateral membrane; *circle with opposite-pointing arrows,* Na^+,K^+-ATPase.

Transport of Amino Acids During Early Development

GENERAL FEATURES

The reclamation of filtered amino acids by the proximal tubule of the kidney undergoes a process of maturation coincident with other maturational changes in renal function.[1] To understand the ontogeny of renal amino acid transport, it is useful to review general features of renal amino acid transport.

Glomerular filtrate contains amino acids in concentrations essentially identical to those in plasma. It is from this filtered load that amino acids are reabsorbed exclusively by the proximal tubule. Glycine and taurine are reabsorbed in later segments of the proximal tubule, but for most amino acids, more than 80% of reabsorption occurs in the early proximal tubule.[2,3] This reclamation of amino acids back into the extracellular space is not merely movement across a single plasma membrane but is passage through a cell layer–transepithelial transport.

Figure 131-1 depicts a proximal tubule cell with its major reabsorptive surface, the brush-border membrane, oriented into the lumen of the tubule and the remainder of the cell membrane that any reabsorbed solute must transverse: the basolateral membrane. The directional flux for amino acids is from the tubule lumen to the peritubular capillary. Thus the heavier arrows in the figure are pointed in that direction. The net flux is composed of movement into the cell from the lumen and the interstitial space surrounding the basolateral membrane, as well as movement back into the tubule lumen and out of the cell into the surrounding interstitium. This view is somewhat simplistic in that it does not take into account any contribution made by intracellular metabolic processes or the possibility of amino acid movement by paracellular processes across the tight junction. However, Figure 131-1 does define the general components of transepithelial amino acid transport.

The net movement across the renal proximal tubule cell is primarily an active transport process requiring energy.[4] Passive diffusion plays a small role. For every amino acid studied thus far, the movement across the brush-border membrane is inextricably tied to sodium (Na^+) transport. The present model states that energy is expended by the cell to pump Na^+ from the cell into the extracellular space. The pump at the basolateral membrane is sodium-potassium-adenosine triphosphatase (Na^+-K^+-ATPase). The extrusion of Na^+ from the cell creates an inward (into the cell) driving force for Na^+ (down a concentration gradient) at the brush-border membrane. Thus amino acids and Na^+ are cotransported. In studies with brush-border membrane vesicles, in

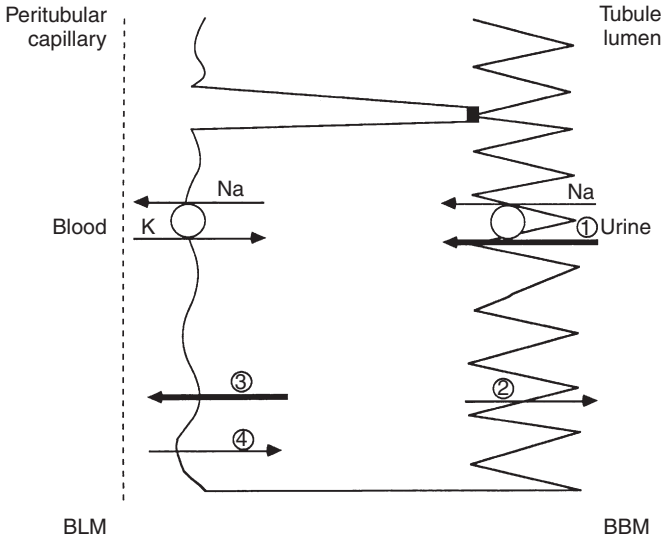

Figure 131-1 Representation of process involved in transepithelial transport of amino acids by the renal proximal tubule: (1) sodium amino acid co-transport; (2) efflux back into tubule lumen (backleak); (3) efflux from tubule to peritubular space (extracellular space) and return to plasma; (4) transport from peritubular space into tubule cell. *BBM,* Brush border; *BLM,* basolateral membrane; *circle with opposite-pointing arrows,* Na^+,K^+-ATPase.

which transport across the brush-border membrane can be studied, amino acid accumulation in the vesicles is nearly completely blunted when Na^+ is excluded from the external medium.[4-6]

Transport characteristics of the brush-border carrier (transporter) for amino acids and Na^+ suggest that the transporter is saturable. In other words, increasing the concentration of amino acids above a certain level does not lead to significant further accumulation. All amino transporters follow Michaelis-Menten kinetics, meaning that under proper experimental conditions, it should be possible to determine the maximal velocity (V_{max}) of transport and the concentration at which half-maximal velocity occurs (K_m). The V_{max} can be viewed as a measure of transport capacity, with the higher the V_{max}, the greater the capacity. The K_m is a measure of affinity. The lower the K_m, the more avidly the substrate is "attracted" to the transporter. As Scriver and Rosenberg[7] have pointed out, the transporters have a higher affinity for the L-isomers of amino acids, and they demonstrate specificity. In many instances, groups of amino acids are transported by the same carrier. Group-specific carriers are, with respect to any single amino acid, high-capacity but low-affinity systems. In a disease such as cystinuria, a group carrier is often involved, and most patients excrete excessive quantities of cystine, ornithine, lysine, and arginine. More selective transporters for single amino acids have lower capacities but higher affinities.

Transport properties at the basolateral membrane resemble those of the brush-border membrane, although Na^+-*independent* transport may play a greater role in transport at the basolateral membrane. Efflux properties are less well understood, although diffusion down a concentration gradient (intracellular → extracellular) may be important in the transepithelial movement of amino acids from the tubule lumen to the extracellular space. With respect to the reclamation of amino acids by the proximal tubule, and thereby the final amino acid concentration in the urine, the important features are the filtered load of amino acids and the transport capability, especially the proximal tubule brush-border membrane transporter properties.

DEVELOPMENTAL ASPECTS

It is generally recognized that very young, developing mammals (including humans) have "physiologic" aminoaciduria. As the term suggests, more amino acid is in the urine compared with in adults, and this aminoaciduria is not pathologic. Perhaps the term *developmental aminoaciduria* would be more appropriate because the failure of the young mammal to reabsorb amino acids to the degree seen in the adult appears to be a developmental process.

The excretion of amino acids by humans is measured by numerous methods. Using any method, the hyperexcretion of amino acids by the human infant can be documented. Table 131-1 shows the normal range of urinary amino acid excretion in infants, children, and adults as measured after a timed collection (μmol amino acid/g creatinine/24 hours). Two other techniques for quantitating the excretion of amino acids have been employed. Scriver and Rosenberg[7] proposed the following renal clearance method:

$$(C_{AA})\ \text{clearance of amino acids} = \frac{(U)\ \text{urine concentration (μmol/mL)} \times \text{volume (mL/minute)}}{(P)\ \text{plasma concentration (μmol/mL)}}$$

and Silbernagel[3] quantified excretion by determining the fractional excretion (FE) of amino acids:

$$FE = \frac{C_{AA}}{C_{cr}} = \frac{U_{AA} \times P_{cr}}{P_{AA} \times U_{cr}}$$

where C_{AA} = amino acid clearance, C_{cr} = creatinine clearance, U_{AA} = urine amino acid concentration, P_{cr} = plasma creatinine concentration, P_{AA} = plasma amino acid concentration, and U_{cr} = urine creatinine concentration.

Fractional excretion and clearance data clearly indicate that higher concentrations of amino acids are present in the urine of newborn infants. Importantly, however, these data also suggest that the excess amino acids are not secondary to higher filtered loads. What then could be the cause of this maturational delay in the reabsorptive capacity of the proximal tubule of the infant?

Scriver and colleagues,[8] in their discussion of the expression of mutations that could lead to hereditary disorders of tubular transport, postulated at least three mechanisms to explain the developmental tubular differences seen in the infant. The first of the possible developmental differences could be at the brush-border membrane transporter site (see *site 1* in Figure 131-1). Diminished transporter function could lead to a decrease in amino acid influx and an increase in amino acid excretion. An increase in amino acid exit at *site 2* in Figure 131-1, that is, increased backflux into the lumen, could represent a second developmental difference that could explain developmental aminoaciduria. A third possibility (see *site 3* in Figure 131-1) is a decrease in efflux. This would lead to increased intracellular concentrations of amino acids that would then result in increased backflux into the tubule lumen, or a direct inhibitory effect on transporters to reduce the amount of amino acid carried into the proximal tubule cell, or both. A further possibility discussed by Scriver and colleagues[8] deals with the metabolic fate of amino acids. In disease states, it is possible that intracellular accumulation may occur because the metabolic end point of an amino acid may be blocked, leading to diminished metabolic "runout" and abnormal intracellular accumulation. This last possibility is not likely to explain developmental aminoaciduria because amino acids that do not undergo metabolic change or incorporation into protein are excreted in high quantities in the young of many mammalian species (see Table 131-1). Certain amino acids seem to contribute more to the high urinary amino acid excretion than do others.[9] This finding suggests that a single defect such as altered energy use cannot explain the developmental changes seen. Rather, it is more likely that any developmental effect is related to the maturation of influx or efflux capabilities and that the influx-efflux transport systems "mature" at separate rates.

Numerous laboratories have studied the ontogeny of amino acid transport. Early studies by Baerlocher and associates[10,11] examined glycine and proline transport in rat kidney cortex slices (Long-Evans rat) from neonatal animals. Their studies were consistent with the presence of a low-affinity, high-capacity transporter at birth and the emergence of a high-affinity, low-capacity system at 1 week of age for proline and 2 weeks of age for glycine. Studies by Segal and colleagues[12] in Sprague-Dawley rats found similar glycine uptake systems in the newborn and the adult Sprague-Dawley rat. Roth and associates[13] reexamined glycine transport in isolated rat tubule segments, and Reynolds and colleagues[14] reexamined glycine transport in the cortex slice. Both groups of investigators found high- and low-affinity uptake systems in newborn and adult renal tissues. However, the efflux of glycine from rat cortex slides[12] or from isolated rat tubule segments[13] was slower in the newborn than in the adult. These data, along with work reported by Meadow and colleagues,[15] suggest that slowed efflux is an important determinant of intracellular amino acid pools and therefore of transepithelial transport in the newborn.

Cystine is another amino acid whose fractional excretion is higher in the immature animal and in the human neonate. Studies with cystine have shed light on additional aspects relevant to amino acid transport. Hwang and colleagues[16] and Foreman and colleagues[17] documented the presence of two transport systems for cystine (high-affinity, low-capacity, and low-affinity, high-capacity). In the report by Foreman and colleages,[17] the affinity

for cystine was actually *higher* in the newborn infant than in the adult, but the V_{max} (capacity) was much lower. This could clearly lead to a decrease in renal cystine reabsorption. These authors further commented on the metabolic potential of the neonatal proximal tubule. Cystine is reduced intracellularly to cysteine. In their studies, tubules from the immature kidney metabolized cystine just as readily as did those from adult kidneys. Therefore, at least for cystine (and perhaps other intracellularly metabolized amino acids), the explanation for developmental aminoaciduria does not rest with an altered intracellular metabolic process. In the same study, Foreman and colleagues[17] investigated the effect of lysine on cystine transport. Lysine inhibited the high-affinity system in the immature kidney tissue just as it did in tissue from adult animals. These data suggest that the properties of shared transport for cystine and dibasic amino acids (lysine, ornithine, citrulline) are intact even in the newborn. This group of studies points to the luminal brush-border membrane as another important site responsible for developmental aminoaciduria (see Figure 131-1).

A structure-function analysis of amino acid transporters has resulted in classification of transporters into four genetic families:

1. *GAT* family: Na^+- and chloride-dependent transporters
2. *CAT* family: Cationic amino acid transporters
3. Glutamate transporters
4. *rBAT* family: Cationic-neutral amino acid transporters

Further follow-up of these gene families has demonstrated two different membrane protein structures. *GAT, CAT,* and glutamate families have multiple transmembrane domains and are considered carriers, whereas *rBAT* family members are considered activators or part of oligomeric carriers. These findings raise an interesting question regarding maturation of amino acid transporters. No information is yet available on the maturation of these transport systems.[18,19]

Chesney and Jax[20] studied the ontogeny of the transport system for the β-amino acid taurine in the rat. Using dietary alterations to help uncover the adaptive response of the kidney to taurine, most of these investigations focused on the brush-border membrane vesicle. The results of these studies can be summarized as follows:

1. Thin renal cortex slices from young rats demonstrated greater accumulation of taurine than did cortical slices from adult rats. This observation is especially striking considering that urinary excretion and fractional excretion of taurine during the first 28 days of life in the rat are much greater than those of the mature rat.[20]
2. Studies with cortical slices and proximal tubule segments revealed two transport systems—a high-affinity, low-capacity system and a low-affinity, high-capacity system.[21-23] Thus maturation of a specific transport system could not explain the developmental taurinuria present in the young mammal.
3. Experiments using brush-border membrane vesicles (isolating the apical portion of the proximal renal tubule) revealed no difference in transport kinetics between the adult and the still-maturing 28-day-old rat.[24,25]
4. In dietary alteration studies in which the mother was fed a low-, normal-, or high-taurine diet, taurine excretion in the 14- and 21-day-old pup mirrored dietary intake in the mother. With a low-taurine diet in the mother, urinary excretion of taurine was reduced in the 14- or 21-day-old pup. A similar positive correlation was seen with a high-taurine diet.[26]
5. This adaptation to dietary intake was reflected in the brush-border membrane, with an increase in V_{max} seen at the brush-border membrane during low dietary taurine intake. This adaptation was observed in rats ranging in age from 14 days to maturity.[25-28]
6. A plausible explanation for the finding of developmental taurinuria (but similar transport kinetics between young [≥14 days] and mature animals) is that efflux from the proximal tubule cell is diminished in the maturing animal (see *site 3* in Figure 131-1), thereby resulting in an increased backleak of amino acid into the tubule lumen and into the urine.
7. Total taurine accumulation was lower in brush-border vesicles prepared from 7-day-old rats compared with any other age studied (14-, 21-, 28-day-old or mature 60-day-old rats). Further, no dietary influence on taurine uptake could be demonstrated in 7-day-old pups. These findings suggest that, in the most immature animal, the developmental aminoaciduria observed may in part result from diminished uptake across the brush-border membrane and not just diminished efflux across the basolateral membrane.[27]

Amino acids are transported across the renal epithelium primarily by NaCl cotransport systems.[29] Studies examining proline transport in experimental animals revealed a reduced uptake of proline in the immature animal and a less pronounced characteristic uptake pattern in the immature animal, attributed to differences in Na^+ permeability and Na^+-K^+ exchange activity in the immature versus the mature animal.[30,31] A faster or higher accumulation of Na^+ would more quickly dissipate the extracellular-to-intracellular Na^+ gradient, thereby reducing the driving force for Na^+-dependent transport, such as amino acid transport. In this way, amino acid accumulation by the renal epithelium of the very young rat could be diminished. Such a hypothesis could explain the aminoaciduria, diminished brush-border vesicle accumulation of amino acids, and failure of the brush border to demonstrate an adaptive response to a dietary deficiency.

Protein phosphorylation has been proposed as a controlling factor for amino acid transport. Intracellular protein kinases, including protein kinase A, protein kinase C, and calcium calmodulin–dependent protein kinase, have been shown to modulate amino acid transport. Studies by Zelikovic and associates[32-34] showed that exogenous and endogenous calcium-dependent protein kinases inhibit proline uptake in brush-border membrane vesicles and differential regulation of calcium-dependent and calcium-independent protein kinase C isoenzymes exists during development.[32-34] Together, these data point to a role for age-related changes in calcium-dependent protein kinases and their differential regulation during development in the maturation of renal amino acid transport.

Overall, studies in the developing animal point to maturational events at both the brush border and basolateral membrane that are necessary for the efficient reabsorption of amino acid seen in the adult mature animal. At present, the two most likely explanations are diminished efflux at the basolateral membrane leading to backleak into the tubule urine (see *site 3* in Figure 131-1) and diminished apical transport in the most immature animals (see *site 1* in Figure 131-1). Of course, questions remain: Is there a qualitative, generalized membrane difference that could explain developmental aminoaciduria? What is the maturational signal?

The interest in developmental amino acid transport is not merely the study of a fascinating biologic question. Geggel and associates[35] reported abnormal retinograms and low plasma taurine levels in infants receiving long-term taurine-free parenteral nutrition. More recently, Zelikovic and colleagues[36] reported that low-birth-weight infants receiving total parenteral nutrition can become taurine depleted, in part because of immaturity of the reabsorptive function of the proximal tubule. For some amino acids, such as taurine, the kidney may be the major regulator of that amino acid's body pools. With immaturity (developmental aminoaciduria), the kidney may not be able to adapt sufficiently during periods of deficient intake, and body stores of certain amino acids will be depleted. This could lead to important growth and maturational effects.

Much has been learned[37] and much remains to be learned, but the studies to date of developmental renal amino acid transport suggest that at least two aspects of transport across the proximal tubule undergo change in the postnatal period: efflux from the tubular epithelial cell increases with age and transport across the apical membrane into the tubular epithelial is lower in the infant compared with the adult. Future study should delineate the exact membrane changes that underlie this developmental change.

Developmental Aspects of Organic Acid Transport

Renal tubular capacity for organic acid secretion undergoes prenatal and postnatal maturation, as do glomerular filtration and other tubular functions. Organic acids include endogenous compounds, such as uric acid, hippurate, and prostaglandins, as well as many exogenous xenobiotics (Box 132-1). Because many drugs are secreted by the organic acid transporter, the development of this system is important. Studies of the developmental aspects of renal organic anion transport primarily have concentrated on renal tubular transport of para-aminohippurate (PAH), the standard substrate for clearance studies. The original developmental studies of organic anion transport often use the tissue slice technique. In this method, the uptake of radiolabeled compounds into tissue slices can be quantified and expressed as a slice-to-media (S-M) ratio. Because the patterns of postnatal development of renal organic acid secretion may differ among species, care must be exercised in generalizing findings of animal models to humans.

ORGANIC ACID TRANSPORT

Organic acids (or anions), such as PAH, are secreted by the proximal tubule. The net direction of movement is from the basolateral (blood side) membrane of the proximal tubular cell and then out into the proximal tubular fluid. The relative magnitude of organic

BOX 132-1

Example of Common Organic Acids Secreted by the Proximal Tubule

Exogenous Acids
- Furosemide
- Thiazides
- Acetazolamide
- Antimicrobials–β-lactam
  - Penicillins
  - Cephalosporins
- Azidothymidine
- Salicylates
- Indomethacin
- Probenecid
- Iodinated contrast media
- Morphine
- Methotrexate
- Losartan

Endogenous Acids
- Uric acid
- Hippurates
- Oxalate
- Prostaglandins
- Bile salts
- Benzoates
- Cyclic adenosine monophosphate
- Folate

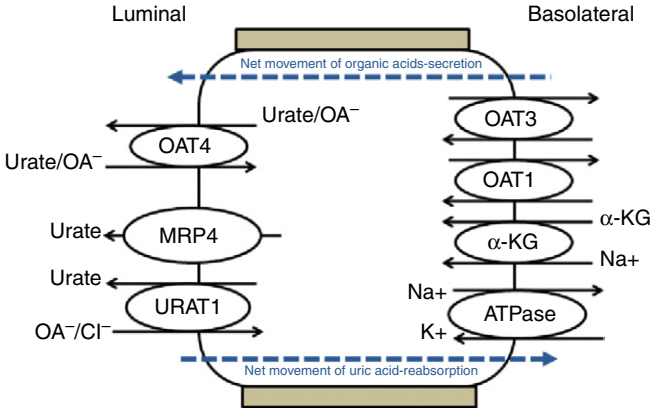

Figure 132-1 Schematic representation of organic acid and uric acid transport by the renal proximal tubular cell. Basolateral systems include the anion exchangers *OAT1* and *OAT3* that exchange organic acids *(OA)* or uric acid for alpha-ketoglutarate *(α-KG),* which is exchanged for sodium by the sodium dicarboxylate cotransporter (NaDC3). Although net movement may be bidirectional, secretion occurs as substrates are extracted from blood down the chemical concentration gradient of sodium. Apical systems include *OAT4,* which exchanges organic acids or uric acid for anions. Addition luminal transport systems for uric acid include the secretory pathway of *MRP4* and the bidirectional exchanger *URAT1.*

acid transport along the proximal tubule segments (S1, S2, and S3) is species specific.[1] PAH secretion is accomplished by two basic steps: at the basolateral membrane, exchange of extracellular organic anions with α-ketoglutarate (OAT1 and 3) allows the transport of substrate against a concentration gradient. Basolateral transport of PAH is indirectly dependent on basolateral sodium because of the coupling of PAH transport to a dicarboxylic acid–Na^+ cotransporter.[1] The latter cotransporter relies on the Na^+,K^+–adenosine triphosphatase (ATPase)–generated Na^+ gradient (Figure 132-1). Once inside the proximal tubular cell, PAH exits the cell in exchange for an anion at the luminal membrane by the organic anion–OH^- antiporter (URAT1), a transport system shared with urate.[1] Additional efflux mechanisms for PAH secretion include MRP4 and OAT4.

The SLC family of organic anion transporters (OAT) includes numerous isoforms.[2,3] There is structural homology of the OAT family of transporters with the organic cation transporters (OCT) and the uric acid transporter, URAT1. Substrates are shared between the two systems: verapamil, clonidine, cimetidine, cortisol, and aldosterone. OAT1 (SLC22A6) and OAT3 (SLC22A8) are localized to the basolateral membrane and OAT4 (SLC22A11) to the apical membrane of the proximal renal tubule. OAT1 is the classic PAH-dicarboxylate exchanger elucidated by physiologic studies.[3] Although the two homologues share substrates, they are distinct: OAT3 does not demonstrate significant affinity for PAH yet has a high affinity for estrone sulfate, whereas the opposite is true for OAT1. These transporters are exchangers that are part of a tertiary transport system, working in parallel with the sodium-dicarboxylate cotransporter (NaDC3) and the Na^+,K^+–ATPase.

Developmental expression of messenger RNA for each OAT isoform has been studied in the rat and sheep. Renal cortical expression OAT1 was primarily localized to the kidney and reached adult levels by day of life 30.[4] Recent studies in the mouse indicate that there is a tendency for expression of organic anion transporters to increase during fetal development with the largest fold increase occurring between the immediate postnatal to mature stages.[5,6] In the ovine model, which is more similar to humans than is the rat, renal cortical expression of OAT1 and OAT3 was present in early gestation but was relatively low until late gestation when parallel increases in both were observed before birth.[7] One theory proposes that a preparturient rise in fetal cortisol levels might stimulate transcription of OAT1 and OAT3.[8] The effect of premature birth on the activity of these transport systems is unknown.

The ability of the kidney to produce a concentration gradient of organic anions is present in early gestation. Both mesonephros and metanephros of the developing chick are able to accumulate PAH.[9] Organic acid transport of the chick mesonephros peaks as early as 9 days after fertilization and then begins to decline by 17 days, when the metanephros displays significant PAH accumulation. Uptake of ^{3}H-PAH in tissue slices from fetal mice increases from 24% of adult values in 16-day-old fetuses to 79% in 19-day-old fetuses.[7] Organic cation transport has a different pattern of maturation, occurring later. Maximal PAH-concentrating ability peaks before that of organic bases or tetraethylammonium (TEA, the standard substrate) in both the mesonephros and the metanephros of the chick embryo. Similarly, the uptake of radiolabeled TEA into tissue slices is only 24% of adult values in 19-day-old fetal mice, whereas PAH is 79% of adult values. The contrasting patterns of development between the organic cation and anion transport systems was also demonstrated in gene expression studies in which the cation transporter OCT1 and OAT2 were late events.[5]

Studies performed in newborn humans,[10] dogs,[11] and rats[12] demonstrate a gradual increase in renal extraction of PAH with age. When PAH transport is examined by using renal tissue slices from rabbits, S-M ratios peak at approximately 150% of adult values by 1 month of age and then decline to values similar to those in adults by 3 months of age. Both clearance and renal extraction of PAH are reduced in human infants and neonates. Calcagno and Rubin[10] found PAH extraction and clearances in infants 3 months of age and younger to be approximately 30% lower than values in older children. Postnatal maturation of PAH clearance

and extraction has been found in most animal species studied. In the neonatal puppy, clearance studies indicate that the maximal tubular transport of PAH gradually increases by ten-fold over the first 8 weeks of life, although values are still reduced compared with those in adult animals.[13] Parallel studies, using the tissue slice technique, demonstrated a rather dramatic peak in the S-M ratio of PAH at 4 weeks of age, after which the S-M ratio declined to adult values over the next several weeks. Kim and colleagues[14] found S-M ratios for PAH to be 3.23 ± 0.27 in tissue slices from 2-day-old rats compared with 6.93 ± 0.337 in 10-day-old rats and 4.94 ± 0.28 in 14-day-old rats. By 20 days of age, S-M ratios were still less than adult levels.

This apparent discrepancy between in vivo and in vitro findings may be explained by the somewhat artificial nature of the slice method, as well as the possible contributions made by maturational differences in PAH efflux and protein binding. Cole and co-workers[15] found different maturational patterns in PAH uptake, efflux, and ligandin binding. Consistent with previous reports, intracellular-media PAH ratios in rabbit cortical slices gradually increased up to 4 weeks of age, at which time the ratio exceeded levels in adults and then declined to adult values by 10 weeks of age. The rate of ^{14}C-labeled PAH uptake reached adult values by 4 weeks of age and was maintained at adult levels from 6 to 10 weeks to adulthood. Efflux of PAH in fetal, 2-week-old, and 4-week-old rabbits was lower than in adult animals and attained adult levels by 6 weeks of age. In addition, ligandin levels were lower in immature animals and gradually increased with age. Thus developmental patterns of PAH transport, observed in vitro, may be the result of the sum of changes in efflux and transport, as well as the fraction of protein-bound PAH at a given age.

Enhancement of PAH transport occurs when organic acids (substrates for the transport system) are administered to animals before the time of study. In rabbits, the S-M ratios of PAH increase from birth to 4 weeks of age, then gradually decline to adult levels.[16] When procaine penicillin was given to 2- and 4-week-old rabbits for 3 consecutive days, PAH transport increased in the 2-week-old animals but not in the 4-week-old animals, suggesting that administration of organic acids to immature animals may induce maturation of the tubular transport process.[16] In addition, when pregnant animals received daily procaine penicillin during the last half of their pregnancy, S-M ratios of PAH in the offspring were markedly increased when compared with those in age-matched controls during the first 2 postnatal weeks, after which time values were equal to those in controls.[16] Subsequent studies have corroborated these findings.[17,18] Species-related or compound-related differences may exist in the response to organic acid exposure. Stopp and Braunlich[18] failed to induce increases in PAH transport after treatment of neonatal (5 day old) rats with sulfamethoxypyridazine, cyclopenthiazide, and phenobarbital, although 2-week-old rabbits did exhibit increases in PAH transport after administration of these compounds.

In vivo administration of thyroxine (T_3) enhances PAH uptake into cortical tissue slices from weanling rats without affecting PAH uptake of adult slices.[15] Other investigators have found conflicting responses of PAH secretion to T_3. Braunlich[19] demonstrated that T_3 stimulates PAH transport in both 10- and 30-day-old rats (Figure 132-2). The stimulatory action of T_3 on PAH transport can be prevented by the simultaneous administration of inhibitors of protein synthesis. One may conclude that the effect of T_3 on PAH uptake is dependent on protein synthesis (possibly reflecting synthesis of new transporters) and that pharmacologic, rather than physiologic, doses are required to stimulate PAH transport.

Kinetic analysis of age-related changes in PAH transport in tissue slices has revealed that transporter affinity (K_m) for PAH remains constant at 0.50 mmol/L, whereas the maximal PAH uptake increases as a function of age.[18] The stimulatory effect of organic anions on renal tubular secretion of PAH during early development is related to their ability to increase the maximal transport capacity for PAH rather than to an effect on K_m.[20] No detectable effect on efflux appears to occur. It is speculated that de novo synthesis of transporters occurs both with maturation and after the exposure to organic acids.

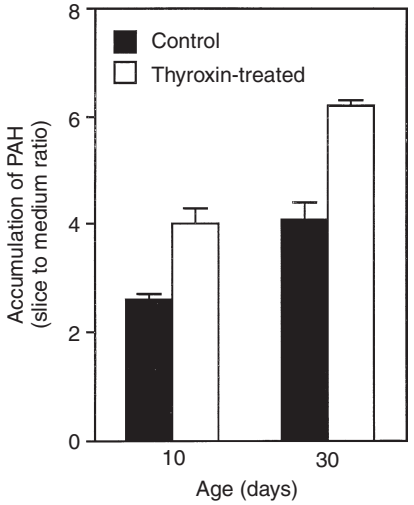

Figure 132-2 Effect of thyroid hormone treatment on PAH accumulation by renal cortical slices from 10- and 30-day-old rats. *(Modified from Braunlich H: Hormonal control of postnatal development of renal tubular transport of weak organic acids,* Pediatr Nephrol *2:151, 1988.)*

Rapid renal growth, as well as the possibility of postnatal nephrogenesis in some species, could explain some of the maturational changes observed in PAH secretion. Schwartz and colleagues[21] measured PAH uptake in isolated cortical tubules from 8- and 16-day-old rabbits. Transport capacity was then standardized for tubule length. An almost five-fold increase in transport capacity was observed in the older animals. Although tubular elongation might explain a fraction of the increasing transport of PAH observed with maturation, acquisition of transport sites was the major factor. Additional studies revealed that penicillin pretreatment increases intrinsic transport capacity by 89%.

Age-related changes in organic anion excretion result from increases in intrinsic renal tubular transport capacity and, to a lesser extent, increases in glomerular filtration and renal blood flow. Exposure to similar organic compounds stimulates the immature renal tubule to enhance transport, probably by increasing the density of transporters. Many drugs, such as antibiotics and diuretics, are secreted by the organic anion transport system. The newborn is less able to eliminate drugs when their elimination is dependent on renal tubular secretion.[22] Continued administration of some drugs, however, such as the penicillins, to the developing kidney may result in alterations of drug clearance via the mechanism of substrate stimulation. Such changes might require modification of drug dosage or dosing interval.[23] In addition, PAH clearance is not a reliable estimation of renal plasma flow in the newborn animal because of the reduced tubular secretion observed with immaturity.

URIC ACID TRANSPORT

Uric acid (or urate) is freely filtered at the glomerulus; however, a wide variation in urate handling has been observed in different species.[24,25] For example, in the monkey, human, rat, and mongrel dog, the fractional excretion of urate is less than 100%, indicating

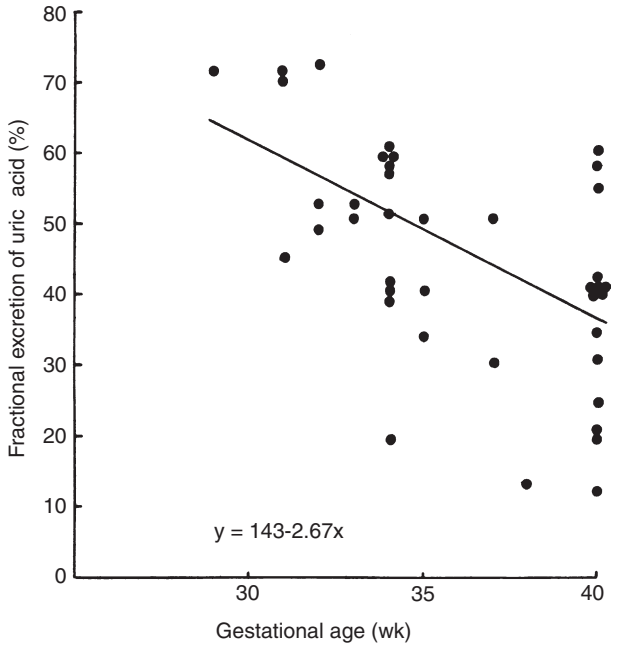

Figure 132-3 Fractional excretion of uric acid during the first day of life in infants according to gestational age. *(From Stapleton FB: Renal uric acid clearance in human neonates,* J Pediatr *103:290, 1983.)*

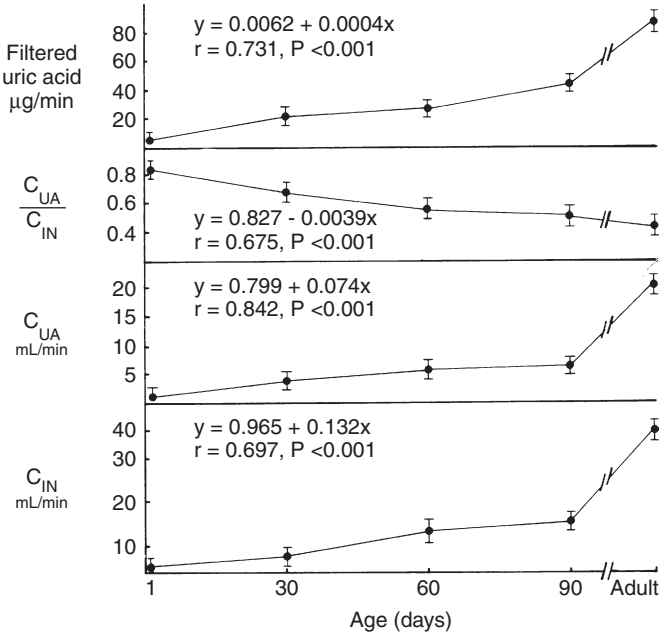

Figure 132-4 Patterns of renal clearance of uric acid and inulin in mongrel puppies during early development are compared with values in adult dogs.

net reabsorption. In other species, such as the rabbit and pig, urate excretion is greater than the filtered rate, which is indicative of net secretion. Species-dependent differences in net urate excretion and the parallel presence of both secretory and reabsorptive processes along the proximal tubule make characterization of the precise mechanisms of urate transport elusive.

The net reabsorption of urate across the proximal tubular epithelium involves an increasingly recognized number of transport systems. Only the major ones will be discussed here; for a more in-depth review, the reader is referred the work of Buist and colleagues.[4] There are three main transporters found on the luminal membrane: the anion exchange transporter, URAT1 (SLC22A12); the organic acid antiporter, OAT4 (SLC22A11); and the multidrug resistance protein, MRP4 (ATP-binding cassette family, ABCC4).[24] URAT1 transports urate in exchange for Cl or organic anions to achieve net reabsorption from the tubular lumen; this process is inhibited by uricosuric agents such as probenecid and losartan.[24] OAT4 reabsorbs urate in addition to organic acids via exchange with dicarboxylates, a process inhibited by hydrochlorothiazide. As a secretory pathway, MRP4 requires ATP to pump urate out of the cell and into the tubular lumen. Basolateral mechanisms for urate transport include OAT1 and OAT3, discussed previously in the section on organic acids. These transporters move urate from the basolateral or blood side into the proximal renal tubular cell.

Details regarding the maturational pattern of uric acid transport are limited. Clearance studies have been performed in humans and mongrel puppies. Newborns have higher serum uric acid levels, as well as elevated urinary urate excretion. As a rule, uric acid clearance increases and fractional excretion decreases during childhood.[26] Values for the fractional excretion of urate in 3- to 4-day-old term newborns were 20% to 59% compared with 13% to 26% in older infants up to 1 year of age and 11% to 17% in children aged 1 to 7 years. When fractional excretion of uric acid was examined during the first 24 hours of life in newborns of differing gestational ages, mean fractional excretion was 61.24% ± 12.21% in infants of 29 to 33 weeks gestation, 44.52% ± 15.23% in neonates of 34 to 37 weeks gestation, and 38.19% ± 13.61% in term infants (Figure 132-3).[27] Serum uric acid levels and uric acid clearances were not significantly different among infants of differing gestational age.

In the mongrel dog, plasma uric acid decreases with age in a manner similar to that in humans. Stapleton and Arant[28] demonstrated that the clearance of uric acid increased and fractional excretion of uric acid decreased as a function of postnatal age (Figure 132-4). Uric acid clearance increased from 0.39 mL/minute at 1 day of age to 3.72, 5.54, and 6.3 mL/minute at 30, 60, and 90 days of age, which is still lower than the adult value of 20.16 mL/minute. At 1, 30, 60, and 90 days of age, the fractional excretion of urate was 83%, 69%, 57%, and 51%, compared with the adult value of 44%. A decreased fractional excretion of urate in the face of an increased filtered load can be explained by either increased reabsorption or decreased secretion with increasing age. Studies done to date have not answered this question; however, the net reabsorption of urate in the mongrel dog increased from 0.2 µg/minute at 1 day of age to 8.8, 11.9, and 22.2 µg/minute at 30, 60, and 90 days. Adult animals exhibited a net reabsorption of urate of 39 µg/minute.[27]

Urate uptake has been measured by using tissue slices obtained from fetal and newborn mice.[29] Accumulation of ^{14}C-labeled uric acid by slices from 16-day fetuses was 49% of adult levels and increased to 79% of adult values at 19 days gestation. At the postnatal age of 1 day, a transient decline in urate accumulation to 58% of adult values was observed; however, urate accumulation increased to 70% of adult values by 7 to 8 postnatal days.[29] This developmental pattern was similar to that observed for PAH. In contrast to PAH, however, uric acid uptake into renal cortical slices is not enhanced by pretreatment of neonatal animals with acetate or procaine penicillin.[22]

The mechanisms responsible for the increase in net tubular urate reabsorption associated with maturation are not fully understood. One might anticipate that nonspecific cellular events, as well as increased transport capacity of either or both luminal and basolateral transport systems for urate, could account for the decrease in fractional excretion with increasing age; however, these events have yet to be characterized by kinetic or molecular studies.

Concentration and Dilution of the Urine

PHYSIOLOGY OF THE URINARY CONCENTRATING MECHANISM

The ability to concentrate and dilute the urine greatly expands our range of habitable environments. To accomplish this, the mammalian kidney must deliver sufficient solute to the medulla, establish a solute gradient that increases from cortex to papilla, preserve the gradient despite its tendency to dissipate from continuous flow of blood, and stimulate or suppress reabsorption of water as needed. A solute gradient can develop because membranes of tubule segments as well as microvessels have varying solute permeability characteristics. When a solute gradient is established, water movement from tubule lumen toward the interstitial gradient depends largely on the tubular response to antidiuretic hormone (ADH, vasopressin) and the anatomic integrity of the tubulovascular structures (Figure 133-1). Because fluid is reabsorbed isotonically in proximal tubules and is not concentrated in distal convoluted tubules, major steps in the concentrating process involve events occurring in the loops of Henle and collecting tubules. A vital site of active salt transport occurs at the thick ascending loop of Henle; deeper nephron segments can move solute and water passively, thereby facilitating conservation of energy. The actual process of urinary concentration requires the presence of ADH and occurs in collecting ducts where water is avidly reabsorbed down an osmolar gradient generated initially by active salt reabsorption in the thick ascending limb of Henle. Good reviews with detailed discussion and extensive references on the urinary concentrating mechanism are available.[1]

Development of the Medullary Gradient

Several processes illustrated in Figure 133-2 occur simultaneously, but it is convenient to start a discussion of the concentrating mechanism at the thick ascending limb of Henle in the outer medulla.[2-4] This segment has a very low hydraulic conductivity, but it can reabsorb NaCl in the relative absence of water (reabsorbs hypertonic NaCl). The result is dilution of fluid remaining in the tubular lumen and an increase in the interstitial concentration of NaCl surrounding the thick limbs and collecting ducts. Isotonic fluid from the proximal tubule enters the descending loop of Henle at the level of the outer medulla and is exposed to the increased interstitial osmolality. Descending loop segments have a high hydraulic conductivity, but a low sodium permeability. As a consequence, water in the descending limb moves osmotically into the interstitium, and fluid in the lumen of this segment becomes more concentrated.

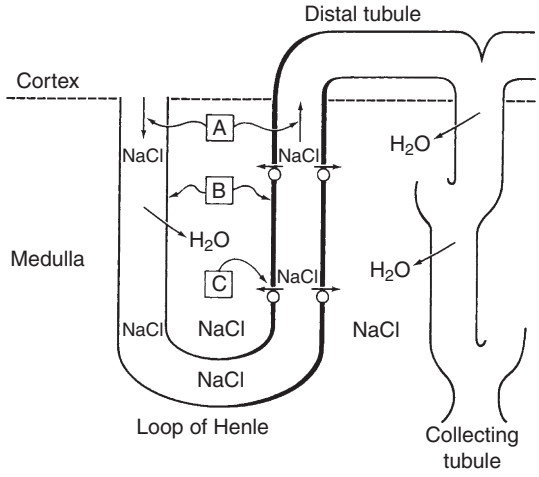

Figure 133-2 The countercurrent movement of water and solutes between the loops of Henle and the collecting tubule. Heavier lines of the ascending thin limb in the inner medulla and of the ascending thick limb in the outer medulla depict impermeability to water. NaCl is actively reabsorbed from the thick limb, diluting urine and increasing osmolality of the outer medulla (1). Water reabsorption continues in the distal tubule and the cortical and outer medullary collecting duct, leading to increased urea concentration (2). Water and urea are reabsorbed from the inner medullary collecting duct (3). Urea accumulates in the interstitium, osmotically abstracts water from the descending limb, and allows NaCl concentration *(A)* in descending limb fluid to increase and *(B)* in interstitium to decrease (4). The thin ascending limb is permeable to NaCl and receives fluid rich in NaCl. NaCl enters the interstitium down its concentration gradient, and urine becomes hypoosmotic to the surrounding interstitium (5). See text for details. *(Reprinted by permission of the* New England Journal of Medicine: *Jamison RL, Maffly RH: The urinary concentrating mechanism.* N Engl J Med *295:1059, 1976.)*

Urine, flowing through the thick ascending limb, becomes progressively dilute by virtue of the relative impermeability of this segment to water and then enters the distal convoluted tubule, a cortical segment in which water and salt reabsorption and equilibration with blood produce a largely isotonic urine entering the outer medullary collecting duct. In a hypertonic outer medulla, water is osmotically removed from the tubule lumen, and solutes in the collecting duct become increasingly concentrated. Urea movement in distal tubules is limited, but water reabsorption is substantial, so cortical collecting tubules receive urine with a high urea concentration. This segment has low urea permeability both in the presence and absence of ADH, so a high urea concentration is maintained in urine entering the outer medullary collecting duct. The outer medullary collecting duct has a low permeability to sodium and urea and is not thought to transport NaCl actively. This segment probably does not contribute to the high interstitial salt content, but its water permeability is high in the presence of ADH.

Vasopressin also stimulates NaCl reabsorption by the medullary thick ascending limb, thereby increasing NaCl content in the outer medullary interstitium.[5-7] This latter step may help counteract the dilution of interstitial NaCl that follows when ADH induces water reabsorption from the outer medullary collecting duct. The net effect of ADH is to increase the osmotic driving force and subsequent reabsorption of water as urine from the collecting tubule traverses the outer medulla. The high water and relatively low urea permeability cause urea to become a dominant solute in the outer medullary collecting duct. The outer medullary interstitium contains relatively little urea, but a significant amount of NaCl reabsorbed from the ascending thick limb. A high luminal urea concentration can drive water toward the tubule lumen. Conversely, a high interstitial NaCl concentration can drive luminal fluid to the interstitium.

Although osmolality is equal across the collecting duct epithelium, the net driving force favors water reabsorption from the lumen because NaCl has a higher reflection coefficient than does urea and exerts a more effective osmotic pressure.[8] This further increases urea concentration in urine entering the inner medullary collecting duct. In contrast to the more proximal collecting duct, the inner medullary collecting duct is permeable to urea in the presence of ADH.[6,7] Vasopressin also increases the permeability of this segment to water, although urea and water may traverse different channels.[9]

Urea diffuses down a chemical gradient to enter the medullary interstitium. Urea can also enter the descending limb, and its concentration actually rises in this segment. Accumulation of urea in the interstitium provides an osmotic driving force that further abstracts water from medullary portions of the descending loop. This increases the luminal concentration of NaCl and

urea. The water leaving the descending loop dilutes interstitial NaCl. When urine flows through the bend of the loop and enters the thin ascending limb of Henle, the high NaCl concentration in this segment is exposed to an interstitium of similar osmolality but now lower NaCl concentration; the remainder of the osmolar concentration is composed mainly of urea. The thin ascending limb has a low hydraulic conductivity, a high NaCl permeability, and a moderate permeability to urea[10]; NaCl can thereby diffuse down its concentration gradient into the interstitium whereas, water tends to remain in the lumen.

The urine begins to become progressively less concentrated, and NaCl accumulates in the interstitium. The presence of this added interstitial NaCl abstracts more water from urine in the inner medullary collecting duct as this segment courses through the interstitium, a step that further concentrates the final urine. In addition, urea can re-enter the lumen of thin ascending limbs to recycle back to the collecting tubule.

Although the hypertonic medulla provides the driving force for water reabsorption and urinary concentration, it is noteworthy that cells in the renal medulla are under considerable osmolar stress from the hyperosmolar state. The major solutes are urea and salt, the latter capable of damaging cellular DNA and causing cell death when salt concentration is sufficiently high. The medullary cells adapt by synthesizing and accumulating relatively nonpermeant organic solutes. A regulatory protein, tonicity-responsive enhancer binding protein, stimulates genes to produce proteins that transport or synthesize the protective organic osmolytes.[11,12]

Role of Short-Loop Nephrons and Urea

Recycling of urea (to maintain a high medullary urea content) is critical for maximal efficiency of the concentrating process and is facilitated by short-looped nephrons that do not descend deep into the inner medulla.[13,14] These nephrons reabsorb a large portion of filtrate, reducing the volume of fluid and solute that needs to be concentrated. Short-looped nephrons also exhibit permeability and anatomic characteristics that place them in good position to receive urea and facilitate its recycling to the inner medulla.[5] For example, in the rat, urea permeability of thin limbs is greater in short-looped than in long-looped nephrons. Moreover, in contrast to long-looped nephrons, short-looped thin descending limbs run within vascular bundles and are closely apposed to vasa rectae that ascend from the inner medulla and contain blood with increased amounts of urea.

The intertubular recycling of urea is thought to be accomplished through three major routes (Figure 133-3). First, urea in the ascending thin limb can remain in the tubule lumen, travel through the distal nephron to the collecting ducts, and then recycle to the interstitium. Second, urea in thin ascending limbs can reach the thick ascending limb, a segment that, in the outer medulla, is permeable to urea and is in close relationship to proximal straight tubules (and therefore descending limbs) of both long- and short-loop nephrons. At this site, urea can return to the inner medulla directly via proximal straight tubules and descending limbs of long-loop nephrons, or it can cycle through loops and collecting ducts of short nephrons to re-enter the medulla. Third, urea can leave the inner medullary interstitium through ascending vasa rectae and re-enter descending limbs of short-looped nephrons. This urea can similarly be carried back through superficial distal nephrons and transported to collecting ducts in the inner medulla.

Urea transfer from vasa rectae to short nephron descending limbs is likely facilitated by the anatomic proximity of these structures in vascular bundles of the inner stripe of the outer medulla. The solute delivered to deep thin ascending limbs of the inner medulla can recycle to maintain a continued presence of deep medullary solute. The solute helps concentrate fluid in the descending limbs of long-looped nephrons and is available to enhance movement of water from the collecting duct before the urine reaches the renal pelvis and ureter. The importance of urea transport in this process is underscored by the presence of urea transporters located in endothelial cells of medullary descending vasa rectae[15] and the ability of ADH to induce insertion of urea transporters in the luminal membrane of the inner medullary collecting duct.[16,17] An additional important site of urea transfer is from ascending to descending vasa rectae (see later discussion).

The role of urea is complex. Urea had been thought to cross cell membranes solely by passive diffusion, but rapid urea transport rates in some tissues suggested a facilitative transport mechanism. As reviewed recently,[18] several urea transporter isoforms (UTs) derived from the UT-A gene have been identified in renal tissue that can facilitate transmembrane movement of urea. These transporters may serve different functions. UT-A genes express medullary proteins in inner medullary collecting ducts and thin descending limbs of Henle. UT-A1 and UT-A3 are restricted to the terminal portion of the inner medullary collecting duct. UT-A2 is localized in the lower part of thin descending limb of short-loops of Henle in the inner stripe of the outer medulla, but also in the thin descending limb of long-loop nephrons in the inner medulla under more prolonged antidiuretic conditions. These transporters can help generate the hypertonic medulla. Thirsting increases levels of UT-A2 protein, a response mediated by ADH. Rapid movement of urea actually may serve to dissipate a transmembrane osmotic urea gradient.[19-21] By contrast, the UT-B gene produces a transporter protein located in endothelial cells of medullary descending vasa recta that allows urea leaving the ascending vasa recta to re-enter the descending vasa recta, become "trapped" in the medulla, and maintain a high medullary urea concentration. It is interesting that the UT-B1 transporter protein is down-regulated by ADH. This may represent a metabolic adaptation to reduce the need for urea transport and allow for reduced urea synthesis in descending medullary vasa recta endothelial cells. It could serve either to favor nitric oxide over urea synthesis (for vasodilation and improved nutrient delivery) or to limit urea production in endothelial cells when a very high inner medullary content of urea is already present.[22,23]

Fenton and Knepper[18] have summarized several interesting experiments with knockout mice designed to clarify aspects of

the concentrating mechanism. According to this model, during antidiuresis, water is reabsorbed in the cortical collecting duct, a segment poorly permeant to urea. The increased urea concentration in urine reaching the urea permeable medullary collecting duct favors movement of urea to the medullary interstitium. The nearly equal concentration of urea across the medullary collecting duct membrane, as proposed by Berliner and colleagues[24] more than 50 years ago essentially eliminates any tendency for urea to cause an osmotic diuresis. The high interstitial urea content helps draw water from the descending loop of Henle into the interstitium, concentrating the NaCl in the loop and diluting the NaCl in the interstitium. As urine enters the medullary thin ascending loop of Henle, a segment not thought to transport NaCl actively, the surrounding interstitial milieu has drawn water from the descending limb by virtue of the high urea content. The now lower concentration of interstitial NaCl favors movement of NaCl from the ascending limb, and perhaps also from the medullary collecting duct. Accordingly, one would expect that if UT-A1 and UT-A3 in the inner medullary collecting duct were nonfunctional, a urea-induced osmotic diuresis would occur. This was tested in knockout mice with no functional UT-A1/A3 transporters on different protein intakes.[25] When these animals with free access to water were placed on a high protein intake, their urine volume and fluid intake was high and urine osmolality was low compared with controls. When they were water restricted, the mice could not reduce their urinary output or increase urine osmolality and became volume depleted. On a low protein intake, where urea production is low, no polyuria or change in osmolality was observed when given access to water, and when water was restricted no difference was observed in urine flow or osmolality between control and UT-A1/A3–deficient animals. Moreover, compared with control mice, knockout mice had essentially identical inner medullary concentrations of Na^+, Cl^-, and K^+, but the knockout mice showed a substantial decrease in urea concentration. These data were interpreted to indicate that a concentrating defect in animals devoid of inner medullary collecting duct urea transporters was mainly the result of a urea-dependent osmotic diuresis. In further studies,[26] an attempt was made to test the relationship between urea transport in the inner medulla as a factor helping generate an increase in interstitial NaCl (see previous discussion). It would be predicted that knockout mice devoid of functional UT-A1/A3 would have impaired ability to concentrate NaCl in the inner medulla because urea movement would not be increased into the medulla from the medullary collecting duct to induce water flow from the descending thin limb that in turn would facilitate reabsorption of NaCl from the ascending limb. Experiments were performed in mice on low, normal, and high protein diets. Compared with control mice, those devoid of UT-A1/A3 had a progressive increase in water intake and urine flow with increasing protein intake but had no increase in urine osmolality. In additional studies, mice were subjected to either a low or high protein diet and measurements were made of the osmolality, urea, and Na^+ concentrations in the cortex, outer medulla, and two levels within the inner medulla. In control mice, increasing protein intake from 4% to 40% led to a dramatic increase in corticomedullary osmotic gradient, related primarily to an increasing corticomedullary urea concentration. By contrast, in knockout mice, no appreciable change in corticomedullary osmolality or urea gradient on either diet was observed, and, on the high protein diet, the inner medullary osmotic and urea content were markedly reduced. However, no differences were seen between controls and knockout mice in the Na^+ concentrations from cortex, outer medulla, or inner medulla and Na^+ profiles, and corticomedullary Na^+ gradients were virtually identical in animals on both diets. Therefore depleting medullary urea either by reducing urea production on a low protein diet or deleting medullary collecting duct urea transporters had no impact on the ability of these mice to accumulate inner medullary Na^+ or develop a well defined corticomedullary Na^+ gradient. It follows that although the passive model of urinary concentration as described is still convenient conceptually, clearly the mechanism is more complex.

Knockout mice have also been used to clarify the relative importance of urea transporters because they help recycle urea to maintain high medullary urea content (see earlier discussion). The lower portion of thin descending limbs of short-looped nephrons contains UT-A2 and descending vasa recta contain UT-B. Part of urea recycling into ascending Henle's limb may involve transfer of urea from ascending vasa recta to thin descending limbs and ascending to descending vasa recta. If these transporters were deleted, less accumulation of inner medullary urea and consequently urea–induced osmotic diuresis from the high urea content in the urine of medullary collecting ducts as it coursed through deeper portions of the medulla would occur. In recent studies,[27] compared with control mice, when the UT-A2 transporter was deleted, knockout mice on normal protein intake had no decrease in urinary concentrating ability or accumulation of inner medullary urea in response to water deprivation. On a low protein intake, UT-A2–depleted mice had only a modest decrease in urinary concentrating ability and medullary urea content without a drop in medullary chloride. It appears that urea secretion into the thin descending limb is not a critical part of the process. By contrast, studies with UT-B–depleted mice are consistent with this transporter playing a larger role.[28,29] Mice were subjected to basal conditions, acute urea loading (intraperitoneal injection) and chronic urea loading (high protein diet). Compared with control animals, knockout mice (deletion of UT-B) on a normal protein intake had increased urine output and lower urine osmolality and had a significantly decreased maximal urine osmolality when water deprived. This was due primarily to a decrease in medullary urea content. After an acute urea load, control animals showed a well-defined increase in urine osmolality and urine urea concentration but only a modest increase in urine output. Knockout mice had a blunted increase in urine osmolality and urine urea concentration and a higher urine output. Even after the urea load had been excreted during 6 to 8 hours, control mice maintained a much higher urine osmolality and urine urea concentration and a lower urine output than the UT-B–depleted mice. These findings are consistent with the need to sequester inner medullary urea to allow for increased urine concentration and decreased urine output. Animals were also placed on 10% (low), 20%, or 40% (high) protein diets for a week. The diets did not induce changes in urine osmolality within groups. However, urine osmolality was consistently lower and urine output higher on each diet in the UT-2–depleted mice. Urea excretion increased to the same extent in both groups of mice with the increase in dietary protein, but this occurred with an increase in urine urea concentration in control animals, whereas the knockout animals required an increase in urine volume with little change in urine urea concentration. Even with a week of high protein intake, the UT-2–depleted mice could not translate the urea load to an improvement in urine concentrating ability. It would appear that UT-B urea transport between descending and ascending vasa rectae is critical to trapping urea in the inner medulla and maximizing conservation of water, and this exchange may contribute quantitatively more than recycling of urea between ascending vasa rectae and thin descending limbs to the urinary concentrating mechanism.

In a series of experiments, Halperin and colleagues[30,31] provided insight about urea as an effective osmole for water transfer in the inner medulla. Only solutes with a concentration difference can affect water movement across a semipermeable membrane. ADH increases water and urea permeability in inner medullary collecting ducts. If urea is highly permeant across this membrane, urea concentration equilibrates and adds to final urine osmolality but induces little increase in urine flow.

By contrast, salts remaining in higher concentration within the collecting duct lumen will act as effective osmoles and obligate water. In one set of experiments, subjects were either fasted or placed on a normal diet and then water-depleted. Those on a regular diet excreted largely urea and NaCl as their nonurea urinary osmoles. Fasted subjects excreted less urea, and their nonurea osmoles were largely NH_4^+ and β-hydroxybutyrate, not NaCl. Their urea excretion rate and total urine osmolality were lower, but both groups had similar nonurea osmolality and urine flow rates. Therefore urine flow was related mainly to nonurea osmolar load. Urea did not act as an effective osmole and did not induce more water excretion as long as the nonurea osmolar load was similar. When water-deprived subjects on a normal diet received a urea load, urine flow rate nearly doubled, and rates of excretion of both urea and nonurea osmoles increased. The total urine osmolality was unchanged because a decrease in nonurea osmolality (diluted by increased urine flow) accompanied the increase in urea osmolality generated by the urea load. However, both urea and nonurea solutes in this setting acted as effective osmoles. Urea could potentially decrease the nonurea osmolality of the inner medullary interstitial fluid by the following process. Interstitial osmolality increases as NaCl, in high concentration in the relatively water impermeant ascending limb, enters the interstitium without water. The interstitial NaCl concentration falls, however, as electrolyte-free water is reabsorbed from the inner medullary collecting duct, in part from added salt and in part from water moving osmotically with urea. As more urea enters the deeper medullary collecting duct, the intratubular nonurea solute will be necessarily lower because total osmolality will be equal across the tubular membrane. This should help drive even more electrolyte-free water toward the interstitium. As a result, interstitial nonurea osmolality should be lower, maintaining the effectiveness of residual intratubular salt as effective osmoles.[30]

In further studies,[31] human subjects on a regular diet were water deprived, given vasopressin, and then given hydrochlorothiazide to increase the proportion of urinary electrolytes comprising total urinary osmoles. After the diuretic, the proportion of urea osmoles in urine dropped from 50% to 20% of total urinary osmoles. When these subjects, now excreting a high proportion of nonurea osmoles, also received a urea load, urea concentration increased, nonurea osmolality or nonurea excretion rate did not change, and urine flow rate did not change. By not increasing urinary flow, urea acted as an ineffective, highly permeant osmole. Under a different protocol, subjects received furosemide to induce negative NaCl balance and were placed on a low-salt diet to generate an electrolyte-poor urine. Subjects were then water deprived and given a urea load. With a low nonurea (electrolyte) osmolality, the urea load now induced a marked increase in urine flow rate and a decrease in nonurea osmolality, but no change in total urine osmolality. In this setting, urea acted as an effective, less permeant osmole.

Rats behaved similarly. When rat papillary tip and urine solute content were compared, total as well as urea and nonurea osmolalities were similar when urine had a high proportion of urinary electrolyte osmoles, indicating equilibration of urea and nonurea solutes between papillary interstitium and urine. By contrast, when rats were electrolyte deprived on a low-salt diet and given a urea load, urea concentration was higher in urine than in interstitium, nonurea (electrolyte) concentration was higher in the interstitium, and the total omolalities were similar. Urea now acted as a relatively impermeant osmole and did not equilibrate across the interstitium.

The authors concluded that urea acts as an ineffective urine osmole, unable to obligate more water excretion, when there is a high rate of salt excretion. Conversely, when the rate of electrolyte excretion is low, urea acts as an effective osmole, thereby obligating water and increasing urine flow. When a urea load is sufficiently large, it becomes an effective osmotic agent, increasing urine flow to help remove excess urea. However, at low or modest excretion rates of urea, this solute equilibrates between collecting duct and interstitium so that urea exerts no significant osmotic effect and thus causes no increase in urine flow. In addition, relatively impermeant nonurea solutes such as NH_4^+ and β-hydroxybutyrate can ensure a minimal urine flow even during chronic fasting, reducing the risk for hyperkalemia and formation of calculi.[30]

The importance of these findings is apparent when considering that kidneys must reduce urine volume when water conservation is needed (dehydration) without reducing volume so much as to increase the risk for hyperkalemia or stone formation. In the setting of volume depletion and low renal electrolyte excretion, urea becomes less permeant and obligates water, maintaining urine flow to more than severe oliguria. In the setting of adequate urinary electrolytes, the kidney excretes urea (main protein metabolic product) without increasing the minimum urine volume needed to excrete other solutes. Were urea not highly permeable, it would remain in the collecting duct lumen (obligate water excretion) and blunt the ability of the kidney to lower water excretion in times of water depletion. This is accomplished because urea becomes more permeant, equilibrates across the medullary interstitium, and thereby is excreted without obligating more water. It is unclear how the kidney alters urea permeability in these situations, but the mechanism may involve a change in the function or number of urea transporters.

Halperin and colleagues[32] have more recently suggested a mechanism by which the renal concentrating mechanism is regulated using the observations that the majority of thin descending limbs of Henle (those from short-looped nephrons) lack aquaporin-1 and that inner medullary loops of Henle lack urea transporters. In their conception, NaCl is reabsorbed across the thick ascending limb via the Na-K-2Cl co-transporter along with some passive Na reabsorption driven by a lumen-positive voltage. Reabsorption depends on K movement to the lumen across a K channel. Water reabsorbed from the collecting duct in response to this interstitial NaCl may dilute an inhibitor of the K channel, allowing more NaCl to be reabsorbed. The authors suggest, for several reasons, that the calcium sensing receptor (Ca-SR) may provide such an inhibitor. When enough Ca is reabsorbed to occupy the receptor, the K channel will be inhibited, interfering with the cotransporter and preventing excessive NaCl reabsorption that in turn, if not curbed, might lead to excessive water reabsorption, increasing the potential to form kidney stones. The absence of aquaporin-1 in the majority of descending thin limbs serves to limit the amount of water that could potentially interfere with this inhibitory feedback system. In the absence of substantial water abstraction from this segment, it is likely that NaCl enters this segment so as to provide sufficient salt in the deeper portions of the medulla. As mentioned previously, the mechanism is unclear, but does not appear to be dependent on water and urea reabsorption from the medullary collecting duct resulting in dilution of interstitial NaCl. Therefore this permits passive reabsorption of NaCl from the ascending limb, as suggested by the passive model of urinary concentration, because interfering with the medullary collecting urea transporters does not interfere with medullary interstitial content of NaCl. Urea recycling is critical to inner medullary function. The large amount of reabsorbed urea, along with water from the medullary collecting duct, leaves via the ascending vasa rectae. Urea can enter the lumen of descending thin limbs to reach the distal convoluted tubule and later enter the collecting duct, but this occurs only in the lower portion of the descending thin limbs of short looped superficial nephrons that contain the UT-A2 transporter. The site where urea re-enters this segment occurs deeper in the outer medulla than the site where most of the water is reabsorbed to the interstitial compartment. This facilitates the medullary recycling of urea. As a final point, the authors again point to the need for an adequate

number of effective osmoles in the urine, namely NaCl. When NaCl in the urine is insufficient (e.g., on a low salt diet), urea concentration in the lumen is higher than in the papilla, and urea then acts as an effective osmole, obligating water to prevent a urinary concentration high enough to increase the risk for stone formation. The purpose of the inhibitory mechanism involving the thick ascending reabsorption of Na is to ensure that not only can adequate water be conserved, but also that the amount of water to eliminate urinary solutes will be adequate.

Role of Vasa Rectae

Vasa rectae are blood vessels coursing through the interstitium. Vasa rectae provide substrate for, and remove end products of, metabolic reactions and also, because they are highly permeable, remove solute and fluid reabsorbed by tubules. If the vessels traversed the medullary interstitium only once, they would remove reabsorbed urea and NaCl, depleting the interstitium of solutes and compromising the solute gradient. To avoid this, they descend into the medulla to varying degrees, break up into small capillaries that course through localized areas of interstitium, and rejoin to ascend toward the cortex (Figure 133-4 and described later). A recent review of the renal medullary microcirculation is available for the interested reader.[33] Juxtamedullary glomeruli send efferent arterioles into the outer medulla. In the outer stripe these vessels divide into descending vasa rectae that form vascular bundles in the inner stripe of the outer medulla. Peripherally located vessels can form an interbundle capillary plexus in close proximity to metabolically active thick ascending limbs and collecting ducts. More centrally located descending vasa rectae penetrate to the deep portion of the inner renal medulla. Vascular bundles form in the inner stripe of the outer medulla. As the descending vasa rectae move into the inner medulla, vascular bundles are not present, but the descending vasa rectae course close to nephron segments and at the bottom of the medulla form a capillary plexus that eventuates in ascending vasa rectae that course toward the vascular bundles of the inner stripe. In the inner stripe vascular bundles, descending and ascending vasa rectae as well as thin descending loops of Henle from short-looped nephrons are in close apposition. Ascending vasa rectae are fenestrated and highly permeant. Descending vasa rectae have continuous endothelial cells and pericytes (contractile smooth muscle remnants). They also contain the urea transporter UT-2 as well as aquaporin-1. Descending vasa rectae are well situated adjacently in vascular bundles and also in deeper portions of the medulla to receive NaCl and urea from ascending vasa rectae and to deliver water toward the ascending vessels down concentration gradients.[14,34] Accordingly, solutes such as NaCl and urea found in high concentration in ascending vasa rectae, can enter descending vasa rectae that contain fluid of lower solute concentration, whereas water can move in the opposite direction. As a result, fluid in the descending vessel penetrates deep in the medulla and carries a high solute concentration close to that in the interstitium. The driving force for passive loss of this solute from interstitium to vessels is thereby minimized. Part of the vascular bundle may include descending limbs of short-loop nephrons. This segment can take up solute from ascending vasa rectae and recycle it to collecting ducts traversing the deep medulla, where solute and water are further reabsorbed.

Role of the Renal Pelvis

The renal pelvis may contribute to urinary concentration.[35] Epithelium covering the inner medulla and papilla and facing the pelvic space is similar to that of papillary collecting ducts. During water diuresis, these cells are closely apposed and intercellular spaces are narrow. During antidiuresis, individual cells are more distinct, and intercellular spaces are widely dilated. This

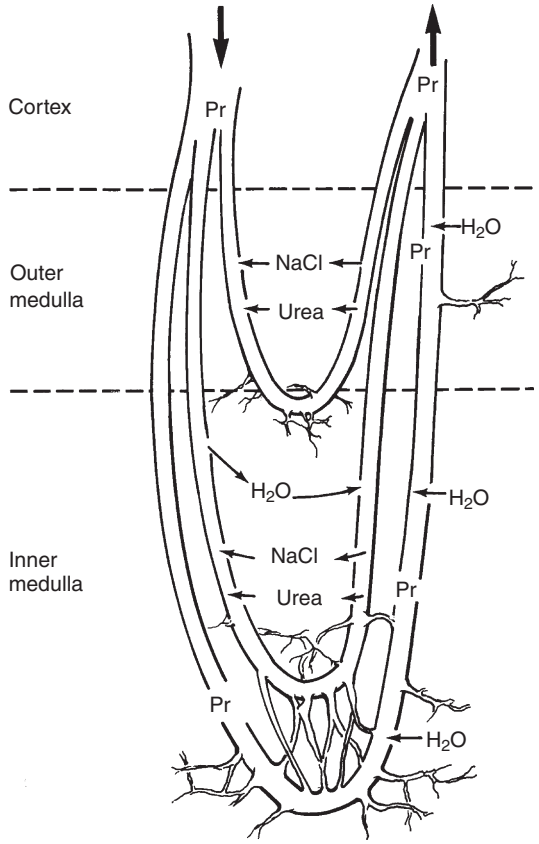

Figure 133-4 Countercurrent exchange in vasa recta. Medullary circulation includes network of interconnecting vessels and main thoroughfares. Vessels are freely permeable to NaCl, urea, and water. Type size denotes solute concentration relative to its location in medulla but not relative to concentration of another solute. Loops of Henle and collecting ducts are responsible for increasing concentration of interstitial NaCl and urea. Solutes can enter descending vasa recta and leave ascending vasa recta to remain trapped in medulla. As water leaves and descends the vasa recta, protein concentration increases. High osmotic and oncotic pressures in ascending vasa recta enhance capillary fluid uptake, returning water, reabsorbed from tubules, to general circulation. Therefore vasa rectae trap solute and remove water, preserving hyperosmolality of the renal medulla. *Pr,* Plasma protein. *(Reprinted by permission of the* New England Journal of Medicine: *Jamison RL, Maffly RH: The urinary concentrating mechanism.* N Engl J Med *295:1059, 1976.)*

may reflect enhanced transepithelial movement of fluid.[36] Pelvic extensions in some species allow the urinary space to surround vascular bundles and much of the papillae and may reach the cortex.[13] Increased urine concentration has been related to an increase in contact surface area between papilla and pelvic urine.[36,37] Moreover, an intact renal pelvis may be necessary to produce a maximally concentrated urine. If one excises the ureter to expose the renal papilla of a rat, urine osmolality at the papillary tip drops sharply by nearly 40%.[38] Urine in the renal pelvis circulating around the papillae and inner medulla may reach an area in the medullary interstitium where urea concentration is less than that in the urine. Urea could then recycle from pelvic urine to the medullary interstitium and help maintain a high medullary urea concentration gradient, enhancing abstraction of water from thin descending limbs of Henle. In this regard, the concentration of urea in fluid bathing the papilla, rather than the total osmolality, seems to be a critical factor in determining the

final urine concentration. If the papilla is bathed with solutions of varying osmolality and urea concentration, the osmolality of urine from the papillary tip increases when the urea bath concentration is increased, but not necessarily when the bath osmolality is altered.[39] This hypothesis remains uncertain. Other investigators have not found significant urea reabsorption across this epithelium. In addition, not all rodents show a relation between extensions of renal pelvis and fornices around their papillae and the ability to maximally concentrate urine.[35]

Confusion about the impact of urine flow and pelvic reflux on papillary function is evident from some of the following considerations. After urine leaves the papillary tip, it can descend the ureter, reflux slightly to surround a small portion of the papillary tip, or reflux fully over the entire fornices and pelvic extensions and cover more of the medulla in which solute and water exchange may occur. Full retrograde flow of urine over the entire papillary surface and up toward the outer medulla occurs with bladder and retrograde ureteric contractions. It can be stimulated by increasing hydrostatic pressure in the pelvis by as little as 1 cm of H_2O. When the renal pelvis is removed, urine flow is nonpulsatile and continuous, a state not associated with full pelvic reflux. In contrast, when the renal pelvis is intact and performs its contractile or pulsatile action, urine flow in terminal collecting ducts is intermittent rather than continuous. During antidiuresis, when urine flow is slow and urine becomes highly concentrated, full pelvic refluxes also do not occur, even with an intact pelvis. Therefore the importance of an intact renal pelvis to an efficient urinary concentrating ability may be related more to the contractile nature of the pelvis than to the actual degree of reflux. During a peristaltic contraction, a urine bolus through the terminal papillary collecting duct is seen to enter the renal pelvis quickly, after which urine flow ceases and collecting ducts become empty and remain collapsed for 95% of the time. When urine flow rates are slow, the velocity of a urine bolus is rapid, and the contact time between urine and epithelium at a site approximately 1 mm from the papillary tip is brief. At higher rates of urine flow, the urine bolus leaves the papillary tip more slowly, and contact time between urine and papillary epithelium is actually greater. Therefore, during antidiuresis, when urine flow is slow and urine becomes highly concentrated, the urine is in contact with the reabsorbing epithelium for a shorter time, and retrograde flow of pelvic urine, rich in urea, is an uncommon event.[35,40-42]

Schmidt-Nielsen and colleagues[35,40-42] proposed that during antidiuresis, urinary concentration is augmented by peristaltic action of the renal pelvis that causes intermittent flow of urine and helps urine equilibrate with the hypertonic papillary interstitium. The relatively small "tip" reflux in an antidiuretic state, coupled with the small area occupied by the papillary tip and the short contact time of urine with papillary epithelium, might lead one to conclude that solute and water exchange at this site are rather limited. More important, other papillary structures are also affected by the milking, contractile action of the renal pelvis. When the pelvis contracts and constricts the papilla, blood flow in the vasa rectae stops. This may reduce medullary solute washout by allowing more complete solute equilibration between ascending vasa rectae and interstitium. Flow in the loops of Henle is also slowed. This could help accumulate interstitial solute. Therefore, without full reflux, pelvic contraction may alter flow of solute in papillary structures to facilitate the increase in the interstitial solute gradient.[35,40-42]

Role of Aquaporins

Aquaporins are proteins that traverse the cell membrane lipid bilayer. They appear to represent molecular water-transporting channels and are expressed in a wide variety of tissues.[43-46] Several reviews are available.[47-55] The first water channel protein to be identified, originally named CHIP-28 for the 28-kDa channel-forming integral protein, was abundant in red blood cells and proximal renal tubules. These tissues have high water permeability and facilitate the constitutive movement of water down an osmotic gradient. To determine whether this protein behaved as a water channel, investigators employed *Xenopus* oocytes, which can survive in fresh water owing to their very low water permeability. When complementary RNA of CHIP-28 was expressed in these oocytes, a dramatic increase in membrane water permeability was observed. The membranes behaved as though they contained water channels. This observation was confirmed by reconstituting the purified protein into proteoliposomes and demonstrating a dramatic increase in osmotic water permeability.[55-57] Seven aquaporins now identified in kidney tissue appear to have specific cellular localization.[42] Some features of aquaporins 1 to 4 are summarized in Table 133-1. Little is known yet about aquaporins 6 to 8.

TABLE 133-1

Characteristics of Aquaporins Found in Kidney Tissue

Genetic Designation	Renal Localization	Proposed Physiologic Role
Aquaporin-1	Proximal tubule S1, S2, S3 segments of short- and long-looped nephrons	Major transmembrane pathway for H_2O flow, including entry and exit sites
	Descending thin limb of Henle in long-loop nephrons	Not under hormonal control
	Nonfenestrated descending vasa rectae	
	Limited in vesicles and vacuoles	
	Present in both apical and basolateral membranes (basal and lateral aspects)	
Aquaporin-2	Outer and inner medullary collecting duct	The vasopressin-regulated H_2O channel; ADH induces movement of an intracellular vesicle pool of H_2O channels to the apical membrane
	Primarily apical membrane and intracellular vesicles	
Aquaporin-3	Collecting duct principal cells in cortex and medulla; strongest medullary label is at base, not tip, of papilla	Major exit site for osmotically driven H_2O transport; not regulated through vesicular trafficking via ADH; may provide for small nonelectrolyte solute movement
	Mainly in lateral and basolateral infoldings, not in basal aspect, of basolateral plasma membrane	
	Virtually absent from apical membrane; minimally found in intracellular vesicles	
Aquaporin-4	Inner medullary collecting duct principal cells, especially proximal two thirds of segment; little in cortex and outer medulla	Basolateral exit site of cellular H_2O transport of inner medullary collecting ducts
	Distributed roughly equally in basal and lateral domains of basolateral plasma membrane, and not in intracellular vesicles	

ADH, Antidiuretic hormone.

Aquaporin-1 is found in renal proximal tubules, long-loop thin descending limbs of Henle, and nonfenestrated endothelium of descending vasa rectae. It is not found in other tubule segments, including thin descending limbs of short-looped nephrons, collecting ducts, or in ascending vasa rectae. Aquaporin-1 imparts high osmotic water permeability. In nephron segments, this protein is identified in both apical and basolateral membranes, including both basal and lateral infoldings, but not to any substantial degree in cytoplasmic vesicle and vacuole membranes. Accordingly, aquaporin-1 is poised to facilitate transcellular water movement in segments responsible for reabsorbing a major portion of the glomerular filtrate, but it does not appear to require hormonal regulation and therefore is not the ADH-sensitive water channel.[58-60] This protein is also abundant in red blood cells, where it is thought to increase membrane permeability. Although individuals without functional CHIP water channels do not appear to have clinical abnormalities, such as polyuria,[61] rare individuals lacking aquaporin-1 have a urinary concentrating defect in response to ADH or to water deprivation.[62] The role of aquaporin-1 in maintaining urinary concentrating ability is appreciated from studies of transgenic knockout mice lacking aquaporin-1. These mice are polyuric and do not tolerate water deprivation.[63] Moreover, perfused proximal tubules[64] as well as descending thin limbs[65] from such mice have reduced osmotic water permeability. Thus aquaporin-1 is necessary for maximal concentrating ability. This is likely related to the need for rapid equilibration of water across the thin descending limb of Henle in helping establish the countercurrent multiplication process.

As mentioned earlier, it has recently been shown that aquaporin-1 is not expressed in descending thin limbs of short-loop nephrons.[66] Water permeability across this segment appears to be lower than that of descending thin limbs of long-loop nephrons, probably because of the absence of aquaporin-1. Because osmotic equilibration across ascending thin limbs of short-loop nephrons occurs, likely some other feature facilitates fluid movement, perhaps an as yet unidentified aquaporin. Alternatively, there may be solute transfer across this segment associated with aquaporin independent water flow.

Aquaporin-2 appears to be the ADH-regulated water channel and mediates the short-term renal response to the hormone. This conclusion is supported by the following cumulative observations. Vasopressin binds to a basolateral membrane receptor and initiates a cyclic adenosine monophosphate (cAMP)-mediated chain of signaling events leading to insertion of water channels and increased osmotic water permeability of the collecting duct apical membrane.[67,68] Aquaporin-2 protein is present primarily in cytoplasmic vesicles and in apical plasma membranes of collecting duct principal cells. Also some staining occurs of basolateral plasma membranes of inner medullary collecting duct principal cells.[51] When expressed in *Xenopus* oocytes, aquaporin-2 induces a dramatic increase in osmotic water permeability.[69] In the water-loaded state, staining for this protein is more prominent in cytoplasmic vesicles. After stimulation by ADH, apical membrane staining for aquaporin-2 intensifies, but it decreases in the subapical vesicles (i.e., aquaporin-2 redistributes from vesicles to membrane).[70,71] That there is a reservoir of cellular aquaporin-2 protein capable of actually recycling between intracellular cytoplasmic vesicles and the plasma membrane is suggested from studies using LLC-PK1 epithelial cells.[72] Despite inhibition of protein synthesis, aquaporin-2 staining was primarily localized to intracellular vesicles in nonstimulated cells and quickly redistributed (within 10 minutes) to the plasma membrane after exposure to ADH. The pattern was reversible on removal of ADH.

There is also evidence that aquaporin-2 plays a major role in the long-term adaptation to pathophysiologic stimuli known to alter urinary concentrating ability. For example, lithium, a drug used in affective disorders, induces an ADH-resistant concentrating defect characterized by a down-regulation of aquaporin-2 expression in rat inner medullary membranes that coincides with the development of polyuria.[73,74] The ADH-resistant urinary concentrating defect occurring after release of bilaterally obstructed ureters is also associated with a marked down-regulation of inner medullary aquaporin-2 expression that correlates with polyuria. In addition, the slow recovery is marked by persistence of decreased aquaporin-2 expression.[75]

Chronic hypokalemia may lead to ADH-resistant nephrogenic diabetes insipidus. When hypokalemia was induced by potassium deprivation for 11 days, polyuria correlated with down-regulation of aquaporin-2 in both the cortex and inner medulla of rat kidneys. Polyuria expression of aquaporin-2 corrected within a week of potassium repletion.[75] Hypercalcemia is another electrolyte disorder in which a concentrating defect and polyuria have been associated with down-regulation of aquaporin-2.[76,77] Thirsting increases expression of aquaporin-2 in rat collecting ducts, and in Brattleboro rats, a model of central diabetes insipidus, expression of aquaporin-2 in collecting ducts is reduced in the basal state and is significantly increased upon exposure to ADH.[78,79] The decreased urinary concentrating ability associated with protein-depleted or malnourished subjects is thought to relate to a decrease in the deep medullary urea content. However, rats kept on a low-protein diet for 2 weeks, without malnutrition, demonstrate decreased maximal urine osmolality after water deprivation and reduction in ADH-stimulated osmotic water permeability, as well as expression of aquaporin-2 protein in terminal portions of the inner medullary collecting ducts.[80]

These examples of limitations in urinary concentrating ability associated with long-term alterations in aquaporin-2 are of particular interest considering the presence of aquaporins in fetal and neonatal renal tissues (see later discussion). Moreover, aquaporin-2 appears to be necessary for ADH-dependent concentration of urine in humans, as evidenced by a patient with autosomal recessive nephrogenic diabetes insipidus who had two mutations in the gene encoding aquaporin-2. Expression of the defective proteins in *Xenopus* oocytes showed nonfunctional water channel proteins that failed to increase osmotic water permeability.[81] Such abnormalities may become definable by analyzing urine from such patients.[82,83] Tsukahara and colleagues[84] reported urinary excretion of aquaporin-2 in premature and term infants. Levels were lower than in adults and correlated with urinary osmolality and ADH, suggesting that early in life (within the first 4 days) aquaporin channels contribute to urinary concentrating in the newborn infant.[84]

In some studies, microdissected arcade segments (branched tubule segments that connect distal convoluted tubules of deep and midcortical nephrons to cortical collecting ducts) were found to express both aquaporin-2 and the V2 ADH receptor protein. Staining of aquaporin-2 was not as intense as in cortical collecting ducts but nevertheless was present in large amounts and was up-regulated in segments dissected from animals that had been thirsted. This indicates that the tubule arcades represent another site of water reabsorption stimulated by water deprivation and probably regulated by ADH.[85] This finding is of interest because extensive water reabsorption in these segments, which are present in the renal cortex, will foster absorption of large amounts of water in the cortex. Water not reclaimed in the cortical vascular circulation but delivered to the deeper medulla might dilute the medullary interstitium and impair maximal concentrating ability.

Aquaporin-3 is expressed along the connecting tubule and entire length of the collecting duct (in principal cells) from the cortex and the outer and inner medulla, especially the base, rather than the tip, of the inner medulla.[86,87] The protein is found primarily in lateral and basal infoldings of the basolateral membrane, not the basal portion of the membrane. Labeling is virtually absent from the apical plasma membrane and is modest for intracellular cytoplasmic vesicles. Limited labeling of this protein

in cytoplasmic vesicles suggests aquaporin-3 does not regulate short-term H_2O movement by vesicular trafficking. However, both water restriction for 48 hours and chronic ADH infusion for 5 days in rats increase expression of aquaporin-3, suggesting that this protein is under long-term influence of ADH and therefore integrally involved in urinary concentration.[88] Moreover, experiments have shown that transgenic knockout mice lacking aquaporin-3 have a concentrating defect and polyuria.[89] Aquaporin-3 also appears to conduct small, nonelectrolyte solutes such as urea.[90]

Aquaporin-4 expression is found primarily in inner medullary collecting duct principal cells, not in the cortex or outer medulla. It is more prominent in the inner medullary base than in the papillary tip and is found in basolateral (both basal and lateral domains) rather than apical membranes. Little staining is found in intracellular vesicles. When rats were either water restricted for 48 hours or infused chronically during 5 days with ADH, no increase in expression of aquaporin-4 over a baseline water-loaded state was observed.[87,88] These findings are consistent with a role for aquaporin-4 as a basolateral exit pathway for transcellular movement of water in the inner medulla—perhaps in response to osmotic gradients, but not in response to secretion of ADH. The role of aquaporin-4 has been further assessed in transgenic knockout mice lacking aquaporin-4. Such mice had a mild urinary concentrating defect,[91] and their perfused inner medullary collecting ducts had reduced ADH-stimulated osmotic water permeability.[92]

Three other aquaporins have been identified in kidney tissue, but their physiologic roles are unclear.[51] Aquaporin-6 is expressed in collecting duct intercalated cells from cortex to inner medulla. The protein appears to be present in intracellular vesicles, not plasma membranes, and may represent an intracellular water and ion channel.[93] Aquaporin-7 is present in the proximal tubular brush border, particularly in the S3 segment,[51] and aquaporin-8 is found in proximal tubule and collecting duct cells as well as other tissues.[94]

Role of Chloride Channels

Rapid abstraction of NaCl down its concentration gradient occurs in medullary thin ascending limbs and is an integral part of the countercurrent multiplication process. This segment is particularly permeant to chloride. Chloride channels would be poised to facilitate transmembrane movement of solute and, in fact, such channels (e.g., ClC-K1) have been identified in the inner medullary thin ascending limbs of Henle in rat kidney. The channel was localized to both apical and basolateral membranes in one study[95] and primarily on the basolateral membrane in another.[96] The channel was not observed in the descending medullary thin limb, a segment that largely abstracts water, rather than NaCl. Although this channel is also found in other, more distal segments in both cortex and medulla, its location in the thin ascending limb underscores its role in concentrating and diluting the urine. In this regard, dehydration was shown to increase expression of the ClC-K1 channel in cortical and medullary segments. Moreover, knockout mice deleted of ClC-K1 showed clinical nephrogenic diabetes insipidus, a defect that was attributed to impaired generation of inner medullary hypertonicity rather than decreased collecting duct water permeability.[97,98] The role of chloride channels in urinary concentration as well as other ion channels along the nephron has recently been reviewed.[99,100]

To summarize, as a result of the countercurrent relationship of loops of Henle, vasa rectae, and proximal straight and collecting tubules, several cycles of solute transfer appear to take place more or less simultaneously. At all levels of the medulla (outer and inner stripes of the outer medulla as well as the inner medulla), but particularly in the inner stripe, in which the vessels located within the vascular bundle are separated only by a thin layer of interstitium, solute has the potential to leave ascending vasa rectae and enter descending vasa rectae. Some of this solute can be taken up by descending loops of Henle from short-loop nephrons that are also within the bundle. This solute can ascend to the cortex and then move to collecting tubules. When deep in the medulla, the solute can be transferred to ascending vasa rectae or to ascending loops of Henle and can then re-enter the descending loop of Henle to recycle in the medulla. In the outer stripe of the outer medulla, fluid in the ascending loop, as well as the ascending vasa recta, may also be able to enter the proximal straight tubules of short- and long-looped nephrons. These relationships provide an ongoing, if complex, transfer of solute between vessels and tubule segments to maintain sodium chloride and urea gradients in the medulla, allowing extraction of water from collecting ducts when there is need to concentrate the urine. Urine leaving the renal papillary collecting ducts enters the renal pelvis and may be able to circulate in the pelvic spaces to bathe portions of the outer medulla. Then is the potential for urea to recycle back to the medulla and contribute further to urinary concentration. Functional water channels appear to be amply present in both apical and basolateral membranes and are neatly poised to reclaim water by processes that are dependent on, as well as independent of, ADH.

URINARY CONCENTRATION IN THE FETUS

The placenta, not the kidneys, seems to maintain normal extracellular salt concentration in utero, and the practical need for the fetus to concentrate or dilute urine during pregnancy is little. However, kidneys may play a homeostatic role under conditions of fetal stress, and survival of premature infants 24 to 26 weeks of age must depend on kidneys deprived of 3 to 4 months of anatomic and functional in utero development. Such infants, fetal in some of their functions, require special attention to their fluid and electrolyte needs. Information on human fetal renal tubular reabsorption of water and response to ADH is limited. Most information comes from animals in which chronic catheters are inserted. Fetal metabolism, ontogeny, and ADH secretion are conveniently studied in the third trimester of sheep. This model is similar to humans because both placentas are impermeant to ADH, so that fetal blood ADH levels reflect fetal production.[101] To maximally concentrate urine, ADH must be synthesized, released to the circulation, and carried to collecting tubules, which must respond to the hormone. Loops of Henle, vasa rectae, and tubules must have established the necessary anatomic relationship. Fetal urine, in a variety of species, is usually hypotonic to plasma.[102-108] This observation led to the conclusion that fetal kidneys could not concentrate urine, perhaps because ADH is either unavailable or the fetus is unresponsive to it. That such is not the case is evident from the following considerations.

Maturation of Fetal Water Reabsorption

A slight increase in urinary concentration occurs during fetal development.[107,109] At a time when plasma solute concentrations are stable, fetal sheep late in gestation (130 days of a normal 145-day gestation) have a urine osmolality significantly higher than that in younger fetuses of less than 130 days. Both urea and nonurea urinary solutes are seen to increase, but whereas some investigators[110,111] find that intrarenal urea and salt gradients are present in fetal lamb medulla by midgestation (Figure 133-5), the actual contribution of urea to total urinary osmolality is relatively small (Figure 133-6). During late gestation, urine flow rates decrease, but osmolar clearance remains unchanged. Therefore free water clearance, defined as urine flow rate minus osmolar clearance, is reduced, indicating that free water is more effectively separated (reabsorbed) from solute in the older fetal kidney.[109] Although the degree of urinary concentration in late

gestation is unimpressive, the increase in water reabsorption is consistent with a heightened response to endogenous levels of ADH in the older fetus.

Availability of and Responsiveness to Vasopressin

Although fetal pituitary content at term is much less than that of the adult, ADH has been identified in the human pituitary by the week 12 of gestation, with a demonstrable increase over ensuing weeks.[112-114] Neurosecretory granules and material are found in hypothalamic nuclei, the hypothalamohypophysial tract, and the infundibular process of the neurohypophysis by 16 weeks gestation in the human fetus.[115] Clearly, ADH is available at an early fetal age. Vasopressin mediates its tubular effect on water permeability by stimulating the generation of cAMP.[116-118] Compared with adults, fetal ADH causes a smaller increase in cAMP from renal medullary tissue obtained from the early fetus.[119-122] To achieve osmotic equilibrium (i.e., osmolality approximately 300 mOsm/kg H_2O), the fetal kidney needs higher plasma levels of ADH (approximately 5 μU/mL) than the adult, who requires only approximately 0.7 μU/mL. Moreover, maximal urine osmolality is achieved in both the fetus and adult at similar plasma levels of ADH, 4 to 6 μU/mL, but adult urine is much more concentrated.[109] Therefore the fetal nephron appears to be less sensitive than the adult to vasopressin.

Exogenous Vasopressin

The fetus responds to exogenous ADH by increasing urine osmolality,[123] a response linearly related to age over the third trimester of the fetal ewe[124,125] (Figure 133-7). The human fetal nephron responds to ADH as shown in an isolated, perfused human medullary collecting duct obtained from a 5.5-month male abortus with trisomy D.[126] This tubule increased transmembrane water flow from 2.1 to 12.0 μL/cm^2/Osm/minute on exposure to peritubular ADH. Cells swelled with conspicuous dilation of intercellular spaces, indicating outward net flow of water through intercellular spaces and through cell membranes. Thus collecting duct receptors to ADH are well developed functionally in prenatal life.

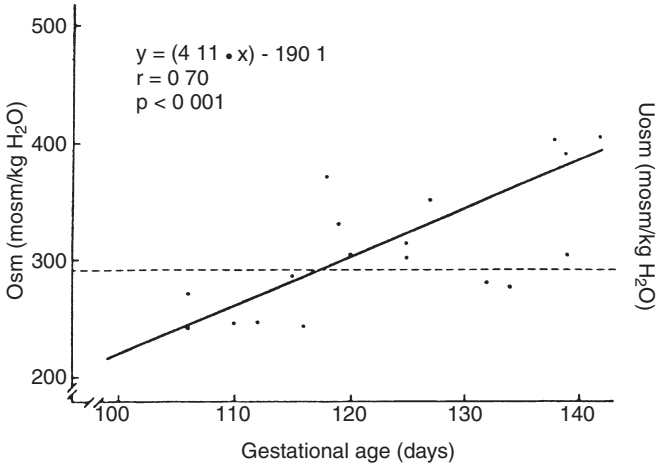

Figure 133-7 The relationship between gestational age and urine osmolality in fetal lambs during an infusion of vasopressin, 600 μU/min/kg. The *horizontal dotted line* represents mean plasma osmolality (291 mOsm/kg) during infusion of vasopressin. *(From Robillard JE, Weitzman RE: Developmental aspects of the fetal renal response to exogenous arginine vasopressin.* Am J Physiol *238:F407, 1980.)*

Endogenous Vasopressin

In addition to the availability of ADH and tubular reactivity to the hormone, the fetus responds to osmotic, nonosmotic, and volume stimuli (hypertonic saline, hypoxia, hemorrhage, furosemide, and dehydration) by a prompt increase in endogenous plasma levels of ADH.[127-132] Infusing hypertonic saline into

a fetus causes an increased level of plasma ADH that closely relates to plasma osmolality.[107,108,131] Fetal infusion of hypertonic saline increases fetal urine osmolality and decreases fetal urine flow rate. This response can be blocked by an ADH antagonist.[133] When water deprivation is imposed on a pregnant ewe, the older fetus, compared with the young fetus, has a higher plasma ADH level for a given plasma osmolality and, for a given plasma ADH level, the older fetus has a greater reduction in urinary water clearance.[127,129] When varying degrees of hemorrhage are induced in lamb fetuses during the third trimester of pregnancy, plasma ADH levels increase nearly 50-fold and correlate with the degree of blood removed.[134] In late gestation, more than 130 days, a hypoxic stimulus causes fetal plasma ADH levels to rise, which are accompanied by an increase in urine osmolality and a decrease in water clearance without change in osmolar clearance. This response occurs in nearly all (9 of 10) near-term fetuses of more than 130 days and approximately half (5 of 9) of young fetuses of less than 120 days.[109,129,135] Therefore fetal hypoxemia induces antidiuresis, particularly in a near-term fetus.

It appears then that in a fetus during the last trimester, volume, osmotic, and nonosmotic receptors for production and release of ADH are functional, ADH is available, and tissue response to the hormone is intact. Other factors may contribute more to limited concentrating ability. Loops of Henle are short,[136,137] and salt reabsorption in thick ascending limbs is limited in early life.[138] Total cortical flow exceeds that to the medulla, but blood flow/nephron is proportionately greater in the medulla than in the outer cortex in early development.[139-141] These factors tend to limit the efficiency with which a medullary osmotic gradient can be generated and maintained in fetal kidneys. Regardless of quantitative limitations on urinary concentration, a mature fetus or a premature infant is establishing means to tolerate stresses that may alter the osmolality or volume of its fluid environment.

Other Effects of Vasopressin

Vasopressin receptors are found in mesangial cells, aortic smooth muscle, liver, brain, and anterior pituitary. Thus ADH has other potential roles,[142] including (1) blood pressure control by effects on vasculature and baroreceptor reflexes, (2) platelet aggregation, (3) regulation of Factor VIII and von Willebrand factor, (4) release of adrenocorticotropic hormone, (5) glomerular mesangial cell contraction with some control of filtration, (6) synthesis of prostaglandins, and (7) control of/effects on hepatic metabolism by stimulating gluconeogenesis and exerting a glycogenolytic effect on hepatocytes. Some of the responses require high ADH concentration and may be more of pharmacologic interest.

Vasopressin may influence fetal water and electrolyte balance in ways separate from its effect on the kidney. Vasopressin appears to exert some control over fetal osmolar homeostasis through an effect on the placenta.[112] An osmolar gradient, generated by infusing hypertonic saline or mannitol into the mother,[112,129,143] favors transfer of fluid from fetus to mother, and water leaves the fetus to enter the maternal circulation. In the presence of hypertonic saline, neither sodium nor ADH appears to cross the placenta, but fetal serum sodium and plasma ADH increase and fetal ADH levels exceed those in the mother. Infusing hypertonic saline into the mother causes net water flux from the fetus to the maternal fluid compartment, inducing fetal water loss and increased fetal secretion of ADH. This effect is blunted if the fetus is given an ADH infusion. Similarly, mannitol infused into the mother does not cross the placenta but induces sufficient fetal water flow to raise fetal serum osmolality. Infusing ADH into the fetus blunts this response and may even drop fetal and slightly raise maternal osmolality. Therefore fetal ADH can induce transplacental water flow and cause a net gain of fetal water by inhibiting fetal to maternal water flow despite a hyperosmolar stimulus sufficient to move water from the fetus to the mother.

Vasopressin may help regulate the volume of amniotic fluid by its direct effect on urine flow and its regulatory effect on lung fluid production.[144] Vasopressin also affects fetal cardiovascular homeostasis.[145,146] Vasopressin infusion into a sheep fetus slows heart rate and raises blood pressure within 4 to 5 minutes. Vasopressin also causes redistribution of blood flow so that the proportion of cardiac output to gastrointestinal and peripheral circulation drops, and the percentage of cardiac output to umbilical-placental, cerebral, and myocardial circulations increases. These changes are similar to those following hypoxia and suggest that ADH release helps support the fetal cardiovascular response to stress. Moreover, fetal hemorrhage drops blood pressure, but ADH provides some protection; the fall in pressure is less, and the time for fetal blood pressure recovery toward normal after hemorrhage is shorter in the presence of the hormone.

Aquaporins

Aquaporin-1 expression was shown to increase dramatically (approximately seven-fold) from 60 to 140 days gestation in the ovine fetus, reaching adult levels by 6 weeks of postnatal age. This correlates with the maturational changes occurring in the kidney. Although nephrogenesis is complete by birth in the ovine fetus, there is a marked increase in postnatal glomerular filtration rate (GFR) and considerable tubular growth. This relates to the need for an increased capability for Na and water reabsorption and the need for functional and abundant water channels in portions of the nephron where a large amount of filtrate is absorbed.[147] Expression of aquaporin-2 is limited early in gestation in the ovine fetus. None was detected in 40-day-old or younger fetuses. It was present in low levels at 64 days, and expression increased from 80 through 140 days gestation and much more by adulthood. The increased expression of aquaporin-2 during gestation correlates with the heightened sensitivity of the older fetal kidney to ADH in obtaining a concentrated urine. It is emphasized that this process is physiologic. The purpose of fetal urine is mainly to provide an adequate volume of amniotic fluid. Maximal concentrating ability is not needed. ADH and aquaporin-2 expression are poised low enough to allow continued excretion of high volumes of dilute urine in the fetal kidney.[148]

In summary, fetal renal concentrating ability increases with gestation, but actual concentrating capacity is small, and the impact of ADH on urine concentration is relatively unimportant. Adult and immature subjects differ in tissue sensitivity to ADH, generation of cAMP, and tubule permeability to salt and urea. However, ADH is present early in gestation, nephrons respond to the hormone, and volume and osmotic responses for ADH release appear to function in the last trimester of pregnancy in the fetal lamb. Therefore the absence of or nonresponsiveness to ADH does not explain limited concentrating ability in the premature or term neonate. A more likely explanation is inadequate generation and maintenance of a hypertonic medulla. ADH under adverse circumstances helps alter electrolyte and water transfer across the placenta, maintain adequate blood pressure, and redistribute circulating blood volume, all of which would help stabilize fetal circulation. The response to exogenous ADH and to adverse stimuli for release of ADH both mature with advancing age. Therefore, although kidneys are not needed to maintain electrolyte balance in utero, fetal kidneys respond to hypoxemia, asphyxia, and volume depletion and probably contribute to electrolyte, volume, osmolar, and blood pressure homeostasis. In late gestation, amniotic fluid is regulated through fetal urine and lung fluid. Accordingly, fetal kidneys and ADH may be important for normal fetal and lung development.

TABLE 133-2

Average Maximal Urine Osmolality in 212 Children 3 Days to 18 Years of Age

Age	Maximal Urine Osmolality (mOsm/kg)
Third day	515
Sixth day	663
First month (10 - 30 days)	896
1 - 2 months	1054
End of first year	1118
Puberty (14 - 18 years)	1362

Data from Polacek E, Vocel J, Neugebauerova L, et al: The osmotic concentrating ability in healthy infants and children. *Arch Dis Child* 40:291, 1965.

URINARY CONCENTRATION IN THE NEONATE

In practical terms, low neonatal concentrating capacity is of little importance unless the infant is given insufficient water to compensate for dietary solute load and high rate of insensible water loss. A low concentrating ability makes the infant more vulnerable to extrarenal water depletion, as occurs in diarrhea, febrile states, and excessive insensible skin loss. Water needs of premature infants are even greater because of higher skin losses, but the higher water intake needed to offset these losses must be provided with care to prevent overhydration since the ability to excrete a water load is limited by a very low GFR until approximately 34 weeks gestation. In general, 100 to 160 mL/kg/day of water can be given to infants without major concern for dehydration or fluid overload.

Neonatal Urinary Concentrating Capacity

In the presence of ADH, human newborn infants produce a urine that is only modestly more concentrated than plasma and much less concentrated than that in the adult.[149-154] Svenningsen and Aronson[153] gave 10 μg of 1-deamino-(8-D-arginine)-vasopressin (DDAVP) to 20 healthy term and preterm infants (30 to 35 weeks gestational age) and found that by 4 to 6 weeks of age, their mean maximal urinary concentrating capacity was only 565 and 524 mOsm/kg, respectively, although some infants concentrated urine to greater than 600 mOsm/kg.[153] Pratt and Snyderman[152] found that premature infants, 11 to 23 days of age, ingesting evaporated milk and small amounts of water, concentrated their urines to a maximal osmolality of 637 to 985 mOsm/kg.[152] Calcagno and colleagues[149] found maximal urine osmolality to range from 588 to 648 mOsm/kg in five premature infants 5 to 25 days of age after 12 to 18 hours of water restriction.[149]

The dramatic maturation in concentrating ability is appreciated from data in a larger group of children reported nearly 40 years ago.[151] Urine osmolality exceeded 600 mOsm/kg within a week of life, was greater than 1000 mOsm/kg by 1 to 2 months, and was more than 1100 mOsm/kg by 1 year (Table 133-2). Children reached the adult level of maximal urine concentrating ability, 1300 to 1400 mOsm/kg by 2 years of age.[155] These values are comparable with the concentrating ability of a group of children 2 to 16 years of age reported by Edelmann and colleagues.[156] After nearly 20 hours of standardized water deprivation, these children concentrated urine to a mean osmolality of 1089 mOsm/kg (range, 873 to 1305 mOsm/kg), with little change occurring beyond 2 years of age. Clearly, with a urine osmolality of 1000 mOsm/kg, the 1- to 2-month-old infant is well protected from transient mild to moderate reductions in water intake. In fact, a nonhighly concentrated urine of 600 to 700 mOsm/kg is adequate for physiologic needs of the neonate and would even be adequate for an adult under most clinical circumstances. Physiologic and anatomic factors contributing to a low neonatal renal concentrating capacity are summarized in the next section.

Factors Limiting Concentrating Ability in the Neonate

Physiologic Considerations

Fluid Transport in Superficial Nephrons

Micropuncture studies reveal a maturation in water and solute transport in loops of Henle from superficial nephrons.[138,157-159] For example, in the rat,[159] the tubular-fluid-to-plasma inulin ratio of fluid distal to the loop (a measure of water reabsorption) increased from 13 through 39 days of age, a time when there was no change in the fraction of filtered water remaining at the end of the proximal tubule. Therefore the increase in tubular-fluid-to-plasma inulin ratio was due to increased water reabsorption along the loop. This increase in water reabsorption does not necessarily reflect greater water reabsorption in the thick ascending limb. It may relate to increased water reabsorption from the descending limb as this segment courses through the increasingly hypertonic outer medulla. In the final urine, inulin concentration increased by a factor of 5 during this time interval, indicating increased water reabsorption along the collecting ducts. In addition, the osmolality of the final urine increased from 700 to 1500 mOsm/kg. An increase in fractional reabsorption of sodium and chloride occurred along the loop. Furthermore, the potential diluting ability was also enhanced, as shown by a drop in sodium and chloride concentrations in early distal tubule fluid.

Ascending Thin Limb

Urinary concentration requires a countercurrent multiplication process allowing the medullary interstitium to become progressively hypertonic and the osmotic equilibration of medullary collecting duct fluid with the hypertonic medullary interstitium. To accomplish this, cells require a variety of channels and transporters. The ascending thin limb of Henle is highly permeable to chloride, likely related to its chloride channel ClC-K1. By facilitating efflux of NaCl to the interstitium, salt can osmotically induce movement of collecting duct water to the interstitium and increase the osmolality of collecting duct fluid. Failure to express this channel causes diabetes insipidus in the mouse.[97] Kobayashi and colleagues[160] related concentrating ability in the rat to expression of this channel. Maturation of the channel and the thin ascending limb correlated with an increase in concentrating ability. After dehydration, urine osmolality remained low until postnatal day 19. Concentrating ability then increased rapidly, with a marked increase by day 21.

The chloride channel was first noted near the papillary tip on day 5, increased by day 14, and was actually comparable with that of the adult by day 19. Its expression during development coincided with the increase in concentrating ability. Aquaporin-1 was present in inner medullary tubules by postnatal day 1, but its expression was weak. It increased to reach adult levels by day 14. Aquaporin-2 was present in the premature kidney throughout the inner medullary collecting duct, and its pattern did not change with maturation. Therefore water channels were present to allow for urinary concentration by water abstraction, and chloride channels matured to facilitate solute movement from the medullary ascending thin limb to interstitium to help establish and maintain a medullary gradient.

Fluid Transport in Collecting Tubules

The adult collecting tubule is a "tight" epithelium with high transepithelial electrical resistance and a low rate of reabsorbed sodium backfluxing to the lumen. Basal permeability to water is low, and the epithelial cells can maintain transepithelial osmotic and sodium gradients. By contrast, newborn (3 to 5 days of age) rabbit collecting tubules allow substantially more sodium backflux to the tubule lumen and have a lower transepithelial voltage and electrical resistance (Table 133-3). Therefore the newborn collecting tubule may be unable to maintain an adequate sodium (osmolar)

TABLE 133-3

Comparison of Baseline Characteristics of Newborn (3 - 5 Days) and Adult Rabbit Cortical Collecting Tubules

Characteristic	Neonate	Adult
Net sodium flux (pEq/mm/min)	−83.9 ± 21.3 (19)	−1.4 ± 25.3 (8)
Water absorption (nL/mm/min)	0.35 ± 0.13 (19)	0.12 ± 0.11 (8)
Transepithelial voltage (mV)	−0.1 ± 0.3 (32)	−2.8 ± 0.6 (10)
Transepithelial electrical resistance (Ω/cm^2)	83.2 ± 11.6 (10)	220.6 ± 55 (6)

Data from Reyes JL, Roch-Ramel F, Besseghir K: Net sodium and water movements in the newborn rabbit collecting tubule: lack of modifications by indomethacin. *Biol Neonate* 51:212, 1987.

Values expressed in mean ± SE; (*n* = number).

With bath to lumen sodium gradient (142.5 versus 100 mEq Na/L), adults maintained gradient, but neonates showed net luminal entry of Na; PD of newborn tubules is similar to zero; with perfusate hypotonic to bath, water reabsorption in adult tubules is similar to zero.

gradient and, consequently, be unable to build a driving force to abstract water efficiently from more distal parts of the nephron.[161]

Urea

It is curious that a urinary waste product performs a homeostatic function. The importance of urea to mammalian urinary concentration was recognized nearly 70 years ago when Gamble and colleagues[162] noted that adult rats fed urea excreted a more concentrated urine than rats fed a nonurea diet made equimolar by adding inorganic solutes. High-protein diets and urea loads increase urine concentration in the human adult.[163] Urea, a protein metabolic waste product, normally represents approximately 50% of the solute in maximally concentrated urine, but this is not the case in the neonate. Infants and adults have similar urinary content of nonurea (electrolyte) solute, but the urinary urea solute content of the infant is distinctly lower. Most of the increase in concentrating capacity occurs after birth and can be augmented by dietary alterations.[164,165]

Edelmann and colleagues[156] determined maximal urine concentrating ability in nine full-term and premature infants (7 to 39 days of age) who had been placed on diets varying in protein. Before a protein load, concentrating ability in infants was about half that of adults. When given a high-protein diet or a urea load, infants increased their maximal urine osmolality independent of fluid intake or urine output (Table 133-4). The low neonatal concentrating ability seemed to reflect the type of solute available to the renal medulla rather than an intrinsic problem with the newborn kidney. It was postulated that because the infant is in a highly anabolic state, concentrating ability was limited by the efficient use of protein, which would tend to minimize the amount of urea available to build up a medullary gradient. However, despite the high-protein diet, urine osmolality still did not reach adult levels, and the levels actually reached required an extremely high protein intake (i.e., 8 g/kg) and a very high blood urea nitrogen ranging to 45 mg/dL.

It is evident from other studies as well that urinary concentrating ability does not depend on diet alone.[166-169] Rats are weaned and accordingly change their diet during the third week of life when concentrating capacity is increasing sharply. Rane and colleagues[169] found that maximal concentrating ability increased during the third week both in rats who were normally weaned and in those who continued to nurse, indicating that the improvement in concentrating ability was independent of dietary composition or protein content (Figure 133-8). Also no concomitant change occurred in the serum level of ADH. Therefore the maturational effect is intrarenal. Rather than simply an insufficient urea content, the low level of neonatal urinary concentration is more likely related to some difference in the manner in which urea is handled by the kidney. Although the gradual increase in urea

28 (n = 3)	536 ± 56 (75%)
60 (adult; n = 6)	719 ± 68

From Imbert-Teboul M, Chabardès D, Clique A, et al: Ontogenesis of hormone-dependent adenylate cyclase in isolated rat nephron segments. *Am J Physiol* 247: F316, 1984.

Values (stimulated minus basal adenylate cyclase activity) are mean ± SE; response to 1 μM vasopressin of immature rat as percentage of the response of cyclic adenosine monophosphate (cAMP) formed in adult rat tubules given in parentheses. Note progressive sensitivity of tubule cAMP stimulation by vasopressin.

stimulates adenylate cyclase to form cAMP from adenosine triphosphate. The cAMP binds a protein kinase that catalyzes phosphorylation of apical membrane proteins. Cytoplasmic tubular structures are present in cells at rest. In the presence of ADH, these structures, containing small particles or aggregates, fuse with the apical membrane. The particles represent water channels (membrane proteins) that promote transmembrane osmotic water movement. This requires an intact cytoskeleton; disassembling microtubules interferes with the cellular response to ADH.[171,172] The newborn lamb responds to stimuli such as hypertonic saline, water loading, furosemide, dehydration, and blood loss[131,173] (Table 133-5), by appropriately elevating or suppressing ADH levels. The human newborn infant responds to hypertonic saline.[174] Human neonatal concentrating capacity remains limited even in the presence of elevated plasma ADH levels typical of the immediate newborn period in term and preterm infants.[112,175-178] Clearly lack of ADH does not explain a gross reduction in neonatal concentrating ability. Nonetheless, investigators still consider that the neonatal ADH-renal axis may be inadequate because, in the immediate newborn period of the rat, urinary osmolality is lower than papillary tip osmolality, and hormone levels in young animals are further increased (to levels comparable with that of older animals) in response to dehydration. Rather than an insufficient circulating level of ADH, the limited newborn concentrating ability may reflect decreased responsiveness to the hormone or a decreased number of ADH receptors.

Supporting this hypothesis, Schlondorff and colleagues,[121,122] studying isolated cortical collecting tubules of 10- to 12-day-old and adult rabbits, found that in the newborn rabbit, basal adenylate cyclase activity was considerably lower and stimulation of adenylate cyclase by ADH was much less than in the adult. The adult basal level of adenylate cyclase was 2.5 times that of the newborn rabbit. After stimulation with ADH, adult levels increased 10-fold in contrast to the 2.5-fold increase observed in newborn tubules.[121,122] In isolated rat collecting tubules, Imbert-Teboul and colleagues[119] reported a blunted ability of ADH to stimulate adenylate cyclase in the neonate[119] (Table 133-6). They found an initial increase in ADH-dependent adenylate cyclase during the first week of life, a plateau of activity from days 7 to 14, and a second period of increase in enzyme activity after day 14. Adult levels were reached by day 35.[119] However, the period of greatest increase in activity corresponded to a time when Edwards and colleagues[167] observed the sharpest increase in concentrating ability. In studies of the ontogenetic development of ADH receptors, Rajerison and colleagues[120] found a progressive increase in ADH stimulation of medullary adenylate cyclase in animals over a 2- to 46-day period with a concomitant, although slightly earlier, development of ADH binding capacity.[120,179,180] Vasopressin binding rapidly increased after birth so that the 3- to 4-week-old rat had a capacity to bind ADH to kidney medullopapillary membranes that was similar to that of the adult.[120,179,180] These findings suggest that the cAMP system or the binding properties or response to ADH are immature in the neonate.

In more recent studies, immature, isolated, perfused cortical collecting ducts were shown to have basal osmotic water permeability similar to mature tubules. However, the increase in water permeability after exposure to ADH was considerably less than that observed in adult tubules. The blunted response of immature tubules to ADH could not be abolished by exposing tubules to the stimulating effect of cAMP or to the inhibition of prostaglandin synthesis by indomethacin. The investigators concluded that in addition to any impairment in ADH-stimulated cAMP generation or antagonism of cAMP by prostaglandins, there is likely a more distal pathway disruption, perhaps at the level of the basolateral membrane.[181]

Sulyok[182] suggested that the response of a premature infant kidney to ADH may become blunted by the presence of hyponatremia, a state that may occur in the first few weeks of life. Premature infants with late hyponatremia show an *increase* in ADH excretion with age, even though their serum sodium levels and osmolality fall and their urine osmolality *diminishes* as urine flow rate increases. Renal salt wasting and hyponatremia may hinder establishment of an intrarenal salt gradient at a time when salt, rather than urea, would be the primary medullary solute. Although there might be a delay in maturation of concentrating ability, a blunted response to ADH could minimize the retention of excess water and may thereby serve to limit the severity of the hyponatremia. The late development of hyponatremia in premature infants can be prevented by administration of supplemental NaCl. Such infants have increased sodium excretion; nevertheless, they are in positive sodium balance and their ADH secretion is increased. The salt supplement appears to enhance ADH secretion with resultant retention of water, although in proportion to salt retention, because serum sodium remains relatively constant.[183]

Aquaporins

Aquaporin-1 is present in rat renal proximal tubules and thin descending limbs of Henle and is expressed in these tissues shortly before birth. However, the amount of renal aquaporin-1 messenger RNA is small in the kidney before and shortly after birth. Significant expression of aquaporin-1 does not occur until after birth.[184] Peak levels appear around 3 weeks of postnatal age. It is present in both apical and basolateral membranes in an equivalent staining intensity, suggesting that this protein appears simultaneously in both membranes.[185,186] Betamethasone stimulates a significant, modest induction of aquaporin-1 in neonatal rat kidneys 4 days of age. Adult rats showed no such response.[43] By contrast, aquaporin-1 was detected by immunohistochemical staining techniques in the human fetus at 14 weeks gestation in a newly developing proximal tubule, and, by 17 weeks, staining

was evident in both developing proximal tubules and in newly forming thin limbs from the outer cortex. By 24 weeks, staining was noted in thin limbs of the medulla. At 1 month of postnatal age, aquaporin-1 immunostaining was prominent over apical and basolateral membranes of proximal tubules and thin descending limbs of Henle.[187] This finding correlates with differences in concentrating ability; the human kidney concentrates urine at birth, and concentrating ability approaches that of the adult by 1 to 2 months (see earlier discussion), whereas the rat concentrates urine primarily at the time of weaning.[169]

In other studies, aquaporin-1 was observed as early as 12 weeks gestation in the human fetus, although not at 8 weeks, and was shown to increase steadily to reach 47% of adult levels at birth and 79% of adult levels by 15 months of postnatal age.[188] This coincides approximately to the age when urine concentrating ability reaches adult values (see Table 133-2). In this study, aquaporin-1 was initially localized to newly forming proximal tubular structures in the inner cortex. S-shaped bodies, glomeruli, and tubular structures of ureteric bud origin were not stained for aquaporin-1. By 15 to 20 weeks, proximal tubular structures in the cortex were better differentiated, and staining could be seen to localize mainly in the apical membrane of polarized epithelial cells to include proximal tubules and thin descending limbs of Henle. Basolateral staining, evident in proximal tubules and thin descending limbs in adult kidneys, was not clearly defined in the fetal kidneys, even at 24 weeks[188] (Figure 133-9).

As mentioned earlier, aquaporin-1 is poised to facilitate reabsorption of large amounts of water in proximal tubules and development of the countercurrent multiplication process by allowing rapid movement of water across thin descending limbs. Whereas osmotic water permeability of neonatal proximal tubules is higher than that of adults, osmotic permeability of brush-border membrane vesicles in neonates is lower. Quigley and colleagues[189] reported that in rabbit proximal tubular basolateral membrane vesicles, both expression of aquaporin-1 protein and osmotic water permeability were lower in neonates than in adults, although solute permeability (NaCl, $NaHCO_3$) was similar. They concluded that the higher neonatal transepithelial osmotic permeability in the neonate is not related to increased water movement across water channels.

Aquaporin-1 is also present in descending vasa rectae of adult kidneys. However, an interesting pattern of distribution of this protein is seen in the developing rat kidney.[190] Aquaporin-1 was found throughout the arterial vascular tree of fetal and neonatal kidneys from 17 days gestation to 7 days of postnatal age. During the next week expression regressed, becoming limited to descending vasa rectae. After about 3 weeks of age, aquaporin-1 also appeared in lymphatic vessels. This persisted in adults. The investigators suggest that the transient developmental expression may relate to fluid equilibrium in the developing kidney, or perhaps to a role in regulating fetal growth or branching of the vascular tree.

Aquaporin-2 protein and aquaporin-2 messenger RNA have been reported in rats to increase during 10 to 40 days of life and particularly over the weaning period from 15 to 20 days of life, a period of time when urinary concentrating ability dramatically increases. When rats were exposed to a single injection of betamethasone, known to accelerate maturation in other organs, an increase in renal medullary aquaporin-2 protein and messenger RNA as well as in urine osmolality occurred.[191] In studies of aquaporin expression during human nephrogenesis, aquaporin-2 was seen by week 12 of gestation, but not at 8 weeks. In contrast to aquaporin-1, aquaporin-2 was found only in structures derived from the ureteric bud. For example, in a 13-week fetal human kidney, aquaporin-2 stained in apical cell membranes in the collecting system and branching ureteric bud as it extended from the medulla toward the cortex. Comma- and S-shaped bodies, glomeruli, and proximal tubular structures did not stain for aquaporin-2, and this pattern continued throughout development. Therefore, it was evident from early in gestation that aquaporin-1 staining was limited to proximal segments and thin descending limbs, whereas aquaporin-2 was exclusively found in ureteric bud-derived cortical and medullary collecting duct segments[188] (see Figure 133-9).

Bonilla-Felix and Jiang[192] found that aquaporin-2 expression was reduced in immature rats compared with adults. The relation between aquaporin-2 expression and urinary osmolality on ad libitum fluid intake was close. However, whereas immature rats increased their aquaporin-2 content after stimulation with both dehydration and ADH, concentrating ability was not concurrent or equal. Immature rats did show an ability to translocate aquaporin-2 from intracellular vesicles (during water loading) to plasma membranes (during dehydration or treatment with ADH). Thus, although aquaporin-2 expression and trafficking were present in immature kidneys, concentrating ability was still limited.

Baum and colleagues[193] found expression of aquaporin-2 (apical membrane) and aquaporin-3 (basolateral membrane) in rat epithelial cells derived from ureteric bud and collecting ducts. Expression was detected as early as 16 to 18 days gestation. They also found expression of both aquaporins in comparable membranes of collecting ducts in human 3-day-old and adult kidneys. The rat kidneys showed little change in aquaporin expression over the first 3 days of life, but showed a dramatic (2.5-fold) increase in aquaporin-2 messenger RNA by 10 to 14 days of life. Given the presence of fetal and neonatal aquaporins, delay in maturation of maximal concentrating ability in neonates is not related to a simple lack of water channels. However, the importance of functional aquaporin-2 protein in neonates was illustrated in an aquaporin-2 knockin mouse model of recessive diabetes insipidus. Gene replacement caused a mutant protein leading to death within approximately 6 days of life without supplemental fluid.[194]

In one study, aquaporin-3 and aquaporin-4 expression was demonstrated in rat kidney basolateral membrane collecting duct cells after birth, but staining intensity was stable throughout life. By contrast, aquaporin-2 staining increased with age.[184] In another study, aquaporin-4 was detected early in the postnatal period of mice and rats, and there was a gradual increase in immunostaining during development.[195] Although the correlation between aquaporin expression and increasing concentrating ability during maturation may not be unequivocal, a general increase in aquaporin expression that occurs as concentrating ability matures is clearly seen.[196]

Prostaglandins

Prostaglandins, synthesized in renal medullary interstitial and collecting duct cells, are thought to regulate medullary functions such as blood flow, sodium chloride transport, and water reabsorption. Accordingly, prostaglandins could play a role in urinary concentration.[197,198] In experimental animals, prostaglandin E_2 (PGE_2) was found to inhibit sodium chloride transport in the medullary thick ascending limb.[199] PGE_2 antagonizes ADH-mediated water flow across the collecting tubule and bladder,[4] inhibits urea flux across toad bladder epithelium, and decreases urea reabsorption in the rat collecting tubule.[200,201] PGE_2 also can induce renal vasodilation and increase medullary blood flow.[53] These effects tend to wash out a medullary osmolar gradient and decrease maximal concentrating capacity. In fact, prostaglandins reduce the corticomedullary osmotic gradient and the medullary solute (salt and urea) content,[202] thereby reducing the driving force for water reabsorption. It has been suggested that increased prostaglandin synthesis in fetal and neonatal kidneys and blood vessels may interfere with neonatal concentrating ability.[203-205] However, the relationship between prostaglandin excretion and maturation of renal function is not firmly established,[206] and a role of prostaglandins becomes clouded when one recognizes that prostaglandin excretion increases with age. Benzoni and colleagues[207] noted that urinary excretion of PGE increased

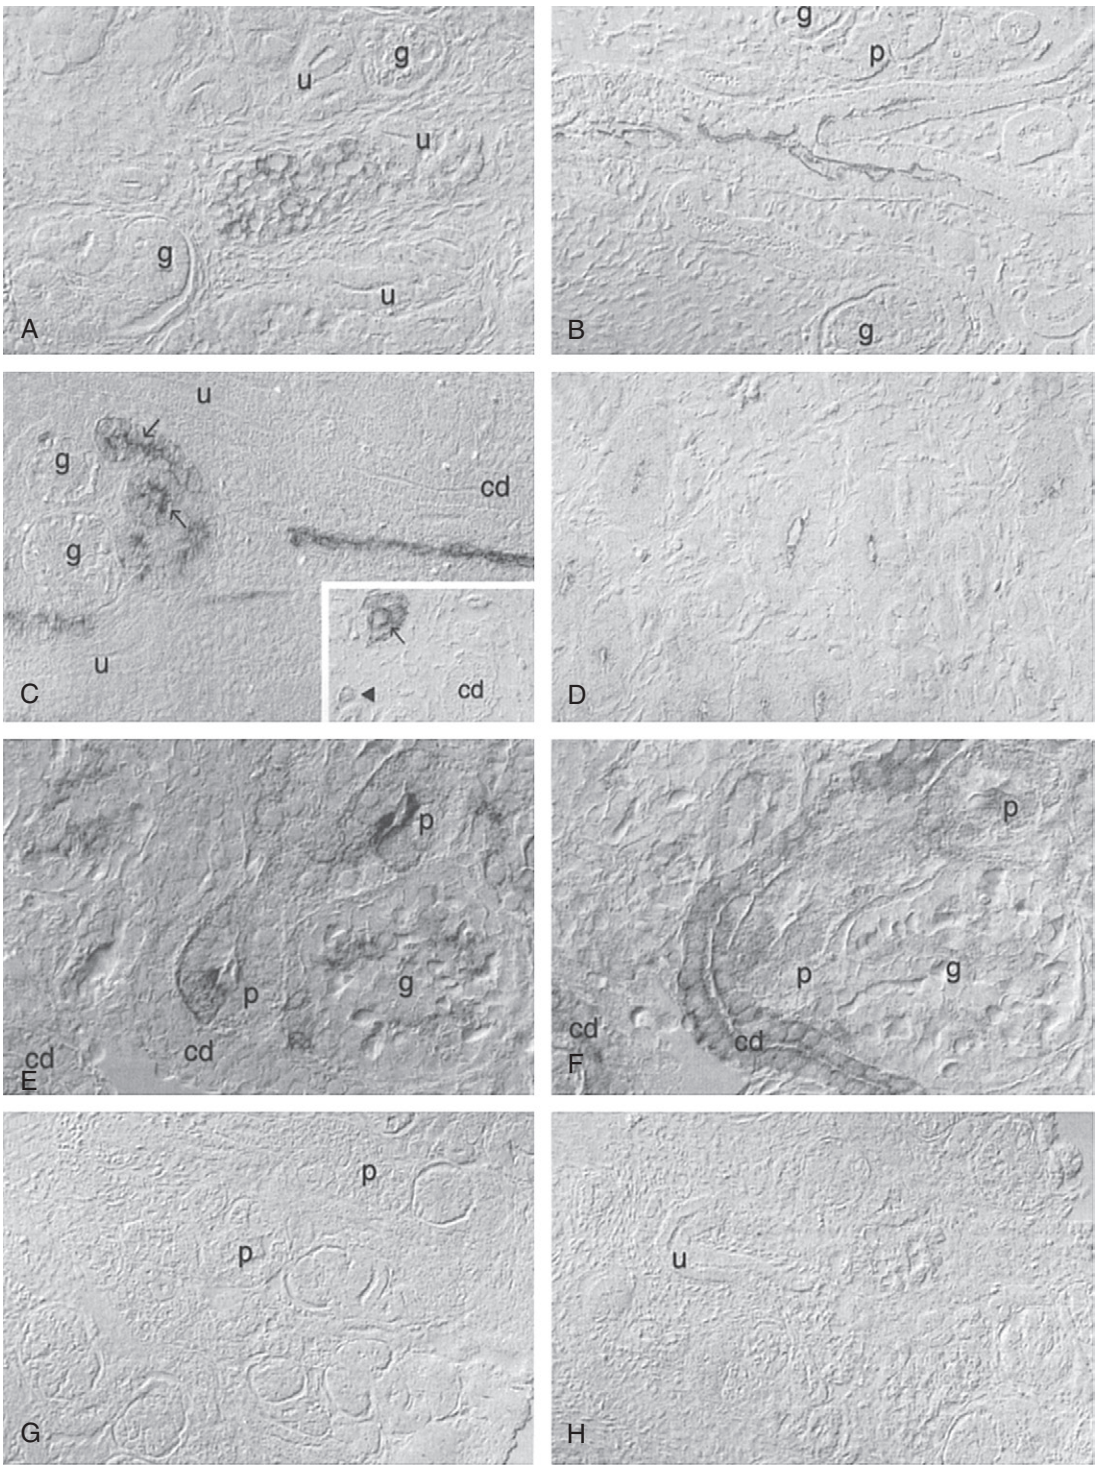

Figure 133-9 Immunohistochemical staining to localize aquaporin-1 and aquaporin-2 during human nephrogenesis. **A,** Positive staining for aquaporin-1 is restricted to a developing proximal tubule in the inner cortex of a 13-week human fetal kidney. Adjacent ureteric buds *(u)* and immature glomeruli *(g)* are unstained. No membrane polarity is localized. **B,** Staining for aquaporin-2 is positive in a branching ureteric bud and localized to the apical membrane in the inner cortex of a 13-week human fetal kidney. Glomeruli *(g)* and immature proximal tubules *(p)* are unstained. **C,** Positive staining for aquaporin-1 in a 15-week human fetal kidney. Staining is present for juxtaglomerular proximal tubules extending to the medulla, where an early descending thin limb of Henle is stained *(inset);* apical membranes are stained in proximal tubules *(arrows)* and thin descending limbs *(inset arrowhead).* Glomeruli *(g),* ureteric buds *(u),* and collecting ducts *(cd)* are unstained. **D,** Positive staining for aquaporin-2 is restricted to the apical membrane region of medullary collecting ducts in an 18-week human fetal kidney. **E** and **F**, Sections from the cortex of a 24-week human fetal kidney. In **E**, staining for aquaporin-1 is positive in the apical membrane of proximal tubule cells *(p).* Collecting ducts *(cd)* are unstained. In **F,** staining for aquaporin-2 is positive in collecting ducts *(cd)* and not in proximal tubule cells *(p).* Minimal glomerular *(g)* staining for aquaporin-1 and basolateral collecting duct staining for aquaporin-2 were nonspecific. **G,** Cortex of an 18-week human fetal kidney shows no aquaporin-1 staining in proximal tubules *(p)* when tissue is incubated with preimmune serum for aquaporin-1. **H**, Inner cortex of a 14-week human fetal kidney shows no ureteric bud *(u)* staining when tissue is incubated with preimmune serum for aquaporin-2. See reference 188 for details. *(From Devuyst O, Burrow CR, Smith BL, et al: Expression of aquaporins-1 and -2 during nephrogenesis and in autosomal dominant polycystic kidney disease.* Am J Physiol *271:F169, 1996.)*

during the first 24 months of life and correlated linearly with urine osmolality. Although this period is precisely when urinary concentrating ability shows the most dramatic degree of maturation, a clear cause and effect relationship was not established.

Perhaps any limiting effect of prostaglandins on the neonatal concentrating ability is largely masked by the relentless maturation of the many other factors that come to bear on the concentrating process. Nevertheless, studies using molecular biologic techniques are of interest. At least three different receptors for PGE_2 have been identified. These activate different intracellular signaling mechanisms, and the EP3 receptor, which is coupled to an inhibitory guanine nucleotide-binding G protein, inhibits generation of cAMP when stimulated by PGE_2. Immature collecting ducts have decreased generation of cAMP when stimulated by ADH. This response is mediated by prostaglandin, probably by activating the inhibitory G protein.[208] Receptor mRNA expression was found primarily in the distal nephron, (i.e., in medullary thick ascending limbs) as well as cortical and inner medullary collecting ducts. During development, rabbit kidney expression for the EP3 receptor mRNA increased to a maximum at 2 weeks of postnatal age and then decreased to reach adult levels by 8 to 10 weeks of postnatal age.[209] This finding lends credence to the idea that part of the blunted concentrating ability in maturation relates to increased expression of an inhibitory receptor stimulated by PGE_2 that blunts the ability of ADH to stimulate cAMP in collecting ducts.

Renin-Angiotensin System

It has become clear that the renin-angiotensin axis must be intact during nephrogenesis for normal development of urinary concentration. Profound adverse effects on adult renal function occur when the angiotensin-converting enzyme inhibitor enalapril or the angiotensin II type 1 receptor antagonist losartan is given early in neonatal life during nephrogenesis. For example, use of these agents in neonatal rats and piglets causes irreversible histologic changes, including chronic interstitial inflammation and fibrosis, renal vascular changes involving interlobular arteries, and, most particularly, profound papillary necrosis. Functionally, as adults, such animals show polyuria and a decreased urinary concentrating ability. The effect on other functions is variable. Proximal tubular fluid reabsorption is reduced, whereas glucose reabsorption, urinary acid excretion, acidifying ability, glomerular filtration, and renal blood flow are largely unaffected.[210-214] The most critical period for renal vulnerability for adverse effects appears to be the first 13 days of life in the rat, coinciding with the duration of continued postnatal nephrogenesis.[211] Of interest, histologic and functional abnormalities were normalized in enalapril-treated rats when they were concomitantly treated with insulin-like growth factor-I, another renal growth-promoting factor.[215] In functional studies, decreased urine concentrating ability was associated with a decrease in negative water clearance (T_cH_2O), medullary tissue osmolality, Na and urea concentration, and density of inner medullary aquaporin-2. Because density of aquaporin-2 is higher in the proximal one third than the more distal two thirds of the inner medullary collecting duct located mainly in the papilla, it would seem that the decreased concentrating ability is not wholly due to papillary atrophy.[213]

Anatomic Considerations

Loops of Henle of Deep Nephrons

Maximal concentrating ability directly correlates with the lengths of long loops of Henle as they descend into the medulla. Species able to develop highly concentrated urine tend to have both longer loops of Henle and a greater proportion of nephrons that send their loops deep into the medulla.[13] In the newborn infant, the length of loops and the renal papillae are relatively short, but they increase during maturation.[136] In the newborn rabbit, the inner medulla and papilla are underdeveloped, but during the first week of postnatal life the medulla becomes larger and the papillae become longer. Maximal concentrating ability in the rabbit increases from an osmolality of 600 mOsm/kg at birth to approximately 2000 mOsm/kg by 3 weeks of age. When osmotic solute gradients in the papilla are measured during development, sodium and urea concentrations are seen to increase gradually and roughly in parallel to approach adult levels by 6 weeks of age[155] (Table 133-7). Improved concentrating ability during development, therefore, might reflect the development of these anatomic parameters. However, Rane and colleagues,[169] evaluating the role of steroid hormones in the development of the concentrating mechanism in rats, observed an increase in urine osmolality and papillary tissue sodium and urea content from day 16 to day 20 that was temporally related to an increase in serum corticosterone. The increased concentrating ability was augmented by treating rats with exogenous glucocorticoids (betamethasone) and prevented by adrenalectomy. However, the length of the papilla (i.e., length of long loops of Henle) was not affected by adrenalectomy, indicating that the growth of long loops of deep nephrons contributed little to maturation of concentrating ability during this time. Perhaps glucocorticoids can modulate enzyme systems that help augment maturation of the hypertonic medullary gradient and the urinary concentrating mechanism.

TABLE 133-7

Comparison of Sodium and Urea Content in the Cortex and Papilla of Maturing Rabbits

Loops of Henle of Short Nephrons

Long loops of juxtamedullary nephrons help determine the degree to which urine can be concentrated, but the shorter loops of superficial nephrons also play a pivotal role.[13,167] These nephrons allow accumulation of urea in the inner medulla by increasing the load and concentration of urea delivered to medullary collecting ducts and recycling urea to minimize its loss from the medulla. Were interstitial urea to enter long loops and vasa rectae and leave the medulla, the medullary urea gradient would become depleted. By entering descending limbs of superficial nephrons, urea can recycle to the medulla and maintain the gradient. In fact, the descending limbs of short loops of superficial nephrons, not long loops of deep nephrons, are the ones that accompany vascular bundles of the inner stripe of the outer medulla.

Edwards and colleagues[167] clarified the role of short-looped nephrons in maturation of the concentrating mechanism (Figure 133-10). In the rat, 40% to 50% of total solute in the adult papillary interstitium is urea. During nephrogenesis, superficial nephrons are the least mature and the last to develop. Their entrance or elongation into the deeper cortical and outer medullary portion of the kidney coincides with improvement in concentrating ability. During the first 16 days of life, the length of the

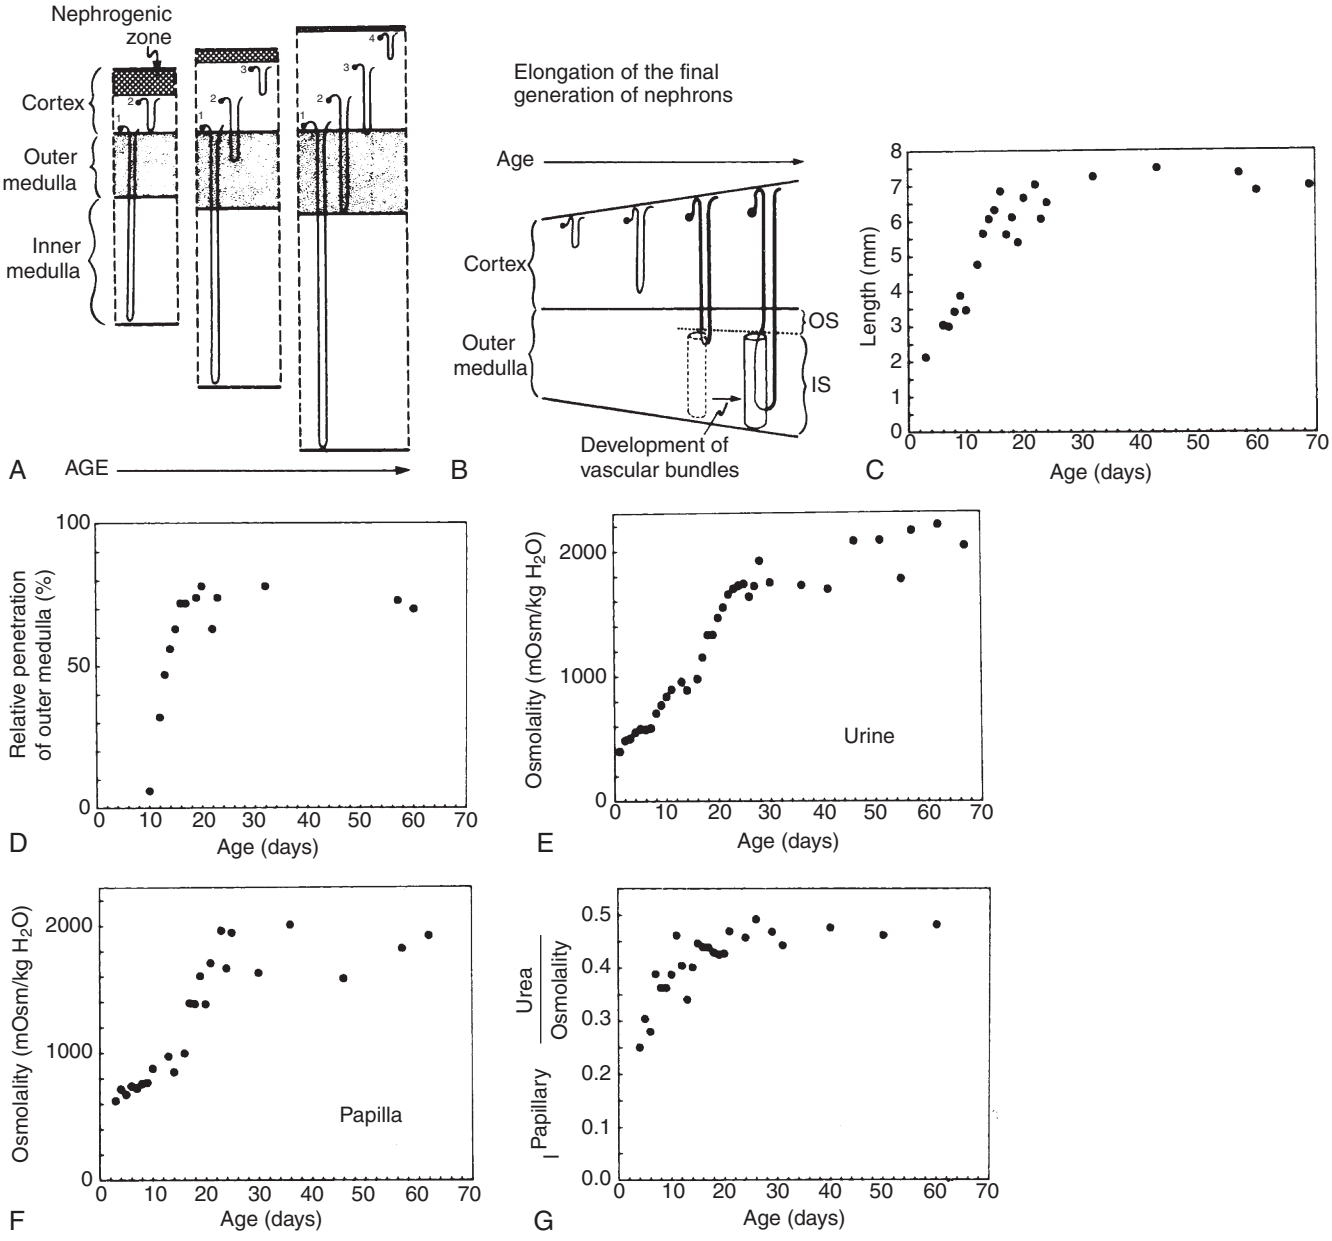

Figure 133-10 These figures depict anatomic maturation of superficial and deep nephrons, penetration of short-looped nephrons toward outer medulla, and maturation of concentrating ability. **A,** Simplified scheme of nephrogenesis in the rat. Numbers refer to successive generations of nephrons. **B,** Diagrammatic representation of elongation of the loop of Henle belonging to a surface nephron. In the rat, the vascular bundles are recognizable at 20 days of age but not at 10 days. The descending limbs of superficial loops become incorporated with these structures. *IS,* Inner stripe; *OS,* outer stripe;. **C,** Length of the corticopapillary gradient as a function of age in the rat ($N = 28$). Each point represents a single animal except for days 13, 15, and 18 (two rats each) and day 14 (three rats), for which averages are shown. **D**, Penetration of outer medulla by superficial loops of Henle. Each point represents a single animal except for day 13 (two rats) and day 14 (three rats). An average of three loops per rat was examined. **E,** Urinary osmolality, after 8 hours of dehydration, as a function of age in the rat ($N = 138$). Each point represents the average value for one to eight rats (mean rats). **F,** Osmolality of the papillary tip, after 8 hours of dehydration, as a function of age in the rat ($N = 56$). Each point represents the average value for one to five rats (mean = 2.3 rats). **G,** Fraction of total papillary osmolality contributed by urea as a function of age in 67 rats dehydrated for 18 hours. Length of corticopapillary gradient increases with age, particularly in the first 16 days, corresponding to time of most marked elongation of superficial loops. Urine and papillary tip osmolality increase primarily in the first 3.5 weeks and most steeply after approximately day 16. The proportion of urea composing papillary osmolality increases until adult proportions are reached by approximately 15 to 20 days. *(From Edwards BR, et al: In Spitzer A [ed]:* The Kidney During Development: Morphology and Function. *New York, Masson, 1982, pp 223-240.)*

corticopapillary gradient increased 3.4-fold and the superficial nephrons elongated markedly so that they came to cross more than 70% of the outer medulla. During this time, urinary osmolality increased following a period of water deprivation. After maximal penetration of superficial loops to the outer medulla had occurred, urinary concentrating ability increased even more sharply, coincident with a marked increase in papillary tip osmolality and an increase in the proportion of the papillary solute composed of urea. It should be re-emphasized that the bulk of filtered fluid is reabsorbed in the cortex.This decreases the amount of fluid delivered to the collecting ducts.Therefore deeper tissues are not faced with the need to reabsorb so much water that the medullary solute gradient would be diluted and dissipated. The arcade segments in the renal cortex appear to play an important role in this regard (see later discussion).

The ability to use urea to enhance urinary concentration matures over the first 3 weeks of life in rabbits and rats.[216,217] For example, Trimble[217] found that an acute exogenous nondiuretic urea load given subcutaneously had no effect on urinary concentrating ability in rats 10 days of age, but it increased the medullary urea content and maximal concentrating ability in rats 20 days of age (Table 133-8). During this time, developmental changes occur in the length of the corticopapillary gradient and the length of superficial loops so that they penetrate well into the outer medulla. In addition, complex vascular bundles appear in the outer medulla, and the diluting capacity of superficial loops of Henle improves.

Zink and Horster[138] found that in young rats up to 15 days of age on a high-salt diet, fluid from the early distal tubule was isotonic with plasma and contained primarily NaCl as the solute. However, in rats 4 to 5 weeks of age, the early distal tubular fluid became hypotonic and contained a much smaller proportion of total solute as NaCl. Therefore the loop more efficiently reabsorbed NaCl without water. In other studies, Horster[157,158] reported a maturational increase in NaCl reabsorption in rabbit cortical thick ascending limbs. These factors help accumulate urea in the medulla. Edwards and colleagues,[167] in fact, found that the urea contribution to rat papillary osmolality increased sharply over the first 2 to 3 weeks of life, but thereafter further increases in papillary osmolality were associated with proportional increases in urea and nonurea solute.[167] Therefore urea accumulated in the papilla coincident with an increased activity of sodium absorption in the loop of Henle and a rearrangement of nephrons so that superficial nephron loops came to penetrate the outer medulla.

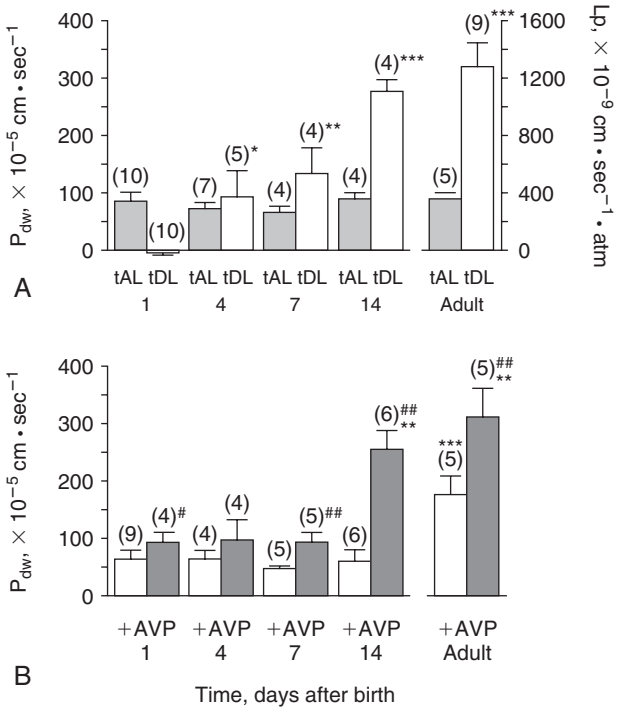

Figure 133-11 Maturational changes in water transport. **A,** Water permeability *(P_{dw})* was constant and low through adulthood in thin ascending limb *(tAL),* emphasizing its impermeability, and remained low in thin descending limb *(tDL)* until day 14, indicating low water permeability during the neonatal period. **B,** In the inner medullary collecting duct, basal water permeability *(clear bar)* remained low until adulthood. Vasopressin 1 nmol/L *(hatched bar)* stimulated water transport only modestly in the early neonatal period, but did not reach adult levels until day 14. $^{*}p < .05$; $^{**}p < .01$; $^{***}p < .0001$ versus day 1; $\#p < .05$; $\#\#p < .01$ versus baseline. Number in parentheses indicates number of tubules examined. *(From Liu W, Morimoto T, Kondo Y, et al: "Avian-type" renal medullary tubule organization causes immaturity of urine-concentrating ability in neonates.* Kidney Int *60:680, 2001.)*

Renal Inner Medullary Tubule Organization

Liu and colleagues[218] analyzed organization and function of inner medullary tubules during development in isolated perfused tubules from rat kidneys. In thin descending limbs, hydraulic water conductivity was absent on day 1, appeared by day 4, but remained low until day 14 of life. This segment was impermeable to water early in life. Diffusional water permeability of thin ascending limbs was low from day 1 to adulthood, emphasizing low water permeability of this segment. Basal water permeability remained low in inner medullary collecting ducts until adulthood. Water permeability was mildly enhanced by vasopressin in this segment early in life, but remained low and only reached adult levels by day 14 (Figure 133-11).Therefore little water reabsorption occurred from these segments early in life.

Urea permeability was low in thin descending limbs throughout development and adulthood. In thin ascending limbs, urea permeability was low, but reached two thirds of adult value by day 14. In the inner medullary collecting duct, basal urea permeability was negligible until day 7 and remained low into adulthood. Vasopressin induced little increase in urea permeability in this segment until day 14, although this value was still less than a third that of the adult (Figure 133-12). Expression of the urea transporter UT-A1 was not apparent until the late neonatal period. Therefore urea transport contributed little to neonatal urinary

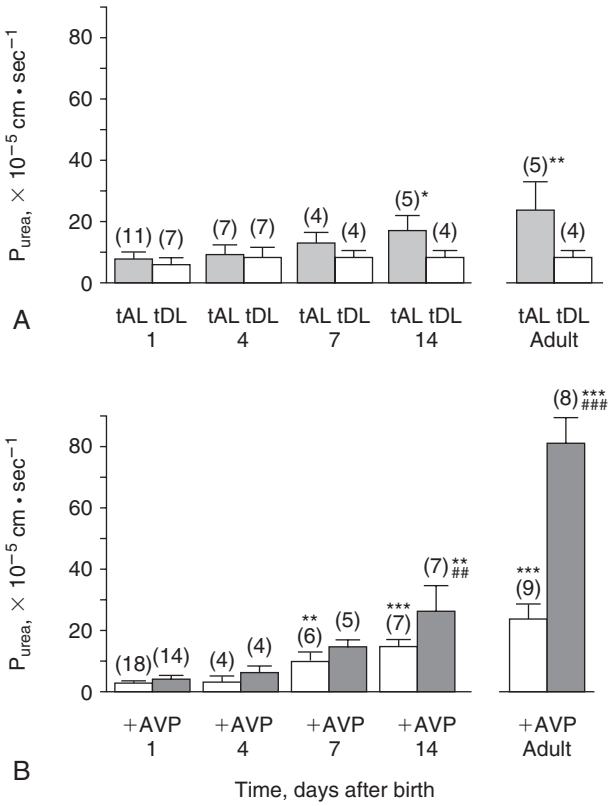

Figure 133-12 Maturational changes in urea permeability.
A, Urea permeability *(P_{urea})* was low through adulthood in thin descending limb *(tDL)* and gradually increased in thin ascending limb *(tAL),* approaching adult values only by day 14.
B, In the inner medullary collecting duct, basal urea permeability increased by day 7 and increased only mildly thereafter. Vasopressin *(AVP)* stimulated urea transport by day 14, but the value was considerably less than that of the adult. Number in parentheses indicates number of tubules examined. *$p < .05$; **$p < .01$; ***$p < .0001$ versus day 1; ##$p < .01$; ###$p < .0001$ versus baseline. *(From Liu W, Morimoto T, Kondo Y, et al: "Avian-type" renal medullary tubule organization causes immaturity of urine-concentrating ability in neonates.* Kidney Int *60:680, 2001.)*

concentration. The chloride channel ClC-K1 was expressed in thin ascending limbs from day 1 through adulthood, but it was functionally absent early in life because chloride permeability via this channel was not appreciable. The Na-K-Cl2 co-transporter CCC2 was prominent in the thin ascending limb early in life, similar to that in the thick ascending limb, but it regressed in the thin limb by adulthood to be replaced functionally by the chloride channel. In addition, early in life, transepithelial voltages in the thin ascending limb could be inhibited by bumetanide (inhibitor of the Na-K-Cl2 cotransporter in the thick ascending limb) and ouabain (inhibitor of the Na pump), and transepithelial voltages in the inner medullary collecting duct could be inhibited by amiloride (inhibitor of Na channel and active electrogenic Na reabsorption). These results indicate capability for active NaCl reabsorption in the thin ascending limb early in life, in contrast to its passive reabsorption in this segment in adults. Aquaporin-1 was observed by day 4 in thin descending limbs, persisting into adulthood, and aquaporin-2 was present throughout development. These findings, taken with others, indicate that water channels became poised to support water transfer once other medullary relationships are in place.

The investigators concluded that there is a fundamentally different organization of the inner medulla between neonates and adults (Figure 133-13). Transiently early in life, the inner medulla is characterized by active reabsorption and accumulation of NaCl. Compared with that of the adult, the thin descending limb is much less permeant to water. Because the thin ascending limb remains impermeant to water, the neonatal inner medulla is poised to reabsorb NaCl actively without water transfer, allowing urinary dilution early in life. At the same time, the inner medullary collecting duct is not geared to recycle urea. Subsequently, tubular transport properties appear that include increased thin descending limb water permeability, passive NaCl reabsorption in the thin ascending limb with functional maturation of a chloride channel, and increased urea permeability and responsiveness to vasopressin. Efficient urinary concentration requires that these properties be in place.

Renal Blood Flow

In the adult kidney, 90% of blood flows through the cortex only, 10% perfuses the outer medulla, and 1% to 2% reaches the inner medulla and papilla. This arrangement helps preserve the osmotic gradient established by the countercurrent mechanism. Rapid flow through the medulla tends to dissipate it. Neonatal renal blood flow is proportionately greater to deeper medullary regions of the kidney, and glomerular blood flow is greater in deep than in superficial nephrons.[139-141] After birth, renal vascular resistance drops more than resistance in systemic vessels, cardiac output and surface area increase briskly, and renal blood flow rises. Increases in single-nephron blood flow are proportionally greater in outer than in deep cortical nephrons. A relatively greater medullary flow in neonatal kidneys may delay establishing the corticomedullary gradient.

Renal Pelvis

The renal pelvis in the newborn animal is relatively narrow and does not extend too far into the body of the kidney. As the animal matures, secondary fornices and outpouchings of the renal pelvis come to extend well toward the renal cortex (Figure 133-14) so that urine in the pelvis will bathe a greater part of the papilla.[155,217] As mentioned previously, this pelvic maturation may facilitate recycling of urea from pelvic urine back to medullary interstitium to further increase both interstitial solute concentration and final urine osmolality. It is of interest that ADH appears to have some impact on the growth of the renal medulla and renal pelvis. In young growing lambs, treatment with ADH (DDAVP) for 13 weeks starting at 2 weeks of life induced an increase in the size of the renal medulla, especially the outer medulla, and the surface area of the renal pelvis. Ruminants have particularly well-developed renal pelvic fornices in their outer medulla. This is the area where dimensions were most impressively enlarged by vasopressin. Therefore the outer medulla may play a particularly important role in the reabsorption and recycling of urea in these animals.[219] Nevertheless, the role of this whole process in maturation of the urinary concentrating mechanism remains speculative at this point.

In summary, the low urinary concentrating capacity of newborn mammals is related to a variety of anatomic and functional factors. The loops of Henle are relatively short, the transport properties of the thick ascending limb of Henle are immature, and the number of loops of Henle from more superficial nephrons that penetrate deeper into the cortex and outer medulla is insufficient. Renal blood flow to deeper juxtamedullary nephrons is proportionally greater in the newborn than in the adult. Enhanced prostaglandin production has the potential to reduce salt, water, and urea transport at critical sites and to increase medullary blood flow. These factors may all contribute to the smaller medullary gradient and the lower medullary urea content found in the newborn. Neonatal collecting duct cells have decreased responsiveness to ADH and limited ability to maintain a transepithelial sodium (osmolar) gradient. Pelvic spaces surrounding

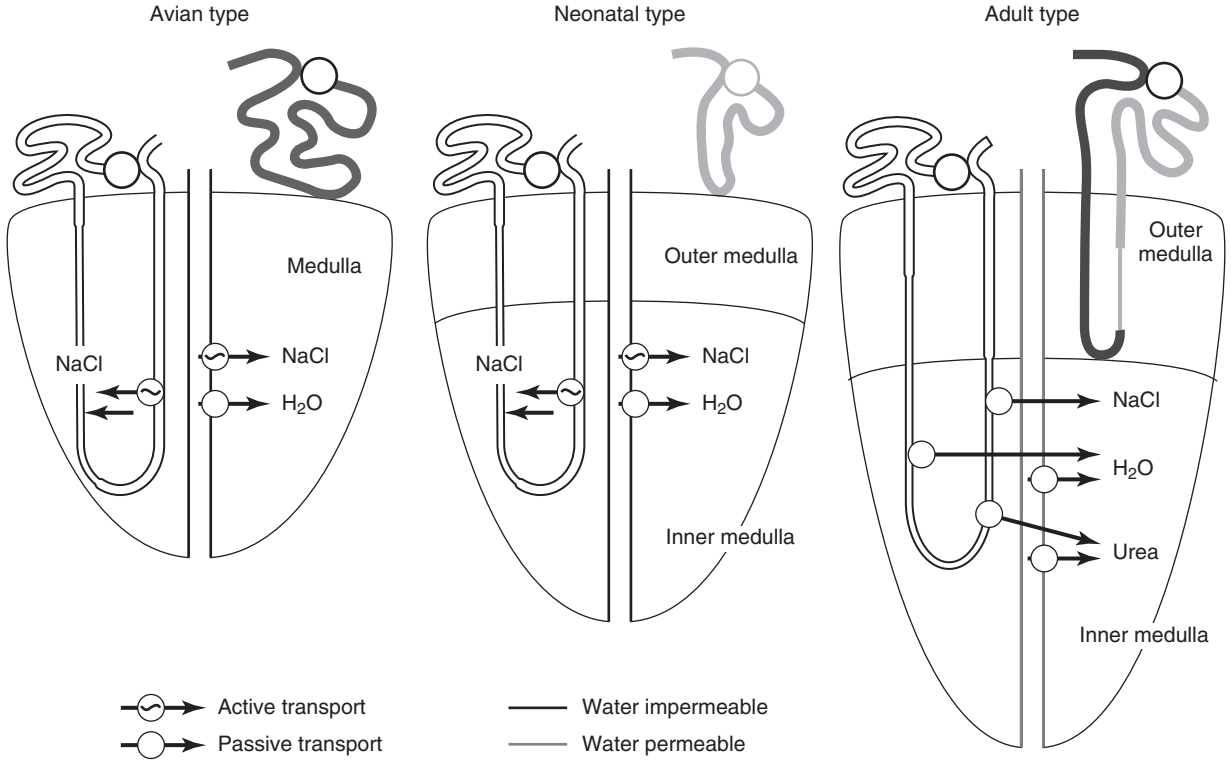

Figure 133-13 Comparison of neonatal and adult renal medullary tubule organization. In the neonatal kidney, only long-looped nephrons penetrate the medulla, and the medulla has essentially no water movement in loops of Henle. Medullary NaCl accumulates by active transport in the thin ascending limb, and there is amiloride-sensitive Na reabsorption in the inner medullary collecting duct. During maturation, cortical loops come to penetrate the outer medulla. In addition, NaCl reabsorption becomes passive in thin ascending limb, collecting duct amiloride-sensitive Na reabsorption disappears, the thin descending limb becomes water permeant, and urea permeability in the inner medullary collecting duct becomes highly sensitive to vasopressin. Neonatal tubule organization is likened to the avian kidney. Delayed maturation of neonatal concentrating ability is related to a more "primitive" tubule organization early in life. *(From Liu W, Morimoto T, Kondo Y, et al: "Avian-type" renal medullary tubule organization causes immaturity of urine-concentrating ability in neonates.* Kidney Int *60:680, 2001.)*

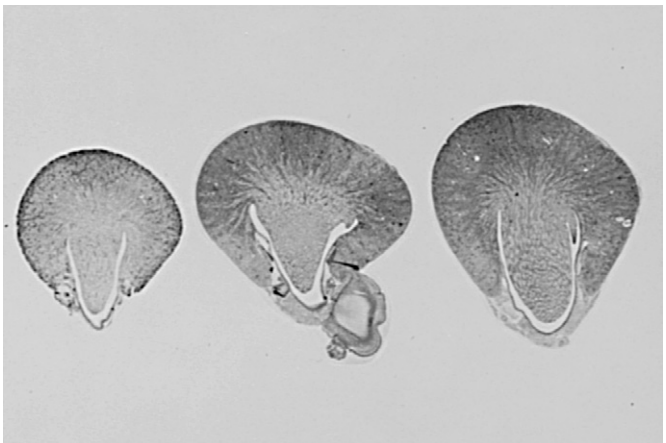

Figure 133-14 Cross-section showing gross structure of kidney and renal pelvis. In a 3-day-old rat *(left),* specialized fornices, evaginations of pelvic space, are absent and the pelvis is of the simple type. In a 10-day-old rat *(center),* specialized fornices are just beginning to appear, and by 20 days of age *(right),* fornices are well developed and extend into kidney tissue between the cortex and outer zone (× 7). *(From Trimble ME: Renal response to solute loading in infant rats: Relation to anatomical development.* Am J Physiol *219:1089, 1970.)*

papillae are narrower and more extensive in adults. This latter anatomic difference may contribute to a low concentrating ability during maturation because urine bathing the papillae may enhance urine and papillary osmolality. Aquaporin-1 may also limit neonatal concentrating ability because the amount of this protein is decreased in the human kidney at birth and increases gradually to approach adult levels at a time when the young kidney concentrates urine nearly as well as the adult. Less likely to play a role is aquaporin-2 because this protein is not only present in utero at 20 weeks gestation but also must be functional as evidenced by the response of the isolated human fetal medullary collecting tubule of similar gestational age to vasopressin.

PHYSIOLOGY OF THE URINARY DILUTING MECHANISM

Urinary dilution is thought to have developed when our primitive ancestors left the briny seas for more freshwater habitats. In so doing, they were forced to evolve mechanisms that could separate water from solute to preserve needed solute, eliminate imbibed excess water, and avoid fatal dilution of body fluids. It was considerably later in evolution when creatures had to develop a renal concentrating system to retain water as they traveled from one water locale to another.[220] Diluting capacity is considerable in the human adult, who can excrete 10% to 12% of the filtered load, or approximately 14 to 17 liters of water/day if the GFR is 100 mL/minute. More water can be excreted with higher rates of filtration. In terms of absolute volume, this

capacity is considerably more limited in the infant, although the young subject can excrete 15%, and perhaps more, of the filtered load.

Our ability to dilute urine and remove excess water is more efficient than our ability to concentrate urine and retain needed water. For example, suppose a 70-kg subject has a serum osmolality of 300 mOsm/kg and a daily renal solute excretory load of 600 mOsm. If urine osmolality is 300 mOsm/kg and the 600 mOsm solute load is excreted in 2 liters of water, the subject is in water balance because the urine is isotonic to plasma and the kidney has neither to concentrate nor dilute the urine to maintain a normal serum sodium level. If the subject is water deprived, urine osmolality can increase to a maximum of approximately 1200 mOsm/kg. At this urine concentration, 500 mL of water is needed to excrete the 600-mOsm solute load. Stated another way, of the 2 liters of water/day needed to excrete this solute isotonically, a maximum of approximately 1500 mL of water/day can be retained to maintain normal serum osmolality; however, 600 mOsm cannot be concentrated in a volume of less than 500 mL. If the subject is water loaded, excess water can be excreted by reducing urine osmolality to a minimum of approximately 50 mOsm/kg. In this case, the kidney can excrete the 600 mOsm of solute in a urine volume of 12 liters and remove 10 liters of "pure" water in the process to maintain a normal serum sodium level.

In this example, renal diluting capacity (10 liters water) is nearly seven-fold the concentrating capacity (1.5 liters water) in terms of actual volume of water handled to maintain osmolar balance. This translates to a 24-fold increase in urine osmolality and urine volume when the urine changes from maximally dilute (osmolality, 50 mOsm/kg; volume, 12,000 mL) to maximally concentrated (osmolality, 1200 mOsm/kg; volume, 500 mL). Renal excretory solute loads in children usually range from 10 to 40 mOsm/100 calories expended. Urine volume required to excrete this solute varies with diet and availability of water.[221] Ingested water enters the total body water compartment where it is partly incorporated into new cells during growth. Extra water is eliminated by insensible losses and urine output, the latter allowing removal of the renal excretory solute load. A net excess or deficit of water leads to alterations in electrolyte balance.

When water intake is sufficient to lower serum osmolality by 1% (approximately 3 mOsm/kg), ADH secretion is suppressed. Solute reabsorption continues in the thick ascending limb, distal nephron, collecting tubule, and collecting duct. The latter segments become less permeable to water when ADH is absent. As a consequence, fluid traversing the distal nephron and entering the medulla becomes progressively dilute. Because water remains in the tubule lumen, urea concentration is reduced, and a major urea concentration difference between collecting duct fluid and interstitium will fail to develop. Because urea permeability in the medullary collecting duct is also decreased in the absence of ADH, urea entering this segment will be more easily excreted. The overall effect is that urea tends to be eliminated from, rather than recycled in, the medullary system. Interstitial as well as urinary urea concentrations decrease, whereas total urea excretion actually increases, but in a larger volume of water.

Reduced tubule permeability to water and continued reabsorption of solute in more distal parts of the nephron might be expected to increase interstitial solute concentrations. However, interstitial solute concentrations are actually reduced compared with the antidiuretic state. It is likely that the water gradient from lumen to interstitium at the medullary collecting duct is high enough to overcome the low water permeability induced by lack of ADH. As a result, reabsorption of water in medullary collecting ducts is actually greater, not less, during water diuresis. Perhaps as much as half the water delivered to collecting ducts backdiffuses into the interstitium, but NaCl is sufficiently reabsorbed along this segment so that the urine actually becomes more dilute.[4,222]

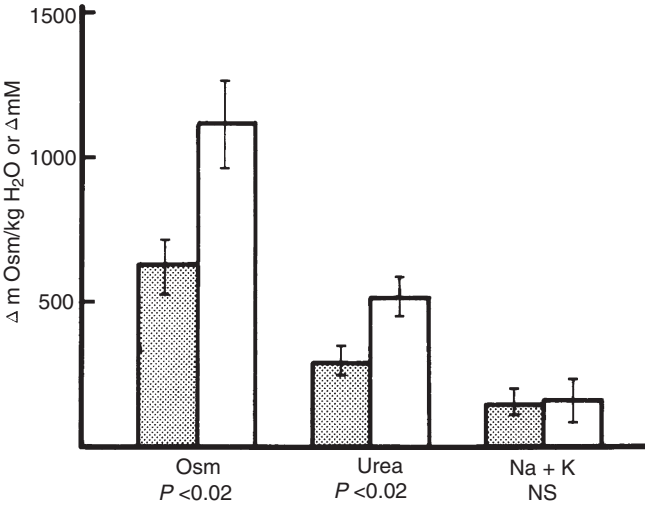

Figure 133-15 Effect of full pelvic refluxes during rising urine flow on solute concentrations in hamsters. Urine flow was increased to a rate just below that needed to cause full pelvic reflux. Refluxes were then mechanically induced for 20 minutes in experimental kidney *(filled bar)*. The other kidney served as a control. Values (mean ± SE) are difference in osmolality (mOsm/kg H_2O), urea (mM), and Na + K (mM) concentrations between renal papilla and refluxing or nonrefluxing kidney. *(From Schmidt-Nielsen B: The renal pelvis.* Kidney Int *31:621, 1987.)*

Another factor is of potential importance to urinary dilution and water excretion.[35] The renal pelvis has contractile properties and can induce reflux of urine around the renal papilla and medulla. Full retrograde pelvic reflux is not typical of the antidiuretic state, but exposure of medullary structures to urine occurs much more often with the high flow rates associated with dilute urine. Urine refluxing into the fornices may actually reduce the amount of urea in the renal medulla (Figure 133-15). Accordingly, full pelvic reflux may help eliminate a fluid load. Investigators have noted a lack of clear correlation between concentrating ability and size and complexity of pelvic extensions, but a correlation exists between the size of pelvic extensions and the need to excrete a water load. Animals living in arid areas and requiring no drinking water exhibit a high urinary concentrating ability but have difficulty excreting a water load rapidly enough to avoid water intoxication and possible death. Such animals do not have large pelvic fornices. Animals that tolerate dehydration but periodically need water must be able to eliminate water reasonably rapidly and tend to have large pelvic extensions. Experimental evidence shows that during antidiuresis water exchanges across the pelvic epithelium and hypotonic fluid can be added to pelvic urine from the medulla to enhance papillary osmolality.[223] Although it has not been directly studied, one might similarly predict that during water diuresis, water from dilute urine could enter the medulla from pelvic extensions and dilute the medullary interstitium, facilitating excretion of water.

Fluid along the proximal tubule is reabsorbed isotonically and does not directly add to urinary dilution. However, the amount of fluid reabsorbed at this site determines, to a major extent, the volume of dilute urine that can later be formed. A drop in filtration rate or an increase in proximal tubular reabsorption allows less fluid to arrive at the diluting site and therefore will limit the actual amount of water excretion. Some segment must be capable of reabsorbing solute in excess of water to allow luminal fluid to become dilute. This process occurs along the entire length of the ascending limb of Henle, especially along its thick portion. Any problem in solute reabsorption along this site will effectively prevent excretion of dilute urine. After urine passes

into the distal nephron, in which solute reabsorption continues, water must remain largely in the lumen. Vasopressin determines the degree to which water will be reabsorbed because the water permeability of collecting duct epithelium depends on the presence of this hormone.

It becomes apparent, then, that to dilute urine, three fundamental conditions must be met. First, a sufficient amount of filtrate must escape reabsorption along the proximal tubule and reach the diluting segment (ascending loop of Henle) to deliver a sufficient amount of potential pure water. Second, this segment must be able to reclaim NaCl and separate reabsorbed solute from water so that urine becomes dilute (water stays in the lumen for excretion). Third, as solute continues to be reabsorbed from more distal sites, further diluting the urine, the ADH-sensitive nephron segments must be able to eliminate the excess water (these segments must not be exposed to secreted ADH and thereby forced to reclaim free water). Accordingly, urinary dilution results from the active reabsorption of NaCl along the thick ascending limb of Henle and the continued reabsorption of solute along more distal nephron segments in concert with a disproportionate reduction in reabsorption of water. Absence of any of these factors may lead to a defect in urinary dilution.

Urinary Dilution in the Fetus

The human kidney can dilute urine early in fetal life.[155] Urine voided at birth (i.e., formed in utero) is hypotonic compared with the infant's serum. In contrast, maternal urine osmolality is five-fold more concentrated than that of the infant. Urine voided during the first 24 hours after birth becomes more concentrated than serum but still has an osmolality less than half that of the mother's urine.[224] Therefore the fetal kidney behaves as though it is trying to excrete a water load, whereas the newborn kidney seems to be stimulated to retain water. Amniotic fluid is hypotonic, particularly toward the end of pregnancy. A term fetus ingests substantial amounts of dilute amniotic fluid (approximately 5 mL/kg/hour).[225] This value is similar to the estimated urine flow rate of 5 mL/kg/hour in primates[104] and is close to the amount of breast milk ingested per day by a healthy newborn infant. A need to excrete this fluid load would account for dilution of fetal urine. Because infants often are not given oral fluid immediately after birth, subsequent concentration of urine represents another appropriate response.[155]

Urinary Dilution in the Neonate

One might expect that limitations in concentrating ability would enable an infant to excrete water more easily and protect itself from water intoxication. However, despite effective urinary dilution, limitations to water excretion exist early in life.[226,227] Low GFR limits the volume of water that can be excreted. A reduced ability to separate solute from water along the immature ascending limb may further limit the amount of free water cleared from this segment,[138,157,158] but this factor is probably of limited importance beyond a few weeks of age. In fact, urine from infants can be maximally diluted to an osmolality of approximately 50 mOsm/kg,[228-230] a value comparable with that in older children and adults. Although data were not strictly limited to neonates, Rodriquez-Soriano and colleagues[229] found that at periods of maximal free water clearance, urine osmolality in infants dropped to 52 mOsm/kg on average, and urine flow rates reached nearly 23 mL/dL of glomerular filtration. These infants and children effectively eliminated a water load with minimal impact on serum sodium and osmolality. In this study, fractional delivery of sodium to the distal nephron was high, indicating decreased proximal tubular salt reabsorption. However, reabsorption of salt along diluting segments of the distal nephron increased, indicating that enhanced distal reabsorption compensated for decreased proximal reabsorption. In general, the youngest infants tended to have high rates of delivery of sodium to the distal nephron, but they also had high rates of distal tubular sodium reabsorption. Clearly, at a young age, diluting segments have the potential to reabsorb solute avidly, and ADH-sensitive segments can be inhibited effectively from reabsorbing excess water. The primary limitation in neonatal water excretion, therefore, falls largely on the low rates of filtration.

The rapidity of maturation of an infant's ability to excrete an acute water load was illustrated by Ames.[231] In this study, premature and term infants of different postnatal ages received 30 mL/kg of either an oral water load or an intravenous 2.5% dextrose solution load. Water excretion was initially low (Figure 133-16). On average, infants in the first 24 hours of life excreted only 10% to 15% of the fluid load in 2 to 3 hours, with only a mild increase by 3 days of age. However, the ability to excrete the water load improved quickly. Infants 8 to 14 days of age excreted 60% of the load, and most infants older than 15 days (and all infants older than 30 days) excreted the total fluid load within 2 hours. One premature infant of birth weight 1.2 kg excreted 50% of an infused fluid load by the fourth day of life and excreted 100% by 12 days of age. Infants older than 7 days of age effectively reduced urine specific gravity to 1.002. The increasing ability to excrete the water was associated with a higher GFR. This finding is consistent with the notion that the low GFR limits the absolute amount of water that can be excreted.

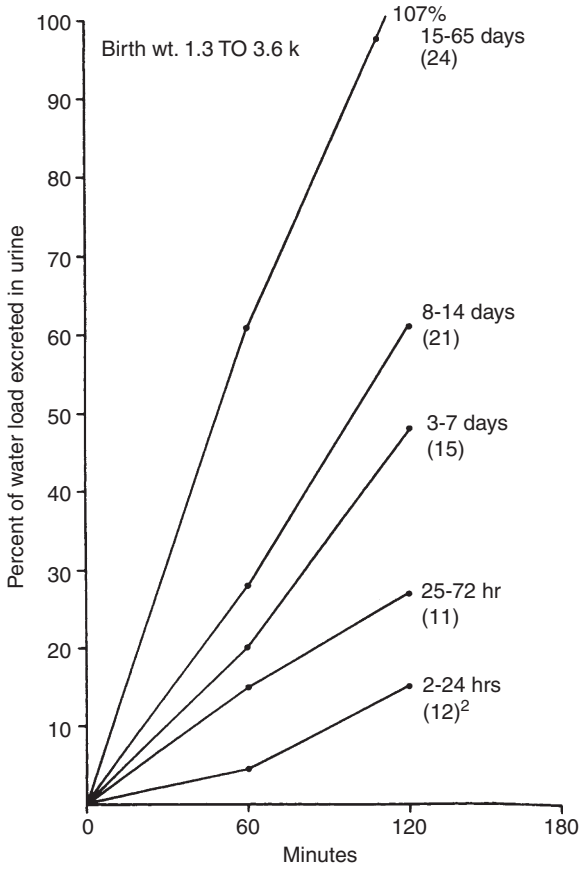

Figure 133-16 Comparison of ability to excrete water load by infants of various ages after intravenous administration of 2.5% glucose, 30 mL/kg body weight given at -10 to 0 minutes. Number in parentheses is number of infants per group. *(Reproduced by permission of* Pediatrics: *Ames RG: Urinary water excretion and neurohypophysial function in full term and premature infants shortly after birth.* Pediatrics *12:272, 1953.)*

Calcagno and colleagues[149] found that 60 minutes after an acute water load, a 1.6-kg, 23-day-old premature infant was able to increase urine flow to 8.3 mL/minute/1.73 m^2 (compared with 12 to 14 m:/minute/1.73 m^2 in the adult) and to decrease urine osmolality to 50 mOsm/kg. In the study by Barnett and coworkers,[228] five premature infants were given a 40-mL/kg oral water load. Urine osmolality dropped to 41 to 63 mOsm/kg. Although their urine flow rates after an hour were, in general, only about half that of adults, one 36-day-old premature infant not only diluted the urine maximally, but also had a urine flow rate fully comparable with that of the adult. Clearly, the postnatal maturation of this particular function is fairly rapid.

It should be noted that although ability to excrete an acute water load matures quickly, a sustained water load is more difficult to excrete in infants who have a low GFR and a limited ability to reabsorb solute along the distal nephron.[230] Fortunately, GFR matures relatively early in life and allows efficient elimination of a sustained water load. This is illustrated by a 6.5-kg, 2-month-old infant who had been given water whenever he became fretful. He ingested up to 2100 mL/day, developed polyuria, excreted urine with an osmolality of 42 mOsm/kg, and had only mild hyponatremia. His free water clearance was nearly 11 mL/minute/dL of glomerular filtration.[232] In the acutely or chronically water-loaded state, ADH is suppressed. Aquaporin-2 staining is more prominent in cytoplasmic vesicles and less so in the apical membrane of collecting ducts. Because aquaporin-2 is thought to be the actual ADH-sensitive water channel, excretion of a water load is likely made possible largely by acutely removing or more chronically down-regulating water channels from the membrane, thereby reducing apical membrane water reabsorption.[70,71,88] Recovery from the down-regulation of apical membrane water channels will take time because this protein up-regulates its production and membrane content in response to subsequent water restriction.

Torres and colleagues[233] provide a compelling example of potential clinical utility of such observations. In patients with autosomal dominant polycystic kidney disease, cAMP stimulates epithelial cell proliferation and fluid secretion into cysts, leading to cyst enlargement and renal dysfunction. Cyclic AMP is promoted by ADH acting through V2 receptors. Decreasing cyclic AMP may delay cyst/renal enlargement. Water loading can suppress ADH. The authors suggest that in patients with this disease and normal renal function, continuous water intake evenly throughout the day may mitigate the effect of cAMP and delay progression toward renal failure. This should also apply to children in whom diluting capacity matures rather quickly. Frequent voiding and attention to volume would reduce the risk of bladder dysfunction and hyponatremia.

CONCLUSION

In summary, diluting function depends on the ability to deliver adequate quantities of filtrate to nephron segments that can separate solute from water. More distal segments must be relatively water impermeant. Infants can maximally dilute their urine at an early age. Their ability to excrete an acute water load matures within a few weeks of birth. Limited excretion of a sustained water load likely relates to the low GFR typical of this age. However, moderately large amounts of ingested water can be effectively eliminated even in relatively young infants. Diluting capacity is quantitatively greater than concentrating capacity and tends to mature at an earlier age. The range of these functions is such that infants, even those of very low birth weight, tolerate a large range of fluid intake without having to sustain major alterations to their fluid and electrolyte stability. It is interesting that the staple infant food, breast milk, is dilute with a low renal solute load. The infant kidney must soon become adept at excreting a water load, an important adaptation if extra "free" water is ingested. The delay in maturation of urinary concentration for several months becomes less critical in the healthy infant because generally introducing foods of greater solute content is delayed until later in infancy.

ACKNOWLEDGMENT

We acknowledge with great sadness the passing of Dr. Michael Linshaw, the renowned pediatric nephrologist who contributed the "Concentration and Dilution of the Urine" chapter to this text for several editions. He was a beloved teacher and mentor who enjoyed solving the mysteries of the kidneys. His passion and tenacity for doing so improved the lives of many children and their families.

134 Urinary Acidification

Eileen D. Brewer

The mature kidney plays an important role in the regulation of normal acid-base balance and provides secondary compensation for primary respiratory acidosis or alkalosis. The kidney accomplishes these functions through reabsorption of filtered bicarbonate (HCO_3^-) and excretion of hydrogen ion (H^+) as ammonium (NH_4^+) and titratable acids, all of which are mediated by renal tubular H^+ secretion.[1-3] The resultant urinary pH is usually acidic (<7.4) with respect to blood pH.

Urinary acidification has been studied infrequently in human neonates. Some of the current knowledge has come from actual studies in newborn infants, but much more information has come from studies of fetal and newborn animals, which may not be directly applicable to human infants. Studies in preterm infants, especially those of extremely low birth weight (gestational age <29 weeks), have helped to clarify our knowledge,[4,5] but more studies are needed. Understanding developmental changes in the fetus and neonate first requires an understanding of current concepts of acid-base physiology in the mature kidney.

TUBULAR REABSORPTION OF FILTERED BICARBONATE IN THE MATURE KIDNEY

Buffering of strong acids is divided approximately equally between HCO_3^- and non-HCO_3^- buffers (hemoglobin, plasma and intracellular proteins, and phosphate).[6] The most important extracellular fluid (ECF) buffer is HCO_3^-, which is filtered from the plasma almost completely by the glomerulus and is reclaimed by reabsorption along the renal tubule to maintain a normal ECF HCO_3^- concentration. The majority (90%) of reabsorption occurs in the proximal tubule and the thick ascending limb of Henle of the renal tubule. As much as 20% of filtered HCO_3^- may be reabsorbed passively along paracellular pathways from proximal tubular lumen to peritubular blood.[6] Reabsorption of the rest of the filtered HCO_3^- is mediated by equimolar secretion of H^+ into the tubular lumen. H^+ secretion occurs mostly via an electroneutral sodium (Na^+)-H^+ exchanger (NHE), specifically isoform NHE-3 in both segments of the tubule and to some extent NHE-2 in the thick ascending limb.[1,2,6] Na^+ exchange for H^+ is driven by a downhill Na^+ concentration gradient, higher in the tubular lumen than in tubular cell cytoplasm, and maintained by active cellular extrusion of Na^+ at the basolateral cell surface mediated by a Na^+, potassium (K^+)–adenosine triphosphatase (ATPase) pump within that membrane. In the proximal tubule, a vacuolar H^+-ATPase pump also participates in H^+ secretion, but to a lesser extent, contributing less than one third of the H^+ secretion.[1-3,6] Both the NHE and H^+-ATPase pump are located in the apical (luminal) membrane of the cells of these renal tubular segments.

The distal nephron accounts for the other 10% of tubular HCO_3^- reabsorption and also depends on H^+ secretion to facilitate HCO_3^- reabsorption. However, H^+ secretion in the distal tubule occurs by a different mechanism and occurs within specialized collecting duct cells called intercalated cells, which are interspersed among principal cells.[1,3,6] In the mature kidney intercalated cells account for approximately one third of the tubular cells in the cortical and outer medullary collecting duct but fewer than 10% in the inner medullary collecting duct. In α-intercalated cells, H^+ secretion is mediated by a translocating H^+-ATPase and H^+,K^+-ATPase pumps in the apical membrane.[1,6] Vacuolar H^+-ATPase is also present in a specialized tubulovesicular system in the apical pole cytoplasm and may be important for acute response to acidosis.[7]

A second type of intercalated cells, the β-intercalated cells, located only in the cortical collecting duct, do not secrete H^+ but secrete small amounts of HCO_3^- in exchange for chloride (Cl^-) at the apical membrane and then extrude H^+ across the basolateral membrane via an H^+-ATPase pump.[1,3,6] β-Intercalated cells may be more important for secreting HCO_3^- in the process of renal compensation during chronic metabolic alkalosis.[1,6] Acid loading stimulates functional and morphologic changes in β-type intercalated cells[1] and can lead to a redistribution of vacuolar H^+-ATPase from the tubulovesicular system to the apical membrane itself in α-type cells.[7] Whether acid loading stimulates a change from β-type to α-type intercalated cells as a compensatory mechanism for chronic metabolic acidosis remains controversial.[1]

In the cortical collecting duct, principal cells adjacent to α-intercalated cells mediate Na^+ reabsorption, which creates negativity in the tubular lumen favorable for H^+ secretion out of the intercalated cells.[1,6] The rate of H^+ secretion is influenced by a variety of factors that allow the kidney to respond to changes in acid-base homeostasis. Factors favoring H^+ secretion include avid renal tubular Na^+ reabsorption, increased HCO_3^- concentration and fluid flow rate in the tubular lumen, angiotensin II, aldosterone, and K^+ depletion (hypokalemia); the rate may be decreased by ECF volume expansion and parathyroid hormone.[1-3,6]

Once H^+ is secreted into the tubular lumen, it combines with HCO_3^- filtered from the plasma by the glomerulus to form carbonic acid (H_2CO_3).[6] H_2CO_3 dissociates to water (H_2O) and carbon dioxide (CO_2). The reaction is driven in that direction, partially because CO_2 diffuses easily through apical membrane aquaporin 1 (AQP1) gas channels into the renal tubular cell for further metabolism[8] and, in the proximal tubule only, because of the presence of carbonic anhydrase isoenzyme IV attached to the apical membrane brush border to catalyze the reaction.[1,6,8] Once CO_2 is inside the cell, cytosolic carbonic anhydrase isoenzyme II catalyzes the conversion of CO_2 and H_2O back to H_2CO_3 to yield H^+ and HCO_3^-.[3,6] HCO_3^- then exits the cell across the basolateral membrane by mass action or via either of two transport systems, an electrogenic Na^+-$3HCO_3^-$ (NBC-1) cotransporter (primarily in the proximal tubule and loop of Henle) or a Cl^--HCO_3^- (AE1) exchanger (primarily in the distal collecting duct).[1,6,8] HCO_3^- leaving the tubular cell then returns to the circulation via the peritubular capillaries. H^+ is secreted back into the tubular lumen to help reclaim filtered HCO_3^- all over again by the same process.

In the proximal tubule, where 80% of HCO_3^- reabsorption occurs, carbonic anhydrase isoenzyme IV attached to the apical brush border membrane greatly increases the capacity for HCO_3^- reabsorption by catalyzing the rapid dissociation of luminal H_2CO_3 to H_2O and CO_2 to minimize luminal concentrations of H_2CO_3 and H^+ and facilitate more H^+ secretion.[1,3,6] The proximal tubule thus has a high capacity for H^+ secretion and HCO_3^- reabsorption. When luminal carbonic anhydrase IV is inhibited by acetazolamide, H^+ secretion and HCO_3^- reabsorption are

notably diminished.[3] Proximal tubular reabsorption of HCO_3^- is also decreased by expansion of ECF or effective arterial blood volume.[9]

The filtered HCO_3^- not reabsorbed proximally is reclaimed partially or completely as needed in the distal tubule, primarily in the collecting duct as noted earlier.[1,3,6] When distally delivered HCO_3^- is entirely reabsorbed and luminal fluid pH falls to less than 6.4, H^+ buffers in the lumen can facilitate further H^+ excretion and regeneration of HCO_3^-. This mechanism allows for the excess acid produced daily by normal metabolism to be excreted in the urine (see Urinary Excretion of Hydrogen Ion by the Mature Kidney later). The primary urinary buffers are ammonia (NH_3) and sodium phosphate (Na_2HPO_4), which combine with H^+ in the tubular lumen to be excreted in the urine as ammonium (NH_4^+) or titratable acid (NaH_2PO_4).[1,3] Aldosterone directly enhances distal tubular secretion of H^+, both by direct stimulation of H^+-ATPase in α-intercalated cells and by stimulation of Na^+ reabsorption by the adjacent principal cells.[3,6] Because carbonic anhydrase is not present in the brush border membranes of the distal tubule, the capacity of the distal tubule to reabsorb HCO_3^- is much less than that of the proximal tubule.[1,6] Hence, a relatively small increase in distal delivery of HCO_3^-, such as that occurring with ECF or effective arterial blood volume expansion, may exceed the HCO_3^- reabsorptive capacity of the distal tubule, increase distal tubular fluid pH to greater than 6.4, and thereby limit formation of NH_4^+ or titratable acids for net H^+ excretion.

RENAL BICARBONATE THRESHOLD

The renal HCO_3^- threshold, which has been measured frequently in studies of renal acidification in neonates,[10-13] is defined as the plasma HCO_3^- concentration at which HCO_3^- is no longer completely reabsorbed in the renal tubule and begins to appear in significant amounts in the urine. The HCO_3^- threshold does not necessarily characterize the intrinsic renal tubular capacity for HCO_3^- reabsorption, because it is significantly altered by ECF volume status.[8,14] When ECF volume contraction is maintained during HCO_3^- loading, the HCO_3^- threshold is increased, even in neonatal animals.[15] When ECF volume is expanded during HCO_3^- loading, the HCO_3^- threshold becomes apparent at a plasma HCO_3^- concentration of less than 24 mEq/L, but when ECF volume expansion is minimized or prevented, the threshold may not be reached until the plasma HCO_3^- concentration exceeds 27 mEq/L. Thus alterations in the renal HCO_3^- threshold often reflect the effects of ECF volume status on renal tubular HCO_3^- reabsorption rather than the intrinsic properties or maturity of the renal tubular cells. This phenomenon has clinical consequences in both preterm and term infants (see Developmental Aspects of Bicarbonate Reabsorption section later).[14]

URINARY EXCRETION OF HYDROGEN ION BY THE MATURE KIDNEY

Normal metabolism generates H^+ in the form of volatile and fixed acids, which must be excreted to prevent acidosis.[16] Volatile acid, primarily H_2CO_3, is excreted by the lungs as CO_2. Because the fixed acids, which include lactic acid, ketoacids, sulfuric acid, and phosphoric acid, are initially buffered by extracellular buffers, including HCO_3^-, HCO_3^- must be regenerated by the kidneys, a process that occurs through excretion of H^+ in the urine as NH_4^+ and titratable acids. NH_3 is produced in the kidney principally in the proximal tubule by metabolism of glutamine, which is catalyzed by glutaminase and phosphoenolpyruvate carboxykinase.[1,3,6] The NH_3 generated is secreted into the luminal fluid of the proximal tubule both by diffusion and by exchange of NH_4^+ (NH_4^+ substituted for H^+) with Na^+ via the NHE exchanger in the apical membrane. NH_3 and NH_4^+ traverse through the tubular lumen to the thick ascending limb of Henle, where NH_4^+ is subsequently actively reabsorbed from the relatively alkaline luminal fluid via an apical cell membrane Na-K-2Cl cotransporter (NH_4^+ substituted for K^+), thereby greatly increasing the concentration of NH_3 in the medullary interstitium.[1] NH_3 from the medullary interstitium then diffuses into the acidic luminal fluid (pH <6.4) along the length of the collecting duct, where it buffers secreted H^+ and is entrapped as NH_4^+ for excretion in the urine.[1,3,6] Substantial trapping of H^+ by NH_3 occurs in the lumen of the inner medullary collecting duct, where urine pH is lowest and NH_3 concentration is greatest.[3,6] The other major buffer system is the titratable acids, of which NaH_2PO_4 is the most abundant. NaH_2PO_4 is derived from filtered Na_2HPO_4, which escapes proximal tubular reabsorption and is delivered to the distal nephron, where it reacts with secreted H^+ to be excreted as NaH_2PO_4.[6]

NET ACID EXCRETION

The quantity of H^+ excreted as NH_4^+ and titratable acids minus any excreted HCO_3^- (normally a negligible amount) is called the net acid excretion.[3,6,16,17] Net acid excretion accounts for 3% or less of the H^+ secretion by the renal tubule and leads to HCO_3^- regeneration back to the blood. Urinary pH itself is not a good indicator of net acid excretion, because the pH does not reflect the amount of buffering capacity available as NH_3 and titratable acids. More H^+ can be excreted in urine with excess buffers and a slightly higher pH that is nearer the pK_a of the buffer (e.g., pK_a 5.75 for NH_3).

DEVELOPMENTAL ASPECTS OF URINARY ACIDIFICATION

In the human fetus, nephronogenesis is not complete until 34 weeks gestation.[14] Functioning renal tubules can be identified by 9 weeks gestation.[14] During fetal life, because H^+ is removed primarily through the placenta for excretion by maternal organs,[14,18] renal acidification is not important until birth. Exactly when renal acidification mechanisms become functionally active and reach maturity in the developing human kidney is not known. In fetal lambs, urinary pH is always lower than plasma pH, a finding indicating the ability of the developing fetal renal tubule to establish a concentration gradient for H^+.[18] Carbonic anhydrase is present in the human fetal kidney in late gestation[18] and increases with gestational age,[19] perhaps explaining in part the observed increase of renal HCO_3^- reabsorption with gestational age. However, after birth human neonates have similar renal carbonic anhydrase activity compared with adults.[20]

DEVELOPMENTAL ASPECTS OF URINARY EXCRETION OF HYDROGENION

The renal tubular mechanisms for net acid excretion are already mature in the last-trimester fetal kidney. Although net acid excretion per unit body weight is reduced in near-term fetal lambs compared with nonpregnant ewes, the fetus responds appropriately to acid loading by increasing urinary excretion of both NH_4^+ and NaH_2PO_4 and by lowering urinary pH.[18]

Term infants are able to respond appropriately to an NH_4Cl acid load within the first month of life,[10,12] although it is uncertain whether preterm infants have the same capacity. Svenningsen[12] reported that net acid excretion in NH_4Cl-loaded preterm infants (gestational ages 29 to 36 weeks, birth weights 1300 to 2470 g) was not comparable with that of term infants until after the third week of life. Schwartz and co-workers[11] found that preterm infants (birth weights 1630 ± 250 g) were able to acidify their urine to less than 5.5 and to excrete NH_4^+ and NaH_2PO_4 appropriately during an NH_4Cl-loading test performed just before hospital discharge at least 3 weeks after

birth. Unfortunately, Schwartz and colleagues[11] gave no estimates of gestational age at birth or postconceptional age at the time of the NH_4Cl loading to allow comparison with the data of Svenningsen.[12] Kalhoff and associates[4] evaluated urinary pH in a large number of premature infants (83 weighing 1.5 to 2.4 kg and 87 weighing 1.0 to 1.4 kg; no gestational ages given). In approximately one third of infants in each group, urinary pH values spontaneously decreased to less than 5.4 by the third to fourth weeks of postnatal life, a finding indicating maximal stimulation of tubular H^+ secretion. At the same time that urinary pH was low, however, capillary blood pH and base excess showed mild metabolic acidosis, a finding suggesting inadequate net acid excretion, possibly as a result of immaturity of the renal tubule for ammoniagenesis or decreased availability of phosphate (especially low in breast-fed infants).[17] Unfortunately, net acid excretion was not measured. Studies of neonatal rats have shown that renal ammonia production is reduced and the capacity to increase ammoniagenesis during acidosis is less than in adult rats.[20] More studies in human preterm infants of different gestational ages, especially those less than 29 weeks gestation and at different postconceptual ages, are needed to evaluate the postnatal development of renal tubular H^+excretion and the capacity for net acid excretion.

DEVELOPMENTAL ASPECTS OF BICARBONATE REABSORPTION

The normal range for plasma HCO_3^- concentration has been reported to be lower for preterm infants (16 to 20 mEq/L) and term infants (19 to 21 mEq/L) than for children and adults (24 to 28 mEq/L).[10,11] This relative acidosis likely results from both physiologic factors and immaturity of the renal tubule.[3,6,14,21,22] During the first few weeks of life, the wide range of low but normal values of plasma HCO_3^- concentration is the most likely explanation for the designation in the past of late metabolic acidosis in otherwise healthy preterm infants with values of plasma HCO_3^- concentration in the acidotic range for children or adults.[11,17,23,24]

The renal HCO_3^- threshold measured in term and preterm infants in studies reported before 1980 was found to be low compared with that in older children and adults.[10-12] These studies were done before our current understanding of the obligatory need for neonatal diuresis of excess ECF in the first week after birth.[5,14] Excess fluid and Na^+ administered during obligatory diuresis may perpetuate ECF volume expansion. ECF volume expansion, which is a major determinant of the HCO_3^- threshold regardless of the acid-base status of the infant, accounts at least in part for the reduced HCO_3^- threshold measured in the classic studies. The likelihood that ECF volume status contributes importantly to the apparently low renal HCO_3^- threshold is suggested by studies of fetal lambs[25] and neonatal puppies.[15] During HCO_3^- loading in fetal and neonatal animals in which the ECF space is volume contracted, the HCO_3^- threshold and tubular reabsorption of HCO_3^- increase, and the urinary pH becomes more acidic. Conversely, in neonatal puppies with ECF volume expansion, the HCO_3^- threshold and tubular reabsorption of HCO_3^- decrease. These findings suggest that the renal tubule in the fetus and neonate can increase its HCO_3^- reabsorption appropriately when stimulated by volume contraction, and, conversely, a reduced HCO_3^- threshold is at least in part, if not all, a physiologic phenomenon caused by an expanded state of ECF volume.

The ECF volume of the human fetus and newborn at birth is normally 40% to 60% of body weight, and it decreases to less than 30% after birth.[14] The usual ECF volume expansion of the fetus and newborn probably results in depressed proximal tubular HCO_3^- reabsorption, increased delivery of HCO_3^- to the distal nephron, and an alkaline urinary pH. After birth, when obligatory diuresis of excess ECF is complete and ECF volume is contracted, renal tubular HCO_3^- reabsorption increases, and urinary pH can become more acidic. These phenomena were confirmed in studies of extremely low-birth-weight infants. Ramiro-Tolentino and colleagues[5] studied 22 preterm infants (23 to 29 weeks gestation; birth weight 540 to 982 g) during the first 5 days of life. Intravenous fluid and electrolyte therapy were carefully controlled to allow body weight loss between 1% and 4% per day during obligatory diuresis and to maintain serum Na^+ concentrations between 130 and 145 mEq/L, serum K^+ concentrations between 4 and 6 mEq/L, and plasma HCO_3^- concentrations between 18 and 22 mEq/L. When diuresis began at approximately 24 hours after birth, measured glomerular filtration rate and filtered load of HCO_3^- increased, and so did urinary HCO_3^- excretion. After diuresis, when ECF was contracted and glomerular filtration rate was only slightly decreased, urinary HCO_3^- excretion markedly dropped, and cumulative HCO_3^- balance became positive. If prescribed fluid therapy had continued to supply an excess of salt and water during the period of diuresis, and if ECF volume expansion had persisted, relative metabolic acidosis caused by continued depression of renal tubular reabsorption of HCO_3^- might have developed in these infants.[14]

Immaturity of tubular function may also play a role in the expression of a lowered plasma HCO_3^- threshold in the neonate. Histochemical and biochemical analyses of human fetal kidney tissue suggest that carbonic anhydrase is present in sufficient amounts to allow normal reabsorption of HCO_3^- at 24 to 26 weeks gestation in fully formed juxtamedullary nephrons but not in immature nephrons in the more cortical nephrogenic areas.[26] In preterm infants born at less than 35 weeks gestation, when nephrogenesis is not yet complete, heterogeneity of nephron development could contribute to a reduced overall capacity to reabsorb HCO_3^-. In studies of renal tubule segments of infant rats, Karashima and associates[27] found carbonic anhydrase II activity of 1-week-old rats to be only 14% of adult values, increasing to 40% at 3 weeks and 97% by 7 weeks.

Direct studies of tubular HCO_3^- reabsorption[28] and NHE activity[21,22] in isolated proximal tubular segments of neonatal rabbits suggest that postnatal maturation of the proximal tubule occurs both quantitatively and qualitatively. HCO_3^- reabsorptive capacity abruptly and markedly increases after the fourth week of life in this rabbit model. A similar abrupt and marked increase in tubular reabsorptive capacity occurs 3 weeks after birth in the proximal tubule of newborn guinea pigs.[29] Nephronogenesis is complete before birth in guinea pigs, but not until 4 weeks after birth in rabbits; neonatal guinea pig kidneys therefore are more comparable with those of term infants, and neonatal rabbit kidneys compare more favorably with those of preterm infants. In both experimental models, the abrupt increase in reabsorption has been associated with a concomitant marked increase in the basolateral membrane surface area of the proximal tubule. Studies of rat proximal tubules also demonstrate maturational changes from neonate to adult in NHE activity, which is associated with an increase in NHE-3 gene expression,[30] and a conversion from the predominance of isoform NHE-8 present in brush border membrane vesicles of neonatal rats to isoform NHE-3 in adult rats.[22]

Increased production of glucocorticoids and thyroid hormone may play an important role in promoting postnatal maturation of proximal tubule acidification.[21,22] Administration of exogenous glucocorticoids or thyroid hormone to neonatal rabbits or directly to opossum kidney cells in culture caused a marked increase in proximal tubular NHE and Na^+,K^+-ATPase activity measured in vitro.[21,22] In studies in preterm extremely low-birth-weight infants, however, urinary HCO_3^- excretion in the first week of life was the same whether infants had received antenatal glucocorticoids or not.[5] More studies in human infants are needed to determine the importance of postnatal renal tubular maturation for HCO_3^- reabsorption during the first few weeks of life.

INHERITED DISORDERS OF RENAL ACID-BASE BALANCE

A variety of genes encode for the protein transporters, exchangers, and enzymes required to carry out normal urinary acidification. Mutations in any of these genes can lead to inherited clinical diseases. Rare forms of proximal renal tubular acidosis (RTA) have been associated with mutations in genes encoding for the Na^+-HCO_3^- exchanger NBC-1 (also known as SLC4A4), carbonic anhydrase II, and pyruvate carboxylase deficiency.[3,31] Several types of distal RTA have been associated with mutations, including the most common autosomal dominant distal RTA caused by mutations in the Cl^-/HCO_3^- exchanger AE1 (SLC4A1) and a rare autosomal recessive distal RTA with sensorineural deafness caused by mutations in the vacuolar H^+-ATPase pump (ATP6V1-B1 subunit).[31] As knowledge of the molecular basis of urinary acidification increases, more diseases of abnormal renal acid-base balance may be identified, and our knowledge of the basis of known forms of RTA will be increased.

NEONATAL METABOLIC COMPENSATION FOR RESPIRATORY ACIDOSIS OR ALKALOSIS

The ventilatory response to retained CO_2 increases with gestational age and postnatal age,[32] so is relatively impaired in preterm compared with term neonates and adults and may predispose preterm infants to bouts of respiratory acidosis. In addition, if the lungs are diseased and alveolar ventilation is ineffective, as occurs in infants with respiratory distress syndrome or bronchopulmonary dysplasia, CO_2 is retained, blood CO_2 tension rises, and respiratory acidosis occurs. Retained CO_2 is buffered initially by intracellular proteins, phosphates, and plasma hemoglobin.[33] Within 12 to 24 hours of the onset of respiratory acidosis in adults, renal metabolic compensation begins to occur and is not complete for 3 to 5 days.[6,33,34] The kidneys attempt to return blood pH toward normal by excreting H^+ in the urine as NH_4^+ and titratable acids and by reclaiming filtered HCO_3^-. As blood HCO_3^- concentration rises, serum chloride concentration decreases because of loss of chloride in the urine and a shift of chloride into red blood cells; hypochloremia therefore is a consistent finding in compensated respiratory acidosis.[34]

Hyperventilation whether disease related or iatrogenic leads to respiratory alkalosis. The initial reduction in blood CO_2 tension is acutely titrated by intracellular buffers.[33] In adults, renal metabolic compensation for respiratory alkalosis begins within hours and is complete within 1 to 3 days. Renal compensation is characterized by suppression of renal acidification with excretion of HCO_3^- in the urine, alkaline urinary pH, and decreased excretion of NH_4^+ and titratable acids.[6,33,35] Reduced renal tubular HCO_3^- reabsorption enhances tubular chloride reabsorption and leads to hyperchloremia as a consistent finding in compensated respiratory alkalosis.[35]

Maturation of the ability to compensate for respiratory acid-base disorders has not been carefully studied in the developing kidney. A study in 5- to 12-day-old rabbits[36] suggested that metabolic compensation for both acute hypercapnia and hypocapnia is intact. Studies in human infants are needed to elucidate further the compensatory response and capacity of renal acidification.

135 Response to Nephron Loss in Early Development

Robert L. Chevalier

OVERVIEW

The developing kidney depends on a complex program of morphogenesis resulting in a delicate balance of growth and differentiation. A number of factors can interfere with this process in fetal, perinatal, or neonatal life. The resulting nephron deficit, in turn, leads to adaptive responses that have short- and long-term consequences. This chapter reviews the causes and consequences of nephron loss with emphasis on the unique features of the developing kidney that increase its vulnerability.

EXPERIMENTAL STUDIES

Renal Mass and Number of Nephrons

Renal growth occurs as a result of normal development or in response to a reduction in renal mass. It is therefore not surprising that the compensatory increase in renal mass following nephron loss is proportionately greater in the newborn than in the adult.[1-3] Despite a significant increase in glomerular volume, both normal and compensatory renal growth are primarily caused by an increase in proximal tubular mass.[4,5] It is now recognized that there is considerable variation in the number of nephrons in normal subjects, and there is a linear relationship between the number of glomeruli and birth weight in humans.[6,7] Moreover, there is an overall negative correlation between the number of nephrons at birth and blood pressure in adulthood, suggesting that conservation of nephrons is particularly important in early life.[8-10] In a particularly striking report of autopsies of middle-aged hypertensive patients killed in accidents, the median number of glomeruli was 50% of that in matched normotensive subjects.[11] These observations have spurred greater interest in the determinants of nephron number at birth.

There are at least three broad categories of factors contributing to the number of nephrons in the metanephric kidney: developmental factors, nutritional factors, and toxic/iatrogenic influences (Table 135-1). Reduced nephron number may result from excessive apoptosis in the developing ureteral bud, the result of loss of an endogenous survival factor such as PAX2.[12] Administration of specific growth factors may also alter nephrogenesis in developing kidneys in vivo or in vitro—transforming growth factor-β1 impairs nephrogenesis whereas insulin-like growth factor 1 stimulates nephrogenesis.[13,14] Early human fetal urinary tract obstruction results in a reduced number of nephrons, and the number of glomeruli can be related to the time of developmental arrest.[15] In animal models, ureteral obstruction also results in reduced glomerular number, and ureteral obstruction impairs nephrogenesis in direct proportion to the duration of obstruction.[16-19] Fetal rats of mothers whose uterine artery has been ligated, or rats with spontaneous intrauterine growth restriction, have reduced nephron number.[20,21] Infants with intrauterine growth restriction are born with fewer nephrons than those whose birth weight is appropriate for gestational age.[22] The timing of intrauterine growth restriction may determine whether nephron number is reduced.[23] Infants of diabetic mothers have an increased incidence of congenital malformations, and maternal hyperglycemia in rats leads to nephron deficit.[24] Reduced maternal protein intake leads to reduced nephron number in experimental animals and may program the individual for salt-sensitive adult hypertension.[20,25] Intrauterine malnutrition in aborigines is associated with low birth weight and impaired nephrogenesis, suggesting that optimizing fetal growth may reduce renal disease, hypertension, and cardiovascular disease in this population.[26] In a provocative study, mild vitamin A deficiency was shown to lead to inborn nephron deficit in the rat—there was a linear relationship between maternal plasma retinol levels and the number of glomeruli in the fetus.[27] This study suggests that small variations in maternal nutritional status may have significant implications for the ultimate complement of nephrons. The electrolyte environment may also play a significant role—fetal mouse kidneys grown in vitro exhibited impaired nephrogenesis if potassium concentration was reduced.[28] Perinatal asphyxia or severe circulatory disturbances can cause irreversible nephron loss.[29] Exposure of the fetus to maternal administration of angiotensin-converting enzyme inhibitors or to prostaglandin inhibitors impairs nephrogenesis and renal maturation.[30,31] Maternal exposure to glucocorticoids, aminoglycosides, beta lactam antibiotics, or cyclosporine may impair nephrogenesis and may lead to hypertension.[32-36] Fetal exposure to toxins such as maternal smoking or alcohol consumption can impair kidney development.[37] Finally, emerging reports suggest that extremely preterm birth itself can curtail nephrogenesis, with serious long-term implications (see later: Postnatal Adaptation to Nephron Loss).[38,39]

Renal Hemodynamics

The hemodynamic response to nephron loss is proportional to the amount of renal mass removed. Thus uninephrectomy in the rat doubles glomerular blood flow, but removal of 75% of renal mass increases flow more than threefold 2 to 3 weeks later.[40] In 8-week-old dogs subjected to 75% nephrectomy at birth, renal plasma flow was not different from that of control littermates; however, flow in 14-week-old dogs studied 6 weeks after 75% renal ablation was 50% less than that in controls.[41] This study indicates that hemodynamic adaptation to nephron loss is more complete in early development than in later life.

A potentially important difference in the hemodynamic response to nephron loss in early compared to later development has been shown for autoregulation of renal blood flow (RBF), whereby flow is kept constant during changes in renal perfusion pressure. Uninephrectomy in the adult rat causes renal vasodilation at reduced as well as normal perfusion pressure; however, uninephrectomy in the neonatal rat increases RBF at normal, but not at reduced, arterial pressure.[42] Thus autoregulation is reset to higher flows in the uninephrectomized adult but is impaired in the newborn rat with a single kidney.[42] The neonate with reduced renal mass may therefore be more susceptible than the adult to ischemic renal damage. Another difference between the response to uninephrectomy in neonates compared to adults relates to the development of hypertension— uninephrectomy in the neonatal rat leads to salt-sensitive hypertension in adulthood, which in turn leads to glomerular damage.[43,44]

Because of the critical dependence of the fetal and neonatal glomerular capillary pressure on angiotensin-mediated efferent arteriolar constriction, the fetus and neonate are particularly susceptible

TABLE 135-1

Causes of Reduced Nephron Number

1. Developmental factors
- Genetic determinants
- Renal maldevelopment, including obstructive nephropathy
- Intrauterine growth restriction
- Maternal diabetes

2. Nutritional factors
- Reduced maternal protein intake
- Reduced maternal vitamin A intake
- Reduced fetal potassium intake

3. Toxic/iatrogenic influences
- Fetal hypoxia-perinatal asphyxia
- Severe fetal-perinatal circulatory disorders
- Maternal angiotensin-converting enzyme or angiotensin receptor inhibitors
- Maternal prostaglandin inhibitors
- Maternal glucocorticoids
- Maternal aminoglycosides
- Maternal beta lactam antibiotics
- Maternal cyclosporine
- Extremely preterm birth

to a marked reduction in glomerular filtration rate (GFR) after exposure to angiotensin-converting enzyme (ACE) inhibitors.[45] Both the potency and duration of action of captopril are significantly greater in neonates than in older children.[46] Following a reduction in renal mass, the remaining hyperfiltering immature nephrons are even more susceptible to the action of ACE inhibitors, which can induce renal failure and additional nephron injury.

Stimuli for Compensatory Renal Growth

Numerous studies indicate that reduction in renal mass results in release of renotropic factors and/or suppression of inhibitors of renal growth.[47] Although blood-borne renotropins are probably not released from the kidneys themselves, renal tissue factors may be necessary to activate the humoral compounds.[48,49] The enhanced compensatory renal hypertrophy observed in the neonate may relate to differences in tissue factors. In this regard, kidneys of adult rats and mice have been found to contain a renal growth inhibitory factor, although none was found in neonatal kidneys.[50] The initial phase of compensatory renal growth following unilateral nephrectomy in immature rats is independent of growth hormone secretion, but is associated with an increase in insulin-like growth factor-1 (IGF-1) and IGF-1–receptor gene expression.[51,52]

In addition to reduction in functional renal mass, numerous compounds have been shown to stimulate renal growth, including sodium, ammonium chloride, folic acid, thyroxine, growth hormone, and mineralocorticoids.[53] One stimulus to renal hypertrophy and hyperfunction that has generated much interest is increased dietary protein intake. Increased protein intake can enhance compensatory renal hypertrophy.[54,55] The ribonucleic acid (RNA)-protein ratio and DNA content of the remaining kidney are increased as a result of uninephrectomy, but not with increased dietary protein.[56] Thus the additive effect of dietary protein is probably caused by a separate mechanism rather than being an amplification of the normal hypertrophic response. Although angiotensin II has been shown to act as a renal growth factor, compensatory renal growth in neonatal mice subjected to unilateral ureteral obstruction is not impaired in animals lacking functional angiotensinogen genes.[57] Perhaps as important as what stimulates compensatory renal growth is what limits compensatory renal growth. Mice lacking the gene for cyclin-dependent kinase inhibitor p21 do not develop progressive renal insufficiency following renal ablation.[58] A shift from renal cellular hypertrophy to proliferation in these mutants may underlie the protective effect.[59]

Adaptation Versus Maladaptation

As described earlier, structural and functional adaptation appear to be more "complete" after reduction of renal mass in the neonate compared to adaptation that follows nephron loss later in life. However, increased intraglomerular pressure and blood flow, and consequent hyperfiltration, may lead to progressive glomerular injury, a maladaptive response.[60,61] The mechanisms responsible for this process are not completely understood, but they include increased filtration of protein and other macromolecules that are taken up by mesangial cells, which are thereby damaged.[61,62] Proteinuria also leads to injury to the renal tubules and interstitium. Proteinuria can lead to apoptosis of tubular cells and the development of interstitial fibrosis.[63,64] Uninephrectomy in the neonatal rat has been shown to result in greater proteinuria and glomerular sclerosis of the remaining kidney than occur following uninephrectomy in the adult.[65,66] Increased protein intake in the young rat can stimulate kidney growth by promoting cell proliferation as well as by increasing the GFR.[67] Studies of young rats undergoing unilateral nephrectomy reveal that survival was significantly reduced in animals receiving a high-protein compared to a low-protein diet.[68] Moreover, this was preceded by an increase in urinary protein excretion.[69] These data have disturbing implications for neonates with nephron loss, as a more vigorous early adaptive response in remaining renal tissue may lead to progressive renal insufficiency during development. However, attempts to slow the progression by restricting protein in infancy carry the risks of protein malnutrition and impairment of normal somatic growth.

Compensatory Renal Adaptation in the Fetus

Until recently, experimental evidence for compensatory renal growth in the fetus had not been clearly established. Peters and colleagues[70] induced unilateral ureteral occlusion in the fetal lamb at midtrimester and observed a significant increase in contralateral kidney weight within 2 weeks, which became maximal by 1 month (50% increase). Although the increase in renal mass in this study was not associated with an increase in the total number of nephrons, ovine fetal uninephrectomy results in a 45% increase in the number of nephrons but a lower glomerular volume.[71] Because the placenta provides the excretory function for the fetus, the results of this study indicate that an increased excretory or homeostatic burden on the kidney is not required to initiate compensatory growth. Rather, alterations in growth factors or inhibitors presumably modulate the prenatal changes.

CLINICAL ASPECTS OF RENAL RESPONSE TO NEPHRON LOSS

Because of the relatively small numbers and heterogeneity of patients with lesions resulting in nephron loss during early development, there remains a paucity of clinical data. However, in general, the results of studies addressing this problem are consistent with the experimental findings discussed earlier. Thus compensatory renal hypertrophy following uninephrectomy appears to be proportionately greater the younger the age at the time of nephrectomy.[72] If nephrectomy is delayed beyond the first year of life, however, a significant effect of age on the compensatory response may be difficult to demonstrate.[73,74]

Prenatal Nephron Loss

Unilateral Multicystic Kidney and Renal Agenesis

Most nephron loss in the neonate results from fetal renal maldevelopment. Unilateral multicystic renal dysplasia results in a nonfunctional kidney early in gestation and therefore affords an opportunity to study the adaptation by the remaining kidney.

An autopsy study of 20 human fetuses with a unilateral kidney revealed a significant increase in the proportional weight of the single kidney.[75] These findings are corroborated by two prenatal ultrasound studies of fetuses with unilateral renal agenesis or multicystic kidney. In both reports, the single functioning kidneys were significantly longer than those in the control patients.[76,77] Sonography permits serial measurement of renal size in the fetus such that renal growth can be compared with normal ranges and followed beyond birth. Such tracking of renal size may be clinically useful in monitoring the function of an abnormal contralateral kidney in infants with two functioning kidneys. An exaggerated rate of increase in renal size has been correlated with contralateral renal function that contributes less than 15% of total function.[78]

In infants born with unilateral renal agenesis, renal volume increases to 188% of that of a single normal kidney during postnatal development.[73] Consistent with the hypothesis that hypertrophy and prolonged hyperfiltration by remnant glomeruli lead to progressive renal injury, patients with unilateral renal agenesis may develop focal glomerular sclerosis and renal insufficiency in adulthood.[79-81]

Renal Hypoplasia and Dysplasia

Because of the wide variation in functional nephron loss resulting from renal hypoplasia and dysplasia, it has been difficult to systematically examine the adaptation of remaining nephrons in these disorders. However, in oligomeganephronia, a rare form of congenital renal hypoplasia, infants are born with less than 25% of the normal nephron number.[82] Presumably, because of the severity of nephron loss, compensatory hypertrophy is pushed to its limits, resulting in glomerular volumes that are several fold greater than normal.[79] This disorder is associated with the eventual development of focal glomerular sclerosis.[79,82]

Congenital Hydronephrosis

Along with renal hypoplasia-dysplasia, congenital urinary tract obstruction accounts for most cases of nephron loss in the neonate. Complete ureteral obstruction (atresia) early in gestation results in multicystic dysplasia and a nonfunctional kidney.[83] However, most forms of hydronephrosis in the neonate result from incomplete obstruction of the urinary tract or vesicoureteral reflux. Severe bladder obstruction resulting from posterior urethral valves can cause renal maldevelopment in utero such that adaptive renal growth is impaired despite either prenatal or postnatal relief of obstruction.[84,85] Unilateral ureteropelvic junction obstruction, on the other hand, may be relatively mild in utero such that most renal damage occurs postnatally unless the obstruction is relieved.[86] Severe vesicoureteral reflux can eventually lead to glomerulosclerosis, proteinuria, and renal insufficiency if both kidneys are involved.[87]

Postnatal Adaptation to Nephron Loss

In cases of unilateral loss of nephrons (or more severe impairment of one kidney than the other), the contralateral kidney generally compensates accordingly. This phenomenon, first called *renal counterbalance* by Hinman,[88] appears to be exaggerated in early development.[89,90] The postnatal hypertrophic response of the less impaired kidney can be further compromised by the presence of vesicoureteral reflux or infection.[91,92] As in experimental studies, the hypertrophic response by the intact kidney is dependent on the proportion of nephron loss that is caused by scarring of the affected kidney.[40,93] Adaptation by remaining nephrons can also be influenced by iatrogenic factors such as radiation or chemotherapy, which may impair compensatory hypertrophy to a greater extent in patients younger than in those older than 2 years of age.[94] Although compensatory growth of the contralateral kidney has been suggested as an index of functional impairment in children with unilateral ureteropelvic junction obstruction, biologic variability and limitations of clinical ultrasonographic imaging limit the early detection of compensatory renal growth.[95,96]

It is disturbing that children born prematurely have smaller kidneys than term children, without catch-up with age through 18 months.[97] It appears that nephrogenesis continues after birth in extremely preterm infants, but ceases after 40 days.[38] Surviving infants develop glomerular hypertrophy and mesangial proliferation, which may predispose them to vasomotor or nephrotoxic injury in the postnatal period or in later life.[39] When these infants develop acute renal failure, long-term outcome is poor. Despite improvement of GFR by 1 year of age, nearly 50% of one cohort of such patients over a period of years developed decreased renal function and increased urine protein excretion.[98]

Prediction of Ultimate Renal Function

Progression of Renal Insufficiency

A major problem confronting the physician caring for the infant with reduced functioning renal mass is the lack of a reliable means of predicting the ultimate compensatory renal adaptation. Will the infant require dialysis or renal transplantation, and if so, when? As described earlier, normal and compensatory renal development are interdependent and significantly influenced by the etiology of nephron loss, the proportion of intact nephrons remaining, and the presence of factors that impair the adaptive process. It is becoming increasingly clear that many of the data currently available are marginalized because of an insufficient follow-up period. Although unilateral renal agenesis was previously thought to represent a benign condition, in fact the deleterious consequences may not appear until late adulthood. Nevertheless, it is still reasonable to predict that an infant with a single normal kidney can have a relatively normal life expectancy, particularly if dietary protein intake is not excessive. In the neonatal period, it may be difficult to demonstrate that a single functioning kidney is entirely normal, particularly if the contralateral kidney is multicystic.[99] Because nephrogenesis is not complete until the thirty-fourth week, preterm infants with nephron loss may have a slower increase in renal mass and function than term infants. Moreover, because even an abnormal kidney undergoes accelerated growth at the time of the pubertal growth spurt, the patient with limited "renal reserve" may not manifest significant renal insufficiency until adolescence.[93,100] As shown in Figure 135-1, maldevelopment of the kidneys or urinary tract, intrauterine or perinatal insults, or extreme prematurity can reduce renal function at birth. In general, the better the initial renal function, the better the outcome (trajectory 1, Fig. 135-1). Infants with compromised renal function at birth can subsequently develop a gradual decline in function (trajectory 2), or a more rapid decline (trajectory 3). Every attempt should be made to slow the progression of renal insufficiency.

Adults subjected to partial removal of a solitary kidney (after contralateral nephrectomy for renal malignancy) are at increased risk for proteinuria, glomerulopathy, and progressive renal failure.[101] Twenty-five to 30% of patients undergoing unilateral nephrectomy in childhood (mean age 7 years) developed proteinuria and renal insufficiency after a median follow-up of 25 years.[102] The infant with a GFR of less than 50% of normal for age at the time of diagnosis is even more likely to experience progressive renal insufficiency.[100,103] Although infants with posterior urethral valves and a serum creatinine concentration less than 0.8 mg/dL during the first 12 months of life are likely to maintain adequate renal function for a number of years, acceleration of the rate of renal deterioration may increase at adolescence or during adulthood.[104] As discussed above, a number of conditions are associated with impairment of nephrogenesis (Table 135-1), which may predispose patients to hypertension, proteinuria, and renal insufficiency in adulthood.[105]

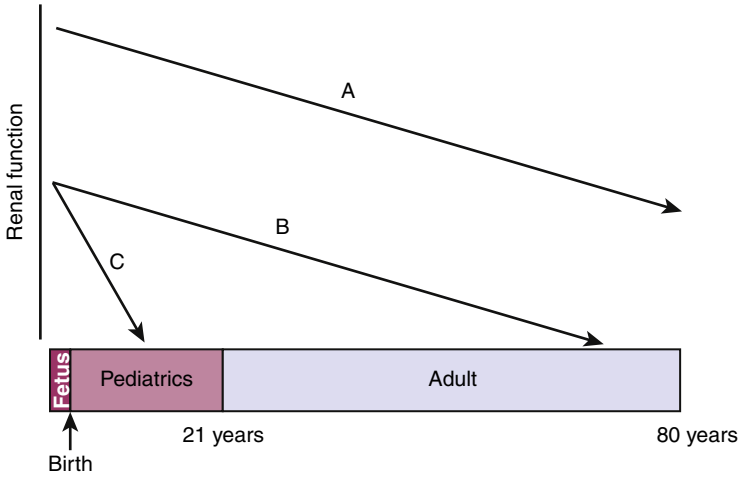

Figure 135-1 Scheme showing long-term impact of congenital renal disorders. The urinary tract abnormality develops in embryonic and fetal life, but if mild, **A,** the consequences of the condition may become apparent only later in adulthood, if at all. If moderate, **B,** progression of renal insufficiency may develop earlier in adulthood. If severe, **C,** renal failure develops in infancy or childhood. Long-term follow-up of blood pressure and urine protein excretion is desirable in virtually all patients discharged from a neonatal intensive care unit. *(Modified from Chevalier RL: Obstructive Uropathy: Assessment of Renal Function in the Fetus. In Oh W, Guignard JP, Baumgart S [eds]:* Nephrology and Fluid/Electrolyte Physiology: Neonatology Questions and Controversies. *Elsevier, 2008, Philadelphia, pp 226.)*

Long-term Follow-up

Until more comprehensive predictive data are available, the most prudent approach to follow-up of the neonate with possible nephron loss from any cause is periodic measurement of somatic and renal growth (by ultrasonography), blood pressure, GFR (by serum creatinine concentration), and urine protein excretion (by urine protein-creatinine ratio). In addition, urine culture; urinalysis; and serum calcium, phosphorus, and total carbon dioxide concentration should be monitored in selected high-risk patients. By continual tracking of these parameters, ultimate renal adaptation can be optimized for each patient. It appears that the progression of renal disease may be slowed by the judicious inhibition of intrarenal angiotensin II by using either an angiotensin-converting enzyme inhibitor or an angiotensin receptor blocker.[106] In addition to controlling hypertension, a number of experimental studies have shown a salutary effect of angiotensin inhibition on proteinuria and the development of interstitial fibrosis. As noted above, because angiotensin II is necessary for normal renal development and for maintaining renal hemodynamics perinatally, inhibition of angiotensin should be avoided if possible during the perinatal and neonatal periods. Recent studies in neonatal rats with partial ureteral obstruction show that angiotensin-converting enzyme inhibitors or angiotensin receptor blockers can actually exacerbate the renal lesions if administered too early.[107,108] However, if given after the period of nephron maturation (after weaning in the rat), the effects are salutary.[109,110] In view of their vasoconstrictor effects, patients with a reduced number of nephrons should also avoid the use of nonsteroidal antiinflammatory drugs. The combination of improved perinatal/neonatal evaluation and management, as well as seamless longitudinal follow-up by the pediatrician and internist, should lead to optimal preservation of renal function in infants born with a reduction in renal mass.

Pathophysiology of Acute Renal Failure in the Neonatal Period

Acute renal failure (ARF) is the precipitous development of azotemia resulting from a depressed rate of glomerular filtration. Specific causes of ARF have conventionally been classified into prerenal, renal, or postrenal, thereby localizing the primary site of the disorder. *Prerenal failure* describes a process whereby a disorder in the systemic circulation causes renal hypoperfusion, and it reflects contraction of the intravascular volume or cardiac pump failure, or both. The implication of this disorder is that correction of the underlying disturbance, with volume repletion or improvement in cardiac function, or both, will restore glomerular filtration. When correction of the circulatory impairment does not restore a normal level of filtration, development of renal parenchymal damage and transition to *intrinsic renal failure* are implied. An important subset of intrinsic renal failure is *acute tubular necrosis*. Although necrosis is not always evident histologically, the term connotes a clinical syndrome that results from ischemia and excludes prerenal and postrenal failure, as well as intrinsic renal damage resulting from vascular, glomerular, or interstitial lesions. *Postrenal failure* refers to obstruction of urine flow by a bilateral lesion or a site within the bladder or urethra. An important example of the latter in the neonate is posterior urethral valves.

The final common pathway that underlies ARF, regardless of the cause or primary site of injury, is a fall in the glomerular filtration rate (GFR), which becomes inadequate to eliminate metabolic waste products. The total GFR in both kidneys depends on the number of filtering nephrons and the GFR in each individual nephron. Thus reduction in the total kidney GFR may result from a loss of a number of filtering nephron units or a decrease in the rate of filtration in individual nephrons. However, unless the cause of ARF is trauma, surgery, or thrombus involving circumscribed areas of the kidney, a reduction in nephron numbers ordinarily does not contribute to the decreased GFR in ARF in neonates. This finding is in contrast to the pattern in chronic renal failure, in which, because functional internephron heterogeneity predominates, some nephrons are severely damaged or even completely nonfunctional, whereas others attain normal (or increased) function. Some studies have revealed considerable variability in nephron number among physiologically normal individuals.[1] Although it is not known whether such variability in the complement of nephrons affects the occurrence or severity of acute injury, it appears to have profound impact on development of hypertension and progressive renal damage including chronic renal failure after acute injury (see later).

Certain nephron populations may be at greater risk for damage. In experimental studies of adult animals, deeper nephrons sustain greater injury after ischemia than do superficial cortical nephrons, and the deeper medullary region of the kidney appears metabolically at greater risk for ischemic damage.[2,3] These observations may be relevant in the premature infant in whom glomerulogenesis proceeds in a centrifugal manner and continues through the 36th week of gestation.[4,5] It is possible, therefore, that renal injury in an extremely premature baby would occur in the deeper, perhaps more vulnerable, areas of the kidney before

the relatively more resistant cortical nephrons have developed. This is an especially pivotal locus with respect to nephron generation, and injury at this site may have additional adverse implications in limiting the number and integrity of future nephrons. It is important to point out that recovery of renal function in a premature baby after renal insult likely represents healing of some injured nephrons and acquisition of new nephrons, at least through 34 to 36 weeks gestation, after which no further nephrogenesis occurs, no matter how extensive the loss of renal parenchyma. In this connection, a recent study in neonates in whom an autopsy was performed at 30 to 105 weeks postconceptual age found that extremely premature infants who sustained maximum creatinine above 2.0 mg/dL had radial glomerular count of only 60% of normal. Of interest, extremely preterm infants without a history of such creatinine increase had radial glomerular count of 80% of normal, indicating the possibility that even subtle degrees of renal insult may contribute to reduction in the complement of nephrons in survivors.[6]

Not only are certain nephron populations at greater risk of damage, but also certain nephron segments, particularly those located in the outer medulla, appear especially susceptible to injury. Thus the straight segment of the proximal tubule (S3 segment) and the medullary thick ascending limb demonstrate heightened susceptibility to ischemic and nephrotoxic injuries.[7] This susceptibility relates to low oxygen tension in this region, limited capacity to achieve anaerobic respiration, and high workload in these segments.[7,8] Impairment of oxygen delivery to the susceptible outer medullary region has been linked to endothelial injury of the peritubular capillaries, together with leukocyte activation that physically impedes blood flow.[9] The endothelial injury, in turn, is related to reactive oxygen species, whereas leukocyte infiltration has been related to adhesion molecules, such as selectins and integrins, as well as inflammatory cytokines such as interleukin (IL)-1 and tumor necrosis factor α (TNFα).[9-13] Medullary vascular congestion appears pivotal to the central pathologic lesion of ARF, namely, tubular injury.[11-13] Intravital videomicroscopy after renal artery occlusion and release demonstrates an immediate recovery of erythrocyte velocity in peritubular capillaries, which is followed by a profound and sustained deceleration in blood flow.[14] Morphologically, disruption of peritubular endothelial cell actin cytoskeleton and junctional complexes has recently been documented in peritubular endothelial cells as well, allowing extravasation of capillary contents into interstitial space.[15] Functional importance of the peritubular capillary endothelium has been demonstrated by intraaortic injection of endothelial cells at the time of renal reperfusion (after 45 minutes of renal ischemia). which prevented the four-fold increase in creatinine observed in control ischemic rats and normalized the renal histologic injury scores.[14] Injection of HEK-293 cells, stably transfected with endothelial nitric oxide synthase, also ameliorated the postischemic rise in creatinine and fall in peritubular capillary blood flow.[14] These same investigations subsequently demonstrated that adult skeletal muscle stem cells differentiated in vitro into endothelial lineage cells and infused at the time of ischemia-reperfusion not only were incorporated into renal vascular structures including peritubular capillaries but also ameliorated the subsequent rise in creatinine.[16] Persistent abnormalities in peritubular capillaries may also link acute renal dysfunction with persistent or progressive renal injury later. Thus, in a rat model of renal ischemia-reperfusion, although renal tubular morphology had normalized by 4 and 8 weeks after injury, significant reduction in the density of peritubular capillaries persisted to 40 weeks.[17] Moreover, chronic reduction of renal interstitial oxygen delivery was documented in postischemic rats with reduced density of peritubular capillaries. Thus chronic tissue hypoxia may be among the mechanisms leading to renal interstitial scarring and progressive deterioration in renal function seen after ARF in the neonatal period (see later).[18]

As noted earlier, regardless of the origin or primary site of injury, the decrease in whole-kidney GFR in ARF reflects a decreased rate of glomerular filtration in individual nephrons. It is useful, therefore, to review the conceptual factors determining single-nephron GFR, along with pertinent clinical examples and molecular studies that illustrate their individual roles in decreasing the GFR. Reduction in the single-nephron GFR in ARF can be attributed to changes in one or more of the following parameters (Figure 136-1)[19]: (1) the rate of glomerular plasma flow; (2) glomerular transcapillary hydraulic pressure difference (the pressure within the glomerular capillary bed favoring ultrafiltration of fluid minus the pressure in the proximal tubule opposing ultrafiltration); (3) systemic plasma colloid osmotic pressure; and (4) permeability properties of glomerular capillaries. Although perturbations in these parameters can describe any type of ARF,[19-21] this discussion focuses primarily on the pathophysiologic mechanisms in intrinsic ARF.

PLASMA FLOW RATE

A decreased glomerular plasma flow rate is seen in systemic circulatory impairment (prerenal failure) and may continue even after systemic and circulatory impairments are apparently restored (intrinsic renal failure). This hypoperfusion reflects enhanced

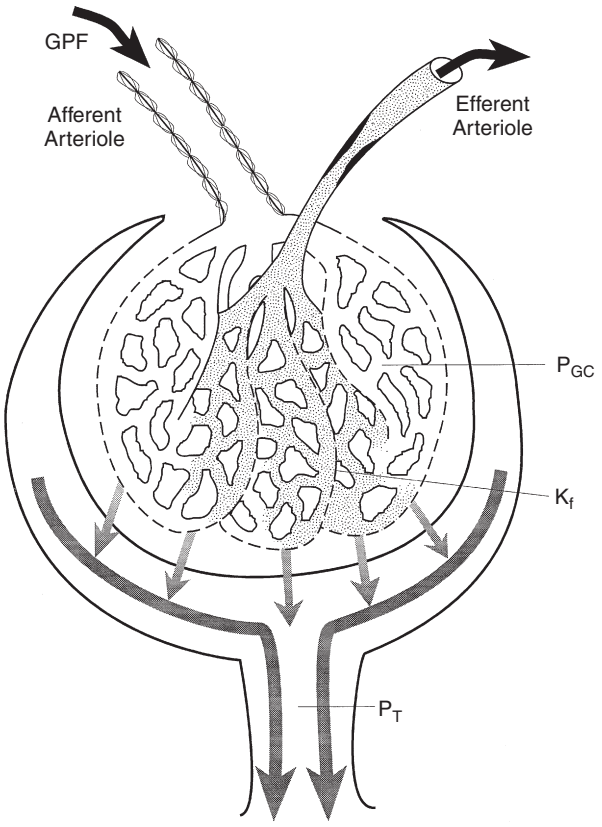

Figure 136-1 Schematic presentation of the glomerular filtration process. Glomerular filtration is determined by the rate of glomerular plasma flow (GPF) entering the afferent arteriole; hydraulic pressure within the glomerular capillary (P_{GC}) minus hydraulic pressure in proximal tubule (P_T); and glomerular capillary ultrafiltration coefficient (K_f), which describes the permeability properties of the glomerular capillary membrane. *(Modified from Winkler D, Elger M, Sakai T, Kriz W: Branching and confluence pattern of glomerular arterioles in the rat,* Kidney Int *39[Suppl 32]:S2, 1991.)*

vasoconstriction of the renal vasculature.[22,23] Increasing renal blood flow by volume expansion or administration of vasodilators before or soon after the onset of renal failure can prevent or ameliorate the development of certain human and experimental ARF. Most treatments designed to increase filtration by increasing renal blood flow failed once renal failure was established. Several agents, however, have been shown to increase renal blood flow with resultant improvement in GFR, even in well-established ARF in animal models and in humans. These agents include atrial natriuretic peptide, insulin-like growth factor I, hepatic growth factor, α-melanocyte–stimulating hormone, osteogenic protein-1, and antagonists of adenosine or endothelin.[24-31] Theophylline, which blocks binding of the vasoconstrictor adenosine to its receptor, has recently been shown to reduce renal dysfunction after perinatal asphyxia.[32,33] Two different studies found that, among those who received treatment, the rates of renal dysfunction were less, peak creatinine was less, and urine output was increased, whereas death rates and neurologic outcomes were similar to those in the untreated group. However, caution has been urged in interpreting these data as death in babies given treatment with theophylline was linked to persistent pulmonary hypertension from both studies (with no persistent pulmonary hypertension deaths in the placebo groups).[34] It should be noted that decreased blood flow does not typify all cases of ARF, and attempts to increase renal blood flow in this setting would not be expected to be universally successful. The clinical implications of these observations are that trials of volume infusion and vasodilators may be useful in the prevention and treatment of ARF, especially in the early stages. However, these maneuvers carry the risks of systemic vasodilation and hypotension that could worsen renal perfusion, as well as volume overload and congestive heart failure once the transition has been made to established renal failure.

Despite the near-normal renal plasma flow observed in many forms of clinical and experimental ARF, vascular responsiveness of the kidney is impaired and may contribute to hypofiltration. The ability of the renal vasculature of healthy persons to vasodilate and vasoconstrict is the basis for maintaining remarkably constant levels of renal blood flow and glomerular filtration in the presence of sudden changes in systemic pressure, that is, renal autoregulation.[35] For example, decreasing renal perfusion pressure causes the preglomerular, afferent arteriole to vasodilate and the postglomerular, efferent arteriole to constrict (see Figure 136-1). The sum total consists of a decrease in total renal vascular resistance and preservation of renal blood flow. In contrast, because blood flow autoregulation appears to be impaired in ARF, decreasing renal perfusion pressure increases renal vascular resistance and decreases renal blood flow, and this may be sufficient to cause hypofiltration.[36-40] This is important because even minimal (not hypotensive) decreases in systemic blood pressure may cause additional renal ischemia and may perpetuate hypofiltration or even parenchymal renal damage in the already injured kidney.[37] These observations underscore that seemingly normal values of renal blood flow belie the abnormal autoregulation of injured kidneys. Abnormal vasomotor response in ARF is multifactorial and includes increased responsiveness to renal nerve stimulation, norepinephrine, endothelin, and increased afferent arteriolar cytosolic calcium (Figure 136-2).[12,41,42] Decreased renal microvascular responsiveness to vasodilators such as prostaglandins, acetylcholine, bradykinin, and nitric oxide also appears to exist.[43,44] In this connection, endothelial nitric oxide synthase knockout mice, despite higher systemic blood pressure, have lower baseline renal blood flow and higher renal vascular resistance than wild-type mice.[45] When administered a dose of endotoxin not associated with a fall in mean arterial pressure, endothelial nitric oxide synthase knockout mice demonstrated a fall in GFR and renal blood flow not seen in wild-type mice. This was accompanied by acute tubular injury in approximately 10% of renal tubules versus none in wild-type mice.

At first glance, newborn babies seem to be at risk for hypoperfusion. When compared with adults, normal newborns have a low level of renal plasma flow, and their systemic blood pressure is less than the lower limits for autoregulation in adults (80 to 90 mm Hg). However, normal young animals autoregulate blood flow efficiently at the lower prevailing systemic blood pressure.[39,40,46] By contrast, young animals that undergo removal of one kidney demonstrate impairment in renal blood flow autoregulation immediately after uninephrectomy, and this impairment persists for at least 4 to 5 weeks.[46] Furthermore, young uninephrectomized animals that are also volume contracted have a higher renal vascular resistance and lower renal blood flow over a range of decreasing renal perfusion pressures when compared with saline-infused animals. Thus renal injury and neonatal volume status determine the effectiveness of renal blood flow autoregulation in the setting of ARF. The clinical implication is that volume depletion negatively affects this protective autoregulatory mechanism and makes the infant more susceptible to the development and propagation of ARF.

GLOMERULAR TRANSCAPILLARY HYDRAULIC PRESSURE DIFFERENCE

Glomerular capillary hydraulic pressure favors glomerular filtration. It is opposed by pressure in the proximal tubule (see Figure 136-1). Although both these pressures are fairly stable under

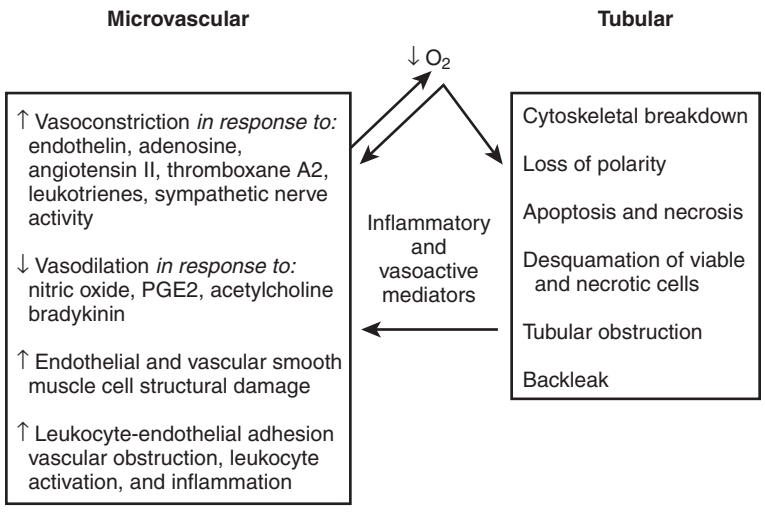

Figure 136-2 Interacting microvascular and tubular events contributing to the pathophysiology of ischemic ARF. *(Modified from Bonventre JV, Weinberg JM: Recent advances in the pathophysiology of ischemic acute renal failure,* J Am Soc Nephrol *14:2200, 2003.)*

normal circumstances, the pathophysiologic processes of ARF can affect either or both by several mechanisms. Decreased renal perfusion pressure normally causes a selective increase in the postglomerular, efferent arteriolar resistance, thereby maintaining intraglomerular capillary pressure, which contributes to constancy in GFR. When the systemic blood pressure falls to less than the autoregulatory range, glomerular capillary pressure, renal plasma flow, and the GFR follow the fall in systemic blood pressure.[35] Thus, in circulatory collapse, as may precede the development of ARF, the autoregulatory response of the renal vasculature is exceeded, and severe hypofiltration may result. In addition to profound hypotension, which overwhelms the normal autoregulatory mechanisms, under certain conditions even relatively modest systemic hypotension is associated with apparent ineffective autoregulation and a decrease in the GFR. As noted earlier, in animals with volume depletion or congestive heart failure, a 30% decrease in renal perfusion pressure (which did not affect GFR in normal rats) caused a more than 25% fall in the GFR.[47] The impaired ability to preserve the GFR in the presence of reduced renal perfusion pressure in both conditions was, at least in part, the result of a fall in the glomerular capillary pressure, which, in turn, reflected an inadequate vasoconstrictive response within the efferent arterioles.

As noted earlier, afferent arteriolar dilation and renal blood flow adjust to decreasing renal perfusion pressure in adult and immature animals. However, one study found that although decreasing the renal perfusion pressure by approximately 30% from baseline was accompanied by a minimal fall in the GFR in adult rats, in young rats the GFR plummeted by more than 80%.[39] Micropuncture experiments revealed that the profound hypofiltration in young rats largely reflected decreased glomerular capillary pressure. Because angiotensin II (AII) is known to vasoconstrict the efferent arteriole and to maintain glomerular capillary pressure, it is thought to have an important role in autoregulation of the GFR. A similar degree of water deprivation causes a greater increase in plasma renin activity in adult animals than in immature ones, and a higher dose of exogenous AII is required in immature than in adult animals to cause a similar increase in glomerular capillary pressure.[39] With these factors taken together, young animals have limited ability to activate at least one vasoconstrictor system, namely, AII, and the immature efferent arteriole may have limited responsiveness to AII. Thus, even in the presence of afferent vasodilation after decreasing renal perfusion pressure, young animals may develop hypofiltration. These observations provide a mechanism for dissociation between renal blood flow and the GFR in that dilation in the afferent arteriole without sufficient vasoconstriction in the efferent arteriole is insufficient to maintain a transcapillary pressure that promotes glomerular filtration. Of the two currently recognized receptors for AII, AT1 and AT2, the AT1 is most abundantly expressed and transduces the bulk of the recognized actions of AII including efferent arteriolar constriction.[48,49] Glomerular AII hyporesponsiveness in the neonatal kidney does not appear to reflect inadequate AT1 receptor density, because kidney AT1 expression peaks after birth at twice the adult level.[50] Further, AII availability is also maximized, reflecting an abundance of renal angiotensin-converting enzyme that increases after birth such that within 2 weeks of birth it surpasses adult levels, as does circulating angiotensin-converting enzyme.[51] Moreover, renin production in neonates is robust and extends beyond the juxtaglomerular apparatus to include more proximal segments of the renal arterial tree.[52] Angiotensinogen also undergoes a dramatic postnatal increase in liver expression before decreasing and settling to the adult level.[53] Overall, the receptors and the enzymes required for production of the mature AII ligand are exuberantly expressed in the neonatal kidney. The observed hyporesponsiveness of the neonatal kidney therefore appears to reflect inadequate postnatal maturation of postreceptor processes. It is possible, however, that the blunted vasoconstriction of the neonatal efferent arteriole in response to AII reflects the vasodilatory contribution of the AT2 receptor. This may occur though a direct effect of the AT2 receptor or though AT2-mediated stimulation of nitric oxide and bradykinin.[54]

The transcapillary hydraulic pressure difference includes not only the hydraulic pressure within the glomerular capillaries favoring filtration but also the opposing pressure in the tubules. Tubular injury is an important component in the pathophysiology of ARF.[7-13,19-22] Studies have clarified the cellular and molecular events that underlie the tubular injury.[55,56] Under normal conditions, tubular epithelial cell function depends on maintenance of defined apical and basolateral membranes with distinct protein populations. One such class of protein consists of the integrins, which are membrane-spanning glycoproteins located on the basolateral surface. Integrins interact with the intracellular cytoskeleton, as well as the extracellular matrix, and they mediate tubular cell adhesion.[57] Renal ischemia and subsequent adenosine triphosphate depletion induce redistribution of integrins to the apical surface and cause the actin cytoskeleton to move from its normal circumferential position to a perinuclear location (Figure 136-3). These injury-induced changes culminate in cellular rounding, retraction, and detachment from the basement membrane. Moreover, redistribution of integrins to the apical surface in the detached cells may contribute to aggregation of detached tubular cells within the lumen. This may, in turn, contribute to tubule obstruction, increased intratubular pressure, and decreasing transcapillary pressure. Indeed, infusion of the tripeptide arginine–glycine–aspartic acid that interferes with integrin adhesion mechanisms has been shown to abolish tubule obstruction and to improve renal function.[58] By contrast, in patients who underwent renal transplantation, persistence of increased tubular pressure and obstruction were documented in those patients with delayed graft function, characterized by mean GFR of 8 ± 8 mL/minute at 7 days after transplantation.[59]

Noteworthy are the observations that intratubular material contains not only cellular debris but also viable cells. Thus viable cells have been recovered from the urine of patients with ARF, a finding implying lethal cellular injury, as well as disturbance in mechanisms of normal cellular adhesion as underlying tubule pathophysiology in ARF.[60] It is also important to point out that nonviable exfoliated tubular cells are not uniformly necrotic. In fact, apoptosis appears to predominate as the mechanism of tubular cell death after ischemia, though necrosis and apoptosis appear to constitute a spectrum with apoptosis favored in the distal nephron.[61] A variety of apoptosis-instigating pathways are stimulated by tubular injury, but caspase activation appears to be the final common step.[13] In this connection, tubular injury by myoglobin (in experimental glycerol-induced ARF) was shown to be ameliorated by concomitant pan-caspase inhibition. Not only was apoptosis lessened by pan-caspase inhibition, but activation of IL-1β and IL-18 was blocked, limiting subsequent macrophage infiltration.[62]
